Fluorescein is perhaps the most widely recognized fluorescence-based reporter group used for immunoassay detection. Fluorescein is a synthetic dye that absorbs light maximally at a wavelength of ~494 nm and fluoresces maximally at a wavelength of ~544 nm; the exact wavelengths vary slightly depending on the fluorescein derivative. There are several important fluorescein derivatives useful for antibody labeling. Fluorescein isothiocyanate (frequently abbreviated as FITC) and the succinimidyl esters of fluorescein or carboxyfluorescein are amine-reactive and can be used to label the ε-amino group of lysine on the surface of the antibody or label the antibody's amino-terminus. Similar to succinimidyl esters of biotin, these fluorescein derivatives are available with a variety of spacer atoms between the fluorescein and the succinimidyl ester. Carboxyfluorescein is frequently abbreviated as FAM (fluorescein amidite), which actually refers to the phosphoramidite derivatives used to label nucleic acids. There are many other commercially available fluorescent dyes such as the Molecular Probes' Alexa Fluor dye series (Life Technologies, Inc.) that are useful for antibody labeling. A thorough description of these is outside the scope of this article, and the reader is referred to some of the supplemental readings listed at the end of the article.

Enzymes are another highly versatile type of reporter group that can be used to label antibodies. Enzyme-conjugated antibodies yield a signal upon the addition of the appropriate substrate. Three types of signals can be obtained depending on the choice of substrate and are chromogenic, fluorescent, and chemiluminescent. Two of the more common enzymes used to label antibodies are alkaline phosphatase and horseradish peroxidase. Alkaline phosphatase catalyzes the dephosphorylation of nucleic acids and proteins in cells. Its

ability to recognize synthetic substrates makes it a valuable reporter group. The substrate *p*-nitrophenyl phosphate is hydrolyzed by this enzyme into *p*-nitrophenyl and inorganic phosphate; the former is chromogenic with an absorption maximum at a wavelength of 405 nm. Another synthetic substrate, AMPPD (3-(2′-spiroadamantane)-4-methoxy-4-(3″-phosphoryloxy) phenyl-1,2-dioxetane), gives a chemiluminescent signal, and 4-methylumbelliferyl phosphate (4-MUP) gives a fluorescent signal in the presence of alkaline phosphatase. Upon dephosphorylation of AMPPD, the remaining AMPD is unstable and splits, resulting in the production of a phenolate ion, which is in an excited state resulting in the emittance of light. Dephosphorylation of 4-MUP yields the fluorescent methylumbelliferone molecule. Horseradish peroxidase is a heme-containing enzyme that uses hydrogen peroxide to catalyze oxidation reactions on a variety of substrates in the plant cells. Similar to alkaline phosphatase, this enzyme also recognizes several synthetic substrates that are exploited for use in immunoassays. The three synthetic substrates 2,2′-azino-bis(3-ethylbenzthiazoline-6-sulfonic acid) (ABTS), luminol, and 3-*p*-hydroxyphenylpropionic acid (HPPA) can be used to obtain chromogenic, chemiluminescent, and fluorescent signals, respectively.

Immunoassay Platforms

Enzyme-Linked Immunosorbent Assay

The enzyme-linked immunosorbent assay (ELISA) is a widely used immunoassay platform for the detection of pathogens, their toxic metabolites, or allergens in foods. In an ELISA, signal detection is achieved by enzymatic activity on an appropriate substrate as detailed in section '**Signal/Detection Chemistries**.' The enzyme is covalently attached (i.e., linked) to the antibody. The ELISA is most commonly performed using a 96-well microplate; however, other styles of microplates (e.g., 48-well, 24-well, and 384-well, among others) are also popular. Nonmodified antibodies are added to wells of the microplate where they bind nonspecifically; these are referred to as capture antibodies. Because many antigens can also bind nonspecifically and because the test sample may contain multiple highly similar targets, it is important that any remaining sites in the wells not occupied by antibodies be blocked by the addition of nonantigenic proteins such as bovine serum albumin, which will bind nonspecifically to those sites. Once the wells have been blocked and the excess blocking solution removed, the test sample can be added. If the target antigen is present, it will bind to the capture antibodies. Any nonbound test sample is removed by washing the wells with a high-stringency buffer or mild detergent solution. The presence of the target antigen is revealed by the addition of labeled detection antibodies. This type of ELISA is known as an antibody capture ELISA because the antibody that is bound to the plate captures the target antigen (**Figure 1(a)** and **1(b)**).

If the target antigen is capable of binding to the wells of the microplate, then the ELISA can also be performed by first adding the test sample. The target antigen binds nonspecifically to the wells of the plate. The nonbound test sample is removed by washing, and the wells of the plate are blocked using a blocking solution. The purpose of blocking is to prevent detection antibodies from binding nonspecifically, resulting in false-positive signals. The presence of the target antigen is revealed by the addition of a labeled detection antibody. This type of assay is known as a direct antigen-binding ELISA or sometimes antigen capture ELISA (**Figure 1(c)** and **1(d)**). It should be noted that depending on the composition of the test sample, there may be other biological molecules competing for binding sites within the microplate well. This could lower the levels of antigen binding, resulting in an overall decrease in the sensitivity of the assay.

Once the target antigen has been captured in the well of the microplate, it has to be detected. The detection step typically uses either one or two antibodies; if two antibodies are used, only one is labeled. When a single enzyme-labeled primary antibody is used, the type of detection is referred to as direct detection (**Figure 1(a)** and **1(c)**). When a nonlabeled primary antibody followed by an enzyme-labeled secondary antibody is used, the type of detection is referred to as indirect detection (**Figure 1(b)** and **1(d)**). The benefits of using a labeled secondary antibody are described in section '**Signal/Detection Chemistries**.'

The two different binding arrangements (i.e., antibody capture and direct antigen binding) and the two different detection types (i.e., direct antibody detection and indirect antibody detection) can be used in various combinations, yielding several different ELISA formats. Each format can be used with chromogenic, chemiluminescent, or fluorescent substrates; when fluorescent substrates are used, the assay is often referred to as an enzyme-linked fluorescence assay (ELFA). The ELISA/ELFA format using antibody capture and either direct or indirect detection is commonly referred to as a 'sandwich ELISA' because the target antigen is sandwiched between two antibodies.

Immunofluorescence Detection Assay

The ELISA, which utilizes fluorogenic substrates (i.e., ELFA) described in section 'Enzyme-Linked Immunosorbent Assay,' is also considered an immunofluorescence assay. In addition to this type of assay, others that use antibodies directly labeled with fluorescent reporter molecules and that do not rely on enzyme activity for signal production are also immunofluorescence assays. Simple immunofluorescence detection assays share many similarities with ELISAs/ELFAs. These assays can be used with both antibody capture (Figure 2(a) and 2(b)) and direct antigen-binding arrangements (Figure 2(c) and 2(d)). Also, these assays can be used with either direct antibody detection (Figure 2(a) and 2(c)) or indirect antibody detection (Figure 2(b) and 2(d)).

Immunofluorescence assays are not limited to the microplate format. The use of flow cytometry has recently gained interest, driven by the development of fluorescently colored microspheres that allow for multiplex-type analysis. For multiplex analysis, multiple microspheres, each with a unique fluorescence signature, are individually labeled with antibodies recognizing target antigens. For instance, microspheres of one fluorescence color might be labeled with anti-*Salmonella* antibodies, microspheres of a second fluorescence color might be labeled with anti-*Listeria monocytogenes* antibodies, and microspheres of a third fluorescence color might be labeled with anti-*E. coli* O157:H7 antibodies. The labeled microspheres are pooled and then used for applications such as screening enrichments for multiple pathogens or identifying unknown purified colonies. Antibody-labeled microspheres can also be used for identifying pathogenic variants within the same species of bacteria. For example, various fluorescently colored microspheres can be labeled with specific antibodies for identifying various enterohemorrhagic *E. coli* serotypes or *S. enterica* serotypes. The fluorescence signature of the microsphere identifies the target antigen (e.g., bacterial cell or microbial toxin), and the attached antibody serves as a capture antibody similar to an ELISA. The formation of a signal is needed for the analyst to determine if the target antigen is present. For signal detection, antigen-specific detection antibodies directly labeled with a fluorescent reporter are used. Because it is the fluorescence signature of the microsphere that identifies the target, the same fluorescent reporter can be used to label all of the detection antibodies in the multiplex analysis. During the analysis, fluorescence signals resulting from the microsphere and the detection antibody indicate the presence of the target.

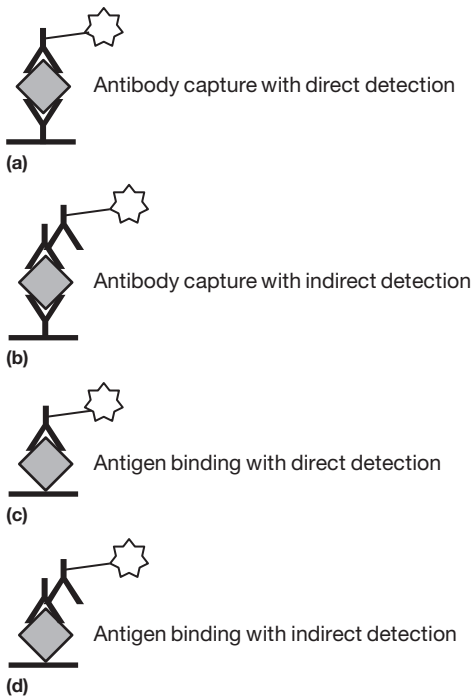

Figure 2 Depiction illustrating various simple immunofluorescence detection formats (star, fluorescence reporter attached to either primary or secondary detection antibody; diamond represents the target antigen).

Immunochromatographic Assay

Immunochromatographic assays are another type of immunoassay that has become extremely popular for food safety testing because of the relative ease of use and ease of interpretation. These assays use a solid support strip (e.g., nitrocellulose) capable of capillary action that has three distinct functional zones. At one end of the support strip is an application site where the prepared sample is added or the support strip is immersed in the sample (for this reason, these assays are sometimes referred to as 'dipsticks'). Commonly used immunochromatographic assays for food safety applications typically only require minimum sample preparation such as boiling of a small aliquot from an overnight enrichment. Once the application site is saturated, the sample flows through capillary action into the first zone where target-specific antibodies conjugated to colloidal gold or colored latex particles are present. If the target antigen is present in the sample, it will be labeled, forming an antibody–antigen complex, as it passes through the first zone. As the sample continues to flow through the test strip, it enters the second zone and encounters nonlabeled target-specific antibodies that are immobilized to the solid support of the test strip. The target antigen, labeled in zone 1, is held in place by the immobilized antibodies in zone 2, resulting in their increased localized concentration and forming a visible line. Because of their mode of action, these assays are sometimes referred to as immunoprecipitation assays. As the sample continues to flow through the chromatographic matrix, it enters the third zone where it encounters immobilized particle-specific antibodies that bind to the remaining colloidal gold or latex particles, resulting in their increased localized concentration and forming a visible control line that indicates that the assay performed properly. Because these assays rely heavily on the flow of the sample for functionality, they are often referred to as lateral flow devices. If the target antigen is present in the test sample, then two lines are observed, one indicating a positive reaction and the other, the control line (Figure 3(a)). If the target antigen is not present, then only the control line is observed (Figure 3(b)).

Antibody Magnetic Capture Assay

In some of the immunoassays previously mentioned, one of the functions of the antibodies was to capture the target antigen (e.g., bacterial cell or bacterial toxin) so that it could be more readily detected. This capturing ability has been further

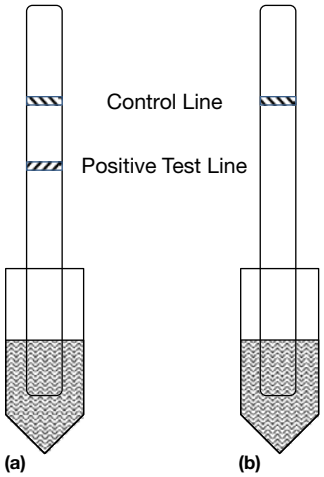

Figure 3 Immunochromatographic assay depicting a positive (a) and negative (b) test result. In both instances, the presence of the control line indicates successful assay functionality.

exploited by tethering target-specific antibodies to paramagnetic beads (microspheres). Paramagnetic beads become magnetized in the presence of magnetic field but lose their magnetic property when the external magnetic field is removed. This is an important property because if the beads maintained their magnetic properties, they would be attracted to each other (i.e., clump) and could not be easily dispersed, making them difficult to work with and lowering their capturing efficiency.

The antibody-labeled paramagnetic beads are simply combined with the sample, or sample blended in an appropriate buffered solution, which is then thoroughly mixed. This can be done in batch using a beaker or a disposable 50 ml conical tube (Figure 4(a)). After mixing, an external magnetic field is applied to one side of the container using a simple magnet. The target–antibody–paramagnetic bead complex is attracted to the magnet, holding it in place and allowing the remaining sample to be removed (Figure 4(b)). While the magnetic field is still applied, the captured cells can be washed to remove any potential matrix interferences that might hinder subsequent detection. There are commercially available magnetic stands designed specifically to use with 15 and 50 ml conical tubes. Additionally, there are commercially available sample recirculation systems that continually circulate the blended sample over antibody-labeled paramagnetic beads, which are held in place by a magnetic field. After a period of sample recirculation, the sample can be replaced with a buffer solution for washing the captured cells, or the cell–antibody–bead complex can be recovered and washed in batch using a conical tube. Immunomagnetic cell capture can be used to prepare samples for any number of detection technologies including polymerase chain reaction (PCR), immunoassays, and even plating onto microbiological recovery media.

Latex Agglutination Assay

Latex agglutination (LA) assays use antibody-labeled latex beads to capture target bacterial cells and rely on multiple binding interactions for cell–antibody–bead complex formation, resulting in clumping, which is evident by visible

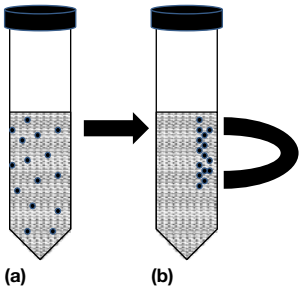

Figure 4 Illustration of an immunomagnetic capture assay. After thorough mixing, the antibody-labeled paramagnetic beads are well dispersed in the test sample (a). When exposed to a magnetic force, the beads become magnetized and are attracted to the magnet where they are fixed in place (b).

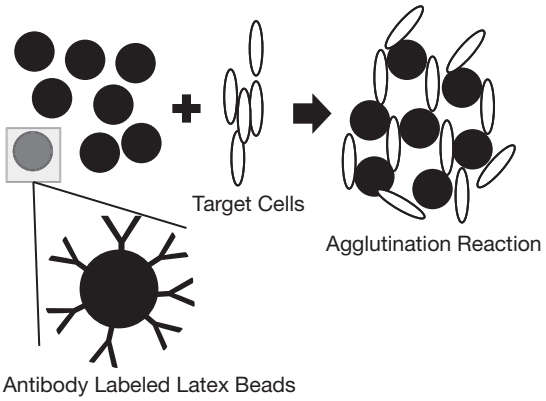

Figure 5 Latex agglutination assay. Target-specific antibody-labeled latex beads are mixed with the cells. Multiple interactions between the cells and beads result in the formation of a visible precipitate.

turbidity (Figure 5). LA assays are quick and simple to perform and do not require specialized instrumentation for signal measurements. Because LA assays rely on visible turbidity for determining positive results, these assays are not well suited for sample screening as food matrix material will regularly interfere with the determination of the results. However, these assays are frequently used, particularly by regulatory agencies, for serotype determination of foodborne pathogens and as way of determining pathogenic from nonpathogenic subtypes as in the case of *E. coli* O157:H7. For these uses, a small drop of the antibody-labeled latex beads in solution is placed on the surface of a glass microscope slide or petri plate lid. A single pure colony is then thoroughly mixed with the beads, and the slide is rocked back and forth and observed for granular clumping. The surface of the slide or lid should be well cleaned so that dust particles are not mistaken for clumping, a sign of agglutination. Additionally, the cells must initially be thoroughly mixed with the antibody–bead solution or clumps of the original colony can be mistaken for agglutination.

Applications of Immunoassays in Food Safety Testing

The isolation and identification of foodborne pathogens typically follow a sequential procedure. Because pathogen contamination is typically low and frequently < 1 cell per gram, the

test sample is manipulated in a manner that allows for the growth of the target pathogen so that it can reach detectable levels. During this pathogen enrichment period, selective agents (e.g., antibiotics, dyes, and salts) are typically added that allow the target organism to grow with little to no hindrance and that also minimize the growth of other microorganisms that are present in the test sample. Although not applicable to every type of food matrix, antibody capture methods have been successfully used to effectively concentrate pathogen levels from foods, thus eliminating or greatly reducing the time required for selective enrichment. Following enrichment, the target pathogen must be isolated; this is typically accomplished by 'steak plating' an aliquot of the enrichment onto a selective/differential agar plate. This is another step where antibody-based detection assays have become extremely popular particularly with analytic microbiology laboratories that frequently process many samples. Immunoassays such as lateral flow devices, ELISAs, and ELFAs have become increasingly relied upon for screening selective enrichments. Enrichments that test negative during the immunoassay screen are culled, and testing efforts are focused on the remaining enrichments that yielded positive screening results. Presumptive colonies (colonies that appear typical of the target pathogen for a particular medium) that form on the selective/differential medium must still be confirmed. This task has historically been done using the results of series of biochemical reactions. Colony confirmation is another area in which antibody-based assays (e.g., LA, ELISAs, and ELFAs) are becoming more popular. This is especially true when antibody reaction-based nomenclature is inherently tied to the organism's identification such as the serological classification of *S. enterica* or is used to identify nonpathogens from pathogens such as *E. coli* and *E. coli* O157:H7. Although other types of technologies have been and are being applied and developed (e.g., PCR and mass spectrometry) for pathogen detection, the reliability of immunoassays ensures their continued place in food safety testing programs.

Infants: Feeding Problems

EME Poskitt, London School of Hygiene and Tropical Medicine, London, UK

This article is reproduced from the *Encyclopedia of Food Sciences and Nutrition*, volume 5, pp 3300–3306, © 2003, Elsevier Science Ltd., with an updated Bibliography section supplied by the Editor.

Introduction

Nutrition is of great importance in infancy. Infants are entirely dependent on others for their nutrition and carers may have difficulty recognizing their needs. This dependence and infants' high nutritional requirements for growth and development make malnutrition a relatively common problem. Prolonged malnutrition can impair both somatic growth and brain development.

Failure to Thrive

Failure to thrive (Figure 1) is failure to gain in height and weight at the expected rates (determined from recognized growth data). The causes are numerous (Table 1), but if the precipitating causes can be successfully treated, failure to thrive is followed by accelerated or 'catch-up' growth (Figure 1(a)), provided extra food meets the nutritional needs of accelerated growth. Without extra nutrients, catch-up growth is likely to be incomplete. Affected infants may then resume normal growth rates, but along lower growth centiles than previously (Figure 1(b)).

Some children with growth below the third centile or ≈−2sd weight-for-age or below (outside the recognized 'normal' range) may be labeled as failure to thrive although growing at more or less normal rates for age. They may have been low weight for gestational age at birth and always small (Figure 1(c)). These constitutionally small children may show delayed bone age, delayed adolescence, and sometimes late catch-up to more normal adult size.

Careful dietary histories should indicate which infants are failing to thrive because of inadequate intakes, inappropriately constituted feeds, or inappropriate weaning practices. Average milk or formula intakes are 150 ml kg^{-1} day^{-1} (441 kJ kg^{-1} day^{-1}) for full-term normal infants. Around 6–8 weeks of age, intakes often stabilize despite continuing increases in weight and intakes per kilogram per day thus decrease.

It may be difficult to assess the adequacy of milk intake in breast-fed infants. Normal growth velocities and general contentment after feeding suggest intakes are adequate. If there is concern, weighing infants in clean diapers prior to breast-feeding and then weighing them again after feeding without diaper change provides some indication of the weight, and thus the volume, of milk consumed. This test weighing must be for all feeds over 24 h since infants may consume large feeds early in the morning and in the evening, but relatively small amounts at other times of the day.

When breast milk output seems insufficient for an infant's needs, improving maternal nutrition and increasing the frequency of suckling may improve milk secretion. Current recommendations are that infants should be exclusively breast-fed until at least 4 months of age and preferably until 6 months of age. Usually, breast-feeding failure arises because of inappropriate feeding practices (e.g., infrequent suckling, especially in early lactation, or incorrect positioning and failure by the infant to latch on). Advice on feeding technique may resolve the problems. However, mothers who are sick or very malnourished may sometimes fail to produce sufficient milk to support normal infant growth. The decision whether to continue struggling to increase breast milk production, to introduce infant formula feeds, or to introduce weaning foods early is determined by individual circumstances such as the age of the child and cause of breast-feeding failure. Failure to thrive without evidence of nutritional inadequacy, or secondary to persistent anorexia and vomiting, requires urgent medical investigation.

Occasionally, failure to thrive occurs without evidence of clinical disease or nutritional inadequacy. Children with such nonorganic failure to thrive may eat well, sometimes excessively, but grow poorly. Typically, they are apathetic, showing little social interaction, although some are restless and inattentive. Developmental delay, particularly in social and cognitive skills, is common. These children come from home environments of social and/or emotional deprivation. Environmental stress and lack of love inhibit normal growth. Changing the home environment without necessarily changing the diet can induce accelerated growth giving a dramatically improved effect – confirming the diagnosis.

Vomiting

Most normal infants vomit occasionally and some vomit frequently. Probably the most common cause of persistent vomiting in infancy is laxity of the gastroesophageal sphincter. The sphincter is the spiral muscular area, 2–3 cm in length, at the lower end of the esophagus. Sphincter competence is related to the length of intra-abdominal sphincter (which increases with age) and to intragastric pressure. Competence tends to be poor at birth but improves after the first 2 weeks of life, regardless of gestational age. The fluid diets of young infants and the high volumes of liquid needed to meet nutritional requirements produce gastric distension, high intra-abdominal tension, and easy regurgitation. Thickening feeds to increase resistance to regurgitation, feeding smaller feeds more frequently, and raising the head end of the cot help reduce gastric distension and regurgitation. As infants grow, consume more solid food, and adopt an upright posture, reflux ceases to be a problem.

Feeding problems, including gastroesophageal reflux, are common in children with neurological handicap. Failure to

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00394-9

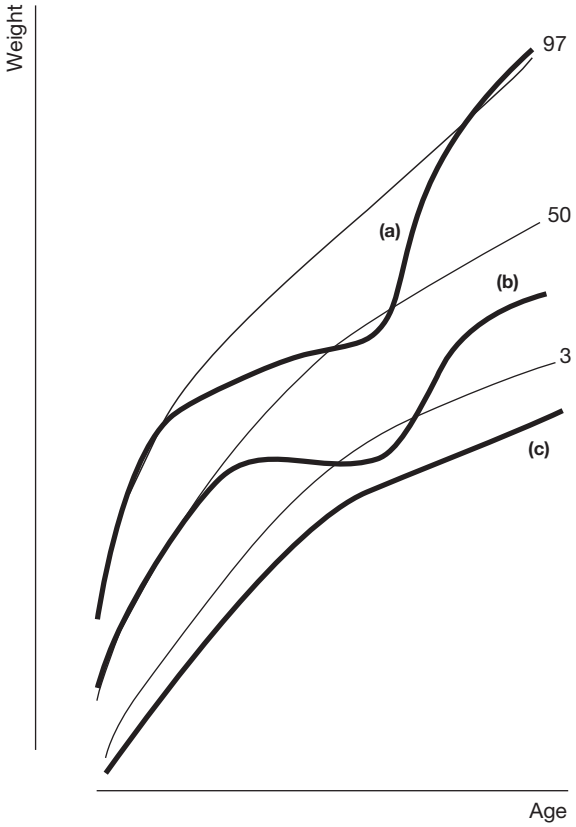

Figure 1 Weight of children with (a) failure to thrive and complete catch-up growth; (b) failure to thrive and failure of complete catch-up growth; and (c) constitutional small size plotted against the 3rd, 50th, and 97th weight-for-age centiles.

Table 1 Classification of nutritional problems associated with failure to thrive

Basic problem	*Examples*
Inadequate intake	Poverty; famine; ignorance of nutrient needs
	Vomiting: all causes
	Feeding problems, including neurological damage
	Anorexia
Increased losses	Protein-losing enteropathy
	Glycosuria; proteinuria
	Exfoliative skin conditions
	Suppuration
Failure to absorb food	Cystic fibrosis
	Gluten-sensitive enteropathy
	Giardiasis
	Lactose intolerance
Failure to utilize food	Inborn errors of metabolism
	Endocrine problems
	Micronutrient deficiencies, for example, zinc
	Chronic renal failure
	Emotional deprivation
Increased requirements	Small-for-dates and premature infants
	Catch-up growth
	Congenital heart disease: left-to-right shunt

thrive can be severe and may improve with intragastric feeding through gastrostomy, but this exacerbates gastroesophageal reflux. Surgical fundoplication is usually performed, prior to gastrostomy, to control reflux.

Vomiting can be a symptom of serious gastrointestinal or parenteral disorder. When infants vomit and fail to thrive, vomit bile or blood, or vomit to the extent of causing dehydration, medical investigation is required urgently.

Diarrhea

Diarrhea is an increase in total stool output, usually from increase in water content, volume, and frequency of stools. The color, consistency, and frequency of stools vary widely both between different infants and in the same infant on different occasions. Exclusively breast-fed infants tend to have frequent watery yellow stools. Formula-fed infants have less frequent, greenish, drier-looking stools.

In infancy, diarrhea is commonly part of either a specific gastrointestinal or a generalized (usually viral) infection. Infectious diarrhea has an acute onset but is usually short-lived and associated with other signs of infection: pyrexia, vomiting, anorexia, and general malaise. Weight loss from anorexia and dehydration is common. Weight recovery is generally rapid and complete. Acute diarrhea has little effect on long-term weight for age and even less impact on long-term height for age. However, chronic diarrhea and significant growth faltering are common with some gastrointestinal infections (especially rotavirus, *Giardia lamblia*, and *Entamoeba histolytica*).

Malnutrition causes profound changes to gastrointestinal mucosal structure and function. This predisposes malnourished children to severe diarrheal infection and high mortality from diarrheal illness.

All diarrhea should be managed with extra fluids, usually in the form of oral rehydration solution (ORS). ORS suitable for most infant diarrhea has lower sodium and chloride content than that intended for rehydration in adults.

Diarrhea, which is persistent and associated with failure to thrive, dehydration, bleeding, or other obvious illnesses, requires medical investigation.

Toddler Diarrhea

Some young children persistently pass watery stools or have bouts of loose watery stools alternating with episodes of constipation without evidence of infection, malnutrition, or other ill health. The diarrhea stools are typically voluminous and watery with bits of undigested food in them, indicating the visible bean husks, tomato skins, and other vegetable matter present, although less obviously so, in normally formed stools. Children with toddler diarrhea are active and thriving but their parents are usually very concerned.

Toddler diarrhea has no recognized specific pathology and probably has many causes. Whole-gut transit time is reduced but there is no evidence of abnormal duodenal or jejunal secretion, nor of malabsorption. Minor infection may set off bouts of diarrhea, and in some children, there is a family history of response to stress with diarrhea. Poor hygiene and low-grade infection associated with constant pacifier (dummy) sucking and prolonged bottle-feeding may contribute to the problem.

Many affected children have high intakes of sweetened fruit juices and/or low intakes of dietary fat. High fluid intakes with high simple carbohydrate content encourage rapid intestinal transit, which overwhelms small intestinal function, so sugars reach the large intestine unabsorbed. These and their fermentation products in the colon stimulate osmotic diarrhea. Reducing fluid intakes, particularly of sweetened juices and carbonated drinks, reduces the symptoms in some toddlers. Changing to more adult diets with higher concentrations of complex carbohydrates and fats can also reduce diarrhea. Lipids in the ileum slow duodenal and jejunal transit time (the ileal brake) and may modulate mucosal contact time and the absorption of intestinal luminal contents. Graduating to cup-feeding usually results in less excessive fluid intakes and, particularly if pacifiers are avoided, encourages more hygienic feeding practices.

Toddler diarrhea usually resolves as children move on to more mature diets and develop continence. It is unusual after the age of 6 years.

Micronutrient Deficiencies

Significant micronutrient deficiencies, other than for iron, are rare in normal-weight, full-term healthy infants in developed countries. Vitamin D deficiency rickets can be a problem in low-birth-weight (LBW) infants and non-Caucasian infants. In developing countries, low levels of vitamin A are associated with high morbidity and mortality from diarrheal diseases, respiratory infections, and measles. Iodine deficiency is also common. Many countries now have supplementation programs to prevent vitamin A and iodine deficiency.

Iron Deficiency

The human fetus has high hemoglobin levels to accommodate low oxygen tension *in utero*. After birth, in response to the high oxygen tension in the extrauterine environment, the bone marrow becomes relatively quiescent and hemoglobin levels decline. Eventually (usually at 4–6 weeks of age), the bone marrow becomes more active again, but by then, infants have grown and their blood volumes have expanded. Hemoglobin levels remain below adult levels, at 11–12 g dl^{-1}, until late childhood.

Where infants are small and growing very rapidly (e.g., premature and small-for-dates (SFD) infants), with initially low total blood volume and low total body iron, the need for iron for new blood formation may soon exceed the iron stored, so anemia results. Once body weight has doubled, all infants are at risk of iron deficiency since, without good external sources of iron, iron stores of the body will be distributed over twice the blood volume and hemoglobin levels will have halved. However, iron supplementation should probably be avoided in exclusively breast-fed infants unless they show clinical evidence of deficiency, since lactoferrin is a major immunologic component of breast milk. It binds iron in the small intestine, speeding absorption and inhibiting multiplication of iron-dependent bacterial pathogens. Iron fortification of infant formulas reduces the prevalence of severe iron deficiency in non-breast-fed infants.

Table 2 Classification of problems predisposing to iron deficiency in childhood

Basic nutritional problem	*Example*
Inadequate intake	Early introduction to cows' milk
	Prolonged exclusive breast-feeding
	Poor quality of weaning diet
	Strict vegetarian diet
Increased losses	Bleeding disorders
	Reflux esophagitis
Failure to absorb	Celiac disease
	Pyrexia
	Iron in ferric form
	High-phytate diet
Failure to utilize	Chronic infection
	Hypothyroidism
	Riboflavin deficiency
Increased requirements	Rapid growth: low-birth-weight infants
	Catch-up growth

Iron sufficiency is important. Table 2 lists some factors predisposing to iron-deficiency anemia. The frequency of iron-deficiency problems is an indication of the small margin of safety between requirements for iron and the quantity of iron young children are likely to ingest and absorb from their diets. Low-grade iron deficiency can impair growth rates, intellectual function, and the immunologic response to infection. In countries where malaria is common, anemia resulting from iron deficiency puts infants at great risk of life-threatening severe malarial anemia.

Vitamin D Deficiency: Rickets

Rickets used to be common in weanlings. The Clean Air Act (1956) probably did as much to reduce rickets in the United Kingdom as any medical intervention, since vitamin D metabolites are predominantly derived from irradiation of 7-dehydrocholesterol in the skin by sunlight of wavelength around 300 nm.

Rickets is still seen in the United Kingdom in newborn Asian infants and mothers. The mothers have both inadequate absorption of dietary vitamin D and inadequate skin synthesis of endogenous vitamin D because of indoor habits and clothing cover when out of doors. Low calcium absorption due to low dietary intake and the high phytate content of traditional flours exacerbates the need for vitamin D to optimize calcium absorption from the small intestine. Skin pigmentation increases the need for sunlight exposure when the levels of ultraviolet light of appropriate wavelength are low (e.g., winter in northern latitudes).

Infants born to vitamin D-deficient mothers may present with hypocalcemic tetany and convulsions soon after birth or with rickets in the weaning period. The incidence of rickets in Asian children is diminishing in the United Kingdom as Asian women in this country adopt lifestyles more suited to northern latitudes and their need for vitamin D supplementation is better recognized. However, signs of vitamin D deficiency in mothers and children are widely reported from the Middle East where there is plenty of sunshine of vitamin D

synthesizing wavelength, but little social opportunity for women and children to expose their bodies to the sunlight.

Vegetarian Diets in Infancy

Infants weaned on to vegetarian diets may become deficient in a variety of nutrients. If diets include eggs and milk, it is not difficult to achieve dietary requirements, particularly if breast milk or infant formula is continued as a milk source beyond the first year of life. Milk usually provides a substantial proportion of riboflavin, calcium, and total energy intake in weanling children. Infant formula can provide a fairly absorbable dietary source of iron, which may otherwise be deficient.

Vegetarian diets tend to be of low energy density because of high-fiber and low-fat content. Children should be fed frequently (at least four times a day) to enable them to consume the volumes of food necessary to meet nutrient needs. No vegetable protein contains the full range of essential amino acids so diets should include a variety of protein sources (e.g., beans, lentils, cereals, dark green leaves, soya, and homogenized nut products).

It is difficult to achieve adequate nutrition in very young children with vegan, macrobiotic, and other strict vegetarian diets. These diets are not recommended for infants unless there is close pediatric dietetic supervision.

LBW Infants

The problems of both premature and LBW for gestational age (SFD) infants are similar, although the greater immaturity of the premature infants' gastrointestinal tracts and of other organs makes the nutrition of the former more difficult than that of the latter. In both groups, there is a need for more nutrients per unit of body weight to cope with the rapid growth to parallel intrauterine growth in premature infants and catch-up growth in SFD infants. The small stomach volumes of LBW infants restrict the volumes that can be fed at any one time without causing apnea, vomiting, or necrotizing enterocolitis. Respiratory problems in premature infants may also restrict the amount of enteral food tolerated. Thus, there is a conflict between increased (proportionate to body weight) nutrient needs, especially for protein, calcium, phosphate, fluid, and energy, and the amounts of food that can be administered safely. Even when LBW infants are fed parenterally, there are restrictions on the fluid volumes, and thus the quantity of nutrients, that can be given safely. The high demands for growth and development, particularly for the brain, lead to deficiencies of some nutrients that are usually synthesized by the body. This critical nutrient status applies to the long-chain polyunsaturated fatty acids, docosahexaenoic and arachidonic acids, and possibly also carnitine, nucleotides, and other nutrients. For this reason, breast milk, which has high levels of these nutrients, may have advantages over infant formulas for the nutrition of LBW infants, if supplemented with energy to meet the high requirements of these infants. However, manufacturers, aware of the physiological needs of LBW infants, are gradually developing formulas that aim to meet these special needs.

Table 3 Nutritional problems of low-birth-weight infants

Problem	*Precipitating factors*
Immediate hypoglycemia	Limited liver glycogen Delay in mobilizing fat stores Problems with supplying nutrition
Immediate hypocalcemia	Loss of high calcium flux across the placenta Immaturity of calcium homeostasis Occasionally maternal vitamin D deficiency
Later poor growth	Low energy density of breast milk Poor tolerance of other energy/nutrient-dense feeds Poor fat absorption by immature infants Increased needs due to bronchopulmonary dysplasia
Bone disease of prematurity	Substrate deficiency, especially phosphate Renal calcium loss from acidosis and/or diuretics Vitamin D, protein, or copper deficiency
Anemia	Vitamin E deficiency increasing early hemolysis Folate deficiency Iron deficiency

Table 3 lists the problems of LBW infants, which are discussed elsewhere. LBW infants should be supplemented at least with vitamins A, C, and D and folate over the first year of life. Iron supplementation in the neonatal period risks encouraging bacterial infection and damage by free iron radicals, since iron stores are replete following temporary bone marrow inactivity associated with high hemoglobin levels at birth. However, iron supplementation is advisable in formula-fed infants after the first 4 weeks. Iron supplements should probably not be given at all to wholly breast-fed infants unless they show hematologic evidence of iron deficiency, since free iron in the gastrointestinal tract can counteract the protective effects of lactoferrin.

Allergy

Cows' Milk Protein Intolerance

Food allergies, particularly cows' milk protein intolerance (CMPI), are frequently diagnosed in infants. True CMPI affects between 1.5% and 5% of the population of western Europe. In families with a strong atopic history, the incidence may be much higher. CMPI most commonly develops in children under 2 months of age, although it may develop at a later age after gastrointestinal surgery, malnutrition, or gastrointestinal infection.

Children with diarrhea and/or blood loss in association with CMPI may show villous atrophy and increased inflammatory cell infiltrations on jejunal biopsy or acute colitis on sigmoidoscopy. Those with respiratory symptoms may present with pulmonary hemosiderosis, which resolves on removal of all cows' milk-containing products from the diet. However, for most children, manifestations of CMPI are varied and nonspecific.

Infants, who vomit, have diarrhea, have a rash, or cry a lot, are liable to be diagnosed as CMPI. They are put on to commercial

cows' milk-free formulas and may seem to improve. Improvements may have been coincidental or as a result of mothers feeling reassured that 'something was being done.'

Commercial cows' milk protein-free formulas are also lactose-free. Excluding formula and cows' milk products from the diet does not distinguish between CMPI and lactose intolerance. Children with lactose intolerance commonly have a preceding history of gastrointestinal infection, surgery, or malnutrition. They have loose stools, weight loss, and abdominal distension. Stools are acid and contain reducing substances. Thus, if infants' stools show pH < 5.1 and have no reducing substances in them and symptoms resolve on cows' milk protein-free diet but recur when milk protein is reintroduced, CMPI is likely.

Where the child's symptoms have been dramatic (e.g., angioneurotic edema and profuse life-threatening diarrhea), challenging the diagnosis of CMPI by reintroduction of milk and milk products can be dangerous. Children should only be challenged with milk under hospital supervision and even then with great care.

The particular elements of the cows' milk protein causing allergenic responses vary. At least 18 components that can induce antibody formation have been identified. When purified protein fractions are used as challenges, β-lactoglobulin levels and casein produce symptoms in over 60% of affected individuals. Antibodies to cows' milk protein are widespread and neither their presence nor their levels in the blood correlate well with reactions to cows' milk.

Breast-fed infants often show circulating cows' milk protein antibodies. Changing from breast-feeding to cows' milk formula feeding can, very rarely, precipitate dramatic anaphylactic symptoms of angioneurotic edema with acute and very dangerous swelling of tissues around the neck and airway. Relevant proteins from the cows' milk consumed by the mother are thought to be transferred to affected infants either across the placenta or in breast milk, causing sensitization. The infants are then desensitized by the small amounts of antigen in maternal milk but are overwhelmed when confronted with a large load of antigen from formula feeding.

The management of CMPI involves the removal of all cows' milk protein-containing products from the diet. Pediatric dietetic advice is advisable since milk and milk products continue to contribute significant amounts of energy and other nutrients to normal children's diets, even after the start of mixed feeding. Difficulties in meeting nutritional needs on milk-free weaning diets can lead to undernutrition. Soya-based infant formulas can be helpful but infants with CMPI may also develop soya protein intolerance. Hydrolyzed cows' milk protein formulas are more suitable for the treatment of CMPI but are rather unpalatable (to mothers anyway), not available in supermarkets in the United Kingdom, and costly.

Tolerance to cows' milk protein usually develops as children move into the second or third year of life.

Eczema

The extent to which food intolerance is relevant to the development of infantile eczema remains controversial. Some infants with atopic eczema show significant improvement in their skin problem when all milk products are withdrawn from the diet. Others only improve when put on very restricted lists of foods. Studies of infants with familial high risk of atopic eczema suggest that eczema may be prevented in some infants by exclusive breast-feeding for the first 6 months of life. Moreover, exclusively breast-fed infants who do develop eczema may have become sensitized to foreign proteins transferred through the breast milk.

Other Food Allergens

Other food allergies are quite common in infancy, especially in those with an atopic family history. Common precipitants are egg protein, citrus fruits, nuts (not advised for young children anyway because of the risks of inhalation), and the food colorants tartrazine and quinoline yellow. Diarrhea, vomiting, rashes, wheezing, and – rarely – behavioral disturbances may occur. (Most behavioral problems are disciplinary rather than allergic.) The pattern of response in each child is usually repeated on subsequent contact with the allergen but there is great variation in the pattern of individual responses.

Colic

Around 3 months of age, healthy infants often develop bouts of fractiousness and inconsolable crying, usually in the early evening. Their abdomens become tight and distended, probably because of the air swallowed while crying. Infants tend to flex their legs when crying and this may be interpreted as abdominal pain. 'Three-month colic' is an ill-defined problem with a wide range of symptomatology. In the long term, colic resolves without specific treatment. It may be a behavioral rather than a medical problem. Nevertheless, it causes great distress to the child and parents. Removal of cows' milk formula and substitution with nonallergenic formula or soya protein formula have sometimes been associated with improvement. However, it is difficult to know if this has anything to do with resolution of symptoms in a benign self-limiting condition.

Cot Death: Sudden Unexpected Infant Death Syndrome

Sudden unexpected infant death (SUID) affects about 1 in 500 infants in the United Kingdom. The condition is of mixed etiology, since detailed history and autopsy reveal the cause of death or evidence of illness in many of the infants. There remains a group of SUID infants for whom detailed investigation shows no adequate explanation for death. These are the cases of true 'sudden infant death syndrome' (SIDS). In the past, anaphylactic shock from acute CMPI was sometimes cited as possible etiology for SIDS since SUID is more common in formula-fed than in breast-fed infants. Some infants have postmortem evidence of milk/formula in the respiratory tract, perhaps as a terminal event. However, true SIDS is probably not more common in formula-fed than in breast-fed infants. It now seems likely that a major component of death in SIDS relates to impaired cardiorespiratory arousal. Putting infants to sleep supine, rather than prone or on their sides, has reduced SIDS by about 35% in many countries.

Another nutritional explanation proffered for some forms of SUID is undiagnosed inborn errors of metabolism involving inhibition of breakdown of long-chain fatty acids. Children with inborn errors of this kind are unable to metabolize fats to cope with the stress of fasting and die of hypoglycemia. Postmortem examination reveals acute fatty degeneration of the liver. In such very rare cases, SUID may be familial since inborn errors of metabolism involving fatty acid breakdown are inherited, usually by autosomal-recessive genes.

Teething Problems

Teeth are erupting more or less continuously between 6 and 30 months. Teething children may show excessive salivation, gingival swelling, and general irritability. These symptoms may exacerbate existing illness but there is no evidence that teething causes fever or diarrhea. Rubbing the gums with cool cloths or giving infants firm objects to bite may reduce teething discomfort.

Most children develop their first teeth around 6 months of age but some do not develop teeth until around 2 years. Late tooth erupters usually cope well with chewing and should be encouraged to progress in the weaning process in the normal way.

Nursing Bottle Syndrome: Rampant Caries in Infancy

Nursing bottle syndrome is the rampant carious destruction of the upper incisors in young children. Although associated with offering bottles of juice/milk or pacifiers sweetened with sugary solutions to infants when they are ready to sleep, rampant caries in this age group probably also reflect underlying enamel hypoplasia in the primary teeth, which is secondary to prematurity or to maternal nutritional deficiencies in pregnancy.

Constant bathing of the upper incisors with sugary fluids, together with reduced salivary secretion and reduced mouth movements at night, encourages the development of plaque. *Streptococcus mutans*, which survives well at low pH, collects under plaque and adheres to tooth enamel. Enamel is eroded, allowing the opportunity for further tooth infection by other bacteria. Excessive vomiting, by creating an acid environment in the mouth, may contribute to the risk. Teeth in the front of the upper jaw are reduced to carious discolored stumps. Children may become faddy eaters due to the discomfort of chewing meat and biting vegetables and fruit.

Fluoridation of water supplies with one part per million of fluoride protects against dental caries. If water is not fluoridated, children can be supplemented with fluoride 1.25 mg day^{-1} in infancy and 1.5 mg day^{-1} between 1 and 3 years. Regular, at least daily, tooth brushing should be taught from the first appearance of teeth. Adults should supervise loading children's toothbrushes with small pea-sized lumps of toothpaste since small children may eat toothpaste rather than spit it out after cleaning their teeth. As much as 1.66 mg of fluoride could be consumed by small children brushing their teeth inexpertly twice a day with fluoridated toothpaste.

All food, and particularly sweetened drinks, should be discouraged after tooth brushing at night.

Infants: Nutritional Requirements

Introduction

The beginning of the twentieth century was characterized by periods of low access to food, thus restraining optimum growth and leading to nutrition-related diseases such as pellagra, rickets, and goiter. In the last decades, however, the scene has changed dramatically in the developed world. Economic growth and high access to food in developed countries have led to food overconsumption, which in turn resulted in increasing prevalence of obesity, high blood pressure, and metabolic syndrome in all layers of the population, including children. This shift in observed health risks has led the scientific community to develop new recommendations for macro- and micronutrients, which are both adequate and balanced to help individuals optimize their health, preventing diseases and avoiding excessive consumption of a specific nutrient.

Infancy and childhood are both critical periods of rapid physical growth and cognitive and emotional development. It is also well recognized that nutrition in these age groups is not only an important factor for the normal development but also fundamental for future health status. It has been shown that the right nutrition in the first 1000 days (i.e., *in utero* and during the first 2 years of life) builds the foundation for a child's ability to grow, learn, and thrive. Nutrient supply, in terms of both quantity and quality, during these early days is instrumental in differentiation of tissues and organs and has both short- and long-term health effects. Breastfeeding is the preferred and recommended form of nutrition for healthy infants for the first 6 months of life. Breast milk not only contains the necessary nutrients for a healthy growth and development but also serves as the first immunization against illness and disease. After the sixth month, complementary feeding is introduced, and thus, the assessment of the adequacy of infants' nutrient intake becomes more important.

Physiological Considerations in Setting Nutritional Requirements for Infants

Infants are considered a vulnerable group because they have a relatively high requirement of nutrients per unit body weight during a sensitive period of rapid growth and development. In addition, recent research has shown that infancy is a critical period, setting the foundation of long-term health and reduced risk for chronic diseases such as cardiovascular disease, dyslipidemia, obesity, and osteoporosis. Some of the main physiological considerations include weaning, increased growth rate, occurring brain development, and the still immature function of kidneys and the gastrointestinal system.

Weaning

Breastfeeding benefits for the health and well-being of infants have been well documented and recognized. According to the World Health Organization (WHO), "adequate nutrition during infancy is essential for lifelong health and wellbeing. Infants should preferably be exclusively breastfed for the first six months of life to achieve optimal growth, development and health. Thereafter, to meet their evolving nutritional requirements, infants should receive nutritionally adequate and safe complementary foods, while ideally continuing to breastfeed for up to two years or more."

The WHO recommends that infants start receiving complementary foods at 6 months of age in addition to breast milk, initially 2–3 times a day between 6 and 8 months, increasing to 3–4 times daily between 9–11 months and 12–24 months with additional nutritious snacks offered 1–2 times per day, as desired.

The estimated intakes of fully breastfed infants are used to derive nutrient requirements for infants up to 6 months old. For older infants (7–12 months), the estimated intakes from complementary foods are also used for reference in addition to that of human milk. It should be noted though that it is difficult to determine the actual intakes of breastfed infants due to not only the variability of available milk volume and composition between women but also the changing composition of the milk during the course of lactation, during the day or even during a single feeding.

Increased Growth Rate

Growth rate during infancy is faster compared to the other life stages; it represents ~33% of daily energy needs in the first 4 months of age, decreasing to 7.4% between the ages of 4 and 12 months. In general, most healthy infants double their birth weight by 6 months of age and triple it by 12 months of age.

The critical processes of physical, mental, and psychomotor development of the infant imply increased demand for energy and nutrients, such as essential fatty acids, iron (as a component of hemoglobin and several enzymes), and zinc (since infants do not have any stocks since intrauterine life). Breast milk ideally meets these needs until the sixth month; after that, complementary feeding is necessary to meet the required intakes for iron and zinc. Especially for zinc, intake should be as close as possible to the recommendation since higher amounts are associated with lower copper levels and suppression of the immune system.

Brain Development

Approximately 20% of the dry weight of the brain is composed of essential fatty acids (incorporated into phospholipids), which

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00391-3

are critical for the structural integrity of neuronal membranes. About 1/3 of these fatty acids are omega-3 fatty acids. The optimal development of the nervous system is ensured by the intake of omega-3 fatty acids, as they reduce cholesterol levels in neuronal membranes, keeping their liquidity constant. Elevated cholesterol levels would reduce the liquidity of the membranes making it difficult for the cell to carry out its normal functions and increasing the potential for injury or cell death. Inadequate intakes of essential fatty acids in infancy are associated with impaired memory and learning ability, impaired vision, and, in general, reduced functionality of the sensory organs, possibly due to a delay in the myelination process. Infants can receive essential fatty acids through breast milk, and it is therefore important that the mother's diet contains a good supply of omega-3 fatty acids. Breast milk provides $\sim 5.6\ g\ l^{-1}$ of linoleic acid and $0.63\ g\ l^{-1}$ of omega-3 fatty acids (including alpha-linolenic acid and docosahexaenoic acid). Manufacturers of infant formulas usually add blends of vegetable oils, which are high in linoleic acid, to improve essential fatty acid content. Food sources of essential lipids in the older infant's diet, other than breast milk and infant formula, include fatty fish, vegetable oils, nuts, meats, and eggs.

Kidney Function

Despite the fact that nephrogenesis is complete by the 34–36th week of gestation, the kidneys continue to mature through the postnatal period. The immature kidneys of very young infants have difficulty handling high-protein foods due to their high renal solute load. Breast milk has a lower renal solute load compared to infant formulas and as such is better handled by infants' immature kidneys. A balanced dietary intake is particularly important in the case of protein, which should on the one hand provide the necessary amino acids for the support of anabolic processes but on the other hand should not be extremely high so that it does not burden infants' immature kidneys and liver.

Gastrointestinal System

Due to the immaturity of the digestive system and the increased risk of infections, the intake of antioxidant vitamins and prebiotic fiber is rather important to ensure the healthy development of the intestinal flora. There are some naturally occurring oligosaccharides in breast milk that function similarly to prebiotics, stimulating the growth of highly specific strains of bifidobacteria and thereby selectively altering the infant's microbiota. The use of prebiotic-supplemented formula to healthy infants does not raise safety concerns with regard to growth and adverse effects although more research is needed on the long-term effects of its use. Similarly, due to the insufficient intestinal colonization by bacteria, the intestinal synthesis of vitamin K is low, and therefore, the adequate dietary vitamin K intake should be ensured.

Nutritional Recommendations for Infants

Different countries and committees have set micronutrient reference values for infancy, which vary considerably among them. The variability is caused by various factors, for example, disparities exist between underlying concepts, the terminologies used, and the methodologies and assumptions that have been made in the definition of micronutrient requirements and derivation of reference values for intake.

Ideally, an average requirement (referred to as AR (term used by, i.e., European Commission, Nordic countries, and the Netherlands), average nutrient requirement (term used by, i.e., France and UNU/FAO/WHO), or estimated average requirement (term used by, i.e., the United Kingdom and the United States) is established, referring to the level of (nutrient) intake that is adequate for half of the people in a population group, given a normal distribution of requirement. When an AR can be established, then it is also possible to establish the level of (nutrient) intake that is adequate for virtually all people in a population group (usually corresponding to two SDs above the AR). This value is referred to as recommended dietary allowance (term used by the United States), population reference intake (term used by European Commission), recommended nutrient intake (term used by the United Kingdom), or individual nutrient level 97.5 (INL97.5) (term used by UNU/FAO/WHO). When however the establishment of the AR is not possible due to the lack of scientific information, then the adequate intake (AI), that is, the average observed daily level of intake by a population group (or groups) of apparently healthy individuals that is assumed to be adequate, is used for the purposes of dietary assessment. Upper levels have also been set for some of the nutrients and refer to the highest level of a nutrient intake that is likely to pose no risk of adverse health effects for almost all individuals in the general population. As intake increases above the set upper level, the risk of adverse effects increases. Figure 1 provides a graphic representation of the risks of nutrient inadequacy and nutrient excess as we move from a low intake of a nutrient to a high intake.

AIs for young infants (ages 0–6 months) are generally estimated to be the average intakes of full-term healthy infants who are exclusively fed with human milk. Deriving dietary intake data for exclusively breastfed infants is already a challenge due to uncertainties pertaining to the variation in breast milk volume and composition. The introduction of complementary food introduces a further number of issues, some of which are the bioavailability of different forms of the nutrient in different formula types and the non-identification of the milk source in most intake surveys.

In the first 6 months of life, the AI is usually based on the average concentration of the nutrient in human milk using an average volume of milk intake of about $0.75\ l\ day^{-1}$. For older infants aged 6–12 months, extrapolation has been used in some cases to establish ARs or AIs. Values were either extrapolated down from those for young adults or extrapolated up from those of young infants; in both cases, adjustment for metabolic or total body size and growth was used. In this age category, the AI is derived based on the content of the nutrient provided by the average volume of $0.6–0.65\ l\ day^{-1}$ of human milk and the content of the nutrient provided by the usual intakes of complementary weaning foods consumed by infants in this age category.

The following sections include information on the food sources, functions, and concerns regarding major nutrients

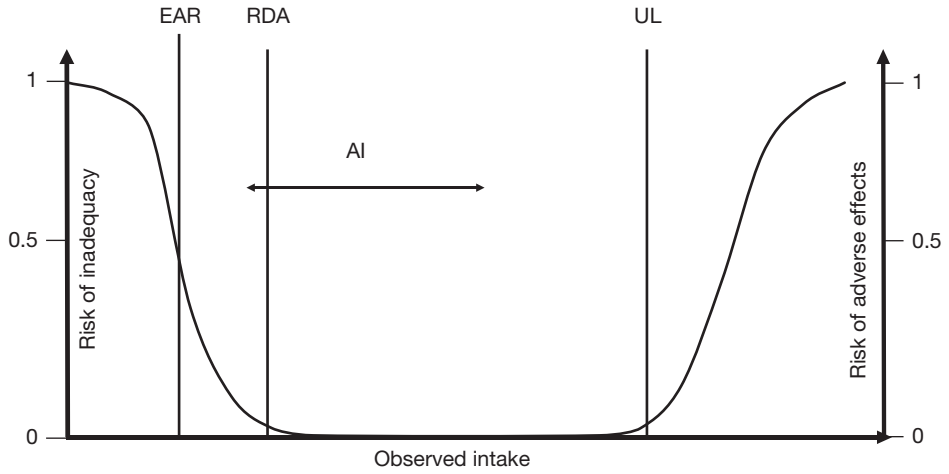

Figure 1 Graphic representation of the risks of nutrient inadequacy and excess when moving from a low intake of a nutrient to a high one. The terminology used by the Institute of Medicine has been used in this graph. EAR, estimated average requirement; RDA, recommended dietary allowance; AI, adequate intake; UL, upper level.

and nutrients considered to be of public health significance to infants. A review of existing recommendations for infants can be found in Tables 1–5.

Energy and Macronutrients

The energy requirements of infants and young children should balance energy expenditure for achieving normal development and allowing for growth of tissues. Satisfactory growth is a sensitive indicator of whether energy needs are being met. The brain, liver, heart, and kidney account for most of the basal metabolism of infants. The contribution of the brain to basal metabolic rate is exceptionally high in the neonatal period and throughout the first years of life.

The determination of the AI for protein for infants is based on data from infants fed with human milk as the principal source of nutrients during the period 0–6 months of age. For older infants, the protein recommendations are set to cover the estimated requirements for maintenance (nitrogen intake and nitrogen balance), protein deposition, and miscellaneous losses.

For carbohydrates, most bodies suggest a percentage of consumed energy that ranges between 45% and 60%, while the American recommendations have set an AI of 60 g day^{-1} for infants up to 6 months of age and 95 g day^{-1} for older infants.

Lipids are the main energy source in the infant diet and are therefore necessary for normal growth and physical activity. Fats normally provide around half of the energy in human milk (and in most artificial formulas). Special consideration is given to the essential fatty acids, that is, alpha-linolenic and linoleic acids, which are important for the development of the nervous system, while some bodies have set recommended values for long-chain polyunsaturated fatty acids as well. Some of the nutrient recommendation bodies also provide values for saturated fatty acids and monounsaturated fatty acids based mainly on their link to the development of coronary heart disease or risk factors for coronary heart disease (such as blood concentrations of total cholesterol and LDL cholesterol).

Vitamins and Minerals

Tables 4 and 5 provide an overview of the available recommendations for vitamins, minerals, and electrolytes. Some detailed information can be found in the succeeding text for a selected number of vitamins and minerals particularly of interest for this age group.

Infants constitute a population at risk for vitamin D deficiency because of relatively large vitamin D needs brought about by their high rate of skeletal growth. At birth, infants have acquired *in utero* the vitamin D stores that must carry them through the first months of life. Breastfed infants are particularly at risk because of the low concentrations of vitamin D in human milk. This problem might be further reinforced by a restriction in exposure to sun for seasonal, regional, cultural, or social reasons. Most nutrient recommendation setting bodies suggest the use of a vitamin D supplement of 10 μg day^{-1}.

In infants up to the age of 6 months, vitamin K deficiency, although rare, represents a significant public health problem throughout the world and can cause the so-called vitamin K deficiency bleeding. As there is no screening test, it is common pediatric practice to give oral or intravenously injected vitamin K in the immediate perinatal period.

The iron endowment is directly proportional to the lean tissue mass and blood volume of the baby, both functions of its intrauterine growth. Most full-term infants are born with adequate iron stores to sustain its hematopoiesis for the first 6 months of life and even beyond, because breast milk is physiologically low in iron. In comparison, low-birth-weight and preterm infants (including twins) have lower iron stores at birth due to their lower lean tissue mass and blood volume, and, because of their rapid growth rate, their iron stores may get depleted by 2–3 months of age. For these first months, as the mobilization of body iron stores is very high, the requirement for exogenous iron is virtually zero. The interaction

between iron, zinc, and copper should be noted as they act as antagonists. Iron supplements may inhibit intestinal zinc and copper absorption because these elements may compete for binding to a transporter molecule located in the small intestine (divalent metal transporter 1). Zinc causes an elevation of metallothioneins (small cysteine-rich proteins that bind to heavy metal ions, protecting cells from metal toxicity), which can bind both zinc and copper but have higher affinity for the latter, thus making copper unavailable.

Recommendations and Priorities for Future Research

Although the nutrition-related health problems have changed over the last decades, the need to monitor children's health and diet-related indices is still emerging. It was previously considered that malnutrition takes only the form of undernutrition, which is characterized by a diet that does not provide adequate calories, protein for growth and maintenance, and micronutrients. Thus, the focus was on the quantity of food in order to continuously meet dietary energy requirements. Nowadays, malnutrition also takes the form of hidden hunger, that is, chronic inadequate supply with essential micronutrients through the diet. A person may have access to a sufficient amount of calories but lack adequate micronutrients, and thus, the symptoms of hidden hunger are not always obvious. As the right nutrition (in terms of both quantity and quality) in the first 1000 days is crucial for child survival, growth, and development, the continuous recording of food and nutrient intakes is a necessary practice, because it can provide guidelines for the health professionals and help in forming legislation on food fortification.

Infants: Weaning

A MacDonald, The Children's Hospital, Birmingham, UK

This article is reproduced from the *Encyclopedia of Food Sciences and Nutrition*, volume 5, pp. 3293–3299, © 2003, Elsevier Science Ltd., with an updated Bibliography section supplied by the Editor.

Introduction

The term 'weaning' comes from the word 'wenian,' which means 'to accustom.' It is a gradual process through which an infant moves from total dependence on milk to eating normal family meals. The most widely used definition is the process of introducing semisolid food into the infant's diet in addition to milk. Definitions of weaning vary from country to country and include 'the process of expanding the diet to include food and drinks other than breast or infant formula,' 'cease to be suckled,' or 'complete discontinuation of breast-feeding.' As many of the foods initially introduced are not truly solid, the German word 'beiokost' is sometimes used to refer to these foods as a group.

History of Weaning

In ancient Egyptian and Babylonian times, the common age of weaning was 3 years. In the sixteenth and seventeenth centuries, pap (mixtures of flour, water, and sometimes milk) and panada (a broth of bread, flour, meat or lentils, and sometimes milk) were described as infant foods in the literature. Weaning was quite a dangerous time when started in early infancy, and Queen Anne is said to have lost 18 children from spoon-feeding and wet-nursing. The infant food industry started in 1867. By the latter part of the nineteenth century, there was a more cautious approach to solid-food introduction. It was widely recommended that vegetables, particularly green, were not given to infants before 2–3 years of age, although cereals and custards were commonly introduced by 4 months. The situation changed again in the early part of the twentieth century with the trend toward earlier weaning in developed countries. This continued in the United Kingdom until the 1970s and 1980s, although the latest Office of National Statistics (ONS) report would suggest that more parents are delaying the introduction of solids until at least 3 months of age.

Why Wean?

There are four important reasons for weaning. These are as follows:

- If an infant is still unweaned by 6 months, the intake of energy is likely to be inadequate. Infants double their birth weight in the first 4–5 months of life, and breast or formula milk can no longer meet energy needs. Late weaning is associated with a failure to thrive in infants.
- Breast milk provides little iron and vitamin D. In the later stages of lactation, zinc and copper concentrations also begin to fall. However, the bioavailability of nutrients in breast milk is good, and no other foods are usually needed until the age of 4 months, provided the mother is taking a good mixed diet. In addition, for the first 4 months, the full-term infant relies on iron stores to help meet requirements. Sooner or later, these stores will be depleted, and iron-deficiency anemia will occur unless there is a supply from the weaning diet. Formula milk contains higher quantities of iron, vitamin D, zinc, and copper, but with a different bioavailability than breast milk, but for other reasons, it is still recommended that solids be introduced by 6 months.
- There are important developmental reasons for introducing solid food. The neuromuscular coordination needed to eat solid foods develops during the early months of life. At 4 months, most infants can put objects to their mouths, take soft foods from a spoon, form a bolus, and swallow (Table 1). From about 5 months, teeth begin to erupt, and infants are able to chew. Feeding behavior therefore proceeds from sucking to biting and chewing. Chewing improves the mouth and tongue coordination, which is important for speech development. The introduction of different tastes and textures promotes biting and chewing skills. However, if introduction of solids is delayed beyond 6 months, the weaning process becomes more difficult. Infants are less receptive to new tastes, and it is more difficult to teach older infants to chew. From 7 months of age, infants learn to shut their mouths, turn their heads, and refuse to feed.
- The fourth reason is to provide a variety of tastes and flavors. This will enable the infant to eventually accept and enjoy normal family meals.

When to Wean?

The ideal time to introduce solids will vary between infants and differ between cultures. In traditional societies, it is still a practice for infants to be almost entirely breast-fed for the first year of life. In many Western countries, particularly Europe and North America, it is recommended that 'the majority of infants should not be given solids before the age of four months but a mixed diet should be offered by the age of six months.' Early weaning is discouraged for a number of reasons:

- Poor muscular coordination. Before 3 months of age, infants have poor head control, and back support is weak, so it is difficult to hold infants in a position where they can be fed and can swallow semisolid food.
- The kidney is immature and may not be able to cope with a higher renal solute load, and this could lead to higher

Table 1 Developmental changes relevant to weaning

4 Months
Can maintain posture if supported in a chair
5 Months
Can take soft, pureed food from a spoon, form a bolus, and swallow it
Can hold objects and put them to their mouths to suck
6–8 Months
Teeth begin to erupt
Sits without support
Can chew
Can hand-feed items like biscuits
Learns to shut mouth, turn head, and indicate feed refusal
9–12 Months
Can sit easily
Attempts to use spoon
Indicates and understands 'no'
Pincer grasp of small objects

plasma concentrations of sodium and urea if there is insufficient water available for their excretion.

- The gastrointestinal tract is immature, the intestinal and pancreatic enzyme production is not fully developed, and the gut is more permeable to some of the foreign proteins introduced with food, thus increasing the risk of allergic reactions.
- Early weaning in the developing countries has been associated with a poorer growth velocity than in infants who are exclusively breast-fed. This is probably associated with the lower energy density of the cereal-based gruel offered, resulting from the addition of extra water to produce a food of suitable consistency. Also, iron bioavailability from cereal-based gruel is low. Another major problem is that contaminated weaning foods causes infection and diarrhea. This, in turn, increases nutritional requirements but often reduces an infant's appetite and overall nutritional intake.
- Solid feeding before 15 weeks is associated with increased wheeze during the first 7 years of life. There is also evidence that early exposure to solids is associated with an increased risk of eczema. In a group of children studied until the age of 10 years, it has been reported that infants given solids during the first 4 months were 1.6 times more likely to develop eczema than infants not given solids before 4 months.
- There is evidence that early introduction of solids is associated with increased body fat and weight in childhood.
- There is some suggestion that early introduction of gluten in solids may contribute to a higher incidence of celiac disease. In Glasgow, for example, records indicate that increased numbers of children were admitted to hospital with celiac disease and were diagnosed earlier during 1958–65 and 1966–73 than during 1950–57. Cereals containing gluten were also introduced earlier in Glasgow during 1958–63, and 91% of infants were given gluten by 3 months of age in 1965.

In Western countries, there is still a trend toward early weaning. The ONS survey reported that 55% of infants had been given solids by 3 months and 91% by 4 months. Babies of Asian origin in the United Kingdom were given solids slightly later than white babies, but 90% still had solids by 4 months.

Table 2 Estimated average requirements for energy during weaning

Age (months)	*Energy requirement (kcal kg^{-1} day^{-1})*

Nutritional Requirements of the Weaning Infant

In the early months of infancy, the nutrient intake is derived almost totally from human or infant formula, but in later months, the diet becomes more diverse with the introduction of solid foods. In ensuring that the provision of all nutrients is met for infants, a careful selection of solid foods given in the appropriate amount is required.

Energy

Energy should be provided in adequate quantities throughout infancy to provide fuel for the basal metabolic rate (BMR), growth, and physical activity. The amount of energy required per kilogram of body weight declines gradually, owing to a decreasing growth rate and BMR, even though the energy requirements for activity will increase as the infant becomes older.

The UK estimated average requirements for energy are given in Table 2. These are based on the results of studies using the doubly labeled water technique of measurement that reflects the total energy expenditure in free living infants and children with additions made for the energy value of new tissue deposited during normal growth.

Despite the introduction of solids, milk still needs to provide a significant proportion of the total energy intake throughout the first year of life. Fat contributes 50% of the energy in breast and infant formula milk and is the main source of energy in infants <6 months of age. It still continues to be important in childhood, and infants over 6 months of age will still need 500–600 ml of milk daily. From studies estimating the nutrient intake of older infants, solids contributed 52%, 57%, and 64% of the total energy intake at between 7 and 8 months, 9 and 10 months, and 11 and 12 months, respectively, while milk made up the rest of the energy deficit.

However, adequate energy from weaning foods should be assured, and the energy density of weaning foods is important. If it is high in carbohydrate and low in fat, the food will be very bulky, and it may be difficult for the infant to eat sufficient quantities to meet their energy needs. Failure to thrive, which is a common problem in developing countries, may result.

Protein

Protein is a crucial determinant of linear growth; it provides nitrogen and essential amino acids for synthesis of body tissue. The DOH recommends an adequate intake of protein with a proper balance of essential amino acids during weaning

(Table 3). The protein/energy ratio is also important, and it is recommended that infants between 6 and 9 months have an intake of not <1.74 g of protein per 100 kcal. In developed countries, there should be few problems in achieving an adequate energy/protein ratio, but in developing countries, if weaning foods such as rice and maize are supplemented with oil to improve energy density, this would significantly reduce the energy/protein ratio below the minimum safe ratio.

Vitamins and Minerals

Vitamin A

This is required for growth, normal development, and differentiation of tissues. The 1988 FAO/WHO expert group considered that a daily intake of 350 μg retinol equivalents would meet the needs of all healthy infants and allow the building and maintaining of sufficient liver stores (Table 4).

Vitamin D

This has an important metabolic role in the control of calcium homeostasis and deposition of calcium in the bones and teeth. There are two main forms of vitamin D: cholecalciferol, formed by the action of sunlight on 7-dehydrocholesterol, which occurs naturally in the skin of man, and ergocalciferol, a synthetic source of vitamin D. Weaning infants are vulnerable to poor vitamin D status. Weaning diets are generally low in vitamin D, and breast milk contains little vitamin D. Infant formula is fortified with vitamin D, and provided adequate amounts are consumed, infants fed with these products are unlikely to become depleted. In the United Kingdom, it is recommended that vitamin supplements including vitamin D be given to breast-fed infants from the age of 6 months and to formula-fed infants when the volume of milk decreases below 500 ml daily.

Table 3 Reference nutrient intake for protein during weaning

Age (months)	*Protein ($g^{-1}kg^{-1}day^{-1}$)*
4–6	1.6
7–9	1.6
10–12	1.5

Table 4 Reference nutrient intake for vitamins and minerals during weaning

	Age		
Nutrient	*0–3 Months*	*4–6 Months*	*7–12 Months*
Vitamin A (μg)	350	350	350
Vitamin D (μg)	9	9	7
Vitamin C (mg)	25	25	25
Calcium (mg)	525	525	525
Iron (mg)	1.7	4.3	7.8
Zinc (mg)	4.0	4.0	5.0

Source: Department of Health (1991). *Dietary reference values for food energy and nutrients. Report on Health and Social Subjects No. 41*. London: HMSO.

Iron

This is an important nutrient during weaning, which is necessary for the structure of the heme part of hemoglobin, as well a component of myoglobin and many enzymes. For breast-fed infants, after the age of 6 months, the amount of iron from breast milk is insufficient to meet increasing needs. Therefore, adequate intakes of iron, from heme (meat) and nonheme sources (cereals, pulses, and vegetables), should be encouraged with foods rich in vitamin C to aid absorption. Furthermore, the absorption of iron from breast milk is greater if breast-feeds are given separately from solid food as inhibitors in the food bind the iron from breast milk in unabsorbable complexes. Formula milks in the United Kingdom are fortified with iron, and provided infants are taking over 500 ml daily, they are at less risk of iron-deficiency anemia. However, it is still important that iron-rich weaning foods be encouraged.

Zinc

This is a component of several mammalian enzymes and is active in many metabolic pathways. Zinc deficiency may limit growth and may be a vulnerable nutrient during the weaning period. In the United Kingdom, there is evidence that the average daily intake of zinc is below the reference nutrient intake. Although meat and meat products are the richest sources of zinc, these foods provided only 10% of the dietary zinc intake.

Which Foods Should Be Given?

Initial foods should be semisolid and have a smooth consistency and bland taste, and suitable first foods are cereal, such as baby rice or pureed home-cooked rice; mashed potato; custard; plain (unsweetened) yogurt; and pureed fruit and vegetables. This should then progress to pureed meat, pulses, and a wider variety of cereals. In many parts of the world, the first food to be introduced is traditionally a cereal. In western European cultures, a commercially prepared infant cereal containing added vitamins and minerals is commonly the first food. In developing countries, the local staple cereal is more likely to be given, and this may include cereals such as corn, barley, oatmeal, millet, sweet potato, cassava, rice, plantain, yam, arrowroot, potato, and sago. These are mixed to a porridge or paste with milk or water.

Between the ages of 6 and 12 months, the texture of foods given should gradually progress from semisolid to soft family foods. From the age of 6 months, minced or mashed food with soft finger foods can be encouraged. Meat should be coarsely pureed; whole wheat cereals or instant oat cereal can be given in addition to well-cooked egg. Suitable finger foods include soft fruits, for example, banana and melon; cheese fingers; soft cooked carrot; and fingers of toast, chapati, and pita bread.

From the age of 10 months, foods such as meat should be minced or finely chopped. Cooked vegetables need only be chopped, and pasta dishes with small-shaped pasta can be given. Finger foods are particularly important at every meal to encourage the infant to participate in self-feeding.

Commercial Versus Homemade Family Weaning Foods

Homemade family weaning foods

The use of appropriately homemade foods is encouraged, and in the United Kingdom, about 40% of infants are given some homemade weaning foods. They have several advantages: (1) they accustom an infant to the taste of adult-based food; (2) they are cheap and easy to prepare; (3) wastage is low; and (4) meat-based halal weaning foods can be prepared for Muslim infants. Unfortunately, analysis of homemade weaning foods from the United Kingdom has revealed that some meals contain low amounts of energy, iron, and zinc but high amounts of nonstarch polysaccharides, protein, and sodium. Intakes of iron are also lower in infants receiving mainly family foods. Typical homemade foods given to a group of 6- to 8-month-old infants from a deprived inner city area in the United Kingdom were mashed potato, tinned spaghetti, and baked beans. However, breast or infant formula milk or cereal can be added to homemade weaning foods to the improve energy and nutrient density.

Commercial baby foods

In the developed world, commercial weaning foods (tins, jars, and packet foods) are popular, especially cereals, ready meals, and desserts. They may be fortified with extra vitamins and minerals and contain no added salt. Even with commercial baby foods, there are some cultural differences concerning manufactured foods given to infants. The Italians prefer individual constituents, that is, a meat dish to which pasta can be added, whereas the British prefer composite sweet and savory dishes.

The Codex Alimentarius Commission (WHO/FAO) has set compositional standards for baby foods. In 1996, the European Commission issued a directive on processed cereal-based foods and baby foods for infants and young children (96/5/EC); it was amended in 1999. The regulations prescribe manufacturing, compositional, and labeling requirements and prohibit the sale of any processed cereal-based food or baby food, unless it complies with the regulations. The UK government has also published an expert report on additives in food especially prepared for infants and young children, which recommended that additives should only be used when there is a strong justification on technological grounds.

Although not essential, most mothers in developed countries use commercially produced weaning foods at some stage because they are so convenient. In the early stages of weaning, dried products can be made up in small quantities, so avoiding waste. However, commercial weaning foods are relatively expensive, there is a limited range of vegetarian foods, and there is a tendency for some parents to keep infants on strained varieties for prolonged periods of time, which may contribute to the delayed acceptance of more lumpy food.

Foods Avoided During Weaning

Salt

In the West, it is widely recommended that salt should not be added either to weaning foods during the cooking process or to the food at the table, as the developing kidney is unable to excrete large sodium intakes. Excessive sodium intake in young infants is associated with hypernatremia. In addition, there is some concern that a high salt intake in infancy and childhood may cause hypertension in later life; the evidence for this is unconvincing.

Sugar

It is recommended in North America and Europe that sugar should be kept to a minimum and should not be added to foods during preparation. The preference for sweet foods and drinks has been demonstrated even in preterm infants. To avoid encouraging the taste for sweet foods and to reduce the risk of dental caries, sugar should be avoided as much as possible. Even so, in the United Kingdom, it is common to introduce sugar-based foods early in the diet. In the MAFF survey looking at infant-feeding practices between 6 and 12 months, 62% had been given sweets and chocolate, 70% received biscuits, and 45% of mothers gave milk-based dishes sweetened with sugar.

Gluten

There are many disputes about the best time to introduce gluten into the diet. Delayed introduction is associated with an increased age of onset, although there are those who maintain that it decreases the incidence. Challacombe et al. suggested that later introduction of gluten, increased use of gluten-free foods for weaning, and increased incidence of breast-feeding are associated with a decreasing incidence of celiac disease and transient gluten intolerance. However, in Sweden, a doubling of the gluten content of commercial baby foods was associated with an increased incidence of celiac disease from 1.7 children per 100 live births during 1978–82 to 3.5 per 1000 thereafter. This occurred in spite of an increased prevalence and duration of breast-feeding and the delay in the introduction of dietary gluten from 4 to 6 months. Gluten-sensitive individuals who are breast-fed and who are introduced to gluten relatively late may not present clinically during weaning, although the disorder is still thought to manifest at an older age, and the cumulative prevalence is unaffected. Therefore, to prevent celiac disease developing at least during the early weaning period, when the infant is particularly vulnerable nutritionally, it is recommended by most health professionals that cereals given to infants under 6 months should be gluten-free.

Food Allergens

Infants are most vulnerable to the initiation of food allergy in the first months of life, and the risk of food allergy is greatly increased by family history of atopic disease such as eczema and asthma. When there is a strong family history of allergy, mothers should be encouraged to breast-feed for 6 months or longer. Weaning should be particularly discouraged before 4 months, and foods traditionally regarded as allergenic (e.g., cows' milk, soya protein, gluten, eggs, fish, and nuts) should not be introduced until 6 months of age at the earliest. In the United Kingdom, a working group for the Committee on Toxicity of Chemicals in Food, Consumer Products and the Environment recommended that peanuts or peanut products

should be avoided until 3 years of age in all children with a parent or sibling with an atopic disease.

Suitable Milks During Weaning

Breast milk

This should be encouraged, but from 6 months of age, breast milk cannot supply the requirements for several micronutrients, including iron, copper, zinc, and vitamin D. Dietary sources should be given either as part of the weaning diet or as specific supplements, for example, vitamin D supplements.

Infant formula

Providing it is iron-fortified, it should be continued until the age of 1 year. It is a particularly good source of vitamin D, and infant formula sold in the United Kingdom is also rich in iron. Provided that a volume of 500 ml daily is taken, there should be no need to give extra vitamin supplements.

Follow-on formula

This is intended for older infants over the age of 6 months. It is based on modified cows' milk. It contains less protein, calcium, and phosphorus than cows' milk but more than standard infant formula. Most follow-on formula contains almost double the iron and 45% more vitamin C than standard infant formula. It can provide a useful drink for older infants if breast-feeding has been stopped or the volume of standard infant formula is <400 ml daily. However, follow-on formula should not replace breast milk or standard infant formula if the volume of either is adequate.

Whole cow's milk

This is not suitable for infants under 1 year as the main drink. It is low in iron, vitamin C, and vitamin D. It may be used in small quantities in the preparation of solid foods.

Goat's and sheep's milks

These are low in iron, vitamin D, and folic acid and should not be given to infants under 1 year of age. Although these milks may be perceived as less allergenic or else providing special nourishment, none of these claims have been substantiated.

Problems Associated with Weaning

Iron-Deficiency Anemia

Iron-deficiency anemia in later infancy and the toddler years is common throughout the world, and simple dietary iron deficiency is the most common cause. In the United Kingdom, it is particularly frequent in ethnic and socioeconomically deprived toddlers, and 4–28% of older infants have been reported to have iron-deficiency anemia. It can cause psychomotor delay, apathy, irritability, reduced attention span, pallor, decreased resistance to infection, reduced exercise capacity, and poor appetite. It is associated with prolonged use of breast-feeding, early introduction of whole cow's milk, and inadequate dietary iron during weaning. There have been many initiatives to try and reduce the prevalence of iron-deficiency anemia in the Western world. These include screening, health education, iron fortification of food, and extension of the use of iron-rich infant formula. Although large-scale dietary education has failed to reduce iron-deficiency anemia in the United Kingdom, programs to provide supplemented food containing iron to target groups have been shown to be successful in the United States. In addition, in the United Kingdom, a project extending the use of iron-fortified follow-on formula beyond 1 year significantly reduced the prevalence of iron-deficiency anemia.

Rickets

Prolonged deficiency of vitamin D can result in rickets. The main symptoms include skeletal deformity, delayed dentition, bone pain, muscle weakness, hypocalcemia, misery, and failure to thrive or short stature. Children under 3 years are particularly vulnerable to a poor vitamin D status because of demands resulting from the high rate at which calcium is being laid down in the bone. Although it is uncommon in Europe and North America, new cases are still being reported particularly in northern climates and immigrant children. In the United Kingdom, low-serum 25-hydroxycholecalciferol concentrations have been noted in 20% of Bangladeshi, 34% of Pakistani, and 25% of Indian 2-year-old children living in England. Low 25-hydroxy vitamin D levels have been noted in the winter in British children not taking vitamin D supplements.

Rickets is commonly reported in some hot climates. In a recent Nigerian study, overt rickets was found in 2.4% of households. Factors in hot climates such as increasing urbanization and the tendency of mothers and their young children to avoid exposure to sunlight, either by remaining indoors or in the shade or by covering the skin, must all contribute to a decreased endogenous synthesis of vitamin D, in combination with a poor vitamin D or calcium intake. In Western countries, prolonged breast-feeding by mothers of poor vitamin D status, early introduction of whole cows' milk, poor weaning sources of vitamin D, little exposure to sunlight, and even the use of sunscreen are contributing factors.

Vitamin A Deficiency

In the developing world, vitamin A deficiency is one of the most common causes of blindness in children, particularly in the Middle East, the Indian subcontinent, and Southeast Asia. It causes xerophthalmia, keratomalacia, and eventually blindness. This is due to reduced infant stores of vitamin A due to maternal deficiency, low vitamin A-containing breast milk, and weaning diets low in preformed retinol from animal food. Vitamin A deficiency is often accompanied by protein-energy malnutrition. Vitamin A supplements, even in the absence of clinical overt deficiency, reduce child mortality.

Weaning Practices in Developing Countries

The weaning infant is potentially at risk in developing countries, and many nutritional problems arise with the introduction of solids. The need to introduce nonmilk food sources with only the availability of rather crude preservation processes, poor hygiene, sanitation, and inadequate water supplies

introduces the risks of gastrointestinal and parasitic infection because of the heavy contamination of foodstuffs with infecting organisms. In rural Bangladesh, a significant association has been found between the frequency of isolation of *Escherichia coli* in the weaning foods and *E. coli* diarrhea in the infants consuming them, and there can be little doubt that food plays an important role in the epidemiology of diarrhea in young children. The effects of infection lead to anorexia and pyrexia with increased metabolic requirements, and this can only serve to exacerbate any effects of a poor nutritional intake. In addition, many infants have been breast-fed for prolonged periods of time without weaning solids, and when they are introduced, it is probably a low-energy-density, cereal-based gruel that may be given only once or twice a day. The continued effects of deteriorating nutritional status and infection may lead to protein-energy malnutrition.

Infrared Spectroscopy: Applications

E Capuano and SM van Ruth, Wageningen University and Research Centre, Wageningen, The Netherlands

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Infrared spectroscopy (IRS) is one of the most important analytic techniques available to food scientists and industry nowadays. IRS provides qualitative and quantitative information in a fast, cost-effective and nondestructive way, does not require the use of polluting chemicals, and can be carried out even by minimally trained personnel. This makes IRS a potent tool for the quality control/assurance in a variety of different (industrial) settings and suitable for applications under steady process conditions, that is, on-line. IRS has also widened the horizons for the detection of adulteration and the authentication of food products. The first IRS instrumentations became available in the late 1940s. The earliest applications of IRS were reported in the 1950s, but it was not until the 1960s that IRS was used for the analysis of food samples. The most significant advancement in IRS has resulted, however, from the introduction of Fourier transform (FT) instruments that has made IRS even more rapid, reproducible, and sensitive.

IR Spectra and Spectral Analysis

In IRS, a test sample is irradiated with infrared radiation and the transmitted or reflected radiation is measured. Infrared spectra are obtained by plotting the measured absorbance against the corresponding wavelengths. IR radiation triggers transitions in the vibrational states of the sample molecules. Each functional group of a molecule shows characteristic IR absorption at specific wavelengths. The IR region of the electromagnetic spectrum can be divided into three portions: The far IR (FIR, 400–10 cm^{-1}) has the lower energy and induces rotational transitions in the molecules. It has very limited applications in the food domain. The mid-IR (MIR, 4000–400 cm^{-1}) induces fundamental vibrational transitions in the molecules. The near-IR region (NIR, 14 000–4000 cm^{-1}) induces transitions over two (first overtone), three (second overtone), or higher energy levels. A typical spectrum in the NIR region is shown in Figure 1. In general, the absorption bands in the MIR region are more intense than those in the NIR region. Besides, the NIR spectra mainly arise from the superposition of combination modes and overtones, which makes NIR spectra more complex and difficult to interpret than MIR spectra. Besides the chemical composition of the test sample, the IR spectral characteristics also depend on the test sample light scattering properties and thus to its microstructure. Chemical information can be extracted from an IR spectrum from the bands position, intensity, and shape. In pure component systems or very simple mixtures, the band position can be easily related to the molecular structure of a component in the mixture, whereas the band intensity is related to its concentrations through the law of Lambert–Beer. However, foods are very complicated and heterogeneous systems, constituted of countless chemical compounds, which gave rise to complex IR spectra with overlapping bands. In such a situation, when the effect of all the functional groups is taken together, the whole spectrum represents a molecular fingerprint that can be used to verify the nature of the sample. This means that the whole information contained in the IR spectrum (or a selected part of it) is used to infer about the properties of the system under study. To extract relevant information from this complex spectra, however, a special statistical tool is necessary, that is, chemometrics.

Multivariate Statistical Analysis of IR Data

Chemometrics can be defined as the science of extracting chemically relevant information from multivariate datasets by using appropriate statistical techniques. Chemometrics are used to reduce the dimensionality of the data, to reveal relationships between samples, and to detect characteristic patterns that can be used to identify a certain material. As a first step, unsupervised pattern recognition techniques (so-called because they do not require any prior knowledge of the sample properties) are applied to investigate the natural relations between the samples. Examples are hierarchical cluster analysis, cluster analysis, and principal component analysis (PCA). As a further step, supervised pattern recognition techniques may be applied to either classify a certain product or quantify a certain property of the product. Classification models aim to classify new unknown samples in one of the known classes on the basis of its pattern of measurements. The techniques most widely used are k-nearest neighbors, soft independent modeling of class analogy, partial least square regression discriminant analysis (PLS-DA), linear discriminant analysis, support vector machine, and artificial neural network. Regression models establish a functional relationship between a quantitative sample property and a set of independent variables, and the model is used to predict the property of interest in the unknown sample. Multivariate regression methods are used such as principal component regression and partial least square regression.

The building of a classification (or regression) model based on IR spectra normally comprises the following steps: Spectral pretreatment (1) is necessary to exclude all the irrelevant information contained in the spectra (noise) before further modeling. Centering of the data (subtracting the average from each variable) is often the first preprocessing procedure. It may be followed by spectral standardization (dividing every wavelength by the standard deviation of the spectrum at that wavelength), which is not always advisable in IRS because of the amplification effect it may have on spectral noise. Normalization procedures are used to compensate for additive (baseline shift) and multiplicative (tilt) effects in the spectral data induced by physical effects, such as the nonuniform scattering throughout the spectrum (the degree of scattering depends on the wavelength of the radiation) or the particle size. The standard normal variate (SNV), multiplicative scatter correction, and wavelet transforms are typical normalization procedures

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00644-9

in IRS. Derivation (calculation of first and/or second derivatives) is sometimes applied to remove baseline shifts and correct additive or multiplicative effects. One of the effects of derivation is to enhance the spectrum resolution and the importance of small peaks and shoulders compared to bigger peaks. Other manipulative techniques such as smoothing (reduction of the spectrum 'resolution' and hence of the associated noise) and deconvolution may help in improving the interpretation of IR spectra. The following step is the selection of a training set (2), which consist of objects of known class membership (or known quantitative values of a sample property) for which the IR spectra are measured. In the variable selection step (3), the wavelengths that contain information for the target classification/regression are retained, whereas those with no discriminating power are eliminated. Then, a model is built using the training set (4). A mathematical model is derived between the selected wavelengths measured on the training set and their known categories (or quantitative values of the sample property). Finally, the model is validated (5) to test the reliability of the classification achieved using either an independent set of samples (external validation) or the training set (cross validation). The accuracy of classification models is usually expressed as sensitivity (% of samples of class 1 correctly allocated to their actual class) and specificity (% of samples of class 2 correctly allocated to their actual class). The accuracy of regression models is estimated by the root-mean-square error of calibration, cross validation, and prediction, which measure the difference between predicted values and those measured by the standard reference method on samples of the calibration, training, and test set, respectively.

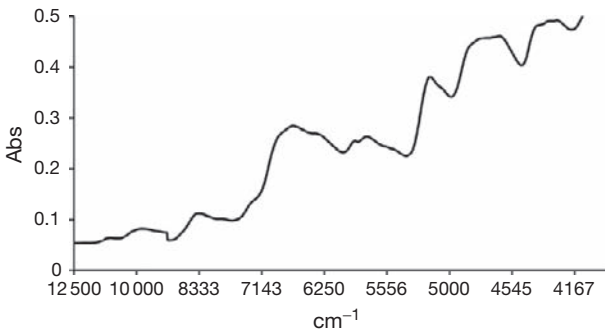

Figure 1 Typical NIR spectrum of a milk powder sample.

Instrumentation and Measurement Setup

Conventional IR instruments consist of a light source, accessory for the sample preparation, a monochromator, a detector, and optical components (lens, collimators, beam splitters, etc.). A schematic description of a typical dispersive IR instrument with double-beam operation is given in Figure 2. Radiation produced by a broadband source is split into two by a beam splitter. One radiation is sent to the sample and the other to a reference. The radiation transmitted (or reflected) by the sample and the reference is then dispersed by a monochromator into component frequencies and collected by the detector, which compares the two radiations and generates an electrical signal, which is converted to an IR spectrum. The radiation source is commonly an inert solid electrically heated to 1000–1800 °C. Based on the type of monochromator, IR spectrophotometers can be classified as filter instruments, scanning monochromator instruments (a grating or prism is used to separate the single wavelengths), or FT spectrophotometers. In a FT spectrophotometer, conventional prisms or grating monochromators are replaced by an interferometer. FTIR utilizes interferometric modulation of radiation to measure multiple frequencies simultaneously, producing an interferogram that is converted to the original spectrum using the Fourier mathematical transform. The most common IR detectors may be either thermal-sensitive (thermocouples, thermistors, and pneumatic devices) or photon-sensitive (based on the interaction of IR radiation and a semiconductor material).

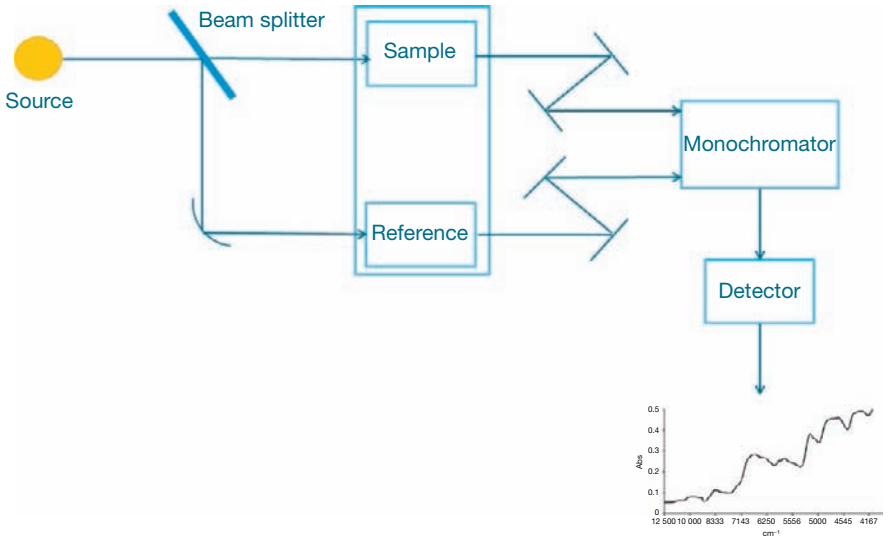

Figure 2 Schematic representation of a typical conventional dispersive IR instrument in transmittance mode and double-beam operation.

Three different acquisition modes are possible according to the arrangement between the sample, the radiation source, and the detector. In the (diffuse) reflectance mode, the IR radiation that is reflected by the test sample surface is acquired by the detector, which is positioned on the same side as the source. The radiation penetrates in the samples to a depth depending on the geometry of the optical probe and the scattering properties of the sample before being reflected so that information on sample surface and, partially, interior is obtained. Under specific conditions, light can undergo internal reflection, which occurs when a beam of radiation enters from a more dense medium (with a higher refractive index) to a less dense medium and which forms the basis for the attenuated total reflection (ATR) technique. In internal reflectance, information on the sample surface is obtained. The reflectance mode is well suited for opaque or strongly absorbing materials. In the transmittance mode, the IR radiation passes through the sample and is collected by the detector that is positioned opposite to the light source. The transmittance mode is more suited for translucent or weak absorbing media. In the interactance mode, the light is at the same time absorbed and reflected by the test sample and collected by the detector that is positioned in a way that prevents specular reflection to reach the monochromator. Sample preparation and presentation as well as the acquisition mode differs according to the instrumentation setting used, the localization of the compound(s) to be measured, and the mode of measurement (off-line, on-line, or at-line). Solid samples can be measured as such (intact material) or after grounding to reduce particle size and related scattering and, for heterogeneous solids, to ensure that surface is representative of the sample thickness. Normally, an amount of sample variable from 0.1 g to few grams is needed depending on the food materials and measurement mode. Thicker samples will usually require more energetic radiation (shorter wavelengths) than thin samples to obtain useful information.

IRS has also been combined with imaging techniques and microscopy to yield hyperspectral imaging (HSI) technologies and IR microspectroscopy (IRMS), respectively. In HSI, spectral and spatial description of a test sample is obtained, which is contained in hyperspectral images or hypercubes, that is, three-dimensional datasets, which contain spatial information on the X,Y plane and spectral information along the *Z*-axis. Thousands of spectra can be obtained each from a specific spot on a sample surface that may give information, for example, on the distribution of chemical compounds in a sample. Hyperspectral camera makes use of the same essential parts of conventional IR spectrophotometers with the addition of an area detector, that is, a device that is able to scan and acquire spectral information from the whole of the object area. In IRMS, the IR spectrophotometer is combined with an optic microscope. In IRMS, the spectra can be acquired from a sample area measuring only few micron, which allows to obtain spectral information from a small amount of sample or from small regions within a sample.

Applications of IRS

The chemical and physical information contained in an IR spectrum can be used for several purposes. Currently, applications of IR spectroscopy in the food domain have been reported in the following fields: (1) chemical characterization of a food sample, (2) detection of spoilage and analysis of foodborne pathogenic bacteria, (3) prediction of food quality, and (4) authentication and detection of adulteration. The selection of the most suitable IR technique, instrumentation, and acquisition mode will depend on the problem at stake, the property to be measured, and the micro- and macrostructure of the test food. In practice, NIR spectroscopy (NIRS) requires less sample preparation and is thus more suited for on-line or *in situ* analysis but is less sensitive (especially toward minor components), selective, and reproducible than MIR spectroscopy (MIRS). On the other hand, NIRS provides more complex structural information that is advantageous for fingerprinting approaches and is able to probe food at higher depth and through NIRS transparent packaging materials. Finally, NIRS is less sensitive to water but it is more sensitive to the diffusion of light. Most of the reported applications have been carried out in a laboratory environment, but several implementations on-line or in-line in industrial settings have been reported as well. An overview (not exhaustive) of the applications of IRS in the food domain is reported in Table 1.

Chemical Characterization of Food Products

One of the major applications of IRS for food quality control is the rapid and nondestructive quantitative analysis of food constituents. Both major (water, protein, fat, and carbohydrates) and minor components can be quantified as well as groups of chemically or functionally similar compounds. For quantitative purposes, a multivariate regression model has to be developed based on a specific set of wavelengths of the IR spectra. Conventional IRS provides spot measures of the concentration of the target compound. This information can be extended to the whole test sample if the constituent has a homogeneous distribution throughout the sample or across its surface. Several foods are, in fact, heterogeneous in composition. HSI has the potential to provide a detailed description of the spatial distribution of compounds and their concentration gradients.

The advantage of IRS is that several food constituents can be quantified at once from the same spectrum. For instance, MIRS is applied for the quantitative analysis of major milk components (proteins, fat, and lactose) since decades and is extensively employed for routine compositional quality control analysis in the dairy industry. For quantification purposes, the absorption bands at approximately 1175 cm^{-1} (corresponding to the triglyceride ester bond, C–O), 1750 cm^{-1} (corresponding to the carbonyl group of fatty acids (FA)), and 2800–3000 cm^{-1} (corresponding to the C–H bonds in FA acyl chain) are used to quantify fat. The bands at 1653 cm^{-1} (amide I) and 1567 cm^{-1} (amide II) are used for the quantification of proteins and give information on protein secondary structure. The region between 1100 and 1000 cm^{-1} (arising from C–O and C–H stretch) is used to quantify lactose. NIRS has also been successfully applied to the quantification of major food constituents. Indeed, an NIRS-based method has been approved by AOAC INTERNATIONAL as official method for the analysis of moisture, fat, and protein in meat and meat products (AOAC 2007.04). The quantification is carried out by

Table 1 Overview (not exhaustive) of the reported applications of IRS in food analysis

Food category	*Chemical characterization*	*Microbiological quality*	*Quality grade and sensorial/ technological attributes*	*Authentication and detection of adulterations*
Dairy	Proximate composition	Total viable count in milk	Sensorial attributes in cheeses	Geographic origin of cheese
	Dry matter	Detection and quantification of pathogens	Freezing point depression of milk	Pasture grazing and animal diet for cows' milk
	Water-soluble nitrogen			Adulteration of sheep/goat milk with cow milk
	Urea			Adulteration of milk, milk powders, and infant formula with melamine
	Free FAs			
Meat and meat products	Proximate composition	Total viable count	Quality grade	Adulteration with cheaper meat
	Collagen	Level of spoilage	Tenderness	Discrimination between fresh and frozen/thawed meat
	Individual FAs		Juiciness	Farming system
			Texture	Organic meat
			Chewiness	Animal diet
			Water holding capacity	Adulteration with pork meat
			Press and cook loss	Storage conditions
			2-day loss postmortem	Animal breed
			Drip loss	
			Warner–Bratzler shear force	
			Fecal contamination of carcasses	
Edible oils	Peroxide value		Antioxidant stability	Adulteration of EVOO
	Free fatty acids		Freshness	Adulteration of animal fat
			p-Anisidine value	Botanical origin
				Geographic origin
Fish and fish products	Proximate composition		Freshness	Farming system
	Dimethylamine		End-point temperature	Authentication of wild fish
				Discrimination between fresh and frozen-then-thawed fish
Grain and cereals	Proximate composition		Mixogram midline point	Varieties
	Trans FAs		Digestibility by cellulase	Organic farming
	Amylose			
	Ash			
	Protein secondary structure			
	Starch gelatinization/ Retrogradation			
	Dry matter			
	Starch			
	Dietary fiber			
Fruits and vegetables	SSC	Total viable count	Sensorial attributes	Geographic origin
	°Brix		Firmness	Adulteration of jam, fruit juices
	Dry matter		Stiffness	Adulteration of maple syrup
	Sugars		Internal defects and diseases	Varieties
	Carotenoids and antioxidants		Ripeness and maturity	
	Starch		Mechanical damages	
	Acidity			
	Essential oil			
	Cell wall pectins			
Honey				Authentication of specialty honey
				Geographic origin
				Botanical origin
				Adulteration with cheaper honeys/ components

measuring the absorbance of O–H bonds at 6895 and 5140 cm^{-1} (water), of the N–H bonds at 6370–6850 cm^{-1} and 4590–5000 cm^{-1} (proteins), and of the C–H bonds of FA at 7150–9000, 5900, and 4160–4500 cm^{-1} (fat). Similarly, grain proximate composition can be accurately predicted by NIRS. These methods have already been adopted in inspection programs by the Canadian Grain Commission and the Grain Inspection, Packers and Stockyards Administration in United States for testing protein content in wheat since early 1980s and have been adopted by the American Association of Cereal Chemists and AOAC for grain analysis. Nowadays, NIRS field instruments that can analyze grain composition directly on grain elevators or harvesting machines are available.

Minor food constituent can also be predicted with acceptable accuracy by NIRS and MIRS. Normally, the prediction of food constituents that occur in lower concentrations MIRS is more advantageous compared to NIRS. Some examples are urea and free FA in milk (by MIRS), single FA in milk and beef (by NIRS and MIRS), total fibers in grains and cereal-based goods (NIRS), soluble sugars and starch in a variety of food products (NIRS and MIRS), alcohol content in wine and spirits (NIRS), and many more. Applications of IRS for the quantification of toxins and other harmful compounds have been also reported. Two ATR-FTIR methods have been recently adopted as official standards for the quantification of *trans* FA content of food (AOCS Cd 14d-99 and AOAC method 2000.10). These methods are based on the IR band at 966 cm^{-1} corresponding to out-of-plane deformation of the C–H bond. Applications are also reported for mycotoxins, tetracyclines, and pesticides.

The applicability of IRS for the quantification of minerals and ash is limited because IR radiation does not interact with minerals or inorganic compounds in their ionic forms. However, information on the mineral composition can be obtained from the modification of the IR spectra induced by the associations with organic acids, organic ions, and chelating agents.

Besides the quantitative determination of single food constituents, IRS can be used to monitor complex chemical and physical changes during food processing. Such changes would reflect in changes in the IR spectrum that may therefore be used to gain insight in the advancement of a process (thermal treatments, fermentation, curd formation in cheese-making, and fruit ripening) or on structural (and functional) changes of its constituents (changes in the protein secondary structure during dough mixing or compositional changes during the gelatinization and retrogradation of starch).

Detection of Spoilage and Analysis of Foodborne Pathogenic Bacteria

One of the most promising applications of IRS in food is the rapid and cost-effective quantification of microbial contamination, the identification of microbial species or strains, and the monitoring of food spoilage. This is especially important because the traditional microbiological methods for the quantification and identification of bacteria or fungi in food are extremely time-consuming and expensive and require highly trained personnel. Spectra can be acquired indirectly from cultured microorganisms or directly from the surface of the food.

The principle behind the application of IRS for the detection and the monitoring of food spoilage is that spoilage is accompanied by chemical modification of the substrate due to the microbial enzymatic activity that is reflected in changes of the IR spectra of the test food sample. Applications have been reported for meat, minced beef, fish, milk, and cabbage, most employing FT-MIRS. The enumeration of spoilage bacteria in milk, for instance, is possible with acceptable accuracy with bacterial loads as low as 10^3 cfu ml^{-1} for whole milk and 4×10^2 cfu ml^{-1} for semiskimmed and skimmed milk. Microbial load from the surface of comminuted chicken breast can be also predicted with acceptable accuracy (RMSE = 0.27 log units in independent test set external validation) by FT-MIRS and to a less extent in rump steak or minced beef. In meaty matrices, the changes in the MIRS spectra involve in particular the fingerprinting region and especially the wave numbers corresponding to the vibration of C–N bonds in amides and amines, which is consistent with the fact that the main biological event occurring during spoilage of meat is proteolysis. Where microbial load cannot be predicted with acceptable accuracy, classification models can be developed in order to discriminate well-defined sensory groups or groups characterized by different levels of spoilage (for instance, fresh, semi-fresh, and spoiled) as reported, for example, on beef fillets and minced pork meat.

Another IRS application is the identification and quantification of selected microorganisms (bacteria and fungi) in food systems. Each bacterial or fungal species possesses a distinctive molecular structure that depends on the protein, lipid, nucleic acid, and carbohydrate composition of its cell wall/membrane and cytoplasm. As a result, each species or strain has its own 'whole organism' spectral fingerprint that can thus be used for species/strain identification. Applications have been reported by both NIRS and MIRS as well as by IR microspectroscopy. When the MIRS region of the spectrum is used, the fingerprinting region (900–1500 cm^{-1}) is especially important for the discrimination of bacteria at strain level. The results reported in the scientific literature do not allow general conclusions to be drawn. In some studies and for certain bacteria, the identification is highly accurate at the species and even the strain level, whereas in other cases, accurate prediction could be obtained only at the genus level. The identification and quantification of pathogenic microorganism are clearly of major interest in food systems. This is more conveniently achieved by first extracting and isolating the microorganism from the food product and then comparing the IR spectra with a spectral library of known bacteria. Several pathogens can be, for instance, detected and quantified directly in apple juice, whereas there are few reports on detection of pathogens from solid food by FTIR. The limit of detection of pathogens in food is reported ranging from 10^3 to 10^6 CFU g^{-1} depending on bacteria and food.

Another interesting application of IRS is the discrimination between dead and injured bacterial cells in a food product. The presence of injured cells poses a serious health threat to the food industry if they revive at a later step. Investigations have been reported for several bacterial species (*L. monocytogenes*, *S. typhimurium E. coli*, etc.) injured with a variety of methods (heat, denaturants, sonication, and radicals). Normally, the differences between live and injured cells are minimal, which

requires special data processing of the IR spectra, for example, derivation, for those small spectral differences to be amplified and mainly concern the absorption bands for proteins and nucleic acids that are most sensitive to denaturation.

Determination of Quality Grade, Technological, and Sensorial Attributes

IRS can be used for the assessment of the quality grade or qualitative properties of food. This is especially important because this might require extremely time-consuming and expensive analyses such as sensory analysis by trained panelists. For instance, FT-MIRS has been found to predict with acceptable accuracy the sensorial attributes (chewiness, creaminess, meltability, etc.) of cheddar cheese or the instrumental texture and meltability attributes of processed cheese. Some quality attributes are correlated with major chemical food constituents and may be therefore predicted with accuracy. For instance, fruit maturity is correlated, even though not exclusively, to sugar content and can be therefore successfully predicted by NIRS. Another example is the antioxidant capacity of fruits and vegetables, which is obviously correlated to the content in antioxidant compounds and can be predicted with acceptable accuracy by MIRS. Reasonable results have been achieved by NIRS for the texture attributes of fruits and vegetables that are related to the scattering properties of their tissues. Technological attributes can also be predicted by NIRS or MIRS with varying degree of success. Several efforts have been made to predict important technological attributes of meat such as texture, water holding capacity, drip, cook and press loss, and shear force, generally with unsatisfactory results. On the other hand, NIRS can accurately predict meat quality grade and sensory tenderness. Other examples include the assessment of fish freshness and the detection of internal browning in apples. Finally, HSI is naturally suited for the (1) monitoring of fruit surface quality attributes such as bruises and other mechanical damages, (2) the detection of surface or internal defects and diseases in fruits and vegetables, and (3) detection of contamination with fecal matter or parasites in chicken carcasses and fish.

Food Authentication and Detection of Adulteration

In recent years, countless IRS applications have been reported in the scientific literature for the authentication of food and detection of adulterations. Those applications span from the verification of the geographic origin and traditional production to the genetic origin of raw ingredients, from the verification of farming management system (organic, biodynamic) to processing (irradiation, freezing/thawing, and heat treatment), and from the verification of sustainable productions. For the authentication of food products, IRS can be used quantitatively, that is, to detect and quantify the amount of a target adulterant, or qualitatively, that is, by discriminating and predicting the real nature of an unknown sample (e.g., organic food). There are two major advantages in using IRS for food authentication. The first advantage relies on the fingerprinting nature of IRS. Indeed, some quality attributes such as the geographic origin or the farming management systems (organic, free range, etc.) cannot be easily verified by traditional approaches based on target analysis of one single marker. The second advantage is that traditional quality control strategies are not designed to look for all the potential adulterants so that an adulteration can be detected only if the adulterant is known beforehand and explicitly searched for by the analyst. IRS may allow the detection of yet unknown adulterants by highlighting untargeted differences between the test material and a genuine reference standard.

One of the most relevant examples of application of IRS is the detection of melamine adulteration in dairy products. Melamine (2,4,6-triamino-1,3,5-triazine) is a nitrogen-rich compound (N makes up approximately 60% of the melamine molecule) that may be fraudulently added to milk to increase the apparent protein content when this is measured by Kjeldahl method, which measures the total nitrogen content as indicator of protein level. Reference methods for the detection of melamine in dairy products are sensitive and specific but are time-consuming and labor-intensive. Both MIRS and NIRS can be successfully applied to detect melamine in dairy products (infant formula, milk powder, and liquid milk) with a limit of detection below 1 ppm, which is the threshold limit set, by FDA in infant formulas. The spectral regions 6900–6780 cm^{-1} (attributed to aromatic amine structures) and 12 497–6098 and 5450–4249 cm^{-1} (attribute to the overtone absorbance of NH_2 stretching and bending) are the most important for the discrimination between genuine and adulterated samples.

Another example of successful application of IRS for detection of adulteration concerns oils and fats adulteration. Olive oil is probably the most popular vegetal oil consumed. The extra virgin olive oil (EVOO) represents the highest quality and most expensive olive oil category. EVOO is frequently adulterated with recycled oils, refined olive oil, or cheaper edible oils. NIRS and MIRS have been both investigated for the detection of such adulteration. The adulteration of EVOO with a wide range of oils may be detected by FT-MIRS at a level that depends on the type of oil and may be as low as 1% w/w (palm oil). The region of the MIRS spectra that contains the most valuable information for the authentication of oils is the fingerprinting region (1500–900 cm^{-1}), in particular the bands associated with bending of the C–H bonds of FAs. NIRS is reported to be as successful as MIRS for the detection of adulteration of EVOO with cheaper edible oils such as sunflower oil, at a level as low as 1% (w/w). IRS has also been employed for the authentication of lard and other animal fats. For instance, the adulteration of shortening with lard can be detected at levels ranging from 0 to 100% and a standard error of calibration of 1.75% by using the regions 1.117–1.097 cm^{-1} and 990–950 cm^{-1} of the NIRS spectrum. The standard of identity for butter requires that no vegetable oil nor margarine is added to the product. The presence of margarine can be detected by NIRS coupled with PLS with a standard error of cross validation $<1.2\%$.

IRS can also be proficiently used for the authentication of food products, for example, specialty honey. Manuka honey is a high-quality monofloral honey produced exclusively in New Zealand and Australia from the nectar of the manuka tree. It is classified as a therapeutic good in Australia because of its proved antibacterial properties related to the high content in methylglyoxal. Manuka honey can be successfully discriminated from non-manuka honey by NIRS. In Figure 3(a), the raw IRS

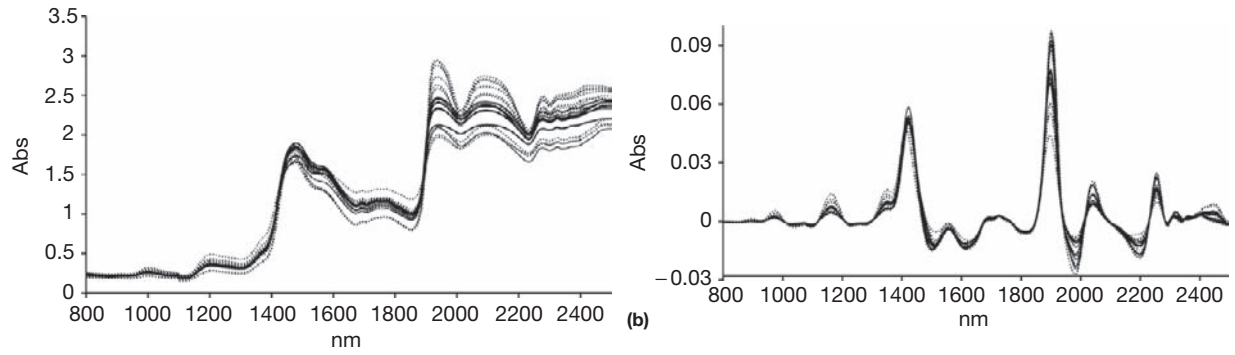

Figure 3 NIR spectra of conventional (full line) and manuka (dotted line) honey before (panel a) and after preprocessing (SNV and first derivative, panel b).

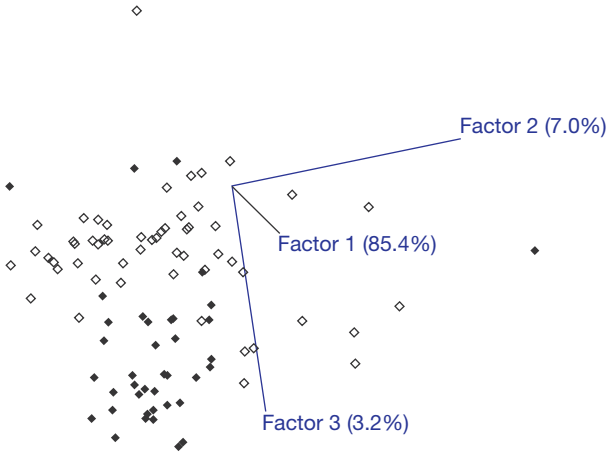

Figure 4 PCA score plot of the first three principal components of the preprocessed (mean centering, SNV, and first derivative) NIR spectra. Black diamonds = manuka honey; white diamonds = non-manuka honey.

reflectance spectra obtained from manuka honey and non-manuka honey samples are compared. The differences in the scattering properties of the honey samples caused a drift in the baseline, which made it mandatory the preprocessing of the spectra to normalize the physical effect. In Figure 3(b), the preprocessed spectra (mean centering, SNV, and first derivative) are illustrated. At this stage, some differences between the two classes are visible at several wavelengths, but to detect the distinctive patterns for the two groups, a chemometric treatment of the data is necessary. In Figure 4, a PCA score plot of the first three principal components of the NIRS data is depicted. In the PCA score plot, a discrimination between the manuka honey samples and the conventional honey samples appears. The two groups form relatively distinct and separate clusters. A PLS-DA model developed on the preprocessed NIR spectra correctly classified 8 out of the 10 manuka honey samples and 12 out of the 14 conventional samples in external validation.

Further examples of IRS applications in the authentication field are (i) verification of fresh grass feeding/pasture grazing for cows' milk; (ii) assessment of the ripening time in cheese; (iii) discrimination between wild and farmed fish and verification of the fish rearing system (extensive, intensive, cage, pond, etc.); (iv) discrimination between fresh and frozen/thawed fish and meat (related to modification of the myofibrillar proteins and the corresponding change in their water holding capacity); (v) verification of the geographic origin of cheeses, strawberry, saffron, honey, tea, wines, and orange; and (vi) authentication of organic feeds and coffee varieties (arabica and robusta).

Advantages and Limitations of IRS

One of the great advantages of IRS is that virtually any sample in any state may be studied with the choice of the proper sampling technique, acquisition mode (transmittance, interactance, and reflectance), and instrumentations. Moreover, since all the molecules adsorb radiations in the IR region to undergo transitions in the vibrational state, IRS has a wider applicability compared to other spectroscopic techniques such as fluorescence spectroscopy, which relies on the presence of fluorescent compounds or visible spectroscopy.

Another advantage of IRS (as well as of other spectroscopic techniques) over the traditional wet analytic techniques is that IRS is incomparably faster and has more high throughput. For instance, the determination of the protein content in a food samples by IRS requires few seconds (the time needed to acquire the IR spectrum, if a reliable calibration curve has already been developed), whereas the reference Kjeldahl method would require several hours. This advantage is even greater if one considers that several parameters (not only chemical properties but also physical properties, quality attributes, and the genuine/adulterated nature of a food sample) can be estimated simultaneously from the same IR spectra. Moreover, the information contained in an IR spectrum can be stored for a formally indefinite time to be used in the future.

Another remarkable advantage of IRS is that it is a non-destructive analysis, which makes it suited for the in-line quality control in a variety of different industrial settings. The food and beverage industry has indeed long used IRS for the quality control of raw materials and intermediate and final products and for the process monitoring. The assembling of an IRS equipment on the production line allows a monitoring of the process at any desired time and the early detection of failure or deviations. From this standpoint, the appearance of fiber-optic probes has significantly improved the ability of IRS to monitor and control processes remotely. However, this mainly holds true

for NIRS, whereas traditional MIRS instruments normally require a certain level of sample preparation before analysis. The introduction of the ATR technique has partially overcome this problem making it possible the analysis of food samples by MIRS regardless of their physical state with little or no sample preparation.

Finally, a big advantage of IRS (as well as other spectroscopic techniques where no sample preparation is needed) is that this technique is more environmental friendly and more respectful of users' health because it does not require the use of solvents and chemicals and does not produce any waste and the measurements of potentially hazardous compounds can be carried out remotely. Finally, the routine use of an IRS instruments from the sample preparation for analysis (where needed) to the spectrum acquisition is extremely simple and does not require specialized but only minimally trained personnel.

However, there are also some limitations in the use of IRS. First, even though the collection of the spectrum is fast, the model building phase can be laborious and time-consuming. Robust calibration/classification models may require hundreds or even thousands of samples to be analyzed by IRS. Indeed, it is essential that in the model building phase, most of the potential variability in the parameter to be estimated is included in the experimental plan. It would also stress the importance to rely on an independent test set (samples that originate from a batch different to that used for the model-building phase). However, in many cases, regression or classification models are extremely product-specific so they need to be frequently updated to accommodate changes in the sample matrix (e.g., in a product recipe), even for the same type of sample and analyte. The model building phase also requires time and proper expertise in multivariate statistics. Furthermore, when used for quantification purposes, a conventional, well-accepted reference method must be used to supply the analytic results required for the calibration of IR spectral data against the concentration of the target analyte (this, of course, would not hold true when IR spectra are used as fingerprints of the test samples for authentication purposes). This means that in the calibration phase, a large amount of samples have to be analyzed by the reference method as well. The fact that the calibration models are developed against a reference method also implies that total predictive error is higher compared to the reference method because the uncertainty in the IRS estimate will sum up to the uncertainty of the reference method measurement. Finally, the classification or regression models are theoretically valid only on the instruments with which the calibration has been carried out. This is because different spectrophotometers may differ in wavelength calibration and photometric response. The commercial implementation of IRS requires that calibration models can be transferred to an instrument to another that requires the use of dedicated calibration transfer techniques.

Conclusions and Future Perspectives

IRS represents a valuable tool for fast and nondestructive qualitative and quantitative analysis of food products and is already a common instrumental platform available in most QA laboratories. IR spectra can provide information on the chemical composition of food, as well as on its nutritional, sensorial, and technological quality in either static or dynamic conditions (on-line analysis). IRS has also showed its potential for the authentication of food products and the detection of fraud. Its advantages include the possibility of authentication of products for which target analysis based on specific markers is not yet available and detection of adulterations based on yet unknown adulterants. However, despite the numerous successes claimed in the scientific literature, it is questionable whether many of the applications reported in this area so far have the necessary robustness to ensure a consistent and accurate prediction. Most of the studies have been carried out on a limited number of samples, which is unlikely to include all the potential variability in the categories of interest and/or lack a proper external validation. The combination of IR with microscopy and imaging techniques is regarded as the natural expansion of conventional IRS and is likely to broaden its applicability in the food domain, provided that low-cost equipment for dedicated applications will be available in the future and, in the case of HSI, proper processing algorithms for handling the huge crop of data obtained are developed. Finally, it is reasonable to assume that with further advancements in IR technology and computational power, IRS may become a promising diagnostic tool for routine investigation and detection of food spoilage and foodborne bacteria.

Insect Pests

S García-Lara and SO Serna Saldivar, Centro de Biotecnología-FEMSA, Tecnológico de Monterrey, Monterrey, México

© 2016 Elsevier Ltd. All rights reserved.

Introduction

There are more than six million identified insect species and an estimated ten million that yet have not been described. Of these, probably no more than about 0.5% interact directly or indirectly with man. Approximately 3000 species constitute pests that in conjunction with others organisms cause significant damage to agricultural products and goods. Historically, farmers have had to compete with insect pests for crop products grown for human foods and animal feed consumption. In addition to direct losses caused by insects to plants, fruits, and seeds, these biotic agents cause indirect losses because they leave behind important contaminants such as body parts or exoskeletons, weblike material, insect eggs, feces, urine, and off-odors. Some types also have the ability to attack and damage packaging materials and the structure of grain elevators and transportation facilities.

Insect Biology

Arthropods, the group of joint-limbed animals to which insects belong, have been evolving for about 350 million years. Insects have been such successful inhabitants of the Earth because of their tremendous reproductive potential, survival capacity, small size, and diversity. They have come to occupy most of the ecological niches, and in many instances, insects are also beneficial to human activity especially in food production through their role in plant pollination and as agents of biological control and other activities.

In general, adult insects are characterized by having an external skeleton and a main body divided into three anatomical parts: head, thorax, and abdomen. The head is composed of antennae, eyes, and mouth parts, which are adapted for chewing, piercing–sucking, and chewing–lapping, among other functions. The thorax is divided into three segments, each of which usually possesses a pair of jointed legs; winged forms have pairs of wings on the second and third segments. Among some flying insects, the pair of wings on the third segment of the thorax is modified to serve as a balancing organ. The external reproductive organs are carried on the abdomen.

Insects generally pass through metamorphosis of four developmental stages: egg, larva or nymph, pupa, and adult. In the immature stages (larva or nymph), insects do not have wings, and some may lack legs and other typical structures, giving them an appearance totally different from that of the pupa and adult forms. The primitive wingless insects are an exception. Metamorphosis process is gradual (as in the development of nymphs into adult grasshoppers, leafhoppers, and bugs) and only in some groups is it complete (as with the moths, beetles, and flies, which pass through all stages from larva to adult). In a few cases (e.g., aphids), the mature parthenogenesis female (one that reproduces without fertilization) gives birth to living nymphs, though it may also eventually produce eggs.

Main crops are a substrate for more than 3000 insect species although only 20–30 of these are important pests. Temperate/cold environments inhibit insect activity, whereas tropical and subtropical areas are the preferred habitat for these insects. The tropical zones have all the essential elements for their survival and proliferation: food, favorable conditions of relative humidity, and warm and adequate temperatures throughout the year. Most insects have the capacity to hibernate and cause important damage during the seasons that favor their biology.

Food moisture and environment humidity are the most relevant factors that affect insect growth and development. A high moisture content and adequate temperature conditions favor a rapid growth in the insect population. In general terms, from 9% to 100% moisture content favors insect reproduction, which translates into important overpopulation. Temperature is the most important environmental factor affecting insect development and reproduction. Most insects do not reproduce at temperatures lower than 12 °C or higher than 34 °C. The optimum temperature for reproduction is about 26 °C. However, if a gradual temperature increase is present, this will increase insect metabolism and reproduction rate until achieving a point in which the excess temperature will inhibit or even kill insects.

Insect Damage

Insects are the main biotic stress responsible for crop losses in the world. The direct losses are related to the amount of dry matter consumed and the indirect losses due to contamination of damaged kernels and processed products. Total losses of all food crops in the world are estimated at 30–40% despite an annual expenditure of more than $30 000 million on insecticides. Insect pests are highly adaptable to man-made manipulated habitats where crops are selected for their large size, high yield, and nutritious value and clustered in confined areas. This provides a highly conducive environment for herbivorous insects. In the process of artificially selecting suitable crops for human consumption, highly susceptible plants for insect infestation are also selected. Insect pests are also capable of evolving to biotypes that can adapt to new challenges such as host plant resistance, insecticides, or climatic changes.

Among crops, the total global potential loss due to pests varies from about 50% in wheat to more than 80% in cotton production. The responses are estimated as losses of 26–29% for soybean, wheat, and cotton and 31%, 37%, and 40% for maize, rice, and potatoes, respectively. Overall, weeds produced the highest potential loss (34%), with animal pests and pathogens being less important (losses of 18 and 16%). As an example, global losses in maize production associated with biotic stresses are ~10.9% due to diseases, 14.5% due to

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00396-2

insects, and 13.1% due to weeds. An additional 10% postharvest loss brings the total estimated loss to 48.5%. A summary of current global losses due to various categories of pests in major crops is presented in Figure 1.

Insects are classified, as primary or secondary pests, according to their habits and characteristics. Primary insects are more harmful because they have the capacity to damage intact plant and crop derivatives. They usually perforate the plant and grain for feeding and reproductive purposes. These insects mainly consume plant tissues (root, shoot, fruit, and kernel) and use them as the ideal site for oviposition and the future growth and development of the larvae. Secondary insects are opportunistic because they attack plant tissues that have already been damaged by primary insects or processed products such as flours, grits, or end products. Both primary and secondary insects use the plant tissues as the ideal place to complete their life and reproductive cycle. In addition, they obtain all the substrate and food and the microenvironmental ideal conditions of temperature and relative humidity. It is noteworthy to mention that both types of insects lower field yield, food value, grain viability, and grain quality as raw material for mills and terminal food industries.

In general, the group of insects represented by moth, which includes cutworms, armyworms, earworms, borers, and grain moths, are the most damaging to crops worldwide followed by the beetles (rootworms, wireworms, grubs, grain borers, and weevils). Next in importance is the group of insects that serve as carriers (vectors) for disease agents (viruses, mycoplasma, bacteria, and fungi) among which the sap-sucking bugs (leafhoppers and aphids) are the greatest problem. In the taxonomic point of view, the primary pests are located in the Orthoptera, Lepidoptera, Coleoptera, and Hymenoptera orders. According to their feeding habits, insects are classified as monophages or polyphages. The first type only feeds from one crop and grain, whereas the second type is adapted to consume various types of plant tissues and grains. The main recognized group of insect pest that cause major losses are summarized in Table 1.

An example situation of insect pests associated with crops can be given by maize. Maize is grown over a wide range of agroecologies, ranging from the tropical lowland at sea level to temperate environments slightly above 50° N/S latitude. For each distinct environment, a different suite of biotic stresses is encountered from the time of seed germination (soil pests, diseases, and weeds) to grain storage (storage insects and diseases). Since all

[a]Ranking on a 1–5 scale with 1 being very important and 5 being of low importance at a global level (with data of Bergvinson et al., 2006).

pests are poikilotherms, their development is largely regulated by temperature, making tropical environments ideal for rapid population growth and subsequent crop damage. In order to manage this diversity of agroecosystems and associated pests, maize production areas have classified the major pests and abiotic stresses of maize for the different agroecologies, namely, highlands, upper wet midaltitude, lower wet midaltitude, dry midaltitude, and wet lowlands. The major pests are summarized in Table 2. Using this approach, we are better able to identify the stress traits required for yield stability in a given agroecology, thereby focussing our regional breeding efforts to address the production constraints faced by maize producers over the wide range of environments where maize is produced.

Insects in Stored Food

Storage of cereal food is critical in terms of food security for the more than 7.3 billion people inhabiting the world. The main purpose of grain and food storage is to equilibrate supply and demand, and this postharvest operation is a key step in the complex logistics of moving grain from producers to processors and grain products from processors to consumers.

The FAO has estimated that grain storage losses in most developing countries, mainly located in tropical and subtropical areas of the globe, are much higher compared to developed counterparts due to lower investments in proper infrastructure and a climate that favors grain respiration and growth of insects, molds, and rodents. Therefore, there is a great opportunity to upgrade storage systems in order to diminish losses and assure food for the most needed. If new and better storage facilities are built, the world can save at least 15% of the total cereal production estimated in 2013 in more than 2.78 billion tons.

Most cereal grains have to be stored on farms or commercial grain elevators because they are harvested in specific seasons of the year and are gradually utilized by the various industry segments. Generally, imported grains are also stored for significant periods of time because they are usually acquired in large quantities in order to keep low costs and large inventories. The main objective of storage is to provide wholesome grains, free of insect and mold damage, mycotoxins and pesticides, and insect fragments and rodent filth. Furthermore, the storage of cereals also allows the standardization, classification, and selection of grains for trading purposes. The final target is to manage stored grain wisely with insignificant losses while maintaining its nutritional and functional qualities.

There are only 20–30 insect species that attack cereal grains during storage. The warm temperatures of tropical and subtropical areas are the preferred habitat for these insects, whereas cold weather inhibits insect activity. Insects are the main factor responsible for grain losses throughout the world.

Primarily, pests of stored food cause most of the insect damage in storage and shipment. These are the granary, rice, and maize weevils; the large and lesser grain borer; and the Angoumois grain moth. In dry subtropical areas around the

world, the larger grain borer is of economic importance. Insects that specialize in attacking stored grains belong to the Coleoptera or Lepidoptera orders. Most insects belong to the Coleoptera order that includes beetles, grain borers, and weevils. The Lepidoptera order that includes all butterflies or moths has three important cosmopolitan species that attack stored grains: the Angoumois grain, Indian meal, and Mediterranean flour moths. Primary pests that cause most grain damage are the granary, rice, and maize weevils; the lesser grain borer; and the Angoumois grain moth. The large grain borer is of economic importance in tropical areas around the globe.

Temperature is the most important environmental factor affecting insect development and reproduction. Most insects do not reproduce at temperatures lower than 12 °C or higher than 34 °C. The optimum temperature for reproduction is about 26 °C. Other relevant factors are grain moisture and water activity. The presence of foreign material, dockage, and damaged kernels enhances insect development, growth, and reproduction. Kernels containing more than 14% moisture will have a higher respiration rate and will produce heat spots and enhance insect and mold growth. These interactive effects will increase the stored grain temperature and moisture making the grain more prone to further damage. Insect damaged kernels will lose 25–60% weight and nutrients and leave important contaminants such as body parts, cocoons, feces, and eggs. Some insects such as the confused flour beetle and red beetle usually feed from flours and processed products, secreting odoriferous compounds and irritants. These substances also produce a pinkish coloration to white flours. Other insects such as the worms or larvae of the Indian moth and Mediterranean flour moth leave silken threads and webs that ruin the appearance of flours.

Pest Control

The objective of pest control under the concept of integrated pest management is to achieve a crop production system in a way that optimizes the use of natural resources, protects the environment, and maximizes output in a sustainable way. Control of pests assumes a prominent position, especially in developing countries where insect and disease pressures tend to be severe due to the subtropical and tropical climates found there. Insect control strategies emphasize the reduction and/or use of selective pesticides and include the use of natural control and cultural control. Natural control involves the reduction of insect pest populations by the use of insect natural enemies, while cultural control consists in the deliberate alteration of the production system to reduce pest populations or avoid pest injury to crops.

Chemical

There are four types of chemical insecticides, which protect against insect infestations: organophosphate, carbamates, organochlorine, and pyrethroid. Organophosphate and carbamate insecticides affect the nervous system by disrupting the enzyme that regulates acetylcholine, a neurotransmitter, and usually are not persistent in the environment. Organochlorine insecticides were commonly used in the past, but many have been removed from the market in some parts of the planet due to their health and environmental effects and their persistence (e.g., Dicloro Difenil Tricloroetano (DDT) and chlordane). Parathyroids were developed as a synthetic version of the naturally occurring pesticide pyrethrin, which is found in chrysanthemums. Some synthetic pyrethroids are toxic to the nervous system.

One of the most effective organophosphate insecticides is malathion due to its relative high insect toxicity and low human toxicity. In addition, it is effective against all insects and has a long-lasting effect or good residual power that makes it ideally suited to treat surface areas of grain elevators and machinery. Pyrethrins such as permethrin and bioresmethrin are popular insecticides due to their low toxicity to mammals and safe use. Other insecticides such as methoxychlor and ethylene dichloride are used to protect contact surfaces and storage equipment. Piretrolones are fast-acting insecticides and are particularly effective against adults. Although pyrethrins rapidly lose toxicity, they maintain their repellent power for a long time. Fumigants are chemicals that produce gas at ambient temperature and therefore can reach practically all areas. Due to their excellent distribution, they generally kill all insect population due to the toxicological effect on the insect nervous system. Examples of fumigants are methyl bromide (CH3Br, highly toxic and efficient against all adult insects and larvae), phosphine gas (PH3, tablets that gradually release phosphine, carbon dioxide, and ammonia), and carbon tetrachloride (CCl4). Insecticides have several advantages over fumigants: Their effect is long-lasting, and they are easier to apply, are less dangerous, and can be applied both as preventive agents or to kill established insect populations.

Botanical

Botanical insecticides are naturally occurring chemicals extracted from plants. Natural insecticides are available as an alternative to chemical control. Some of the most deadly, fast-acting toxins and potent carcinogens occur naturally. More than 3500 compounds in ~400 plant families have been described to have toxic insect effects. Some botanical insecticides are similar in toxicity to humans. Botanical insecticide effects are not as efficient as synthetic ones.

Citrus oils (limonene and linalool), which are extracted from citrus peels, have been combined with soaps as contact poisons against aphids and mites. Nicotine derived from tobacco is commonly sold as a 40% nicotine sulfate concentrate. Nicotine is a fast-acting contact killer for soft-bodied insects. Pyrethrin, which is found in chrysanthemums, is the most popular botanical insecticide that acts by contact as a poison. Pyrethrin is effective on most insects, but does not control mites. It rapidly breaks down in sunlight, air, and water. Rotenone is derived from the roots of over 68 plant species. It is toxic to animals because direct contact may cause skin and mucous membrane irritation. It has a broad-spectrum poison mainly used to control leaf-eating caterpillars and beetles. Sabadilla is derived from the seeds of South American lilies with a broad-spectrum contact poison, but it is most effective against true bugs such as harlequin and squash bugs. Sabadilla degrades rapidly in air and sunlight and has little residual toxicity with low toxicity for humans. Neem (*Azadirachta indica*) is derived from the tropical neem tree. Neem extracts has effective control for over 200 types of insects, mites, and nematodes. The solution is effective for only

8 h after mixing. Neem is most effective under humid conditions or when the insect and plants are damp. It has a low toxicity to mammals.

Biological

The use of beneficial insects, pheromones, and growth regulators has been studied as a possible alternative for insect control. Among the most promising biological control techniques are the use of predators and the release of sterile insects. Sterile insects treated with mutating agents can considerably lower grain infestations especially when insects belong to the Lepidoptera order. The main disadvantage of the use of beneficial insects is that they leave behind body casts, exoskeletons, and other insect residues. Pheromones are chemical agents secreted by insects as sexual attractors. These chemicals are used to attract insects and predict populations. Pheromone traps are used to catch insects especially when the number of insects infesting is low. This gives the opportunity to detect and control insect populations before they cause economic damage. The use of pheromones when insect populations are reduced also lowers their reproduction rate because these chemicals confuse insects. The use of growth agents and hormones that are essential for metamorphosis has potential in insect control programs. These chemical compounds inhibit important physiological processes and have a very low toxicity for mammals.

Iodine: Iodine Deficiency Disorders (IDD)

K Menon and S Skeaff, University of Otago, Dunedin, New Zealand

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Iodine (I) is an essential anionic trace element and occurs naturally in the environment as iodide found in seawater and soils. The distribution of iodine varies widely in the Earth's crust. The soils of mountainous and volcanic areas have low iodine content. The soil iodine content directly determines the iodine content of foods and water and indirectly determines the iodine status of human and animals in the region. Humans derive iodine through their diets, ~90% via food and ~10% from water. Rich sources of dietary iodine include seafood and seaweeds due to high concentrations of iodine in the ocean, good sources include eggs and dairy products, while trace amounts of iodine are present in grains and vegetables. Additionally, foods such as breads, fish sauce, salt, and water can be fortified with iodine. The use of iodized salt is widely recommended for populations inhabiting endemically iodine-deficient regions. Dietary iodide in food is absorbed in the stomach and duodenum and enters the circulation where it is cleared by the thyroid and kidney. The thyroidal uptake of iodine in the blood depends on iodine status, with 10% in iodine-sufficient and >80% uptake in iodine-deficient individuals.

The adult human body contains 15–50 mg of iodine with two-thirds found in the thyroid gland and the remaining one-third in the circulating blood, primarily contained in the thyroid hormones (TH). Iodine is an essential component of the TH, which include the prohormone, thyroxine (T_4), and the active hormone, 3,5,3′-tri-iodothyronine (T_3). T_4 contains four iodine atoms with a half-life of 5 days, while the bioactive and more potent T_3 contains three iodine atoms and has a half-life of 1.5–3 days. TH regulate a wide variety of physiological processes such as protein synthesis and enzymatic activities; cell differentiation, growth, and development of different tissues, especially of the central nervous system; maturation; and energy production and cellular respiration, which influences the metabolic rate of the body. The main organs influenced by TH are the developing brain, muscle, heart, pituitary, and kidney. The human body regulates TH concentrations through thyroid-stimulating hormone (TSH) secreted by the pituitary gland via a negative auto-feedback mechanism. In addition, TSH influences iodine metabolism through uptake of iodine by the thyroid and synthesis and secretion of TH.

Iodine requirements vary throughout the life cycle. The World Health Organization (WHO)-, United Nations Children's Fund (UNICEF)-, and the International Council for Iodine Deficiency Disorders (ICCIDD)-, now known as the Iodine Global Network (IGN)-recommended iodine intakes for different stages of the life cycle are outlined in Table 1. The requirement for iodine is highest in pregnant and lactating women. In pregnancy, iodine requirements escalate due to increased production of TH and transfer of iodine to the fetus and, in lactating women, to support the excretion of iodine in breast milk.

A constant low daily intake of iodine below the requirement leads to chronic iodine deficiency (ID), which decreases TH secretion and, eventually, impairs normal thyroid function; this is the most important cause of ID. Low iodine content in the diet is caused by environmental factors such as glaciation, floods, and erosion resulting in the depletion of soil iodine content. Consequently, locally grown foods in these regions contain insufficient iodine for human beings and animals. Also, some foods contain a variety of substances or goitrogens that interfere with thyroidal iodine uptake (Table 2). Industrial pollutants such as perchlorate are competitive inhibitors of thyroidal iodine uptake. Cigarette smoking increases serum thiocyanate levels that compete with iodine for uptake into both the thyroid and the secretory epithelium of the lactating breast. When iodine intakes are adequate, goitrogens are normally not harmful; however, in the presence of ID, goitrogens might exacerbate the clinical effects of ID. Further, coexisting deficiencies of selenium, iron, and vitamin A aggravate the effects of ID either via impairing activities of mineral-dependent enzymes such as selenium-dependent deiodinases and iron-dependent thyroperoxidase or by vitamin A-mediated suppression of the pituitary TSHβ gene. Thus, chronic insufficient intakes of iodine eventually precipitate ID in human beings.

Epidemiology

ID is the most common cause of preventable mental impairment and affects about 2 billion people worldwide; it is a major public health challenge. ID is widespread in both developed and developing countries. According to ICCIDD, 29.8% of school-age children worldwide are iodine-insufficient and more than a half of these children reside in two regions: 78 million in Southeast Asia and 58 million in Africa. The proportion of school-age children with insufficient iodine intake is highest in Europe (43.9%; 30.5 million), followed by Africa (39.5%; 58.1 million). There has been a decline in the global prevalence of ID in school-age children from 36.5% in 2003 to 29.8% in 2011, the overall progress being marginal in Africa. In 2011, ICCIDD classified 32 countries with ID (9 moderately with ID and 23 with mild ID), 69 countries as iodine adequate, 36 as more than adequate, and 11 as excessive. Globally, there is a dearth of nationally representative prevalence estimates of ID in pregnant and lactating women.

Iodine Deficiency Disorders

ID has several adverse effects on human beings. As coined by Hetzel in 1983, the term iodine deficiency disorders (IDDs) collectively refers to the adverse effects of ID on growth and development in human and animal populations (Table 3). Chronic insufficient iodine intake stimulates the production

Table 1 Recommended iodine intake

Age or population group	*Recommended iodine intake ($\mu g\ day^{-1}$)*
Children 0–5 years	90
Children 6–12 years	120
Children >12 years and adults	150
Pregnant women	250
Lactating women	250

Table 2 Goitrogens and their mechanisms

Goitrogens	*Mechanism of action*
Foods	
Cassava, lima beans, linseed, sorghum, sweet potato	Contain cyanogenic glucosides; they are metabolized to thiocyanates that compete with iodine for thyroidal uptake
Cruciferous vegetables such as cabbage, kale, cauliflower, broccoli, turnips, rapeseed	Contain glucosinolates; metabolites compete with iodine for thyroidal uptake
Soy, millet	Flavonoids impair thyroid peroxidase activity
Industrial pollutants	
Perchlorate	Competitive inhibitor of the sodium/iodine symporter, decreasing iodine transport into the thyroid
Others (e.g., disulfides from coal processes)	Reduce thyroidal iodine uptake
Smoking	An important goitrogen; smoking during breastfeeding is associated with reduced iodine concentrations in breast milk; high serum concentration of thiocyanate due to smoking might compete with iodine for active transport into the secretory epithelium of the lactating breast
Nutrients	
Selenium deficiency	Accumulated peroxides might damage the thyroid, and deiodinase deficiency impairs thyroid hormone synthesis
Iron deficiency	Reduces heme-dependent thyroperoxidase activity in the thyroid and might blunt the efficacy of iodine prophylaxis
Vitamin A deficiency	Increases TSH stimulation and goiter through decreased vitamin A-mediated suppression of the pituitary TSHβ gene

TSH, thyroid-stimulating hormone

Table 3 Spectrum of iodine deficiency disorders

Age groups	*Health consequences of iodine deficiency*
All ages	Goiter, including toxic nodular goiter Increased occurrence of hypothyroidism in moderate-to-severe iodine deficiency; decreased occurrence of hypothyroidism in mild-to-moderate iodine deficiency Increased susceptibility of the thyroid gland to damage and thyroid cancer from iodine radio isotopes (e.g., from radioactive fallout)
Fetus	Abortion Stillbirth Congenital abnormalities Perinatal mortality Psychomotor defects
Neonate	Infant mortality Endemic cretinism Impaired physical growth Neonatal hypothyroidism
Child and adolescent	Impaired mental function Delayed physical development
Adults	Impaired mental function Lower intelligence quotient and cognitive index Iodine-induced hyperthyroidism, goiter Overall, moderate-to-severe iodine deficiency causes subtle but widespread adverse effects in a population secondary to hypothyroidism, including decreased educability, apathy, and reduced work productivity, resulting in impaired social and economic development
Pregnant women	Subclinical hypothyroidism Poor pregnancy outcomes Premature delivery

Source: WHO/UNICEF/ICCIDD (2007). *Assessment of iodine deficiency disorders and monitoring their elimination*. Report of a joint WHO/UNICEF/ICCIDD consultation. Geneva: WHO.

of TSH from the pituitary gland. A series of TSH-mediated adaptations occur in the thyroid gland before the onset of goiter. TSH stimulates thyroidal uptake of iodide, enhances the breakdown of thyroglobulin (Tg), and promotes secretion of T_3 and conversion of T_4 to T_3 in peripheral tissues to conserve the number of iodine atoms used. The serum Tg concentration increases due to TSH stimulation. Increased iodide uptake by the thyroid leads to decreased renal clearance, thus a fall in the urinary iodine concentration (UIC). Further, the hyperplasia (i.e., increase in the number of cells) and hypertrophy (i.e., increase in the size of cells) of the thyroid cells enhance the use of available iodine efficiently to synthesize TH and underpin the enlargement of the thyroid gland or goiter. Goiter is the classic and most visible effect of IDD. In chronic ID, the initial diffused homogeneous enlargement of the thyroid gland gradually results in the formation of thyroid nodules. Women over 50 years with chronic ID have a high prevalence of multinodular goiter. IDD affects all ages of the population in manifold ways. Goiter, physical sluggishness, growth retardation, and decreased productivity are the well-known adverse outcomes of ID.

WHO/UNICEF/ICCIDD recommends the use of UIC to assess the iodine nutrition of children >2 years old, adults,

pregnant women, and lactating women. The use of UIC centers on the fact that ~90% of ingested iodine is excreted in the urine. Although useful to estimate recent dietary intake, the collection of 24 h urine samples is cumbersome in the field. Thus, to facilitate the process of sample collection, WHO/UNICEF/ICCIDD recommends the use of nonfasting casual or spot urine samples from a representative population. The median UIC, expressed as $\mu g\,l^{-1}$, determined in spot urine samples are only useful as a population estimate and cannot be used to assess iodine status in individuals (Table 4). IDD is considered as a public health problem when a population has median UIC $<100\ \mu g\,l^{-1}$ in a representative sample of school-age children; the median UIC of the sample can also be used to categorize the degree of ID, which can be mild, moderate, or severe as shown in Table 4. UIC has only been validated in school children although it is used for adults. Given the higher dietary iodine requirements of pregnant women, a median UIC between 150 and 250 $\mu g\,l^{-1}$ is used to indicate adequate iodine status in this group.

Recently, the use of Tg concentrations in school-age children to assess iodine status has been proposed to assess iodine status in a population. A median Tg concentration $>13\ \mu g\,l^{-1}$ and/or >3% of Tg values $>40\ \mu g\,l^{-1}$ indicates ID in the population. In pregnant women, TH and TSH are used to determine the optimum thyroid function, which may be used as a surrogate marker for ID; however, the normal reference ranges of TH and TSH are wide; thus, these measures are considered insensitive in areas of moderate-to-mild ID. The epidemiological criteria for the assessment of severity of ID based on the TSH concentration in neonates and total goiter rate in school-age children are extensively used in some countries (Table 5).

Table 4 WHO epidemiological criteria for assessment of iodine nutrition in a population based on median or range of UIC

Median UIC ($\mu g\,l^{-1}$)	*Iodine intake*	*Iodine nutrition*
School-aged children		
<20	Insufficient	Severe iodine deficiency
20–49	Insufficient	Moderate iodine deficiency
50–99	Insufficient	Mild iodine deficiency
100–199	Adequate	Optimum
200–299	More than adequate	Risk of iodine-induced hyperthyroidism in susceptible groups
>300	Excessive	Risk of adverse health consequences (iodine-induced hyperthyroidism, autoimmune thyroid disease)
Pregnant women		
<150	Insufficient	
150–249	Adequate	
250–499	More than adequate	
≥500[a]	Excessive	
Lactating women[b]		
<100	Insufficient	
≥100	Adequate	
Children <2 years of age		
<100	Insufficient	
≥100	Adequate	

[a]The term excessive means in excess of the amount needed to prevent and control iodine deficiency.

[b]In lactating women, the numbers for median urinary iodine are lower than the iodine requirements, because of the iodine excreted in breast milk.

IDD in Pregnancy, Lactation, and Infancy

ID during pregnancy has a deleterious impact on the fetus and the mother. Healthy women from iodine-sufficient areas have about 15–20 mg of iodine stores in the thyroid. There is a 50% increase in iodine requirements in pregnant women to produce adequate TH that meets maternal and fetal needs. Additional iodine is needed to maintain maternal TH concentration and transfer TH to the fetus before the fetal thyroid begins to function in the second trimester (around 16–20 weeks of gestation), transfer iodine to the fetus during late gestation, and maintain iodine levels in response to increased renal iodine clearance by the mother. Until the second semester, maternal T_4 serves as the only source of TH for the developing fetus. Pregnant women in chronic ID areas have little iodine stored in their thyroid. In such situations, poor iodine intake may lead to the onset of ID in the mother, and subsequently the fetus. Despite mild-to-moderate maternal ID during the first trimester of pregnancy, maternal TH concentrations typically remain within the normal reference range due to suppression of TSH secretion by the human chorionic gonadotrophin in response to an increase in maternal T_4 (i.e., maternal euthyroidism or normal thyroid function) and the physiological adaptations of the thyroid gland in response to ID. Regardless of the maternal euthyroidism, the fetus is exposed to hypothyroxinemia (i.e., low T_4 in the blood). Consequently, specific parts of the developing fetal brain suffer from a hypothyroxinemic insult, which impairs neurodevelopment. In the second trimester, the fetal thyroid begins to function but is not fully matured and cannot autoregulate the mechanisms needed to normalize TH secretion. This may lead to a surge in fetal TSH production and subsequently fetal hypothyroidism.

Normal concentrations of maternal TH are essential for fetal brain growth. TH influence two phases of brain growth;

Table 5 WHO epidemiological criteria for assessment of severity of iodine deficiency in populations

Criteria	*None*	*Mild*	*Moderate*	*Severe*
Total goiter rate (%)	0–4.9	5–19.9	20–29.9	>30
Neonatal TSH >5 mIU ml^{-1} (%)	<3	3–20	20–40	>40
Classification of goiter by palpation				
Grade 0	No visible or palpable goiter			
Grade 1	A goiter that is palpable but not visible when the neck is in the normal position			
Grade 2	A palpable, visible, and enlarged thyroid when the neck is in the normal position			

TSH, thyroid-stimulating hormone

Source: WHO/UNICEF/ICCIDD (2007). *Assessment of iodine deficiency disorders and monitoring their elimination*. Report of a joint WHO/UNICEF/ICCIDD consultation. Geneva: WHO

the first phase takes place between the third and fifth months of gestation when neuronal multiplication, migration, and organization occur, while the second phase takes place from the third trimester to the second and 3rd years after birth and involves glial cell multiplication, migration, and myelinization. Evidence from animal studies indicates that TH deficiency may impair intelligence, language function, and visuospatial and memory functions or result in autism. Also, TH insufficiency at different stages of pregnancy affects different regions of the brain. For instance, TH insufficiency in early gestation influences basal ganglia while in late gestation impairs cerebellar and hippocampal development. Early maternal TH deficiency can impair visual attention, visual processing, and gross motor skills, while in later gestation, it can influence visual skills, processing speeds, and fine motor skills. Studies in Dutch pregnant women showed that maternal hypothyroxinemia impaired psychomotor development of infants at 10 months of age and that psychomotor damage persisted even at 1 and 2 years of age. Additionally, a recent Dutch study reported that maternal hypothyroxinemia increased risk of children's verbal language and nonverbal cognitive delays and a low maternal UIC in early gestation was associated with inhibition problems and executive functioning impairments in children at 4 years of age. There is increasing concern that even a mild decrease in maternal TH production may cause cognitive delays in offspring. Collectively, these studies highlight the important roles of TH in normal brain development.

Severe ID *in utero* results in gross mental defects along with varying degrees of physical impairments including short stature, deaf-mutism, and spasticity referred to as cretinism. Cretinism is the most severe consequence of ID (**Figure 1**). The two types of cretinism observed are neurological and myxoedematous cretinism; however, the presentation of neurological abnormalities is similar in both types. These include severe mental retardation, intellectual impairment, deafness, motor spasticity, and squint. Nevertheless, myxoedematous cretinism may be differentiated based on postnatal manifestations of progressive thyroid atrophy in neonates, with clinical manifestations of growth retardation, sexual immaturity, and persistent hypothyroidism. Evidence suggests that the clinical characteristics of endemic cretinism occur as result of severe ID at different times in the development of the fetus and neonate; the first occurs *in utero* due to a lack of TH that manifests as neurological impairment in the fetus resulting in neurological cretinism, while the second reflects the progressive thyroid atrophy and hypothyroidism in the postnatal life of neonates resulting in myxoedematous cretinism. In addition to overt cretinism, severe ID *in utero* leads to 10–20% lower developmental scores in young children, lower birth weights, and increased risk of infant mortality. In pregnant women, severe ID is associated with poor pregnancy outcomes such as abortions, stillbirths, prematurity, congenital abnormalities, and increased perinatal mortality.

Conversely, the effects of *in utero* mild-to-moderate ID on psychomotor development of offspring are less clear. Recent studies have shown an association between mild-to-moderate ID in pregnancy and cognitive outcomes such as verbal intelligence quotient (IQ), reading accuracy, and reading comprehension in 8–9-year-old children born to mild-to-moderately deficient mothers compared with iodine-sufficient mothers. A meta-analysis of controlled and observational studies from areas of mild-to-moderate ID reported that adequate iodine intake in pregnancy resulted in normal thyroid volume in both the mother and their newborns and serum Tg concentrations compared with women of lower iodine intake. Further, adequate maternal iodine intake prevented a rise in the maternal TSH concentration with little impact on maternal free or total TH concentrations. More information is needed on the influence of mild-to-moderate ID on the neuromotor development and cognition in infants and children. Additionally, little is known about the adverse clinical outcomes of maternal mild-to-moderate ID in pregnancy.

IDD in Children

The prevalence of ID in school-age children is widely studied as a part of regular health surveillance systems. Cretinism in children is now nonexistent even in areas where severe ID had been common over 30 years ago. Evidence from several observational studies suggests that ID during childhood may impair psychomotor skills and cognition. A few systematic reviews and meta-analyses have assessed the effects of ID on cognition in school-age children by comparing children from iodine-deficient and iodine-sufficient areas. A meta-analysis of 21 observational or experimental studies in children, adults,

and infants with 2214 participants investigated the influence of iodine status on IQ and reported a 13.5 point deficit in intelligence in participants with moderate-to-severe ID. A Cochrane review of 26 longitudinal trials suggested that increased iodine intake in children was associated with reduced goiter rates; however, the results for cognition and psychomotor development were mixed with a few studies showing no improvement. The previously mentioned evidence collectively suggests the beneficial effects of adequate iodine intake in children from moderate-to-severely iodine-deficient areas; however, there is limited information available on the effects in mild-to-moderate ID in children.

The association between mild-to-moderate ID in school-age children and cognition has only been investigated in two studies using randomized controlled trials. The first trial tested the effect of improving the iodine status of moderately ID Albanian children aged 10–12 years using a battery of tests for cognition and motor performance. Children who were given a bolus dose of iodine became iodine-sufficient after 6 months with resulting improvements in four out of seven tests for cognition and motor performance compared with children who remained iodine-deficient. In the second trial of mildly ID New Zealand children aged 10–13 years, daily iodine supplementation for 28 weeks resulted in adequate iodine status and better performance on two out of four subtests of cognition, compared with children who took a placebo containing no iodine. These findings are important because poor school performance adversely affects the productivity and economic growth of countries with mild-to-moderate IDD. However, more randomized control trials are required to elucidate and establish the benefits of improving the iodine intakes of mild-to-moderate ID populations.

The effects of ID on growth have been explored in many observational and cross-sectional studies. Iodine status may influence growth via TH; TH stimulates the secretion of growth hormone, insulin-like growth factor, and insulin-like growth factor-binding protein. In hypothyroidism, lower than normal concentrations of growth hormone, insulin-like growth factor, and insulin-like growth factor-binding protein have been reported. Three randomized control trials have evaluated the implications of iodine supplementation using iodized salt or oral iodized oil on growth of school-age children from severe, moderate, and mildly ID areas. The results showed that children from severe and moderately ID areas supplemented with iodized salt and oral iodized oil, respectively, had significantly increased TH, insulin-like growth factor, insulin-like growth factor-binding protein concentrations, weight-for-age z-scores, and height-for-age z-scores compared with children receiving a placebo; there was no effect on these indexes in supplemented children from the mildly iodine-deficient area.

IDD in Adults and the Elderly

The majority of the studies investigating the effects of ID on physical and mental growth, development, and cognition have focussed on reproductive-age women, neonates, and children. Limited information is available on the implications of ID in adults and the elderly. An 11-year follow-up study evaluated changes in thyroid volume in adults pre- and post-mandatory iodine fortification of salt in two Danish areas, one with mild ID and the other with moderate ID. The results indicated a significant increase in the thyroid volume in adults from the mild ID area, while the adults from moderate ID showed a slight decrease in thyroid volume, post iodine fortification. Additionally, a recent meta-analysis investigated the dose–response relationship between iodine intake and biomarkers of iodine nutrition such as UIC, TSH, and Tg. In adults and elderly populations, it was found that doubling iodine intake increased UIC by 57%; a single dose of iodized oil (200–500 mg of iodine) decreased TSH by 5%; and 200–1500 μg of iodine as potassium iodate resulted in a slight decrease in Tg.

An abrupt increase in iodine intake causes excessive production of TSH that results in hyperthyroidism or iodine-induced thyrotoxicosis. The hyperthyroidism is characterized by high metabolic rates, weight loss, irritability, tachycardia, nervousness, and elevation of body temperature. The condition initially develops as simple goiter that subsequently progresses to toxic nodular goiter. Elderly adults who have lived in areas of ID for long periods of their life are particularly susceptible to iodine-induced thyrotoxicosis. The National Bureau of Economic Research (NBER) has recently evaluated the effect of the salt iodization program in the United States implemented in the first half of the twentieth century. Between 1910 and 1960, the United States witnessed a rise in death rates due to iodine-induced hyperthyroidism post implementation of salt iodization; this was highest among the elderly population and was attributed to longer exposure of suboptimal iodine intakes in the elderly (compared with other age groups), followed by a sudden exposure to increased iodine intake from salt iodization. A New Zealand study reported that short-term high doses of iodine (i.e., >50 mg of iodine for 8 weeks) also resulted in hypothyroidism in some elderly adults and hyperthyroidism in others; however, this resolved for most cases 4 weeks' normalization of iodine intakes. Evidence from different parts of China, with varying degrees of ID, showed that more than adequate or excessive iodine intake not only results in hypothyroidism but also may cause autoimmune thyroiditis. Excessive iodine intakes are believed to have an inhibitory effect on the thyroid or induce autoimmunity in genetically susceptible individuals. Although these studies indicate an increase in the proportion of thyroid disease post salt iodization program, this is outweighed by the benefits of a universal salt iodization program to combat IDD and its potential consequences, especially those on the developing brain.

IDD Control Programs

The ICCIDD, UNICEF, and WHO in association with the Network for Sustained Elimination of ID have been instrumental in the implementation of the IDD control program in various countries. These programs aim to reduce the incidence of IDD and to improve the iodine status of the populations. Different food-based vehicles have been used to provide iodine, including iodine in the form of iodized oil, iodinated water, iodized salt, and foods fortified with iodized salt, and control IDD in different countries.

The WHO recommends universal iodization of salt (USI) for human and animal consumption to improve the iodine

nutrition of populations worldwide. Iodized salt was first introduced in the United States and Switzerland in the mid-1920s. The use of salt as a vehicle for iodine has proved to be a cost-effective and successful strategy to combat IDD. Salt was preferred over other foods for a number of reasons including the widespread daily use of salt, the quantities of salt used remaining constant throughout the year regardless of season and socioeconomic status, the ability of salt to be integrated easily into animal feeds, and the simple and straightforward technology used to produce iodized salt. Additionally, the aesthetic and culinary properties of salt are unaffected, and the iodine levels in the salt can be adjusted to suit the needs of the local population. The factors considered while determining the amount of iodine used to fortify salt take into account the degree of ID, daily salt intake of the local population, and the losses incurred during transportation and storage. The recommended iodine content per kilogram of salt typically varies between 15 and 40 ppm of iodine and added as potassium iodate. Many countries including the United States, United Kingdom, the Netherlands, Switzerland, Australia, and New Zealand practice voluntary fortification of salt, while in China, India, and Denmark, fortification of salt is mandatory. Presently, about two-thirds of the world population is covered by adequately iodized salt (i.e., 15–40 ppm of iodine). The implementation of USI needs frequent monitoring and evaluation to ensure that iodine intakes do not become excessive. Excessive intakes of iodine may result in iodine-induced thyrotoxicosis or autoimmune thyroid disease as discussed earlier.

Monitoring the iodine intake of special groups such as pregnant and lactating women is important, as additional iodine in the form of supplements may be warranted to meet their higher iodine requirements. For instance, a study in Thailand observed that pregnant women were ID despite school-age children being adequate in iodine. There are different strategies used to improve the iodine status of pregnant and lactating women in some countries. For example, in order to meet the additional iodine requirement of pregnant and lactating women, especially from regions of moderate-to-severe ID, the WHO/UNICEF/ICCIDD recommends either a daily dose of 250 μg day^{-1} as potassium iodide or one annual depot dose of 400 mg as oral iodized oil and exclusive breastfeeding of the infant. Iodized oil is used in some areas where the distribution of iodized salt to remote areas is difficult and not a practical measure. Such periodic use of iodized oil was observed in some of the severe iodine-deficient areas in Papua New Guinea, Indonesia, Zaire, and some parts of China, as a provisional measure before the implementation of salt iodization programs in 1970s, especially among young women of childbearing age and children. Iodized oil was administered either as intramuscular injection or as oral drops. In Australia and New Zealand, regions with a long history of mild ID due to low soil iodine, and where only bread is fortified with iodized salt, the daily use of an iodine supplement with 150 μg of iodine for pregnant and lactating women is recommended. In many countries, despite regional or smaller studies indicating mild-to-moderate ID in pregnant and lactating women, strategies to combat ID in these special groups are yet to be implemented. A recent study in lactating Moroccan women found that giving mothers a single dose of oral iodized oil (e.g., 400 mg of iodine) immediately after delivery was more effective at ensuring adequate iodine status of infants in the first 6 months of life than giving iodine supplements directly to the infants. The benefits of maternal iodine supplementation are twofold, by maintaining adequate iodine status of the lactating women and by increasing iodine content of breast milk and consequently the iodine status of the infant.

Other food-based vehicles of iodine include food items such as bread and processed foods that are made with iodized salt; iodine can be directly added to sugar, fish sauce, or water. Iodized bread has been used in Australia and New Zealand, Tasmania, Russia, and the Netherlands with reasonable success to control IDD. In Malaysia, water supplied to schools and communities was iodinated. Concerted activities by government and nongovernment organizations through the implementation of locally suited IDD control measures have been instrumental in the eradication of severe forms of IDD; however, mild-to-moderate IDD remains unabated in many parts of the world and has even seen a reemergence in some countries due to changing food patterns and farming practices.

IDD control programs including USI are beneficial in two ways. Firstly, they have improved the iodine status of the populations and thereby reduced the adverse outcomes of IDD. These programs have been highly effective in eradicating severe ID and endemic cretinism globally while improving iodine status of populations in the mild-to-moderate ID regions. Secondly, the improvements in neuropsychomotor growth and development will result in increased economic growth and productivity. An economic cost–benefit analysis from the United States of universal salt iodization in developing countries showed an approximate gain of 35 billion US dollars. Further, correcting mild ID through adequate dietary iodine intakes may have added developmental gains and reduced health-care costs.

Iodine is an essential nutrient for thyroid hormone production. It exists in oxidation status −1 to 7 (atomic mass weight 126.9 Da) and occurs widely in trace amounts, with local concentration depending on geologic and water condition. Most iodide ($IO3^-$ anion, oxidation state +5) is found in the oceans (50–60 $\mu g\, l^{-1}$) and the concentration in freshwater is 1–10 $\mu g\, l^{-1}$. Iodide ions in seawater oxidize to form elemental iodine, which is volatile and evaporates into the atmosphere, then dissolves into water droplets that fall as rain. However, the cycle of iodine in many regions is slow and incomplete, leaching due to glaciation, frequent flooding, and erosion and depletes surface soils iodine (and soils). Consequently, groundwater easily becomes deficient in this element. Crops grown in these soils may be tenfold lower in iodine content (as low as 10 $\mu g\, kg^{-1}$ of dry weight) than those from iodine sufficient region (about 1 $mg\, kg^{-1}$ of dry weight in plants). The iodides in the sea accumulate in marine organisms, whereas on land, small amounts of iodine are taken up by plants that are subsequently ingested by herbivores. The only stable isotope of iodine is ^{127}I.

Iodine is essential for the synthesis of the thyroid hormones, thyroxine or 3,5,3,5-tetraiodothyronine (T4), and the biologically active form 3, 5, 3′-triiodthyronine (T3), which maintain the body's basal metabolic rate by controlling energy production and oxygen consumption in cells. Reverse T3 (rT3) is an inactive form of T3 that is produced in the body, particularly during periods of stress. Under normal conditions T4 will convert to both T3 and rT3 continually, and the body eliminates rT3 quickly. The synthesis of thyroid hormones requires a normally developed thyroid gland, an adequate nutritional intake of iodide, and a series of sequential biochemical steps. Thyroid hormone (T4 and T3) has pleiotropic effects, affecting multiple biological processes. These iodide-containing thyroid hormones are essential for normal growth and maturation along with the development of the central nervous system and regulation of numerous metabolic pathways. The physiological function of T4 and T3 encompasses the regulation of mitochondrial energy metabolism as well as cellular oxidation, thermoregulation, intermediate metabolism, carbohydrate, lipid and protein metabolism, and nitrogen retention. Iodine is primarily obtained through the diet but it is also a component of some medications. Various mechanisms can lead to thyroid disorders, and hypo- and hyperthyroid status can be observed in cases of both insufficient and excessive iodine intakes.

Intestinal Absorption

Iodine is ingested in a range of forms that are readily reduced to iodide (I^-) in the gut prior to absorption. The amount of iodide absorbed is largely dependent on the level of dietary iodine intake, rather than on its chemical form or the composition of the diet. Absorption is extremely efficient and takes place mainly in the stomach and upper small intestine, that is, the duodenum. Iodide is almost completely absorbed, whereas the absorption and metabolism of iodized oils is not entirely known. Under normal conditions, the absorption of dietary iodine is greater than 90%. The iodate ($IO3^-$) from supplements is reduced in the gut to iodide, but most dietary iodine is an inorganic salt form of iodide. Organic iodine is usually ingested only in the form of thyroid hormone T4 supplements and about 75% of an oral dose of the T4 is absorbed intact. For iodine and iodate from salt and supplements, absorption in the gut is high and not modified by other food components. However, iodine bioavailability may be influenced when encapsulation methods are used for iodine supplements, for example, tablets versus gelatin capsules, different coating substances, or the amount of pressure used to form the tablets, but only limited data is available The Institute of Medicine (IOM) in 2001 brought the consideration an absorption efficiency of 92% (Figure 1).

Iodide is absorbed by an active transport protein called the sodium-iodide (Na^+/I^-) symporter present in the brush border of the membrane and mediates active iodine accumulation. As its name indicates, the sodium–iodide symporter (NIS) simultaneously transports both Na^+ and I^- ions from extracellular fluid (i.e., blood) into the thyroid epithelial cells. NIS cotransports two sodium ions along with one iodide ion, with the sodium gradient serving as the driving force. The energy required to produce the sodium gradient is provided by the ouabain-sensitive Na^+/K^+-ATPase. NIS is expressed on the enteral apical surfaces of enterocytes and in numerous organs of the body including the thyroid gland, stomach, breast, placenta, salivary glands, and eyes. The genetic expression of the NIS is negatively regulated, depending on the concentration of iodine. That is, high concentrations of iodine in the plasma directly decrease NIS expression. However, NIS expression in many parts of the body remains to be completely understood.

Some foods contain goitrogens, that is, substances that interfere with thyroid hormone production or utilization. It should be recognized that goitrogens are usually active only if iodine supply is limited and/or goitrogen intake is of long duration. Goitrogens in some foods (thiocyanates from cassava, glucosinolates from cruciferous vegetables like cabbage, broccoli, cassava, and lima beans), presence of humic acids in drinking water, and nitrates, fluorides, calcium, magnesium, and iron in food and water, and a deficiency of other micronutrients, such as selenium or iron, interfere with thyroid metabolism and can aggravate the effect of iodine deficiency (Table 1). Foods containing goitrogenic cyanoglycosides such as sweet potato release thiocyanates that compete with iodine for absorption, blocking its uptake by the thyroid. Iodine absorption efficiency from water is influenced by the content and nature of humic substances in water. There has been

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00398-6

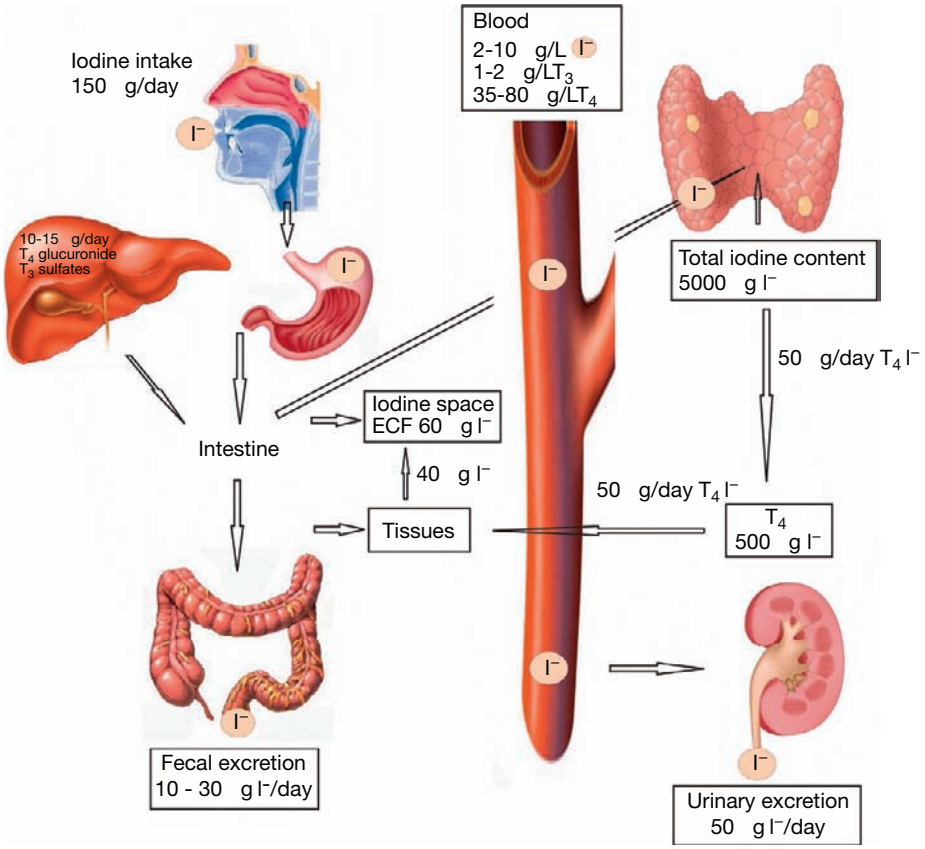

Figure 1 Iodine physiology.

Table 1 Goitrogens in food, industrial pollutants, and micronutrient deficiency and their mechanisms that interfere with thyroid hormone production or utilization

Foods	*Mechanism of action*
Cassava, lima beans, linseed, sorghum, sweet potato	Contain cyanogenic glucosides (they are metabolized to thiocyanates that compete with iodine for thyroidal uptake)
Cruciferous vegetables such as cabbage, kale, cauliflower, broccoli, turnips, rapeseed	Contain glucosinolates (metabolites compete with iodine for thyroidal uptake)
Soy, millet	Contain flavonoids (impair thyroid peroxidase activity)
Industrial pollutants	
Perchlorate	Competitive inhibitor of the Na/I symporter (decrease iodine transport into the thyroid)
Others (e.g., disulphides from coal processes)	Reduce thyroidal iodine uptake
Smoking	Smoking during breastfeeding (reduced iodine concentrations in breast milk) High serum concentration of thiocyanate (compete with iodine for active transport into the secretory epithelium of the lactating breast)
Nutrients	
Selenium deficiency	Accumulated peroxides (might damage the thyroid, and deiodinase deficiency impairs thyroid hormone synthesis)
Iron deficiency	Reduces heme-dependent TPO activity in the thyroid
Vitamin A deficiency	Increases TSH stimulation and goiter (through decreased vitamin A-mediated suppression of the pituitary TSHβ gene)

Source: Zimmermann, M. B. (2009). Iodine deficiency. *Endocrinology Reviews* 30, 376–408; Vanderpas, J. (2006). Nutritional epidemiology and thyroid hormone metabolism. *Annual Review of Nutrition* 26, 293–322.

concern about the presence of perchlorate in foods and drinking water because perchlorate inhibits the uptake of iodine in the thyroid gland.

Transport in the Blood

Total plasma iodine concentrations in euthyroid subjects (persons with adequate thyroid hormone status) range from 40 to 80 $\mu g\,l^{-1}$. Under normal circumstances, absorbed iodine has a half-life of approximately 10 h in plasma. This half-life value may be shortened in patients with iodine deficiency due to a more rapid thyroid intake. In blood plasma, the concentration of inorganic iodide is proportional to dietary intake and ranges from 2 to 6 $\mu g\,l^{-1}$ for average intakes below 200 $\mu g\,day^{-1}$. Concentrations between 80 and 250 $\mu g\,l^{-1}$ are generally associated with hyperthyroidism. Most organic iodine is present as T4, which accounts for more than 10 times the iodine content of T3, reverse T3 (rT3), mono-iodinated tyrosine (MIT), and di-iodinated tyrosine (DIT). Less than 1% of T3 and T4 is free in plasma. T4 occurs either free (fT4) or bound to proteins, mainly to thyroxine-binding globulin (TBG) and to a lower extent to transthyretin (or prealbumin) and albumin.

Distribution to Tissues

Fifteen percent of ingested iodine is actively taken up by the basal membrane of the thyroidal follicular cells using NIS, within 24 h of ingestion. The specific activity of NIS in thyroid cells is three to four times greater in thyroid tissue than in other tissue in body. Goitrogens including bromine (from fruit fumigants and processed bakery products), chlorine (chloramine by-product from drinking water chlorination), ammonium perchlorate (rocket fuel found in tap water), fluorine (naturally occurring in well water plus drinking water fluoridation), and thiocyanate (from cigarette smoke) can bind to the NIS receptor and damage it preventing iodine from entering the cell. The basal membrane of the thyroid cell has the specific ability to pump iodine into the interior of the thyroid cell. This is called *iodide trapping*. Once the iodide is inside the thyroid follicular epithelial cells, it is then transferred across the apical membrane to the follicle lumen by pendrin, a sodium independent iodide/chloride transport protein. In the thyroid, the follicular cells synthesize intracellular glycoprotein thyroglobulin (Tg), which is then stored in the central intrafollicular colloidal lumen. Thyreoperoxidaze (TPO), an iron-containing enzyme, is then catalyzed by the process of *organification*, in which iodide is oxidized and attached to the phenyl ring of Tg tyrosyl residues either in the form of MIT or DIT. T4 is formed by the coupling of two DIT molecules, whereas T3 is formed by one MIT and one DIT molecule. Soy isoflavones and goitrogens such as sulfur-containing thionamides present in vegetables of the brassica family impair the building of iodine to Tg and prevent oxidation of iodine by TPO. Depending on the overall iodine status, the thyroid intracellular colloid space stores enough covalently bound iodine in Tg for the synthesis of hormones for several weeks. The synthesis and release of T3 and T4 is regulated by a thyroid-stimulating hormone (TSH, or 'thyrotropin') secreted by the anterior pituitary gland. This regulation is subject to feedback inhibition deficiency. Increased TSH stimulates thyroglobulin peroxidase and subsequently releases thyroid hormones into circulation by endosomal and lysosomal cellular proteases. When the presence of thyroid hormone is low, thyrotropin-releasing hormone (TRH) is secreted by the hypothalamus and stimulates the secretion of thyrotropin. TRH secretion is also stimulated by noradrenergic impulses and inhibited by dopaminergic impulses. TSH is increased resulting in the positive regulation of NIS. Within 15–20 min, TSH stimulates the secretion of thyroid hormones and causes an increased iodide uptake by the thyroid and an increased Tg breakdown. To release thyroid hormones, thyroglobulin is engulfed by pinocytosis, digested in lysosomes, and then secreted into the bloodstream at the basolateral membrane. The iodined tyrosines are removed from the Tg by proteolitic enzymes, and T4 is released into circulation. Circulating T4 and T3 are bound to various iodine-binding transport proteins including albumin, TBG, and transthyretin. Once delivered to the relevant target tissues T4 is de-iodinated to the metabolically active form, T3. De-iodination requires selenocystein as the active form of selenium in the iodothyronine deiodinases. About one-third of iodine is present in the form of T3 and T4; the rest is present as MIT and DIT. Iodine consists of 65% and 59% of the weights of T4 and T3, respectively. Released MIT and DIT are de-iodinated by an iodotyrosine deiodinase providing an efficient intrathyroidal recycling of iodide. The turnover is slow: the half-life of T4 is about 5 days and for T3, 1.5–3 days. The released iodine is returned to the serum iodine pool where it can be taken up by the thyroid or excreted by the kidney. Other tissue sites for iodide uptake from plasma are the salivary glands, the choroid plexus, the mammary gland, the kidneys and the gastric mucosa. Within the range of usual intakes, the iodine flux in saliva is up to 10 $\mu g\,h^{-1}$, depending on the level of intake.

Elimination

Extrarenal clearance of iodide (range 3–40 ml of serum/min) in euthyroid subjects is assumed to represent thyroid clearance, corresponding to the capture of iodine by the thyroid gland, There is an inverse relationship between thyroid uptake and dietary iodine intake or urinary excretion. The percentage of capture by the thyroid can change within 12–14 weeks, and sometimes faster, in response to changes in iodine intake in euthyroid subjects. More than 90% of ingested iodine is ultimately excreted in the urine. Clearance of iodine by the kidneys remains relatively constant as a percentage of filtered iodide in plasma, depending on the glomerular filtration rate and physiologic rate. In adults with adequate iodine intake, excess iodine not taken up by the thyroid is excreted in urine, with partial reabsorption occurring in the renal tubules. Renal iodide clearance significantly decreases both in patients with impaired renal function or with myxedema. In comparison with habitual fluid intakes, an increase in fluid volume intake can lead to additional iodine losses: for an increase in urinary volume of one liter, there are additional iodine losses of around 15 $\mu g\,day^{-1}$.

Feces losses vary, but are generally low (10–30 $\mu g\,day^{-1}$). Small amounts are also lost via the skin. Compared with urinary

iodine (UI) concentrations, iodine concentrations in sweat appeared to be relatively constant at around 35–40 $\mu g\,l^{-1}$ over a large range of iodine intakes (UI from 8 to 280 $\mu g\,l^{-1}$), and in various climatic conditions, meaning that, in contrast to urinary excretion, sweat excretion is less adaptive. There is evidence that the mean correlation coefficient (r) between iodine elimination for blood/saliva was 0.99; for blood/urine, 0.95; and for saliva/urine, 0.97. The absolute value of iodine concentrations in urine revealed marked variability, which was corrected by adjusting for creatinine levels. Biliary conjunction of T4 (enterohepatic circulation) may occur with concomitant fecal elimination almost entirely as conjugate thyroid hormone. The expression of the NIS is positively regulated in the lactating mammary gland, and the uptake of iodine and secretion in breast milk, with the concentration in milk being 20–50 times higher than in plasma. More than 80% of iodine in breast milk is in the form of inorganic iodide, whereas T4 is $<2\,\mu g\,l^{-1}$, and T3 is $<0.05\,\mu g\,l^{-1}$. The iodine concentration of breast milk varies between 10 and 300 $\mu g\,l^{-1}$ (interindividual variability from 25–87%). Assuming an average dietary reference value (DRV) for iodine concentration in breast milk was 75 $\mu g\,l^{-1}$ and with average breast milk secretion of 0.8 $l\,day^{-1}$, calculated mean iodine loss was of 60 $\mu g\,day^{-1}$. Maternal T4 crosses the placenta before the onset of fetal thyroid function at 10–12 weeks and represents up to 20–40% of T4 measured in cord blood at birth. In colostrum, the iodine concentration ranges from 200 to 400 $\mu g\,l^{-1}$.

Storage

The thyroid gland accumulates iodine depending on the body's iodine and thyroid hormone status. The body of a healthy adult contains approximately 10–20 mg of iodine, of which 70–80% is in the thyroid, which is on average 8–15 mg of iodine. The main function of the thyroid gland is to store iodide and make it available for the biosynthesis of thyroid hormones. In chronic iodine deficiency, the iodine content of the thyroid might drop to less than 20 μg. In iodine-sufficient areas, the adult thyroid traps about 60 μg of iodine per day to balance losses and maintain the synthesis of thyroid hormones. The iodide cycle consists of a series of transport, oxidation, and coupling steps in thyroid follicular cells to produce thyroid hormones. NIS transports iodide into the thyrocyte at a concentration gradient 20–50 times that of plasma. TSH regulates NIS transcription and biosynthesis but also mediates NIS activity by posttranscriptional mechanisms. In the presence of TSH, NIS is active and inserted in the basolateral membrane of thyrocytes. Upon TSH withdrawal, NIS protein's half-life decreases from 5 to 3 days, and it translocates from the plasma membrane to intracellular compartments. Iodide is another factor that can regulate its own accumulation in the thyroid. It has been shown that high doses of iodide block iodide organification in a rat's thyroid; this phenomenon, known as the acute *Wolff-Chaikoff effect*, is a reversible process, because iodide organification resumes when the iodide concentration in the serum decreases. The mechanisms underlying the *Wolff-Chaikoff effect* are complex and involve acute regulation of several key genes and proteins within the thyrocytes. In the lactating mammary gland, NIS plays an important role by concentrating iodide in the milk, thereby supplying newborns with iodide for thyroid hormone syntheses. The thyroid iodine content at birth is around 100–300 μg and increases progressively to around 0.8–374 mg at 4–6 years of age. At the same time, the thyroid hormone requirements of a developing infant are at their highest per kilogram body weight compared with subsequent growth periods and is also at a time when adequate thyroid hormone is critical for ongoing neurodevelopment. Uptake and storage by the placenta are dependent on maternal iodine intake. The placenta has an iodine content of 30 $ng\,g^{-1}$ compared with the content of below 2 $ng\,g^{-1}$ for the myometrium. The concentration of iodine in amniotic fluid (around 15 $\mu g\,l^{-1}$) is weakly correlated with maternal UI excretion, and it can be independent of the ingestion of iodine supplements.

Iodine Metabolism During Pregnancy

Healthy women maintain iodine stores of 15–20 mg in the thyroid, and during pregnancy, the stored iodine can be used to help meet the approximate 50% increase in maternal iodine requirement. Iodine requirements increase during pregnancy due to a variety of physiological changes. Beginning in early gestation, maternal thyroid hormone production normally increases by approximately 50% in response to increased levels of serum TBG (resulting from the increase in estrogen levels) and because of the stimulation of TSH receptors by ß-human chorionic gonadotropin. For pregnant women, endogenous T4 production is estimated to be increased by a mean of 37 $\mu g\,day^{-1}$, corresponding to an additional iodine demand of 25 $\mu g\,day^{-1}$ for hormone synthesis in the thyroid. The glomerular filtration rate increases, resulting in increased maternal UI excretion. The glomerular filtration rate of iodide increases in early pregnancy by 30–50%, resulting in increased maternal UI excretion and decreasing the circulating pool of plasma iodine. The placenta is a rich source of the type 3 inner ring deiodinase, which enhances the degradation of T4 to biologically inactive T3. As human chorionic gonadotropin concentrations fall after week 10 of gestation, TSH concentration tends to rise. Thus, there is a normal physiological rise in TSH and a drop in FT4 from the beginning to the end of pregnancy that needs to be considered in assessing thyroid function. Fetal thyroid hormone production does not start until 14–16 weeks of pregnancy; before that time, the fetus is reliant on the transplacental passage of small amounts of maternal TSH. The additional requirements due to the development of the fetus, placenta, and amniotic fluid are equivalent to a net transfer of 1 μg iodine per day. Iodine needed for fetal synthesis of thyroid hormones leads to a total additional iodine intake rounded to 50 $\mu g\,day^{-1}$. Fetal thyroid hormone production increases during the second half of pregnancy, further contributing to increased maternal iodine requirements because iodide readily crosses the placenta. Thus, thyroid hormone demand increases, which requires an adequate iodine supply that is obtained primarily from the diet and/or as supplemental iodine.

Interactions with Other Nutrients

Selenium and iron deficiencies may impair iodine/thyroid metabolism. Deficiencies of iodine and selenium intake often show up together, with selenium status influencing the outcome of iodine deficiency. Glutathione peroxidase and the deiodinases, the selenium-dependent enzymes, are impaired in selenium deficiency. This leads to accumulation of peroxidases, which can damage the thyroid, whereas deiodinase deficiency impairs thyroid hormone synthesis. In anemic pregnant women, endemic goiter may provoke anemia. Iron deficiency anemia during pregnancy can result in both higher TSH and lower T4 concentrations. Chronic iodine deficiency favors subclinical hypothyroidism, and the risk of hypothyroidism is increased in anemic goiter patients. Iron deficiency reduces heme-dependent TPO activity in the thyroid, resulting in impaired production of thyroid hormone. Iron supplementation use with iodized salt affects both anemia and goiter in children. Also, intervention trials in iodine and iron-deficient populations have shown that the addition of both iron and iodine results in greater improvements in thyroid function and volume. Iron supplementation improves the efficacy of iodized oil and iodized salt. Also, deficiencies of vitamin A, and possibly zinc, may interact with iodine nutrition and status and thyroid function. Vitamin A supplementation given alone or in combination with iodized salt significantly improved thyroid function and thyroid size. Vitamin A deficiency can worsen goiter in populations with iodine deficiency, through decreased vitamin A-mediated suppression of the pituitary TSHβ gene and is not relevant in the European context (Asia and Africa). However, further research is needed to establish a conclusive relationship between iodine and other micronutrients.

Effect on Genotype

Iodine is responsible for gene expression and the synthesis of xenobiotic-metabolizing enzymes in the liver. Excess iodine intake also altered mRNA and protein levels of numerous thyroid genes involved in lipid metabolism and inflammatory activities. Alterations in the expression of these genes may contribute to the progression of iodine-induced autoimmune thyroid disease. Genotypes that predict differences in requirements have not yet been identified as important at the population level, although genotype may influence the risk of thyroid autoimmune disease in iodine repletion studies.

Dietary Sources and Intake Data

Iodine is found in food and water mainly as iodide. The main dietary sources of iodine are iodized salt, saltwater fish, seaweed, and grains (if grown in iodine-repleted soils). The native iodine content of most foods and beverages is low (Table 2). Most commonly consumed foods provide 3–80 μg of iodine per serving. Saltwater fish, shellfish, and seaweed are food sources with the highest natural iodine content. Because seaweeds are not a component part of the Western diet, ocean fish are the only good sources of iodine. Iodine content in fish and shellfish varies from less than 5 to more than 200 μg/100 g (haddock, cod fish, and sole contain > 140 μg/100 g, freshwater fish contain only 2 μg/100 g). The mean iodine content in commercial fish feed was reported to be 4.6 mg kg^{-1} and ranged between 1.2 and 10.5 mg kg^{-1}. One cup of low-fat plain yogurt and milk have 75 and 56 μg iodine, respectively (50 and 37% DRV). Fish sticks, 3 oz, have 54 μg iodine (36% DRV); tuna canned in oil, drained, 3 oz, 17 μg iodine (11% DRV); ice cream, chocolate, ½ cup, 30 μg iodine (20% DRV); large egg 24 μg iodine (16% DRV); apple juice, 1 cup 7 μg iodine (5% DRV); and medium banana 3% (2% DRV).

Table 2 Iodine content in food

Food type	*Content*[a]	*Food type*	*Content*
Marine fish	1456 μg kg^{-1}	Meat	68 μg kg^{-1}
Freshwater fish	103 μg kg^{-1}	Cereals	56 μg kg^{-1}
Nuts	89 μg kg^{-1}	Oils and fats	36 μg kg^{-1}
Leafy vegetables	89 μg kg^{-1}	Fresh fruits	31 μg kg^{-1}
Other vegetables	80 μg kg^{-1}	Bread	17 μg kg^{-1}
Dairy	84 μg kg^{-1}	Water	6.4 μg kg^{-1}

Foods of marine origin have higher iodine content because of a high concentrated amount of iodine in seawater. Japanese diets in the coastal regions of Japan contain large amounts of seaweed, and they have remarkably high iodine intakes ranging from 50 to 80 mg day^{-1}. A bowl of common soup in the Japanese diet can contain 5 mg of iodide. Major dietary sources of iodine in the United States and Europe are dairy products and whole grains. Mean iodine content in milk in northern Europe is at the level of 15–20 μg/100 g. The iodine content in cow's milk depends on the amount of iodine given to the animal in mineral mixture, and iodophors (preparation containing iodine complexed with a surfactant or povidone resulting as a water-soluble material that releases free iodine when in solution) used for cleaning milk cans and teats in the dairy industry can increase the native iodine content of dairy products. Also, iodine content in milk shows seasonal variation, with the highest content during winter and the lowest content during summer. Fifty years ago, bread was a major source of dietary iodine, with a content as high as 150 μg/slice. Traditionally, iodate is used in bread making as a conditioner for dough, but today it is being replaced by non-iodine-containing conditioners. The decreased use of iodate bread conditioners is thought to have contributed to the reduction in dietary iodine levels.

Salt iodization is a term used to describe the iodization of salt for human consumption (food industry and household) and for livestock feed. In many countries, the use of iodized salt in households for cooking and at the table provides additional iodine. Boiling, baking, and canning of foods containing iodated salt causes only small losses (≤10%) of iodine content. Iodine can be added to salt as potassium iodide (KI), potassium iodate (KIO_3) or less frequently, sodium iodide. North America and some European countries use KI as a form for fortification, whereas most tropical countries use KIO_3, which

is more stable in the presence of salt impurities, humidity, and porous packaging. To meet the iodine requirements of a population, it is recommended to add 20–40 mg iodine/kg salt, depending on local salt intake. According to the World Health Organization (WHO), the United Nations Children's Fund (UNICEF), and the International Council for the Control of Iodine Deficiency Disorders (ICCIDD), iodine fortification of salt has been implemented in 40 European countries and is mandatory in 13. The amount of iodine added varies from 10 to 75 mg kg^{-1} salt.

The iodine concentration in drinking water is highly variable within different regions. Denmark covers a relatively small geographic area; however, its iodine content in drinking water varies from 2 to 100 μg l^{-1}. In Germany, a variation from 0.2 to 15.5 μg l^{-1} (median 2.6 μg l^{-1}) is shown when traveling from the north to south.

Results of dietary studies show the following general order of percentage of daily iodine intake from the main food groups in Western countries: dairy (50%), cereals (20%), fish (9%), meat (8%), vegetables (7%), sweets (5%), and fruits (1%). On the basis of these reports, the average (geometric mean) iodine content of 494 foods is 87 μg kg^{-1} (Table 2). Without adventitious sources of iodine or a marine foods component, most diets would fail to provide the recommended daily intake of 150 μg day^{-1}. Based on data from the Third National Health and Nutrition Examination Survey, 12% of men and 15% of nonpregnant women took a supplement that contained iodine, and the median intake of iodine from supplements was approximately 140 g day^{-1} for adults. Supplements vary in iodine content and form and may be available as KI tablets, prenatal multivitamin preparations, or iodized oil. Iodine readily binds to the double bonds in fatty acids, allowing the preparation of iodized oils that are used for supplementation outside the EU. Iodized oil, intramuscular, or oral administration, provides significant and prolonged iodine supplementation without inducing any clinical or laboratory adverse effects. Supplements with iodized oil give effective prophylaxis in iodine-deficient subjects. The intramuscular route has a longer duration of action than does oral administration. Other sources of iodine include water purification tablets, radiographic contrast media, and medicine (e.g., a 200 mg tablet of amiodarone, an antiarrhythmic drug, contains 75 mg), and skin iodine-based disinfectants are commonly used in clinical settings. (e.g., povidone iodine contains approximately 10 mg ml^{-1}).

Assessment of Iodine Status

To date, expert bodies have used physiological or mechanistic (balance and turnover) iodine studies to derive DRVs for iodine. Clearly, the shape of the intake–status relationship has an important bearing on the predicted adequate nutrient requirement estimates using iodine status biomarkers. In populations, median UI concentrations of 100–200 μg l^{-1} indicate adequate iodine intake and optimal iodine nutrition (Table 3). As an indicator of iodine intake, median UI concentration does not provide direct information about thyroid function and longer-term iodine exposure.

In a systematic review, the available evidence, with regard to the usefulness of iodine status biomarkers, was assessed. UI, serum Tg, serum T4, and TSH were found to be useful biomarkers of iodine status depending on age and population group and their iodine status. The model of dose–response quantification used to describe the relationship between iodine intake and biomarkers of iodine status indicated that the doubling of dietary iodine intake increased UI concentrations by 14% in children and adolescents, 57% in adults and the elderly, and 81% in pregnant women. The dose–response relationship between iodine intake and biomarkers of iodine status indicated a 12% decrease in thyroid-stimulating hormone and a 31% decrease in thyroglobulin in pregnant women. Serum TSH and Tg concentrations primarily indicate thyroid function, which is largely dependent on iodine intake, as a means of detecting functional iodine deficiency.

Serum Tg is easier to assess than thyroid volume measurement, and is a useful biomarker of iodine status in children and adolescents. Methods for Tg determination on dried blood spots have been developed. Serum Tg represents a very sensitive index of thyroid hyperstimulation and reflects iodine deficiency. In iodine adequacy, the concentration of Tg is below 10 μg l^{-1}.

Serum TSH is a suitable biomarker of iodine status in neonates and possibly in pregnant and lactating women. Measurements can be performed on dried blood spots on paper. The normal serum TSH range is 0.1–5 mIU l^{-1}. An important caveat is that

Table 3 Assessment of iodine nutrition in a population based on UI concentrations

UI concentration (cutoff values in μg l^{-1})	*Iodine intake*	*Iodine nutrition*
Children <2 years of age		
<100	Insufficient	
>100	Adequate	
School-aged children		
<20	Insufficient	Severe ID
20–49	Insufficient	Moderate deficiency
50–99	Insufficient	Mild deficiency
100–199	Adequate	Optimum
200–299	More than adequate	Risk of iodine-induced hypothyroidism
>300	Excessive	Risk of adverse health
Pregnant women		
<150	Insufficient	
150–249	Adequate	
250–499	More than adequate	
>500	Excessive	
Lactating women		
<100	Insufficient	
>100	Adequate

Public Health Nutr 2007; 10: 1606–11.

newborn testing must be performed >48 h after birth to be valid because there is a normal physiological surge in infant TSH concentrations after birth. Serum concentrations of T4 and T3 are generally less sensitive for estimating iodine status. The normal serum concentrations are around 100 nmol l^{-1} (80 μg l^{-1}) for total T4 and around 1.8 nmol l^{-1} 569 (1.2 μg l^{-1}) for total T3; concentrations of free T4 forms are in the ranges of 11–18 pmol l^{-1} and free T3 3.5–570 pmol l^{-1}, respectively.

Goiter prevalence and thyroid volume are useful long-term clinical indicators of iodine status. Thyroid size can be determined by the palpitation method, expressed in percentages of the different stages at population level and by thyroid ultrasonography with the thyroid volume given as ml. Thyroid volume is best determined from ultrasound measurements rather than by palpation, which is less sensitive in the case of mild or moderate iodine deficiency. In an adult population, thyroid enlargements, defined as a thyroid volume >18 ml for adult women and >25 ml in adult men, are generally considered to represent goiter.

Dietary Requirements

Optimal dietary iodine intake is between 100 and 200 μg day^{-1}. With respect to adequate iodine intake, the cutoff values are set at the levels that should be optimal for general health and the prevention of deficiency. Alternatively, other endpoints used to assess adequacy are adequate iodine concentration in the thyroid gland and iodine turnover (the Nordic countries, the DACH-countries, WHO/FAO, 2002), or more generally, a proper thyroid function (Belgium, the UK, WHO/FAO, and EC) and iodine balance (EC). For setting recommendations, there are two parts of the factorial approach: the calculation of basic requirements (needs for growth, maintenance, losses etc.) and the application of a bioavailability factor. For iodine, bioavailability can be defined as the combination of absorption of dietary iodine and of thyroid uptake and the utilization of iodine. It is based on the definition that bioavailability should be sufficiently broad to cover changes in absorption or/and excretion attributable to physiologic regulatory mechanisms that maintain and restore optimal homeostasis.

Iodine intake is difficult to determine by dietary assessment because the iodine content of foods is variable, and reliable values are not always available in food composition tables. There are only a few food composition databases containing information on iodine-rich foods. Food composition databases generally contain information on the salt content of foods, but they rarely specify if the salt used in processed foods is iodized or not. Dietary assessment methods FFQ, food diaries, or 24-h food intake recall are not reliable quantitative methods for assessing the total iodine intake. The lack of accuracy in measuring iodine intake from iodized salt is thus a major limitation of dietary assessment. Dietary data can be used to identify the most important food sources of iodine but do not accurately quantify the usual iodine intake, The FFQ method captures iodine-rich sources that are irregularly consumed and day-to-day variation in the overall consumption patterns such as frequency and portion sizes of iodine-containing foods. Food diaries or 24-h recalls measure short-term intakes, and often underestimate salt consumption.

Adequate dietary iodine intake is essential for the production of thyroid hormones. The recommended daily allowances for iodine intake vary by age. A prevalence of goiter below 5% in school-age children was almost systematically observed in all the areas of the study for a UI concentration above 100 μg l^{-1} (corresponds to an approximate iodine intake of 150 μg day^{-1} in adults). The European Commission, the EFSA Panel for iodine DRV concluded that an adequate intake (AI) for iodine for adult men and women can be set at 150 μg day^{-1} (Table 3). For infants ages 7–11 months and for children and taking into account age-specific urinary volumes and body weights, AIs of 70 μg day^{-1} to 130 μg day^{-1} were derived. According to the EPSA panel the same AI is proposed for lactating as for pregnant women, that is, 200 μg day^{-1}.

The WHO established recommended nutrient intakes (RNIs) that cover the needs of nearly all healthy individuals for specific life-stage groups. WHO has set criteria for the assessment of school-age children and pregnant and lactating women based on UI concentrations. WHO/ UNICEF/ ICCIDD recommend daily iodine intakes of 90 μg day^{-1} for preschool children and 150 μg day^{-1} for adults, reaching 250 μg day^{-1} for pregnant/lactating women (Table 4). For the United States

Table 4 Recommendations for iodine intake

Age	*EFSA (μg day^{-1})*	*Age*	*U.S. Institute of Medicine (μg day^{-1})*	*Age*	*WHO (μg day^{-1})*

and Canada, the IOM established dietary reference intakes for iodine, and specifically an AI for infants and an estimated average requirement and recommended dietary allowance for children, adolescents, and adults. The following simplified equation to calculate daily iodine intake has been proposed by the IOM: UI ($\mu g\ l^{-1}$) $\times$ 0.0235 $\times$ body weight (kg). European and United States expert committees have recommended tolerable upper intake levels for iodine (**Table 5**). The tolerable level for iodine intake is set at 1.2 mg day^{-1} for adults.

Importance and Functions of Heme in Metabolism

Heme or iron protoporphyrin IX is a unique and ubiquitous tetrapyrrole that has various and versatile functions in living organisms. This heterocyclic macromolecule consists of four pyrrole rings, which are joined together by methene bridges. Furthermore, the pyrrole rings are coordinated axially by four nitrogen atoms to ferrous ion (Fe^{2+}) in heme or ferric ion (Fe^{3+}) in hemin. Moreover, the central Fe ion can exchange or transfer electrons as it exists in more than one oxidation state and can also axially coordinate one or two additional ligands to histidine, cysteine, or methionine (sometimes tyrosine or lysine) of proteins. The tetrapyrrole ring structure has eight side chains that interact with coordinating proteins – 4 methyl, two vinyl, and two propionate (see Figure 1). There are two common ligation motifs, namely, a 5-coordinate monohistidine (e.g., in hemoglobin or myoglobin) and a 6-coordinate bis-histidine as in cytochrome *c*. Heme is covalently ligated to holoproteins by heme lyase. Some heme-binding proteins have the unique sequence motif CXXCH (C: cysteine, X: any amino acid, and H: histidine) in which the two cysteine units are linked to protoporphyrin and the histidine is coordinated to Fe. Heme can also be reversibly attached to gases such as oxygen, nitric oxide (NO), and carbon monoxide (CO). Consequently, the structural components of heme enable a repertoire of interactions, coordination and binding with diverse molecules to exert a broad array of metabolic reactions, and physiological functions that sustain life. Moreover, complexities in this diverse and divergent array of functions are induced by chemical modifications and substitution of side chains of the pyrrole rings, hydrophobic interactions, and electrostatic interaction such as salt bridges with numerous hemeproteins. Consequently, the binding versatilities of heme favor conformational variations in protein scaffolds and architecture that culminate in vastly disparate functional capabilities. There are five types of heme ligands (a, b, c, d, and d_1), in general, based on positions of and differences among side chains and the types of bonds to various apoproteins. Heme b (Figure 1) bears the basic structure from which other types are formed. The heme variants function as cofactors or prosthetic group of hemeproteins apart from serving as effector molecule involved in signal transduction, cell growth and differentiation, drug and steroid metabolism, circadian rhythm, microRNA processing, and gene regulation among others. A summary of examples of functions of hemeproteins are listed in the succeeding text.

Functions of Heme in Systemic Metabolism

Heme as cofactor or prosthetic group of hemeproteins:

- Archetypal and quintessential functions of hemeproteins arise from reversible binding of small molecules and conformational changes that facilitate cellular transport of gaseous molecules for exchange or storage and gaseous ligand binding that senses diatomic gases, for example, hemoglobin (Hb), myoglobin, nitrite reductase, and NO regulator.
- Cytochromes are heme proteins that are involved in electron transfer reactions based on reversible oxidation–reduction of heme Fe in the mitochondria. For example, cytochrome reductase catalyzes electron transfer from ubiquinol to cytochrome *c* and is also involved in proton pumping across mitochondrial membrane. Cytochrome *c* complex catalyzes electron transfer from reduced cytochrome *c* to molecular oxygen on the mitochondria inner membranes.
- Some other hemeproteins such as cytochrome P450, peroxidases, NO synthase, nitrite reductase, and soluble guanylate cyclase are involved in both electron transfer and catalytic functions. Cytochrome P450 monooxygenase enzymes are involved in phase I drug metabolism and xenobiotic reactions. They catalyze such reactions as deamination, hydroxylation, and epoxidation among others to catabolize hydrophobic toxicants into polar forms for excretion and detoxification.
- Cystathionine β-synthase (CBS) is a unique heme-dependent enzyme that catalyzes the condensation of serine and homocysteine into cystathionine using pyridoxal 5-phosphate as a cofactor. Deficiency of CBS results in homocystinuria, an inherited disease that is characterized by high levels of toxic homocysteine in the serum. Enzymatic activity of CBS is influenced by the reduction or replacement of Fe by CO in the noncovalently bond heme ligand.

Heme as a regulator of transcription:

- Heme is a transcriptional regulator of the mammalian repressor BtbAndCnc homology 1 (Bach1), a basic leucine zipper protein. When intracellular heme level is low, genes containing the Maf recognition element (MARE) sequence in the promoter region, for example, globin, erythroid δ-(aminolevulinic acid) ALAS, and HO-1, are bound by Bach1–Maf dimer and are transcriptionally repressed in the nucleus. However, when heme levels are high, heme binds to the heme response motif (HRM) on Bach1 causing dissociation of Bach1-Maf hererodimer from MARE. A leader protein, exportin 1 (Crm1), binds Bach1 and facilitates its export from the nucleus into the cytoplasm for subsequent degradation and ubiquitination and degradation by HOIL-1. Heme nullifies the repressor function of Bach1. Dissociation of Bach1 from MARE DNA sequence, its nuclear translocation, and its cytoplasmic degradation all require heme binding to HRMs to enhance the transcription of genes such as erythroid δ-ALAS and HO-1.
- Heme stabilizes the nuclear factor erythroid-2-[NF-E2]-related factor 2 (Nrf2) that binds small MAF proteins.

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00402-5

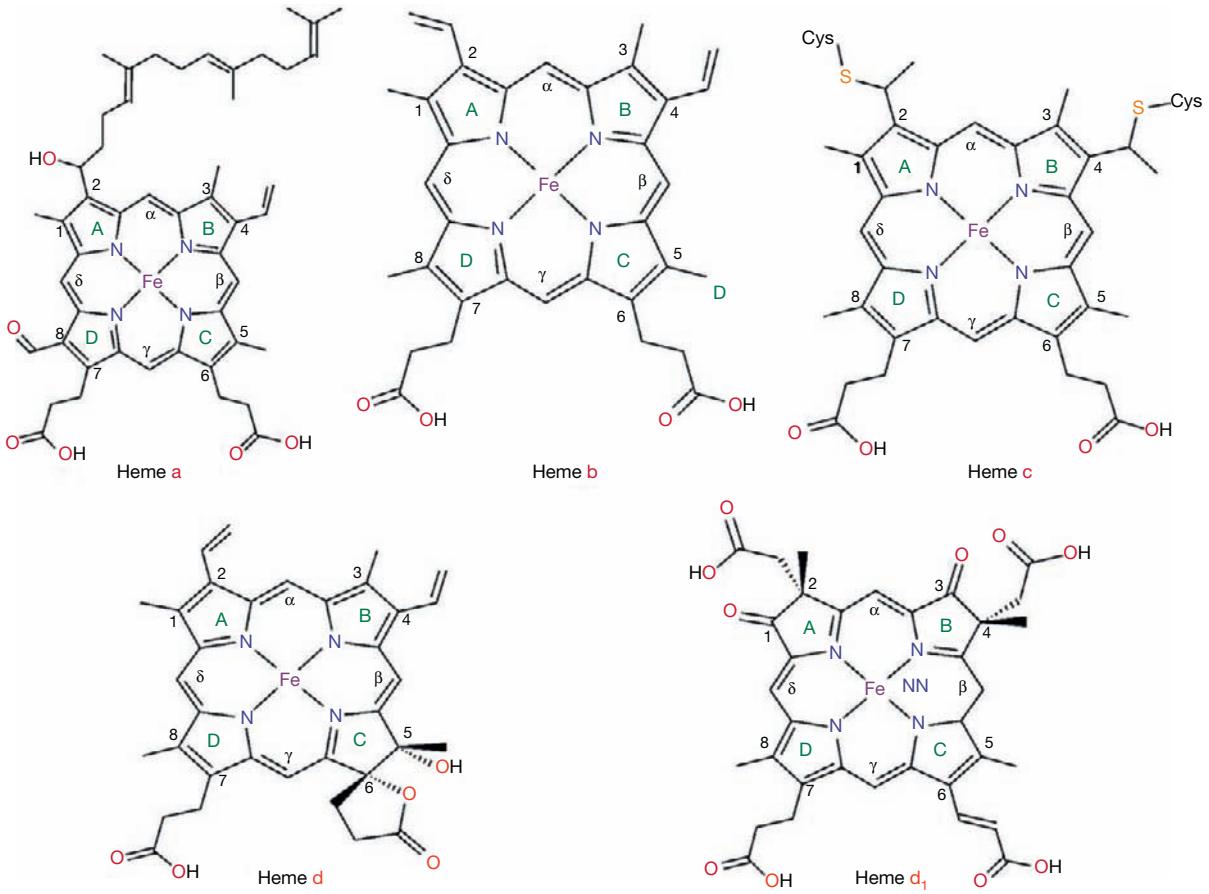

Figure 1 Structure of naturally occurring hemes a, b, c, d, and d1. http://metallo.scripps.edu/PROMISE/HAEMMAIN.html.

Unlike Bach1, Nrf2–Maf dimers activate MARE-containing genes. When heme level is low, Nrf2 binds to Kelch-like ECH-associated protein 1 (KEAP1) in the cytoplasm. However, when heme levels are high, heme binds to KEAP1, freeing Nrf2, and Nrf2–Maf binds to the promoter region to activate gene transcription via antioxidants response element-mediated gene expression, for example, antioxidant genes.

Heme regulates translation:

- Heme regulates translation through a heme-regulated elF2α kinase inhibitor (HRI). Translation initiation factor elF2α is phosphorylated by the kinase to inhibit protein synthesis when heme level is low. When heme levels are high, however, heme binds to the HRI kinase to inhibit phosphorylation, thereby suppressing its activity. Consequently, elF2α initiates translation of α and β globin chains. HRI senses heme levels to coordinate and regulate heme and globin synthesis during erythropoiesis.

Heme regulates cell cycle progression:

- Heme may modulate cell cycle indirectly through the activity of zinc protoporphyrin (ZnPP) when iron is deficient. Zn is incorporated into protoporphyrin IX during iron deficiency. ZnPP subsequently inactivates transcription factors such as Egr1 and Sp1 to inhibit cell cycle progression. Hemin is a regulator of the growth and differentiation of erythroid and nonerythroid cells.

Heme in microRNA processing:

- DiGeorge syndrome critical region gene 8 (DGCR8), an RNA-binding protein, forms a heterodimer with the nuclease, RNase Drosha, and the complex recognizes and cleaves primary transcripts of microRNAs (pri-miRNAs) in the processing of mammalian microRNAs (miRNAs). Heme binds to DGCR8 to regulate its activity in the processing and maturation of pri-miRNA to microRNA. The heme-binding motif on DGCR8, IPCL (isoleucine, proline, cysteine, and leucine), shares a close similarity with HRM.

Heme in circadian transcriptional regulation of genes:

- Heme plays a pivotal role in circadian-coupled transcriptional regulation of genes. Evidence suggests the regulation of circadian-linked transcription by availability of intracellular heme and heme-based sensing of CO and possibly NO. Transcription of several circadian genes is activated by binding of the NPAS2-Bmal1 or clock-Bmal1 heterodimer to the promoter region. These genes can be regulated by a feedback mechanism where the gene products bind to NPAS2-Bmal1 or clock-Bmal1 and inhibit binding to DNA. Furthermore, binding of heme and CO to NPAS2 or clock induces dissociation of the heterodimer, thereby switching off

transcription of circadian genes. In addition, NPAS2-Bmal1 or clock-Bmal1 transcription is also regulated in another heme-dependent mode. Rev-ErbA, a nuclear hormone receptor, binds to heme and forms a heterodimer with nuclear receptor (NR) corepressor (NCoR) in partnership to repress transcription of circadian genes. It cannot inhibit transcription in the absence of heme.

Heme Biosynthesis

Heme may be synthesized *de novo* in all human cells as required, but the major sites of biosynthesis are in the bone marrow by erythrocytes for incorporation into hemoglobin and the liver in humans. Most of the heme produced in the liver is for the synthesis of cytochrome P450 for the detoxification of xenobiotics. Heme biosynthesis in erythroid cells in humans occurs in eight sequential enzymatic reactions (Shemin pathway) of which the first and the last three steps occur in the mitochondria, while the intermediate steps occur in the cytosol (Figure 2).

Formation of the Pyrrole

The first step in pyrrole biosynthesis is the condensation of glycine with succinyl-CoA in the mitochondria to produce δ-ALA by the catalytic action of δ-aminolevulinic acid synthase (ALAS2). This is the rate-limiting step, which is regulated by the availability of iron and heme. ALAS1 is the ubiquitous housekeeping, nonerythroid isoform that is expressed in most tissues and, in particular, in the liver. ALAS1 is regulated by heme, and this could involve a number of transcriptional factors, ubiquitination of the protein, energy metabolism transcription coactivators, nuclear receptors, chemicals, and drugs. ALAS1 regulation is therefore a therapeutic target for the treatment of porphyrias. Solute carrier family 25, SLC25A38, and ABCB10 have been shown to be transporters of ALA from the mitochondria to the cytosol. The second step involves the condensation of two molecules of ALA by a zinc-dependent ALA dehydratase (ALAD) enzyme in the presence of pyridoxal phosphate to form porphobilinogen (PBG). This step and the subsequent four enzymatic reactions take place in the cytosol. ALAD is inhibited by lead (Pb).

Formation of Tetrapyrrole

Four molecules of PBG are condensed (oligomerization) in a head-to-tail fashion to form a linear tetrapyrrole hydroxymethylbilane (HMB), in a reaction catalyzed by PBG deaminase (PBGD, also called HMB synthase). Next, HMB undergoes intramolecular rearrangement and ring closure to form a tetrapyrrole uroporphyrinogen III (URO III) molecule, with constituent eight carboxylic (four acetyl and four propionyl) side chains. This reaction is catalyzed by URO III synthase.

Modification of Carboxylic Side Chains

Four acetyl groups on URO III are subsequently decarboxylated to methyl groups by URO decarboxylase (UROD) to form coproporphyrinogen III (Copro III), which is transported

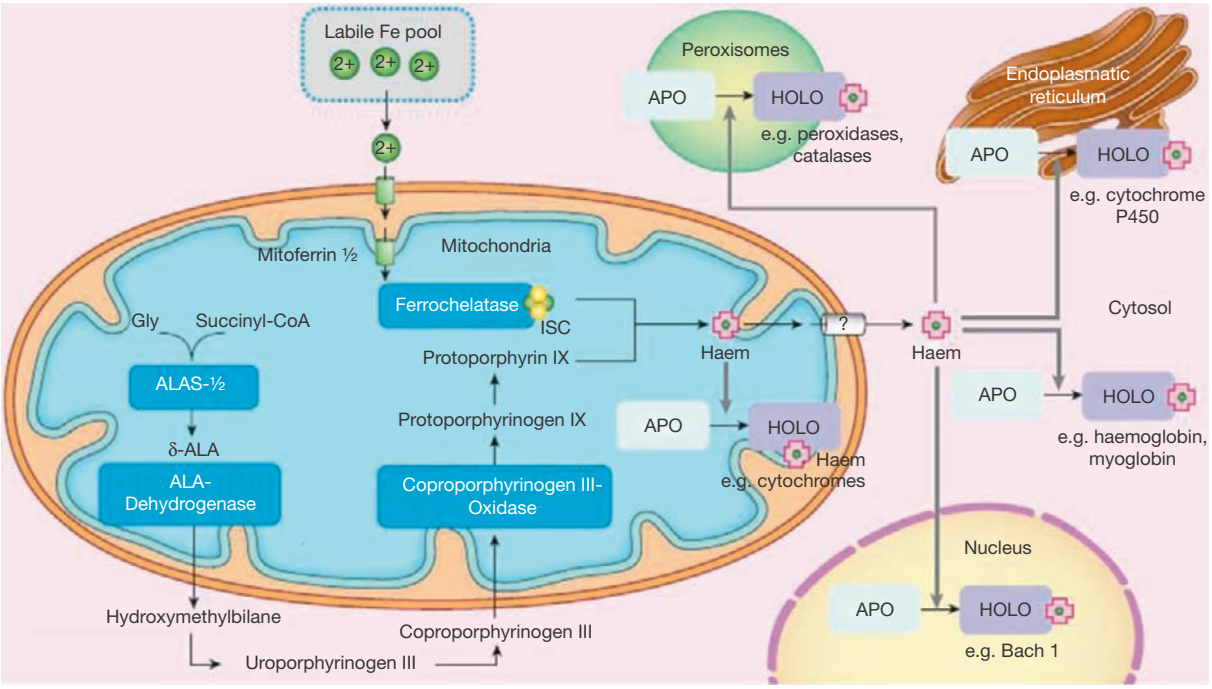

Figure 2 Heme biosynthesis. The rate-limiting reaction of heme biosynthesis is the generation of delta-aminolevulinate (d-ALA) from succinyl-CoA and glycine, assisted by d-ALA-synthase (ALAS). Synthesis of the porphyrin ring is then achieved in a multistep process, taking place in both the mitochondria and cytosol. Iron is loaded onto protoporphyrin IX by the iron–sulfur cluster-containing enzyme ferrochelatase. Heme is then transported to apoproteins by yet unknown pathways. Reproduced with permission from Evstatiev, R. and Gasche, C. (2012). Iron sensing and signalling. *Gut* **61**(6), 933–952.

into the mitochondria and further decarboxylated and oxidized by coproporphyrinogen oxidase to produce protoporphyrin IX in the mitochondria in an oxidative decarboxylation step. In this reaction, two propionate groups are converted into vinyl groups and the methylene bridges of the pyrrole rings become methane. The putative transporter of Copro III from the cytosol into the mitochondria is ABCB6. Protoporphyrin oxidase catalyzes the enzymatic oxidation of methylene to methane bridges in protoporphyrin IX.

Insertion of Iron into Protoporphyrin IX

The final step in heme biosynthesis is the insertion of ferrous ion Fe^{2+} by ferrochelatase (FECH), also known as proheme ferrolyase, into the center of protoporphyrin IX to form heme in the mitochondria. Heme is presumed to be exported out of the mitochondria by feline leukemia virus subgroup 1b, (FLVCR1b), catalysis by FECH is also a rate-limiting enzyme and it is transcriptionally regulated by GATA factors, Sp1 and NF-E2. In general, the posttranscriptional regulation of heme synthesis in erythroid cells is by iron–sulfur clusters (ALAD2 and FECH), whereas heme regulates biosynthesis in nonerythroid tissues instead. Iron is transported by FECH into the mitochondria by mitoferrin1 (MFRN1) and mitoferrin2 (MFRN2), respectively, in erythroid and nonerythroid tissues. Alternate splice variants of the enzymes ALAD, PBGD, and UROS are employed in reactions in heme biosynthesis in nonerythroid tissues. ALAS exist in two forms, ALAS1 and ALAS2, coded for by distinct genes, ALAS1 on chromosome 3 and ALAS2 on the X chromosome. While ALAS1 is regulated by heme, ALAS2 levels are modulated by erythroid-specific cis-acting transcriptional factor GATA-1 and by iron translationally via iron-response element and iron-response protein (IRE-IRP) regulatory system. Mutations or defects in ALAS2 and the subsequent seven enzymes in heme biosynthetic pathway cause chromosome X-linked sideroblastic anemia (acquired or inherited) and porphyrias, respectively (Table 1). It is of major significance that some key intermediates of the heme biosynthetic pathway, namely, delta-ALA (5-ALA), and its esters have clinical application in photodynamic therapy of cancer malignancies. Delta-ALA is administered to induce the production of protoporphyrin IX (PpIX), a potent photosensitizer, which when activated by light and oxygen produces reactive oxygen species (ROS) that destroy tumor cells. Photodynamic therapy is manipulated for low ROS toxicity, tissue selectivity, and specificity.

Erythropoiesis

A significant amount of heme is synthesized by normoblasts (also known as erythroblasts) in the bone marrow during erythropoiesis. In mammals, erythropoiesis also takes place in the mesoderm of the yolk sac of the early fetus and in the liver of midterm fetuses. Extramedullary erythropoiesis may take place in the spleen. Pluripotent stem cells generate hematopoietic progenitors that differentiate along various lineages. In the erythroid lineage, the detectable precursor is called burst-forming unit-erythroid (BFU-E). BFU-E cells proliferate and differentiate to form colony-forming unit-erythroid (CFU-E), the progenies of which divide and progress through proerythroblasts, basophilic erythroblasts, polychromatic erythroblasts, orthochromatic erythroblasts, and finally reticulocytes that are released into the circulation. These stages are accompanied by chromatin condensation, increasing hemoglobinization, enucleation and culminates in erythrocytes, which are devoid of organelles. Iron required for erythropoiesis is delivered by transferrin receptor 1 (TfR1) in an endocytic cycle comprising DMT1 (a six-transmembrane epithelial antigen of the prostate 3 (STEAP3)) and SEC15 (an exocyst complex component 6). Mice lacking TfR1 die *in utero*, while the haploinsufficiency of this receptor or of any other component of the endocytic cycle causes microcytic anemia. Conversely, excess iron is effluxed from erythroblasts by ferroportin 1b, an isoform that lacks the 5′ IRE, while excess heme is extruded principally by feline leukemia virus subgroup C receptor (FLVCR1). Thus, FLVCR1 is therefore involved in the heme detoxification process during erythroid differentiation and erythrophagocytosis. Excess heme that is not effluxed in mutant FLCVR mice causes cellular apoptosis, maturation arrest, and macrocytic anemia. The iron requirement for erythropoiesis is from dietary absorption of the nutrient, even though significant amounts of iron are available from the reticuloendothelial recirculation by macrophages of degraded erythrocytes principally in the spleen and, to some extent, in the liver. This iron source

Table 1 Disorders associated with heme biosynthetic pathway

Diseases	*Gene mutation*	*Features/symptoms*
Sideroblastic anemias		
X-linked sideroblastic anemia (XLSA)	ALAS-2	Ringed sideroblasts and mitochondria iron accumulation, microcytic anemia
X-linked sideroblastic anemia with ataxia (XLSA/A)	ABCG7	Spinal ataxia and cerebrum hypoplasia, mild microcytic anemia
Glutaredoxin 5 (GLRX5)-related sideroblastic anemia	Glutaredoxin	Hypochromic, microcytic anemia, and iron overload
Erythropoietic porphyrias		
Congenital erythropoietic porphyria (CEP)	UROS	Photosensitivity, hemolytic anemia
Erythropoietic protoporphyria (EPP)	FECH	Photosensitivity, microcytic anemia, and liver malfunction
Hepatic porphyrias		
ALA dehydratase deficiency porphyria (ALAP)	ALAD	Acute neurological disorder
Acute intermittent porphyria (AIP)	HMBS	Acute neurological disorder
Hereditary coproporphyria (HCP)	CPOX	Photosensitivity, acute neurological disorder, abdominal pain
Variegate porphyria (VP)	PPOX	Photosensitivity, neurological disorder, abdominal pain
Porphyria cutanea tarda (PCT)	UROD	Photosensitivity, skin lesions, and liver malfunction

contributes significantly to the maintenance of plasma iron homeostasis and is regulated by hepcidin, the liver-expressed peptide hormone that controls iron efflux functionality of ferroportin. Hepcidin binds ferroportin to cause internalization, ubiquitination, and degradation of the protein to inhibit iron efflux from macrophages, enterocytes, and hepatocytes. In the event of stress enhanced erythropoiesis, however, erythroferrone represses hepcidin expression to promote enhanced iron absorption and release from stores by ferroportin activity. Iron deficiency due to poor diets, dysfunctional absorption machinery, or sequestration in tissues could inhibit heme biosynthesis and result in anemia. Iron deficiency anemia is a public health disorder affecting vulnerable population groups globally. It is often associated with poor dietary iron and low bioavailability of iron from foods. Anemias are characterized by increased gastrointestinal iron absorption and enhanced iron release into the circulation from macrophages and hepatocytes due to low levels of hepcidin expression. Other forms of anemia include hemolytic (increased RBC destruction), pernicious (vitamin B12 deficiency), and aplastic (bone marrow stem cell malfunction). Sickle cell anemia, congenital dyserythropoietic anemia, polycythemia vera, and thalassemias (α and β) are examples of anemia and blood disorders arising from specific gene defects.

Heme Degradation

The RBC reaches senescence after a 120 day life span to become engulfed at extravascular sites of the reticuloendothelial system particularly in the spleen. Hb within the RBC is consequently metabolized to globin and the four heme groups incorporated into 2α and 2β globin chains. Heme is catabolized into one molecule of iron, bilirubin IXα, and CO by sequential actions of a NADPH-cytochrome P450 reductase (CR), heme oxygenase (HO), and biliverdin reductase (BR). The initial reaction is an electrophilic attack on the ferrous ion by CR to form a ferric–heme complex in the presence oxygen and NADPH. Next, HO catalyzes the specific cleavage of the α-methene bridge of the porphyrin ring to yield iron, biliverdin IXα, and CO. Three isozymes of HO, namely, HO-1, HO-2, and HO-3 are known, of which the inducible HO-1 plays the major function of heme degradation. HO-1 is inducible by heme, heavy metals, hypoxia, ischemia perfusion, and oxidative stress factors among other influences. Tissue-specific regulation of HO-1 and its general regulation have wider implications in various metabolic disorders. Consequently, a new paradigm has emerged to describe the induction of HO-1 in response to oxidative and inflammatory stimulus as being protective against tissue damage. These stimuli modulate HO-1 gene expression through transcription factors such as AP1, Bach1, and Nrf2. Biliverdin IXα is reduced to the major bile pigment, bilirubin IXα, by BR and, once released into the circulation, binds to serum albumin and is cleared by the liver. Bilirubin, before it enters the biliary circulation, is rendered water-soluble by conjugation with glucuronic acid in a reaction catalyzed by the bilirubin UDP-glucuronyl transferase. First, heme degradation by HO-1 therefore permits the reuse of iron from heme, as this porphyrin molecule is not recyclable due to its potential toxicity in the circulation. Second, degradation eliminates equally toxic porphyrin compounds, and third, CO produced in the degradation of heme has been shown to be a second messenger neuromodulator, akin to NO in the nervous system. CO induces vasodilation and a number of anti-inflammatory reactions. In addition, CO regulates p38 mitogen-activating protein kinase signaling pathway. Lastly, biliverdin, bilirubin, and their glucuronides are potent antioxidants, which confer protection against oxidative tissue damage. HO-1 deficiency in humans is characterized by the condition asplenia characterized by arteriogenesis, intravascular hemolysis, inflammation, and heme-induced endothelial dysfunction. Asplenia culminates, ultimately, in intracranial hemorrhage and fatality. Remarkably, however, hemin by its propensity to induce HO-1 has been shown to protect cells from drug-induced cytotoxicity, oxidative stress, apoptosis, and tissue injury. Other defects in heme degradation are manifest in forms of hyperbilirubinemia arising from bilirubin accumulation in the skin and resulting in jaundice. Neonatal jaundice is caused by low amounts of bilirubin UDP-glucuronyl transferase in the first few days of life post parturition. Hyperbilirubinemia is also caused by disorders that are associated with increased hemolysis such as sickle cell anemia or hereditary spherocytosis. Other forms of hyperbilirubinemia are the Dubin–Johnson, Rotor, Gilbert, and Crigler–Najjar syndromes, which are caused by the partial or complete loss of UDP-glucuronosyltransferase activity, which contributes to inhibition of bilirubin degradation. Consequently, bilirubin levels are high in the blood for these syndromes, but differences arise in each type according to the pattern of inheritance, manifestation of either conjugated or unconjugated bilirubinemia, degree of molecular defects, and clinical symptoms.

Intercellular and Intracellular Transport of Heme

Heme is hydrophobic and highly insoluble in water and readily forms aggregates in aqueous solution. Sources of free labile heme include impaired heme coupling to apoproteins, increased heme protein oxidative catabolism, and deregulated HO activity. Free heme attaches to proteins and membranes to induce peroxidation and generate toxic ROS. The lipophilic property of heme favors its intercalation into phospholipid bilayer where it causes oxidation and peroxidation of membranes. Moreover, free heme is a repository of high redox-active iron that can generate toxic hydroxyl radicals in the Fenton reactions. Recent compelling evidence has shown that chemotaxis of heme to the RBC membrane causes hemolysis and membrane rupture resulting in the activation of pro-inflammatory signal transduction. Thus, heme directly induces inflammatory responses, increases cytokine production, and promotes platelet aggregation and endothelial activation, which consequently culminate in vascular and immune dysfunction. Moreover, Hb in RBC in extravascular space could either lyse or oxidize spontaneously or be induced by NO to form methemoglobin (MetHb). Peroxidation of MetHb produces FerrylHb, which could also act directly as an inflammatory agent. FerrylHb is a complex mixture of globin, porphyrin, and heme radicals, which directly stimulates synthesis of adhesion molecules and induces actin polymerization in endothelial cells. The ramifications of the ensuing cascade of signaling events are evident in vascular inflammation in hemolytic and

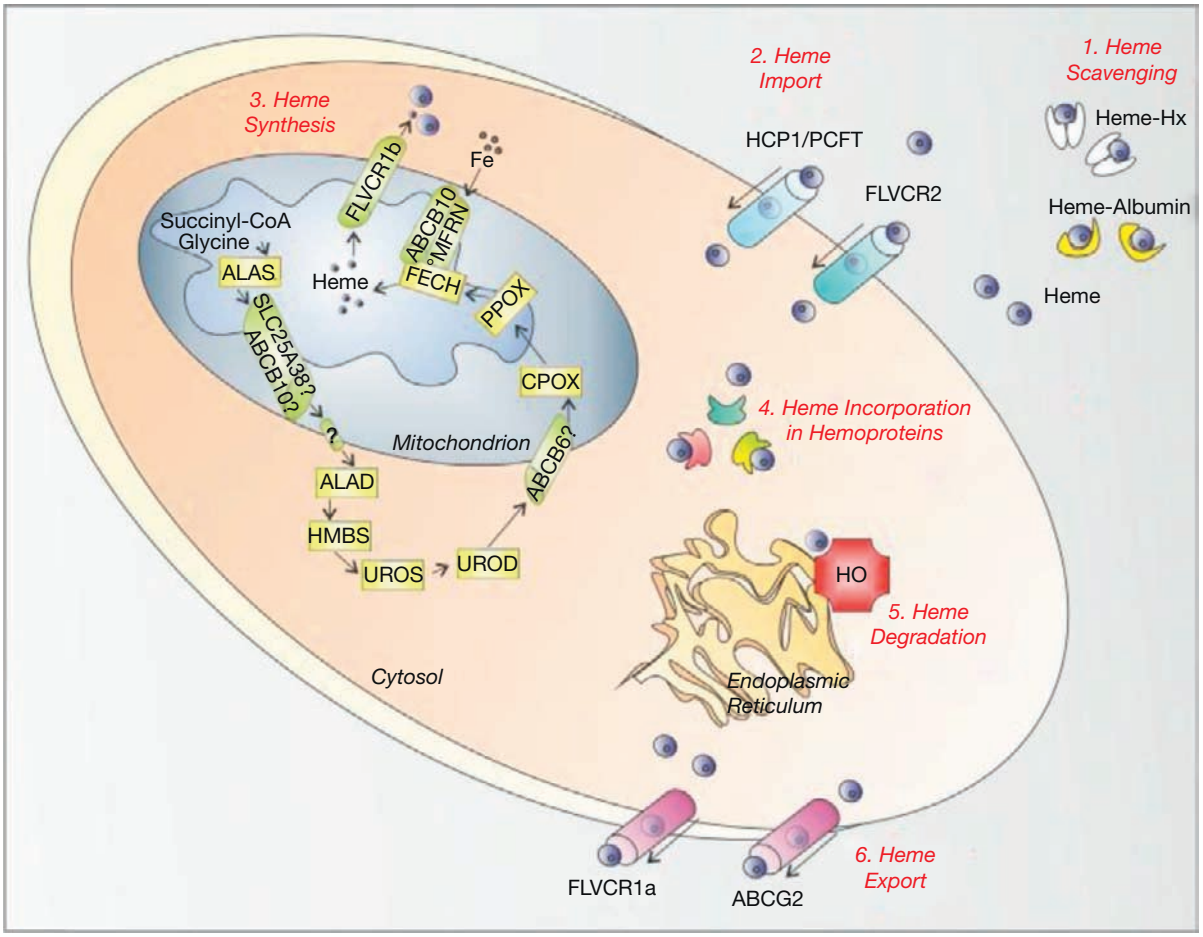

Figure 3 Inter- and intracellular heme metabolism. The main mechanisms involved in the inter- and intracellular control of heme are depicted. (1) Heme scavenging: Circulating free heme toxicity is averted by the action of the scavenging proteins Hx and albumin. (2) Heme import: Heme might be imported into the cell via the putative heme importers HCP1/PCFT and FLVCR2. (3) Heme synthesis: Starts by the formation of ALA from succinyl-CoA and glycine in the mitochondrion, traversing through the cytosol before the final step of Fe incorporation into PPOX to form heme in the mitochondrion. Heme export out of the mitochondrion to the cytosol is by heme exporter FLVCR1b. (4) Heme incorporation in hemeproteins: In the cytosol, heme is inserted in apo-hemeproteins to form functional hemeproteins. (5) Heme degradation: In the endoplasmic reticulum, the heme-degrading enzyme HO catabolizes heme into iron (Fe), carbon monoxide, and biliverdin. (6) Heme export: The heme exporters FLVCR1a and ABCG2 regulate heme export out of the cell across the plasma membrane. Heme in pathophysiology: a matter of scavenging, metabolism and trafficking across cell membranes. *Frontiers in Pharmacology* **5**, 61.

hemorrhagic disorders as sickle cell disease, thalassemia, malaria, and infectious processes. Moreover, these pathological disorders could release significant amounts of free heme into the circulation. Consequently, labile free heme is maintained at very low concentration ($<10^{-9}$ M) in systemic metabolism. Intercellular regulation ensures the availability of sufficient heme for its functions in the mitochondria, nucleus, and cytosol where spatial and temporal dynamics favor coordinated channeling of substrates, reaction intermediates, and products across membranes of these organelles. A number of intercellular heme transport proteins in particular in the mitochondria and lysosomes have been characterized (Figure 3). While the transit of heme by passive diffusion is a possibility, a number of cytosolic heme-binding proteins for targeted transport have also been characterized. These include Z-protein or fatty acid-binding protein, ligandin or glutathione transferases, heme-binding protein 23 (HBP23), HBP22 SOUL, and more recently identified HeBP1 and HeBP2 that are possibly involved in heme detoxification during erythroid differentiation. Homologues of HBP23 (peroxiredoxins) in some species such as yeast and mouse exhibit peroxidase and antioxidant properties rather than heme binding. These buffering proteins bind free heme, thereby neutralizing reactivity and toxicity in cells. Other potent detoxifying mechanisms are heme degradation by HO-1

(described earlier) and the coupling of heme catabolism with ferritin sequestration of the iron released.

There are specific adaptive responses that prevent and avert the pro-oxidant and cytotoxic consequences of intracellular free heme in the circulation. Principal among these are soluble acute-phase proteins, namely, haptoglobin (Hp) and hemopexin (Hx), that scavenge and sequester, respectively, free hemoglobin (Hb) and heme. Both of these acute-phase serum proteins have very high affinities for heme with dissociation constants Kd $\sim 10^{-13}$ and Kd 10^{-8} for heme and Hb, respectively. It is presumed that a transient first-order heme buffering sink is provided by low- and high-density serum lipoproteins (LDL and HDL) before the subsequent transfer to Hp or albumin. Hp–Hb complex is engulfed and binds to receptor CD163 on macrophages of the reticuloendothelial system, while heme–Hpx complex is internalized by LDL receptor-related protein 1 or CD91 on hepatocytes for subsequent catabolism to release inorganic iron. Hemopexin, akin to transferrin, is recycled for reutilization, while haptoglobin is degraded in the lysosome. Consequently, these acute-phase buffers, namely, haptoglobin, hemopexin, and serum albumin (Kd $\sim 10^{-8}$), ensure reutilization of Hb- and heme-bound iron and protect cells from potent free heme- and Hb-induced oxidative and from free radical damage. Moreover, hemopexin is an exogenous antioxidant that is capable of binding heme extracellularly to inhibit influx of free heme into cells and consequently confers cytoprotection against intracellular toxicity and tissue damage. It is significant to note, however, that both innate and adaptive infectious responses could induce Hb lysis and degradation in tissues and organs. Resultant heme produced from Hb could lead, via the c-Jun N-terminal kinase signaling transduction pathway, to program cell death and tissue damage. Moreover, during chronic intravascular hemolysis, megalin and cubilin complexes in the kidney endocytose reabsorb free Hb. Megalin and cubilin possess broad substrate specificities and capacity for reabsorption and intracellular trafficking of free Hb during chronic hemolysis and are involved in the transport of other nutrients and metabolites as well.

Extracellular transmembrane heme transport also encompasses apical intestinal heme absorption and putative basolateral heme efflux. While the absorption of inorganic iron is obligatory, that of heme is dispensable to virtually all organisms because of the inherent capacity for *de novo* synthesis. Paradoxically, however, heme iron sources are quantitatively more highly bioavailable than nonheme iron. The unique porphyrin structure of heme also confers a nutritional advantage to the mode and mechanism of its absorption and transport in the gastrointestinal tract (GIT). Consequently, dietary heme is of significant importance in iron nutrition. However, the molecular mechanisms of the vectorial apical transit of heme in the gastrointestinal tract still remain enigmatic and unresolved. Heme carrier protein 1 (HCP1), a putative heme transporter, has also been shown to be a higher-affinity proton-coupled folate transporter (PCFT). Nevertheless, heme, as an intact metalloporphyrin, protected from luminal dietary inhibitors (except calcium), is highly absorbed in the proximal section of the GIT. Internalized heme is possibly trafficked from the cytoplasm into lysosome vesicles by intracellular heme-responsive gene 1 (HRG1) protein where it is catabolized by an inducible heme oxygenase (HO-1) to yield ferrous iron, CO, and biliverdin that is reduced to bilirubin (as described earlier). HGR1 has also been implicated in phagolysosomal heme recycling. Fe that is liberated enters the inorganic iron pool of the enterocytes and is effluxed by ferroportin. Although ^{59}Fe nonheme was found at the basolateral side of the duodenum after absorption of ^{59}Fe heme, studies carried out in guinea pigs provided evidence that some heme effluxed from the enterocytes into the circulation occurred as an intact metalloporphyrin. FLVCR1 and ABCG2 could be putative basolateral heme efflux proteins pumping intact heme into the circulation. ABCG2 furthermore averts protoporphyrin accumulation in the GIT. These areas of heme research remain subjects of intensive investigations. Another facet of heme iron nutrition is the positive correlation between high meat consumption and the incidence of metabolic disorders. A large body of data from epidemiological studies has demonstrated an association of high heme intake, particularly from red or processed meat, with increased risk in humans of various cancers and metabolic diseases. The GIT modulates iron absorption according to physiological requirements. However, dysregulation may arise from mutations in the genes involved in the iron transport machinery and in the components of the systemic signal transduction regulatory pathway for iron. There are different types of hereditary hemochromatosis (HH), and those with other iron overload disorders are caused by mutations in iron metabolism and in genes regulating hepcidin expression. Consequently, enhanced iron absorption and that of the highly bioavailable heme leads to tissue iron overload in HH, β-thalassemia, and the other forms of iron loading conditions. Heme that is released from hemeproteins contributes significantly to toxic free iron pool and generates ROS, which damages DNA and proteins and causes peroxidation of lipids. Moreover, nitrites and nitrosamine in processed meats have been shown to be cytotoxic and damaging to specific cells of the colon, pancreatic, and liver hepatocytes. The resultant effects have implications in the etiology of diverse cancers and metabolic diseases such as type 2 diabetes, obesity, coronary heart disease, alcoholic steatohepatitis, and some neurodegenerative diseases.

Heme Homeostasis

Heme metabolism in mammals is composed of biosynthesis of heme for varied vital hemeproteins and for erythrocytes in a circuit that recirculates iron from heme catabolism. In essence, biosynthesis and biodegradation (erythrophagocytosis) of heme must be balanced and regulated to maintain homeostasis. Three essential substrates, iron, porphyrin, and heme, are potentially toxic if permitted to accumulate. Iron, heme, and photosensitized porphyrin are pro-oxidants, which can cause damage to DNA, proteins, and cell membrane systems. The exogenous supply of iron, a limiting nutrient, and the *de novo* synthesis of heme and porphyrin are therefore strictly coordinated and channeled to avert the accumulation of excess toxic metabolites. Consequently, inter- and intracellular transport of heme requires specific membrane proteins that are possibly responsive and adaptive to demands in the respective habitat, niche, or site locale of and within the organism. Advances in

Table 2 Some heme transport genes in mammals

Genes	*Functions*	*Features/symptoms*
HCP1/PCFT	High-affinity folate transport, low-affinity heme transporter	Hereditary folate malabsorption syndrome (HFM), macrocytic normochromic anemia
ABCG2	Porphyrin efflux in erythroblast, intestine	Photosensitization, PPIX accumulation
FLVCR1a	Heme efflux in erythroblast, red cell aplasia, erythrophagocytosis	Embryonic lethality; impaired erythropoiesis
FLVCR1b	Heme efflux from mitochondria into cytosol	Hepatic heme and iron loading; reduced heme synthesis and cytochrome P450 expression/activity in hepatocytes
FLVCR2	Extracellular endocytosis of heme	Decreased Zn mesoporphyrin import
ABCB10	ALA efflux from mitochondria into cytosol	Increased oxidative stress, erythrocyte apoptosis and embryonic fatality
ABCB6	Coproporphyrinogen III transport from cytosol into mitochondria	Abnormal erythropoiesis, abnormal mitochondrial physiology, decreased physiological sensitivity to xenobiotic
ABCB7	Fe–S cluster transport from Mitochondria into cytosol	Refractory anemia with ring sideroblasts, mitochondrial ferritin accumulation
Mitoferrin1 (MFRN1) and mitoferrin2 (MFRN2)	Iron import from cytosol into mitochondria	Embryonic lethality. Severe anemia, protoporphyria, cholestasis
HRG-1	Heme transport from cytosol into endosomes/lysosomes	Erythropoietic defects and accumulation of heme analogs

heme metabolism research particularly with the use of mouse knockout models have revealed a number of heme transport proteins in organelles and in inter- and intracellular membranes of tissues and organs. Table 2 shows some heme transport genes and their functions.

Heme (iron protoporphyrin IX) is an essential molecule for diverse biological processes. Heme is found as a prosthetic group in numerous hemeproteins such as respiratory cytochromes, cytochrome P450, catalases, peroxidases, NO synthases, and guanyl cyclases, among others. Heme is therefore involved in the transport, sensing and storage of oxygen, electron transfer reactions, xenobiotics detoxification, signal transduction, and transcriptional, translational, and microRNA gene regulation. Heme biosynthesis comprises eight enzymatic reactions, the initial reaction of which commences in the mitochondria and proceeds in the cytosol and the last three steps conclude in the mitochondria. Consequently, metabolites of the biosynthetic pathway and heme product must be shuttled in and out of the mitochondria by specific transporters. Porphyrias are manifestations of loss of function mutations of the genes coding for the heme biosynthetic enzymes of which phenotypes could be either the cutaneous damage or the exhibition of neurological symptoms. ALAS2 gene mutation, however, leads to a gain of function X chromosome-linked sideroblastic anemia. Heme catabolism by HO-1 recycles iron and produces CO and bilirubin. Excess heme is potent and toxic and has the propensity to activate oxidative stress and inflammatory processes. Maintenance of heme at levels for optimal beneficial functions that avert toxicity is ensured by a number of mechanisms. These include the regulation of anabolism, storage, catabolism, and inter- and transcellular transit of heme across membranes and into the blood circulation. Disequilibrium of heme homeostasis occurs under disorders and diseases such as hemolysis, hemorrhage, and ischemia reperfusion. Consequently, cytosolic heme-binding proteins operate as buffers, while acute-phase proteins, haptoglobin and hemopexin, respectively, scavenge extracellular Hb and heme. HO-1 and ferritin also acute-phase partners are rapidly induced to degrade heme and mop up the resultant toxic free iron. In essence, the biogenesis, biodegradation, and inter- and intracellular trafficking of heme are regulated and coordinated to maintain optimal heme levels for metabolic processes in the whole organism.

Iron: Physiology of Iron

J Coad, R Stewart, and K Pedley, Massey University, Palmerston North, New Zealand

Introduction

Paradoxically, although iron is the fourth most common element in the Earth's crust, iron deficiency is one of the most prevalent nutritional deficiencies. Iron is essential for life but can also be toxic; mammals have evolved many mechanisms to keep free iron levels as low as possible. Iron exists in two stable oxidation states, ferrous iron (Fe^{2+}) or ferric iron (Fe^{3+}), which confers the ability to combine with or donate an electron. This means that iron is involved in oxidation/reduction (redox) reactions in the body such as in the mitochondrial respiratory chain, but it can also be a prooxidant and generate hydroxyl radicals via the Haber–Weiss and Fenton reactions.

Intracellular iron catalyzes the formation of hydroxyl radicals ($HO\bullet$), which have unpaired electrons and are highly reactive:

$$Fe^{3+} + O_2^{\bullet -} \rightarrow Fe^{2+} + O_2 \quad (\text{Haber} - \text{Weiss reaction})$$

$$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + HO^- + HO^{\bullet} \quad (\text{Fenton reaction})$$

The combination of these two reactions leads to the formation of highly reactive hydroxyl radicals and can be summarized as

$$O_2^{\bullet -} + H_2O_2 \rightarrow O_2 + HO^- + HO^{\bullet}$$

Hydroxyl radicals can cause damage to membrane lipids, proteins, and DNA and are implicated in a wide range of pathologies and in the aging process itself.

Physiological Roles for Iron

Iron is essential in the body for many processes including the transport of oxygen to tissues, the production of mRNA and proteins from DNA, and the regulation of energy metabolism. All cells require iron but some cells have distinctive roles (see Table 1): enterocytes that are involved in the absorption of dietary iron; the erythroid cells ('erythron') of the bone marrow that produce red blood cells and have the highest iron requirements; hepatocytes that store iron; and macrophages, predominantly in the spleen, that salvage and recycle iron from senescent red blood cells.

Approximately 70% of body iron is located in red blood cells where, as part of the heme cofactor, it is essential for the oxygen-carrying capability of hemoglobin. Heme is also present in myoglobin where it provides a short-term oxygen store in muscle and contains ~10% of body iron. Numerous iron-containing metalloproteins are involved in essential cellular processes including the cytochromes and dehydrogenases of mitochondrial electron transport, which provide the vast majority of energy for all cellular processes in all but a few cell types. Numerous other iron-containing enzymes are essential in many metabolic pathways including the TCA cycle (aconitase), protein and DNA metabolism, liver detoxification (cytochrome p450), neurotransmitter synthesis, myelin formation in oligodendrocytes, and antioxidant protection.

Iron Balance and Sources of Iron

Most of the daily iron requirements are for erythropoiesis in the bone marrow where ~200 billion new red blood cells are produced by the body each day requiring about 20 mg of iron. Most of this iron comes from the recycling of senescent red blood cells; abut 5–10% of daily iron requirement comes from the diet. Essentially, the dietary contribution is to replace obligatory iron losses, which are primarily due to cell loss. Cell loss is associated with the continuous loss of the short-lived enterocytes into the gut lumen, skin desquamation, and blood loss. Blood loss may be physiological such as that lost in menstruation (approximates to an average of 1 mg day^{-1}) or associated with pregnancy, or it may be pathological due to gut bleeding, excessive menstrual loss (menorrhagia), surgery, injury, or loss in the urine (hematuria; usually associated with renal stones or kidney failure). Blood loss is one of the biggest variables in iron balance. Iron balance is controlled by gut absorption and storage; there is no regulated route of iron excretion and no mechanisms to up- or downregulate iron loss.

Dietary Iron Absorption

About 1–2 mg of iron is absorbed per day corresponding to about 10% of dietary iron from a typical intake of about 12–30 mg in food. Women absorb more iron, to replenish their losses that exceed those of men during their reproductive life. The proportion of dietary iron absorbed depends on physiological state and the quality of a person's diet. The presence of dietary inhibitors and enhancers of iron absorption affects the bioavailability of iron. Dietary iron is in excess so that most of it either is not absorbed or remains in enterocytes and is shed into gut as cells are lost.

Dietary iron is predominantly in the form of heme or nonheme iron, and absorption occurs within the duodenum. A small amount of nonheme iron may also be absorbed within the large intestine. The mechanisms of brush border iron transport are different for heme iron and nonheme iron. All of these mechanisms require iron to be in a soluble form and to be accessible to the brush border membrane. Once absorbed, both heme iron and nonheme iron join a common iron pool. Iron is stored within the enterocyte and/or exported across the basolateral membrane for distribution to extra-intestinal tissues. All processes of iron transport across cell membranes, storage, and distribution are tightly regulated.

In acidic conditions such as the stomach, dietary nonheme iron is reduced from the relatively insoluble ferric (Fe^{3+}) form to the soluble ferrous (Fe^{2+}) form. As the acidic chyme moves

Table 1 Characteristics of key cells involved in iron metabolism

Cell	*Enterocytes*	*Erythroid cells*	*Hepatocytes*	*Macrophages*
Primary location	Duodenum and small intestine	Bone marrow	Liver	Spleen
Main role in iron metabolism	Dietary iron absorption	Synthesis of red blood cells	Iron storage	Recycling/phagocytosis of red blood cells (erythrophagocytosis) Maintain plasma iron
Predominant source of iron	Fe^{2+} via DMT1 Heme Dietary ferritin	$(Fe^{3+})_2$-Tf (holotransferrin)	Holotransferrin plus NTBI	Heme from degraded red blood cells
Iron stores	Ferritin	Ferritin	Ferritin	Ferritin
Iron export	Via ferroportin (in cooperation with hephaestin)	Probably no export mechanism (all iron is used by erythron and incorporated into hemoglobin)	Via ferroportin (in cooperation with ceruloplasmin)	Via ferroportin or sequestered
Notes	Iron may be sequestered and lost when enterocytes are sloughed off from tip of villus	These cells have the highest iron requirements	Hepatic iron storage is higher in males and increases in women postmenopause	Retention of iron in macrophages is an important mechanism to restrict iron available to pathogens

Fe^{2+}, ferrous iron (divalent); DMT1, divalent metal transporter 1; $(Fe^{3+})_2$-Tf, diferric transferrin; NTBI, nontransferrin-bound iron.

from the stomach to the duodenum, pancreatic bicarbonate oxidizes Fe^{2+} back to Fe^{3+}, the majority of which aggregates into long insoluble polymers, which cannot access the brush border membrane and so cannot be absorbed. Iron solubility within the small intestine can be significantly altered by the presence of specific dietary components. Phytates and tannins have a high affinity for Fe^{2+} and chelate nonheme iron within the stomach. However, like nonheme iron, phytates and tannins are also insoluble under oxidizing conditions and further promote the precipitation of iron into insoluble polymers within the small intestine. Conversely, vitamin C and components within meat, fish, pork, chicken, and shellfish have a high affinity for Fe^{2+} and so maintain the solubility and, therefore, the bioavailability of nonheme iron within the small intestine.

Heme Iron Absorption

Heme iron accounts for over half of the iron absorbed from Western diets in which red meat is consumed but contributes much less in other diets with low red meat intake. Unlike nonheme iron, heme iron is soluble under oxidizing conditions. This is because the porphyrin ring prevents heme iron from forming insoluble polymers in the oxidizing environment of the small intestine. Additionally, heme iron transport across the brush border membrane is not inhibited by the presence of divalent cations.

Heme iron is cleaved from globin in the intestine by mechanisms that are not well characterized. Heme iron can be transported across the brush border membrane by two independent mechanisms:

1. Facilitated transport through the folate transporter PCFT/HCP1 where heme iron enters the cytosol
2. Receptor-mediated endocytosis where heme iron enters the enterocyte bound within an endosome

Once within the enterocyte, iron is released from the porphyrin ring by the enzyme heme oxygenase. The activity of heme oxygenase is different depending on the route of heme iron entry and appears to be the rate-limiting step for heme iron absorption. Once released from the porphyrin ring via degradation of the heme molecule, iron is either stored in ferritin or transported across the basolateral membrane as ferrous iron via ferroportin (FPN). This ferrous iron is oxidized by the multicopper oxidase, hephaestin, so that exported Fe^{2+} is oxidized to Fe^{3+}, which can be bound by transferrin (Tf) and transported in plasma. FPN is important in many other cell types such as hepatocytes and macrophages. In these cells, an alternative multicopper oxidase to hephaestin, ceruloplasmin, oxidizes exported Fe^{2+} to Fe^{3+}, which can be transported via plasma Tf. The porphyrin ring is exported by the transporter feline leukemia virus subgroup C. This process is illustrated in Figure 1.

Nonheme Iron Absorption

Nonheme iron is transported from the intestinal lumen across the enterocyte brush border membrane into the cytosol by the divalent metal transporter 1 (DMT1). The transport of iron by DMT1 is actively driven by the concurrent flow of hydrogen ions traveling into the cytosol down their own concentration gradient. This hydrogen ion gradient is maintained by a sodium/hydrogen exchanger also present within the brush border membrane (Figure 2).

DMT1 transports Fe^{2+}, but not Fe^{3+}. For this reason, any soluble Fe^{3+} must be reduced to Fe^{2+} prior to transport. Fe^{3+} is reduced to Fe^{2+} by duodenal cytochrome B (DcytB), a brush border membrane protein in close vicinity to DMT1. DcytB utilizes the cofactor ascorbic acid to provide the electrons for this reduction of ferric to ferrous iron. Once iron has been transported across the brush border membrane into the

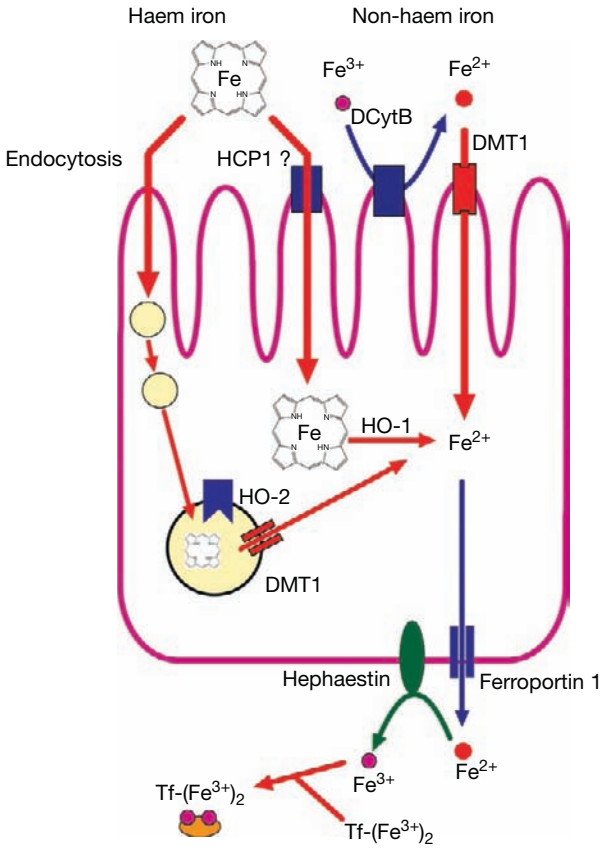

Figure 1 Nonheme iron uptake and the proposed pathway for heme iron absorption. Dietary iron is absorbed across the gut wall as heme iron (from animal food sources) and nonheme iron (from animal and plant food sources). Heme iron is absorbed directly and this has been suggested to be via heme carrier protein 1 (HCP1) though this protein has been recently shown to be a proton-coupled folate transporter. Once transported across the apical membrane, cytosolic heme is catabolized by HO-1 and released into the labile iron pool. Heme iron may also be absorbed by receptor-mediated endocytosis and processed in endosomes to release Fe^{2+}, which is transported to the cytosol via DMT1. Fe^{2+} derived from both sources is released across the basolateral membrane via ferroportin1 and oxidized by hephaestin to Fe^{3+} so that it can be transported in plasma by transferrin. The mechanism of heme iron efflux from the absorptive enterocyte is unknown but may include the transporter FLVCR.

enterocyte cytosol, it joins the cytosolic labile iron pool. Fe^{3+} reduction and DMT1 transport are illustrated in Figure 1.

DMT1 is not specific for nonheme iron and can transport other divalent cations including copper, manganese, cobalt, cadmium, zinc, nickel, and lead. When present together within the intestinal lumen, these cations directly compete for transport by DMT1. Indirect competitive inhibition can also occur in the presence of calcium. Calcium inhibits the flow of hydrogen ions through DMT1 (which are required to drive divalent cation transport) and stimulates the removal of DMT1 from the brush border membrane. The presence of direct and indirect competitors of DMT1 iron transport within the diet will, therefore, reduce the bioavailability of iron from the diet.

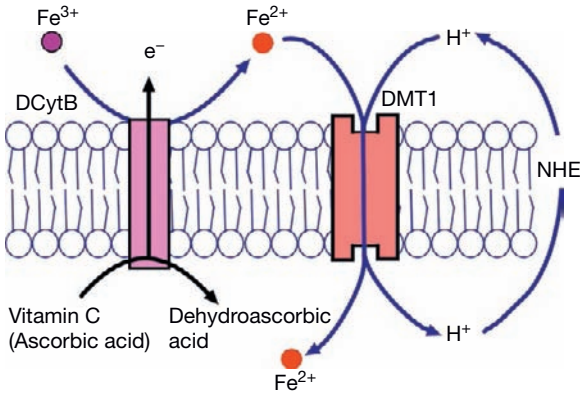

Figure 2 Iron transport across the brush border membrane. Soluble ferric iron is reduced to ferrous iron by DcytB, a process facilitated by the oxidation of cytosolic ascorbic acid to dehydroascorbic acid. Ferrous iron is transported across the brush border membrane by DMT1, a symport transporter driven by the proton gradient, which results from the entry of gastric acid into the duodenum and is maintained by the Na–H exchanger (NHE).

Alternative Mechanisms of Iron Absorption

Other mechanisms of nonheme iron transport across the brush border membrane have been proposed including the integrin/mobilferrin/paraferritin pathway and the Zrt- and Irt-like protein pathway. However, genetic mutation studies suggest that DMT1 is by far the most important brush border nonheme iron transporter and the possible significance of these alternative pathways has not been established.

Destination of Absorbed Iron

There are several possible destinations for iron absorbed in the small intestine:

1. Iron may be directly used by the absorptive enterocyte.
2. All cell types have a requirement for iron for a range of cell functions. Mitochondria have dedicated mitochondrial iron transporters and use iron for the synthesis of iron–sulfur clusters and heme proteins. In addition, iron metalloproteins are crucial in many aspects of intracellular metabolism.
3. Iron may be donated to specific target proteins within the enterocyte.
4. Absorbed iron may be stored within the enterocyte in ferritin and exported from the enterocyte via FPN with subsequent transport in the circulation by Tf.

Ferritin

Ferritin is a self-assembling nanocage that functions as a cell storage protein able to sequester ~2000 iron atoms per ferritin cage under normal conditions. Ferritin prevents free iron concentrations from increasing in the cytosolic and nuclear compartments. The highest intracellular concentrations of ferritin occur in hepatocytes that are involved in iron storage, in the spleen reticuloendothelial macrophages that recycle red blood

cells, and in the bone marrow where most erythropoiesis occurs. During intracellular iron overload, excessive iron deposition in ferritin (>3000 iron atoms/nanocage) can cause ferritin degradation to hemosiderin, which forms iron-rich deposits that cannot be mobilized.

Although most ferritin is intracellular, there is some release of ferritin into the blood. Serum ferritin levels reflect total intracellular iron and hence body stores and iron status. If body iron stores are low, serum ferritin concentration will be low and dietary iron absorption will usually be promoted. Conversely, high iron stores are associated with high serum ferritin concentrations and decreased dietary iron absorption. However, while low serum ferritin levels always indicate low iron status, high levels need to be interpreted carefully. Serum ferritin increases with iron overload and is also an acute-phase reactant, which increases in chronic inflammatory conditions such as obesity and high alcohol consumption and in the presence of infections, tumors, and renal disease. This is a protective mechanism; mammals have evolved mechanisms to sequester iron within cells to limit its availability for pathogenic microorganisms. This is effective for acute challenges such as infections, but modern conditions associated with inflammation can be chronic and lead to anemia of chronic disease, which is refractory to oral iron therapy. Thus, serum ferritin is a useful indicator of iron status and more sensitive than the measurement of hemoglobin concentration in populations unlikely to be affected by infections, but markers of infection and inflammation such as C-reactive peptide need to be measured concurrently to exclude coexisting infection.

Ferroportin

The only known transporter of Fe^{2+} from the cell is FPN. All cell types express FPN, but it has been characterized in macrophages and on the basolateral membrane of duodenal enterocytes. Export of iron from cells is controlled by hepcidin and FPN is the hepcidin receptor. When FPN transports Fe^{2+} out of the cell, it is immediately oxidized to Fe^{3+} by multicopper oxidases such as hephaestin and ceruloplasmin. This is the reason why copper deficiency impairs iron export and results in iron deficiency anemia.

The magnitude of iron release from enterocytes, hepatocytes, and macrophages is regulated by the hepatic bactericidal protein hepcidin (see Figure 3). Hepcidin is a small, highly conserved peptide hormone (a defensin) with antimicrobial activity, which is expressed in the liver in order to regulate the concentration of utilizable iron within the circulatory system. Hepcidin is expressed in response to systemic iron loading and in response to infection and inflammation. Hepcidin expression is reduced by the hormone erythropoietin in response to erythropoiesis (during training, acclimatization to altitude, pregnancy, growth, or blood loss) and by the expression of hypoxia-inducible factor (HIF) proteins during hypoxia. Increased hepcidin levels are associated with a decreased release of iron from enterocytes, hepatocytes, and macrophages, whereas low levels of hepcidin have the opposite effect.

Hepcidin expression can be stimulated by bone morphogenetic proteins in response to intestinal and hepatic iron loading or by holo-Tf (iron-saturated Tf) in response to high concentrations of utilizable iron within the circulatory system. Hepcidin expression can also be stimulated by proinflammatory cytokines released during infection or inflammation, in order to restrict the amount of iron available for utilization by pathogens as part of the innate immune response.

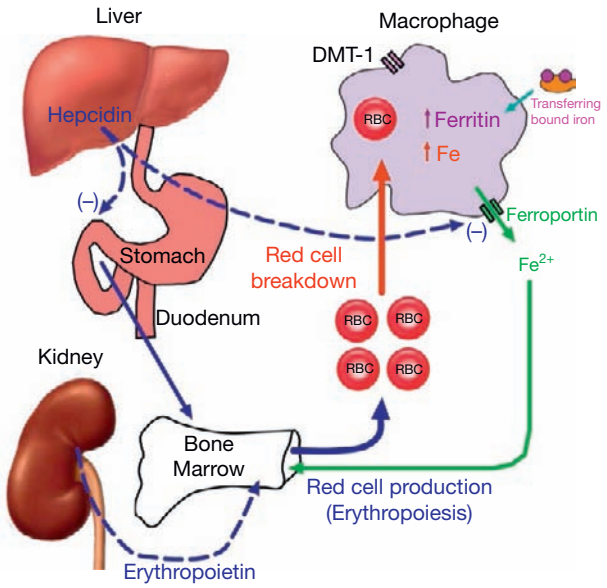

Figure 3 Control of iron export by hepcidin. Iron is absorbed predominantly in the proximal small intestine (duodenum) and its major requirement is for red cell production (erythropoiesis) in the bone marrow, a process that is regulated by erythropoietin secreted by the kidney. The main regulator of iron status is hepcidin, which is produced by the liver and inhibits the release of iron into the circulation from absorptive enterocytes and from heme breakdown from red cells scavenged by macrophages. Infection and inflammatory conditions increase hepatic hepcidin production via proinflammatory cytokines. Hepcidin binding causes endocytosis of ferroportin in enterocytes, macrophages, and hepatocytes, resulting in sequestration of iron in intracellular stores. This not only decreases iron availability for pathogens but also compromises iron availability for erythropoiesis that can cause functional anemia, which is refractory to oral iron therapy.

Once released into the circulatory system, hepcidin binds to receptors present on the plasma membrane of intestinal enterocytes, hepatocytes, and macrophages. Binding of hepcidin to its receptor stimulates the endocytosis and lysosomal degradation of FPN, and, because FPN is the only iron-efflux transporter, its removal inhibits iron export from these cells. Any dietary iron stored within intestinal enterocytes is lost in feces when the cells are shed from the tip of the villus. Any iron stored within hepatocytes or macrophages must be retained until required by the body for assimilation into body tissues.

Control of Iron

There is very little free iron in the body; most iron is tightly bound to proteins. This limits iron availability for pathogens and nontransferrin-bound (free) iron (NTBI), which could be involved in the production of damaging free radicals.

Iron Transport

Iron is transported in the circulation in red blood cells and bound to Tf. The iron component of hemoglobin cannot be exchanged or released from circulating red blood cells.

In the plasma, 95% of the iron is in the form of Fe^{3+} bound to Tf. Absorbed iron is loaded onto apotransferrin (apo-Tf) to give Tf-$(Fe^{3+})_2$, which is referred to as holotransferrin (holo-Tf). Transferrin is an iron-binding glycoprotein with high affinity for iron, which is mostly produced by the liver although other tissues such as the brain also contribute. It transports Fe^{3+}, mostly from macrophages, enterocytes, and hepatocytes, around the body and delivers it to cells requiring iron, the major target being the erythroid cells of the bone marrow. Transferrin has two lobes each with a single Fe^{3+}-binding site; binding requires the presence of an anion (HCO_3^-). Iron is released from transferrin if the pH falls below 5.5.

Transferrin can be used as a marker of iron status; Tf production increases if the body is iron-depleted, whereas iron repletion and overload result in decreased Tf production, but serum transferrin also decreases in acute reactions. Transferrin is usually about 30% (range is 25–50%) saturated with iron but, in deficiency states, it can be <5% saturated, which means there will be insufficient iron delivery for erythropoiesis. If transferrin saturation exceeds 60%, there starts to be measurable amounts of NTBI.

Uptake of iron from transferrin is determined by the number of specific Tf receptors (TfR) for the diferric-transferrin complex. There are two types of Tf receptors expressed on cell membranes; TfR1 is expressed by all dividing cells (such as the erythron) and TfR2 is expressed primarily by hepatocytes, which are involved in iron storage. TfR expression on cells increases with increased iron demand so that iron stores are diminished.

When the diferric transferrin binds to the transferrin receptor, the iron–transferrin receptor complex is internalized by receptor-mediated endocytosis via the formation of clathrin-coated pits, which form endosomes (Figure 4). The ATP-dependent proton pump inserted in the endosome membrane reduces the pH to below pH 5.5, which means the Fe^{3+} is released from holo-Tf. A ferrireductase (STEAP3) in the endosomal membrane reduces Fe^{3+} to Fe^{2+}, which is then released into the cell cytosol by cotransport with hydrogen ions via DMT1. The transferrin receptor bound to apo-Tf is returned to the cell surface, which has a neutral pH so apo-Tf dissociates from TfR. The TfR remains inserted in the cell membrane and apo-Tf reenters the circulation to bind and deliver more exported iron (Figure 4).

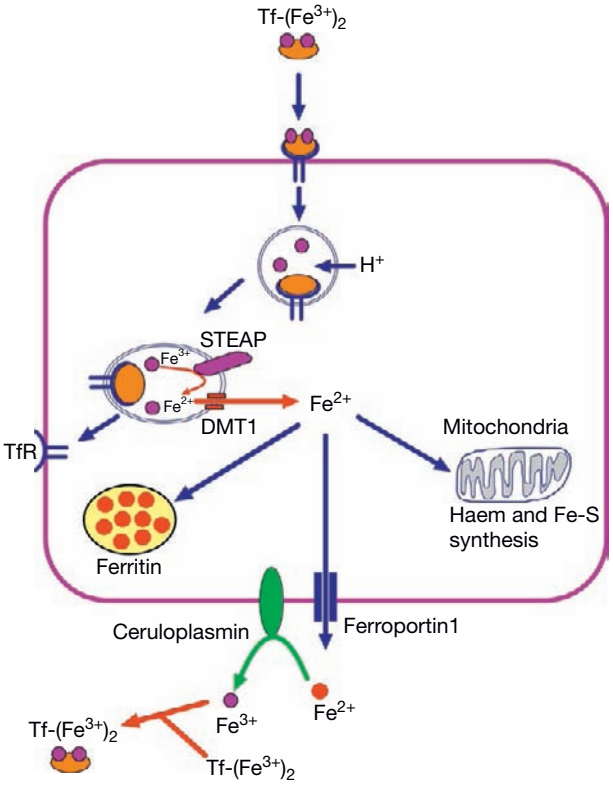

Figure 4 Cellular iron uptake from holotransferrin. Holotransferrin with two ferric atoms binds to the transferrin receptor (TfR) on the cell membrane, and TfR–Fe^{3+} complex is endocytosed via a clathrin-coated pit into the cell. The vesicular membrane proton pump lowers endosomal pH to liberate free ferric iron, which is then reduced to ferrous iron by STEAP. Ferrous iron leaves the endosome to enter the cytosol via DMT1. The apotransferrin receptor complex is recycled to the cell membrane, liberating transferrin at the near neutral pH.

Regulation of Dietary Iron Absorption

The human body has no mechanism to excrete excess iron. For this reason, iron homeostasis must be maintained by regulating the amount of iron that is absorbed from the diet by the absorptive intestinal cells (enterocytes) and the amount of iron that may be utilized or stored by extraintestinal tissues. Iron transport across the enterocyte is regulated by its own iron status, the iron status of the liver, the concentration of utilizable iron within the circulatory system, hypoxia, erythropoiesis, and the presence of inflammatory cytokines.

Iron absorption is increased if dietary iron bioavailability is low, when body iron stores are low, or if there is a drive for increased erythropoiesis, for example, because of altitude, pregnancy, low hemoglobin concentration, or hypoxia. Conversely, absorption of dietary iron is decreased in iron repletion and in the presence of systemic inflammation or infection, which promotes hepcidin production. Low iron status leads to an increased expression of DcytB, DMT1, and FPN, which results in increased iron absorption. Transferrin expression and the expression of its receptor (TfR) on cells can also increase under these conditions. Furthermore, exposure of enterocytes to high concentrations of iron such as dosing regimens used to treat low iron status downregulates DMT1. This has led to studies investigating the efficacy of intermittent iron supplementation.

Iron Regulatory Proteins

The amount of iron that can be transported or stored by the enterocyte is regulated by the concentration of iron and oxygen within the cytosol. If the enterocyte iron concentration is too high, the expression of brush border iron transporters will be reduced and the expression of storage proteins enhanced. If the

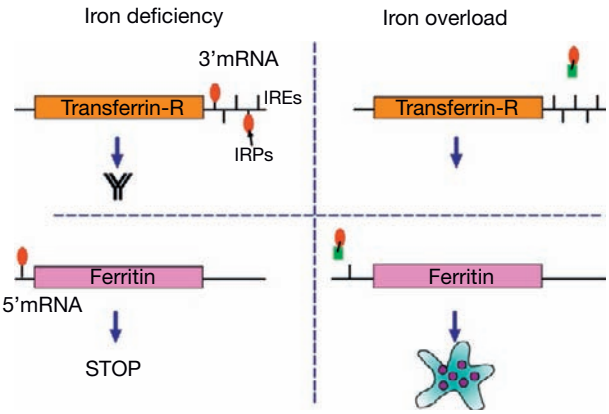

Figure 5 Changes in transferrin receptor and ferritin mRNA under low or high iron concentrations. When cytosolic iron concentrations are low, IRP has a high affinity for IRE and will stabilize 3′ mRNA strands promoting the expression of iron transport proteins (e.g., transferrin receptor) and block 5′ mRNA strands, inhibiting the translation of iron storage proteins (e.g., ferritin). When cytosolic iron concentrations are elevated, IRP will lose its affinity for IRE; therefore, transport protein mRNA translation is reduced and ferritin mRNA translation is increased.

enterocyte iron or oxygen concentration is too low, the expression of iron transporters is enhanced and the expression of storage proteins is reduced by transcriptional and post-transcriptional mechanisms.

The expression of iron transporters in response to cytosolic iron concentrations is regulated by the iron regulatory element/iron regulatory protein (IRE/IRP) system. The iron response element (IRE) is a conserved mRNA sequence on the 5′ end of ferritin mRNA and the 3′ end of DMT1, Dcytb, and TfR mRNA. IRPs are a family of cytosolic iron-binding proteins that bind specifically to IREs. IRPs will only bind to IREs when the cytosolic iron concentration is low. When cytosolic iron concentrations increase, IRPs undergo a conformational change and lose their affinity for IREs (see Figure 5).

Binding of IRPs to IREs can either inhibit or enhance mRNA translation depending on the specific location of the IRE. If the IRP binds to the 5′ IRE, the IRP blocks mRNA from being translated. If the IRP binds to the 3′ IRE, the mRNA is stabilized and the protein is translated. Two examples of this process are illustrated in Figure 5.

In addition to the IRE/IRP system, the HIF system augments the transcription of TfR, FPN, and HO-1 genes within the enterocyte during hypoxia. Low cytosolic oxygen concentrations promote the expression of HIF proteins, a family of gene regulators that collectively promote the transcription of iron transporter genes in order to facilitate systemic iron distribution. When cytosolic oxygen concentrations are normalized, HIF expression is significantly reduced and iron transporter gene transcription is no longer enhanced.

Iron Pathologies

Iron Deficiency Disorders

Iron deficiency can result in anemia and compromised oxygen transport. Anemia can be a result of dietary deficiency but can also be genetic or acquired. Iron deficiency anemia is the most common form, but anemia can be due to either insufficient intake or excessive loss of iron. The ability to upregulate the iron acquisition mechanisms is limited, so excessive blood loss may not be matched by increased absorption of dietary iron. In developing countries, blood loss due to parasitic infection is a significant cause of iron deficiency anemia. In developed countries, causes of excessive blood loss include heavy menstrual loss, frequent blood donation, and gastrointestinal bleeding. Because copper is required for the oxidation of iron exported from the enterocyte, dietary copper deficiency can result in secondary iron deficiency. Genetic anemias are due to mutations of genes for proteins involved in iron acquisition.

Acquired anemias can be a consequence of inflammation or infection or be anemia of chronic disease. Conditions, such as obesity and cancer, which result in raised hepcidin, cause iron retention by enterocytes; this promotes hypoferremia, which deprives potentially pathogenic bacteria of iron. The sequestration of iron in cells makes it unavailable, not only for bacteria but also for the synthesis of hemoglobin by erythroid cells, so if hepcidin is raised for a prolonged period, the consequence will be anemia, which is refractory to oral iron therapy. Hepcidin mRNA transcription is induced by cytokines such as interleukin 6. Some tumors may also produce hepcidin and promote inflammatory responses that promote hepatic production of hepcidin. In older age, cytokine production can be dysregulated resulting in raised hepcidin causing anemia of old age. This may be compounded by age-related compromised gastric acid production, which abrogates the conversion of Fe^{3+} to Fe^{2+} with a negative impact on iron absorption in the duodenum.

There is a hierarchy of iron requirements as iron becomes deficient. Hemoglobin production is protected at the expense of other tissue iron requirements, so iron required for brain use, for example, may be compromised even though hemoglobin concentrations are within the normal range. This state is known as iron deficiency without anemia and is indicated in subjects by normal hemoglobin concentrations but low iron stores (reflected by low serum ferritin concentrations). Iron deficiency without anemia is of concern because it affects cognition and endurance and may have negative consequences for immune function.

Iron Overload Disorders

In iron overload disorders, plasma iron exceeds the binding capacity of transferrin so free iron levels are raised, which can generate dangerous free radicals. This is usually because iron absorption is not controlled. In hereditary hemochromatosis, there is inadequate hepcidin production or mutations in FPN, so iron uptake from the gut is high. The parenchymal tissues such as the liver, heart, pancreas, and skin accumulate the excess iron, which can lead to tissue damage and fibrosis. Hemochromatosis can lead to liver cirrhosis, 'bronze' diabetes, and discoloration of the skin as iron is deposited in the tissues.

Intravascular Hemolysis

Hemolysis (breakdown) of red blood cells in the circulation results in the contents of the cells including iron being released into circulation. This can occur as a consequence of

autoimmune disorders, hemolytic anemias, and viral and bacterial infections and as a side effect of drug use. As with the iron overload disorders, there is a consequent risk of damage due to iron compounds generating hydroxyl radicals in the Fenton reaction. Free hemoglobin from hemolyzed red blood cells binds to haptoglobins, which are taken up and metabolized by the liver. Free heme from the oxidation of the free hemoglobin binds to hemopexin or albumin, which is also taken up by the liver. The liver metabolizes heme into bilirubin, which is excreted via feces and urine. Any heme passing through kidney is resorbed.

Sources of Iron in the Earth

Iron originates in the large stars where it is formed by alpha nucleosynthesis, originating from silicon. During evolution, iron was present as soluble ferrous iron in the oceans, but with the evolution of photosynthetic life and the release of oxygen as a by-product, such ferrous iron was oxidized and became insoluble banded iron formations, magnetite (Fe_3O_4) or hematite (Fe_2O_3), deposited within sedimentary rock during the pre-Cambrian age, between 2400 and 1800 million years ago. Such formations consisted of repeated, thin layers of silver to black iron oxides, alternating with bands of iron-poor shales and cherts, which were often red in color. Today, these rocks are an important commercial source of iron ore, for example, in Western Australia, the Pilbara region, and in Minnesota, the United States, the Animikie Group.

Physical and Chemical Properties

Iron, element 26 in the periodic table, is the second most abundant metal after aluminum and the fourth most abundant element in the Earth's crust. Iron, a transition element, is redox-active, is a good Lewis acid, and is capable of forming bonds with electronegative elements (oxygen, nitrogen, and sulfur). The biological importance of iron resides to a great extent in its capacity to exist in several oxidation states, the principal ones being ferrous (Fe^{2+} or Fe(II)) and ferric (Fe^{3+} or Fe(III)), although higher-valent Fe^{4+} or Fe^{5+} is generated during the catalytic cycle of a number of enzymes such as catalases, peroxidases, and cytochromes P450. However, iron is potentially toxic since it can react with oxygen to generate reactive oxygen species, which may trigger cell damage.

Sources of Iron in Food

Iron is present in food that is derived from both animals and plants and exists in two forms: heme iron and nonheme iron (Figure 1).

Heme Compounds

Heme iron, derived from hemoglobin and myoglobin, is present in meat and fish while seafood and poultry contain both heme and nonheme irons (Table 1). In meat, 30–70% of the total iron content is present as heme iron, of which 15–35% is absorbed. Heme iron is highly bioavailable and absorbed to a much greater extent than nonheme sources, predominantly in the alkaline environment within the lumen of the small intestine, its absorption not being affected by other dietary components. However, cooking will decrease heme iron, the severity of the heme losses being dependent on the cooking method.

Nonheme Iron

Nonheme inorganic iron is the predominant form of iron in dietary components of plant origin and accounts for 80–90% of iron in a standard diet although a very small amount of this iron is absorbed, <10%. The richest sources of nonheme iron are shown in Table 1. The absorption of nonheme iron is influenced by a wide number of constituents within food, which either enhance or decrease iron absorption (Table 2). For example, vitamin C, present in fruits and vegetables, could enhance the potential availability of iron for mucosal uptake. Excessive alcohol consumption may increase iron status in susceptible individuals. This is attributed to increased rates of iron absorption from the intestine, possibly reflecting alcohol-induced downregulation of hepcidin expression in the liver. Other constituents may diminish the absorption of iron (Table 3). Calcium and phytates, present in cereals and vegetables, and phenolic compounds, in tea, coffee, and other beverages, could bind iron and restrict its availability for absorption.

In some developing countries, contamination of iron from mechanical or chemical reactions may occur during food production and preparation and be an important source of iron. In the early studies of the Bantu tribe in South Africa, the high intake of iron in this tribe was caused by the consumption of beer that had been brewed in nongalvanized steel drums. Iron contamination is not considered to be a significant source of iron in the United Kingdom and developed countries since the use of cast-iron cookware is not widespread.

Iron Fortification of Food

Food fortification is an attractive public health strategy and has the advantage of reaching wider at-risk population groups through existing food delivery systems, without requiring major changes in generalized consumption patterns. Various approaches can be utilized, such as mass fortification in foods that are widely consumed and fortification of target foods consumed by specific age groups, for example, infant complementary foods.

In the 1930s, fortification of flour with iron and B complexes was introduced in a number of developed countries and, as can be seen in Table 4, is now widespread in many products. Iron deficiency remains the commonest nutritional deficiency worldwide (affecting approximately 20% of the world's population), which could be effectively ameliorated by promoting nutritious foods and fortifying food with iron.

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00403-7

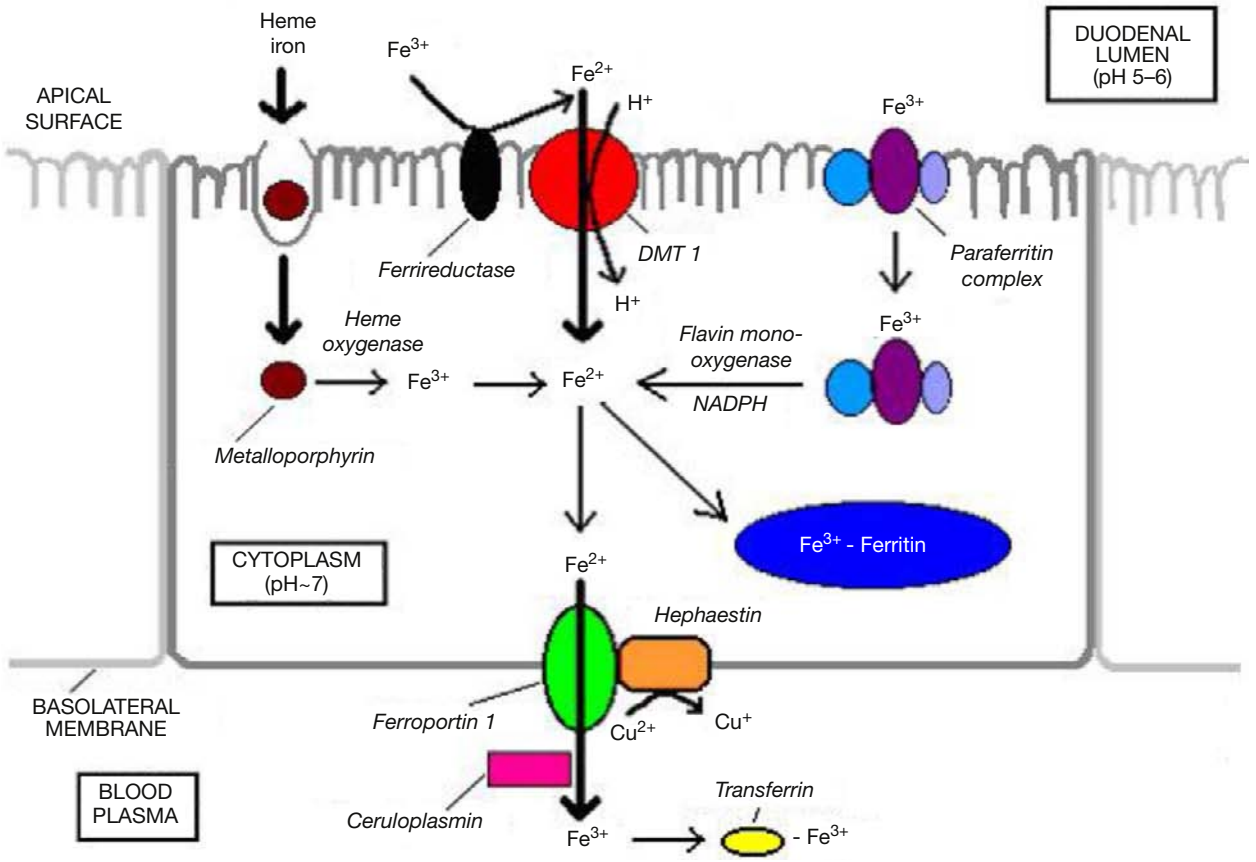

Figure 1 Possible pathways of heme and nonheme iron uptake and transport in enterocytes. From info@medchemtherapeutics.co.uk.

However, these strategies are not easy to implement and practice, especially for poor families with limited financial resources. Vegetarians may be at particular risk from iron deficiency due to the low levels of poorly bioavailable iron in plants. Iron deficiency could be mitigated by increasing the iron content and bioavailability of food grains, such as wheat and rice. Recently, three approaches were combined to increase the iron content of rice seeds: (i) enhancing iron storage in grains *via* the expression of the Fe-storage protein, ferritin; (ii) enhancing Fe translocation from roots to seeds through overproduction of the iron chelator, nicotinamide; and (iii) enhancing Fe flux into the endosperm through overexpression of *OsYSL2*, the gene responsible for long-distance translocation of NA-chelated Fe into sink tissues, including leaves and grains. The iron concentration of polished seeds of field-grown rice increased fourfold in comparison to that of wild-type plants. It is apparent from the figures shown in Table 4 that there are vast differences in the amounts of iron added to the different foods throughout the world and there appears to be no clear consensus as to what a safe amount of iron might be. However, since such iron fortification regimes rely on the fact that iron uptake, storage, and utilization are meticulously coordinated to prevent excessive amounts of iron being absorbed (only 1–2 mg of iron is needed to replace daily losses), it is assumed that excessive amounts of iron will not be absorbed. However, in Northern Europe, hereditary hemochromatosis has a prevalence of 1 in 200 in the population where a gene defect may enhance iron loading. Indeed, in Norway, where there is an even high prevalence of hereditary hemochromatosis, it has been argued successfully that iron supplementation is an unacceptable risk for this population. Excess iron stores may promote cancer and increase the cardiovascular risk. Furthermore, increasing the iron status in the population of developing countries by such fortification may also impose risk, since there could be an increased morbidity, due to pathogenic bacteria competing effectively for iron in the circulation, resulting in an exacerbation of existing infections.

Iron Salts and Complexes Used for Food Fortification

It is necessary to protect the supplemented iron in the food from potential inhibitors of iron absorption. Different forms of iron have been utilized: (a) freely water-soluble (ferrous sulfate, ferrous gluconate, ferrous lactate, and ferric ammonium citrate), (b) poorly water-soluble, but soluble in dilute acids such as gastric juice (ferrous fumarate, ferrous succinate, and ferric saccharate), (c) water-insoluble and poorly soluble in diluted acid (ferric orthophosphate, ferric ammonium orthophosphate, ferric pyrophosphate, and elemental Fe powders), and (d) protected iron compounds (Fe–EDTA and hemoglobin) (Table 4). In addition, new forms of iron administration are under development, for example, ferrous sulfate,

Table 1 Iron content of different foods

	Iron content in 100 mg	*Heme iron in 100 mg*
Heme iron		
Chicken, breast leg, thigh	0.4–0.7	0.12–0.29
Turkey, breast leg, thigh	0.5–1.0	0.14–0.49

stabilized and microencapsulated. Ferrous sulfate is commonly used as an iron supplement (Table 4), while other compounds, such as ferrous lactate, have the advantage of being white and more stable and are unaffected by high humidity. $NaFe^{3+}EDTA$ remains stable during processing and storage and causes fewer organoleptic problems than other water-soluble iron compounds. Hemoglobin is also a form of food although it has low iron content (0.34%) and an intense red-brown color. Lastly, some problems may occur with iron fortification, since various adverse effects with the iron compounds utilized, such as poor solubility, metallic taste, discoloration, stability, speckling development of off-flavors, and fat oxidation, may arise.

Iron Salts and Complexes Used in Medications for Iron Deficiency

Oral Iron Therapy

Table 5 shows the different iron formulations used for (a) oral, (b) intravenous, and (c) intramuscular iron administration.

Table 4 Iron fortification of food stuffs

Product	*Iron form supplement*	*Concentration*
(*A*) *Bakery products and cereal*		
Bread	Ferrous sulfate	10, 20, 30, 40 mg
	Fe–EDTA	Fe per 100 g flour
Wheat bread	Ferrous sulfate heptahydrate	
Cookies	Bovine hemoglobin concentrate	6%
Wheat rolls (100 g flour)	$FeSO_4$, $NaFe^{3+}EDTA$	5 mg per 100 g per day
Whole maize	Ferrous sulfate	
	Ferrous bisglycinate	
	Ferric trisglycinate	
Flour and breakfast cereal	Ferrous iron	1 mg
Stimulated rice	Ferrous sulfate heptahydrate	1:100, 1:200
Weaning cereal	Ferrous sulfate	200–500 mg kg^{-1}
White wheat flour		65 mg kg^{-1}
Milk infant cereal		12 mg l^{-1}
Infant cereal	Ferric pyrophosphate	
	Ferrous fumarate	
Maize	Ferrous sulfate	30 or 60 mg kg^{-1}
	Ferrous bisglycinate	
	Ferric trisglycinate	
	$NaFe^{3+}EDTA$	
(*B*) *Dairy products*		
Infant formula	Ferrous sulfate, microencapsulated[a]	6% Ferrous sulfate + 15% GMS
Milk and dairy products	Ferrous sulfate, microencapsulated[b]	
Cheese	Iron–casein and ferric chloride	
Ras cheese	Iron citrate	40, 80, and 120 mg Fe per kg
	Iron chloride	
	Iron gluconate	
Mozzarella cheese	Casein-chelated iron	25, 50 mg kg^{-1}
	Whey prochelated Fe	
White soft cheese	Electrolytic iron	40, 60, 80 mg Fe per kg
	Ferric chloride	
	Ferrous sulfate	
Havarti-style cheese	Ferrous sulfate	4 mg oz^{-1}
	Ferrous sulfite	
	Ferrous sulfate + ascorbic acid	
Cheddar cheese	Ferric chloride	40 mg kg^{-1}
	Iron–casein	
	Iron–whey protein complexes	
Yogurt	$FeCl_3$	10 mg Fe per 100 ml
	Fe complexed with casein	
	Fe complexed with whey protein	
Flavored yogurt		10, 20, 40 mg kg^{-1} yogurt
Edam cheese	Ferrous chloride, ferrous citrate	150 mg kg^{-1}
	Ferrous gluconate	
Milk	Ferrous sulfate	15 mg l^{-1}
(*a*) *Other products*		
Whole wheat peanuts		16.5%
Cereal products, salt, sugar	$NaFe^{3+}EDTA$	5 g per 100 g
Chocolate drink	Ferrous sulfate	6.3 mg
Turkey meat	Ferrous sulfate	100, 250, 500 mg kg^{-1}
Soy sauce	Sodium feredetate	
	$NaFe^{3+}EDTA$	

[a]Spray-drying using glycerol monostearate as wall material.
[b]Spray-drying using lecithin.

Ferrous forms of iron (sulfate, glutamate, fumarate, and succinate) are frequently administered orally to iron-deficient patients, while ferric compounds (ferric–hydroxide polymaltose complex) and carbonyl iron powder (prepared by chemical decomposition of purified iron pentacarbonyl) are less frequently utilized. Such iron will be absorbed in the duodenum and proximal jejunum although only one-tenth of the dose (100–200 mg per iron per day) is absorbed under normal conditions and, during inflammation, even less. Bioavailability is also reduced when other drugs are coadministered.

Table 5 Oral, intramuscular, and intravenous iron complexes utilized for iron supplementation

(a) *Oral iron medication*			
Iron salt	*Generic name*	*Dosage*	*Elemental iron content*
Ferrous salts	Ferrous sulfate	Tablet 300 mg	60 mg
	Ferrous fumarate	Tablet 300 mg	90 mg
	Ferrous gluconate	Tablet 300 mg	35 mg
	Ferrous succinate	Tablet	92.5 mg
	Ferrous glycine sulfate		
	Ferroglycine sulfate		
Ferric compounds	Nonionic ferric–hydroxide polymaltose complex[a]	Tablet	100 mg
Iron powder	Carbonyl iron	Tablet	50 mg
(b) *Iron formulations for intravenous use*			
Preparation	*Molecular mass* (*kDa*)		*Carbohydrate*
Iron sucrose	43		Sucrose
LMW iron dextran	80–103		Dextran
HMW iron dextran	265		Dextran
Sodium ferric gluconate in sucrose solution	38		Gluconate
Iron carboxymaltose	150		Carboxymaltose
Ferumoxytol	185		Polyglucose sorbitol carboxymethylether
Iron isomaltoside	69		Isomaltoside
(c) *Intramuscular iron preparations*			
Iron sorbitol complex with citric acid			
Iron dextran	100–150		Dextran

[a]Slow-release formulations.

Therefore, administration 1–2 h before meals of any drugs is recommended for such therapy. Care should be taken in that excessive doses of iron are not administered since iron could generate oxidative damage with local and systemic lesions in the digestive tract. Various side effects occur with oral iron supplementation such as nausea, heartburn, epigastric pains, bloating, and constipation or diarrhea. Therefore, slow-release ferrous preparations have been developed to alleviate such symptoms.

Parenteral Iron Therapy

Such iron therapy (intravenously or intramuscularly) is given when (a) oral therapy has failed, (b) oral absorption is seriously compromised, (c) benefit from oral therapy cannot be expected, or (d) fast improvement is required. For intravenous injections, colloidal solutions of spherical or ellipsoidal nanoparticles, composed of an iron core of polynuclear ferric–oxyhydroxide complexes with various carbohydrates, are utilized (Table 5). The carbohydrate capsule stabilizes the gel and retards the liberation of bioactive iron from the core to the plasma and sustains the nanoparticle in colloidal solution. The chemical form and structure of such iron compounds are comparable with those of ferritin, which explains their low toxicity. After parenteral administration, the nanoparticles are phagocytosed, mainly by macrophages of the reticuloendothelial system (Figures 2 and 3).

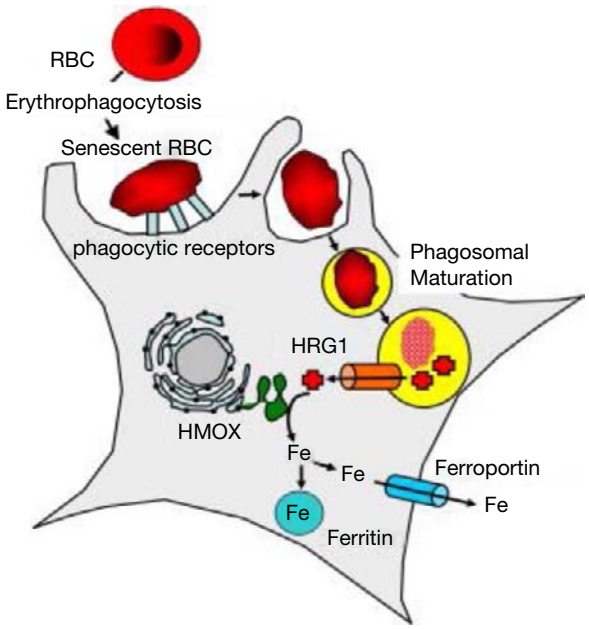

Figure 2 Macrophage heme iron recycling.

Determination of Iron in Food

In order to determine the iron content of food, it is necessary to remove organic matter by ashing techniques to leave only noncombustible ash, which is then analyzed for its elemental composition. Two major techniques are utilized, wet ashing and dry ashing.

Wet Digestion

Samples need to be digested with strong acids, such as nitric, perchloric, or sulfuric acid, in a Kjeldahl flask for many hours.

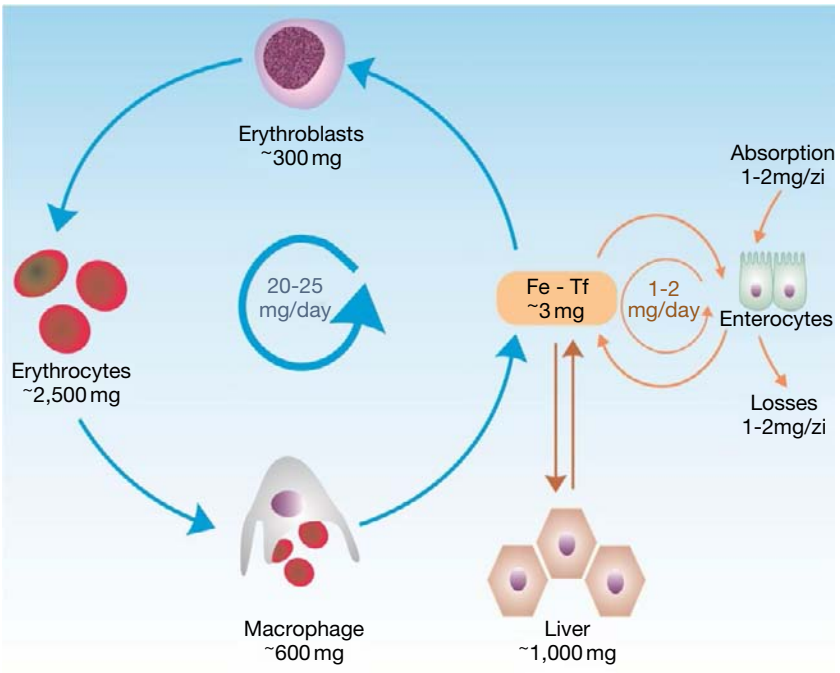

Figure 3 The cycle and distribution of iron in individuals with a balanced iron metabolism. Most of the iron is in the circulating erythrocytes (2150 mg). Daily 20–25 mg iron follows the blue circuit: macrophages, which catabolize heme iron to Fe^{2+}, and erythroblasts, which incorporate iron into newly formed red blood cells. A smaller amount of iron, 1–2 mg per day, follows the orange circuit, losses, and absorption of iron. The balance between the two circuits is maintained by iron stores in the liver, 1000 mg, and in the macrophages, 500 mg, through the small transport pool, 3 mg.

Organic matter will be oxidized to water and carbon dioxide with the iron remaining in an uncomplexed form.

Dry Ashing

Dry ashing is usually performed by placing the sample in an open inert vessel and destroying the combustible (organic) portion of the sample by thermal decomposition using a muffle furnace. Typical ashing temperatures are 450–550 °C. Magnesium nitrate is commonly used as an ashing aid. Charring the sample prior to muffling is preferred, which is accomplished by an open flame.

Analysis: Spectroscopic and Electrochemical Techniques

Spectroscopic Methods

UV/visible absorbance

Both Fe^{2+} and Fe^{3+} form colored complexes. After ashing, the iron will be present as Fe^{3+}. The addition of thiocyanate (SCN^-) will react with Fe^{3+} ions to form a blood red-colored complex

$$Fe^{3+}(aq) + SCN^-(aq) \rightarrow [FeSCN]^{2+}(aq)$$

the intensity of which is measured at 490 nm.

If iron is present as Fe^{3+}, it can be reduced to Fe^{2+} through reaction with hydroxylamine hydrochloride:

$$2Fe^{3+}(aq) + 2NH_2OH(aq) + 2OH^-(aq) = 2Fe^{2+}(aq) + N_2(g) + 4H_2O$$

The presence of Fe^{2+} can be detected in solution after reaction with various compounds such as 1,10-phenanthroline and ferrozine.

Atomic absorption spectroscopy

Both flame atomic absorption spectroscopy (FAAS) and electrothermal atomic absorption spectroscopy (EAAS) can be utilized to analyze iron. For FAAS, the solution containing the iron complexes is introduced into the flame as an aerosol where the atomization occurs. In EAAS, the sample can be placed directly into the small graphite or pyrolytic tube where a sequence of drying, ashing, and atomization is carried out. Free atoms released after the atomization will absorb light at a specific wavelength, which is characteristic of iron.

Inductively coupled plasma atomic absorption spectroscopy solutions containing the solubilized iron complexes are introduced into the plasma as an aerosol and the emissions specific for iron are assayed in a spectrophotometer.

Iron in Biological Systems

There are a considerable number of techniques available for the study of iron in biological systems, some of which are highly specific and others with more general applicability. Such data will give information on the coordination chemistry of the metal ion in relationship to other elements (Table 6).

Table 6 Spectroscopic methods in the study of iron in biological systems

Magnetic susceptibility	*Number of unpaired electrons/ground spin state*
Mössbauer spectroscopy	For Fe57 sites, oxidation and spin state: chemical environment
Electron paramagnetic resonance (EPR)	Usually for odd electron metal sites
Electron-nuclear double resonance	Combines sensitivity of EPR and NMR to probe ligand superhyperfine interaction
Nuclear magnetic resonance (NMR)	For paramagnetic proteins giving structural information
Vibrational spectroscopy (Raman and IR)	Identification of ligands coordinated to a metal center
Electrothermal atomic absorption	Concentration of metal in biological tissue
Electronic absorption spectroscopy (ABS)	Direct probe of ligand field and charge transfer excited states
Magnetic circular dichroism	Greater sensitivity than ABS
Circular dichroism	Allows detection of transitions not readily observable in absorption
Resonance Raman spectroscopy	Study of chromophoric active sites in biological molecule
Extended X-ray absorption fine structure (EXAFS)	Identification of ligand atoms, their distance from metal: number of scattering ligands of a given type
X-ray diffraction	Identification of ligands to metal center more precise that EXAFS

Table 7 Laboratory analysis for the assessment of iron status in a healthy individual

Measurement	*Reference range*
Functional iron	
Hemoglobin	
12–16 g l^{-1} female	
13–18 g l^{-1} male	
Red cell indexes	
MCV	80–94 fl
MCH	27–32 pg
Tissue iron supply	
Serum iron	10–30 μmol l^{-1}
Transferrin saturation	16–60%
Red cell zinc protoporphyrin	<80 μmol mol^{-1} Hb
Red cell ferritin	3–40 ag per cell
Serum transferrin receptor	2.8–8.5 mg l^{-1}
Iron stores	
Tissue biopsy iron	3–33 μmol g^{-1} dry wet
Serum ferritin	15–300 μg l^{-1}
Urine chelatable iron	>2 mg $24\ h^{-1}$
Serum TIBC/transferrin	47–70 μmol l^{-1}

Table 7 shows the various laboratory tests to ascertain iron status in an individual, with respect to functional iron, for example, hemoglobin; tissue iron supply, for example, transferrin saturation; and storage iron, for example, ferritin (Figures 4 and 5).

Irradiation of Foods: Processing Technology and Effects on Nutrients: Effect of Ionizing Radiation on Food Components

Introduction

Irradiation of Food

The world food needs require more advanced processing techniques and storage since there are increasing losses caused by the absence of appropriate technologies. The process of food irradiation is able to facilitate this demand because it preserves the food's chemical, physical, and sensory components.

The use of ionizing radiation for food preservation arose after the discovery of radioactivity in 1895. In 1905, patents were filed in the United States and Britain for the use of irradiation in foods. World War II contributed to the development of technologies related to irradiation area. The first commercial use of ionizing radiation in food occurred in Germany in 1957, in spices, with the use of irradiation with electrons in condiments. In 1980, the Food and Agriculture Organization, the International Atomic Energy Agency and the World Health Organization (FAO/IAEA/WHO) published 'food irradiated with doses up to 10 kGy had no toxicological effects or nutritional changes.'

Ionizing radiation includes gamma rays (from radioactive isotopes of Co and Cs), beta rays generated by electron accelerators, and X-rays. These sources do not have sufficient energy to induce radioactivity in food, but have enough energy to remove electrons from atoms and form ions or free radicals. These free radicals interact with other chemical bonds in different molecules present in the food, including microbial DNA and insects, promoting the impossibility of survival and reproduction. The radiation dose is the quantity of absorbed ionizing radiation, which the measurement unit is Gray (Gy). A Gray is equivalent to a $J\,kg^{-1}$ or 100 and 1 rad is equal to 100 erg g^{-1}.

The main advantage of ionizing radiation use in food is a total absence of direct use of chemical compounds that may leave residues in treated food, making the food unsafe for consumption. Therefore, ionizing radiation use in food attracted interest around the world from various organizations such as the IAEA, FAO, Organization for Economic Cooperation and Development (OECD), and WHO along with the participation of 24 countries in studies to unravel the changes that are caused in the food with the use of radiation.

Since 1988, the WHO recommends the use of this process, and in the 90s, following experiments with food irradiation, concluded that few foods tolerate doses above 10 kGy without loss of sensory quality. Studies with animals fed with irradiated diet, however, showed no adverse effect to health was observed, even at high doses of 70 kGy.

Radiolytic Effects on Foods

Basic Considerations

The aim of the food irradiation process is comparable with other preservation methods. The main purpose is the destruction of microorganisms and to create a longer shelf life for the food. The process is capable of sterilizing meat or meat products (high dose, 10–50 kGy); of extending the useful life of fresh fish and chilled chicken, fruits, and vegetables (mean doses, 1–10 kGy); of inhibiting sprouting bulbs and tubers; of delaying the ripening of fruits; and of killing insects in grains and cereals (low doses, below 1 kGy).

As with heat treatments, chemical changes are induced in foods as a result of treatment with the irradiation process.

The energy of radiation can cause chemical reactions. If the irradiated material is a food, some chemical changes are expected, and the extension of these increases with increasing the radiation dose.

When energetic electrons pass through a food they cause:

Primary Chemical Effects

Excitation of Molecules

There are two mechanisms for the production of excited molecules by ionizing radiation:

a. Direct: $A \rightarrow A^*$
b. By neutralization of ions: an excited ion $(A+)^*$ can be formed at the time of ionization: $A \rightarrow (A^+)^* + e^-$

Neutralization can occur subsequently and produce the excited molecule A*: $(A^+)^* + e^- \rightarrow A^*$

An excited molecule can retain its extra energy for a period of about 8–10 s. The loss of excitation energy can occur in many ways and the reactions can produce new products.

The new products formed may be stable molecules, such as molecules or reactive entities like free radicals.

A *Free radical* is an atom or molecule that has one or more unpaired electrons that are available to form a chemical bond; are designated with a point $\rightarrow \bullet(AH)$ or $\bullet E$.

Ionization

Normally, an ion reacts with another of opposite sign to produce a neutral entity $\rightarrow A^+ + B^- \rightarrow C$.

$$A^+ + e^- \rightarrow A$$

Ions can exist as a transitory ion–molecule complex, which under neutralization can form new compounds.

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00405-0

Secondary Chemical Effects

The net result of the primary chemical effects is the formation of free radicals or excited molecules.

The new molecules formed in the primary effect can react with themselves or with other food molecules as well as free radicals.

Because of the high reactivity of the free radicals produced in the primary effect, secondary chemical effects can occur. These effects result from several types of reactions of free radicals, including: adding, combining, dissociation, recombination, disproportionation (dismutation), and electron capture.

The complete process that leads to stable final products as a result of irradiation is called radiolysis, and the products of the primary and secondary effects are the radiolytic products. This process occurs in fractions of microseconds. Because some final products are not stable, post-irradiation effects may occur in some systems for days or months.

Free radicals do not only occur in irradiated products. Several biochemical reactions in plants and animals, as well as in drying and heating, produced free radicals.

The instrument that detects free radicals is the electron resonance spectrometer.

Effects of Ionizing Radiation on Water

Water is present in nearly all foods. These proportions are roughly 90% in vegetables; 80% in fruits; 60% in meat; and 40% in breads. Dried products contain some water: wheat flour 13%; dried vegetables around 10%; and nuts 5%. The water radiolysis is therefore of particular interest in food irradiation.

When pure water is irradiated, the radiolytic products formed are:

●OH radical hydroxyl; e^-_{aq} aqueous electron; ●H hydrogen atom; H_2 hydrogen; H_2O_2 hydrogen peroxide; H_3O^+ proton hydrated.

The electron e^- and H^+ hydrogen ion cannot exist freely in water. They are associated with water molecules.

Final Products of Water Radiolysis

While ●OH, e^-_{aq} and ●H are highly reactive transient species, hydrogen and hydrogen peroxide are the only stable end products of water radiolysis, because of the reactions.

$$H_2O_2 + e^- \rightarrow \bullet OH + OH^- H_2 + \bullet OH + H_2O + \bullet H$$

Hydrogen and hydrogen peroxide are widely consumed. They are therefore produced in low yield, even when irradiated with high doses. When the water is saturated with oxygen, it can greatly enhance the production of hydrogen peroxide.

The formation of hydrogen peroxide has great significance in irradiated foods. Like all foods contain substances that can oxidize or reduce, many reactions can occur when foods containing water are irradiated.

Influence of oxygen

The presence or absence of oxygen during the irradiation process may have an important influence on the radiolysis course. The water, when in equilibrium with the oxygen in the air, contains a low concentration of oxygen (about 0.27 mM at room temperature). Hydrogen atoms can reduce the oxygen to a hydroperoxyl radical: $\bullet H + O_2 \rightarrow \bullet HO_2$ which is an oxidizing agent. This is in equilibrium with a superoxide anion: $\bullet HO_2 \rightarrow H^+ + \bullet O^-_2$.

Both hydroperoxyl radicals and superoxide can form hydrogen peroxide:

$$2 \bullet HO_2 \rightarrow H_2O_2 + O_2 \rightarrow \bullet O^-_2 + HO_2 + H^+ \rightarrow H_2O_2 + O_2$$

The hydrogen peroxide formation in irradiated aqueous systems depends on the presence of oxygen. Very little H_2O_2 is produced when oxygen is excluded.

Several other radicals are produced when foods are irradiated. Oxygen can form some of these radicals, known as peroxides.

$$\bullet R + O_2 \rightarrow \bullet RO_2$$

To prevent the formation of these radicals may irradiate the products under vacuum, in nitrogen, or other shielding gases.

The extent the exclusion of oxygen will benefit an irradiated food varies according to its chemical composition, particularly its fat content, but also according to other factors, such as temperature at the radiation process and the time of storage after irradiation. Foods containing lipids are particularly affected by O_2 during irradiation and can develop strange and rancid flavors. The presence of oxygen is very important in the production of damage during irradiated foods storage: their exclusion preserves nutrients.

The retention of vitamin E during storage is considerably improved by the exclusion of oxygen, an effect that is more pronounced in irradiated foods than non-irradiated.

Effect of temperature

The temperature during irradiation process also influences the extent of radiolytic changes. The cold can have a big effect on protection. Generally, damage is greater when irradiating at room temperature. In the frozen state, the rates of diffusion of free radicals and the reactivity of gatherers are drastically reduced. A notable increase in protection against radiation damage becomes evident near −20 °C.

Little benefit is obtained by radiating at low temperatures when the aim is pasteurization (doses lower than 10 kGy) where vegetative cells are the primary targets of treatment. The improvement in quality obtained by irradiation in the frozen state is lost by the high doses required to inactivate bacteria, but bacterial spores are more resistant to radiation and are usually not very protected by the freeze. So, for sterilization by irradiation, where the aim is to kill all microorganisms, including spores, there is a considerable benefit that is obtained by irradiating frozen foods.

These effects are advantageous both organoleptic and nutritionally.

Influence of pH

The pH of aqueous systems is another factor that can influence the outcome of radiation because the equilibrium reactions are

pH dependent. An acidic environment may favor the disappearance of e^-_{aq} for the first reaction,

$$e^-_{aq} + H^+ \rightarrow \bullet H$$

while a basic environment can favor the formation of the second e^-_{aq}

$$\bullet H + OH- \leftrightarrow e^-_{aq}$$

Effect of dilution

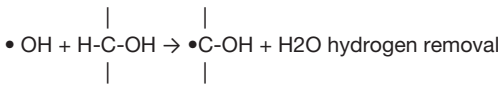
When dilute solutions are irradiated, the extent of degradation of the solute depends on the number of reactive radicals which will react with the molecules of the solute. The most crucial differences between the radiation chemistry of pure substances and complex food is rather quantitative than qualitative. While diluted aqueous solutions of amino acids, enzymes, sugars, and vitamins are commonly quite sensitive to radiation, these same compounds are much more stable when irradiated as a constituent food.

Effects of Radiation on Ionizing Other Food Components

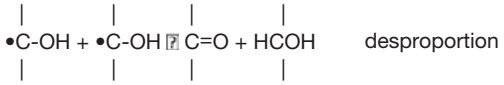
Besides water, the major components of food are carbohydrates, proteins, and lipids.

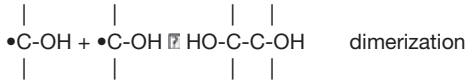
Carbohydrates

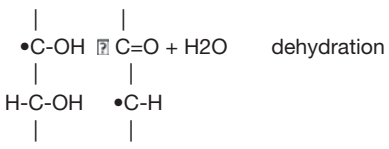
In the presence of water, ●OH radicals especially attack carbohydrates. The ●OH radicals predominantly abstract hydrogen from C–H bonds, forming water:



The resulting radicals react through various mechanisms:







Depending on the C═O molecular position formed by disproportion or dehydration, the resulting product can be an acid, a ketone, or an aldehyde. Thus, removing H of C − 1 of the glucose can induce to gluconic acid.

Since ●OH radicals can remove hydrogen from all six carbon atoms of glucose, a variety of products can be formed.

When disaccharides or polysaccharides are irradiated, the reactions observed with monosaccharides may also occur. Additionally, the glycosidic bonds that connect the monosaccharide units can be broken. Dextrin, maltose, and glucose are produced. This reduction in the degree of polymerization reduces the viscosity of the polysaccharide solutions. The solubility increases with increasing irradiation dose. Quite different results may be obtained irradiating granulated sugar instead of an aqueous sugar solution. The pharmaceutical industry uses crystalline sugar as a carrier of drugs. This sugar is sterilized. When carbohydrates are irradiated as components of food, they are much less sensitive to radiation than in pure form. The protein has a protective action on carbohydrates.

Proteins

Proteins consist of chains of amino acids connected by peptide bonds. The discussion of the effect of radiation in proteins is based on the study of the radiation chemistry of amino acids. Initiated reactions with hydrated electrons are the major route in the radiolysis of amino acids and proteins. When proteins are irradiated in the presence of water, all of the reactions that are possible with amino acids are also possible with proteins containing these amino acids. With 20 constituent amino acids and proteins with three reactive species of water radiolysis, many complex interactions are possible. Additional effects are exerted by the spatial configuration of the protein chain, determined by hydrogen bonds, disulfide bonds, hydrophobic bonds, and ionic bonds. Alone, amino acids, which are susceptible to attack by radicals when irradiated, are less sensible when they are part of the protein structure and are more or less inaccessible to reactions with radicals. Another factor that likely contributes to the increased strength compared with the protein isolated amino acid sequence is, due to a greater or lesser rigidity of the spatial structure of the protein, radicals formed as a result of irradiation molecule are safe in the position and have a high chance of recombination.

A large proportion of radiant energy deposited in irradiated proteins apparently advances to denaturation, changes in secondary and tertiary chains, before the destruction of the amino acid constituents. This denaturation is much less extensive than that caused by heat. This is because sterilizing radiation in food for long time storage combines with heat treatment. Enzymes are more sensitive to heat.

Lipids

In the presence of oxygen, irradiation can also accelerate the autoxidation of fats. This may be because the irradiation accelerates one or more of the following reactions: free radical formation, which can combine with oxygen to form hydroperoxides; breaking hydroperoxides, giving action to various decomposition products, particularly carboxyl compounds; and destruction of antioxidants.

Lipids are usually exposed to irradiation as food constituents coexisting with others to a greater or lesser amount. The

radiolytic products obtained in isolated lipids are found when they are part of food, but in smaller proportions, and the effect of radiation is divided among all the constituents of the food.

It has been reported that when triglycerides were irradiated with very high doses 250 kGy, volatile and non-volatile products formed were similar to those obtained by heating and frying 180 °C for 1 h. Irradiation results in partial destruction of fat soluble vitamins, and tocopherol is particularly sensitive.

Main Types of Food Irradiation

Radiopasteurization

Related to decontamination and destruction of bacteria and parasites, this term refers to the treatment of foods by applying a dose of ionizing radiation in the range from 2 to 8 kGy sufficient to reduce the number of viable pathogenic non-sporulating bacteria at such a level that none is detectable in the treated food when it is examined by any known bacteriological method.

Radurization

When applied to food at a dose of ionizing radiation around 0.4–10 kGy it is enough to reduce the number of pathogenic microorganisms and contaminants and to promote the decontamination of harmful insects to the food, thereby increasing their quality and prolonging the storage period without affecting the sensory characteristics. This process is considered ideal for use in products that are in nature and can also be used to preserve seafood, dried fruit, and some meat products.

Radapertization

This term corresponds to food characterized as 'sterile commercially,' because the radiation within a range of dose above 10 kGy, considered high by experts, is applied in order to reduce the number of activity of pathogenic microorganisms, such that few or none, with the exception of viruses, are detectable by the methods of analysis recommended, independent of time and under what conditions food is stored, provided that it is properly packed.

The doses of radapertization that are submitted to foods like fish, raw and cooked meats, vegetables, dehydrated foods, salt, sugar, herbs, and spices, among others, are high doses above 10 kGy, which sterilizes food for a variety of uses, such as feeding astronauts during space travel, hospitalized immunocompromised patients, hikers, boaters, and other sportsmen.

The Safety of Irradiated Food

Food irradiation has been the subject of intense research for more than 40 years. International organizations such as FAO and the WHO reviewed this research and concluded that food irradiation is safe and beneficial. Similarly, the nutritional value of irradiated foods was compared with the food processed by other methods, with favorable results.

In 1983, the Codex Alimentarius Commission, a group of the United Nations, that develops international food standards, concluded that foods irradiated below 10 kGy do not show toxicological risk. Currently, treatment levels within this range are used throughout the world. Neither gamma energy, nor international levels established for electron beams can cause food to become radioactive. The radiation processing does not make food radioactive in the same way that X-rays used for security at airports do not make radioactive baggage.

Storage Post-Irradiation

Changes in composition during storage deserve special attention in the case of fresh fruits and vegetables. Irradiated or not, plant metabolism materials are constantly changing, which can be accelerated by factors such as mechanical damage, low temperature storage, or modified atmosphere. Depending on the applied dose and the product to be considered, the irradiation can accelerate or decelerate the metabolic changes. At low radiation doses, tolerated by fresh fruits and vegetables – usually below 2 kGy and in some cases below 1 kGy – direct chemical effects are minimal in vitamins.

Heating

Another factor is the possibility of loss of vitamins during the cooking. In oat bran, the losses of vitamin B1 (thiamine) caused by heating for 10 min in oven at 100 °C, were always higher than in the irradiated samples. After a storage period of about 6 months unheated, the sample had 50% loss of B1 vitamin, smaller than the non-irradiated control, whereas after heat treatment, irradiated samples had lost about 70% less the non-irradiated control.

Low Temperatures

Radio-sensitive vitamins cannot be protected only by the exclusion of oxygen, but also by irradiation at low temperatures. Although the losses of vitamins increase with the increasing of radiation dose, food irradiated with high doses always requires processing conditions which minimize unpleasant sensory effects. Oxygen must be excluded, that is, the vacuum packaging and irradiation is conducted at cryogenic temperatures. Under these circumstances, even vitamins usually considered radio-sensitive can be well protected.

Dose Rate

There are reports of better retention of vitamins when irradiating by electron beam than with gamma radiation. Research using 60 kGy at −45 °C found retention of 60% in electron beam, while gamma radiation was 35%. It was explained that the best retention was in meat irradiated by electrons as a result of the higher rate of dose released by the electron beam, which produces a situation of free oxygen in the irradiated sample.

Liposoluble Vitamins

Vitamin A (retinol) and pro vitamin A (carotenoids)

In early studies of the effects on food vitamins, researchers observed a loss of vitamin A in different products irradiated

at a dose of 4.8 kGy: milk 70%; butter 68%; cream cheese 54%; cheddar 47%; and margarine 14%. When they treated porcine liver with 5 kGy at 0 °C, it contained 4% less retinol than the non-irradiated control after 1 week and 13% less after 4 weeks.

The liposoluble vitamins in decreasing order of radiation sensitivity are: Vitamin E > carotene > Vitamin A > Vitamin D > Vitamin K.

Vitamin E (alpha tocopherol)

The radiation sensitivity of this vitamin depends on the presence of oxygen. Researchers found no loss of vitamin E in meat irradiated with 30 kGy and nitrogen, but observed a loss of 37% when the meat was irradiated in the presence of air. High temperatures also influence the losses of this vitamin.

The main sources of vitamin E in human nutrition are butter, margarine, vegetable fats, and oils. None of these foods are indicated to irradiation. Therefore, despite the radiation sensitivity of this vitamin, it is difficult to imagine a situation where irradiated foods would supply any deficiency of vitamin E.

Vitamin K

Many species of bacteria synthesize vitamin K. This also occurs in the human gut (except for in newborn children and patients treated with antibiotics), so they are independent of the diet for the supply of vitamin K. Vitamin K is present in fresh green leafy vegetables. Liver contains comparable concentrations. Most other food sources are poor.

Studies have shown that vitamin K is more resistant to radiation of fat-soluble vitamins. Broccoli, kale, spinach, and other vegetables irradiated with between 28 and 56 kGy, and stored for 9–15 months at room temperature, showed no loss of activity of vitamin K.

Water Soluble Vitamins

Vitamin B1 (thiamine)

This water-soluble vitamin is more sensitive to radiation. A research showed an increase of losses of this vitamin with increasing of the radiation dose, and losses are smaller after irradiation at low temperatures. Similar loss of thiamine can be observed in various types of meat. The losses of thiamine in irradiated foods become more apparent after storage and cooking. The level of this vitamin loss is directly proportional to the radiation dose applied into the sample. Even so, their losses are minimum when compared the other processes of conservation of foods. Those losses do not get to take the tianina deficiency to arrive to the clinical condition of a cerebral lesion potentially irreversible, or even to take to the lack condition that can cause some physiological and morphological alterations.

Vitamin B2

The combination of irradiation and cooking can occasionally result in improvement in retention of the vitamin. The time required for cooking dried vegetables can be considerably shortened by irradiation. Breakfast products are the largest source of vitamin B2 in human nutrition, and are generally considered unsuitable for irradiation because they develop a bad flavor. In order to have breakfast products for patients in immunosuppressive therapy, radiation techniques, such as keeping these products in a nitrogen atmosphere at −78° C, have been developed, providing a dose of 40 kGy in the breakfast dietary for these patients.

Vitamin B12

This vitamin seems to be pretty stable for irradiation. No loss was observed in irradiated haddock filets at 25 kGy, and several species of fish irradiated with doses of 30 kGy.

Folic acid

No loss of folic acid in radiation sterilized meat has been presented by some researchers, as well as with poultry meat.

Vitamin C

The major sources of vitamin C in human nutrition are fruits and vegetables. The total activity of vitamin C is the sum of ascorbic acid (AA) and dehydroascorbic acid (DHAA). In the human body, DHAA has the same vitamin activity of AA. Fresh agricultural products contain many AA and researchers analyzed only AA as a measure of vitamin C. However, both AA and DHAA and AA and DHAA together can change dramatically during storage and processing.

The sensitivity of the vitamins varied depending on the process conditions in which irradiate the food. Vitamins C and B1, the most sensitive and water soluble; vitamins E and A are the most sensitive among the fat soluble vitamins. However, during irradiation, these changes can be minimized simply by changing process conditions, such as the use of controlled atmosphere packaging.

Vitamin C (AA) in solution is very sensitive to irradiation, but in fruits and vegetables it is already more stable at low doses. AA by irradiation becomes DHAA, which is active, such as vitamins.

Effect of Enzymes

Existing enzymes in foods must be inhibited before they undergo radiation, because these are resistant. This inactivation must be realized through heat treatment, this form being stronger than that used for microorganisms, because enzymes are stronger than microorganisms. Irradiated foods are unstable during storage due to their sensitivity to enzymatic attack.

The high resistance to irradiation of enzymes is demonstrated by the milk phosphatase, which is not destroyed by the irradiation doses used for the sterility of the milk. Enzymes are affected by the indirect effects of free radicals formed in the solvent phase effects. Thus, the diluted solutions of enzymes are relatively more sensitive to radiation than concentrated solutions. In addition, enzymes in their natural environments, such as in foods, are relatively resistant. The enzyme activity is affected in doses used for food conservation, and thus extend the shelf life of fruits and vegetables.

Conclusion

Irradiation has been the subject of intense and rigorous studies for decades. It is a safe and effective method of processing. The products have good quality, in particular, the level of food security and conservation. The nutritional value, compared

with other foods that have undergone such a process, reveals favorable results. Conservation methods, such as heating, can cause much greater reductions on food's nutritional value.

The lack of information about this technology and its benefits has led to many controversies. Correct information must be guaranteed, scientifically based, so that consumers can make informed choices. The labeling of irradiated products provides the decision to buy them or not.

The market for irradiated products is still small, including in countries where this process of conservation is allowed. The legal and safety aspects of the process, the factors of equipment, costs, and consumer acceptance contribute to their low marketing.

In summary, the macronutrients – proteins, fats, and carbohydrates – are not significantly altered by irradiation in terms of nutritional value and digestibility. Micronutrient and some of the vitamins are susceptible to irradiation, which greatly depend on the composition of the food as well as its processing and storage. Whether or not the losses of vitamins in irradiated food are of great importance will depend on the circumstances, such as the contribution that food makes the total diet.

Taking these factors into consideration, it seems that thiamine is the only vitamin that may require special attention, because it is highly sensitive to radiation, and because foods that contribute significantly to supply this vitamin, such as pork meat, are candidates for irradiation process in a large scale. However, even in the case of thiamine, there is no reason to assume greater nutritional consequences of irradiation.

We can also say that potential nutrient losses in irradiated foods are not basically different from losses in food undergoing other treatment processes. Rather, heating, drying, and using other traditional methods can cause loss of nutritional value higher than with the use of irradiation.

Ketone Bodies

PAC McPherson, Belfast Metropolitan College, Belfast, UK

© 2016 Elsevier Ltd. All rights reserved.

Introduction

The ketone bodies comprise three small, water-soluble compounds produced by the liver in response to reduced glucose availability. Their formation may signify prolonged fasting or a pathophysiological state, such as type I diabetes (insulin-dependent diabetes mellitus). As their synthesis is linked to the metabolism of fatty acids, certain dietary regimes can induce ketone body formation, either as a means of weight loss or to control certain neurological conditions such as refractory epilepsy. In a more contemporary context, novel compounds have been developed, which enhance the formation of ketone bodies *in vivo*, and have been suggested to improve athletic performance.

Brief Review of Metabolism

In the normal, well-fed state, glucose is the primary substrate for energy production, achieved through the three well-known pathways glycolysis, tricarboxylic acid (TCA) cycle, and electron transport chain. Following digestion, the liver receives the first pass of dietary glucose, initially used not only for ATP production but also for synthesis of storage forms of glucose such as glycogen. As humans have the capacity to consume food at a faster rate than is required for survival, the excess glucose is also converted to palmitic acid, which is esterified to triacylglycerol and packaged as nascent very low-density lipoproteins, which are secreted into the circulation. This is distinct from dietary fat, which is packaged in the intestines as chylomicrons; both lipoproteins, however, have the same eventual metabolic fate – they circulate in the blood until they are acted upon by lipoprotein lipase, an enzyme particularly abundant in adipose tissue, which hydrolyzes triacylglycerols to free fatty acids, which are taken up by adipocytes and reesterified for storage.

When blood glucose levels are low, for example, during fasting, lipolysis of triacylglycerols stored in the adipose tissue yields free fatty acids, which are used in preference to glucose by many tissues, most notably in the heart and muscle where fatty acids inhibit glycolysis. In the liver, fatty acids are oxidized through β-oxidation to produce acetyl-CoA, a thioester that plays a central role in metabolism. The acetyl-CoA produced by hepatic β-oxidation provides most of the ATP required for gluconeogenesis; however, there is a large surplus of acetyl-CoA that is converted to ketone bodies in the mitochondria of perivenous hepatocytes. Ketone bodies represent a usable form of lipid-derived energy, as they can penetrate the blood–brain barrier and supply the brain with a source of energy (fatty acids cannot pass the blood–brain barrier) (Figure 1).

Ketone Body Metabolism

General Features

The three endogenous ketone bodies, acetoacetic acid, (*R*)-3-hydroxybutyric acid, and acetone, are structurally simple compounds derived from acetyl-CoA (Table 1). Ketones as a whole are more acidic than the corresponding alkane owing to the resonance stabilization of the enolate ion (Figure 2). Therefore, we see from the values of their pK_a that both acetoacetic acid and (*R*)-3-hydroxybutyric acid are present in their conjugate base forms at physiological pH, that is, acetoacetate and (*R*)-3-hydroxybutyrate. As acetoacetate is a β-keto acid, it undergoes spontaneous decarboxylation to give the more stable keto isomer, in this case acetone. When the levels of acetoacetate are particularly high, the enzyme acetoacetate decarboxylase can also mediate this reaction. As acetone has a relatively high vapor pressure (boiling point 56.5 °C), it is released on exhalation. This accounts for the often fruity smell on the breath of individuals who are in a state of ketosis.

As outlined briefly in the previous section, under hypoglycemic conditions, when the levels of acetyl-CoA are high due to increased β-oxidation, acetyl-CoA is converted to acetoacetyl-CoA by the ubiquitous enzyme 3-ketothiolase (also known as β-ketothiolase or 2-methylacetoacetyl-coenzyme A thiolase). This enzyme catalyzes the Claisen condensation of two moles of acetyl-CoA, forming acetoacetyl-CoA and free CoA (Figure 3):

$$2\text{Acetyl-CoA} \rightleftharpoons \text{Acetoacetyl-CoA} + \text{CoA}$$

$$K_{eq} = \frac{[\text{Acetoacetyl-CoA}][\text{CoA}]}{[\text{Acetyl-CoA}]^2} = 6.0 \times 10^{-5}$$

The equilibrium constant for this reaction is lower than expected ($\Delta G^o \approx 24$ kJ mol^{-1}), so to shift the position of equilibrium to favor the products, the 3-ketothiolase is bound to the second enzyme in ketogenesis, 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA) synthase, which converts the recently formed acetoacetyl-CoA to HMG-CoA virtually instantaneously. As this

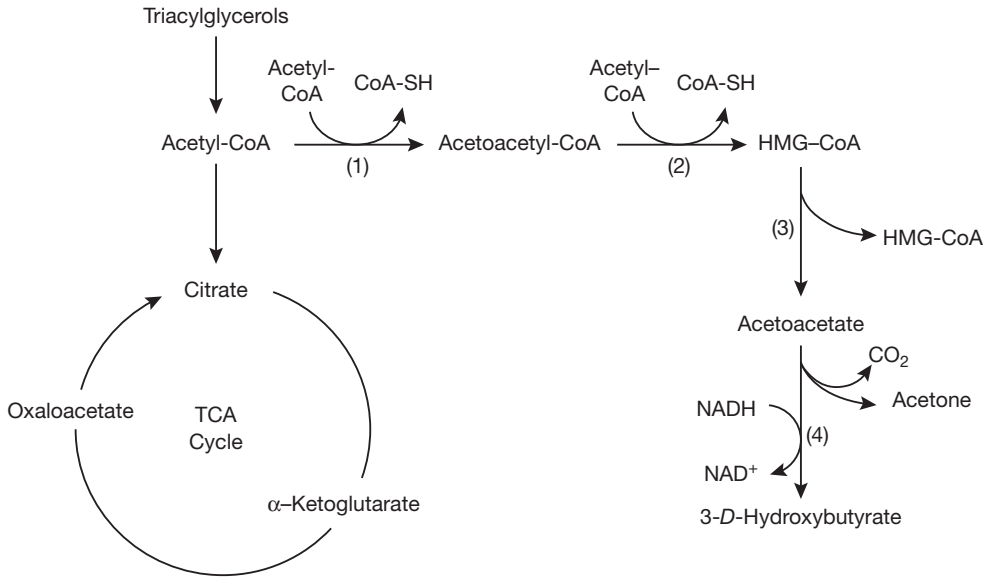

Figure 1 Overview of metabolism. Acetyl-CoA plays a crucial role in ketone body synthesis. It initially undergoes conversion to acetoacetyl-CoA through the action of 3-ketothiolase (1), which is then converted to HMG-CoA, mediated by 3-hydroxy-3-methylglutaryl-CoA synthase (2). The HMG-CoA undergoes cleavage by HMG-CoA lyase (3) to give acetoacetate, which may spontaneously decarboxylate to (*R*)-3-hydroxybutyrate or be converted by acetoacetyl-CoA deacetylase (4).

Table 1 Physicochemical properties of the ketone bodies

	Acetoacetic acid	*(*R*)-3-hydroxybutyric acid*	*Acetone*
IUPAC name	Oxobutanoic acid	3-Hydroxybutyric acid	Propanone
Structural formula			
Relative formula mass (g mol^{-1})	102.88	104.10	58.08
pK_a	3.58	4.70	19.2
Reference range (blood) (mM)	<4	<4	<0.01

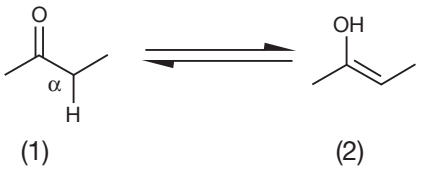

Figure 2 Keto–enol tautomerism. The keto form (1) exists in equilibrium with the enol form (2) such that the α-hydrogen of the former is lost, causing a rearrangement of bonds, leading to the enol tautomer.

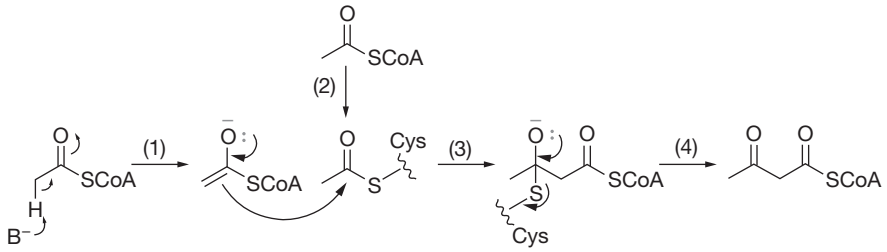

Figure 3 Mechanism of acetoacetyl-CoA formation. The formation of acetoacetyl-CoA involves a so-called ping-pong mechanism within the active site of 3-ketothiolase. Initially, one molecule of acetyl-CoA is deprotonated, forming an enolate (1). This is then combined with a second molecule of acetyl-CoA (2) in a nucleophilic attack mediated by a catalytic cysteine residue (3). The tetrahedral intermediate then rapidly collapses, expelling the acetoacetyl-CoA.

latter reaction is associated with the hydrolysis of a high-energy thioester linkage, the overall reaction has a much higher equilibrium constant, further compensating for the unfavorable equilibrium in the earlier step ($\Delta G^{o} \approx -0.7$ kJ mol^{-1}):

$$3\text{Acetyl-CoA} + H_2O \rightleftharpoons \text{HMG-CoA} + 2\text{CoA}$$

$$K_{eq} = \frac{[\text{HMG-CoA}][\text{CoA}]^2}{[\text{Acetyl-CoA}]^3[H_2O]} = 1.33\,\text{dm}^3\,\text{mol}^{-1}$$

HMG-CoA has two potential metabolic fates: the first is to undergo reduction to mevalonate by HMG-CoA reductase, the rate-limiting step in isoprenoid biosynthesis, and the second is to undergo cleavage by HMG-CoA lyase to form acetoacetate and acetyl-CoA. If this reaction occurs in the cytosol, the first pathway is favored; if it occurs in the mitochondria, the second pathway occurs. This level of control originates from a slight difference in the structure of the HMG-CoA synthase found within the mitochondria. The gene encoding the mitochondrial form of HMG-CoA synthase (HMGCS2) has three steroid-responsive elements, such that fatty acids increase its transcription. This ensures that HMG-CoA produced during hypoglycemia is directed toward ketogenesis rather than mevalonate synthesis. The cleavage of HMG-CoA to acetoacetate and acetyl-CoA is the primary route for synthesis of acetoacetate; however, acetoacetyl-CoA can alternatively be directly deacetylated to acetoacetate by acetoacetyl-CoA deacetylase. This pathway accounts for a very small proportion of the acetoacetate produced as the K_m of the acetoacetyl-CoA deacetylase is high in comparison to the concentration of acetoacetyl-CoA found in hepatocytes. Acetoacetate is converted to (*R*)-3-hydroxybutyrate by the action of (*R*)-3-hydroxybutyrate dehydrogenase. The relative proportions of acetoacetate and (*R*)-3-hydroxybutyrate can be anywhere in the region of 1:1–1:10 depending on the redox state of the mitochondria (i.e., the ratio of NADH to NAD$^+$).

Many tissues can utilize ketone bodies as metabolic fuel and their small molecular mass ensures that they can cross the blood–brain barrier. The breakdown of ketone bodies (ketolysis) is initiated by the conversion of acetoacetate back into acetoacetyl-CoA by succinyl-CoA-oxoacid transferase (SCOT), the rate-limiting step in this process (Figure 4). The acetoacetyl-CoA so produced is then cleaved by methylacetoacetyl-CoA thiolase to produce acetyl-CoA, which is funneled into the TCA cycle for ATP production. The shift in the equilibrium mediated by (*R*)-3-hydroxybutyrate dehydrogenase as a consequence of the consumption of acetoacetate leads to the conversion of (*R*)-3-hydroxybutyrate to acetoacetate, which is then metabolized as outlined earlier.

Energetics of Ketone Body Metabolism

Experimental models suggest that ketone body metabolism operates at higher efficiency than glucose metabolism. In isolated rat perfusion models, ketone bodies increased the efficiency of cardiac muscle by ~28% when compared to glucose as fuel. We can rationalize this observation by considering the fundamental thermochemistry of the two principal substrates for energy production: pyruvate and (*R*)-3-hydroxybutyrate. The enthalpy of combustion (ΔH^{o}) for pyruvate is -278.5 kcal mol^{-1}, while that of (*R*)-3-hydroxybutyrate is -487.2 kcal mol^{-1}. The greater amount of energy released on combustion of (*R*)-3-hydroxybutyrate is a consequence of the greater number of C–H bonds. Since (*R*)-3-hydroxybutyrate is more reduced than pyruvate, it has the potential to increase the difference in redox potential between the mitochondrial NAD couple and the coenzyme Q couple. The greater this difference, the greater the ATP production. In essence, ketone bodies act as a 'superfuel' for key metabolic processes.

Role of Ketogenesis During Starvation

The importance of ketone bodies was truly highlighted in the 1960s by George Cahill and colleagues working at Harvard. Their work focused on metabolic adaptations to starvation and essentially proved that ketone bodies are normal fuels of

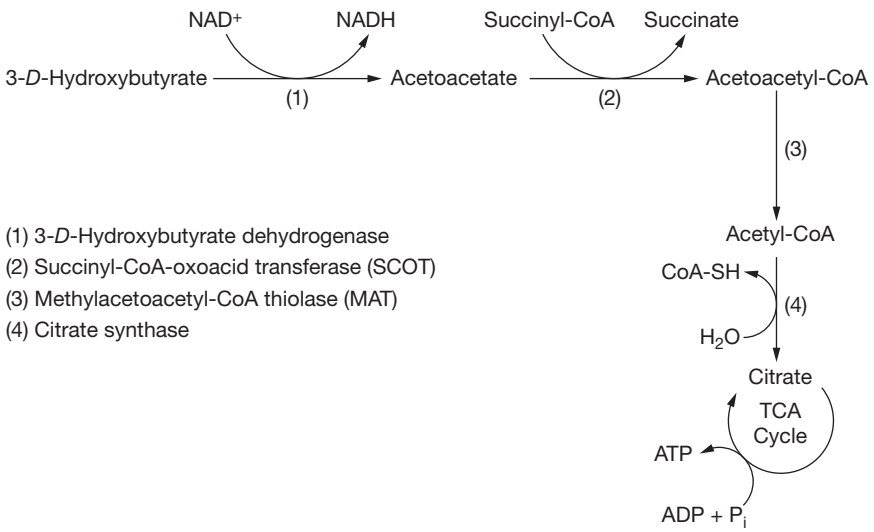

Figure 4 Ketolysis. Ketone bodies are broken down in a series of reactions in essentially the reverse of ketogenesis.

respiration and that they represent a substantial source of energy. Of course, mammals have evolved to utilize glucose as their primary metabolic fuel. However, in the event that glucose availability drops, a series of metabolic events occur to ensure survival. The linchpins of metabolism at this level are the hormones glucagon and insulin, both produced by the pancreas but in histologically distinct structures within the islet of Langerhans named the α and β cells, respectively. Careful glucose homeostasis is of vital importance for long-term survival during starvation conditions, not least because the brain and red blood cells are dependent on glucose as fuel. As the data in Table 2 demonstrate, an average 70 kg man has fuel stores that should ensure survival for about 3 months (assuming a basal energy expenditure of 1600 kcal day^{-1}). The utilization of these reserves was studied by Cahill and coworkers, who divided glucose homeostasis into five stages, charting the levels of glucose over a period of 40 days.

Phase I is the fed stage when glucose is plentiful, the ratio of insulin to glucagon is high, and glucose is directed toward the glycolytic pathway, producing ATP and a range of intermediates, including malonyl-CoA. This latter intermediate controls the fate of excess glucose; malonyl-CoA inhibits the passage of fatty acids to the mitochondrial matrix, the site of ketogenesis. Instead, the excess glucose is converted to fatty acids and ultimately stored as triacylglycerols in the adipose tissues. In phase II, the early fasted stage, glucose levels begin to decline and the ratio of insulin to glucagon decreases, initiating glycogenolysis. The release of glucagon also prevents the absorption of glucose by muscle and adipose tissue, allowing the glucose released to supply higher-priority tissues (viz., the brain and red blood cells). The liver gains energy through β-oxidation, and as the levels of acetyl-CoA and citrate increase, hepatic glycolysis is stopped. Similarly, muscle tissue gains energy through β-oxidation, and the acetyl-CoA formed causes accumulation of pyruvate and lactate, which are exported to the liver for conversion to glucose.

After ~24 h (phase III), glucose requirements are substantially met by gluconeogenesis. As glucagon also activates hormone-sensitive lipase in adipose tissues, lipolysis occurs, liberating 3-monoacylglycerol and fatty acids. The 3-monoacylglycerol acts as the main substrate for gluconeogenesis. The fatty acids liberated by the same process cannot generally be used for gluconeogenesis due to an inability to produce oxaloacetate independent of glycolysis (an exception to this is the metabolism of odd-chain fatty acids, which yield propionyl-CoA, a precursor of succinyl-CoA). As the levels of malonyl-CoA will be low, the fatty acids released can cross the inner mitochondrial membrane and enter the β-oxidation pathway. The acetyl-CoA produced can feed into the TCA cycle and supplement the ATP required for gluconeogenesis. However, as outlined earlier, there is a large surplus of acetyl-CoA, which is then used to synthesize ketone bodies. At phase IV, the levels of ketone bodies are high enough for them to cross the blood–brain barrier and meet some of its energy requirements. After about 3 days' starvation, one-third of the brain's energy demands are met by ketone bodies and cardiac muscle begins to consume ketone bodies for fuel. If starvation continues to phase V, the role of ketone bodies becomes even more significant, until the fat stores are depleted. At this stage, proteolysis supplies further ATP through liberation of glucogenic and ketogenic amino acids.

Table 2 Approximate energy stores in an average 70 kg man

	Available energy (kcal)		
	Glucose or glycogen	*Triglycerides*	*Proteins*
Blood	60	45	0
Liver	400	450	400
Brain	8	0	0
Muscle	1200	450	24 000
Adipose tissue	80	135 000	40

The switch from the well-fed state, when the liver is engaged in glycogenesis and lipogenesis, to the fasting state, when the liver is glycogenolytic, gluconeogenic, and ketogenic, is obviously tightly controlled. The first level of control, particularly for ketogenesis, is the availability of substrate; fat is only stored in the adipose tissue when glucose is in excess of the calorie demands of the individual. Therefore, the ability to synthesize ketone bodies is directly related to earlier excess calorie intake. This is a very coarse level of control but does give some basis for the adage 'fat burns in the flame of sugar.' The first example of fine control of ketogenesis comes from the passage of fatty acids across the inner mitochondrial membrane. In order for this to occur, they must be esterified to carnitine by carnitine acyltransferase I (CAT I), an enzyme only present on the outer surface of the mitochondrial membrane and inhibited by malonyl-CoA. Therefore, when glucose is in excess and fatty acids are being synthesized, the levels of malonyl-CoA will be high and CAT I will be inhibited. In the fasting state, the levels of malonyl-CoA will be low, CAT I will be active, and the molecules of fatty acyl carnitine can traverse the mitochondrial membrane to the mitochondrial matrix where they are broken down by β-oxidation and the acetyl-CoA converted to ketone bodies. Greater control is afforded through acetyl-CoA carboxylase (ACC), which modulates the flow of malonyl-CoA through two metabolic pathways. Citrate, produced by the TCA cycle, partially activates ACC, producing malonyl-CoA at a slow rate, which reduces CAT I activity and promotes lipogenesis. Insulin causes dephosphorylation of ACC, fully activating it toward malonyl-CoA formation, whereas glucagon promotes phosphorylation, inactivating the enzyme. Interestingly, in the long term, it appears that a high-carbohydrate diet increases the synthesis of ACC, while a high-fat diet decreases its synthesis.

Pathological Ketogenesis

Type I Diabetes Mellitus

Type I diabetes mellitus is by far the most studied and most prevalent cause of pathological ketogenesis. In type I diabetes, the pancreatic β cells have been destroyed by an autoimmune reaction, abolishing insulin production, thereby impairing glucose uptake by cells. Glucagon production occurs at higher than normal rates, causing metabolism in type I diabetes to shift to starvation mode. The liver responds by breaking down glycogen and synthesizing glucose through gluconeogenesis. Hence, not only will blood glucose be high due to exogenous glucose, but also this is supplemented by endogenously

produced glucose. As this glucose cannot be absorbed by cells (due to the absence of insulin), glucose is excreted in the urine, leading to dehydration. As the liver is engaged in gluconeogenesis, the supply of oxaloacetate is soon exhausted, and the TCA cycle stops producing citrate, which reduces the supply of malonyl-CoA. Fatty acids are then free to enter the mitochondrial matrix and undergo conversion to acetyl-CoA, which is in turn converted to ketone bodies. As insulin is not produced, there is no regulation of lipolysis, effectively meaning that ketogenesis is similarly unregulated. The resultant hyperketonemia continues until a threshold of about 7 mM, at which point the kidneys excrete excess ketone bodies into the urine.

Urinary excretion of ketone bodies results in the most serious complication of hyperketonemia – diabetic ketoacidosis (DKA). Recall that acetoacetate and (*R*)-3-hydroxybutyrate are relatively strong organic acids, dissociating into H^+ and the corresponding anion in the blood plasma. Initially, the H^+ ions are effectively buffered by bicarbonate anion, producing carbonic acid. The carbonic acid breaks down to give carbon dioxide and water, with the carbon dioxide stimulating the respiratory center in the brain, expelling it through exhalation. The sodium salts of the ketone bodies are then excreted in the urine. If the production of ketone bodies exceeds the clearance rate, a high anion gap metabolic acidosis occurs. When this is coupled to the dehydration associated with the osmotic diuresis caused by high blood glucose levels, hypotension and death can follow.

Ethanol Intoxication

Ethanol cannot be excreted directly and is therefore metabolized by one of two pathways. The first pathway involves two reactions: the conversion of ethanol to acetaldehyde mediated by alcohol dehydrogenase and the conversion of acetaldehyde to acetate using aldehyde dehydrogenase:

$$CH_3CH_2OH + NAD^+ \rightarrow CH_3CHO + NADH + H^+$$

$$CH_3CHO + NAD^+ + H_2O \rightarrow CH_3COO^- + NADH + H^+$$

From the equations, we see that metabolism of ethanol leads to an accumulation of NADH, which among other things prevents the conversion of lactate to pyruvate, causing modest lactic acidosis. The acetate produced is converted to acetyl-CoA, which cannot enter the TCA cycle as NADH also inhibits two of the enzymes involved in this cycle. Therefore, the acetyl-CoA is directed toward ketogenesis, further decreasing the pH of the blood plasma and causing significant metabolic acidosis.

Salicylate Overdose

Acetylsalicylate acid (aspirin) is hydrolyzed to salicylate, which has a pK_a of 2.7. It therefore dissociates in plasma to give a mild metabolic acidosis. As the pH of the blood decreases, the undissociated salicylate becomes increasingly lipid-soluble and can pass through the mitochondrial membrane where it inhibits the enzymes of the TCA cycle, specifically succinate dehydrogenase and α-ketoglutarate dehydrogenase. The accumulated pyruvate can have two main metabolic fates: the first is to undergo conversion to lactate (provided that NADH is in plentiful supply) and the second is to undergo oxidative decarboxylation and coupling to CoA, forming acetyl-CoA. The acetyl-CoA then acts as a substrate for 3-ketothiolase, forming acetoacetyl-CoA and proceeds toward ketone body formation.

Inborn Errors of Ketone Body Metabolism

Inborn errors of metabolism are broadly regarded as a group of rare inherited disorders in which a single gene defect causes a clinically significant effect. Newborns are screened within 7 days from birth for common inborn errors of metabolism, including HMG-CoA lyase deficiency and β-ketothiolase deficiency, both of which affect ketone body metabolism. Two further conditions, HMG-CoA synthase deficiency and SCOT deficiency, also affect ketone body metabolism.

When we consider the production of ketone bodies, the rate-limiting step is the formation of HMG-CoA, which is mediated by mitochondrial HMG-CoA synthase. The autosomal recessive condition, HMG-CoA synthase deficiency, is the only disorder that exclusively affects hepatic ketogenesis, essentially preventing *de novo* synthesis of ketone bodies. Subsequently, when an affected individual is in a fasting (hypoglycemic) state, ketone bodies are not produced to compensate, and pronounced hypoketonemia is present. This is an extremely rare disorder, with the first case only being recognized in 1997. The next stage in ketogenesis, conversion of HMG-CoA to acetyl-CoA and acetoacetate, can be associated with a deficiency in HMG-CoA lyase, first reported in 1976. This disorder has a similar clinical presentation to HMG-CoA synthase deficiency in that it is characterized by fasting hypoketonemia.

Deficiency in the enzymes of ketolysis, namely, SCOT and β-ketothiolase, appears to be marginally more prevalent in the population and is associated with significant hyperketonemia, often leading to ketoacidosis. SCOT deficiency, first recognized in 1972, is characterized by supraphysiological levels of acetoacetate and (*R*)-3-hydroxybutyrate and is a differential diagnosis of DKA. The second step in ketolysis can be affected by β-ketothiolase deficiency, which, as in the previous case, leads to an accumulation of acetoacetate and (*R*)-3-hydroxybutyrate. Both these disorders have a favorable prognosis if detected early and appropriate dietary observance can result in a more or less normal life. For females, pregnancy can carry a higher than normal risk, as pregnancy is associated with mild ketosis, which when combined with nausea and vomiting common in the first trimester can lead to significant hyperketonemia.

Detection and Measurement of Ketone Bodies

In light of the role of ketone bodies in various pathophysiological states, monitoring the levels of ketone bodies in various patient groups is a significant task in modern clinical chemistry laboratories. Urinalysis is the most commonly employed procedure, especially for near-patient testing or home monitoring. The simplest assay is based on the Rothera reaction, in which alkaline sodium nitroprusside reacts with methyl ketones (such as acetoacetate) to form a red adduct:

$$Na_2[Fe(CN)_5NO] + CH_3COCH_2COOH + 2NaOH \rightarrow Na_4[Fe(CN)_5NCHCOCH_2COOH] + H_2O$$

This reaction forms the basis of many commercially available ketone body test kits. Some versions include glycine, which undergoes Schiff base formation with acetone, leading to detection of acetoacetate and acetone. However, this test will not detect (*R*)-3-hydroxybutyrate, and assays based upon it should only be used for initial diagnosis or as an adjunct to more comprehensive analysis.

More reliable and accurate analysis of blood ketones is typically achieved by enzymatic assays, although methods employing gas chromatography or capillary electrophoresis have also been reported. In the enzymatic method, (*R*)-3-hydroxybutyrate dehydrogenase is used to convert (*R*)-3-hydroxybutyrate to acetoacetate in the presence of NAD^+. The associated reduction of NAD^+ to NADH can be followed spectrophotometrically by the action of diaphorase; this latter enzyme reoxidizes the NADH, which in turn reduces a formazan dye (typically WST-1) to produce a red/purple adduct.

Ketogenic Diets

Ketogenic diets are characterized by a high fat to carbohydrate ratio and have been employed in various guises since the early 1920s. The classic ketogenic diet was developed by Russell Wilder following his initial observations that such diets had an anticonvulsant effect in children with refractory epilepsy. Wilder's original diet consisted of the consumption of fats and carbohydrates in the ratio of 4:1, with the fat content comprising mainly of long-chain, saturated fatty acids. Since such a diet was associated with ketosis, Wilder attributed an anticonvulsant effect to ketone bodies. In fact, the Greek physician Hippocrates noted in the Hippocratic Corpus that "epilepsy is cured as quickly as it had appeared through complete abstinence of food and drink." It is now believed that although ketone bodies may have a direct anticonvulsant effect, their major action in refractory epilepsy is to promote the biosynthesis of γ-aminobutyric acid (GABA), a key inhibitory neurotransmitter in mammalian brains. This would seem to be linked to increased TCA cycle activity, such that the increased synthesis of α-ketoglutarate leads to increased GABA production, which dampens the hyperexcitability indicative of epilepsy.

In an evolution of Wilder's original 4-to-1 ketogenic diet, the medium-chain triglyceride diet was developed in the late 1960s by Peter Huttenlocher. In this diet, medium-chain triglycerides (6–12 carbon atoms in length) are found to be significantly more ketogenic than long-chain triglycerides. The real benefit of this diet was that it permitted higher proportions of protein and carbohydrate, increasing the palatability of the diet. Despite various gastrointestinal side effects, the medium-chain triglyceride diet remains in clinical use throughout the world, although the medium-chain triglycerides are significantly more expensive than those obtained from animal fats.

One of the most recent ketogenic diets that became popular in the 1990s is the Atkins diet. In this regimen, the majority of the energy requirements are met by fat metabolism, which, as previously outlined, will be associated with significant ketogenesis. However, as this ketogenesis is driven by dietary fat, rather than stored fat, there is some uncertainty as to the true origin of the weight loss observed in the Atkins diet. More recent investigations of the mechanism of weight loss seem to suggest that it is the restrictive food choices that contributed most significantly to weight loss, rather than increased fat metabolism. In addition, concerns have been raised about the long-term effects on cardiovascular health with a diet high in fat. In this regard, evidence is conflicting, and it seems that, somewhat paradoxically, the Atkins diet decreases total cholesterol and triglycerides. This may be due to increased consumption of polyunsaturated fatty acids, which are known to decrease plasma low-density lipoprotein ('bad cholesterol') and increase high-density lipoprotein ('good cholesterol'). It may also be due to reduced availability of acetyl-CoA for isoprenoid (cholesterol) synthesis.

In the main, ketogenic diets are effective for moderate weight loss. Initial (rapid) weight loss is undoubtedly due to diuresis as excretion of ketone bodies in the urine (ketonuria) increases renal sodium and hence water loss. Furthermore, glycogenolysis, another hallmark of ketogenesis, is associated with water loss (2 g of water released per 1 g of glycogen broken down). The mechanism for later weight loss is much harder to explain. While it is true that the reduced insulin secretion found in high-fat diets increases lipolysis, it is unlikely that this would contribute significantly to overall weight loss. The general consensus is that it is the restrictive food selection that promotes weight loss, which, when coupled with the other factors discussed, leads to an overall moderate reduction in weight. Of course, since many of these diets are not sustainable in the long term, individuals often gain weight after the dietary intervention. A compromise has been suggested to include 30% fat, 50% carbohydrate (with a low glycemic index), and 20% protein.

Applications of Ketosis in Humans

Given the fairly central role of ketone bodies in human physiology, it is unsurprising that they have been the focus of research for many years. For example, consider the application of exogenous ketone bodies to improve athletic performance. We know from empirical evidence that ketone bodies increase the hydraulic output of the heart by ~25%. This would have obvious advantages in terms of increasing the perfusion of oxygenated blood. In a similar sense, the use of ketone body supplements may prove useful in patients following ischemic stroke, where oxygen supply is reduced. As ketone bodies can cross the blood–brain barrier, they may have the effect of reducing collateral damage to neighboring neuronal tissue.

An emerging area of research is in the use of ketosis to reduce the progression of free radical-mediated pathologies, such as Parkinson's disease and Alzheimer's disease. In the former, dopaminergic neurons are destroyed by the various actions of hydroxyl radicals, $HO^{\bullet}$. The underlying mechanisms of free radical generation are based on well-known reactions. Initially, superoxide anion, $OO^{\bullet -}$, is produced from the reaction of molecular oxygen with the partially reduced semiquinone moiety of coenzyme Q:

$$QH^{\bullet -} + O_2 \rightarrow OO^{\bullet -} + H^+$$

The superoxide produced is in itself a free radical and capable of mediating one-electron oxidation of biological molecules, as well as reduction of ferric iron to ferrous iron through the Haber–Weiss reaction:

$$OO^{\bullet -} + Fe^{3+} \rightarrow Fe^{2+} + O_2$$

The ferrous iron then participates in the formation of the highly toxic hydroxyl radical through the Fenton reaction:

$$H_2O_2 + Fe^{2+} \rightarrow HO^{\bullet} + HO^- + Fe^{3+}$$

From this sequence of reactions, it is clear that the initial event is the regulated production of reduced coenzyme Q in dopaminergic neurons. From earlier sections, we know that metabolism of ketone bodies oxidizes coenzyme Q, lowers the intracellular levels of the reduced form, and thus decreases oxidative stress. Similarly, ketone bodies restore the $NADP^+$/NADPH balance, replenishing endogenous antioxidants such as glutathione.

The etiology of Alzheimer's disease is complex, with some six different genes being implicated in its development. However, the formation of β-amyloid is a hallmark of Alzheimer's disease, which is believed to form as a result of an inflammatory response within neuronal tissue. In murine models of Alzheimer's disease, a ketogenic diet was found to reduce the deposition of β-amyloid, in a mechanism believed to involve the transporter protein monocarboxylic acid transporter-1, which maintains a positive energy balance within the brain. Ketone bodies may also have a direct antioxidant effect within cells. Acetoacetate and (*R*)-3-hydroxybutyrate both act as Brønsted–Lowry acids and are therefore capable of acting as proton-donating antioxidants. Also, the standard reduction potential for the reaction

$$\text{Acetoacetate} + 2e^- \rightleftharpoons (R)\text{-3-hydroxybutyrate}$$

has $E^{o'} = -0.346$ V, which is certainly sufficient to bring about the reduction of some radical species *in vivo*.

Given that a mild state of ketosis appears to have beneficial effects, a reasonable question would be 'how do we bring about a ketogenic state.' Obviously, fasting or a diet high in fat would bring about a ketogenic state, but this is not sustainable in the long term. Another approach is to use oral administration of sodium (*R*)(*S*)-3-hydroxybutyrate at a dose of ~ 900 mg kg^{-1} day^{-1}. This is sufficient to give a peak plasma level of around 0.36 mM; however, given the adverse side effects associated with the administration of large amounts of sodium salts, this approach is unsustainable in the long term. An interesting alternative is to use poly-(*R*)-3-hydroxybutyrate (Figure 5), a naturally occurring ester found in certain microbial species. This is extracted in large quantities to serve as a feedstock for polyethylene production, and hydrolysis of the ester into smaller units may serve as a useful source of therapeutic ketone bodies. A derivative of the oligomeric form, (*R*)-3-hydroxybutyl (*R*)-3-hydroxybutyrate (Figure 5), has recently been synthesized and tested in animal models with a view to use in human subjects.

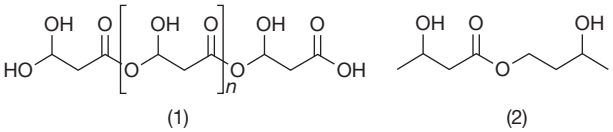

Figure 5 Novel sources of ketone bodies. Poly-(*R*)-3-hydroxybutyrate (1) and (*R*)-3-hydroxybutyl (*R*)-3-hydroxybutyrate (2).

Kiwifruit

P Padmanabhan and G Paliyath, University of Guelph, Guelph, ON, Canada

Introduction

'Kiwifruit' are the edible fruits produced by plants in the genus *Actinidia* Lindl. Kiwi plants originated from China where they grow wild, and they were brought to New Zealand in the early twentieth century by missionaries, where they were eventually domesticated and cultivated. In China, this fruit is known as 'mihoutao' (monkey peach) and it became known as 'Chinese gooseberry' in New Zealand. Its older name 'Chinese gooseberry' was considered unsuitable, and in 1959, the New Zealand fruit handling firm Turners & Growers Ltd. renamed this fruit as 'kiwifruit' to get a better marketing response when they first exported *Actinidia deliciosa* fruit to the United States. Within 10 years, kiwifruit had replaced 'Chinese gooseberry' as the common name for the fruit. *A. chinensis* and *A. deliciosa* are the most important *Actinidia* species under commercial cultivation accounting nearly for all international trade. In china, kiwifruit orchards are diverse with many different cultivars grown. *A. deliciosa*, the fuzzy kiwifruit, is the most widely available species and at present is under cultivation in many countries such as the United States, Italy, Chile, France, Greece, Brazil, and Japan. There is some commercial production in British Columbia (Canada).

Source and Production

Kiwifruit belongs to the family Actinidiaceae and is composed of more than 75 species and cultivars with a variety of sensory attributes and characteristics. Most *Actinidia* species are native to China. All *Actinidia* species are woody climbing vines. Vines are deciduous and dioecious. Male and female flowers are borne on different plants, and to ensure cross-pollination and fruit set, both sexes have to be planted in close proximity in a vineyard at the ratio of eight females to one male. Bees are necessary for pollination. Generally, vines do not flower until 3 or 4 years old. But *A. chinensis* is more precocious than *A. deliciosa*. Important *A. chinensis* cultivars in China are tetraploid, but 'Hort16A' is diploid. All cultivars of *A. deliciosa* are hexaploid ($2n = 6 \times = 164$). *Actinidia* species vary in their climatic requirements. But *A. chinensis* is more susceptible to winter cold and spring frosts. Kiwi plants flower about 2 months after bud break and fruit can be harvested 5–6 months after flowering. Generally, plants are propagated through vegetative or clonal methods. One preferred method of propagation is grafting varieties onto seedling rootstock. Occasionally, plants are also propagated by rooted cuttings of the preferred variety. Micropropagation through tissue culture has also been reported.

Cultivation of Kiwifruit

Commercial orchards of *A. deliciosa* were first established in New Zealand around 1930. Almost all currently cultivated kiwifruit cultivars are either derived from a few generations, removed from the wild, or selected directly from the wild. The most popular variety in New Zealand is 'Hayward'. Hayward was a selection of *A. deliciosa* made by Hayward Wright and subsequently named after him. It descended from a small number of seedlings derived from a single seed introduced into New Zealand from China at the beginning of the twentieth century. 'Hayward' has many favorable attributes such as large fruit, good flavor, and long shelf life. Hayward needs a growing season of about 225 to 240 frost-free days. For many years, Hayward was the only kiwifruit cultivar grown in all countries except China. Hayward and its associated males still account for at least 60% of the kiwifruit grown throughout the world.

The first *A. chinensis* cultivar established for commercial production was 'Hort16A' and the fruit was marketed as Zespri® Gold. 'Hort16A' is the result of a cross between a female (the product of open pollination of seedlings from a wild accession) and a male raised from a seed accession from the wild. It has bright yellow flesh and sweet flavor. 'Jintao' is the only other cultivar of *A. chinensis* becoming established commercially outside China, and its fruit is marketed as Jingold®. Both 'Hort16A' and 'Jintao' are protected cultivars. The Chinese kiwifruit industry produces more kiwifruit than any other country, but almost all are sold within China. In the past decade, other cultivars of *A. deliciosa* and other *Actinidia* species such as *A. arguta* also appeared in the market.

Recently, other *Actinidia* species such as *Actinidia arguta*, *Actinidia kolomikta*, and *Actinidia purpurea* are also gaining interest because of their frost resistance and capability to grow in cooler regions. *A. arguta* is hardy to −10 to −25 °C under most conditions. *A. arguta* is grown in Oregon in the United States, Europe, New Zealand, and Chile commercially and also by hobbyists. *A. arguta* fruits are smaller than the other *Actinidia*, but they can be readily consumed fresh as the fruit skin is edible being smooth and hairless. *A. arguta* or hardy kiwi plants are very vigorous and produce good quality, highly aromatic fruit that is quite different from the fruit of *A. deliciosa*. But their shelf life is limited and harvesting is labor-intensive. *A. kolomikta* is also small and sweet with high vitamin C content and is grown in colder areas. Kiwifruit are firm at harvest and soften during storage. Mature fruit can be stored for long periods. Kiwifruit are stored at or close to 0 °C. 'Hort16A' fruits are softer and have to be handled carefully, since they are more prone to damage. 'Hayward' can be stored for up to 6 months under refrigeration. But other *A. deliciosa* cultivars have short shelf life.

Fruit Morphology

Botanically, *Actinidia* fruits are berries with numerous black seeds embedded in a juicy pericarp. *Actinidia deliciosa*

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00409-8

(A. Chev.) 'Hayward' ('green' kiwifruit), a green fleshed kiwifruit, is the most common commercial variety with superior flavor. It is an oval berry about the size of a hen's egg with a light brown hairy skin and emerald-green flesh with numerous tiny black seeds embedded in a juicy pericarp. *Actinidia deliciosa* fruits have persistent long, hard, bristlelike hairs, which are partially removed during grading and packaging. The green color of the flesh of *A. deliciosa* is due to the presence of chlorophyll, which is retained during fruit maturation and ripening. The flesh has a combination of tangy, sweet, and sour flavors. The most common yellow-fleshed kiwifruit is *A. chinensis*, 'Hort16A'. *A. chinensis* fruits are usually covered with soft, downy hairs that are shed early in fruit development. Fruits of *A. chinensis* have a characteristic 'beak,' which is a protrusion of stylar end. Fruit flesh of *A. chinensis* is yellowish due to partial or complete loss of chlorophyll.

Patterns of Consumption

Ripe kiwifruit are generally eaten fresh. Fruits are served as appetizers as slices or chunks in fruit salads, salsas, yogurt, and ice cream. They are also used for making jelly, jams, chutney, and pickles. Kiwifruit are also freeze-dried and used as health food. Ripe fruits are used for making smoothies, sherbets, and various beverages. Kiwifruit are also processed into purees, sauces, drinks, mixed juices, soft drinks, wines, and spirits. Most processed products lack the attractive attributes of fresh fruit because processing results in changes to color, aroma, texture, and taste. Processing of kiwifruit is common in China than in other countries. Yellow-colored and sweet *A. chinensis* fruits are preferred for processing in China.

Nutritional Composition

The nutritional composition of fresh *A. deliciosa* and *A. chinensis* fruit per 100 g was presented in Table 1 (US Department of Agriculture, 2011). Kiwifruit are high in vitamin C, dietary fiber, and other numerous health-benefiting phytochemicals. It is also high in potassium and magnesium. Ripe *A. deliciosa* contain chlorophylls a and b and the carotenoids such as β-carotene, lutein, violaxanthin, and neoxanthin. In addition, kiwifruit also contain unusually high levels of myoinositol, a cyclic sugar alcohol found in many foods. Myoinositol level was high during the early stages of fruit development and falls to 1–2% with fruit ripening. Kiwifruit is not a significant source of energy.

Fibers

Kiwifruit contain approximately 2–3% (fresh wt) of nonstarch polysaccharide. Recent studies have shown that the dietary fiber of both green and gold kiwifruit constitutes about one-third of soluble fiber and two-thirds of insoluble fiber. However, gold kiwifruit contain less dietary fiber than green. The soluble fraction of fibers is composed of pectic polysaccharides, while the insoluble fiber is mostly cellulose and hemicellulose with small amounts of pectin. Kiwifruit can supply 10% of the recommended daily dietary fiber requirement.

Sugars

Glucose, fructose, and sucrose are the predominant sugars contained in *Actinidia*. The content and ratios of sugars vary with stages of maturity and variety of kiwifruit. A total sugar level of 8.4 g 100 g^{-1} fresh wt was reported in *A. deliciosa* Hayward. Total sugar content ranging from 7.7 to 10.8 g 100 g^{-1} fresh wt was also reported (New Zealand Institute for Plant & Food Research). The glycemic index for kiwifruit is relatively low and its sugar content has a beneficial effect on the blood sugar level.

Protein

Kiwifruit is not a significant source of protein. Kiwifruit contain actinidin, which is a cysteine protease known for its protein hydrolytic properties. Actinidin is the predominant soluble protein in green kiwifruit accounting for 40% of soluble protein. The other proteins identified include kiwellin and a thaumatin-like protein. Scientific reports on the role of actinidin in aiding digestion and digestive mobility are available.

Vitamin E

Kiwifruit contain fairly high levels of vitamin E and the main α-tocopherol form of vitamin E is in the flesh and therefore potentially bioavailable. A new form of vitamin E, δ-tocomonoenol, was reported in kiwifruit. The lipid content in kiwifruit is entirely confined to the seeds. Three vitamin E forms, β-sitosterol, stigmasterol, and its Δ isomer were identified from the crude pulp extracts of Hayward.

Carotenoids

Kiwifruit contain a variety of carotenoid compounds such as β-carotene, lutein, violaxanthin, and neoxanthin. Lutein and β-carotene are the most abundant carotenoids. Among the various commonly consumed fruits, kiwifruit contains the highest level of lutein ranging from 0.09 to 1.08 ± 0.17 mg 100 g^{-1} fresh wt. *A. arguta* and *A. rufa* have the highest lutein content followed by *A. deliciosa* and *A. chinensis*. *A. chinensis* and *A. deliciosa* have similar β-carotene content (0.07 ± 0.01 to 0.15 ± 0.04 mg 100 g^{-1} fresh wt), and *A. arguta* has the highest level of 0.29 ± 0.04 mg 100 g^{-1} fresh wt. In general, green varieties have higher total carotenoid content than the gold/yellow varieties.

Organic Acids

Citric, malic, and quinic acids, together with much smaller amounts of glucuronic and galacturonic acids, form the major acids in kiwifruit. Quinic acid occurs in exceptionally high concentration in kiwifruit. Generally, other fruits contain quinic acid in small amounts. Ascorbic acid also contributes to the acidity of kiwifruit.

Phytochemicals

Phytochemical analysis of crude extracts of kiwifruit pulp from 'Hayward' led to the identification of two caffeic acid glucosyl

Table 1 Nutritional composition of kiwifruit in 100 g edible portion[a]

derivatives, 2 coumarin glucosides, campesterol, chlorogenic acid, and some flavone and flavanol compounds. Phenolic compounds were separated and identified in kiwifruit juice. The level of phenolic compounds in juice was low. The major strongly acidic phenolic acid compounds identified include coumaric and caffeic acid derivatives including chlorogenic acid, protocatechuic acid, and a derivative of 3,4-dihydroxybenzoic acid. Catechin, epicatechin, procyanidin dimers, and oligomers are the weekly acidic phenolic acid in clarified juice. Glycosides of quercetin (glucoside, rhamnoside, and rutinoside) and kaempferol (rhamnoside and rutinoside) are the flavanols present. The total anthocyanin content in kiwifruit is lower than in many other berries, not significantly contributing to the antioxidant capacity of the fruit. In *A. deliciosa*, anthocyanins are found in a ring around the central core of the fruit. The major anthocyanin identified in the *A. chinensis* was cyanidin-3-O-xylo-galactoside, with smaller amounts of cyanidin-3-O-galactoside. In *A. deliciosa*, cyanidin 3-O-galactoside and cyanidin 3-O-glucoside are the major anthocyanins detected, and no cyanidin-3-O-xylo-galactoside was identified.

Health Effects

Antioxidant Capacity

Dietary antioxidants protect the cells from the oxidative reactive oxygen species generated during various cellular processes. Evidence from various studies supports the role of diets rich in fruits and vegetables in helping to reduce the risk from degenerative diseases, including cardiovascular diseases and cancer. Vitamin C, vitamin E, carotenoids, and phenolic compounds contribute to the antioxidant capacity of fruits. Generally, kiwifruit has high antioxidant capacity that appears to be largely influenced by vitamin C and polyphenol levels. The antioxidant capacity of *Actinidia* is strongly influenced by species and cultivars. Kiwifruit contain an array of antioxidants such as vitamin C, vitamin E, lutein, zeaxanthin, and other phytochemicals. Fruits of 8 *Actinidia* genotypes were evaluated for their antioxidant capacity by various assays (DPPH, ABTS, ORAC, FRAP, SASR, and MCC) by Du and coworkers in 2009. Significant genotype differences were noticed in the total antioxidant capacity as well as in the total phenolics and vitamin C contents of fruit. The antioxidant capacity of various kiwifruit cultivars also correlated well with their total polyphenol and vitamin C content. The wild species *A. eriantha* and *A. latifolia* have significantly higher antioxidant capacity (about 3.3–8.7-fold higher) than the other genotypes and ranked highest in antioxidant capacity. Vitamin C content generally varies from 50 to 430 mg 100 g^{-1} fresh wt in the 3 main species of *Actinidia*. *Actinidia chinensis* has higher vitamin C level than *A. deliciosa*. Also, the phytonutrient composition varies with the growing conditions, fruit maturity, and other postharvest conditions.

In a study conducted using Jurkat T cells, Hayward juice concentrate protected cells from cell death induced by hydrogen peroxide-mediated oxidative stress. Additionally, aqueous extracts from 4 *Actinidia* species remarkably suppressed intracellular peroxyl radical generation in Caco-2 colonic epithelial cells. Similarly, ingestion of kiwifruit juice improves free radical scavenging in human plasma. Regular consumption of green or yellow kiwifruit also increased vitamin C, vitamin E, and lutein/zeaxanthin levels in plasma. Consumption of green kiwifruit was associated with increased antioxidant capacity postprandially and thus may play a role in preventing postprandial oxidative stress. Studies also showed increased resistance towards oxidative DNA damage in human lymphocytes with the daily consumption of 1–3 green or gold kiwifruit. Reduced lipid peroxidation was also noticed with the consumption of kiwifruit.

Gut Health and Metabolic Function

Kiwifruit are high in both soluble and insoluble fibers containing about 3.4 g fiber per 100 g fruit. Kiwifruit contain high lignin content, which contributes to their insoluble dietary fiber content. Kiwifruit have also been known for its beneficial effect on gut health and also for its strong laxative properties. Evidence suggests that increased solubilization of polymers

occurs during ripening within the cell walls of kiwifruit, resulting in an enhanced ability to hold water. Several studies have demonstrated the usefulness of kiwifruit consumption in the treatment of constipation in healthy elderly persons. Actinidin, the proteolytic enzyme in kiwifruit, also enhances protein digestion in both the stomach and the small intestine in concert with the gastric and intestinal proteases. In another study, kiwifruit consumption significantly reduced the colon transit time in patients with irritable bowel syndrome. Kiwifruit has also been shown to be effective in treating iron deficiency. Significant improvement in iron status of young women with mild iron deficiency was noticed after consumption of gold kiwifruit along with an iron-fortified breakfast cereal. In a placebo-controlled crossover trial with 25 athletes, kiwifruit drink supplementation during athletic training was beneficial in maintaining blood glucose and mineral levels, with no significant effect on plasma insulin. Improvement in serum ferritin (nearly 50%) and hemoglobin concentrations was also noticed in women who consumed kiwifruit along with an iron-fortified breakfast. Aqueous extract of Gold kiwifruit also showed β-glucuronidase-inhibiting and β-glucosidase-promoting activity. Also, both gold and green kiwifruit extracts could promote the growth of fecal lactic acid bacteria and reduced the growth of *E. coli*.

Immune Functions

Kiwifruit is a good source of various phytonutrients and chemicals associated with healthy immune system. A small number of animal and human cell-based studies have investigated the immunomodulatory effects associated with kiwifruit consumption. Gold kiwifruit extract significantly enhanced innate and adaptive immune cell function of human blood cells *ex vivo*. Studies conducted in older adults and preschool children investigated the effects of regular consumption of gold kiwifruit on the incidence and symptoms of upper respiratory tract infections. These studies demonstrated that consumption of gold kiwifruit reduced symptoms of cold and flu and their severity in the study groups. Increases in plasma vitamin C, tocopherol, lutein/zeaxanthin, and erythrocyte folate concentration were also noticed in the older adults who consumed gold kiwifruit.

Cardiovascular Diseases

Consumption of 2 green kiwifruit daily for 4 weeks favorably affected plasma HDL-C, TC/HDL-C ratio, and apolipoprotein B/apolipoprotein A1 ratio in hypercholesterolemic man compared with a healthy control diet. Some other studies have also showed that the consumption of 1–3 green or gold kiwifruit per day for 4–8 weeks increased HDL-C, decreased TC/HDL-C ratio, and decreased triglycerides compared with baseline concentrations. In male smokers, consumption of 3 green kiwifruit per day for 8 weeks significantly reduced diastolic and systolic pressure compared with the control treatment. Further, a reduction in angiotensin-converting enzyme activity was also noticed.

Several studies investigated on the effect of *Actinidia* on processes and factors associated with the development of cardiovascular diseases. Plasma samples from healthy human subjects who consumed 2–3 kiwifruit per day for two 28-day periods showed a significant decrease in *in vitro* ADP-induced platelet aggregation, compared with control. Antioxidant and vitamin C levels of plasma were increased compared with control. Persons with hyperlipidemia who consumed kiwifruit for 8 weeks showed an increase in HDL cholesterol concentration. Additionally, blood antioxidant status improved and markers of lipid peroxidation was reduced. In another study, consumption of kiwifruit for 3 weeks had no effect on glucose or insulin levels or on lipid profiles. Studies have shown that kiwifruit is effective in the prevention of atherosclerosis as noticed in a study in which kiwifruit consumption resulted in a reduction in the levels of triglycerides in the blood by 15% compared with control.

Anticarcinogenic Activity

Two of the 12 phenolic compounds isolated from the roots of *A. chinensis* showed remarkable cytotoxic activity against P-388 (leukemia) and A-549 (carcinomic human alveolar basal epithelial cells) cell lines. In another study, a polysaccharide compound isolated from the root of *A. chinensis* also demonstrated antitumorous activity in mice. Various extracts from gold kiwifruit showed selective cytotoxicity against human oral tumor cell lines. Two triterpenoids isolated from *A. chinensis* roots also showed cytotoxic actions against human adenocarcinoma and human liver carcinoma cell lines. Extracts from *A. arguta* strongly inhibited the growth of HepG2 and HT-29 cells. In *in vitro* systems, extracts or juices from kiwifruit showed antimutagenic effect towards chemical carcinogens including the heterocyclic amines, such as 2-amino-1-methyl-6-phenylimidazo [4,5-b] pyridine (PhIP).

Other Uses

In ancient China, *Actinidia* plants were used for symptom relief of numerous disorders, such as digestive problems, rheumatism, dyspepsia, and hemorrhoids, as well as a therapy for various cancers. Extracts from various plant parts of *A. chinensis* (leaves, fruit, and stem) showed antibacterial activity against Gram-positive and Gram-negative bacterial strains. The antibiotic activity of fruit was contained in the seeds, and in general, antibacterial activity of fruit extracts was more than the vegetative plant parts.

Kiwifruit Allergy

Kiwifruit also contain allergens that can result in allergenic reactions in susceptible individuals. Allergy to kiwifruit was first reported in 1981 in a 53-year old woman who developed urticaria, wheeze, and laryngeal edema on handling the fruit. Since then, there have been an increasing number of reported kiwifruit allergies as consumption of this fruit continues to expand worldwide. Kiwifruit allergy can take several different forms. Symptoms of kiwifruit allergy are often manifested as oral allergy syndrome and urticaria. Oral allergy syndrome consists of itching of mouth, lips, and throat; swelling of lips and throat; and formation of small blisters in the oral mucosa. Other reported symptoms are indigestion, nausea, vomiting,

wheeze, rashes on skin, and other severe allergic reactions such as anaphylaxis. Some individuals develop allergy as a result of eating kiwifruit, while in others, allergy is associated with pollen and latex allergies. This is due to the similarity between the allergens in kiwifruit and natural rubber latex, a condition known as the latex-fruit syndrome.

Certain varieties of Kiwifruit, gold kiwifruit, contain less allergen than the green variety. However, people allergic to green kiwi fruit can also react to gold or yellow variety. There are also cross-reactions between kiwi and several other fruits such as avocado, banana, fig, chestnut, melon, sesame seeds, poppy seeds, hazelnuts, and rye grain. In the last few decades, occurrence of kiwi fruit allergy in some European countries is increasing. Several components in kiwifruit have been tentatively identified as potential allergenic agents. Eleven allergens from kiwifruit, *A. deliciosa* 'Hayward', have been registered in the Allergen Nomenclature Database including 30 kd cysteine protease actinidin, 24 kd thaumatin-like protein, 26 kd cell wall protein kiwellin, and cysteine protease inhibitor cystatin. Actinidin is the most recognized major kiwifruit allergen. A study conducted among school children in France reported that kiwifruit allergy is as common as egg and peanut allergies. Three allergens from *A. chinensis* were officially recognized.

Kiwifruit are also relatively high in oxalate content and is mainly concentrated in the skin, inner pericarp, and seed. The presence of calcium oxalate may cause oral irritation. Evidence suggests that oxalate may interfere with nutrient absorption and are also involved in kidney stone formation if oxalate-rich foods are consumed in excess. In green kiwifruit, the oxalate content varies between 18 and 45 mg 100 g^{-1} of fresh wt and is concentrated in the skin, inner pericarp, and seed. Oxalate content varies with species and fruit maturation. The oxalate levels vary between species reaching a maximum during fruit development and reducing during fruit maturation and storage.

Laboratory Management: Microbiological Safety

A Kurdziel, Food and Environment Research Agency, York, UK

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Whenever human pathogens are cultured, a risk exists to human health. This risk is both for the workers in the laboratory and to anybody who might be exposed to the pathogens that are inadvertently transmitted to people outside of the laboratory. There is a moral, economic, and legal responsibility to control that risk as far as is reasonably possible.

To help managers of food microbiology laboratories, guidance exists in the form of the World Health Organization (WHO) Laboratory Biosafety Manual, 3rd Edition.

Beyond guidance in most jurisdictions, a legal framework exists describing the requirements for managing laboratory safety. In some parts of the world, laboratories operate outside the main framework to managing occupational safety and health, but in the EU, for example, laboratories are treated as just another workplace and are subject to the same sort of controls that any other workplace is subjected to. In the EU, the Biological Agents Directive (Council Directive 90/679/EEC of 26 November 1990 on the protection of workers from risks related to exposure to biological agents at work, OJ No L 374, p. 1) sets out how member states of the EU must approach workers' safety in relation to work with biological agents.

All of these guidelines rely on particular concepts including

- classification of biosafety levels relating to the types of pathogens that are being examined in a particular laboratory or are likely to occur in such a laboratory (even though these might not be the organisms being examined),
- assessing the risks that these organisms pose and then adopting controls that are appropriate and suitable for these organisms.

This article will go into more detail describing these classifications and then describe how to apply a risk assessment in a food microbiological laboratory.

Hazards

In occupational health and safety, a hazard is defined as something that poses a level of threat to life, health, or the environment. The hazard has the potential to cause harm, with only a theoretical risk of actual harm; however, once a hazard becomes 'manifest,' it can create an actual risk. If a risk is identified, it must be controlled.

The level of risk is often described as follows:

$$\text{Level of risk} = \text{severity of the hazard} \times \text{likelihood of it becoming manifest}$$

Identification of hazard severity is the first step in performing a risk assessment.

Under the WHO system, the severity (i.e., the potential for harm) of the various pathogens is classified using the criteria in Table 1.

This process should be carried out whenever work with pathogens is being planned. In many jurisdictions, government occupational health agencies, such as the Health and Safety Executive (HSE) in the United Kingdom, publish guidance notes that classify pathogens in accordance with this approach.

The aim is to assign pathogens to one of 4 biosafety groups (or hazard groups).

The classifications are shown in Table 2.

The HSE guidance is published as 'The Approved List of biological agents. HSE – Advisory Committee on Dangerous Pathogens. Misc208(rev2).'

Foodborne organisms will fall mainly into risk group 2 with some being classed as being risk group 3. No foodborne organisms fall into risk group 4.

Table 1 Criteria for classifying human pathogens

1. Pathogenicity of the agent and infectious dose
2. Potential outcome of exposure
3. Natural route of infection
4. Other routes of infection, resulting from laboratory manipulations (parenteral, airborne, ingestion)
5. Stability of the agent in the environment
6. Concentration of the agent and volume of concentrated material to be manipulated
7. Presence of a suitable host (human or animal)
8. Information available from animal studies and reports of laboratory-acquired infections or clinical reports
9. Laboratory activities planned (sonication, aerosolization, centrifugation, etc.)
10. Any genetic manipulation of the organism that may extend the host range of the agent or alter the agent's sensitivity to known, effective treatment regimens
11. Local availability of effective prophylaxis or therapeutic interventions

Table 2 Biosafety risk groups

Risk group	*Description*
Risk group 1 (no or low individual and community risk)	A microorganism that is unlikely to cause human or animal disease
Risk group 2 (moderate individual risk, low community risk)	A pathogen that can cause human or animal disease but is unlikely to be a serious hazard to laboratory workers, the community, livestock, or the environment. Laboratory exposures may cause serious infection, but effective treatment and preventive measures are available and the risk of spread of infection is limited
Risk group 3 (high individual risk, low community risk)	A pathogen that usually causes serious human or animal disease but does not ordinarily spread from one infected individual to another. Effective treatment and preventive measures are available
Risk group 4 (high individual and community risk)	A pathogen that usually causes serious human or animal disease and that can be readily transmitted from one individual to another, directly or indirectly. Effective treatment and preventive measures are not usually available

Although a laboratory may be designated for handling a particular risk group, as a laboratory cannot completely control the samples it receives, it might find itself inadvertently handling organisms of a higher risk group than anticipated. There should be a procedure for dealing with these sorts of situation in the individual laboratory's code of practice (CoP).

If a sample is receiving samples of unknown provenance, then it should be assumed that organisms in risk group 2 are present unless there is any evidence to suggest that organisms of a higher risk group are present.

Risk Assessment

When assessing the risk from biological agents in a laboratory, one needs to look at the following:

(a) Biosafety group classification of any organisms being cultured or tested for in the laboratory.
(b) The type of work being carried out, in particular if it gives rise to aerosols such as centrifugation or vortexing.
(c) The concentration of the cultures. The higher the concentration, the higher the risk.
(d) The sort of controls that the laboratory has adopted such as the use of microbiological safety cabinets (MSCs).
(e) The results of relevant health surveillance; is there any evidence of laboratory-acquired infections among the staff?
(f) The results of monitoring by, for example, the use of air plates or culturing swabs taken from work surfaces.
(g) Individual factors such as the physical capability of the staff working in the laboratory must also be taken into account. Particular care must be taken with pregnant staff. They are both physically at risk and directly at risk from certain pathogens such as *Listeria monocytogenes*. This infection during pregnancy can lead to miscarriage, stillbirth, premature delivery, or life-threatening infection of the newborn. In such cases, pregnant women should not be allowed access to the laboratory.

Once a risk assessment has been carried out, it must be recorded and the findings circulated to the relevant stakeholders including the staff.

The risk assessment must be regularly reviewed to make sure that it still valid. In particular, it must be checked to make sure that there has not been any 'method drift.' This occurs when an established method gradually changes over the years and the risk assessment is not updated alongside of this.

The person carrying the risk assessment must be competent to do so. He or she must

- understand local legal requirements in relation to work with human pathogens,
- understand the hazards of working with human pathogen,
- understand the nature of the work taking place within the laboratory and details of the work taking place there,
- be in a position to recommend what the controls might be suitable and to see them carried out.

It might be necessary for the risk assessment to be carried out collectively with several people working together to gather the information necessary and to assess the likelihood of exposure to human pathogens. One individual should coordinate, consult, compile, assure quality, record, communicate, and implement the risk management measures and monitor their effectiveness, as well as consider the need for reviewing the assessment.

Controls

Having created the risk assessment, it is necessary to adopt control measures that will make the risk of infection in the staff as low as reasonably practicable. The biosafety level requirements are compiled in Table 3.

The four key control areas are

- the people working in the laboratory,
- the equipment in the laboratory,
- the methods being used in the laboratory,
- the laboratory environment.

People

No system or level of equipment can create a safe working laboratory unless the laboratory has competent staff. Competency is defined as the ability for an employee to do a job safely without creating risks to themselves, their colleagues, or the wider community. It is a combination of practical and theoretical knowledge, cognitive skills, behavior, and values used to maintain safety. It can also be described as being suitably qualified, having the ability to perform a specific role. Competency can be summarized by saying it demonstrates

Table 3 Summary of biosafety level requirements

	Biosafety level			
	1	*2*	*3*	*4*
Isolation of laboratory[a]	No	No	Yes	Yes
Room sealable for decontamination	No	No	Yes	Yes
Ventilation				
Inward airflow	No	Desirable	Yes	Yes
Controlled ventilating system	No	Desirable	Yes	Yes
HEPA-filtered air exhaust	No	No	Yes/no[b]	Yes
Double-door entry	No	No	Yes	Yes
Airlock	No	No	No	Yes
Airlock with shower	No	No	No	Yes
Anteroom	No	No	No	–
Anteroom with shower	No	No	Yes/no[c]	No
Effluent treatment	No	No	Yes/no[c]	Yes
Autoclave				
On site	No	Desirable	Yes	Yes
In laboratory room	No	No	Desirable	Yes
Double-ended	No	No	Desirable	Yes
Biological safety cabinets	No	Desirable	Yes	Yes
Personnel safety monitoring	No	No	Desirable	Yes
View of working laboratory[d]	Not required	Desirable	Yes	Yes

[a]Laboratory should be separated from general traffic routes with limited or controlled access.
[b]Depends on location of exhaust outlet.
[c]Depends on agents being used in the laboratory.
[d]For example, a window, viewing panel, or closed circuit television showing the working interior of the laboratory.

- workers with the correct skills,
- workers with the correct knowledge,
- workers with a suitable attitude,
- workers with appropriate training,
- workers with relevant experience.

All staff working in a food microbiology laboratory should be trained in good microbiological techniques.

They should understand the equipment that they are working with. Manuals should be kept in the laboratory and be available to the staff.

Young staff tend to be more inexperienced than older staff and as such at higher risk. In some jurisdictions, statutory limits are placed on the age at which people are allowed to work in a microbiological laboratory.

The laboratory needs to be managed. There should be a competent individual chosen to act as the biosafety manager. They should have the authority to oversee all of the work that is being carried out in the laboratory and if necessary stop any work that they believe poses an unacceptable risk.

Human factors such as staff attitudes and morale are key for safe management in a laboratory. Well-motivated staff are generally safer in a laboratory and less likely to have accidents. They are also more likely to be open with management and be willing to discuss any issues including safety issues.

Equipment

General

The equipment in a laboratory should be designed so that it can be easily disinfected.

Figure 1 Typical laboratory hand basin incorporating an eyewash facility.

Ideally, it should be movable or portable so that it can be moved so that floors and bench tops underneath it can be routinely disinfected.

In laboratories working at biosafety level 3 and above, the equipment will need to be able to resist severe decontamination methods such as fumigation with formaldehyde.

The laboratory should have adequate washing facilities. This should consist of a hand basin (equipped with soap), which is separate from any other laboratory sinks.

Some form of eye wash is also required. Ideally, this should be an eyewash connected to the laboratory water supply, but if that is not practicable, then a supply of sterile eyewash bottles might suffice. The risk assessment will inform this decision (Figure 1).

The laboratory should have sufficient benching for the work to be carried out safely. It should be stable and easy to clean. It should be resistant to routine laboratory chemicals, in particular to any disinfectants used in the laboratory.

It should be possible to clean under the bench to prevent the buildup of any debris.

There should be sufficient seating for the staff to work comfortably at the bench where there should be space underneath the benching for them to fit their legs while sitting.

There should be suitable storage within the laboratory; typically, this will consist of shelving, which should be strong enough to support the weight of any items that will be stored on it. The role of such shelving is to clear as much space as possible on the benching, which should be used as far as possible for actual work.

It might be necessary to create special storage facilities for things like toxic reagents and drugs. These need to be secure and might have to be kept under lock and key (often, these matters are regulated under local regulations). The key will need to be kept with a responsible person.

Most laboratories will include freezers and fridges. These might also need to be kept locked if they contain microbiology culture collections.

Incubators need to be kept clean and should be regularly disinfected.

Autoclaves

The WHO Laboratory Biosafety Manual recommends that the laboratory have access to an autoclave for the disposal of contaminated equipment, media, and consumables. This will have to be disposed of in accordance with local laws.

The requirements for the provision of an autoclave in a laboratory are as follows:

1. The autoclave must be capable of maintaining a temperature capable of sterilizing a load safely. Typical temperatures would be 121 °C for 15 min. The risk assessment process will identify what would be the appropriate temperature and duration of sterilization for a particular laboratory and the sort of loads that it needs to deal with.
2. Before the heating cycle takes place, the autoclave must reduce the air pressure in the chamber to ensure that the superheated water vapor penetrates the load completely.
3. There must be a way to confirm that the load has actually achieved this temperature during serialization. This is usually done with an internal temperature probe installed in the autoclave, inserted into a test load, typically a container of water in the middle of the load.
4. There must be a way to test that sterilization has actually occurred. This is usually done using test stripes containing *Bacillus subtilis* spores, which are then cultured.
5. The autoclave must include a pressure relief mechanism that will prevent the chamber from becoming overpressurized.
6. There should be a thermal lock that prevents the chamber from being opened while the internal temperature of the sterilizing chamber is above 80 °C. An override key should not be kept in the machine, but kept securely by an authorized person.
7. The machine and in particular its pressure chamber will need to be checked periodically by a suitably qualified person. There may be local laws dealing with this matter.
8. Care must be taken when loading the autoclave and in particular the staff should avoid placing chemicals (including disinfectants) in any load. This might create vapors containing hazardous chemicals.

If loads of contaminated material are to be taken out of the laboratory (e.g., to be autoclaved), they should be transported in suitable containers with watertight lids, which will not spill their contents if they are accidently dropped or turned on their sides.

Microbiological safety cabinets

MSCs are a form of local exhaust ventilation. They are designed to contain any harmful aerosols from tasks that might be carried out at a bench, for example, centrifuging and macerating.

They should not be confused with fume cupboards, which, as their name suggests, are designed to control volatile fumes. The MSC consists of an enclosed work area, which is under negative pressure (it draws air in) to the room it is in. This prevents aerosols from affecting the operator. Air is exhausted from the MSC through a high-efficiency particulate absorbent (HEPA) filter, which prevents dispersal of any pathogens to the room.

MSCs should not be confused with laminar flow cabinets. The latter are not intended to provide operator protection. Their sole function is product protection; as such, they must never be used for any pathogen manipulation.

There are three types of cabinet available:

- Class I
- Class II
- Class III

Class I cabinets

These types of cabinet draw air from the laboratory through the opening at the front and force it out through a HEPA filter. By maintaining a high negative pressure relative to the laboratory, they ensure that no aerosols produced in the cabinet can escape into the laboratory.

The main disadvantage of these types of cabinet is they confer no aseptic protection on work being carried out in the cabinet.

Class II cabinets

These types of cabinet draw air from the laboratory through a filter. Then the airflow is split. Part of it forms an 'air curtain' at the front opening of the cabinet, and the rest is blown through the cabinet and then out through a HEPA filter. They maintain a negative air pressure relative to the laboratory, but particles from the laboratory should not be able to enter the cabinet directly. This means that a Class II cabinet does provide aseptic protection for work inside it. These cabinets are rather complicated, and it is very easy to disrupt the air curtain in front of the cabinet, reducing or even eliminating user protection.

Class III cabinets

These are in some ways the simplest of cabinet designs. Air is drawn into the cabinet through a HEPA filter and discharged through a HEPA filter. To work in the cabinet requires operators to use long gauntlets attached to ports at the front of the cabinet. These are very restrictive of movement but provide the highest level of operator protection. These are used for work with organisms in biosafety groups 3 and 4.

MSCs should be carefully positioned so that they work at maximum efficiency.

They must be kept as free of clutter as possible (especially class II cabinets).

They should be routinely tested to make sure that they are working correctly by an external engineer or technician. Such testing is often legally mandated and complies with a set standard such as BS EN 12469:2000 'Biotechnology – Performance criteria for microbiological safety cabinets.'

Methods

All people working in a food microbiology laboratory need to be trained in the methods and work procedures that take place there.

All methods and policies and procedures should be written up, and these documents need to be managed in such a way that everybody has current copies of these documents available.

All the methods used should be covered by a risk assessment.

Code of practice

There should be a local CoP that will describe the overall system of work that is to be carried out in the laboratory. It will define the following:

1. What work can take place in the laboratory, in particular what biosafety group organisms will be cultured and tested for in the laboratory.
2. The level of competence of the people working in the laboratory.
3. The level of supervision in the laboratory, identifying those staff who can work alone and those that can only work under supervision. This might depend on what sort of work individuals are actually doing.
4. The code should also describe the sort of training that the staff might need. This might be formal training supplied by a teaching establishment or provider. It might be informal 'on-the-job' training.
5. As well as routine procedures, there must be a procedure for dealing with any sort of emergency, for example, a spillage of a liquid culture. All staff must be aware of what is required of them to be able to deal with the emergency without putting themselves at risk. It would be unacceptable to expect untrained cleaning staff, for example, to clear up microbiological contamination. Such staff should only be used if the area has been rendered safe (by, e.g., disinfection).

General hygiene and disinfection

Food samples once brought into the laboratory must be treated as if they were contaminated. The staff must never be allowed to take food samples home even if they have not been purposefully contaminated or analyzed and found uncontaminated. It should be assumed that any food in the laboratory is contaminated, and eating and drinking are not permitted in any laboratory.

Mouth pipetting of liquids should not be permitted in any laboratory. Liquids should be dispensed using a mechanical or electric pipetting device.

There should be a standard procedure for disinfection, which is available for all staff to follow.

It must describe which sort of disinfectants to use in relation to which sort of materials. There is no such thing as a universal disinfectant. Each disinfectant has its own specific range of activity. Manufacturers should be able to define this range.

A disinfectant cannot act instantaneously but requires a minimum period of contact time for it to produce its microcidal effect. Once applied, a disinfectant must be left for this minimum period before it is cleaned up. Again, the manufacturer's guidance should define this minimum contact time.

Usually, when the efficacy of a disinfectant is established, it is done on a clean surface. This does not always produce a realistic estimation of its actual effectiveness. Disinfectants can be inhibited by substances like blood, soil, and similar biological substances.

Many disinfectants have a limited shelf life especially those that are made up in a solution prior to use. Care should be taken to make sure that only 'in date' disinfectants are used.

There is no such thing as a totally safe disinfectant; all disinfectants pose some risk to users. All staff working in the laboratory must be trained in how to use the disinfectants correctly and safely. In particular, they need to be told when not to mix disinfectants together.

Laboratory Environment

The laboratory environment must be maintained as a comfortable place to work. It should be temperature-controlled and suitably ventilated. This will probably require some sort of forced air ventilation. If this is installed, then the laboratory must be kept at a negative air pressure in relation to the outside of the laboratory. The air exhaust from the laboratory should be discharged in a place where it does not pose a risk to people in the location. There might be local laws defining how and where such air can be exhausted. They might also require that the air be filtered in some way.

The laboratory should have sufficient space for the work being carried out. There should be space to move about safely and to enable people to work at the benches without them colliding with each other. The laboratory should not be used as a thoroughfare between different rooms.

It might be necessary to install some form of access control to the laboratory, for example, a card swipe or combination lock.

There should be sufficient light for the work taking place, so that the staff can see what they are doing. This will involve artificial lighting, and it might be necessary to provide local task lights in some parts of the laboratory.

The floors should be easy to clean and resistant to routine laboratory chemicals and also have a seamless seal between floors and walls, especially in C3 labs.

Table 4 Requirements for the safe management of a food microbiology laboratory

1. A suitable and sufficient risk assessment for the work that is to be carried out in the laboratory
2. Appointment of competent staff to operate the laboratory including a biosafety manager
3. Establishing a code of practice to set out the basic rules for working in this laboratory
4. Equipping the laboratory with all of the necessary equipment and arranging for this equipment to be maintained while in use in the laboratory
5. Proving sufficient training, information, instruction, and supervision to all staff working in the laboratory so that they can carry out their work safely
6. Monitoring the work in the laboratory to ensure that it is being carried in accordance with the requirements of the code of practice
7. Periodically reviewing the code, the policies and procedures, and the methods in use to ensure that they are still fit for purpose and pose the minimum risk to the staff working in the laboratory

All waste should be routinely removed from the laboratory and not allowed to accumulate. It should be disposed of in accordance with local laws. Contaminated material should be autoclaved or sent for incineration.

The lab and especially the benches should be routinely disinfected, usually at the end of the working day.

Summary

The requirements for the efficient safe management for a food microbiology laboratory are summarized in Table 4.

Conclusion

Work with any sort of human pathogens including foodborne pathogens poses a risk to the staff working in the laboratory. This risk can be identified through a process of risk assessment and then mitigated by applying the types of controls described in this article.

There is no reason why people in a food microbiology lab should be exposed to any significant risks to their health through their work.

Introduction

Taxonomy and Metabolism of Lactic Acid Bacteria

Lactic acid bacteria (LAB) are a heterogeneous group of phylogenetically closely related microorganisms that produce lactic acid as the major or sole product of carbohydrate fermentation. LAB are Gram positive, nonsporulating, catalase-negative, acid tolerant, nonrespiring but aerotolerant, usually nonmotile cocci or rods with low Guanidine + Citosine (G + C) content. Except for a few species belonging to the *Streptococcus*, *Enterococcus*, *Lactococcus*, and *Carnobacterium* genera, LAB are nonpathogenic with a generally recognized as safe (GRAS) or food-grade status.

LAB have complex nutritional requirements for amino acids, peptides, nucleotide bases, vitamins, minerals, fatty acids, and carbohydrates, components that are usually present in the natural niches they inhabit. These microorganisms are found in a plethora of environments such as plant materials and dairy-, meat-, and cereal-based (fermented) foods, the animal gastrointestinal tract and vagina, and in soil and water. Their ability to inhabit different niches is trait of their metabolic diversity and adaptability.

The monograph on LAB written by Orla-Jensen in 1919 greatly affected the systematics of these microorganisms; LAB were classified based on their morphology, mode of glucose fermentation, ability to grow at different temperatures, and use of sugars as carbon substrates. Other features, such as configuration of lactic acid produced and tolerance to salt, acid, and alkali, were also considered. According to the current taxonomic classification LAB belong to the phylum Firmicutes, class Bacilli, order *Lactobacillales*. The families include Aerococcaceae, Carnobacteriaceae, Enterococcaceae, Lactobacillaceae, Leuconostocaceae, and Streptococcaceae. Four main genera of LAB, namely *Lactobacillus*, *Leuconostoc*, *Pediococcus*, and *Streptococcus*, were originally described; however, recent taxonomic revisions have proposed the following new genera: *Aerococcus*, *Alloiococcus*, *Carnobacterium*, *Dolosigranulum*, *Enterococcus*, *Globicatella*, *Lactococcus*, *Oenococcus*, *Tetragenococcus*, *Vagococcus*, and *Weisella*. Of all the genera mentioned, the lactobacilli and carnobacteria are rods; the remaining genera are cocci, except for *Weisella* species, which may be either rods or cocci. Researchers classified some of the newly described genera using fatty acid composition and motility features.

With the availability of improved molecular methodologies such as 16S rRNA gene sequencing and studies on the microbial diversity of different environments, many species have been discovered and identified. Thus, the heterogeneous LAB group consists of about 450 species distributed as follows: *Aerococcus*, 7; *Alloiococcus*, 1; *Carnobacterium*, 12; *Dolosigranulum*, 1; *Enterococcus*, 49; *Globicatella*, 2; *Lactobacillus*, 189; *Lactococcus*, 7; *Leuconostoc*, 23; *Pediococcus*, 15; *Oenococcus*, 2; *Streptococcus*, 101; *Tetragenococcus*, 5; *Vagococcus*, 8; and *Weisella*, 18.

LAB are defined as chemotrophic microbes as they generate energy (ATP) by substrate-level phosphorylation. Although these bacteria ferment sugars when they grow under anaerobic conditions, they can also grow in the presence of oxygen. Despite their well-established fermentative metabolism, several LAB species can switch from fermentation to aerobic respiration metabolism when heme or heme and menaquinone groups are provided. Electron transport chains and evidence of cytochromes in heme-grown cultures were reported first in lactococci, leuconostocs, and some enterococci. Interestingly, it has been observed that, in *Lactococcus lactis*, respiration has a positive effect as bacterial biomass increases together with oxygen resistance and survival.

Sugar metabolism

Sugars are the primary carbon and energy sources for LAB grown on substrates used for fermented foods and feed production, as well as in laboratory media. According to the way LAB ferment carbohydrates, they are classified as homofermentative or heterofermentative. Homofermentative LAB (*Lactococcus*, *Streptococcus*, *Pediococcus*, *Enterococcus*, and some *Lactobacillus* species) ferment sugars by the Embden–Meyerhoff–Parnas pathway to pyruvate, which is converted into lactic acid by lactate dehydrogenase (LDH). Two types of lactate isomers, L and D, can be produced by stereospecific nicotinamide adenine dinucleotide (NAD)-dependent enzymes, L-LDH and D-LDH. Under certain growing conditions such as carbon limitation, the homolactic metabolism can be shifted to a mixed-acid metabolism where formate, acetate, ethanol, and/or CO_2 besides lactate, are produced (Figure 1).

Heterofermentative LAB such as *Leuconostoc*, *Oenococcus*, and certain *Lactobacillus* species ferment sugars generally by the phosphoketolase pathway (PKP, also known as the pentose phosphoketolase shunt or the 6-phosphogluconate pathway). Fermentation of pentoses such as xylose and ribose leads to the formation of pyruvate and acetyl-P and their subsequent conversion to lactate and acetate, respectively. Hexoses (i.e., glucose, fructose, and mannose) can be converted to lactate, CO_2, and ethanol. CO_2 is a product of 6-P-gluconate degradation, which occurs during conversion of hexoses to pentoses. The specific enzyme of the heterofermentative pathway is D-xylulose-5P phosphoketolase, which catalyzes the conversion of xylulose-5P into glyceraldehyde-3-phosphate (GAP) and acetyl-P.

The fermentation type (homolactic or heterolactic) is an important taxonomic criterion. The genera *Leuconostoc*, *Oenococcus*, and *Weisella* as well as certain *Lactobacillus* species such as *Lactobacillus buchneri*, *Lactobacillus brevis*, *Lactobacillus fermentum*, and *Lactobacillus reuteri* are obligate heterofermentative. Other lactobacilli, including *Lactobacillus acidophilus*, *Lactobacillus delbrueckii*, *Lactobacillus helveticus*, and *Lactobacillus salivarius*, are obligate homofermentative and not able to metabolize pentoses. Finally, *Lactobacillus casei*, *Lactobacillus curvatus*, *Lactobacillus plantarum*, *Lactobacillus sakei*, and most LAB can homofermentatively ferment hexoses and pentoses and are known as *facultatively heterofermentative*.

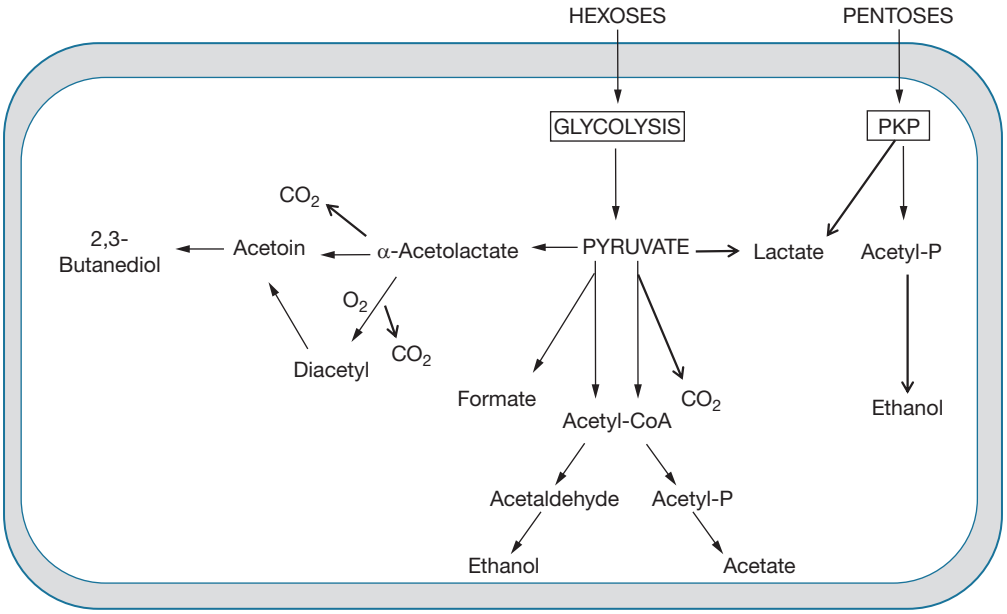

Figure 1 Sugar metabolism in LAB.

Pyruvate has a key role in the fermentation pathways; it usually acts as an electron acceptor to form lactic acid and to help maintain the intracellular redox balance. Nevertheless, and depending on the LAB species, pyruvate can be metabolized by different enzymes leading to the synthesis of different metabolites such as diacetyl/acetoin, formate, and acetyl-coA, which can subsequently yield ethanol or ATP and acetate. Also, oxygen and fructose may be used as alternative electron acceptors rather than pyruvate.

In addition to being capable of fermenting several monosaccharides, LAB can also use disaccharides as energy substrates. In this regard, lactose metabolism has been extensively studied, especially in those species commonly used in dairy applications. In this case, lactose can enter the cell through a lactose-specific permease or a lactose-specific phosphoenolpyruvate–phosphotransferase (PEP–PTS) system or both. In the first system, lactose is cleaved into glucose and galactose by a beta-galactosidase enzyme, which in turn can be fermented through the main fermentation pathways. If lactose enters the cells by a PEP–PTS system, lactose-P is split into glucose and galactose-6-P by the enzyme phospho-beta-galactosidase. On the other hand, the disaccharides maltose (present in barley) and sucrose (present in vegetables and fruits) can also be used by certain LAB members.

Nitrogen metabolism

Many LAB have a very limited capacity to synthesize amino acids from inorganic nitrogen sources so they depend on the availability of amino acids present in the environment or growth medium. Dairy LAB highly depend on their proteolytic system, which in turn can degrade external proteins and transport the resulting peptides and amino acids into the cell. The proteolytic system of LAB has been intensively studied, especially in model organisms such as dairy lactococci but also in many lactobacilli such as *Lactobacillus helveticus* and *Lactobacillus delbrueckii* subsp. *lactis*.

Degradation of casein, the major milk protein, is dependent on a cell wall-associated proteinase; this protease hydrolyzes casein into oligopeptides of varied sizes that in turn enter the cell by different transport systems. Inside, peptides are further degraded into amino acids for microbial metabolism and growth.

Applications of LAB

Microbial fermentation increases the shelf-life of perishable raw materials and imparts a characteristic flavor to the fermented products. In addition, fermentation by beneficial microorganisms often introduces or increases health benefits.

Since ancient times, LAB have been empirically used in the preservation and production of fermented foods of plant or animal origin. Since the 1930s and 1940s, LAB have been used as lactic starter cultures in the fermented food industry. Later, because of increased knowledge in the immunology field, these microorganisms started to be used as probiotics, while much more recently efforts have been made to use LAB as microbial cell factories for the production of interesting metabolites. These applications are discussed later in the section 'LAB as Microbial Cell Factories'.

LAB as Starter Cultures in the Food Industry

LAB, the so-called powerhouse or workhorse microbes of the fermented food industry, are intensively employed in food and feed fermentation as well as in food biotechnology.

The ability of LAB to produce lactic acid from various sugars plays an important role in food fermentation. As lactic acid derives from pyruvate (a glycolysis end product), a fast and desirable lactic acid production rate requires a high glycolytic flux. In addition to lactic acid, other alternative end products such as ethanol, acetic acid, and formic acid are formed by many species. LAB have the ability to ferment a variety of

substrates from dairy, meat, vegetables, and cereals, transforming them into tasty products with unique textures and improved (longer) shelf lives. Depending on the raw material, specific, niche-adapted LAB genera and species are employed to carry out fermentation to produce a variety of fermented foods and beverages such as yogurts, fermented milks, buttermilk, kefir, cheeses, fermented sausages, fermented fish, sourdough, pickles, olives, sauerkraut, and other fermented vegetables and fruits. Examples of such fermented foods and beverages and the LAB involved are shown in **Table 1**.

Despite the desirable role of LAB in food fermentation, some psychrotrophic species (i.e., *Leuconostoc mesenteroides*, *Leuconostoc gasicomitatum*, *Lactobacillus curvatus*, and *Lactobacillus sakei*) have been reported to cause detrimental effects in packaged (air, vacuum, and modified-atmosphere) foods. Souring, strange flavors, gas formation, discoloration, slime production, and decreased pH are some defects caused by the presence of this type of bacteria in ready-to-eat vegetable and fruit salads, fresh raw meat, cooked meat products, and composite foods.

Lactic starter cultures are defined as actively growing cultures of LAB that are used to start and control the fermentation process; in addition, these microorganisms contribute to the sensory characteristics of the fermented products and to their safety. Even today, the most relevant industrial application of LAB is their use as starter cultures in food fermentation. Because the starter industry relies on the use of selected strains of certain species with known metabolic properties, the use of starter cultures has undoubtedly improved the commercial and hygienic quality of the fermented final products and the standardization of the entire process. In contrast, the limited number of available strains with high technological performance and the risk of bacteriophage attack results in the search for new strains to diversify products. In this respect, artisanal or homemade fermentations represent a rich source of indigenous LAB for commercial use. Currently, defined, multi-, or mono-strain cultures prepared as frozen or freeze-dried cell concentrates are commercially available.

During the past few decades because of the huge worldwide industrial market for lactic fermentation (estimated as more

Table 1 Examples of fermented foods and beverages using LAB

Fermented foods and beverages	*LAB species*
Dairy products	
Yogurt	*Lactobacillus delbrueckii* subsp. *bulgaricus* and *Streptococcus thermophilus*
Fermented milks	*Lactobacillus casei*, *Lactobacillus rhamnosus*, *Lactobacillus acidophilus*, *Lactobacillus johnsonii*, *Lactobacillus reuteri*
Kefir	*Lactobacillus kefir*, *Lactobacillus kefiranofaciens*, *Lactobacillus plantarum*, *Lactobacillus acidophilus*, *Lactobacillus kefiri*
Buttermilk	*Lactococcus lactis* subsp. *lactis*, *Lactococcus lactis* subsp. *lactis* var. *diacetylactis*
Cheeses	*Lactococcus lactis* subsp. *lactis*, *Lactococcus lactis* subsp. *cremoris*, *Leuconostoc mesenteroides* subsp. *cremoris*, *Lactobacillus delbrueckii* subsp. *lactis*, *Lactobacillus delbrueckii* subsp. *bulgaricus*, *Lactobacillus helveticus*, *Streptococcus thermophilus*
Meat products	
Fermented sausages	*Lactobacillus sakei*, *Lactobacillus curvatus*, *Pediococcus acidilactici*
Fish products	
Fermented fish	*Lactobacillus alimentarius*, *Carnobacterium piscicola*
Vegetable products	
Olives	*Pediococcus acidilactici*, *Pediococcus parvulus*, *Leuconostoc mesenteroides*, *Leuconostoc pseudomesenteroides*, *Lactobacillus plantarum*, *Lactobacillus pentosus*
Sauerkraut	*Pediococcus pentosus*, *Leuconostoc mesenteroides*, *Lactobacillus plantarum*
Leeks	*Leuconostoc mesenteroides*, *Lactobacillus plantarum*, *Lactobacillus sakei*
Eggplant, mustard, beets, peppers, tomatoes, carrots, capers, cabbage	*Lactobacillus fermentum*, *Lactobacillus pentosus*, *Lactobacillus plantarum*, *Pediococcus pentosaceus*, *Lactobacillus brevis*, *Lactobacillus paracasei*, *Lactobacillus pantheris*, *Pediococcus acidilactici*, *Lactobacillus curvatus*, *Weisella consufa*, *Weisella soli*, *Enterococcus faecium*
Soybeans	*Leuconostocs*, *Lactococcus lactis*
Fermented fruits	
Pineapples	*Lactobacillus plantarum*, *Lactobacillus rossiae*
Kiwis	*Lactobacillus plantarum*

Rice wine	*Lactobacillus sakei*, *Pediococcus acidilactici*
Cereal-based products	
Sourdough	*Lactobacillus sanfranciscensis*, *Lactobacillus farciminis*, *Lactobacillus fermentum*, *Lactobacillus brevis*, *Lactobacillus plantarum*, *Lactobacillus amylovorus*, *Lactobacillus reuteri*, *Lactobacillus pontis*, *Lactobacillus panis*, *Lactobacillus alimentarius*, *Pediococcus pentosaceus*, *Weisella cibaria*
Fermented maize products	*Lactobacillus fermentum*, *Lactobacillus plantarum*, *Lactobacillus delbrueckii* subsp. *bulgaricus*, *Lactobacillus helveticus*, *Lactococcus lactis* subsp. *cremoris*

than 100 billion euros in 2011), especially in Western countries, many efforts have been made to improve the performance of LAB as starter cultures or to better understand their physiology for the production of industrially interesting metabolites. As a result, innovation is leading to the commercialization of more stress-tolerant, phage-resistant strains as well as starter cultures that lead to improved organoleptic properties. In this context, some metabolic traits of lactic starter cultures of technological interest, such as production of aroma compounds, bacteriocins, exopolysaccharides (EPS), low-calorie sugars, and so on, have been the targets of research and will be discussed later in this article.

LAB metabolism results in both decreased carbohydrate content in the raw material they ferment and decreased pH caused by lactic acid production. As mentioned earlier, this rapid acidification process is one of the most desirable effects of LAB growth, enabling the inhibition of detrimental microorganisms including several common human pathogens, and thus prolonging the shelf lives of fermented products. While lactic acid imparts a distinctive, desirable, and fresh acid taste to fermented products, the fermentation process must be controlled to avoid excessive acid concentration, which may be rejected by consumers and may mask more delicate flavors such as diacetyl. In cheese making, lactic acid production is also responsible for milk coagulation and texture properties. The pH decrease indirectly affects flavor by controlling the proteolytic activity of both coagulant and natural milk proteinases and by influencing the biochemical reactions involved in the formation of other aroma compounds. In this respect, LAB may enhance the organoleptic properties of the fermented product by imparting a characteristic flavor, which may derive from the fermentation of lactose or other sugars, citrate, the degradation of milk proteins and fat, and the metabolism of amino acids and free fatty acids. The flavor of the final product depends on several factors such as composition of the starter culture and raw material, type of fermentation, and ripening and storage conditions.

Besides the contribution of LAB to the flavor of fermented foods, some strains may contribute to the texture and nutritional quality of the final product. In addition, some LAB secrete natural food preservatives because of the production of antifungal and antibacterial compounds such as additional carboxylic acids (i.e., phenyl-lactic acid and acetic acid), fatty acids, ethanol, carbon dioxide, hydrogen peroxide, and bacteriocins.

Bacteriocin production is a desirable feature because they help control microbial populations in fermented foods and, thus, extend product shelf-life and safety. Bacteriocins produced by LAB are a diverse group of ribosomally synthesized antimicrobial peptides, which may be classified into different groups depending on the presence of posttranslational modifications and if they are active as single- or two-peptide bacteriocins. Nisin is a broad spectrum bacteriocin, which inhibits Gram-positive foodborne pathogens and spoilage microbes as well as Gram-negative bacteria if combined with additional preventatives. Nisin has been the paradigm, the most studied and commercially applied bacteriocin to date. Narrow spectrum bacteriocins, such as lactococcin A, can also be of value as these bacteriocins have lytic effect on sensitive lactococci and may release key enzymes that can accelerate cheese ripening and enhance the development of important organoleptic properties. In food, bacteriocins may be present via in situ production by bacterial fermentation, by the addition of purified or semipurified preparations, or as an ingredient based on a fermentate of a bacteriocin-producing strain.

Certain LAB strains are able to produce EPS, which are polymers of carbohydrates. Depending on their chemical compositions, EPS can be classified as homopolysaccharides, which contain a single type of monosaccharide, and heteropolysaccharides, which are formed from several repeating units of different monosaccharides. The ability to synthesize EPS is widespread among LAB species; however, a wide diversity in respect to EPS structures and to the amount of polysaccharides produced exists among the LAB producer strains. The inclusion of EPS-producing strains in starter cultures is desirable as these biopolymers naturally confer suitable technological characteristics to dairy products, such as improvement of rheological properties and reduction of syneresis of fermented milks as well as better consistency of curd in low-fat ripened cheeses. In addition, health-promoting effects such as a possible role as prebiotics, serum cholesterol-lowering ability, and immunomodulatory and anticarcinogenic activities have been ascribed to EPS produced by LAB. Conversely, the presence of EPS in wine and beer is detrimental.

LAB as Microbial Cell Factories

The central role of glycolysis in LAB has been at the basis of numerous studies to identify potential bottlenecks of the flux control needed not only for optimizing food fermentation processes but also for novel applications of LAB, such as their use as cell factories for the production of food ingredients, green fuels, and chemicals. In this respect, LAB are being used as 'cell factories' for the production of certain metabolites either to be used as purified compounds or to be produced in situ in fermented foods; examples include the production of bacteriocins, vitamins, amino acids, and low-calorie sugars. The use of LAB as cell factories is mainly because of their food-grade status and beneficial effects in the gastrointestinal tract, the availability of genetic tools for strain improvement, the possibility of using cheap substrates for growth, and direct application of their metabolites in food products. It can be affirmed that LAB applications have currently moved beyond the traditional food fermentation processes to the use of LAB as delivery vehicles for drugs, as vaccines, and as microbial cell factories for industrially relevant metabolites.

Metabolic engineering approaches in LAB were first reported in 1995 in an attempt to deviate pyruvate formation in the production of the buttery aroma compound diacetyl by *Lactococcus lactis*. Gene manipulation techniques together with some features of LAB such as small genomes (1.8–3.4 Mbp), fast growth, high sugar update rates, and a relatively simple metabolism, allowed the generation of efficient microbial cell factories. In the past few years, *Lactococcus lactis* and certain *Lactobacillus* species have been manipulated to synthesize metabolites such as lactate, 1,3-propanediol (1,3-PDO), biofuels, food flavors, sweeteners, and EPS. More recently, efforts are being directed to the production of commodity compounds and chemicals with applications in medicine (Table 2).

Table 2 Use of LAB as microbial cell factories for the synthesis of industrially interesting metabolites

Type of metabolite	*Compounds*	*Applications*
High added-value compounds	Lactic acid	Food additive and food preservative; used in food and plastic industries
	2,3-Butanediol (2, 3-BDO)	Antifreeze in plastic and other industrial processes
	1,3-Propanediol (1, 3-PDO)	Polymer, solvent, and cosmetic industries
	Ethanol	Biofuel alternative to gasoline
	Butanol	Solvent; alternative biofuel
Food ingredients	Alanine	Low-calorie sweetener in food
	Diacetyl	Aroma compound in food
	Acetaldehyde	Aroma compound in food
	Vanillin	Flavoring compound in food
Nutrients	Polyols (mannitol, sorbitol, erythritol, etc.)	Low-calorie sugars and sugar replacers in food industry; in medicine, used as a potent osmotic diuretic
	Vitamins (B_{12}, folate, riboflavin)	Essential nutrients in food
	Short-chain fatty acids (SCFAs)	Beneficial health effects
	Conjugated linoleic acids (CLAs)	Beneficial health effects
	Bioactive peptides	Antihypertensive, antioxidant, antimutagenic, etc.
	Gamma-aminobutyric acid (GABA)	Relaxing effect on gut muscles

High added-value compounds

Recently, the production of high added-value chemicals by LAB has been reported, including lactic acid, 2,3-butanediol (2,3-BDO), 1,3-PDO, bioethanol, and butanol.

Lactic acid has been used in the food industry as a flavor additive and food preservative; however, its main use in the market is in the creation of biodegradable plastics (as a precursor of poly-lactic acid) and pharmaceuticals. Traditionally *Lactobacillus casei* has been used to produce lactic acid because of its ability to convert more than 95% of the available sugar into this organic acid. However, by means of metabolic engineering processes and the use of renewable resources such as agro-industrial wastes as substrate, other species such as *Lactobacillus helveticus* and *Lactobacillus plantarum* have been able to efficiently form lactic acid either by achieving the deletion of the *L-ldh* (lactate dehydrogenase) gene or by introducing the *xyl*AB operon of *Lactobacillus pentosus* in the *Lactobacillus plantarum* genome. By these means, production of pure D-lactic acid with a 0.8 g g^{-1} yield was achieved.

Another important chemical compound is 2,3-BDO which is used as an antifreeze in the plastic, chemical, pharmaceutical, and cosmetic industries. Moreover, acetoin and diacetyl, important buttery flavors in some food products, can be formed by dehydrogenation of 2,3-BDO. Biotechnological processes have produced 2,3-BDO using *Klebsiella* strains; however, the pathogenic status of this bacterium has encouraged its synthesis by LAB members because many species possess the required biosynthetic pathway. In this respect engineered strains of *Lactobacillus plantarum* and *Lactococcus lactis* have been shown to efficiently produce 2,3-BDO from inexpensive substrates such as whey permeate.

1,3-PDO is another compound with multiple applications in the production of polymers, solvents, resins, detergents, and cosmetics. To date, this diol is industrially produced by chemical synthesis; however, its microbial production from glycerol, a byproduct of the biodiesel industry, has been intensively studied. Again, the food-grade status of LAB makes it the preferred option for synthesis of 1,3-PDO, rather than *Klebsiella* and *Clostridium* strains, which are considered opportunistic pathogens and thus are not applicable for food and biomedical products. Among the naturally lactobacilli producers of 1,3-PDO, *Lactobacillus reuteri* has been reported to be the best one so far.

Biotechnological production of ethanol may be one of the most important sources of renewable energy because this compound is used as an alternative biofuel to gasoline. In the past few years, to overcome the natural restrictions of crude oil use, researchers have become interested in using LAB to produce ethanol from renewable biomass such as lignocellulose, given that these microorganisms can metabolize different sugars. So far, the most promising results have been reported for an LDH-negative strain of *Lactobacillus plantarum*, that expresses pyruvate decarboxylase from a strain of the Gram-positive *Sarcina ventriculi*.

Also, butanol is a desirable solvent that may be an attractive fuel alternative. While butanol-producing strains cannot tolerate amounts higher than 2%, researchers may apply genetic engineering strategies to certain LAB members to produce butanol in the presence of 3% butanol.

Food ingredients/additives

Several compounds formed by LAB, such as alanine, diacetyl, and acetaldehyde, are currently employed as food ingredients.

Alanine is an amino acid with a natural sweet taste that is used as a food and pharmaceutical additive. It is produced through pyruvate reduction by alanine dehydrogenase in the presence of ammonium. Homoalanine fermentation is achieved by a metabolic engineering strategy through the heterologous overexpression of alanine dehydrogenase from *Bacillus sphaericus* in an LDH-deficient *Lactococcus lactis* strain.

Diacetyl is an important flavor compound that has a buttery aroma and is typically used for dairy products; diacetyl is naturally produced by LAB from citrate, which limits its production because citrate availability in raw materials is usually low. To surpass this limitation, researchers have created some

metabolic engineering strategies to produce diacetyl from lactose or glucose.

Acetaldehyde is an important aroma compound, especially in dairy products; for instance, it is the main aroma compound in yogurt. Because acetaldehyde is an intermediate metabolite from ethanol metabolism, efforts to increase diacetyl production are usually connected with the ethanol pathway. So far, the best engineered strategy for this purpose consists of the heterologous overexpression of pyruvate decarboxylase from *Zymomonas mobilis* with native NADH oxidase in *Lactococcus lactis*.

Vanillin is one of the most used flavoring compounds worldwide; as the annual world market demand of vanillin cannot be met by natural extraction, chemical synthesis or tissue culture biotechnological approaches have been considered. Biovanillin synthesis using GRAS LAB and metabolically engineered microorganisms is currently being studied.

Low-calorie sugars

Polyols, or low-calorie sugars, are sugar alcohols that naturally occur in nature; among them, mannitol and erythritol are the only ones naturally produced by LAB. These two sugar alcohols, together with sorbitol and xylitol, are widely used in the food and pharmaceutical industries and in medicine because of their interesting physicochemical properties. Moreover, as these low-energy, nonmetabolizable sweeteners do not affect insulin levels, they are employed in dietetic and diabetic food products.

In the past decade, biotechnological production of polyols by LAB has been sought as an alternative to their current chemical production. While heterofermentative LAB may naturally produce mannitol and erythritol under certain culture conditions, sorbitol and xylitol have been synthesized only through metabolic engineering processes. Although strains belonging to the *Oenococcus*, *Leuconostoc*, and *Weisella* genera have been reported to form mannitol, the best mannitol-producing microbes reported so far are heterofermentative lactobacilli such as *Lactobacillus fermentum* and *Lactobacillus reuteri*. Controlled culture conditions using selected LAB strains have yielded amounts of mannitol that are similar to those of current industrial chemical processes.

Sorbitol production by *Lactobacillus casei* and *Lactobacillus plantarum* strains has been achieved by reverting the sorbitol catabolic pathway, taking advantage of the reversibility of the enzyme sorbitol 6-P dehydrogenase, which is responsible for the interconversion of sorbitol 6-P into fructose 6-P.

While metabolic engineering strategies using homologous genes have been employed for sorbitol synthesis by LAB, xylitol production has been achieved only by heterologous expression of D-xylose reductase and xylose transporter genes from the yeast *Pichia stipitis* CBS 5773 and the strain *Lactobacillus brevis* ATCC 8287, respectively.

Nutrients

A wide range of compounds with nutritional relevance such as vitamins, polysaccharides, short-chain fatty acids (SCFAs), conjugated linoleic acids (CLAs), and bioactive peptides are synthesized by LAB.

Vitamins are essential micronutrients for the metabolism of living organisms. Because of insufficient food intake or unbalanced diets, human vitamin deficiencies are still very common. As an attractive alternative to chemical vitamin synthesis, biotechnological production of vitamins using LAB had been under study in the 2000's. Furthermore, fermentation with food-grade LAB offers unique opportunities to improve the nutritional value of food products and the development of novel functional foods with enhanced vitamin content. As a result of secondary metabolism, certain LAB are able to synthesize some group B vitamins such as B_{12} (cobalamin), B_{11} (folate), and B_2 (riboflavin). In this respect, several industrially important LAB such as *Lactococcus lactis* and *Streptococcus thermophilus* are capable of synthesizing folate as has been observed in fermented milks with high vitamin levels. Riboflavin's biosynthesis has been identified in several species, and some applications of riboflavin-producing LAB in dairy and cereal-based products have also been reported. Cobalamin, a complex corrin compound, was found to be produced for the first time by *Lactobacillus reuteri*, a well-recognized probiotic species. In general, vitamin production by LAB varies considerably because it is a species-specific or strain-dependent trait. This feature is generally related to the partial or complete interruption of the genetic information for vitamin biosynthesis. The use of vitamin overproducer LAB strains may be exploited for their in situ production of fermented products.

SCFAs are not produced anabolically in LAB but rather as the final catabolites of the energy metabolism. The most studied SCFA are butyrate, propionate, and acetate. Besides the SCFA acidifying desirable properties, acetate may be metabolized by muscles and other tissues when entering the peripheral circulation while propionate is taken up by the liver. Both acids can lower glycemia, improving insulin sensitivity. Conversely, butyrate has been claimed to have detrimental effects on body weight and obesity because it represents an additional energy source. In contrast, butyrate may control oxidative and metabolic stress at the molecular level by enhancing repair responses and inhibiting the synthesis of pro-inflammatory (IL12, TNF, gamma IF) cytokines.

CLAs are a novel type of biologically beneficial functional lipids. Human metabolism can also be affected by these compounds as some CLA isomers may reduce cancer cell viability and ameliorate insulin resistance while others may lower the HDL/LDL ratio and modify eicosanoid production, with detrimental health effects. So far, the best CLA-producing strains belong to the genera *Lactobacillus* and *Streptococcus*. The most frequently found isomers of linoleic acid have the unsaturation site at positions 9, 11 or 10, or 12, namely, Δtrans 9-, cis11-octa decadienoic acid, and, in lower amounts, Δcis10-, trans12-linoleic acid. CLAs could have health beneficial effects on inflammation, cancer, metabolic disorders, and cardiovascular diseases. However, the beneficial effects of CLAs depend on the isomers and doses.

Bioactive peptides are hidden peptides, which are encrypted in the latent state within the primary sequence of proteins that require enzymatic proteolysis for their release. Bioactive peptides can be produced during gastrointestinal digestion or food processing. LAB that have reduced amino acid biosynthetic abilities harbor a sophisticated proteolytic system, which may contribute to the release of bioactive peptides or their precursors. Thus, proteolytic LAB strains used as starter cultures in the manufacture of different foods (e.g., yogurts, fermented milks, and cheeses) may have a positive effect in this sense. Diverse

health benefits have been ascribed to bioactive peptides derived from LAB, including antimicrobial, immunomodulatory, antithrombotic, opioid, and antioxidant effects as well as enhancement of mineral absorption and/or bioavailability and blood pressure-lowering activities. Today some milk-derived peptides are commercially produced and used as dietary supplements in functional foods, personal care products, or drugs.

Among other compounds, some LAB strains biosynthesize gamma-aminobutyric acid (GABA), which has a relaxing effect on gut smooth muscles, and beta-phenylethylamine, which contributes to the control of satiety and mood.

LAB as Probiotics

The gut microbiota is a highly diverse and relative stable ecosystem that is being increasingly recognized for its impact on human health. Deviation from its normal composition is usually associated with localized and systemic diseases. Modulation of the gut microbiota may help to improve health and can be achieved by different nutritional concepts, varying from specific food ingredients to complex diets or by the ingestion of particular live microorganisms such as probiotics.

Probiotics have been defined as "live microorganisms that when administered in appropriate dose, they confer a health benefit to the host" (FAO/WHO 2001). Probiotics have been empirically used for centuries, but only in recent decades has their contribution to the modulation of immunological, respiratory, and gastrointestinal functions started to be fully appreciated and scientifically evaluated. To date, the majority of the available commercial probiotics are LAB, mainly of the *Lactobacillus* genera but also bifidobacteria (a group of bacteria with a high G+C content included in the phylum Actinobacteria that also produce lactic acid but always in combination with acetic acid). A much smaller number of leuconostocs, pediococci, lactococci, enterococci, and streptococci are also used as probiotics.

Probiotic strains are usually isolated from traditional fermented products and the gut, feces, and breast milk of human subjects. The identification of microorganisms is the first step in the selection of potential probiotics. The ability to examine fully sequenced genomes has accelerated the application of genetic approaches to elucidate the functional roles of probiotics.

Fermented foods and beverages possess various nutritional and therapeutic properties; in this sense LAB play a major role in the positive health effects of fermented milks and related products. Such foods, beverages, and powders are highly acceptable to consumers because of their flavor and high nutritional value. Potential health benefits of fermented milks include antimutagenic and antitumor activity (associated with the cell wall of starter bacteria), prevention of gastrointestinal infections, and reduction of serum cholesterol levels. Although probiotics are mainly used for gastrointestinal benefits, from which the best-demonstrated clinical benefits of probiotics are the prevention and treatment of antibiotic-associated diarrhea, their use can also extend to skin, oral, and vaginal health, as well as the treatment of allergies, liver disorders, and metabolic diseases (Table 3). Recently, investigation of the gut-brain connection suggested that the gut microbiota play a key role in mood and anxiety disorders, supporting the inclusion of probiotics in animal and human products. It has been suggested that an improvement of the intestinal barrier function through microbiota modification can decrease lipopolysaccharide infiltration, reduce inflammatory parameters in the fat tissue, and, consequently, reduce the chances of developing obesity and insulin resistance. Probiotics may also regulate host intestinal microbiota, improve gut immune barrier function, and achieve a balance between pro-inflammatory and anti-inflammatory cytokines.

Table 3 Examples of beneficial health properties of LAB used as probiotics

Beneficial health effect	*Associated LAB species*
Antidiarrheal	*Lactobacillus acidophilus*
Antitumor activity	*Lactobacillus reuteri*
Antimutagenic activity	*Lactobacillus casei*
Anticarcinogenic effects	*Lactobacillus paracasei*
Serum cholesterol reduction	*Lactobacillus rhamnosus*
Prevention of gastrointestinal infections	*Lactobacillus kefir*
	Lactobacillus plantarum
Improvement of the gut immune barrier	*Lactobacillus helveticus*
	Lactobacillus delbrueckii subsp. *lactics*
Modulation of the immune response	*Lactobacillus delbrueckii* subsp. *bulgaricus*
Treatment of allergy disorders	*Lactobacillus gasseri*
Regulation of the gut and vagina microbiota	*Lactobacillus johnsonni*
	Lactococcus lactis
	Lactobacillus salivarius
	Lactobacillus pentosus
	Streptococcus thermophilus
	Enterococcus faecalis
	Enterococcus faecium
	Pediococcus acidilactici
	Pediococcus pentosaceus

Probiotic bacteria typically colonize the intestinal tract first and then reinforce the host defense systems by inducing generalized mucosal immune responses, including modulation of dendritic cell/natural killer interaction, a balanced T-helper cell response, self-limited inflammatory response, and the secretion of polymeric Immunoglobulin A. Many reports have demonstrated that LAB, mainly *Lactobacillus* as well as *Bifidobacterium* and their fermented products, may improve innate and adaptive immunity, prevent gastric mucosal lesions, alleviate allergies, and create a defense against intestinal pathogen infection. Also, probiotic LAB have been included in the production of functional foods with specific properties in order to potentially prevent or treat a range of intestinal maladies including inflammatory bowel disease, constipation, and colon cancer.

It has been shown that fermented animal feed using LAB has been beneficial in pig nutrition and the nutrition of other farm animals as a tool to reduce gut microbial disorders, to increase antibacterial activity, and to enhance immunity. Colonization of the digestive tract in animals begins immediately after birth because adult microbiota dramatically change during the host's life. In farm animals, the role of the gut microbiota, which is similar to that in humans, does not differ much among animal species. To ensure the animals optimal growth, production, and health, the microbiota of the animal

gastrointestinal tract can be manipulated by probiotic bacteria. Probiotics have already been given to different farm animals such as cattle, chicks, piglets, lambs, and small ruminants. In this respect, LAB have been proposed as protective bacteria to reduce *Escherichia coli* O157 in cattle and *Salmonella* in poultry, as well as to prevent diarrheal disease in piglets.

Conclusions

Here I have presented information about the versatility of the heterogeneous, broad LAB group, including findings about their metabolism, food and industrial applications, and health benefits. Their traditional and empirical use in food preservation from the time of the earliest written words has evolved beyond imagination along with scientific progress. This long and challenging journey has allowed not only the development of rational and novel applications of LAB but also a deeper understanding of the involved mechanisms to improve human health and well-being.

Introduction

The disaccharide lactose occurs in milk, mainly free with a small extent as a component of higher oligosaccharides. Its concentration in milk varies with the mammalian source from 2.0% to 8.5%. Cow and goat milks contain 4.5–4.8% and human milk about 7%. It is the primary carbohydrate for developing mammals. In humans, lactose constitutes 40% of the energy consumed during nursing. The utilization of lactose for energy must be preceded by hydrolysis to the constituent monosaccharides, D-glucose and D-galactose. Milk also contains 0.3–0.6% of lactose-containing oligosaccharides, many of which are important as energy sources for growth of a specific variant of *Lactobacillus bifidus*, which is the predominant component of the intestinal microbiota of breast-fed infants.

Lactose is ingested through milk and other unfermented dairy products, such as ice cream. Fermented dairy products, such as most yogurt, dahi, and cheeses, contain less lactose because during fermentation, some of it is converted into lactic acid. It stimulates intestinal adsorption and retention of calcium. Lactose is not digested until it reaches the small intestine, where the hydrolytic enzyme lactase is located. Lactase (β-galactosidase) is a membrane-bound enzyme located in the brush border epithelial cells of the small intestine. Lactase catalyzes the hydrolysis of lactose into its constituent monosaccharides. Only monosaccharides among the carbohydrates are absorbed from the intestines. Both D-glucose and D-galactose are rapidly absorbed and enter the bloodstream.

Status of Lactose

Lactose is the most prominent carbohydrate of milks of most species. It is virtually unique to milk, having been found elsewhere only in fruits of certain members of the Sapotaceae. The presence of lactose is observed in *Forsythia* flowers and ripe fruits of *Achras sapota* (Sapotaceae). Less than 0.1% of lactose is present in the milk of *Echidna* and *Platypus*, while highest concentration of lactose is present in human milk, that is, 7.0%. Its concentration is lowest in the blood and urine especially during pregnancy and lactation. The presence of lactose in urine is known as lactosuria. It is the principal carbohydrate present in milk of all mammals.

It could be seen from the content of Table 1 that the concentration of lactose in milk varies widely between species. Its concentration decreases progressively and significantly during lactation. Mastitis causes an increased level of NaCl in milk and depresses the secretion of lactose. Lactose, along with sodium, potassium, and chloride ions, plays a major role in maintaining the osmotic pressure in the mammary system. Thus, any increase or decrease in lactose content (a secreted constituent, i.e., formed within the mammary gland) is compensated for by an increase or decrease in the soluble salt (excreted) constituents. This osmotic relationship partly explains why certain milks with high lactose content have low ash content and vice versa.

Structure of Lactose

Lactose is a disaccharide consisting of galactose and glucose, linked by a β-L-4 glycosidic bond (Figure 1). Its systematic name is β-0-D-galactopyranosyl-(1–4)-α-D-glucopyranose (α-lactose) or β-0-D-galactopyranosyl-(1–4)-β-D-glucopyranose (β-lactose). The hemiacetal group of the glucose moiety is potentially free (i.e., lactose is a reducing sugar) and may exist as an α- or β-anomer. In the structural formula of the α-form, the hydroxyl group on the C_1, of glucose, is cis to the hydroxyl group at C_2 (oriented downward).

Physical Forms of Lactose

In milk, lactose is normally found as either α-lactose or β-lactose or amorphous glass form (mixture of α- and

β-forms). Several other forms can be prepared under special condition as given in the following:

α-Lactose Monohydrate ($C_{12}H_{22}O_{11}.H_2O$)

Any form of lactose crystallizes below 93.5 °C to α-monohydrate form (if allowed). In milk, α-anhydrous form is not prepared. Supersaturate solution of lactose when allowed to crystallize at 93.5 °C or below will give α-monohydrate form. Above 93.5 °C, it will give β-anhydrous. It contains 5% water of crystallization. It has solubility of 70 g l^{-1} water at 20 °C, specific rotation +89.4°, and melting point of 202 °C. It forms a number of crystal shapes, depending on the conditions of crystallization; the most common type when fully developed is tomahawk-shaped. Crystals are hard and dissolve slowly. In the mouth, crystals less than 10 μm are undetectable, but above 16 μm, they feel gritty or sandy, and at 30 μm, a definite gritty texture is perceptible. The term sandy or sandiness is used to describe the defect in condensed milk, ice cream, or processed cheese spreads where, due to poor manufacturing techniques, large lactose crystals are formed.

Anhydrous α-Lactose

Regular (unstable) anhydrous α-lactose

Anhydrous α-lactose may be prepared by dehydrating α-hydrate in vacuum at temperatures between 65 and 93.5 °C; it is stable only in the absence of moisture. During the reaction, moisture loss is negligible up to 85 °C, whereas it is significant at 90 °C and rapid at 120–125 °C.

Anhydrous α-lactose is stable in dry air and is highly hygroscopic. In the presence of moisture, it forms α-hydrate before dissolving. In a solution that is saturated with α-hydrate lactose, it will not dissolve; this behavior suggests that no change has occurred in its properties.

Stable anhydrous α-lactose

Stable form of α-lactose is prepared by dehydrating α-hydrate in vacuum of 6–80 mm Hg at temperatures between 100 and 190 °C and crystallizing it with suitable solvent especially dry methanol or 95% absolute ethanol.

New crystalline structure reduces tendency to absorb water so this anhydrous form remains stable even in an environment of 50% relative humidity. Product containing 99% anhydrous lactose can be prepared by refluxing α-hydrate crystals with methanol in the ratio of 1:10 for 1 h. At room temperature, reaction is slower. The rate decreases with increasing proportion of α-hydrate in dry methanol. Anhydrous α-lactose is stable, has high density, and is nonhygroscopic. It dissolves in water forming hydrate. It dissolves readily in solution and that is saturated with α-lactose hydrate. It is more soluble in water than either α-hydrate or β-anhydride form.

β-Anhydride Form

Since β-lactose is less soluble than the α-isomer above 93.5 °C, the crystals formed from aqueous solutions at temperatures above 93.5 °C C are β-lactose; these are anhydrous and have a specific rotation of +35° and melting point of 252 °C. β-Lactose is sweeter than α-lactose, but is not appreciably sweeter than the equilibrium mixture of α- and β-lactose normally found in solution. β-Lactose dissolves much faster than α-lactose hydrate at room temperature, as its solubility is about ten times higher and the crystals are usually smaller with a larger surface area.

α- and β-Anhydrous Forms (Lactose Glass)

It is also called as amorphous noncrystalline glass. When a lactose solution is dried rapidly, its viscosity increases so quickly that crystallization cannot take place. The dry lactose is essentially in the same condition as it was in solution, except for removal of the water. This is spoken of as 'concentrated syrup' or an 'amorphous' (noncrystalline) glass. Lactose glass is stable if protected from moisture, but since it is very hygroscopic, it rapidly takes up moisture from the air and becomes sticky. When the moisture content reaches about 8% or a relative vapor pressure near 0.5, the lactose achieves a maximum weight; a discontinuity is observed in the sorption isotherm, and water is desorbed from the lactose.

Lactose in spray-dried milk exists as a concentrated syrup or amorphous glass that is stable if protected from air but is very hygroscopic and absorbs water rapidly from the atmosphere, becoming sticky.

Biosynthesis of Lactose

Lactose is essentially unique to mammary secretions. Lactose is synthesized in the epithelial mammary cells from two molecules of glucose absorbed from the blood. One molecule of glucose is converted (epimerized) to UDP-galactose (uridine diphosphate-galactose) via the four-enzyme Leloir pathway (Figure 2), which is widespread in animal tissues and bacterial cells. The UDP-galactose is then phosphorylated and condensed with a second molecule of glucose through the action of a unique two-component enzyme, lactose synthase. One component, that is, component A, is a nonspecific UDP-galactosyl transferase (EC 2.4.1.22), which transfers galactose from UDP-galactose to any of several acceptor molecules in the biosynthesis of glycoproteins and glycolipids. The specificity of the transferase is controlled and modified by component B (α-lactalbumin – one of the principal milk proteins). The α-lactalbumin reduces the KM for glucose 1000-fold, and in its presence, the transferase

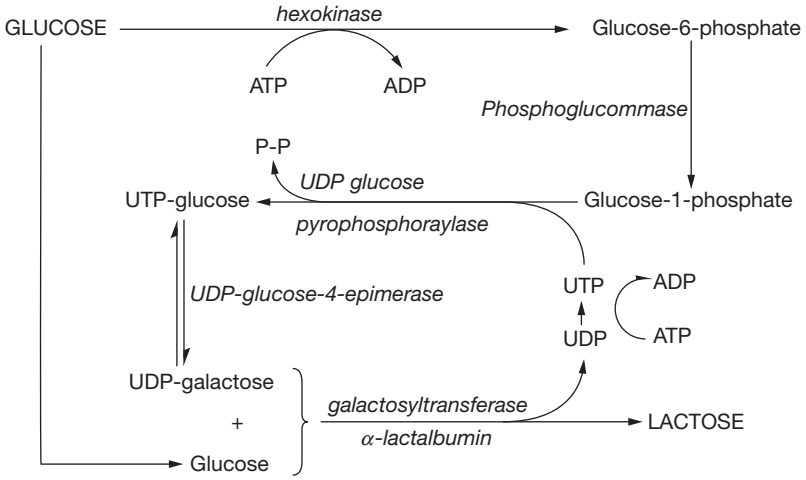

Figure 2 Leloir pathway of lactose biosynthesis.

becomes highly specific for glucose and most of the galactose is transferred to glucose, leading to the synthesis of lactose. Thus, α-lactalbumin is an enzyme modifier and its concentration in the milk of several species is directly related to the concentration of lactose in those milks; the milks of some marine mammals contain neither α-lactalbumin nor lactose (e.g., the milk of the California sea lion or the hooded seal, which contains no lactose and also lacks α-lactalbumin).

Properties of Lactose

The properties of lactose are generally similar to those of other sugars but it differs in some technologically important respects. Some important characteristics of lactose are as follows:

- Lactose is a reducing sugar, that is, it has a free, or potentially free, carbonyl group (an aldehyde group in the case of lactose).
- Like other reducing sugars, lactose exists partially as an open-chain form with an aldehyde group that can form a hemiacetal and, thus, a ring structure. The formation of a hemiacetal creates a new chiral center (asymmetrical carbon), which may exist as two isomers (enantiomorphs), α and β. By alternatively opening and forming the ring structure, the molecule can interchange between α- and β-anomers, a process referred to as mutarotation.
- The α- and β-anomers of lactose have very different properties, the most important of which are specific rotation, $[\alpha]_D^{20}$ (+89° and +35° for α- and β-lactose, respectively), and solubility (70 and 500 g l^{-1} for α- and β-lactose, respectively).
- Like all reducing sugars, lactose can participate in the Maillard (nonenzymatic browning) reaction, resulting in the production of (off-)flavor compounds and brown polymers. The Maillard reaction contributes positively to the flavor and color of many foods, that is, crust of bread, toast, and deep-fried products, but the effects in dairy products are usually negative and must be avoided.
- Redox titration using alkaline $CuSO_4$ (Fehling's solution) or chloramine-T is the principal standard method for the quantitative determination of lactose, although in large laboratories, it is now usually determined by infrared spectrophotometry. It may also be determined by polarimetry, spectrophotometry at a visible wavelength after reaction with phenol or anthrone in strongly acid solution, or high-performance liquid chromatography or enzymatically (using an enzyme assay kit).
- Among sugars, lactose, especially the α-enantiomorph, has low solubility in water, but when in solution, it is difficult to crystallize, which may cause problems in lactose-rich dairy products, that is, skimmed milk powder and whey powder, unless precautions are taken to induce and control crystallization.
- α- and β-lactose are soluble in water to the extent of about 70 and 500 g l^{-1}, respectively, at 20 °C; at equilibrium, the ratio of α:β is about 37:63, giving a total solubility of about 180 g l^{-1} at 20 °C. The solubility of α-lactose is more temperature-dependent than that of the β-anomer and it is more soluble at >93.5 °C (Figure 3). Hence, α-lactose is the form of lactose that crystallizes at <93.5 °C and is the usual commercial form of lactose; β-lactose may be prepared by crystallization at >93.5 °C.
- α-Lactose crystallizes as a monohydrate, while β-lactose forms anhydrous crystals; thus, the yield of α-lactose is approx. 5% higher than that of β-lactose.
- When milk or whey is spray-dried, any lactose that has not been precrystallized forms an amorphous glass that is stable if the moisture content of the powder is maintained low. However, if the moisture content increases to >6%, the lactose crystallizes as α-hydrate, the crystals of which form interlocking masses and clumps that may render the powder unusable if very extensive, that is, inadequately, crystallized powder is hygroscopic. The problem can be avoided by adequate crystallization of lactose before drying or by using effective packaging.

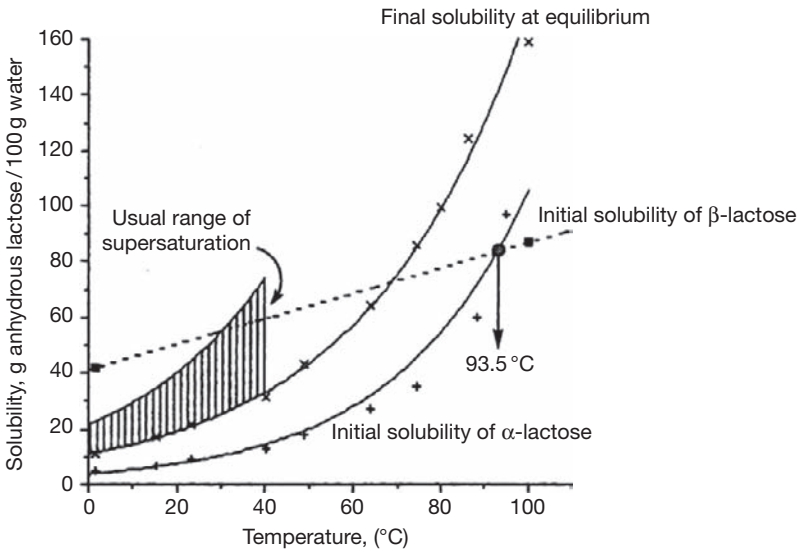

Figure 3 Solubility of α- and β-lactose as a function of temperature.

- Interestingly, crystalline lactose has very low hygroscopicity and is used in icing sugar blends.
- The densities of the various lactose crystals differ slightly from each other. The density of α-hydrate form is 1.540, anhydrous β is 1.589, anhydrous α formed by dehydration under vacuum is 1.544, and anhydrous α-lactose crystallized from alcohol is 1.575. Densities of lactose solutions are not linear functions of concentration.
- Among sugars, lactose has a low level of sweetness; it is only about 16% as sweet as sucrose at 1% in solution and hence has limited value as a sweetening agent, the principal application of sugars in foods. However, it is a useful bulking agent when excessive sweetness is undesirable.
- Lactose is important in the manufacture of fermented dairy products where it serves as a carbon source for lactic acid bacteria (LAB) that produce lactic acid.

Derivatives of Lactose

Like other sugars, lactose has reactive functional groups and can be converted to several more valuable food-grade derivatives.

β-Galacto-oligosaccharides (GOSs) are generally synthesized from lactose by transgalactosylation of lactose by the enzyme β-galactosidase. In contrast, lactosucrose is prepared by a different enzymatic route. Here, lactose, in the presence of sucrose, acts as the acceptor of fructose in a transfructosylation reaction catalyzed by the enzyme β-fructofuranosidase. Fructooligosaccharides are also synthesized from sucrose by similar enzymatic routes.

Lactulose and lactitol are prepared by two different chemical syntheses from lactose. Lactulose is prepared by alkaline isomerization of lactose, while lactitol is synthesized by catalytic hydrogenation of lactose. Lactulose can also be prepared by an enzymatic route, though this is not used commercially. Lactobionic acid is prepared by dehydrogenation of lactose at high pH using a metal catalyst. However, it can also be prepared in high yield by microbial bioconversion and by enzymic oxidation of lactose. Tagatose was prepared initially from galactose by alkaline isomerization in a manner parallel to the preparation of the disaccharide, lactulose from lactose, but it is now manufactured by an enzymatic route from lactose. The basis of the preparation of GOS, lacto-sucrose, lactulose, lactitol, lactobionic acid, and tagatose from lactose is shown in Figure 4.

Properties of Lactose Derivatives

Properties of oligosaccharides

Food-grade oligosaccharides are not pure products, but are mixtures containing oligosaccharides of different degrees of polymerization (dp), the parent polysaccharide or disaccharide and monomer sugars. A typical commercial product

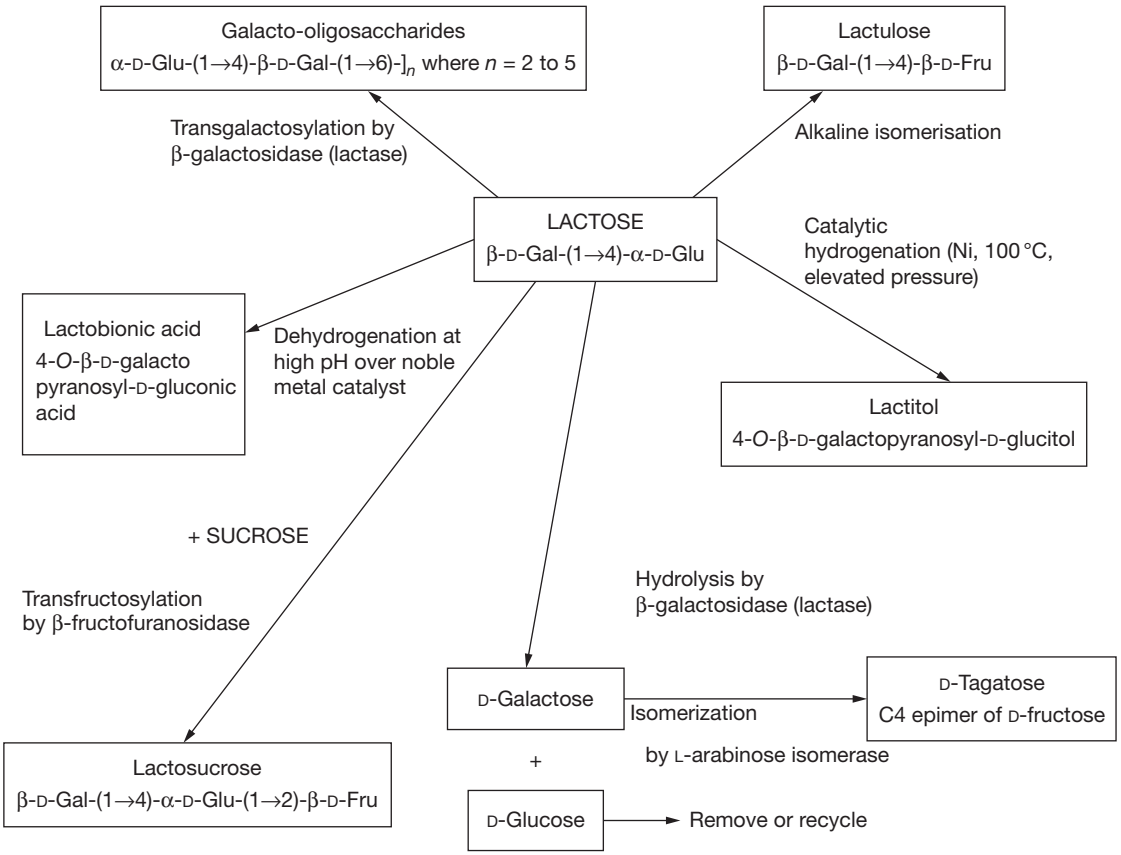

Figure 4 Derivatives of lactose (the preparation of galacto-oligosaccharide, lacto-sucrose, lactulose, lactitol, lactobionic acid, and tagatose from lactose).

composition for an unpurified GOS may comprise glucose and galactose 10%, disaccharides (lactose) 70%, trisaccharides 18.7%, tetrasaccharides 1.2%, and pentasaccharides 0.06%. More advanced manufacturing processes result in much higher concentrations of GOSs in the product. For example, Oligomate 50 produced by the Yakult Company contains 50–52% GOSs, 10–13% lactose, and 36–39% monosaccharides. Purified products are available from many manufacturers, but costs increase considerably because of the extra processing steps required. Purified products usually contain between 85 and 99% GOSs. It is obvious that there are important differences in the properties and actions of food-grade oligosaccharide mixtures depending on the mixture purchased. The applications of oligosaccharides as components in foods will therefore vary considerably. Most producers also provide safety and toxicological data for acute, subacute, and chronic toxicities. Data are also commonly provided to demonstrate changes in colonic microbial flora following ingestion of oligosaccharides. Usually, substantial increases in bifidobacteria are demonstrated relative to the other bacterial classes measured. The physicochemical properties of oligosaccharides are largely dependent on the molecular weight of the particular oligosaccharide product.

General properties of GOSs

Appearance	Translucent/colorless
Sweetness	Typically 0.3–0.6 times that of sucrose
Calorific value	Lower than sucrose
Water activity	Similar to that of sucrose
Viscosity	Similar to that of high-fructose glucose syrup
Heat stability	Stable to 160 °C for 10 min at pH 7.0 and to 100 °C for 10 min at pH 2.0
Acid stability	Stable to pH 2
Indigestibility	Resistant to salivary and pancreatic α-amylases and other carbohydrases and gastric juices and thus reducing the glycemic index of foods
Energy value	About 50% of that of sucrose
Freezing point	Reduces the freezing point of foods
Bacteriostatic property	Through competition for mucosal binding sites and adhesion by pathogens. Some oligosaccharides are also able to absorb lectin-like toxins, for example, VTEC and ETEC
Bifidogenic ability	Able to increase the population of most species of bifidobacteria in mixed populations of bacteria in both *in vitro* and *in vivo* studies in humans and animals
Cariogenicity	Acts as an anticaries agent (anticariogenic)

Physicochemical properties of oligosaccharides

Taste	Sweetness decreases as molecular size increases
Mouthfeel	Larger-sized oligosaccharides have applications as fat replacers
Viscosity	Increases with increasing molecular size
Solubility	Decreases with increasing molecular weight
Hygroscopicity	Oligosaccharides can be used to control the moisture level in foods
Color reactions	Decreases as molecular weight increases
Freezing point	Depression of freezing point is inversely proportional to molecular weight
Osmolality	Decreases as molecular weight increases

The susceptibility to hydrolysis of oligosaccharides during passage through the gastrointestinal tract is an important characteristic. This has been determined in a range of *in vitro* model systems of the stomach and small intestine of humans. Different types of oligosaccharides have been subjected to regimes such as (1) hydrolysis by human saliva (50%, v/v, saliva, 30 min exposure, pH 7.0, 37 °C), (2) hydrolysis by gastric acid (4 h exposure, pH 2.0, 37 °C in acid/pepsin), and (3) hydrolysis by pancreatic and brush border carbohydrases (17%, v/v, porcine pancreatic and duodenal homogenates for 1 h exposure, pH 7.0, 37 °C). Carbohydrate analysis before and after exposure by HPLC then determines the degree of hydrolysis. Tests such as these have shown that xylo-oligosaccharide mixtures, palatinose condensates, commercial GOS mixtures, and lactulose are very resistant to hydrolysis, whereas lactosucrose and gentio-oligosaccharides, soybean oligosaccharides, fructooligosaccharide mixtures, and inulin oligosaccharides are hydrolyzed slightly by such conditions.

Properties of lactulose

Lactulose solution is yellowish, odorless clear syrup with a sweet taste. Dry lactulose is a white, odorless crystalline powder. It is soluble in water, but poorly soluble in methanol and insoluble in ether. Its solubility in water is 76.4% (w/w) at 30 °C, rising to 86% at 90 °C. The melting point is 168.5–170.0 °C. Its sweetness is classified as 0.48–0.62 times that of sucrose. It is 1.5 times sweeter than lactose. Acid hydrolysis of lactulose yields galactose and fructose. Unlike lactose, lactulose cannot be hydrolyzed by human intestinal enzymes. Lactulose can be fermented by some human colonic bacteria and acts as a prebiotic ingredient. Heat sterilization is a common step in food manufacture. Lactulose is stable and little decomposed when heated to 130 °C for 10 min at low pH. This relatively high stability makes it a suitable ingredient for normal food processing.

Properties of lactosucrose

Lactosucrose is very soluble in water (up to 3670 g l^{-1} at 25 °C). It has sweetness relative to sucrose of 0.3. It is stable for 1 h at pH 4.5 and 120 °C. It is most stable at neutral pH and remains fairly stable at pH 3 at 80 °C. As a powder, it has a high moisture-retaining capacity and is highly hygroscopic. It acts as a prebiotic carbohydrate and is not readily digested by intestinal enzymes in the stomach and small intestine. It is selectively fermented by *Bifidobacterium* in the human colon.

Properties of lactitol

Lactitol is an odorless, colorless, sweet, nonhygroscopic, and stable sugar alcohol. As it lacks a reactive carbonyl group, which is characteristic of sugar molecules, it does not participate in Maillard browning reactions with amino groups. It occurs in both monohydrate and dihydrate crystalline forms as pure products with good flowability. Lactitol is stable under both alkaline and acid conditions and at high temperatures likely to be encountered during food processing. Its melting

point is 146 °C and it is very soluble in water. The sweetening power of lactitol is about 40% of sucrose and the calorific contribution of lactitol after it is metabolized by colonic bacteria is less than 2.4 cal g^{-1} (10 kJ) compared to 4.0 cal g^{-1} (17 kJ) for sucrose. Lactitol is not hydrolyzed or absorbed in the small intestine and passes through to the colon. It also acts as a prebiotic carbohydrate and enhances the growth of certain groups of bacteria (e.g., bifidobacteria) in the colon.

Properties of lactobionic acid

Lactobionic acid is best described as a natural polyol acid with a formula weight of 358.30 Da and a pKa of 3.8. It is soluble in water as a free acid or as a salt. The molecule possesses multifunctional groups and thus acts as a metal ion chelator and can sequester calcium. Lactobionic acid inhibits the production of hydroxyl radicals as a result of its iron-chelating capacity and it functions as an antioxidant in tissues. It has a sweet taste despite being a weak acid. Lactobionic acid can be dehydrated to a lactone. Lactobionic acid is hygroscopic and forms a gel containing about 14% water with atmospheric moisture. Concentrated solutions will form gels and films. Its superior water-retention ability is valuable in cosmetic applications. Its main uses derive from its important chelating and emulsifying properties.

Properties of D-tagatose

D-Tagatose is a monosaccharide with a formula weight of 180.16 Da; it is a white solid with a melting point of 133–135 °C. It has a similar texture to sucrose and is 92% as sweet, but its calorific value (1.5 kcal g^{-1}) is only 38% that of sucrose since it is metabolized differently from sucrose. Its indigestibility in the stomach and small intestine results in a minimal effect on blood glucose levels in humans. Values for the absorption of tagatose in the small intestine vary widely from 20% to about 80%. The unabsorbed fraction is then completely fermented in the colon by some intestinal microorganisms. Those genera able to ferment tagatose included *Enterococcus* and *Lactobacillus*, but not *Bifidobacterium*. Many dairy LAB, such as lactococci and streptococci, fermented tagatose readily. It is claimed that its fermentation in the colon results in an increased production of butyrate relative to that of acetate and propionate. It has a glycemic index of only 3 compared to 100 for glucose. Its glycemic index is markedly lower than those for other natural sugars and most sugar alcohols. It is claimed to have prebiotic properties, but its inability to be fermented by *Bifidobacterium* species limits its application as a prebiotic. However, it is noncariogenic and non-plaque-forming.

Uses of Lactose

Lactose has many uses in the food and pharmaceutical industries. In the food industry, its uses are based on its relative sweetness and being a source of energy. It is less sweet than sucrose, with up to 3.3 times the concentration of lactose being required to give the same level of sweetness as sucrose. This means that more lactose can be used without making the product too sweet. Lactose maintains the crystallized sugar texture without causing the food to become too sweet.

Lactose also has a number of low-volume, special applications in the food industry, for example, as a free-flowing or agglomerating agent, to accentuate/enhance the flavor of some foods, to improve the functionality of shortenings, and as a diluent for pigments, flavors, or enzymes.

Lactose is used in the confectionary industry to produce caramel flavors through the Maillard reaction, usually with milk proteins, often added with the lactose in the form of sweetened condensed milk. The Maillard reaction is also important for its use in the bakery industry where it is used to promote crust browning as the yeast used during the rising process cannot utilize lactose, leaving it as a reducing sugar available to undergo the browning reaction. Lactose can also adsorb food dyes and flavors and it finds uses in confectionery where this property is exploited.

In the pharmaceutical industry, lactose is used as the main carrier (about 70% of tablets contain lactose) for drugs because it is not sweet, it is safe, it is available in highly refined form, and it makes good quality tablets. It has found uses in the industry in a number of different product forms. The main one is α-lactose monohydrate, which can be used as a tablet excipient, but it can also be finely milled to produce inhaler-grade lactose. Here, the lactose acts as a carrier for micronized drug materials to reach the lungs. Both anhydrous lactose (β-lactose) and spray-dried lactose are also used to make tablets. The form of the lactose is critical for consistent tablet formulations, and much emphasis is placed on the reproducibility between batches of the particle properties that are required to produce consistent tablets, with an even spread of the active drug dispersed within the lactose powder being used as an excipient.

Nutritional Problems Associated with Lactose

Lactose Intolerance

Mammals cannot absorb disaccharides from the intestine as they are initially hydrolyzed in the small intestine to monosaccharides followed by which they are absorbed. Lactose is hydrolyzed by β-galactosidase (β-gal; also referred to as lactase), which is secreted by cells in the brush border of the small intestine. The young of most mammalian species secrete adequate amount of β-gal, but as the animal ages, its secretion declines and becomes inadequate to hydrolyze ingested lactose, which enters the large intestine. If the ingested lactose is only partially hydrolyzed or is not hydrolyzed at all, a clinical syndrome called lactose intolerance results. If there is a deficiency of lactase, some lactose remains in the lumen of the small intestine. The presence of lactose tends to draw fluid into the lumen by osmosis. This fluid produces abdominal distention and cramps. From the small intestine, the lactose passes into the large intestine (colon) where it undergoes anaerobic fermentation to lactic acid (present as the lactate anion) and other short-chain acids (Figure 5). The increase in the concentration of molecules results in still greater retention of fluid. In addition, the acidic product of fermentation leads to lower pH and irritates the lining of the colon, leading to an increased movement of the contents causing diarrhea. The gaseous products of fermentation cause bloating and cramping.

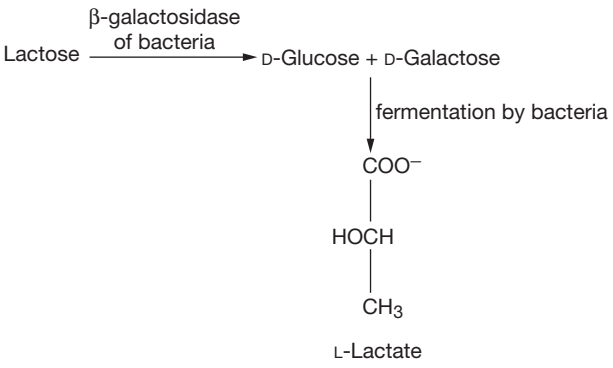

Figure 5 The fate of lactose in the large intestine of persons with lactase deficiency.

Lactose intolerance is not usually seen in children until about 6 years of age. At this point, the incidence of lactose-intolerant individuals begins to rise and increases throughout the life span, with the greatest incidence in the elderly. Both the incidence and the degree of lactose intolerance vary by ethnic group, indicating that the presence or absence of lactase is under genetic control.

Lactase deficiency can be overcome by the removal of lactose by fermentation or by producing reduced-lactose milk. However, both products of hydrolysis, D-glucose and D-galactose, are sweeter than lactose, and at about 80% hydrolysis, the taste change becomes too evident. Therefore, most reduced-lactose milk has the lactose reduced as close as possible to the 70% limit. In a technology under development, live yogurt cultures are added to refrigerated milk. The bacteria remain dormant in the cold and do not change the flavor of the milk but, upon reaching the small intestine, release lactase.

Galactosemia

It is caused due to inability to metabolize galactose on account of a hereditary deficiency of galactokinase or galactose-1-phosphate (Gal-1-P)/uridyl transferase. The lack of the former enzyme leads to the accumulation of galactose, which is metabolized via other pathways, leading, among other products, to galactitol, which accumulates in the lens of the eye, causing cataract in 10–20 years (in humans) if consumption of galactose-containing foods (milk and legumes) is continued. The incidence is about 1: 40 000. The lack of Gal-1-P/uridyl transferase leads to the accumulation of Gal and Gal-1-P. The latter interferes with the synthesis of glycoproteins and glycolipids (important for membranes, e.g., in the brain) and results in irreversible mental retardation within 2–3 months if the consumption of galactose-containing foods is continued. The incidence of this disease, often called 'classical galactosemia,' is about 1 in 60 000. The ability to metabolize galactose decreases on aging (after 70 years), leading to cataract.

Lauric Oils

AJ Dijkstra

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Lauric oils have in common that their main fatty acid is lauric acid, 12:0, or dodecanoic acid. In addition, they contain larger amounts of 8:0 (caprylic acid or octanoic acid), 10:0 (capric or decanoic acid), and especially 14:0 (myristic or tetradecanoic acid) than the common seed oils like soybean oil, rapeseed oil, and sunflower seed oil. Historically, the main lauric oil is coconut oil, an oil produced from copra, the meat inside a coconut. Annual production has been around 3 million tons for some decades but has now increased to 3.5 million tons. However, with the growing production of palm oil, which is now the predominant vegetable oil at more than 60 million tons *per annum*, more and more palm kernels have become available. Palm kernels contain a lauric oil, and the annual production of palm kernel oil is now close to 6 million tons and thus exceeds the annual coconut oil production. In addition to these two major lauric oils, there are also several South American palm kernel oils in which lauric acid is the main fatty acid. Table 1 summarizes their fatty acid compositions and compares these with those of coconut oil and palm kernel oil and Laurical®, a genetically modified rapeseed plant.

Table 1 gives the overall fatty acid composition, irrespective of the position of the fatty acid on the glycerol backbone. When lauric oils are analyzed stereospecifically, it becomes clear that the fatty acid composition of the 2-position differs from that of the outer *sn*-1,3-positions. This is illustrated for coconut oil and palm kernel oil in Table 2.

The fatty acid values in Table 2 are slightly different from those in Table 1 because they originate from different sources. The fatty acid composition of the 1,3-positions has been calculated from the values in the two previous columns. They show that palmitic acid (16:0) and stearic acid (18:0) have a strong preference for the outer, 1,3-positions. This feature is common to most other vegetable oils. It is also valid for myristic acid (14:0), but lauric acid (12:0) on the other hand has a strong preference for the middle position of the glycerol backbone. The preference for the 2-position of linoleic acid (18:2) that is common with seed oils is not present in the lauric oils.

Given the fatty acid compositions of the 1,3-positions and the 2-position, it is possible to calculate a triglyceride composition according to the 1,3-random, 2-random theory. According to this theory, the molar concentration of a certain triglyceride in an oil equals the product of the mole fractions of the three fatty acids concerned. So, if the molar fraction of palmitic acid (P) at the 1,3-positions were to be 40% and the molar fraction of linoleic acid at the 2-position were to be 50%, the triglyceride PLP would have a concentration of $0.4 \times 0.5 \times 0.4 \times 100 = 8\%$. This holds for symmetric triglycerides. If the fatty acid at the 1-position were to differ from the fatty acid at the 3-position, there would be two positional isomers that can be listed separately or together and shown as a group. In the latter case, the calculated percentage has to be multiplied by a factor of 2.

Table 3 shows that coconut oil has relatively more triglycerides with a lower carbon number, whereas in palm kernel oil triglycerides with carbon number >46 are still relatively abundant. This is caused by the higher oleic acid content of palm kernel oil, which is also reflected by the higher iodine value of this oil: about 19 g iodine per 100 g oil for palm kernel oil and half that value for coconut oil.

Because lauric oils are so rich in lauric acid and myristic acid, their saponification values are much higher than those of the common seed oils: 245–265 vs. 185–195 mg KOH per g oil. The free fatty acid content of these seed oils is usually expressed as wt% oleic acid, but in the case of lauric oils, it is more common to express it as wt% lauric acid by assuming a molar mass of 200 instead of 282 for oleic acid.

The low unsaturated fatty acid content of the lauric oils is reflected by their low iodine values. It also retards the formation of rancid off-flavors. However, the presence of medium-chain fatty acids makes the oil more susceptible to hydrolysis, resulting in the formation of free fatty acids and a soapy taste.

The bottom row of Table 1 gives the fatty acid composition of Laurical®, the oil of a genetically modified rapeseed developed by Calgene in 1996. The aim of this development was to provide a cheap and reliable source of lauric acid, away from the Philippines, where typhoons frequently damage crops.

However, the growth of palm oil production increased the availability of the lauric palm kernel oil so that there was less need for alternative sources. Consequently, the entire stock of this oil was sold for use as fuel in 2001.

The oils listed in Table 1 will now be discussed in more detail in alphabetical order.

Babassu Oil *(Orbignya oleifera)*

The babassu palm is native to Brazil. It is a solitary stemmed palm, with stem diameter varying from 20 to 50 cm and attaining some 30 m in height. The crown contains 10–25 erectly arching pinnate leaves. The leaf sheath varies from 40 to

120 cm in length, the petiole from 10 to 40 cm, and the leaf rachis from 550 to 850 cm. There are 300–400 leaflets along the rachis, each 20–185 cm long by 1–6 cm wide depending upon position and tree health and age.

The inflorescences are androdioecious (either exclusively staminate (male) or androgynous (staminate and pistillate (female) together)), one arising from the axil of each leaf, although occasional abortions occur. Before anthesis, the inflorescence is covered by a woody bract that splits open along the lower side to release the inflorescence. The peduncle and the main bunch rachis are 50–180 cm long. In staminate inflorescences, there are 270–400 rachillae, each bearing 15–100 staminate flowers. In androgynous inflorescences, there are 320470 rachillae, each bearing 1–2 (rarely 3) pistillate flowers and one to several staminate flowers that are frequently aborted.

The fruits are broadly elliptic to oblong, 6–13 cm long, 4–10 cm wide, and weighing 40–440 g (dry weight). The epicarp is fibrous and 1–4 mm thick. The mesocarp is mealy, dry, and 2–12 mm thick. The endocarp is woody and 35–75 mm in diameter and contains 3–6 ovate to elliptic seeds, each 3–6 cm long, with an oily white endosperm. The endosperm is used locally to make charcoal.

In comparison with the related species *O. phalerata*, *O. oleifera* has a higher sex ratio (more female inflorescences), resulting in greater fruit yields ($\approx$5 MT ha^{-1} year^{-1} vs. $\approx$1.5 MT ha^{-1} year^{-1} for *O. phalerata*), and a higher kernel to fruit ratio (10–22% vs. 7%), resulting in significantly higher estimated oil yields (0.5–1.1 MT ha^{-1} year^{-1} vs. 0.1 MT ha^{-1} year^{-1}). Oil extraction is mainly artisanal and annual production is around 100000 tons. The oil is used locally in food, soap, and cosmetics and exported when there is a coconut oil shortage after typhoon damage in the Philippines. Outside Brazil, the oil is mainly used in cosmetics.

Coconut Oil *(Cocos nucifera)*

Coconut palms grow in coastal regions between 20° north and 20° south of the equator. Indonesia has now overtaken the Philippines as the main producer; both countries produce close to 20 million tons of nuts per annum. India also produces more than 10 million tons of nuts per annum and is followed by Brazil and Sri Lanka at <3 million tons. Total world production in 2013 was 62 million tons. Because its production is limited to the tropics, more than 50% of the oil is exported either as oil or as copra, the dried meat lining the coconut shell. Copra contains 65–70 wt% oil.

Botanically, the coconut fruit is a drupe, a fleshy fruit with a thin skin and a central stone containing the seed, just like a coffee cherry or a plum. Coconuts sold in Europe have the exocarp removed. Under this skin is a thick layer of fibers, the so-called coir, that have many applications in rope and coarse fabrics used, for instance, in flooring and mats. The actual nut is inside this coir. The very hard shell has three germination pores that are clearly visible after the husk has been removed.

The coconut palm grows to a height exceeding 20 m, but dwarf varieties have also been introduced; the latter have a shorter productive life. The hard shell of the fruit has a diameter of 15–30 cm. Harvesting can be by collecting fallen fruits or by picking manually or mechanically. Many nuts are used locally, and the excess is used to produce copra and oil. Copra is produced by splitting the outer shell and drying the endosperm meat. The yield of dry copra is about 12% of the original nuts.

This meat can be isolated before or after drying. The drying itself can be in the sun or in an oven or kiln. Direct contact of the meat with flue gases causes oil-soluble flue gas components such as polyaromatic hydrocarbons (PAHs) to be absorbed by the meat. They remain dissolved in the oil during extraction so that the PAH content of crude coconut oil has to be closely monitored. Low-boiling PAHs will be removed from the oil during its deodorization/steam refining. High-boiling PAHs need an adsorptive treatment with activated carbon.

Coconut oil is produced by expelling copra using a screw press, followed by solvent extraction of the expeller cake using *n*-hexane. The meal can be used in animal feed. Crude coconut oil has a phosphatide content of only 0.02–0.05 wt%, corresponding to 10–20 ppm phosphorus, which is very much lower than the 2–4 wt% of soybean oil or the 1.5–3.5 wt% of crude rapeseed oil. Its free fatty acid content is at least 3%, which is much higher than the 0.5–1.0 wt% of soybean oil. Consequently, crude coconut oil is very well suited to be physically refined after having been degummed/bleached in the so-called dry degumming process.

In this process, an amount of 0.05–0.15% of relatively strong phosphoric acid is mixed into the crude oil and allowed to react with the phosphatides. Then, bleaching earth is added, and after this has been in contact with the oil for about half an hour, the bleaching earth is removed by filtration. Subsequently, the oil is heated to the deodorization temperature of 220–240 °C and stripped with an amount of 0.3–1.5 wt% of steam under a vacuum of 2–4 m bar. Because coconut oil has a melting point of 23–26 °C, heating is required during storage and transport. During transport, the minimum and maximum temperatures recommended by the IASC (International Association of Seed Crushers) are 27 and 32 °C, respectively. On discharge, they are 40 and 45 °C, respectively.

In comparison with other vegetable oils, coconut oil contains very small amounts of unsaponifiables. These are the compounds that are not hydrolyzed by caustic soda and can be extracted from the soaps with an organic solvent. Major components of the unsaponifiable are the phytosterols and the tocopherols. Vegetable oils may also contain unsaponifiable compounds that are particular to that particular oil such as gossypol in cottonseed oil, oryzanol in rice bran oil, and sesamol in sesame seed oil.

The phytosterol content of coconut oil is only some 700 ppm. This is very low in comparison with soybean oil (3 000 ppm), sunflower seed oil (3 800 ppm), rapeseed oil (8 200 ppm), and especially corn oil (9 200 ppm). Of the major vegetable oils, only palm oil has a similarly low phytosterol content (500–700 ppm). The sterol composition of coconut oil is similar to that of other vegetable oils with β-sitosterol accounting for about 70%, stigmasterol for almost 20%, and campesterol for the remainder. As with most other vegetable oils, less than half the sterols (about 40%) are esterified with a fatty acid.

In comparison with other vegetable oils, the tocopherol and tocotrienol contents of coconut oil are even lower. It

contains 30 ppm tocotrienols and the tocopherol content is only 11 ppm: 5 ppm α-tocopherol and 6 ppm γ-tocopherol. Compare this with 650 ppm tocopherols and 530 ppm tocotrienols in palm oil, about 1000 ppm tocopherols in soybean oil, and almost 3000 ppm tocopherols in sesame seed oil.

Cohune Oil *(Attalea cohune)*

The cohune palm is indigenous to Belize. The tree can reach 30 m in height and produces bunches of nuts that are apparently very hard to crack. Although the meat contains some 70% oil, the oil yield on nuts is only 10% or thereabouts. Oil is produced in an artisanal manner, and attempts to exploit the ample source of cohune nut oil more professionally seem to have failed.

Murumuru Oil *(Astrocaryum murumuru)*

The murumuru palm is confined to Amazonia. It can grow to heights of 30 m and bears yellow fruits, the flesh of which is eaten by animals and man alike. The nuts are indigestible and spread by these animals. The tree is full of black spines that are very sharp; they can reach a length of half a meter. Fruits are therefore harvested by picking them up from the ground. Early last century, small enterprises harvested and processed the nuts that contain 40% of oil and used the lauric oil for food applications or soap, but the oil could not compete with other cheaper oils. Nowadays, some murumuru oil is used in cosmetics.

Ouricury Oil *(Syagrus coronata)*

The ouricury palm is a tree commonly found in *cerrado*, or dry, bush vegetation in many parts of Brazil. In some small communities, especially in the northeast of the country, the fruit is exploited as an oil source. The oil is used for cooking, frying, and soap production. The oil has in common with other, low-tonnage oils that it is often listed in patents as one of a series of lauric oils in an attempt to prevent the competition from bypassing the patent.

Palm Kernel Oil *(Elaeis guineensis)*

Palm kernels are a coproduct of palm oil production, and as opposed to palm fruit, the kernels can be stored after they have been dried. This means that palm oil has to be produced at or near the plantation and that palm kernel oil production can be centralized.

When the fresh fruit bunch (FFB) reaches the oil plant, it is sterilized with steam. The loosened fruits are stripped from the bunches in a threshing machine and passed to a digester with slowly moving arms where a mash is formed. This mash is passed to a screw press where it is separated into a liquid comprising the oil and fruit juice and a press cake that contains the palm nuts that amount to 15% of the FFB weight.

After the screw press, the nuts and the fiber traverse a heated breaker/conveyor that removes moisture from the fiber and causes the fiber and nuts to separate. The fiber and nuts then pass into a pneumatic, vertical separating column, called the 'winnowing column or depericarper.' The fiber is blown into a cyclone close to the boiler and the nuts pass down a polishing drum that removes pieces of stalks and any dirt or fibers attached.

The nuts are dried and conditioned before being cracked in, for instance, ripple mills. Cracking results in a mixture of kernels and bits of shell that are separated via a winnowing system followed by a cyclone or a clay bath. Suspending clay in water causes its specific gravity to increase, and by choosing a value between the specific gravity of the kernel ($1.07\ g\ ml^{-1}$) and that of the shell ($1.17\ g\ ml^{-1}$), the kernels will float and the bits of shell will sink. The clay bath achieves a better separation but consumes about 4.5 kg clay per ton of FFB and consumes more energy to dry the kernels to a residual moisture content of $<7\%$.

The oil content of the palm kernel is about 50%, so the most economical way to extract this oil is by prepressing followed by solvent extraction, just as rapeseed and sunflower seeds are processed. However, this way is only economical on fairly large scale because the investment requirements of a solvent extraction plant benefit strongly from an economy of scale. Consequently, there are also plants that only press the kernels and thus produce a meal that still contains some fat. The expeller oil invariably contains meal particles, so it is allowed to settle. The top oil is decanted and the foots are recycled to the expeller press.

Most oil seeds are passed through a flaker to open their cells and thus facilitate squeezing the oil out (screw press) or washing it out (solvent extractor). So, the kernels are also comminuted in a hammer mill to pieces of about 2 mm, and then, they are conditioned at 110–120 °C to break the cell walls. This conditioning also reduces the moisture content of the kernel pieces to about 2.5%.

Because the phosphatide content of the crude palm kernel oil is low, the oil can be physically refined after having been degummed and bleached in a single operation, the so-called dry degumming process. These processes are very similar to those used for coconut oil; further details have been given under the appropriate heading. The temperatures recommended for transport and discharge are the same as for coconut oil: 27–32 °C during the voyage and 40–45 °C on discharge. For the stearin and olein fractions, some different temperatures are recommended: for olein, the temperature range of 25–30 °C is recommended during the voyage and 30–35 °C on discharge, whereas for stearin, a range of 32–38 °C is recommended during the voyage and the unchanged range of 40–45 °C on discharge.

The sterol content of palm kernel oil has been reported to be some 875 ppm with a composition of 68% β-sitosterol, 14% stigmasterol, and 9% campesterol. Literature values for the tocopherol/tocotrienol content of palm kernel oil are 13 ppm α-tocopherol and 21 ppm α-tocotrienol. These latter values are somewhat higher than the corresponding values for coconut oil but still low in comparison with most other oils.

An important modification process for palm kernel oil is the dry fractionation process. It is a partial (fractional)

crystallization followed by filtration. The filtrate is called the olein fraction and the filter cake is the stearin fraction. In the dry fractionation process, two crystallization systems are used. The main system is the so-called suspension crystallization in which the oil to be cooled is fed into a large crystallization vessel that comprises cooling elements and an agitator. Suspension crystallization is used, for instance, for palm oil and its fractions, anhydrous milk fat, and beef tallow.

The other system of crystallization is the stationary or stagnant crystallization system in which the cooling melt is not agitated but allowed to crystallize in a tray or crystallization chamber to form a block of partially crystallized fat. Originally, this block was wrapped in filter cloth and placed in a hydraulic press in which the olein was squeezed out of the blocks. These had then to be unwrapped to obtain the stearin filter cake. This was a very labor-intensive process of doubtful hygienic standards. The stationary crystallization system is used for oils and fats that do not form a slurry of separate crystals on partial crystallization but tend to form crystal networks and aggregates; palm kernel oil is such an oil.

To eliminate the manual handling of the blocks, several more automated processes have been developed. In an early development, the molten palm kernel oil was poured into trays that were positioned on a moving belt that passed through a cooling tunnel. At the end of the tunnel, the trays were emptied by turning them upside down so that the partially crystallized blocks fell out. The blocks were then worked mechanically into a pumpable paste that was fed into a membrane filter press.

In a more recent development, cooled but still liquid palm kernel oil is fed into crystallization chambers in a piece of equipment (called Statoliser®) that are similar to the chambers in a membrane filter press except that there is no filter cloth and that the space behind the membrane is now fed with cooling medium. After the equipment has been filled, the temperature of the cooling medium is controlled to ensure the partial crystallization of the palm kernel oil. When the desired degree of crystallization has been reached, the press is opened, and the partially crystallized blocks fall down to be crushed and fed into a membrane filter press.

Fats intended for confectionery products that are similar to chocolate can be divided into three main groups. There are the cocoa butter equivalents (CBEs) that are chemically and thus physically very similar to cocoa butter. They have a high content of symmetric monounsaturated triglycerides. CBEs are produced from naturally occurring fats like palm oil, shea butter, and illipe butter. They can be mixed with cocoa butter in any proportion without seriously affecting the physical properties such as solid fat content (SFC) profile and snap on breaking.

Another group is formed by the cocoa butter replacers (CBRs). Their physical properties are very similar to those of cocoa butter, but chemically, they are quite different. CBRs are prepared by fractionating partially hydrogenated blends of vegetable oils, for example, rapeseed oil and palm olein. They have a high *trans* isomer content and can be mixed with cocoa butter without affecting its physical properties when not too much of either component is present. The third group is formed by the cocoa butter substitutes (CBSs) that have similar physical properties to cocoa butter but are totally incompatible with the latter.

Palm kernel oil itself cannot act as a CBS because its SFC is far too low to be of any use: 0.2% at 30 °C; 13.3% at 25 °C, and 37.3% at 20 °C. It is possible to increase the SFC by hydrogenating the palm kernel oil, but this oil contains 8 wt% of triglycerides with two unsaturated fatty acids that on hydrogenation form triglycerides with two stearate groups. Their melting points would be very high and give the hydrogenated product a poor mouthfeel. So, the answer to this problem is to use palm kernel stearin (PKS) since on fractionation, the triglycerides with one or two unsaturated fatty acids are concentrated in the olein because their low melting points prevent them from crystallizing. On hydrogenation, the SFC at 35 °C increases to only 5% so that it also melts at this temperature.

As shown in Figure 1, a single-stage fractionation of palm kernel oil leads to a yield of 40% stearin with IV = 7, which fraction has to be hydrogenated to lower its IV and increase its

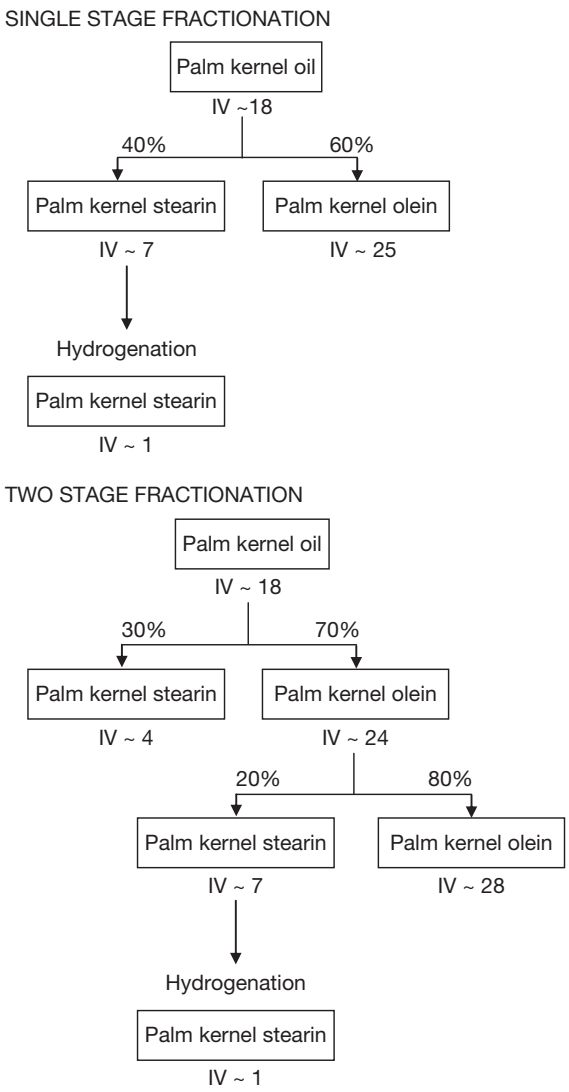

Figure 1 Fractionation of palm kernel oil. Adapted from Figure 12.15 in Chapter 12, Gibon, V. Palm oil and palm kernel oil refining and fractionation technology. 		SFC (%) at temperature (°C)					
Product	*Iodine value*	*20*	*25*	*30*	*35*	*40*	*Melting point*
Palm kernel oil (PK)	18	44	20	0			28
PK stearin (PKS)	7	82	68	29	0		32
Hydrogenated PKS	4	87	70	24	1	0	31
	0.4	95	90	50	5	1	35
Cocoa butter	34.5	76	70	45	0		34
Palm kernel olein (PKO)	17.5	44	20	0			
Hydrogenated PKO	1	73		27	14	6	41
Coconut oil (CN)	8.5	36	0				24
CN stearin (CNS)	4	84	53	2	0		30
Hydrogenated CNS	1.5	92	57	8	2		32

Source: Table 4.20 in Gunstone, F. D., Harwood, J. L. and Padley, F. B. (eds.) (2007). *The lipid handbook* (3rd ed.). Boca Raton: CRC Press; Hamm, W., Hamilton, R. J. and Calliauw, G. H. (eds.) (2013). *Edible oil processing*. Chichester: Wiley-Blackwell; Wambeck, N. (1999). Oil palm process synopsis. In: *Oil palm mill, systems and process* (vol. 1). Kuala Lumpur.

SFC. To maximize the CBS yield, a double fractionation process has been developed in which a first fractionation yields 30% stearin with an IV = 4, which can be used as a CBS without hydrogenation, and a second fraction of the olein yields a further 14% stearin with an IV of 7, which fraction has to be hydrogenated.

Table 4 shows that the SFC profile of the hydrogenated PKS is close to that of cocoa butter but that trying the same with coconut oil does not lead to a suitable CBS.

Tucum Oil *(Astrocaryum vulgare)*

The tucum palm is native to the Amazonian region, possibly to the state of Pará, where its center of distribution is located, and is also found in French Guiana and Surinam. It is a characteristic palm of terra firma, low vegetation cover, or even open fields. The tree is 10–15 m in height and regenerates easily by growing multiple stems. The tucum palm is considered a pioneer plant of aggressive growth, has the ability to grow new shoots after a fire, and mainly inhabits secondary forests and pastures. According to some sources, its resistance to diseases and high productivity make this species an alternative for the production of biodiesel, since the operating costs of an orderly plantation are much lower than those of an oil palm plantation.

The tree trunk is covered with spines and even the inflorescences are covered by a thorny spathe. Fruit bunches can reach >3 m and weigh almost 50 kg. The yellow-orange fruit is about the size of a chicken egg. Like the fruit of the oil palm, both the flesh and the seed/nut contain oil; whereby, the fruit oil contains some 60% of oleic acid (18:1) and 30% palmitic acid (16:0). It is therefore slightly more unsaturated than palm oil and therefore has a higher iodine value of 64 as against 53 g iodine per 100 g oil. Tucum kernel oil is a lauric oil as shown in Table 1.

On average, the fruit weighs 30 g; 34% of this weight corresponds to the external pulp that contains 14–16% of the oil when it is raw. A mature tree can produce up to 50 kg of fruits per year (25 kg per tree on average), which corresponds to 2.5 kg of pulp oil and 1.5 kg of seed oil. This ratio differs from the ratio observed for palm oil, where it is close to 9–1. On 1 ha, 400 palm clusters can be planted, with each cluster having three trunks. In total, this equals to 1200 palm trunks and will result in 4.8 tons of fatty material per hectare. It forms clusters that do not need to be replanted.

Leavening Agents

R Miller, Kansas State University, Manhattan, KS, USA

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Most baked products are leavened by the expansion of the batter or dough. Leavening results in baked products with a larger volume with an open, porous texture. The three major leavening gases are air, steam, and carbon dioxide gas. Other leavening agents include ethanol and ammonia gas. Ethanol, which is a by-product of yeast fermentation, has a leavening effect in yeast-leavened products such as bread and rolls when it vaporizes during baking in the oven. Ammonia gas is produced by the decomposition of ammonium bicarbonate, or ammonium phosphate during heating and is used to leaven some dry cookies and crackers.

Air

Air is present in all baked products and is essential for leavening to occur. The expansion of the air itself during baking can provide some leavening, but it is not enough to get the desired volume. The most important function of the air bubbles in leavening is that they serve as nuclei for the other leavening gases, which diffuse into them and cause them to expand. Air must be incorporated into the dough during mixing. Yeast and chemical leaveners cannot create new bubbles in the dough or batter. Bubble mechanics show that the pressure (P) inside of an air bubble is related to the radius of the bubble (r) and the interfacial tension (γ) as follows: $P=2\gamma/r$. This means that in a dough or batter where the interfacial tension is constant, if the radius is zero, then the pressure required to form a new bubble is infinitely large. Therefore, no new bubbles are formed. The composition of air (~78% nitrogen and 20% oxygen) makes it an ideal gas for leavening. Nitrogen is insoluble in water so it remains as a gas in the dough or batter. The oxygen is soluble in water and will dissolve in the aqueous phase. Carbon dioxide gas, which is produced by yeast fermentation or chemical leavening reactions, is also water-soluble; however, it will quickly saturate the aqueous phase of the dough or batter and then will remain as a gas. The number and size of air bubbles incorporated into the dough or batter are important to the texture of the final product. A low number of large-sized air bubbles will produce a final product with an open, coarse crumb grain, while a large number of small-sized bubbles will produce a fine, uniform crumb grain. Uniform air bubble size is also important. If a small bubble and a large bubble are positioned near one another in the batter or dough, the gas will diffuse from the smaller one into the larger one causing the larger one to expand and the smaller one to disappear. This phenomenon is called disproportionation or the Ostwald ripening. Adjacent bubbles can also coalesce when the film between them ruptures. The result of these instabilities is a lower number of larger-sized air bubbles.

Steam

All baked products contain water. Steam is produced as the water in the dough or batter is heated. As the temperature increases, the vapor pressure of water increases and expands the gas bubbles in the batter or dough. The usefulness of steam as a leavening agent in most doughs and batters is low compared to that of other leavening gases because of the high boiling point of water. The temperature of most baked products reaches the boiling point of the water too late in the baking cycle for a large increase in the size of the product to occur. Steam plays a large role as a leavening agent in products that are heated at a very fast rate such as saltine crackers, in extruded products such as breakfast cereals and snacks, and in products where the temperature exceeds 100 °C such as some types of cookies, crackers, and snacks. Water present in roll-in margarine used in puff pastry and laminated products vaporizes during baking to help provide lift between the layers of dough.

Carbon Dioxide

Carbon dioxide gas is produced by yeast during fermentation and also by chemical leavening agents. In the chemical leavening reaction, a food acid and a leavening base react in the presence of water to form carbon dioxide gas.

Yeast

The majority of bread-type baked products are leavened by yeast. *Saccharomyces cerevisiae*, also known as baker's yeast, is the species of yeast that is most often used. Other species of yeast are used in sourdough bread and in some frozen doughs. Yeast is a living organism that is put into a dormant state by drying or by storage at low temperatures. When the yeast is incorporated into a dough system, the conditions are suitable for it to become active. Once activated, the yeast will quickly consume the air in the dough; thus, dough fermentation is an anaerobic process. During anaerobic fermentation, the yeast organisms do not grow or reproduce, but rather, they metabolize sugar to produce carbon dioxide, alcohol, acids, flavor compounds, and water:

$$\underset{\text{(glucose)}}{C_6H_{12}O_6} + \text{Yeast} \rightarrow \underset{\text{(ethanol)}}{2C_2H_5OH} + \underset{\text{(carbon dioxide)}}{2CO_2}$$

During fermentation, the pH of the dough will decrease from about 6.0 to about 5.0. The decrease is the result of the aqueous phase of the dough becoming saturated with carbon dioxide gas and also by the production of organic acids by bacterial fermentation. Commercial yeast always contains some bacteria. As a result of the pH drop, most of the leavening

gas present in the dough at the end of fermentation will be as carbon dioxide gas with only a small quantity of bicarbonate or carbonate. The carbon dioxide gas produced during the leavening reaction diffuses into the air bubbles that were incorporated into the dough during mixing and makes them larger. These large bubbles are then subdivided into smaller bubbles during the sheeting steps in the dough making process. This results in a larger number of smaller-sized air cells, which are more stable and which also produce a finer, more uniform crumb grain in the final baked product. In addition to subdividing the large air cells, the sheeting steps in the bread production process serve the function of bringing fermentable carbohydrates into contact with the yeast cells to sustain fermentation. The yeast is active in the dough during fermentation, proofing, and the early stages of baking until it becomes inactivated by the heat in the oven. During fermentation and proofing, the yeast functions to produce carbon dioxide gas that diffuses into the air cells and expands them, thus leavening the dough. In the oven, the size of the loaf dramatically increases during the first few minutes of baking due to a phenomenon called oven spring. Oven spring occurs because the increased temperatures cause the yeast to become more active, which results in the fast production of carbon dioxide until the yeast is killed at about 55 °C. Carbon dioxide in the aqueous phase becomes less soluble at the higher temperatures and moves into the air bubbles. The carbon dioxide in the air bubbles expands due to the higher temperature. Finally, the water–ethanol mixture vaporizes.

Chemical Leavening

Essentially all soft wheat products are chemically leavened. Most chemical leavening systems consist of a carbon dioxide source (leavening base) and one or more food acids. Carbon dioxide sources in chemical leavening systems include ammonium bicarbonate, potassium bicarbonate, sodium carbonate, and sodium bicarbonate.

Leavening Bases

Leavening bases are the carbon dioxide sources in chemical leavening systems and include ammonium bicarbonate, potassium bicarbonate, and sodium bicarbonate. Release of the carbon dioxide from the leavening base occurs by two mechanisms: decomposition and chemical neutralization. In decomposition, the leavening base is broken down by moisture and heat to release gases, which can then leaven the product. This is the case for ammonium bicarbonate. Potassium bicarbonate and sodium bicarbonate release carbon dioxide by chemical neutralization where a leavening acid is added, which reacts with the leavening base to produce the carbon dioxide gas.

Ammonium bicarbonate

Ammonium bicarbonate decomposes during baking to produce ammonia gas, carbon dioxide gas, and water. All three of these products act as leaveners. Because ammonia gas dissolves in water, it can be retained in moist products, giving them a sharp, pungent odor and rendering them inedible. For this reason, it is only used as a leavening agent in some dry cookies and crackers that have a final moisture content of less than 5%. Ammonium bicarbonate decomposes completely with heat, so a leavening acid is not needed. One advantage of ammonia bicarbonate is that it does not produce salts, which have an adverse effect on dough rheology:

$$\underset{\text{(ammonium bicarbonate)}}{NH_4HCO_3} \xrightarrow{\text{heat}} \underset{\text{(ammonia)}}{NH_3} + \underset{\text{(carbon dioxide)}}{CO_2} + \underset{\text{(water)}}{H_2O}$$

Sodium bicarbonate

Sodium bicarbonate, also known as baking soda, is the most commonly used leavening base. It is soluble in water and dissolves quickly during mixing. It only partially decomposes during heating, releasing less than half of the available carbon dioxide. It can be used alone in some cookies and snack crackers. However, in products that require higher carbon dioxide gas levels (i.e., cakes and other batter products), a leavening acid is needed to produce complete release of the carbon dioxide. Sodium bicarbonate is inexpensive, easy to handle, nontoxic, has high purity, and gives no aftertaste to the final product. The drawback is that the neutral salts produced in the reaction have a negative effect on the rheological properties of the dough, making it stiffer and less elastic, and some impact the flavor, color, odor, and crumb appearance of the final product:

$$\underset{\text{(sodium bicarbonate)}}{NaHCO_3} + \underset{\text{(acid salt)}}{H^+} \rightarrow \underset{\text{(neutral salt)}}{Na^+} + \underset{\text{(carbon dioxide)}}{CO_2} + \underset{\text{(water)}}{H_2O}$$

Potassium bicarbonate

Potassium bicarbonate can be used as a substitute for sodium bicarbonate to lower the sodium content of the finished product. It is soluble in water and partly decomposes upon heating to give partial release of the available carbon dioxide gas, thus requiring a leavening acid in order to yield complete release of the carbon dioxide. Potassium bicarbonate is seldom used because it has a bitter aftertaste and is highly hygroscopic, making it difficult to store:

$$\underset{\text{(potassium bicarbonate)}}{KHCO_3} + \underset{\text{(acid salt)}}{H^+} \rightarrow \underset{\text{(neutral salt)}}{K^+} + \underset{\text{(carbon dioxide)}}{CO_2} + \underset{\text{(water)}}{H_2O}$$

Leavening Acids

Only a small portion of the carbon dioxide is released when sodium bicarbonate is dissolved in water. The sodium bicarbonate decomposes into carbon dioxide, sodium carbonate, and water. The sodium carbonate raises the pH of the system and inhibits the reaction. The pH must be lowered in order for the remaining carbon dioxide to be released. This is done by adding an acid. The acid may be present in formula ingredients or added in the form of organic acids, food-grade phosphates, or acidic salts. Leavening acids are categorized by the time and rate at which they become soluble and able to react with the sodium bicarbonate to release carbon dioxide gas. This allows for the selection of the appropriate leavening acid to coordinate carbon dioxide release with the setting of the product. The reaction rate is critical to the quality of the final product. If the carbon dioxide gas is produced too soon, most of it escapes before the structure is set, while carbon dioxide gas produced

too late after the product has set may cause blowouts inside the product due to the high pressure. Ingredients in the formula such as calcium, sugar concentration, starch, hydrocolloids, and water level can affect the reaction rate. Leavening acids that solubilize immediately are fast-acting, while those that solubilize slowly or with heating are slow-acting.

Many acidic food ingredients such as buttermilk, sour milk, vinegar, fruit, fruit juice, sour cream, yogurt, honey, cocoa, and molasses are found in bakery product formulas. These foods do decrease the pH and allow the sodium bicarbonate to release more carbon dioxide gas. Drawbacks of these food ingredients are that they do not contain uniform acid content, impart distinct colors and flavors that may not be desirable in some products, and are all fast-acting. Commercial leavening acids (acidic salts) are more reliable and more consistent. Most common leavening systems utilize the reaction of sodium bicarbonate with an acid phosphate salt to produce carbon dioxide gas. The three broad categories of leavening acids are nucleating agents, time-release agents, and heat-release agents.

Nucleating agents solubilize quickly in the dough or batter and are referred to as fast-acting. Organic acids (citric, tartaric, fumaric, adipic, lactic, and malic), cream of tartar, monocalcium phosphate (MCP), and anhydrous monocalcium phosphate (AMCP) are in this category. During mixing, air is incorporated into the dough. Carbon dioxide gas generated in the chemical leavening reaction during the mixing step diffuses into the air cells and expands them. The large air bubbles are then subdivided into smaller-sized air bubbles by the mixer. The result is a larger number of smaller-sized air cells, which are more stable and which also produce a finer, more uniform crumb grain in the final baked product. Fast-acting leavening acids are generally not used alone because much of the carbon dioxide gas released during mixing gets lost during production.

Time-release leavening acids solubilize more slowly to react during a given period of time. Sodium aluminum pyrophosphate (SALP) and glucono-delta-lactone (GDL) are in this category. Both products have a slightly bitter aftertaste, which can be masked with calcium, sugar, and flavoring agents. These leavening acids find use in specific products such as cake doughnuts and refrigerated canned biscuit dough. In cake doughnuts, the carbon dioxide gas should be released in the fryer in order to raise the doughnut up out of the oil and expand it rapidly before it sets. In canned biscuit dough, the biscuits need to leaven inside the can to completely fill it and exclude all of the air from the can but not overexpand and explode the can.

Heat-release leavening acids react only with heating in the oven. Sodium aluminum sulfate (SAS), sodium aluminum phosphate (SALP), dimagnesium phosphate (DMP), and dicalcium phosphate dihydrate (DCPD) are in this category. The temperature at which they solubilize varies. The most commonly used leavening acids are listed in Table 1.

Monopotassium tartrate (cream of tartar) [$KHC_4H_4O_6$]

Cream of tartar was the first leavening acid to be used in baking. However, it is not highly used today. It is expensive and has such as fast reaction rate, generating about 70% of the available carbon dioxide gas during mixing; it is difficult to produce consistent products. It finds use in products such as angel food cakes where it is used not as a leavening acid but to lower the pH to improve the whipping of the egg whites.

Monocalcium phosphate [$Ca(H_2PO_4)_2{\cdot}H_2O$]

MCP is a nucleating or fast-acting leavening acid. It reacts quickly in the mixer, causing 60–70% of the available carbon dioxide gas to be released. There are several granulations available. The granulations do not impact the reaction rate but rather provide more stability during storage. Larger particles are more stable. However, if the particle size is too large and prevents the particle from completely solubilizing during mixing, black spots may occur on the final product. MCP is typically used in combination with other leavening acids. It is often the fast-acting leavening acid in double-acting baking powder.

Anhydrous monocalcium phosphate [$Ca(H_2PO_4)_2$]

AMCP is MCP that is coated with aluminum and potassium phosphates. The coating delays dissolution by a few minutes, causing release of about 15% of the available carbon dioxide gas in the mixer and 35% during the next 10–15 min of bench time. It is still a fast-acting leavening acid and acts as a nucleating agent. The coating basically increases stabilization in storage. AMCP may be used alone in corn-based products like corn bread or corn muffins or used in combination with other leavening acids in other baked products.

Table 1 Properties of common leavening acids

Leavening acid	*Acronym*	*Formula*	*NV*[a,b,c]
Monopotassium tartrate	Cream of tartar	KHC_4H_4O	45
Monocalcium phosphate	MCP	$Ca(H_2PO_4)_2{\cdot}H_2O$	80
Anhydrous monocalcium phosphate	AMCP	$Ca(H_2PO_4)_2$	84
Sodium acid pyrophosphate	SAPP	$Na_2H_2P_2O_7$	72
Sodium aluminum phosphate	SALP	$Na_3H_{15}Al_2(PO_4)_8$	100
Sodium aluminum sulfate	SAS	$Al_2(SO_4)_3{\cdot}Na_2SO_4$	100
Dimagnesium phosphate	DMP	$MgHPO_4$	40
Dicalcium phosphate dihydrate	DCPD	$CaHPO_4{\cdot}2H_2O$	33
Glucono-delta-lactone	GDL	$C_6H_{10}O_6$	50

[a]Neutralizing value (NV) is the parts of sodium bicarbonate that 100 parts of leavening acid neutralizes.
[b]NV for potassium bicarbonate is calculated by multiplying the listed NV by 1.19.
[c]NV for ammonium bicarbonate is calculated by multiplying the listed NV by 0.94.

Sodium acid pyrophosphate [$Na_2H_2P_2O_7$]

Sodium acid pyrophosphate (SAPP) is a time-release leavening acid, which reacts over time. There are several grades of SAPP (SAPP 21, SAPP 26, SAPP 28, SAPP 37, SAPP 40, SAPP 43, and SAPP 45), each with different reaction rates, which are controlled by the manufacturing process. The higher the number, the faster the reaction rate. Typically, the fastest SAPP that the product can tolerate is used to ensure a complete reaction. SAPP 21 and SAPP 26 have the slowest rate within the SAPP products and are commonly used in refrigerated canned biscuits and cake mixes and for products made using long production cycles. SAPP 28 is commonly used in commercial baking powder intended for all-purpose and institutional baking done in large batches that have long holding or bench times. SAPP 37, SAPP 40, SAPP 43, and SAPP 45 have the fastest reaction rates within the SAPP products and are commonly used in cake and cake doughnut production. SAPP is known to impart a characteristic off-flavor termed 'pyro' to the final product. This flavor can be masked with sugar, calcium, and flavoring agents.

Sodium aluminum phosphate [$NaH_{14}Al_3(PO_4)_8{\cdot}4H_2O$]

SALP is a heat-triggered leavening acid, which reacts at 38–41 °C. It is stable at low temperatures and generally does not react with other formula ingredients, so it maintains batter viscosity during holding or bench time. It has a bland, neutral flavor. It imparts a strong structure and gives resiliency to the final product. It is commonly used as the slow-acting leavening acid in double-acting baking powders. SALP is often used in combination with MCP or AMCP in self-rising flour, cakes, pancakes, muffins, dough made using long bench times, refrigerated dough, refrigerated batters, frozen dough, and frozen batters.

Dimagnesium phosphate [$MgHPO_4$]

DMP is heat-activated and reacts at 41–44 °C. It is stable at low temperatures and maintains batter viscosity during holding or bench time. It has a bland, neutral flavor. It imparts a strong structure and gives resiliency to the final product. It contains no sodium so it finds use in low-sodium products.

Dicalcium phosphate dihydrate [$CaHPO_4{\cdot}2H_2O$]

DCP is not an acidic salt and so not a true leavening acid, but it is grouped with the leavening acids. DCP slowly solubilizes over time and thereby lowers the pH and allows the release of carbon dioxide gas from the sodium bicarbonate. DCP does disproportionate to form phosphoric acid, MCP, and tricalcium phosphate, which can react with the sodium bicarbonate. However, this occurs at temperatures of 57–60 °C, which is too high to be effective in most products. DCP is used in combination with other leavening acids to provide continuous carbon dioxide gas evolution late in the bake cycle of products like cakes and muffins and also as a means to adjust the pH of the final baked product.

Sodium aluminum sulfate [$Al_2(SO_4)_3{\cdot}Na_2SO_4$]

SAS is a slow-acting, heat-activated leavening acid. It reacts too slowly to give good oven spring during baking so it not widely used. It has no reaction at room temperature and so is not used alone, but is used often in combination with MCP. SAS has a weakening effect on the crumb texture and a slightly astringent or metallic aftertaste. It is most commonly used as the slow-acting leavening acid in double-acting household-use baking powder. Commercially, it is used in chocolate cake for color adjustment and to produce the characteristic large holes in the crumb of English muffins.

Glucono-delta-lactone [$C_6H_{10}O_6$]

GDL is also not a true leavening acid but is categorized with them. GDL slowly hydrolyzes to gluconic acid, which results in a slow, continuous release of carbon dioxide gas over time. It works well as a yeast replacement in refrigerated and frozen dough products. A drawback is that it has a slightly bitter aftertaste.

Baking Powder

Baking powder provides a complete leavening system in one product. It is composed of sodium bicarbonate, one or more leavening acids, and a diluent. The diluent, typically starch or calcium carbonate, acts as a standardizing agent to dilute the active ingredients and to extend the shelf life of the baking powder by preventing the sodium bicarbonate and leavening acid from reacting in the container.

The proper balance of leavening acid and sodium bicarbonate is critical. In general, there should be little or no unreacted sodium bicarbonate or leavening acid in the final product. If the blend contains too much leavening acid relative to the sodium bicarbonate, the final product will be too acidic and have a tart or bitter flavor, an off color, and a pH that is too low (acidic). On the other hand, blends with too much sodium bicarbonate will produce final products with a soapy taste, yellow color, and alkaline pH.

In order to determine the appropriate amount of leavening acid to add, the neutralizing value (NV) is considered. NV is the number of parts by weight of sodium bicarbonate that can be neutralized (cause to release all available carbon dioxide gas) by 100 parts by weight of the leavening acid. NV is determined in the laboratory using titration. NVs of the common leavening acids for sodium bicarbonate are listed in Table 1. The NV of the leavening acid is different for ammonium bicarbonate and potassium bicarbonate. NV for these bases is calculated by multiplying the NV for sodium bicarbonate by 0.9375 for ammonium bicarbonate and by 1.1875 for potassium bicarbonate.

To calculate the leavening composition, first, the level of the sodium bicarbonate (or other leavening bases) is set based on the amount of leavening that is needed in the product. The level of acid needed to neutralize the sodium bicarbonate is then calculated by multiplying the level of sodium bicarbonate by 100 and dividing by the NV of the leavening acid. If multiple leavening acids are being used, the percentage of each acid is determined; then, the addition level of each is calculated. An example is shown in Figure 1. The calculated values provide a starting level, which may need to be adjusted depending on the product being made. Some products may contain other food acids in the formula, which may neutralize some of the sodium bicarbonate, thus reducing the level of leavening acid that is

Leavening system in formula:

0.75% sodium bicarbonate
10% of CO_2 generated in mixer with MCP (NV = 80)
90% of CO_2 generated in oven with SAPP (NV = 72)

Leavening acid level equation:

$$\text{amount of leavening acid} = \frac{\text{sodium bicarbonate \% x leavening acid \% x 100}}{\text{NV of acid}}$$

Amount of MCP to add:

$$\frac{0.75 \times 0.10 \times 100}{80} = 0.094\% \text{ MCP}$$

Amount of SAPP to add:

$$\frac{0.75 \times 0.90 \times 100}{72} = 0.900\% \text{ SAPP}$$

Figure 1 Sample leavening calculation.

needed. Also, it may be desired to have excess sodium bicarbonate or leavening acid in the formula in order to adjust the pH of the final product. Product pH is important for flavor and color. If a sharper, more astringent flavor is desired, the pH can be decreased (more acidic) by adding excess leavening acid. On the other hand, a more bland-flavored product may require less leavening acid to leave an excess of the sodium bicarbonate to increase the pH (more alkaline). Excess acid can produce undesirable tartness, while excess sodium bicarbonate can produce an undesirable soapy flavor. Product color is also impacted by pH. For example, a slight excess of sodium bicarbonate may be desired in a chocolate cake or muffin in order to provide the desired brown color.

By law, baking powder must release 12% carbon dioxide. Manufacturers often formulate baking powder to release 18% carbon dioxide to account for the loss of activity due to storage time and improper storage conditions to ensure that the final product releases 12% carbon dioxide. Baking powders are classified by type of release (single-acting or double-acting) and market segment (household or commercial). Single-acting baking powders contain only one leavening acid, which may be fast-acting and react in the mixer or may be slow-acting and react in the oven. Double-acting baking powders contain both fast-acting and slow-acting leavening acids. An ideal double-acting baking powder will release a small amount (~20%) of carbon dioxide gas in the mixer and the remainder in the oven. Most baking powders are double-acting. Household baking powders are formulated as 'all-purpose' products to be used in a variety of baked goods. They do not need to be bench-stable as the consumer typically mixes the batter and bakes it immediately. The most common leavening acids used in household baking powder are SAS and MCP. Household baking powders typically have a 1-year shelf life. Commercial baking powders are formulated for slow release as many commercially made or institutionally made products are done in batch operations. MCP and SAPP 28 are the most common leavening acids in commercial baking powders. Shelf life is 6 months.

Baking powder is convenient and reduces the number of minor ingredients that must be weighed out, and the leavening formulation has been properly calculated and balanced. Disadvantages are that the activity varies from 12% to 18% carbon dioxide release depending on the age of the baking powder and the leavening acids are general use and not tailored to specific products. For these reasons, many commercial bakers make their own leavening blends for consistency, economy, and correct timing of carbon dioxide gas generation.

Adjustments for High Altitude

As altitude increases, the atmospheric pressure decreases. This results in (1) greater expansion of leavening gases, (2) lower boiling temperature of water, and (3) faster evaporation of moisture. Alterations to the formula and process to account for these changes should be considered at elevations higher than 2500 ft above sea level.

The greater expansion of the leavening gases means batters and doughs will rise more quickly at higher altitudes. The effect is less pronounced in yeast-leavened products and is easily controlled by reducing the yeast level and increasing the flour level in the formula to make the dough stiffer. Another alternative is to keep yeast level constant but reduce fermentation and proof times. In the case of sweet yeast-raised dough, egg is added or the level of egg is increased to provide more structure.

In chemically leavened products such as cakes and cookies, the levels of sodium bicarbonate and leavening acids should be reduced. The amount of reduction is dependent on the altitude and varies from 25% reduction at 2000 ft to 75% reduction at 10 000 ft. Other suggested formula alterations include decreasing sugar level and increasing the levels of liquid, flour, and eggs.

The lower boiling temperature and faster evaporation of water make it necessary to increase baking time and/or baking temperature to ensure that the product is completely baked and the structure is fully set.

Legal Requirements for Food Hygiene

RH Dwinger, Netherlands Food and Consumer Products Safety Authority, Utrecht, The Netherlands
K De Smet, European Commission, Health and Food Safety Directorate-General (DG SANTE), Brussels, Belgium

© 2016 Elsevier Ltd. All rights reserved.

Introduction

'Hygiene' refers to conditions and practices that help to maintain health and prevent the spread of diseases. It therefore includes a specific set of practices associated with the preservation of health. Implementing hygiene in the entire food chain forms an essential element to prevent major foodborne illnesses such as caused by *Salmonella* or *Listeria* species in humans. For example, the number of *Salmonella* cases in humans reported by all member states of the European Union (EU) has been decreasing due to the introduction of EU-wide control programs, focussing on primary production (farms), and the food hygiene legislation preventing contamination at all stages of the production chain. The number of confirmed *Salmonellosis* cases in humans was 192 703 per year in 25 member states in 2004 as compared to 92 916 in 27 member states in 2012. Since the beginning of the twenty-first century, food hygiene legislation introduced some important new elements, such as that the food producer is held responsible for producing safe food, that all food producers should implement a auto-control system based on the hazard analysis and critical control points (HACCP) principles (except primary producers), and that decisions by regulatory authorities should be based on a risk analysis (consisting of risk assessment, risk management, and risk communication). Additionally, there was an extension of a harmonized set of microbiological criteria for food safety and the introduction of such criteria for process hygiene, which had to be implemented by the food business operators. By requiring strict rules at farm level, at processing and distribution levels, and during retail, hygiene levels of the final products for sale to the end user were further improved. Currently, the food hygiene legislation in Europe has been strengthened to provide a high level of consumer protection and a harmonized set of rules to create a single market and a level playing field. At the same time, the legislation provides flexibility to preserve traditional food products or local processing traditions and to facilitate small- and medium-sized enterprises. The various aspects of the food hygiene legislation in the EU will be explained in detail and related legislative aspects will be mentioned briefly. The European structure will also be compared with some distinguishing elements in the food hygiene legislation of some of the major trading partners.

Food Hygiene in the EU

Food hygiene as part of veterinary health rules has been laid down in the EU legislation almost since its creation. The veterinary health rules were already introduced as early as 1964 in the framework of the Common Agricultural Policy launched in 1962. The aim was to ensure a harmonized approach in order to ensure the safe movement of animals and animal products within the EU market. Such legislation evolved into a set of vertical rules on veterinary public health (and animal health) covering each sector (meat and meat products, milk and dairy products, fishery products, etc.).

In the 1990s, consumer confidence was severely undermined due to a number of events involving food, such as the occurrence of bovine spongiform encephalopathy (BSE) in cattle initially in the United Kingdom and later in many other countries and the detection of polychlorinated biphenyls and dioxins in animal feed in Belgium. As a result, the European Commission (EC) adopted the White Paper on Food Safety in 2000. The white paper outlined a plan for strengthening food safety policy intended to actualize the existing legislation to changing needs and establish a coherent and transparent set of rules, introducing the 'farm to fork' approach and the risk analysis methodology, with the objective to guarantee a high level of human health and consumer protection.

This ambitious program contained a number of recommendations aimed at increasing food safety, improving the traceability of food products, and ensuring consumer confidence in the food industry. To this end, a set of new legislation on food and feed was adopted between 2002 and 2006 with the following characteristics: to complete and update the legislation, improve official controls, and ensure their efficient implementation. The package consists of a number of elements: the general food law, the hygiene rules for food business operators, a comprehensive set of requirements for the official controls by the competent authorities, and a number of related pieces of legislation.

Around 10 years later, experiences gained with this package were evaluated. As a result of this evaluation, adaptations to the legislation were prepared and revisions considered (see section '**Ongoing Legislative Work**').

General Food Law

The objective of the general food law (Regulation (EC) No 178/2002) is to create a framework ensuring consistency between all food- and feed-related legislations. It lays down guiding principles and establishes common definitions, such as for 'primary production,' 'food business operator,' 'retail,' 'risk,' and 'hazard.' It aims at bringing together various related aspects of EU legislation by including not only safety aspects but also protection of consumer interests, by covering all foods and by including action at both national and EU levels. Furthermore, the regulation puts the overall responsibility for producing safe food on the food business operator. It requires the food business operator to have a system in place enabling them to identify the supplier(s) of the raw materials and the immediate customer(s) of their products in order to ensure

traceability. Other issues that are covered within this regulation are the principles of risk analysis, withdrawal of food from the market by the food business operator if safety is at stake, and the precautionary principle, which enables the adoption of provisional risk management measures as long as scientific uncertainty persists. Finally, it lays down the principles and requirements for the rapid alert system for food and feed (RASFF) and for the establishment of the European Food Safety Authority (EFSA).

The RASFF is a network involving member states and the EC. It is part of a global communication network on foodborne hazards (Infosan). Whenever a member of the network has any information relating to the existence of a serious direct or indirect risk to human health, this information is immediately notified to the EC following the RASFF procedures. The EC in turn transmits the information instantly to the other members of the network, which should take corrective measures, if applicable.

EFSA (see section '**European Food Safety Authority**'), based in Parma, Italy, is in charge of risk assessment and related risk communication. Starting from the risk assessment, the legislators and decision makers within the EC and the member states develop and implement risk management measures and communicate these measures accordingly.

Legislation on Food Hygiene Addressed to Food Business Operators

The 'hygiene package' consists of a total of four basic legislative parts, described in this section and in the following one, and of implementing acts described in section '**Transitional and Implementing Measures of the Hygiene Package**' (see **Figure 1**). It became applicable with effect from 1 January 2006. The hygiene package further clarifies the responsibility of the food business operator for producing safe food, while the competent authority of the member state verifies correct implementation of the rules. Production should be based on good hygienic practice and procedures based on the HACCP principles including requirements concerning microbiological criteria and temperature limits. The legislative texts deal with a variety of food types and cover the entire food chain ('from stable to table'). Two basic regulations apply to the competent authorities (see section '**Legislation on Official Controls**'), while the two others apply directly to food business operators:

- Regulation (EC) No 852/2004 on the hygiene of foodstuffs
- Regulation (EC) No 853/2004 laying down specific hygiene rules for food of animal origin

Regulation (EC) No 852/2004

This regulation lays down general hygiene requirements to be respected by all food business operators at all stages of the food chain including primary production (farms) for any kind of food.

The regulation requires all food business operators to put in place, implement, and maintain general hygiene requirements (such as concerning infrastructure, layout and equipment, (pre)operational hygiene measures, pest control, water quality, and personal hygiene). The general hygiene requirements (called prerequisite programs in North American legislation) provide the foundation for effective HACCP implementation and should be in place before an HACCP-based procedure is established. The details of the general hygiene requirements are laid down in Annexes to the Regulation. In addition, all food

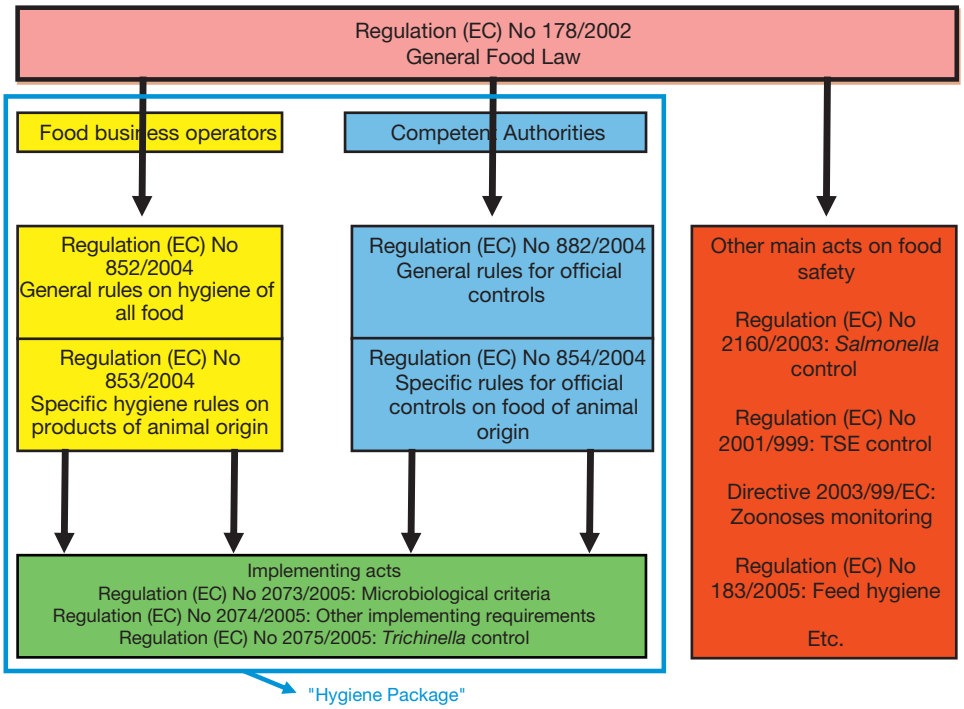

Figure 1 Overview of EU legislation on food safety.

business operators need to implement a program based on the HACCP principles (with the exception of those involved in primary production). The regulation allows the HACCP-based procedures to be implemented with flexibility so as to ensure that they can be applied in all situations including in small businesses. Guides to good practice have been developed by the food business sectors themselves, either at national level or at EU level, to help food business operators to implement general hygiene requirements and HACCP-based procedures tailored to the characteristics of their production.

In addition, the regulation requires food businesses to be at least registered to the competent authority. Such registration is a simple procedure whereby the competent authority is informed about the address of the establishment and the activities carried out. Already existing registration systems used for other purposes (environmental, animal health, or other administrative purposes) can be used. Apart from food business operators producing food of animal origin (see section '**Regulation (EC) No 853/2004**'), certain high-risk establishments may have to be approved before starting production (e.g., farms producing sprouts).

The regulation does not apply to small quantities of primary products supplied directly by the producer to the final consumer or to local retail establishments directly supplying the final consumer. National rules must however be adopted ensuring the achievement of the objectives of Regulation (EC) No 852/2004 but allowing at the same time a proportionate approach to the risk and the local situation. Examples of such products are vegetables, fruits, eggs, and raw milk, directly obtained from the farm, or products collected in the wild such as mushrooms and berries. All beekeeping activities are also considered as primary production. However, fresh meat is not a primary product since it is obtained after slaughter.

Regulation (EC) No 853/2004

This regulation is more specific than the previous one by laying down more detailed hygiene requirements to be respected by food business operators handling food of animal origin such as meat, live bivalve mollusks, fishery products, raw milk and dairy products, eggs and egg products, frogs' legs and snails, collagen, and gelatin at all stages of the food chain. The regulation mostly does not apply to retail, which for food hygiene purposes means all activities involving direct sale or supply of food of animal origin to the final consumer. In such cases, Regulation (EC) No 852/2004 does apply. Establishments handling food of animal origin for which the regulation lays down requirements in an Annex must be approved. Those establishments carrying out only primary production, transport operations, or storage of products not requiring temperature-controlled storage conditions are exempted from the approval procedure. Approval procedures involve an on-site visit by the competent authority to verify if the establishment fulfills all the requirements concerning infrastructure, layout, equipment, and hygiene. One of the requirements for approval is that the HACCP program has been validated and implemented correctly. By granting a conditional approval for 3 months (renewable for up to a maximum of 6 months), the competent authority will be able to assess the correct implementation of the HACPP program in the case of a newly started business under working conditions.

Flexibility Available Within the Legislation

In order to preserve the European heritage in product diversity and to ensure a proportionate approach for certain food businesses with a low throughput, legislation provides several opportunities for flexibility. Flexibility is available with regard to equipment and infrastructure requirements for the production of foods with traditional characteristics. Flexibility is also available to accommodate the needs of food businesses with a low throughput or situated in regions that are subject to special geographic constraints and for the continued use of traditional methods of production (at any stage of production, processing, or distribution of food). Flexibility for businesses with a low throughput is reflected in a reduction of frequency of auto-controls (e.g., for microbiological criteria) or even exclusion of certain provisions (e.g., primary production from procedures based on the HACCP principles and most retailers from the specific requirements in Regulation (EC) No 853/2004).

Finally, in certain cases, the legislation provides for the competent authority to authorize flexibility. These situations are usually introduced by wording, such as 'if the competent authority so permits,' 'unless otherwise authorized by the competent authority,' 'with authorization of the competent authority,' etc.

Apart from establishment-specific assessments mentioned in the previous paragraph, member states have to prepare national measures laying down and detailing the flexibility and need to notify them providing sufficient information to the EC and the other member states. This procedure is needed in order to ensure full transparency and fair trade since food may be distributed throughout the entire EU.

Legislation on Official Controls

This legislation is directed at the competent authorities and lays down the general principles to be respected and checks to be carried out for ensuring the official controls are objective and efficient. Furthermore, the legislation has been designed to promote a more risk-based approach for official controls.

Regulation (EC) No 882/2004 (Official Feed and Food Controls)

Regulation (EC) No 882/2004 on official controls was the result of a review of various EU rules on the subject, which were adopted separately for the feed (animal nutrition), food, and veterinary sector. The regulation covers the basic principles and the entire range of activities dealing with feed and food law, including animal health, animal welfare, and in certain aspects plant health. By means of this regulation, the EU approach to official controls was harmonized.

As a consequence of this regulation, the member states had to reorganize their official controls systems so as to integrate controls at all stages of production and in all the concerned sectors, using the 'farm to fork' principles. They had to submit a multiannual national control plan for the implementation of feed and food legislation and to report annually on the implementation of that plan. The control plans and reports need to take into account guidelines published by the commission as Decision 2007/363/EC.

The regulation provides for a set of general rules applicable to the official controls of all feed and food, whether produced within the EU or exported to or imported from third countries. In addition to the general rules, there are specific control measures to maintain a high level of protection. This is, for example, the case for the specific veterinary control rules on imports of animals and food of animal origin or for the specific control rules for organic products. The regulation also provides the possibility to draw up a list of feed and food of nonanimal origin, which shall be subject to an increased level of official controls at the point of entry. This list can be found in Regulation (EC) No 669/2009 and is regularly updated by adding (or removing) products and countries of origin or by increasing (or decreasing) the percentage of imported products to be retained for analyses. Therefore, it is important to check the latest amendment of Regulation (EC) No 669/2009 or to search for the consolidated version (see section '**How to Find the Legislation**').

Regulation (EC) No 882/2004 also lays down European reference laboratories (EURLs) to be appointed to assist the EC (follow-up and validation of new laboratory methods for the detection of foodborne infections, technical support to specific legislation, etc.). If a EURL has been established, each member state must appoint a national reference laboratory (NRL). Each EURL regularly evaluates the performances of the NRLs by organizing proficiency tests. Annex VII of Regulation (EC) No 882/2004 provides a list of the by now more than 40 EURLs dealing with different subjects (*Salmonella*, *Listeria*, and nine others in the area of food hygiene) with their exact addresses in the various member states.

The Food and Veterinary Office (FVO), a directorate of the Directorate General for Health and Consumers (DG SANTE) of the EC, is based in Grange, Ireland. The role of the FVO is mainly auditing (national) competent authorities with the purpose of verifying the efficiency of the control systems in the member states and legislation and control systems in third countries for compliance or equivalence with EU rules. The requirement for all member states to submit a multiannual national control plan facilitates the carrying out of these audits. The inspectors of the FVO visit all member states and third countries that (wish to) export to the EU. Every inspection results in a report, which is published on the DG SANTE Internet site. With regard to food hygiene, a large number of inspection reports are available not only on individual countries but also an overview on a specific theme of a series of inspections, carried out in member states or third countries. In addition, FVO has compiled individual country profiles, which give an overview of the organization of food safety, animal health, animal welfare, and plant health control systems in each member state.

Currently, a major revision (under ordinary procedure – see section '**Revision by Ordinary Procedure**') of Regulation (EC) No 882/2004 is being undertaken as part of a package of five interrelated texts dealing with animal health, protective measures against pests of plants, plant reproductive materials, official controls, and food and feed expenditure. These texts have been published by the EC as proposals for discussion by the European Parliament and the Council. It usually takes 2 years before the final versions of the texts can be adopted and another couple of years (by way of a transitional period) before the requirements need to be applied by the member states.

Regulation (EC) No 854/2004

Regulation (EC) No 854/2004 supplements the more general Regulation (EC) No 882/2004, with detailed requirements for independent, official controls on animals sent for slaughter, official controls with regard to processing and placing on the market of fresh meat, fishery products, raw milk, and dairy products, and with control procedures concerning imports. Slaughterhouses provide an opportunity for inspection and evaluation of fitness for human consumption as it allows checking the live animals on arrival (antemortem inspection) as well as the carcasses and other parts such as organs of slaughtered animals (postmortem inspection). Meat inspection at the slaughterhouse is therefore a very important part of Regulation (EC) No 854/2004. Meat inspection should be risk-based. Meat inspection can be facilitated by imposing stricter hygiene measures at the farm level and by requiring the farm operator to send animals for slaughter in a clean state together with relevant management and health information, called food chain information. These principles were introduced in the regulation. Currently, a number of initiatives are ongoing with the main purpose to better adapt meat inspection to current and emerging risks (see section '**Risk-Based Meat Inspection**'). In addition, the revision of Regulation (EC) No 882/2004 (see section '**Regulation (EC) No 882/2004 (Official Feed and Food Controls)**') repeals Regulation (EC) No 854/2004 but takes over its major requirements such as the distribution of tasks in meat inspection, taking into account the primary responsibility of the food business operator for his product, but maintaining an independent, risk-based, and cost-efficient supervision by competent authorities.

Transitional and Implementing Measures of the Hygiene Package

Transitional Arrangements

Transitional arrangements have the purpose to facilitate a smooth transition from previous rules to new ones allowing adaptation without causing interruption of trade. Remaining transitional measures are laid down in Regulation (EU) No 702/2013 and Regulation (EU) No 1079/2013. They include a temporary derogation for the accreditation of laboratories located in a slaughterhouse or a game handling establishment, carrying out official testing for the presence of *Trichinella* parasites in meat and import conditions for certain food of animal origin and for composite products (products containing both products of nonanimal origin and processed products of animal origin, e.g., pizza with ham and cheese). Within the ongoing revisions under ordinary procedure, final provisions should be decided on (see sections '**Regulation (EC) No 854/2004**' and '**Revision by Ordinary Procedure**').

Implementing Rules on the Examination of Meat for *Trichinella* Parasites

Detailed legislation has been in place for many years to specify the examination for *Trichinella* of carcasses of swine, horses, and other susceptible animal species. Regulation (EC) No 2075/2005 contains details on the sampling procedure, the

various examination techniques in the laboratory, and the derogations granted. The regulation introduced a number of elements to increase food safety for the consumer and simplify the sampling procedure for those establishments where the parasite has not been encountered for a long time. A substantial review of the rules for *Trichinella* testing in pig meat applies from 1 June 2014 (see section '**Risk-Based Meat Inspection**'). In line with amended standards of the World Organisation for Animal Health (OIE (2014)) and with the 'Guidelines for control of specific zoonotic parasites in meat: *Trichinella* species' intended to be adopted by the Codex Alimentarius Commission in July 2015 and in line with evidence observed at surveillance during the last decennia, systematic testing of slaughter pigs kept under controlled housing conditions is no longer mandatory.

Regulation on Microbiological Criteria for Foodstuffs

By the adoption of Regulation (EC) No 2073/2005, previously existing microbiological criteria were reviewed and some new ones added, taking into account recent developments in food microbiology and updated scientific advice. The main objectives of this regulation are to ensure a high level of consumer protection with regard to food safety and to harmonize the microbiological criteria in the member states. National food safety criteria can only be imposed exceptionally upon agreement after notification to the EC and other member states. Therefore, this harmonization also substantially facilitated trade between member states, who might have applied different national criteria before 2005.

The purpose of the regulation is to reduce the number of specific foodborne diseases in humans. Two different types of criteria for foodstuffs are used, which need to be complied with by the food business operator: food safety and process hygiene criteria.

Food safety criteria have been laid down for agents that commonly cause serious foodborne diseases in humans, such as certain *Salmonella*, *Listeria monocytogenes*, *Enterobacter sakazakii*, staphylococcal enterotoxins, and histamine. If limits of food safety criteria are exceeded, the batch has to be withdrawn from the market. Examples of food safety criteria are the following combinations of food category/microorganism: a *L. monocytogenes* criterion for all ready-to-eat foods (e.g., cheese, ham, and smoked fish) and a *Salmonella* criterion for certain ready-to-eat foods (e.g., ice cream), minced meat, meat preparations, and certain meat products.

In addition, the regulation includes process hygiene criteria, such as *Enterobacteriaceae* and *Salmonella* in carcasses of slaughtered animals, *Staphylococci* in certain types of cheese, and *Escherichia coli* in precut fruit and vegetables. These criteria are indicators of the correct functioning of the manufacturing process and are not related to a direct major public health risk. Noncompliance, therefore, does not result in the withdrawal of the affected batch but must result in measures to improve the hygiene of the production process.

The sampling frequency is stipulated for a few criteria, for example, for *Salmonella* in minced meat and carcasses. In other cases, the food business operators have to decide on the sampling frequency on a case-by-case basis taking into account the risk related to their products and integrated in the procedures based on the HACCP principles. Although the regulation is directed at food business operators, competent authorities must, for various reasons, take samples to verify that the criteria laid down in the regulation are met (a guidance document has been prepared – see section '**Guidance Documents for the Legislation on Food Hygiene**'). It is important to consult the consolidated version (see section '**How to Find the Legislation**') of Regulation (EC) No 2073/2005 since this piece of legislation is continuously evolving due to the addition of new criteria and/or new limits or procedures as scientific insights progress. For example, new food safety criteria were introduced, for example, for *Salmonella enteritidis* and *S. typhimurium* in fresh poultry meat and for certain verotoxin-producing *Escherichia coli* (VTEC) on sprouts as a result of an outbreak implicating sprouted seeds in Germany in May 2011.

In the absence of EU food safety criteria, the evaluation of the food must be done in accordance with Article 14 of Regulation (EC) No 178/2002, which provides that unsafe food must not be placed on the market. On the basis of this article, competent authorities can take corrective measures as long as the measures are proportionate and based on a case-by-case risk assessment.

Other Implementing Measures

A wide range of other implementing measures have been laid down in Regulation (EC) No 2074/2005 including detailed provisions concerning food chain information, fishery products, recognized testing methods for detecting marine biotoxins, calcium content of mechanically separated meat, lists of establishments, and a derogation for foods with traditional characteristics.

Guidance Documents for the Legislation on Food Hygiene

A number of documents have been prepared to give guidance on the implementation of the food hygiene requirements and related subjects. The documents aim to assist the food business operators and the competent authorities of the member states. The guidance documents are not formal acts of legislation, but the EC will defend where necessary the consensus laid down in these documents. Some examples are given in the succeeding text (those with an * have been placed on the DG SANTE Internet site):

- Guidance document on the implementation of the main General Food Law requirements*
- Guidance document on Regulation (EC) No 852/2004*
- Guidance document on Regulation (EC) No 853/2004*
- Guidance document on the implementation of HACCP and facilitation of the implementation of the HACCP principles in certain food businesses*
- Guidance document on community guides to good practice*
- Practical guide on food contact materials*
- Guidance documents on import requirements*
- Guidance document on the preparation of multiannual control plans as laid down in Regulation (EC) No 882/2004 (published as Decision (EC) No 2007/363/EC)

- Guidance document laying down criteria for the conduct of audits (published as Decision (EC) No 2006/677/EC)
- Guidance document on official controls, under Regulation (EC) No 882/2004, concerning microbiological sampling and testing of foodstuffs*
- Document concerning the flexibility available within the various hygiene regulations, namely, two different parts: commission staff working document on the understanding of certain provisions on flexibility provided in the Hygiene Package and Frequently Asked Questions: guidelines for food business operators*
- Commission staff working document on the understanding of certain provisions on flexibility provided in the Hygiene Package and Frequently Asked Questions: guidelines for the competent authorities*

Related Food Safety Legislation

Food hygiene rules set the major framework for safe food, avoiding foodborne infections. When considered appropriate, these rules are supplemented by measures for the control and monitoring of certain specific pathogens (foodborne zoonoses such as *Salmonella*, BSE). In addition, food hygiene is further enhanced and complemented by hygiene rules at preceding steps (feed hygiene) and safe disposal of by-products (not intended for human consumption) of the production of food of animal origin. Finally, although the presence and cross contamination of all hazards, including chemical ones, form part of the hygiene package, specific rules on chemical hazards must also be implemented. These additional rules will be briefly specified.

Provisions on the Control of Specific Foodborne Zoonotic Infections and Monitoring of Zoonoses

Regulation (EC) No 2160/2003 is a specific application of hygiene rules focussing on specific foodborne infections (mainly biosecurity measures at farm level). Implementing rules address *Salmonella* control in poultry but can be extended to other species (e.g., pigs) or pathogens (e.g., *Campylobacter*). Targets for reduction of disease prevalence rates and trade restrictions on infected flocks/herds must ensure that fewer animals affected by a foodborne pathogen are introduced in the food chain.

Directive 2003/99/EC and Decision 2119/98/EC oblige member states to monitor foodborne (and other zoonotic or infectious diseases such as rabies, influenza, vector-borne diseases) in food/animals and humans, respectively. This monitoring is essential to evaluate the effect of measures taken on food hygiene, to assess trends, and to identify emerging risks. The results are published annually in a joint report prepared by EFSA and the European Centre for Disease Prevention and Control (ECDC). This continuous monitoring has triggered a revision of measures for *Salmonella* and *Trichinella* controls.

Legislation on Transmissible Spongiform Encephalopathies (Including BSE)

The recognition of the causal link between BSE and the human variant Creutzfeldt–Jakob disease led to one of the major crises that ever affected the feed and food sectors. The key piece of legislation to protect human and animal health from the risk of BSE and other transmissible spongiform encephalopathies (TSEs) is Regulation (EC) No 999/2001 (the TSE Regulation). The TSE regulation provides measures targeting all animal and public health risks resulting from all animal TSE and governing the entire chain of production and placing on the market of live animals and products of animal origin. It includes rules for the monitoring of TSE in bovine, ovine, and caprine animals, restrictions concerning the use of animal proteins in animal feeding, and the removal of the so-called specified risk material. Specified risk materials are animal tissues being most at risk of harboring the TSE agent (e.g., brain and spinal cord). In order to prevent any recycling of possible TSE agent, these tissues are collected and completely destroyed through incineration. Recently, the commission produced a road map on the TSE strategy, which outlines possible amendments of certain measures in the short, medium, and long terms without endangering the health of the consumer or the policy of eradicating BSE. Due to the stringent and extensive measures taken, the number of cases tested positive in the EU for BSE has been decreasing each year, and the number of countries recognized by OIE as having a negligible BSE risk in accordance with its strict rules as laid down in the Terrestrial Code is increasing.

Feed Hygiene

Regulation (EC) No 183/2005 ensures that hygiene is considered at all stages that may have an impact on feed safety and, consequently, food safety, including during primary production (at farm level). It requires registration of all feed business operators and the approval of some of them using more sensitive feed additives in premixtures or compound feedingstuffs. The regulation requires operators to follow harmonized hygiene requirements and implement HACCP-based procedures. The development of EU and national guides to good practice in feed production has been successfully encouraged.

Legislation on Animal By-Products

Regulations (EC) No 1069/2009 and Regulation (EU) No 142/2011 lay down health rules for the collection, transport, storage, handling, processing, and use or disposal of all animal by-products (ABPs) not intended for human consumption. The regulations complete the hygiene rules by providing a framework for the safe disposal of products that may present a risk to animal or public health directly through (unintended) consumption or indirectly, for example, by contaminating the environment. To that end, the legislation distinguishes three different categories of ABPs, based on risk. Category 1 material has the highest risk and is usually incinerated. Category 2 is less risky material and can not only be incinerated but also be composted or used for biogas production. Category 3 material can be used for animal feed under certain conditions. The last category includes parts of slaughtered animals that have been found fit for human consumption, but are not for one reason or another intended for human consumption. ABPs include among others bones and other parts of slaughtered animals but not intended for human consumption (food), fallen stock, animal feed (e.g., based on fishmeal and processed animal

protein), organic fertilizers and soil improvers (e.g., manure, guano, and products on the basis of processed animal protein), technical products (e.g., pet food, hides and skins for leather, wool, and blood for producing diagnostic tools). In the EU, more than 20 million tons of by-products emerges annually from slaughterhouses, plants producing food for human consumption, and dairies and as fallen stock from farms.

Legislation on Residues

Residues are substances that can occur in foodstuffs as a side effect of using veterinary medicines or phytosanitary products. They are unwanted traces of medicines or plant protection products or derivatives thereof that remain in the final product. Member states need to adopt and implement every year a plan to monitor live animals and products thereof, including meat, for residues of prohibited substances (e.g., hormonal substances for fattening purposes) or for substances permitted below a certain threshold, the so-called maximum residue limit. The latter group of substances includes veterinary medicinal products, pesticides, and environmental contaminants. Details of the substances involved and of the residue monitoring plan can be found in Directives 96/22/EC and 96/23/EC and their amendments. The aim of the national residue monitoring plan is to ensure that permitted levels are not exceeded and that forbidden substances are not present in food. A useful manual on how to design a national residue monitoring plan is available.

Legislation on Contaminants

Contaminants are substances that can unintentionally enter food during the various stages of its production, packaging, transport, or holding or as a result of environmental contamination. Regulation (EEC) No 315/93 lays down the basic principles to minimize contaminants in food, while Regulation (EC) No 1881/2006 sets maximum levels for certain contaminants in foodstuffs. EU measures have been taken for the following contaminants: mycotoxins, heavy metals, dioxins and PCBs, polycyclic aromatic hydrocarbons, 3-MCPD (3-monochloro-propane-1,2-diol is a by-product in soy sauce and can be also present as a contaminant in some food additives and may be present in drinking water as flocculants or coagulant aids), and nitrates.

Other Legislation

Additional legislation may apply, such as rules on food additives (substances added intentionally to foodstuffs to perform certain technological functions), biocides, food contact materials, and labeling requirements.

Animal health requirements apply to the live animals that are going to be slaughtered, while welfare requirements apply to the management of animals on the farm, the transport of animals to the slaughterhouse, and the killing of animals at the slaughterhouse. Additional legislation to take into consideration regarding the production of fruits and vegetables concerns the use of plant protection products (e.g., pesticides), food contact materials, genetically modified organisms (GMOs), etc.

Ongoing Legislative Work

The commission prepared a report to the European Parliament and the Council in 2009, reviewing the experience gained with the application of the hygiene package and recommended changes, amendments, or improvements to facilitate implementation of the hygiene package. Most recommendations have already been effected. Others are still under discussion since amendments can only be made following the (quite heavy) ordinary procedure (see section '**Revision by Ordinary Procedure**') and/or scientific advice from EFSA and comprehensive consultation of all stakeholders involved including member states.

Revision by Ordinary Procedure

Basic provisions of the hygiene Regulation Nos 852/2004, 853/2004, and 854/2004 can only be amended following the ordinary procedure, including consultations and the preparation of an impact assessment before sending an EC proposal to the European Parliament and the Council for discussion and adoption. Two main issues are intended to be addressed in the EC proposal:

- Definitive requirements for import of composite products using a risk-based and proportionate approach
- Simplification of the notification procedure for adaptations of requirements, needed to allow a proportionate application of the hygiene rules by small- and medium-sized enterprises (see flexibility under section '**Flexibility Available Within the Legislation**').

The proposal of the EC may be forwarded to the European Parliament and the Council in 2015. It would be a starting point for discussion and additional possible amendments may be put on the agenda (e.g., revision of certain definitions).

Treatment to Remove Surface Contamination

Regulation (EC) No 853/2004 permits substances other than potable water to remove surface contamination from products of animal origin, subject to approval by the EC.

Treatment to remove surface contamination might constitute an additional element in further reducing the number of pathogens in food, especially *Salmonella*, VTEC, and *Campylobacter*, provided that an integrated control strategy is applied throughout the entire food chain. Surface decontamination may never replace good hygiene practices or procedures based on the HACCP principles.

Before approving, a file must be submitted and assessed by EFSA containing information on the efficacy, safety (including effect on antimicrobial resistance of pathogens), and environmental effects. Following a favorable scientific opinion by EFSA, so far, only the use of lactic acid to reduce microbiological surface contamination on bovine carcasses, half-carcasses, or quarters in the slaughterhouse has been authorized provided that an HACCP-based management system is in place and sampling for compliance with the microbiological criteria has taken place beforehand (Regulation (EU) No 101/2013).

Risk-Based Meat Inspection

Meat inspection has focussed traditionally on the detection of zoonotic diseases, such as tuberculosis and brucellosis, which have been largely eradicated from herds kept under modern management conditions or do not occur in the majority of the very young and generally healthy animals slaughtered nowadays. Other hazards such as *Salmonella* and *Campylobacter* have become the most important foodborne infections, and cross contamination by these pathogens may even be enhanced by incisions and palpations as part of current meat inspection procedures. Therefore, a reorientation of meat inspection toward these current risks is ongoing. EFSA recently adopted a number of opinions, setting priorities for meat inspection in different animal species and making recommendations for the adaptation of official controls. The EC has agreed with the member states on amending inspection of slaughtered fattening pigs, for example, by making visual inspection the general rule, limiting palpation and incisions to cases where needed (Commission Regulation (EU) No 218/2014), simplifying testing procedures for *Trichinella* parasites (Commission Regulation (EU) No 216/2014), and enhancing *Salmonella* monitoring (Commission Regulation (EU) No 217/2014). Step by step, meat inspection in other animal species will be reconsidered and legislation will be revised.

How to Find the Legislation

All the legislative texts can be recovered in the 24 official languages of the EU from the Internet site EUR-Lex, the gateway to the law of the EU. By way of the button 'simple search' and thereafter 'reference number document,' one can type the year of publication and the number of the required legislative text. The entire text can then be read in the desired language. Some legal texts have been amended a number of times following their publication. In such a case, it is advisable to request the 'consolidated version' (instead of the 'reference number document'). When amendments have been made to the original act, they are as quickly as possible inserted and properly indicated in the consolidated version.

European Food Safety Authority

EFSA deals with risk assessment and related risk communication issues on a European scale. EFSA provides scientific advice and recommendations on the control of existing and emerging risks and is independent from the risk managers. Its remit covers food and feed safety, nutrition, animal health and welfare, plant protection, and plant health. In addition, EFSA performs environmental risk assessments of genetically modified crops, pesticides, feed additives, and plant pests. EFSA often collaborates with ECDC, the EU agency aiming to strengthen and develop continent-wide human disease surveillance and early warning systems across Europe. EFSA and ECDC jointly prepare every year a summary report on the occurrence of zoonoses (see section '**Provisions on the Control of Specific Foodborne Zoonotic Infections and Monitoring of Zoonoses**').

Food Hygiene Legislation Outside of the EU

The legislation in the EU can be considered as rather progressive due to its emphasis on placing the responsibility for producing safe food on the food business operators, the efforts to lay down rules concerning the entire food chain from start to finish and due to the great emphasis on risk assessment, risk communication, and risk management. Moreover, various key elements form distinguishing features of the European food hygiene legislation, such as the requirement to implement HACCP in all food-producing establishments (except in primary production), the emphasis on risk-based inspections, separating risk assessment from risk management, etc.

However, for trade purposes, it is necessary to fulfill food hygiene requirements of the importing country (e.g., at import in the EU, third countries need to comply with EU rules), and therefore, it is worthwhile to examine briefly some of the distinguishing features of the legislation in other major trading partners and/or some useful guidance documents.

International Aspects

Where international standards exist, they have been taken into consideration in the development or adaptation of the European food safety legislation. This applies to standards developed by the Codex Alimentarius Commission, which has been created by the Food and Agriculture Organization (FAO) and the World Health Organization (WHO) to develop food standards, guidelines, and related texts such as codes of practice. It also applies to standards related to hygiene rules at animal rearing, animal health, and animal welfare developed by the OIE. Similarly, ISO (International Organization for Standardization) and CEN (European Committee for Standardization) standards have been incorporated in the EU legislation as analytic reference methods as far as possible (as can be seen, e.g., in Regulation (EC) No 2073/2005).

The United States

In the United States, the work regarding food safety is divided between the Food Safety and Inspection Service (FSIS), a public health agency in the US Department of Agriculture responsible for ensuring the safety of the nation's commercial supply of meat, poultry, and egg products, and the Food and Drug Administration (FDA), which regulates foods other than meat, poultry, and egg products. The FDA is also responsible for the safety of drugs, medical devices, biologics, animal feed and drugs, cosmetics, and radiation-emitting devices. Differences exist in inspection approach and procedures between FSIS and FDA. This has an effect on the traceability of food, the implementation of HACCP in some food establishments (e.g., voluntary for dairy processing establishments), and requirements for food business operators. Differences also exist between US and EU legislative requirements regarding *Salmonella* and *Listeria* criteria for food products. In order to facilitate trade in live animals and animal products between the two partners, a veterinary equivalency agreement was signed in 1999. The annexes to the agreement were amended by Decision 2003/833/EC on sanitary measures to protect

public and animal health. On 14 June 2013, member states gave the EC the green light to start trade and investment talks with the United States. The negotiations aim to establish a bilateral free trade agreement focussing initially on cutting barriers to trade and harmonizing regulations across a large range of economic activities including food safety. The current negotiations in the Transatlantic Trade and Investment Partnership will have to resolve some differences in approach between the United States and the EU concerning food safety. Subjects that are likely to be discussed range from differences in microbiological criteria and decontamination in the slaughterhouse to approval for use of GMOs and the use of growth promoters in the animal industry.

Canada

The EU has a veterinary agreement with Canada, while discussions concerning a comprehensive free trade agreement have been quite successful and are in its final stages. Some examples of the issues still under discussion concern an organics equivalence agreement, which aims to recognize each other's organic production standards, trade in products derived from animal cloning, the EU approval system for GMOs, use of growth hormones in cattle and pigs, and decontamination of meat in slaughterhouses.

New Zealand

The New Zealand Food Safety Authority has implemented a new approach to food safety since its inception in 2002. The approach is based on a system of performance-based inspections across the entire food chain and provides for a full cost recovery of inspections. Food businesses manufacturing or processing animal products (all primary processors and certain secondary processors) are required to adopt a risk management program. Those food businesses selling food need to implement a food safety program, which is a risk-based approach to food safety. Detailed guidance is provided by the competent authority and codes of practice are available reflecting acceptable industry-agreed practice.

China

Approximately ten government departments and ministries under the State Council monitor food safety in China. The China Food and Drug Administration has been established to oversee all aspects of food safety regulations and unify food safety controls. However, law enforcement is facing severe challenges due to Chinese food market characteristics: scattered and small production units without quality and safety priorities, lack of consumer awareness of food safety concerns, and overlapping competencies between central and provincial governments. The General Administration of Quality Supervision, Inspection and Quarantine (AQSIQ) is responsible for the supervision of safety concerning imports and exports. The EU SME Centre has published a useful guideline to assist food businesses with understanding the rules for exporting food to China. The Netherlands and China recently agreed to facilitate import of dairy products through electronic certification. The Food Safety Law is currently being revised.

Southeast Asia

A very useful HACCP manual has been developed in 2005 for food business operators in Southeast Asia, while FAO and WHO have issued a year later guidance to governments on the application of HACCP in small and/or less-developed food businesses.

Acknowledgments

We wish to acknowledge the critical comments from J. Ordeig-Vila from DG AGRI and T. Chalus from DG Santé and the helpful information provided by D. Beutener, Canadian Embassy in the Netherlands and N. Runia, Dutch agricultural counselor in Beijing.

Legumes in the Diet

JA Gutiérrez-Uribe, D Guajardo-Flores, and L López-Barrios, Tecnológico de Monterrey, Monterrey, Mexico

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Many diets in developing countries are based on legume and cereal products. Legumes are a good source of proteins, carbohydrates, dietary fibers, and micronutrients such as vitamins, minerals, and fatty acids. There is an increasing interest in other minor components – or phytochemicals – that may provide additional health benefits. Multiple experimental and clinical studies support the role of phytochemicals and functional foods in the prevention and treatment of diseases. The consumption of these compounds has been associated with the reduced risk of cancer, cardiovascular disease, diabetes, chronic inflammation, neural degeneration, and other chronic ailments and illnesses. Legumes are a good source of raw materials for the production of ingredients for nutraceuticals and functional foods.

Most of the phytochemicals, including dietary fibers and polyphenols, are found in the germ and seed coat. Therefore, in general, food products made from whole grains or legumes are preferable. During processing, grains and legumes often have the germ and the seed coat removed; thus, important dietary fibers, vitamins, minerals, and phytochemicals are lost. The processing of beans and other legumes to produce both nutritional and nutraceuticals food-based products represents a major opportunity to the health-conscious market.

This article focuses on the nutritional value, phytochemical composition, the properties of the potential health benefits of legumes, and how these can be used to produce food ingredients in addition to their traditional consumption.

Economic Importance of Legumes

The *Leguminosae* (*Fabaceae*) family (also called legumes) is the third largest family of flowering plants, comprising 751 genera and 19 500 species. Agricultural purposes of legumes include grain and blooms production, medicinal and industrial uses, pasture, forage, fallow, green manure, and timber. It is the seeds (or grains) that are the primary portion of the plant used for human consumption.

Alfalfa (*Medicago sativa*) and clover (*Trifolium sp*) are important legume crops used mostly for silage and forage. Their production is significantly higher than that reported for other legumes (Figure 1). But, it is important to consider that around 80% of their weight is water; which is much higher than the moisture content of other harvested legumes (around 15%), such as soybeans. The United States of America, Egypt, Argentina, and México are among the top producing countries, delivering from 28 to 228 million tons in a 10-year period (2003–13).

Soybeans (*Glycine max*) and peanuts, or groundnuts, (*Arachis hypogaea*) are legumes used for oil extraction or harvested green for food. The top producing countries include USA, Brazil, Argentina, China, and India (Figure 1). Soybean and pulses cover the most harvested area among legumes. By 2012, 105 million hectares worldwide were utilized for soybean cultivation and 80 million were utilized for pulses. Groundnuts, alfalfa, and clover reached a harvested area of 25, 15, and 3 million hectares respectively (Figure 2).

Pulses are another sub-category of legumes used for human consumption. According to the FAO (Food and Agricultural Organization), 11 primary crops of dry seeds are considered pulses: Dry beans, dry broad beans, dry peas, chickpeas, dry cowpeas, pigeon peas, lentils, Bambara beans, vetches, lupins, and minor pulses. Globally, consumption of pulses is 19 g per person per day. Asian countries are among the major consumers and producers. Between 3 and 15 million tons were produced in a 10-year period (2003–13) from the top producing countries, which includes India, China, Canada, Myanmar, and Brazil (Figure 3).

Legumes are used for rotation farming with cereals. They supply nitrogen to the cereal crops. Depending on the crop, plant nitrogen derived from N_2 fixation can range from 36% on common beans to 65% for pulses like the chickpea, lentil, pea, cowpea, mung bean, or pigeon pea. Although much of the N_2 fixed by the legumes is usually removed at harvest, it is well known that legume inclusion in a cropping sequence improves the productivity of the following crops and may replace a significant quantity of N fertilizer.

Nutritional Value of Legumes

Legumes contain 58–63% complex carbohydrates. Compared to cereals, they contain a higher amount of protein. Among legumes, pulses are an inexpensive source of proteins that have long been one of the main – or staple – sources of protein in many parts of the world. They have been used as a substitute for meat in more affluent societies, and play an important role in alleviating protein–energy malnutrition in less affluent societies. In many low-income countries, where they are part of staple diets, pulses provide a significant portion of total protein consumed (Figure 4).

Dietary fiber is another exceptional feature of dry beans; their content is relatively high (10.6–25.0%) compared to rice (1.3–3.5%), corn (7.3–8.5%), and wheat (10.5–12.7%). Dietary fiber intake from legumes has also been associated with the reduction of prostate and colorectal cancer risk.

Micronutrients are involved in all aspects of the human body, and their deficiencies can cause an increased risk of death by infectious and chronic diseases. The most important minerals for human health are iron, calcium, and zinc; their deficiencies in the human diet contribute to high rates of mortality in developing countries. A portion of dry beans (1 cup = 85 g) may contribute up to 22%, 54%, and 29% of the recommended daily intake of calcium, iron, and zinc. Also,

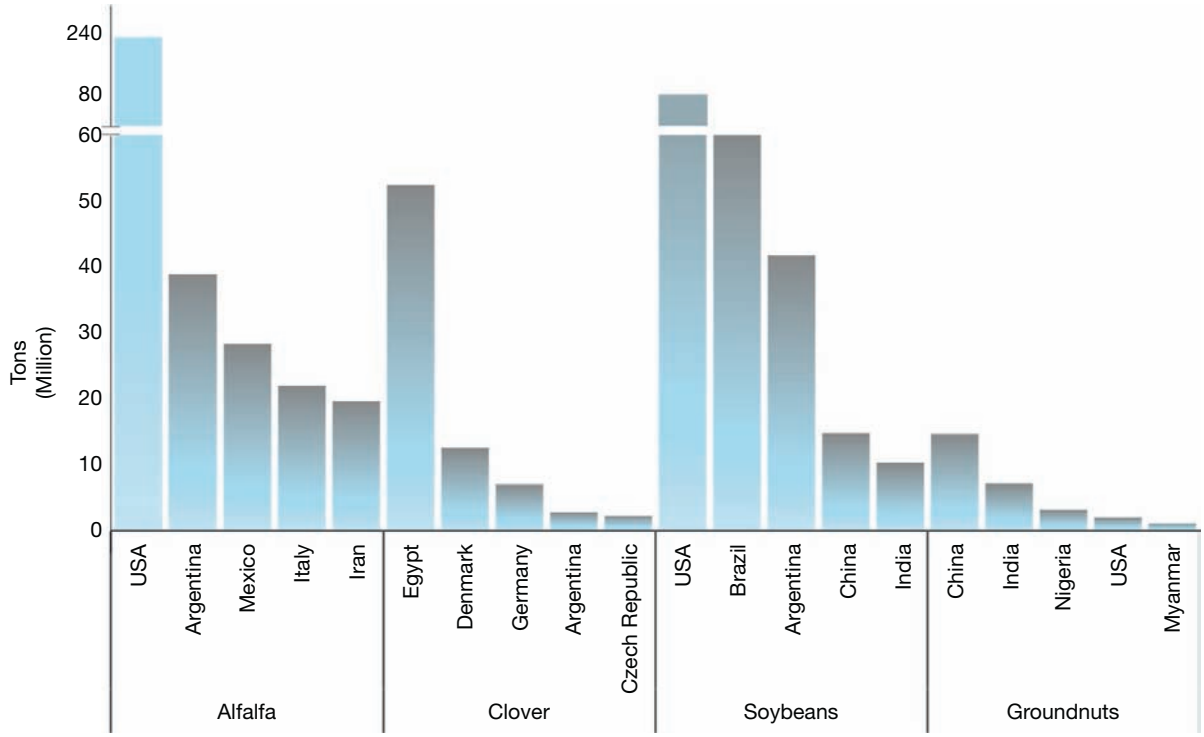

Figure 1 Average production (millions of tons) of the top five producing countries of alfalfa, clover, soybeans, and groundnuts on a 10-year period (2003–13). Data obtained from FAOSTAT (2015).

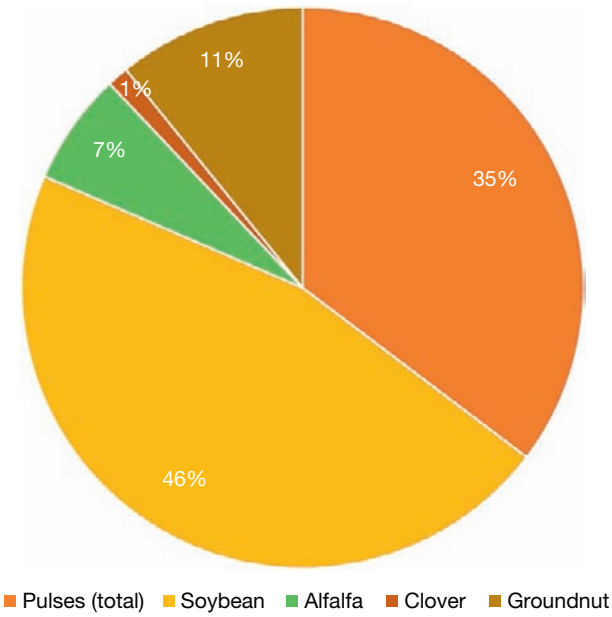

Figure 2 Comparison of the world harvested area in 2012 for: soybean, pulses, groundnuts, clover, and alfalfa. Data obtained from FAOSTAT (2015).

dry beans are an excellent source of Cu, P, Mn, and Mg. Furthermore, legume seeds are an excellent source of water soluble vitamins. A cup of dry beans can satisfy 45–107% of thiamine, 20–27% of riboflavin, and 11–27% of niacin daily requirements according to the United States Department of Agriculture (2015).

Nutraceuticals Found in Legumes

Beyond the relevant nutritional contribution of legumes to the diet, epidemiological studies have shown that the intake of legumes is associated with a reduction in the incidence of various cancers, HDL cholesterol, type-2 diabetes, metabolic syndrome, and heart diseases. Increasing legume consumption, such as dry beans, peas, peanuts and peanut butter, from 1 to 4 times or more per week was associated with a 22% lower risk of coronary heart disease and an 11% lower risk of cardiovascular disease. Incorporation of legumes as part of a low glycemic index diet improves both glycemic control and reduced coronary heart disease risk.

The inverse association between legume intake (including soy), and the risk of metabolic syndrome has been studied – regarding their fiber content. These benefits are also related to legumes' diverse bioactive proteins and peptides, as well as their bioactive micro-constituents (also known as phytochemicals), like phytoesterols, tocopherols, polyphenols, and triterpenic acids.

Bioactive Proteins and Peptides

Most of the protein found in legume seeds is composed of storage proteins, which, depending on the source, can reach up to 80% of the total protein content. The rest of the protein

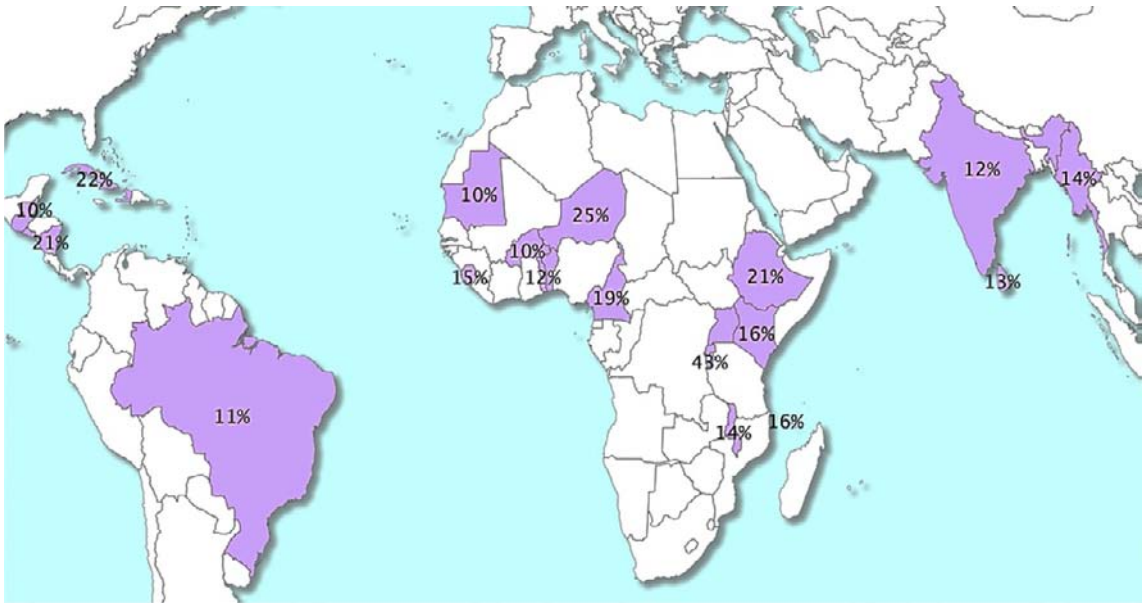

Figure 4 Map showing developing countries with high consumption of pulses and corresponding contribution as percentage to total per capita protein intake.

in pulse seeds include enzymes, as well as two classes of macromolecules typically referred to as 'antinutritional' – protease inhibitors and lectins. Lectins are carbohydrate-binding proteins found in a wide variety of important crop plants. Lectins are commonly found in unprocessed seeds like pea, chickpea, lentil, and other pulse crops; but, once legumes are cooked the lectins are destroyed.

When raw seeds, or their flour, are consumed by humans and livestock, lectins can cause deleterious effects like diarrhea, bloating, vomiting, and red cell agglutination. Nevertheless, it has also been found that lectins may play a key role in preventing certain cancers, and the activation of certain innate defense mechanisms. They have also been evaluated as therapeutic agents for preventing or controlling obesity.

Similar to lectins, protease inhibitors are considered antinutritional compounds since they reduce digestibility and the bioavailability of nutrients. However, some protease inhibitors, such as the Bowman-Birk inhibitor (BBI), have been

shown to reverse the initiation of carcinogenesis according to epidemiological, *in vitro* and *in vivo* studies. BBI has been evaluated as a chemopreventive agent against oral, head, and neck cancer without detectable clinical or laboratory toxicity even at high doses. Common beans contain lower levels of protease inhibitors than soybean. The difference in levels of protease inhibitors relates more to the cultivar (genetics) than to the site of cultivation (environment).

Bioactive peptides generated during proteolysis (protein hydrolysates) have been commercialized as nutraceuticals or functional ingredients. For example, lunasin is a soybean derived bioactive peptide currently commercialized for its anti-cholesterolemic and anti-diabetic properties. Protein hydrolysates and BPs from legumes have been reported to possess antioxidant, hypocholesterolemic and angiotensin converting enzyme inhibitory activities.

Phenolic Compounds of Legumes

Legume phytochemical profiles vary widely, and their survival through the stages of food processing is still under study. Soaking prior to cooking, and germination results in the lixiviation (and loss) of many phytochemicals.

Most phenolics and antioxidants in legumes are concentrated in the hulls or seed coats. These antioxidants have free radical scavenging activity as well as cytotoxic effects against cancer cells. Flavonoids are responsible, in large part, for seed color. For example, anthocyanins in black beans may account for 2.5% of the seed coat, a level comparable to that reported in fruits such as berries.

Some flavonoids have been isolated, specifically from black bean hulls, to be tested against certain human cancer cells *in vitro*, and also to evaluate their antioxidant activity. Particularly, non-glycosylated flavonols such as myricetin, quercetin, and kaempferol have been attributed to the antioxidant capacity of germinated black beans.

Another important group of bioactive flavonoids are the isoflavones, which possess estrogenic and other activities. Particularly, genistein and daidzein have been associated with the prevention of cancer, cardiovascular disease, and osteoporosis. Additionally, supplementation with soybean isoflavones has been used to reduce postmenopausal symptoms.

Controversy surrounds the understanding of the risks and benefits of exposure to isoflavones, especially during early life exposure. Some studies have demonstrated that children consume an even greater amount of phytoestrogens than adults. Most of the beneficial effects of isoflavones consumption have been proven for adults, but some *in vivo* models have demonstrated adverse effects derived from early exposure to these phytochemicals, particularly related to neurological diseases and the early onset of puberty. The Center for the Evaluation of Risks to Human Reproduction of the United States of America expressed a minimal concern for adverse developmental effects related to the consumption of soy infant formula. Additionally, the American Academy of Pediatrics states that "There is no conclusive evidence from animal, adult human, or infant populations that dietary soy isoflavones may adversely affect human development, reproduction, or endocrine function."

Saponins in Legumes

Legumes, particularly soybeans (*Glycine max*), are a rich source of saponins. A wide variety of triterpenoid saponins known as the soyasaponins, have been isolated from soybeans. Other legumes, such as peas (*Pisum sativum*), peanuts (*Arachis hypogaea*), faba beans (*Vicia faba*), and common beans (*Phaseolus vulgaris*) also contain saponins. Saponins in legumes vary depending on the amount and type of sugar bonded to the oleanene structure.

Soyasaponins affect the activity of several enzymes in plants, mammalians, insects, and fungi. They inhibit cholesterol micellar solubility; have anti-inflammatory, anticarcinogenic, antimicrobial and antimutagenic activity. They also exhibit antiviral, cardioprotective, and hepatoprotective effects, as well as interact with biliary acids, and improve immune response.

Legumes, Dietary Fiber, and Resistant Starch

Legumes are also high in fiber, which is now commonly perceived to be a food component that can lead to reduced cholesterol levels and reduced risk of ischemic heart disease. Diets rich in bean fiber enhanced the cholecystokinin response to a meal, and prolonged the presence of apolipoprotein B48 in plasma. These proteins are related to the digestion and absorption of a meal, and small intestine transit time.

Fiber from legumes (common, black, and navy beans) has also been correlated with the reduction of colon cancer by about 50% in animal tumor models, and also with inhibiting the formation of colonic aberrant crypt foci (a pre-cancerous model system) in rats with azoxymethane induced colon cancer.

Other Phytochemicals in Legumes

Phytic acid has long been cited as a phytochemical that reduces bioavailability of minerals, but it is also known as an antioxidant for its ability to reduce blood glucose levels, exert a protective action against colon cancer, and act as a prebiotic due to its ability to bind enzymes. A large number of studies have been published in the last 30 years relating phytic acid to cancer. The studies span effects from therapeutic uses, to prevention, to promotion effects. A great majority of the studies were done using animals, and showed that phytic acid had anti-neoplastic properties in breast, colon, liver, leukemia, prostate, sarcomas, and skin cancer.

Phytosterols are another group of phytochemicals that have potential as nutraceuticals. In particular, phytosterols extracted from black beans showed hypercholesterolemic effects not only by the reduction of cholesterol absorption, but also in the regulation of genes involved in hepatic lipogenesis.

Legumes as a Raw Material and Source of Functional Ingredients

Heat treatments, traditionally used to improve the nutritional value of legumes, have a deleterious effect on many compounds with nutraceutical properties. Considering the

potential of many of the phytochemicals contained in legumes, commercial interest in the exploitation of the use and application of extracts is increasing. For example, some phytochemicals could be recovered from an aqueous extract obtained as a byproduct of canned bean processing and used for the treatment or prevention of cancer, heart strokes, elevated levels of cholesterol, hypertension, obesity, and inflammatory disorders in humans. Black bean seed coat extracts have also been used to purify anticancer compounds. In fact, several efforts are being made to optimize the dehulling process and obtain seed coats to be used as nutraceuticals and cotyledon flours with high protein content and good functionality.

Pulse proteins might be used in different products in a similar way as soy or whey. Besides nutritional functionality, pulse proteins possess functional properties that have been understudied. Furthermore, the addition of legume flour is a good alternative for improving the nutritional value of gluten free bakery products.

Additionally, other biotechnological alternatives have been evaluated to reduce antinutritional components of legumes. Particularly, germination, fermentation, or the addition of phytase has been proven to reduce or remove considerable amounts of phytate that chelates important micronutrients such as iron and zinc.

Lipoproteins

R Zamora and FJ Hidalgo, Instituto de la Grasa, Seville, Spain

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Most lipids are not soluble in aqueous environments. Therefore, organisms have developed an array of strategies for the transport of exogenous and endogenous lipids toward different tissues, where they are employed or stored. In all cases, this transport involves macromolecular protein-containing complexes: lipoproteins. This article will deal with the composition of these aggregates, their structures, and the changes suffered during metabolism and also with their effect on human health because of their great clinical importance. The first part of this article will mainly describe the plasma lipoproteins that play a major role in the transport of lipids in vertebrates, with special attention to human beings. Other lipoproteins and other lipid–protein complexes will be described in the last part of the article.

Plasma lipoproteins are synthesized mainly in the liver and intestines and circulate as soluble particles in body fluids of vertebrates. They are used to facilitate the delivery and clearance of lipids and lipophilic molecules throughout the body. These aggregates are in constant change of composition and physical structure as the peripheral tissues take up components before the remnants come back to the liver. In addition, there are interchanges of proteins, enzymes, and lipid constituents among the heterogeneous mix of all these lipoprotein fractions.

Plasma Lipoprotein Composition and Structure

The general structure of lipoprotein particles includes a hydrophobic core surrounded by a hydrophilic shell (Figure 1). The core comprises the hydrophobic components, mainly triacylglycerols and cholesterol esters, and the hydrophilic shell includes the hydrophilic components, mainly phospholipids (phosphatidylcholine and sphingomyelin especially), unesterified free cholesterol, and various proteins (apolipoproteins), which play a role in lipoprotein assembly and mediate interactions with a variety of other molecules including enzymes, transporters, and receptors through a dynamic process.

Lipoproteins can be classified according to their size, density, electrophoretic mobility, and composition or to the apolipoprotein or apolipoproteins that they contain. However, the practical procedure employed to separate the different lipoprotein classes (their density) is what has determined the commonly employed nomenclature. Thus, lipoproteins are classified as chylomicrons (CMs), very-low-density lipoproteins (VLDLs), low-density lipoproteins (LDLs), and high-density lipoproteins (HDLs) depending on their relative densities on ultracentrifugation. In addition, these classes can also be divided into several subclasses. Thus, intermediate-density lipoproteins (IDLs) and subdivisions of the HDL (such as HDL_1, HDL_2, and HDL_3) are often defined. The density of these particles is a consequence of the relative concentrations of triacylglycerols and proteins and of their diameters. These particles are mostly spherical and diameters vary from about 6000 Å in CMs to 100 Å or less in the smallest HDL. Some compositional details are listed in Table 1.

Plasma Lipoprotein Classes

Chylomicrons

Triacylglycerols are the predominant fats in the diet, contributing to 90–95% of the total energy derived from dietary lipids. In the intestine, triacylglycerols are decomposed by pancreatic lipase into 2-monoacylglycerols and free fatty acids and absorbed from the intestinal lumen into the enterocyte. Both monoacylglycerols and free fatty acids are utilized to resynthesize triacylglycerols in the endoplasmic reticulum. The produced triacylglycerols are incorporated together with dietary cholesterol and a small amount of cholesterol esters into CMs with a surface layer of phospholipids and a single molecule of a truncated form of apoB (apoB-48), which is a characteristic of triacylglycerol-rich lipoproteins of intestinal origin. In addition, CMs also contain some apoA-I, which is synthesized either in the intestines (about 30% of circulating apoA-I) or in the liver (about 70% of circulating apoA-I).

Produced CMs are transported via the intestinal lymphatic system and enter the blood stream at the left subclavian vein. A schematic of the metabolism of CMs and other lipoproteins is shown in Figure 2. As soon as CMs reach circulation, apoA-I is transferred to HDL particles, and apoE and apoC-II are transferred from the HDLs to the surface of the CMs. Triacylglycerols are removed by the peripheral tissues by means of endothelial-bound lipoprotein lipase. The produced fatty acids enter into the muscle for energy production and into the adipocytes for storage. At the end, the depleted, or 'remnant' CMs, mainly containing the dietary cholesterol, apoB-48, and apoE (apoC-II can be transferred back to HDL), reach the liver where they are cleared from circulation by a receptor-mediated process that requires the presence of apoE.

Very-Low-Density Lipoproteins

Triacylglycerols of the remnant CMs, newly synthesized triacylglycerols from the free fatty acids that reached the liver from the adipose tissue, cholesterol, cholesterol esters, and phospholipids are secreted by the liver into the circulation in the form of VLDLs. These particles also contain one molecule of the full-length form of apoB (apoB-100). As occurred with CMs, if VLDLs contain some apoA-I, this apolipoprotein is rapidly transferred to the HDLs at the same time that VLDLs take apoC-II and apoE from HDLs.

Once again, triacylglycerols are hydrolyzed by lipoprotein lipase into free fatty acids and 2-monoacylglycerols. In

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00422-0

addition, this enzyme is also involved in the nonhydrolytic uptake of esters of cholesterol and retinol. As the transport of VLDLs progresses, the core of triacylglycerols is reduced and proteins and phospholipids on the surface are transferred away to the HDLs. VLDL remnants (or intermediate-density lipoproteins (IDLs)) with apoB-100 and apoE as the remaining proteins can be either absorbed by the liver or converted to LDLs with further loss of triacylglycerols.

Low-Density Lipoproteins

LDLs, and also IDLs, are stable particle configurations that are reached sequentially during the course of intravascular catabolism of VLDLs. The transformations from VLDLs to IDLs and LDLs are allowed by the presence of sufficient triacylglycerols to sustain lipolysis. Therefore, LDLs are poor in triacylglycerols (10% lipids vs. 55% lipids in VLDLs) and rich in cholesterol and cholesterol esters (65% lipids vs. 25% lipids in VLDLs). Consequently, LDLs are the main carriers of cholesterol to the adrenals and adipose tissue, where there are receptors requiring apoB-100 that are able to take in the LDLs. Within these tissues, the cholesterol esters are hydrolyzed to yield free cholesterol, which is incorporated into plasma membranes as required. Additionally, LDLs can be taken up by the liver by a process of endocytosis and catabolized. Nevertheless, the liver is able to scavenge CM remnants much more rapidly than LDL particles.

Cholesterol is of vital importance for the human body. It is a constituent for most biological membranes, it is needed for the formation of bile salts, and it is the precursor for steroid hormones and vitamin D. However, excess of cholesterol in the cells might be harmful. Thus, the accumulation of cholesterol in arteries can lead to atherosclerosis. Therefore, a route for cholesterol disposal, which has been termed 'reverse cholesterol transport,' is needed.

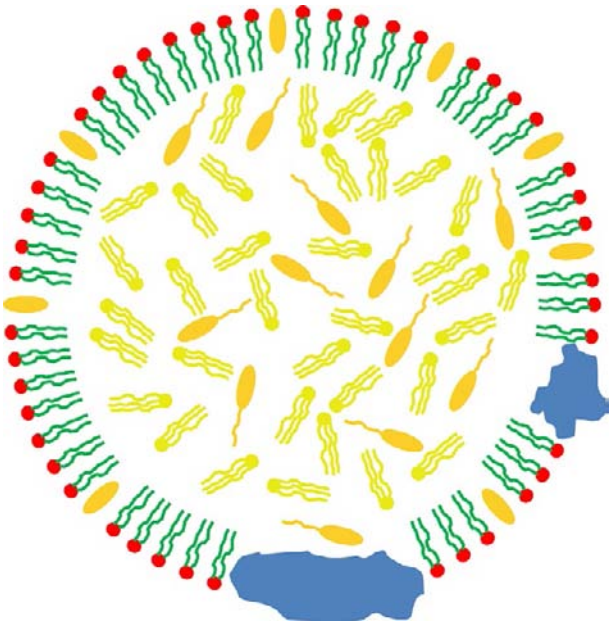

Figure 1 Lipoprotein structure. Lipoproteins usually have a spherical form with phospholipids, cholesterol, and apolipoproteins in the outer layer. The hydrophobic core comprises triacylglycerols and cholesterol esters. Courtesy of Francisco J. Hidalgo-Zamora.

High-Density Lipoproteins

The 'reverse cholesterol transport' is carried out by HDLs. HDLs are a complex group of diverse lipoproteins that can contain many different protein constituents and carry out diverse functions related to the return of cholesterol: secretion of cholesterol from the cells, esterification of cholesterol in the plasma, transfer of cholesterol to other lipoproteins, and return of cholesterol from the peripheral tissues to the liver for excretion in the bile. In addition, these lipoproteins also participate in triacylglycerol transport by facilitating the activation of lipoprotein lipase, in the transfer of triacylglycerols between lipoprotein classes, and in the removal of CM remnants and VLDLs enriched in triacylglycerols.

ApoA-I, either synthesized in the liver or spontaneously released by CMs, is the major protein component of HDL in the plasma and determines most of its functions. In addition to apoA-I, plasma HDLs also contain many other apolipoproteins, including apoC-II and apoE.

HDL biogenesis starts with the formation of the nascent discoidal HDL through apoA-I and ABCA1, a specific transporter molecule that facilitates the transfer of phospholipids and cholesterol to apoA-I. In the plasma, apoA-I activates the

Table 1 Density and average composition of plasma lipoproteins

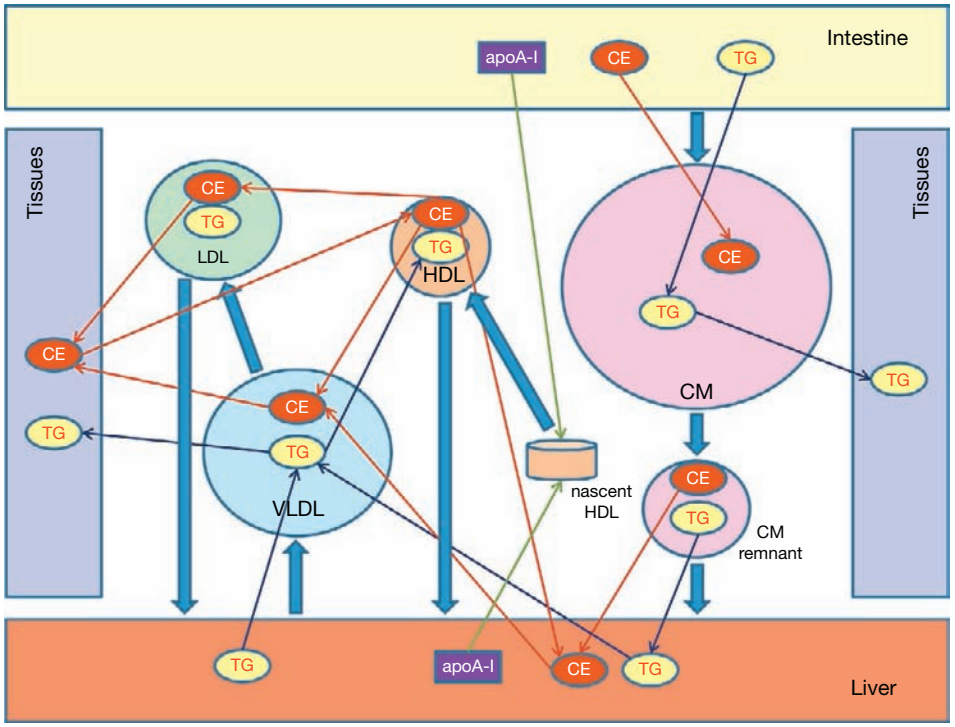

Figure 2 Schematic lipoprotein metabolism. Lipoproteins are in constant change of composition and physical structure as the peripheral tissues take up components before the remnants come back to the liver. In addition, there are interchanges of proteins, enzymes, and lipid constituents among the heterogeneous mix of all these lipoprotein fractions. Only interchanges of triacylglycerols (TGs) and cholesterol/cholesterol esters (CEs) are shown.

enzyme lecithin–cholesterol acyltransferase, which converts discoidal HDL to mature, spherical, cholesteryl ester-rich HDL particles by drawing free cholesterol and phospholipids from IDLs and LDLs until spherical HDL particles are formed with a surface coat of phospholipid, free cholesterol, and apolipoproteins.

Cholesterol is incorporated from cell surface membranes to the spherical HDLs. As a result, the levels of intracellular cholesterol are reduced because the cholesterol stored in the cells in the form of cholesterol esters is mobilized to replace that removed from the plasma membrane. The removal of excess cholesterol from macrophage-derived foam cells present in atherosclerotic plaques is particularly important.

Lipid-rich HDLs can enter the hepatocytes through an apoA-I receptor, where it can transfer cholesterol and cholesterol esters to distinct pools within the cell. The modified HDLs are then secreted back into the circulation where they can acquire further cholesterol before returning to the liver. In a second less-efficient pathway, HDLs can be taken up by the liver analogously to the earlier described for LDLs.

Plasma Lipoproteins and Health

Epidemiological and clinical studies and meta-analyses have shown a relationship between low plasma levels of HDLs and increased risk of major coronary events. In addition, observational studies have found inverse associations between HDLs and risks of ischemic stroke, type 2 diabetes mellitus, and various cancers. Furthermore, HDLs seem to exert many effects *in vitro* and *in vivo* that protect the organism from chemical and biological harm and may interfere with the pathogenesis of diverse diseases. Moreover, in several animal models, overexpression or exogenous application of apoA-I decreased or prevented the development of atherosclerosis, glucose intolerance, or tissue damage induced by ischemia or mechanical injury. This section will review some of the present knowledge of an area that is, at present, under active investigation.

Coronary Heart Disease

Alterations of lipid/lipoprotein metabolism and inflammatory events contribute to the formation of the atherosclerotic plaque, which is characterized by the accumulation of abnormal amounts of cholesterol and macrophages in the artery wall. Therefore, the decrease of cholesterol level by means of the reverse cholesterol transport described in the preceding text may counteract the events that produce the formation and development of atheroma. In fact, *in vivo* studies have shown an inverse relationship between the efficiency of the reverse cholesterol transport and atherosclerotic cardiovascular diseases. HDLs are key lipoproteins in all stages of reverse cholesterol transport: They remove excess cholesterol from cells and they release cholesterol to the liver for final disposal. Therefore, the assessment of HDL function, evaluated as their capacity of promoting cell cholesterol efflux, is considered a strong predictor of atherosclerotic extent in humans and may represent a useful biomarker of predictor of cardiovascular risk.

Type 2 Diabetes Mellitus and Metabolic Syndrome

The cluster of pathologies that constitutes metabolic syndrome (insulin resistance, central obesity, high blood pressure, and hypertriglyceridemia) and type 2 diabetes mellitus is associated with low levels of HDL cholesterol and the presence of dysfunctional HDLs. Recent evidences suggest that HDL modulates insulin sensitivity, insulin-independent glucose uptake, insulin secretion, and beta-cell survival. Thus, HDLs are believed to enhance glucose-stimulated insulin secretion and to reverse the proapoptotic effects of native and oxidized LDLs. In addition, HDL and apoA-I promote glucose uptake and activate AMP-kinase in primary skeletal muscle cells and differentiated adipocytes by an insulin-independent way and also enhance oxidative metabolism in the skeletal muscle. A dysfunction in these actions could play a role in the pathogenesis of these diseases.

Acute and Chronic Inflammatory Pathophysiological Conditions

HDLs have been shown to play a protective and anti-inflammatory role in autoimmune and inflammatory diseases. HDLs are believed to be part of both innate and adaptive immune systems, helping mammals to fight against invading pathogens. HDL activities rely not only on the ability to modulate cholesterol availability in immune cells (the activity of these cells is modulated upon changes in the lipid raft composition and structure) but also on the role of specific molecules shuttled by HDLs. Nevertheless, both acute and chronic inflammatory conditions induce posttranslational modifications of HDL, which impairs both its lipid homeostasis-regulating and anti-inflammatory properties, and can even turn HDLs into proinflammatory molecules.

Infectious Diseases and Sepsis

Significant alterations in lipid metabolism and lipoprotein composition occur during infection. Triacylglycerols and VLDL cholesterol levels increase, while reduced HDL cholesterol and LDL cholesterol levels are observed. Low HDL cholesterol levels inversely correlate with the severity of septic disease and associate with an exaggerated systemic inflammatory response. In addition, HDL particles undergo changes that dramatically alter their composition and function. On the contrary, an increase of HDL cholesterol is associated with an attenuation of gram-negative bacterial lipopolysaccharide-induced inflammatory responses.

Neurodegenerative Disorders

Cognition is a complex brain function that includes all aspects of perception, thought, and memory. This function often declines during aging and neurodegenerative disorders appear, including Alzheimer's disease, Parkinson's disease, Huntington's disease, and amyotrophic lateral sclerosis. Emerging evidence suggests that HDLs may play an important role in preserving cognitive function under normal and pathological conditions. However, the mechanism of action for HDLs to modulate cognitive function remains to be elucidated.

Other Lipoproteins

In addition to the previously described lipoproteins, other lipoproteins are also known. Some of them are described in this section.

Insect Lipoproteins

The circulatory fluid in insects (hemolymph) contains a single multifunctional lipoprotein that transports lipids to wherever they are required. This lipoprotein is termed lipophorin. Lipophorins can be classified as low-density, high-density, and very-high-density lipophorins, depending on their lipid loading. The main lipid components are 1,2-diacylglycerols together with hydrocarbons, phospholipids, and sterols. It has also two apolipoproteins: apolipoprotein I and apolipoprotein II. Lipophorin functions as a reusable lipid shuttle, which delivers lipids to storage or peripheral tissues before returning for another cycle of loading and unloading.

Lipoproteins in Other Invertebrates

Lipoproteins have been studied in insects with preference to other invertebrates because of the high lipid mobilization rates during flight. However, these complexes also exist in these animals and some differences appear. Thus, for example, in crustaceans, the predominant lipid species in lipoproteins are phospholipids (especially phosphatidylcholine) and, to a lesser extent, diacylglycerols. On the other hand, in mollusks, the predominating lipids are also phospholipids and to a lesser extent sterols and triacylglycerols.

Bacterial Lipoproteins

Bacterial lipoproteins are a set of membrane proteins that have been modified through the covalent attachment of a diacylglycerol moiety to the thiol group on the side chain of a cysteine residue. This modification is catalyzed by the enzyme lipoprotein diacylglyceryl transferase, and the diacylglycerol is linked by a thioether bond to the protein. Additionally, the amino group of the terminal cysteine residue can also be esterified producing a triacyl derivative. Therefore, different from the other lipoproteins discussed in this article, lipid and protein are covalently bonded in bacterial lipoproteins. This modification facilitates the anchoring of hydrophilic proteins to the cell wall phospholipids by hydrophobic interaction among all acyl groups. Bacterial lipoproteins have been shown to perform various roles, including nutrient uptake, signal transduction, adhesion, conjugation, and sporulation, and participate in antibiotic resistance, transport, and extracytoplasmic folding of proteins.

Egg Yolk Lipoproteins

Egg yolk is a complex system that can be fractionated into two: plasma and granules. Granules represent 19–23% of yolk dry matter, accounting for about 50% of yolk proteins and less than 10% of yolk lipids. They are mainly constituted by HDLs (70%) and phosvitin (16%) linked by phosphocalcic bridges.

Plasma corresponds to about 77–81% of yolk dry matter and is composed of 85% LDLs and 15% livetins. It accounts for about 90% of yolk lipids (including nearly all the carotenoids) and 50% of yolk proteins.

Egg yolk LDLs are spherical nanoparticles (17–60 nm) with a lipid core of triacylglycerols and cholesterol esters surrounded by a monofilm of phospholipids and proteins. Some cholesterol is also included in the phospholipid layer, increasing its rigidity. LDLs are composed of 11–17% protein and 83–89% lipid, of which 69% are triacylglycerols, 27% phospholipids, and 4% cholesterol and cholesterol esters. LDL particles comprise at least six different apolipoproteins, which have about 40% hydrophobic amino acid residues.

Lipid–Protein Complexes Other than Lipoproteins

The existence of lipid–protein complexes other than lipoproteins with important biological functions has also been widely described. Some few examples are discussed in this section.

Lipid–Protein Complexes in Cell Membranes

Different studies have shown that the folding, structure, and function of membrane proteins are influenced by their lipid environments and that lipids can bind to specific sites. In fact, resistance to membrane protein unfolding correlates with specific-binding events, enabling to distinguish between lipids that merely bind from those that modulate membrane protein structure and/or function.

Fatty Acid Transport Proteins

Because of their low solubility in aqueous solutions such as blood plasma and interstitial fluid, fatty acids need binding proteins to increase their concentration in vascular and interstitial compartments. Albumin acts as the main fatty acid-binding protein in extracellular fluids. Plasma albumin possesses about seven binding sites for fatty acids with moderate to high affinity. On the other hand, cellular fatty acid uptake is carried out by several protein groups including plasma membrane fatty acid-binding protein, the scavenger receptor CD36, and the six fatty acid transport proteins, also called carrier family 27A1-6.

Fat Globules in Milk

Although the fat content of mammalian milks varies enormously, all species, including humans, secrete milk lipids in similar, highly specialized fat globules that are unique to milk. These globules are composed of a central core containing mostly triacylglycerols surrounded by three layers: an inner monolayer of proteins and polar lipids with the fatty acid tails facing the globule core and a bilayer of polar lipids, proteins, glycoproteins, and cholesterol. In addition, there is an entrained layer of cytoplasm about 10–20 nm wide between the inner single membrane and outer bilayer. This membrane is only found in milk and functions to stabilize the milk fat globule as an emulsion in the aqueous milk environment. More importantly, it provides important components that have nutritional and immunologic roles for the infant and the intestinal microbiome, with growing evidence that the lipids are packaged in such a way to contribute to digestive efficiency and preserve biological activity.

The Complex HAMLET (Human α-Lactalbumin Made Lethal to Tumor Cells) in Human Milk

The protein–lipid complex HAMLET was purified from the casein fraction of human milk and was found to consist of α-lactalbumin in a partially unfolded conformation that is stabilized under physiological conditions by the oleic and linoleic acids contained in the human milk. This protein–lipid complex has a potent and specific bactericidal effect against the respiratory tract pathogen *Streptococcus pneumoniae*. In addition, sublethal concentrations of HAMLET potentiate the effect of common antibiotics (penicillins, macrolides, and aminoglycosides) against pneumococci.

Lipid Droplets in Cells

Lipid droplets, also termed lipid bodies or adiposomes, are lipid-rich organelles present in virtually all organisms, from bacteria to mammals. They are characterized by their unique, highly conserved, and simple architecture. It consists of a neutral lipid core containing triacylglycerols and sterol esters encased within a monolayer of phospholipids, which is in turn associated with a unique proteome. This proteome is highly specialized and contains from 40 to 300 different proteins depending on the species. Lipid droplets are involved in a myriad of cellular processes, which are at present under active investigation. Thus, for example, lipid droplets in leukocytes have been related to cell signaling and activation, regulation of lipid metabolism, membrane trafficking, and control of the synthesis and secretion of inflammatory mediators.

Lipoproteins as Additives

Emulsifying Properties of Egg Yolk LDLs

The emulsifying properties of egg yolk are mainly attributed to its LDLs because LDLs form a film at the interface between oil and water, and this film contributes to the stabilization of emulsions made with yolk. The structure of the LDLs seems essential to ensure their interfacial properties because LDLs serve as a vector of surfactants, like proteins and phospholipids, up to the interface. Once at the interface, the LDL particle spreads and the proteins and phospholipids are absorb at the interface. The produced interfacial film assures both the decrease of interfacial tension and the resistance to the rupture and permits the formation and the stability of food emulsions made with yolk.

Cryoprotective Effect of Egg Yolk LDLs in Extenders on Bull Spermatozoa

Semen extenders are liquid diluents added to semen to preserve its fertilizing ability. Egg yolk LDLs have been proposed to be used in extenders with cryoprotective effects on frozen-thawed bull spermatozoa. The addition of egg yolk LDL has

been shown to produce better results (higher sperm motility and better movement characteristics) than the addition of egg yolk. The cryoprotective effect of egg yolk LDLs seems to be related to the ability of the lipoproteins to bind the binder of sperm proteins contained in the seminal plasma of many mammalian ungulates. These proteins modify the sperm membrane by removing cholesterol and phospholipids, which adversely affect the ability of sperm to be preserved. The binding between these proteins and LDL is rapid, specific, and stable even after freeze-thawing of semen.

Functional and Nutritive Properties of Milk Fat Globule Membrane

Because of their amphiphilic nature and original function in stabilizing the fat globules in whole milk, milk fat globule membrane fragments are considered to be efficient, natural emulsifiers. In addition, they have been used to produce liposomes. The obtained liposomes are more stable than analogous liposomes obtained from soya lecithins in a range of pH conditions, at a variety of storage and processing temperatures, and in the presence of mono- and divalent cations. Furthermore, milk fat globule membrane includes many components with attractive properties for the health, including sphingolipids, proteins with bioactive properties, and antigens.

Liqueurs: Cream Liqueurs

SP Heffernan, DM Mulvihill, and AL Kelly, University College Cork, Cork, Ireland

© 2016 Elsevier Ltd. All rights reserved.

Liqueurs

A liqueur is an alcoholic beverage made from a distilled spirit that has been flavored with fruit, cream, herbs, spices, flowers, or nuts and bottled with added sugar or other sweeteners (such as high-fructose corn syrup). Liqueurs are typically quite sweet; they are usually not aged for long after the ingredients are mixed, but may have resting periods during their production to allow flavors to marry. A typical production process involves slicing and steeping plants in alcohol and allowing the resulting extract to mature, yielding alcoholic beverages. Other liqueurs are fermented from grains such as rice, millet, and wheat; anthograin liqueurs, for example, are produced through fermentation of anthograins such as purple wheat.

Liqueurs were historically herbal medicines; they were made in Italy as early as the thirteenth century and were often prepared by monks. Nowadays, liqueurs are made worldwide and are served in many ways: by themselves, poured over ice, served with coffee, or mixed with cream or other mixers to create cocktails. They are often served with or after a dessert and are also used in cooking. Examples of liqueurs include berry liqueurs, chocolate liqueurs, coffee liqueurs, cream liqueurs, crème liqueurs, flower liqueurs, fruit liqueurs, herbal liqueurs, anise-flavored liqueurs, honey liqueurs, nut-flavored liqueurs, and whiskey liqueurs (list extracted from en.wikipedia.org/wiki/List_of_liqueurs).

Fruit liqueurs are alcoholic beverages, the main natural components of which are fruits or fruit extracts. In their preparation, the whole fruit is used, and it needs to be ripe in order to give the maximum flavor to the liqueur. Fruit liqueurs are prepared without fermentation. The manufacturing process may involve alcoholic maceration of fruits or distillation of macerates aromatized with the base fruit. Other techniques are also used, such as alcoholic dissolutions of different fruit aroma compounds; these beverages are usually colored with glucose or sucrose caramel, and they are highly sweetened with grape sugar, honey, glucose, and/or sucrose syrups. Acidity regulators and, occasionally, stabilizers, antioxidants, and other technological aids may also be added. Fruits used for liqueurs are known for their beneficial impact on human health because they are a good source of phenolic compounds endowed with antioxidant activity.

Walnut is a traditionally important and widely spread deciduous tree in many parts of the world. Its ripe fruit has been used for fresh consumption and in confectionery, while unripe fruit can be used to make liqueurs. Walnut liqueur is a dark-brown, bitter, and tasteful beverage and is often served as an aperitif or sometimes taken to treat stomachache. Nocino, a similar after-dinner walnut liqueur of Celtic origin, is very well known and appreciated in Italy and other countries. Walnut fruits and many walnut products, such as walnut liqueur, are rich in phenolic compounds.

Limoncello is a very popular homemade Italian liqueur, traditionally based on an infusion of the flavedo (the outer, yellow skin of lemons). Honey liqueur is an alcoholic drink derived from honey and strong fruit brandy, traditionally made in Serbia and other Balkan countries. Tobacco plants have also been used as a base for making liqueurs.

One particular type of liqueur, first described in an ancient Scottish recipe, is a cream-based alcoholic beverage prepared by steeping oatmeal in whiskey overnight and filtering the following morning. The oatmeal imparted a delicious nutty flavor to the whiskey. Cream and honey were added to the filtered whiskey and mixed well to give Atholl Brose. The modern cream liqueur was first marketed in the United Kingdom in 1974 as Baileys Original Irish Cream Liqueur and is now sold worldwide. The remainder of this article will focus on the manufacture and properties of cream liqueurs.

Composition of Cream Liqueurs

The leading commercial brands of cream liqueurs are reported to contain around 39–40% (w/w) solids, including 15–16% (w/w) butterfat, 3% (w/w) sodium caseinate, 19% (w/w) added sugar, and 1.5% (w/w) milk solids nonfat. The alcohol content is usually 12.7% (w/w) (or 17% v/v). Commercial cream liqueurs may contain small proportions of low-molecular-weight (LMW) surfactants such as glycerol monostearate (GMS). Aspects of the composition, processing, and quality characterization of cream liqueurs were first described in detail in the scientific literature by Banks, Muir, and colleagues in the 1980s.

Cream and milk components

Double cream (48% fat) is normally used for the manufacture of cream liqueurs. Cream is an o/w emulsion comprising a dispersion of fat globules in a continuous phase containing proteins (caseins and whey proteins), lactose, mineral salts, vitamins, and enzymes (milk serum phase).

Milk fat globules are coated by a natural membrane termed the milk fat globule membrane, consisting of amphiphilic molecules with both hydrophilic and hydrophobic sections. Milk fat globules vary in diameter from about 0.2 to 15 μm, with a mean diameter of ~4 μm, and are characterized by a wide size distribution. The density of milk fat at 20 °C is 918 kg m^{-3}, and milk fat is considered to be fully liquid at 40 °C.

There are two categories of proteins in milk: caseins, which are insoluble at pH 4.6 (their isoelectric point) at 20 °C, and whey proteins, which are soluble under these conditions. The caseins, which comprise 80% (w/w) of the milk proteins, exist in a unique colloidal complex known as the casein micelle. The whey proteins, which comprise 20% (w/w) of the milk proteins, exist in their native state as compact, globular proteins that are highly susceptible to heat-induced denaturation and irreversible polymerization via intermolecular disulfide bond formation.

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00423-2

Lactose is the major carbohydrate in milk. Bovine milk contains ~4.5–5% (w/w) lactose, and it is present in cream liqueurs at a concentration of ~1% (w/w). Lactose is a disaccharide of glucose and galactose. Heating lactose in the presence of amino groups results in the Maillard reaction, which involves the reaction of the lactose with the amino group of proteins. In milk, amino groups are mainly lysine residues; heating milk results in a brown color and a cooked flavor, which are important characteristics of many heated dairy products.

Use of sodium caseinate and other emulsifiers

The first step in the isolation of the casein fraction from milk is the removal of the fat by centrifugation to yield skim milk. Following destabilization of the casein by adjusting the pH to 4.6, the insoluble casein is separated from the soluble whey proteins, lactose, and salts and is washed and dried. Sodium caseinate, the water-soluble form of casein most commonly used in food products, is usually prepared by solubilizing acid casein with NaOH.

In the manufacture of cream liqueurs, the milk protein in the cream is usually complemented with sodium caseinate. Sodium caseinate is regarded as a partially aggregated mixture of four individual caseins, α_{s1}-, α_{s2}-, β-, and κ-casein, in an approximate ratio of 4:1:4:1. Proteins make good emulsifiers by virtue of their amphipathic nature and ability to spread at interfaces. Sodium caseinate is the preferred emulsifier for cream liqueur manufacture because of its excellent functional and organoleptic properties. In addition to stabilizing the fat droplets, sodium caseinate also provides a significant improvement in the perceived creaminess and allows the spirit source to impart its characteristic organoleptic properties. No other protein has been found to equal the functional and organoleptic properties of sodium caseinate in cream liqueurs.

When mixed with carbonated or citrus drinks, precipitation may occur in cream liqueurs containing sodium caseinate if the isoelectric point is reached. Calcium in cream liqueurs comes mainly from the cream source, and, even though the calcium concentration in a cream liqueur is only ~16% of that found in milk, this may be sufficient to cause calcium-induced aggregation, with eventual gelation of the product. Calcium-induced aggregation is accelerated when cream liqueurs are stored at high temperatures.

The addition of calcium-sequestering agents such as trisodium citrate to prevent calcium-induced aggregation of cream liqueurs increases the shelf life of these products. The effects of removing calcium (e.g., by the use of anhydrous butter oil or washed cream) and adding citrate on the stability of cream liqueurs have been studied and have been found to have a significant positive influence on shelf life at 45 °C. As washing cream is an expensive process, most manufacturers add trisodium citrate to cream liqueurs to chelate ionic calcium.

In addition to a protein emulsifier, low-molecular-weight (LMW) surfactants such as GMS and sodium stearoyl lactylate (SSL) can be used in cream liqueurs. Studies have been conducted on the effect of LMW surfactants on the stability of cream liqueurs. The presence of glycerol monostearate (GMS) or SSL substantially reduces creaming at ambient temperature and prolongs shelf life. The improved creaming stability appears to be associated with a change in bulk rheological properties of the emulsion, probably arising from complex formation between LMW surfactants and caseinate, both in the bulk aqueous phase of the emulsion and at the surface of the fat droplets.

The role of sugar

The sugar in a cream liqueur can be in the form of sucrose, maltose, dextrose, lactose, corn syrup, invert sugar, high-fructose corn syrup, sorbitol, or glucose. Sucrose is, however, normally used as the sugar source for cream liqueurs. Sucrose, which is a disaccharide of fructose and glucose, primarily functions as a sweetener and bacteriostatic agent while also contributing to viscosity. For ease of blending, sucrose is usually introduced in the form of an aqueous syrup. Alternative sweeteners may be used without changing the color, smell, or viscosity, although the perception of alcohol flavor may be enhanced due to the fact that sucrose, through its sweetness, is very effective at masking this perception.

Ethanol

Most cream liqueurs contain neutral spirit along with spirit from other sources (e.g., whiskey). Spirit with a neutral pH is necessary if sodium caseinate is used as an emulsifier. At concentrations up to 20% (w/w), the presence of ethanol during emulsification leads to fat globules with smaller diameters due to a lowering of interfacial tension. However, at higher ethanol concentrations, the stability of the liqueur decreases due to poor solvent quality, which induces protein aggregation and precipitation. Cream liqueurs with higher alcohol contents may be manufactured by washing the cream to remove serum phase components and proceeding with the normal manufacturing process.

Manufacture of Cream Liqueurs

Conventional processes for the manufacture of a stable cream liqueur involve the preparation of a caseinate–trisodium citrate blend at 85 °C (with or without sugar). This is followed by the addition of cream with continuous high-speed mixing at 55 °C to give a cream base. LMW surfactants are usually incorporated in molten form into the cream base. A major source of variation in the processing of cream liqueur is the stage of alcohol addition.

Figure 1 outlines a typical cream liqueur manufacturing process. In a one-step manufacturing process, alcohol is added to the cream base before the product is homogenized. In this case, an aqueous-alcohol solution (with or without sugar) is added to the cream base and mixed thoroughly. Colors and flavors are usually incorporated in the alcohol. The blended pre-emulsion is normally homogenized twice at 55 °C at a pressure in the range of 20–30 MPa, cooled to 20 °C, and bottled in opaque bottles to prevent light-induced oxidation.

In two-step manufacturing processes, a concentrated alcohol-free cream base is first homogenized; this homogenized mix is then cooled and an alcohol solution is added. The alcohol can also be added as a solution with the sugar. A combination of one-step and two-step processes is also possible, whereby the non-alcohol base is first homogenized, the alcohol is then added, and the product is rehomogenized. The addition of alcohol to a cream base before homogenization

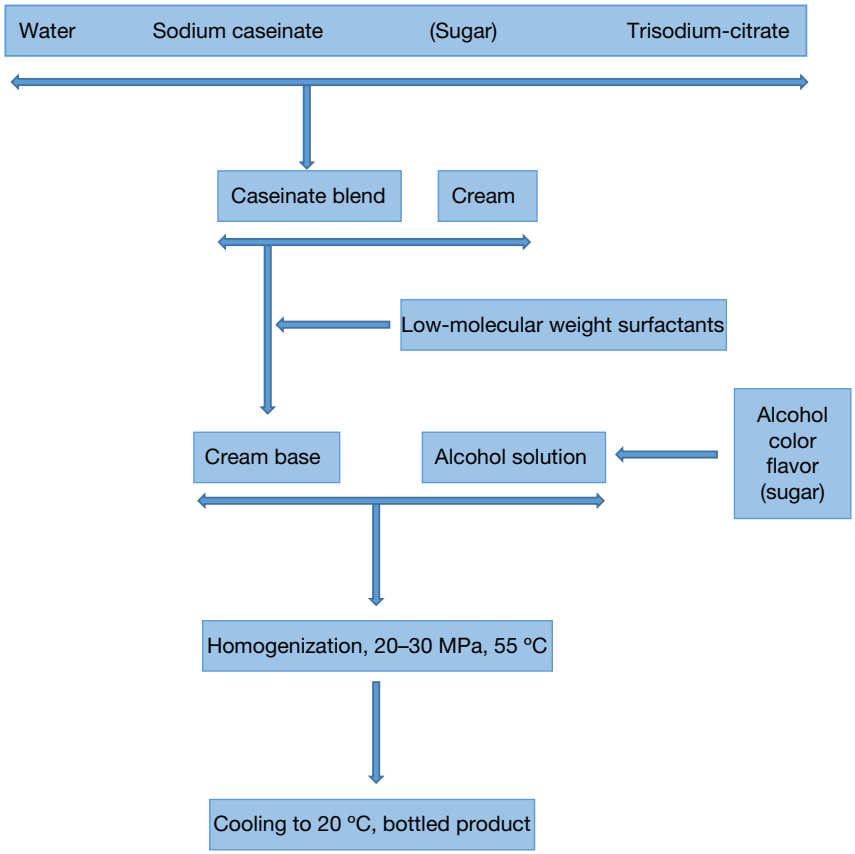

Figure 1 Schematic diagram illustrating a one-step cream liqueur manufacturing process.

results in a cream liqueur with fat droplets of smaller diameters, due to reduced viscosity and interfacial tension during homogenization; the resulting liqueurs are reported to have an increased shelf life.

Homogenization is the most important step in the manufacture of cream liqueurs and is necessary to produce a finely dispersed emulsion with long-term physical stability. During homogenization, the size of the fat globules is decreased and sodium caseinate transfers from the serum phase to the newly exposed fat globule surface to stabilize the product. Cream liqueur manufacturers employ a high protein/fat ratio (~0.19–0.21) in their products to ensure efficient coverage of the fat droplets and to ensure that small droplets are formed during homogenization. The effectiveness of homogenization in reducing fat globule size depends on feed temperature and homogenization pressure; higher homogenization pressures and feed temperatures used in processing are claimed to result in more stable products.

Novel technologies for the manufacture of cream liqueurs

Homogenization technologies for dairy products in general have evolved in recent years, driven in part by demands for longer shelf life products with better stability. Progress in high-pressure technology has led to new opportunities for alternative homogenization technologies for cream liqueurs; these were studied in detail by Heffernan and colleagues at the University College Cork in Ireland (the authors of this article). For example, cream liqueurs with finely dispersed droplets were produced on single-pass homogenization using a high-pressure homogenizer. Standard radial diffuser homogenizer requires multiple homogenization passes to produce a stable cream liqueur. In addition, high-pressure homogenization markedly increased cream liqueur temperature, due to pressure buildup and shear effects associated with the conversion of kinetic energy into heat. Cream liqueurs with small mean fat droplet diameters, homogenized using the high-pressure homogenizer, displayed a slower rate of increase in droplet diameter and in viscosity during storage at 45°C than those produced using a low-pressure homogenization process. Figure 2 illustrates the volume frequency distribution of fat droplets in cream liqueurs homogenized in a high-pressure homogenizer and in a standard homogenizer.

A number of high-pressure homogenizers, including a counter-jet-disperser (Microfluidizer) homogenizer, an orifice nozzle homogenizer, a radial diffuser homogenizer, and an ultrasonic system, have been evaluated and compared in terms of their efficiency in model cream liqueur emulsification. The jet-disperser (Microfluidizer) homogenizer produced cream liqueurs with fat droplets of the smallest diameters, while homogenization by an orifice nozzle or a radial diffuser homogenizer produced cream liqueurs with very wide volume frequency distributions of fat droplet diameters. For all high-pressure homogenization processes, cream liqueurs with fat droplets of smaller mean droplet diameters were produced at higher pressures. Lower fat droplet diameters resulted in cream liqueurs with improved storage stability. Ultrasonic

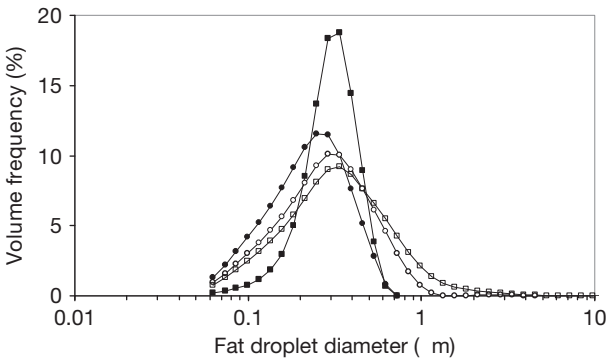

Figure 2 Volume frequency distributions of fat droplet diameters in model cream liqueurs: homogenized once at 20 MPa in a high-pressure homogenizer (○) and in a standard homogenizer (□); homogenized for five passes at 20 MPa in a high-pressure homogenizer (●) and in a standard homogenizer (▪). Adapted from Heffernan, S.P., Kelly, A.L., and Mulvihill, D.M. (2009). High-pressure-homogenized cream liqueurs: emulsification and stabilization efficiency. *Journal of Food Engineering* **95**, 525–531.

homogenization produced a cream liqueur with finely dispersed fat droplets; however, problems during shelf life appeared for highly processed samples.

Defects of cream liqueurs

Cream liqueurs are bacteriostatic; that is, they contain sufficient alcohol and sugar to inhibit bacterial growth. Thus, physical instability is the main defect during storage of cream liqueurs.

Age thickening–age gelation

Age thickening or gelation is one of the most serious problems affecting cream liqueurs and other long-life emulsions. Gelation is a problem in countries with high ambient temperatures. Liqueurs in which skim-milk powder (SMP) was used as an emulsifier were particularly prone to age gelation and exhibited aggregation after a short period of storage at ambient temperature. Flocculation in these systems can lead to full gelation, often followed by syneresis. In the early stages of gelation, the liqueur appears thick and aggregated; this process rapidly progresses to gelation, with subsequent syneresis producing a clear liquid at the bottom. It has been proposed that age gelation is due to calcium-induced aggregation, where the ionic calcium from the cream interacts with the protein and forms a three-dimensional network that gels and syneresis. Replacement of the SMP by sodium caseinate leads to a significant increase in liqueur shelf life. At ambient temperature, the shelf life of cream liqueurs stabilized with sodium caseinate can be increased from months to years by the inclusion of trisodium citrate in the formulation.

Neck plugs

Inefficient homogenization conditions can result in the formation of a distinct creamed layer at the top of the cream liqueur, but this is usually readily dispersed by shaking. On occasion, neck plugs, which are semisolid lumps of fat, 2–3 cm in thickness, occur in the tops of bottles. These structures, which are not readily dispersed by shaking, are considered to be inverted o/w emulsions. Inadequate homogenization (e.g., due to valve wear) and insufficient emulsifier level are the causes of neck plug in cream liqueurs. It has also been reported that there may be a link between neck plugging and excessively severe homogenization. Neck plugs are more likely to occur in cream liqueurs of low pH and high calcium content and in liqueurs that were inadequately homogenized and subject to temperature fluctuations and agitation during storage. Control of pH during the manufacture of cream liqueurs is one of the most important parameters influencing stability.

Granular precipitation

A crystalline precipitate often forms on prolonged storage of cream liqueurs, usually composed of calcium and citrate. Storage at high temperature accelerates the formation of the deposit, corresponding to the decreased solubility of calcium citrate at high temperatures. Lowering the level of trisodium citrate and adding it as late as possible in the manufacturing process were reported to reduce the problem.

Free-fat flecks

Another common observation in cream liqueurs is the presence of a small number of flecks at the surface of the liqueur. These are thought to be composed of protein or protein plus fat and may aggregate at the surface of the liqueur, forming an unappealing ring in the neck of the bottle. This type of instability does not pose a major problem because it is readily reversible by shaking. The presence of free fat may arise in cream liqueurs that are stored at sufficiently high temperatures. Droplets of free oil and flecks that form at the surface of the liqueur may not be noticed in a sufficiently opaque container.

Appearance and color

As discussed in the preceding text, droplet size is one of the most important factors that influence the stability of cream liqueurs, with the aim of emulsification of products, including cream liqueurs, being to produce droplets that are as small as possible, in order to ensure a long shelf life. However, this may have repercussions in terms of the sensory properties, as the droplet size distribution influences the color of emulsions. Cream liqueur lightness decreases with decreasing mean fat droplet diameter (0.40–0.08 μm) and decreasing fat droplet concentration (12.5–6.3%, w/w). Table 1 outlines the effect of mean fat droplet diameter on the instrumental color values and visual appearance of model cream liqueurs.

Table 1 Influence of mean fat droplet diameter ($d_{3,2}$, as measured using a Coulter LS) on the L^* and C values and on the visual appearance of model cream liqueurs

Homogenizer	*Pressure (MPa)*	$d_{3,2Coulter}$ *(μm)*	L* *value*	C *value*	*Visual appearance*
Pre-emulsion		3.340 ± 0.100	50.3 ± 1.90	29.5 ± 1.45

Characterization and Testing of Cream Liqueurs

Freshly produced cream liqueurs should be characterized to establish a baseline against which to measure subsequent long-term stability. Important parameters include viscosity and droplet size distribution.

Viscosity

The viscosity of a fluid emulsion is a very important characteristic, since it influences such aspects as the rate of creaming, the physical shelf life of the product, and the organoleptic properties of the product. Viscosity is defined as the ratio of the shear stress to the shear rate in liquids undergoing laminar flow or, simply, the resistance to flow. Emulsions with flocculated droplets have higher viscosities than those containing the same concentration of unflocculated droplets, because the effective volume of the flocculated droplets is greater than the effective volume of the unflocculated droplets, due to the presence of continuous phase trapped within the flocs.

Droplet size distribution

One of the most important characteristics of an emulsion is its droplet size distribution, since subsequent stability and other properties such as emulsifying characteristics of ingredients are influenced by this variable. Various methods are available for the characterization of the droplet size distribution of dairy emulsions; these include microscopic observation, light scattering methods, ultrasound spectrometry, electrical conductivity, and nuclear magnetic resonance (NMR). The most commonly used technique for the characterization of dairy emulsions, including cream liqueurs, is laser light scattering. Using laser diffraction analyzers (e.g., Coulter LS, Malvern Mastersizer), the shape of the particle size distribution is determined after the measurement of scattering of laser light by a diluted emulsion at different diffraction angles; up to 100 detectors capture data from various angles, and these are processed under a suitable model such as the Mie theory of interaction of light with matter.

Shelf life testing

The amount of visible creaming is usually measured after a given time and expressed as a percentage of the original volume (height of the emulsion). Centrifugal methods may be applied to speed up creaming; however, acceleration of creaming may result in incorrect assumptions as it may not reflect the complexity of changes occurring during the storage period. Various authors have measured the type and amount of creaming in cream liqueurs by incubating samples at elevated temperatures.

Viscosity of cream liqueurs increases over time, and, thus, viscosity can be used as one important index of shelf life; eventually, excessively high viscosity will become a limiting factor to consumer acceptability. Accelerated shelf life testing of cream liqueurs is typically carried out at 30 °C and 45 °C and typically involves measurement of changes in viscosity as an index of physical stability.

Sensory aspects

The flavor of cream liqueurs involves a complex interaction of volatile and nonvolatile favor compounds. The core background flavor originates from the liqueur components such as cream, cocoa, vanilla, and whiskey. The polarity of these flavor compounds determines how they partition in the continuous phase of the cream liqueur emulsion, within the fat globule, or across the globule–aqueous phase interface. Flavor partitioning affects flavor release and ultimately the flavor profile of the liqueur, with the more polar flavors being perceived first and the more nonpolar perceived last perhaps or even as after-taste sensations.

Ethyl esters also contribute to the overall flavor balance of cream liqueurs. However, at high concentrations, they can impart a very fruity flavor, which can become the dominant flavor in the liqueur. Ethyl ester level increases in concentration as cream liqueurs age, and thus, the level of fruitiness may become a limiting factor to consumer acceptance in aged liqueurs. Ethyl esters form via the reaction of the alcohol and fatty acids, and the presence of excessive levels of short-chain fatty acids can result in the formation of ethyl esters such as ethyl acetate, ethylbutanoate, and ethyl hexanoate, which are the principal causes of this fruity defect. The level of ethyl esters may be used as an indicator of the ability of the interfacial protein membrane to maintain compartmentalization of the fat and aqueous/ethanol phases. It has been found that high-pressure homogenized cream liqueurs had lower levels of ethyl decanoate following storage than liqueurs produced using a lower-pressure homogenization process, indicating that high-pressure homogenized liqueurs had a greater ability to maintain fat–aqueous phase compartmentalization during storage.

The levels of these ethyl esters can be monitored and quantified using gas chromatography (GC) or gas chromatography–mass spectrometry (GC-MS) typically following extraction of methylated esters, for example, using solid-phase microextraction (SPME). Cream liqueur manufacturers perform regular sensory profiling of their products over the course of their real-time shelf life. Panels are trained and sensory changes are tracked over time. Producers may also employ triangle tests to differentiate a product at a point in its shelf life from a fresh or gold standard product.

Conclusion

This article gives an overview of liqueurs in general while focussing specifically on cream liqueurs. The main ingredients used in cream liqueur manufacture are described, that is, sodium caseinate, cream, sugar, and ethanol. A typical process for cream liqueur manufacture is outlined, and the critical role of homogenization in the manufacture of cream liqueurs is discussed, as well as the latest research on alternative emulsification technologies. Physical instability, the main problem facing cream liqueurs, is described, and finally parameters, including viscosity and droplet size distribution, used to characterize and test subsequent long-term stability are outlined.

Listeria: Detection

LS Cocolin and K Rantsiou, University of Turin, Turin, Italy

Introduction

Listeria genus contains ten species, namely, *L. monocytogenes*, *L. innocua*, *L. ivanovii*, *L. seeligeri*, *L. welshimeri*, *L. grayi*, *L. rocourtiae*, *L. marthii*, *L. fleischmannii*, and *L. weihenstephanensis*, of which *L. monocytogenes* and *L. ivanovii* are considered pathogenic microorganisms for humans and animals, respectively. *Listeria* spp. are gram-positive, facultatively anaerobic, rod-shaped, and motile at temperatures below 30 °C. They are ubiquitous and widely diffused in the environment. Among the species belonging to the *Listeria* genus, *L. monocytogenes* is a major concern for food producers. Due to its physiological characteristics, such as resistance to acidic stress, ability to grow at low temperature, and possibility to form biofilms, it can persist and/or recontaminate food products, thereby representing an important risk for the safety of the consumers. The term '*Listeria* hysteria' was coined toward the end of 1980s following a series of listeriosis outbreaks due to the consumption of soft cheese and ready-to-eat (RTE) meats in the United Kingdom. The constant occurrence of listeriosis, as reported in the community summary reports on foodborne outbreaks in the European Union, warns for the need for special attention to this foodborne pathogen in order to combat its presence in foodstuffs. *L. monocytogenes* infection presents a high mortality rate, up to 20%, particularly among vulnerable groups such as the elderly. Listeriosis is also very threatening for pregnant women as it can cause fetal infections, miscarriages, and stillbirths. The foods most frequently associated with the outbreaks have been identified as RTE foods, particularly smoked fish and other fishery products, followed by meat products and cheese. Since *L. monocytogenes* is widely diffused in the environment, the route of contamination is often characterized by a postprocessing cross contamination.

Authorities have approached the risk of *L. monocytogenes* in food following different ways, and there are mainly two approaches that have been used worldwide: the zero tolerance and the 100 cfu g^{-1} or ml limit. RTE foods are most often considered in the legislations, and when the 100 cfu g^{-1} or ml limit is accepted, they are usually divided into categories that support or not the growth of the pathogen. For example, in the case of the European Commission Regulation 2073/2005, amended by the 1441/2007, RTE foods are divided first into two categories based on the final consumer: foods intended for risk categories (e.g., hospitalized, elderly, newborns, and pregnant women) and foods intended for the general population. In the first case, the absence of *L. monocytogenes* in 25 g or ml for 10 sampling units is requested, while for the second category, a further differentiation is made, based on the capability of the food product to support or not the growth of *L. monocytogenes*. If the food is not able to permit growth, the limit is below 100 cfu g^{-1} or ml until the expiration date, while if *L. monocytogenes* can grow and multiply in the product, then it must be absent in 25 g or ml, immediately after production, before it is placed on the market or the food business operator has to guarantee that the 100 cfu g^{-1} or ml limit will not be exceeded before the expiration date.

In the last 30 years, microbiologists have put a lot of efforts in the development of methods able to detect, quantify, and identify *Listeria* spp. and *L. monocytogenes*. Due to its low number in foods, the strategy that has been proposed is similar to the one used for the detection of *Salmonella* spp., and it is based on a series of enrichments able to support the selective growth of *Listeria* spp. while inhibiting the other members of food microbiota. After this step, selective and differential agars are used to streak the enriched broth and to allow the formation of colonies with specific color and morphology typical for *Listeria* spp. Recently, a new chromogenic agar, named agar *Listeria* according to Ottaviani and Agosti (ALOA), allowed the specific detection and enumeration of *L. monocytogenes* due to the characteristic green-blue color of the colony surrounded by an opaque halo.

Culture-based methods for the detection of *Listeria* spp. and *L. monocytogenes* in the last years have been criticized. Several authors, in fact, have reported an underestimation of *L. monocytogenes* incidence due to the masking effect of other *listeriae* during the enrichment step, which are able to grow faster (e.g., *L. innocua*). Moreover, it has been previously proven that *L. monocytogenes* undergoing stresses enters a viable but nonculturable (VBNC) state that makes its recovery by culture-dependent methods impossible. These arguments have promoted the development of alternative methods for the detection of this pathogenic microorganism in food and the approaches that most frequently have been used are molecular biology-based. Conventional and quantitative PCR (qPCR) protocols have been developed for the detection, identification, and quantification of *L. monocytogenes*, while less frequently, the other members of the genus have been considered.

In this chapter, a description of the principal detection methods for *Listeria* spp. and *L. monocytogenes* is reported, with an emphasis on the differentiation between culture-dependent and culture-independent methods.

Culture-Based Methods

As outlined earlier, the procedure used for the detection of *Listeria* spp. and *L. monocytogenes* in foods is based on a first step of enrichment in selective broths, followed by growth in selective agar plates, where colonies with a typical aspect are then isolated and further confirmed as belonging to this genus and species. A list of *Listeria* enrichment broths and selective isolation agars is described in Table 1. The list contains media specified by regulatory bodies, such as the US Food and Drug Administration (FDA), the US Department of Agriculture (USDA), and the International Organization for Standardization (ISO). Regarding the enrichment, most

standards foresee a double step, in which two different broths are used. Usually, primary enrichment broths contain a reduced amount of the selective agent (e.g., Half Fraser and UVM I) in order to allow the recovery of cells that are stressed, injured, or in a sublethal state. The selective agents that are most frequently used in enrichment broths are acriflavine, nalidixic acid, and cycloheximide. While the first two are specifically used to inhibit the RNA and DNA synthesis of gram-positive and gram-negative bacteria, respectively, cycloheximide is able to avoid the growth of yeast and molds, since it prevents protein synthesis in eukaryotic cells. As indicated earlier, during enrichment, nonpathogenic *Listeria* may be able to overgrow *L. monocytogenes*, making its recovery on the agar plate very complicated. It should be pointed out, however, that since *L. innocua* and *L. monocytogenes* share the same environmental niches, the detection and identification of *L. innocua* should be considered as an indication of a probable presence of *L. monocytogenes* as well. Moreover, during the enrichment step, different serotypes of *L. monocytogenes* may behave differently in terms of growth speed; thereby, the intraspecies ecology in the sample can be altered. This aspect has a great impact in terms of the epidemiology of the different serotypes involved in food outbreaks, since only those that are favored by the enrichment medium will be isolated on the agar plates.

Considering the selective isolation agars, lots of efforts have been dedicated to the optimization of media, which are highly selective for *Listeria* spp. and especially *L. monocytogenes*. Most of the agars differentiate *Listeria* spp. based on the hydrolysis of the esculin, which in the presence of iron is able to form colonies with a black surrounding. This principle does not allow the differentiation of *L. monocytogenes* from other *listeriae*, and for this reason, when selective media such as Oxford or PALCAM are used, it is common that isolation and identification of at least five presumptive *Listeria* colonies are performed in order to assess the presence of *L. monocytogenes*. This obstacle was partially circumvented by the development of blood-containing

media that allow the separation of the hemolytic species (*L. monocytogenes*, *L. ivanovii*, and *L. seeligeri*) from the nonhemolytic ones (*L. innocua*, *L. welshimeri*, and *L. gray*). However, the determination of this character is not always easy to perform and misidentifications can be reached. The development and introduction of chromogenic agars selective for *L. monocytogenes* have improved the detection of this pathogen in food products. The phosphatidylinositol-specific phospholipase C (PI-PLC), which hydrolyzes a specific substrate producing an opaque halo around the colony, is the basis for the differentiation of *L. monocytogenes* in several chromogenic agars, such as the ALOA, *L. monocytogenes* selective/differential plating medium (LMPM), and the RAPID'*L. mono*. Available data in the literature suggest that the use of these chromogenic agars allows for a better understanding of the prevalence of *L. monocytogenes* in foods. However, it should be emphasized that further improvement of detection of contaminated samples can be reached by the combined use of several selective agars.

Molecular Biology Methods

The exploitation of molecular biology in food microbiology has allowed the development of approaches, which do not rely on the capability of the target microorganism to grow on synthetic media. Molecular techniques are based on the detection of genetic material (nucleic acids, i.e., DNA or RNA) that is unique to the target organism, and for this reason, they are characterized by a high specificity. In this context, the polymerase chain reaction (PCR) is one of the most important rapid methods for the sensitive and specific detection of pathogenic microorganisms. The introduction of qPCR enables the quantification of the number of pathogens in foods.

The PCR technique, first described by Kary Mullis in the mid-1980s, is based on a three-step cyclic *in vitro* procedure, in which the DNA polymerase copies a strand of DNA. By using two primers, the sequence in between is amplified exponentially with each cycle making the technique very sensitive. Theoretically, even one molecule of DNA can be amplified reaching billions of copies. The amplicons of PCR are traditionally (conventional PCR) visualized by agarose gel electrophoresis, where the identification is based on the molecular weight. Further confirmation can be obtained by sequencing.

In the early 1990s, the 'second'-generation PCR technology was introduced exploiting intercalating dyes, for example, SYBR Green, or DNA probes, for example, molecular beacons, TaqMan probes, or Scorpions, enabling real-time detection. qPCR offers the opportunity to quantify a nucleotide sequence since the fluorescence emitted by the reported dye is continuously measured. In addition, qPCR consists of a closed-tube format and does not need postamplification processing of the PCR product (e.g., gel electrophoresis), reducing the risk of contamination. Lastly, qPCR offers a higher sensitivity and more rapid results in comparison with conventional PCR.

Since the introduction of the PCR approaches in the field of food microbiology, the detection of foodborne pathogens has evolved enormously. The optimization of the DNA polymerase enzyme, the PCR master mixes, and PCR equipment has improved the sensitivity and robustness of the technique significantly, pushing the PCR to its theoretical detection limits, that is, almost single DNA copies per PCR tube.

As for other foodborne pathogens, also for *L. monocytogenes*, the literature is rich in papers describing the development, optimization, and application of PCR (both conventional and quantitative) for detection, identification, and quantification in different foods. One of the most common targets for PCR amplification is the *hly* gene; however, others such as *inlA*, *inlB*, intergenic spacer regions, *iap*, *plcA*, and *actA* have been used as well. The food matrices, in which *L. monocytogenes* has been detected by means of molecular methods, are represented by meat and meat products, milk and dairy products, fruits and vegetables, fish (e.g., salmon), and RTE and deli products. The limit of detection of the available protocols is usually 100 cfu g^{-1} or ml, while in the case of qPCR, the limit of quantification is often above 10^3 cfu g^{-1} or ml. These limits are still too high for practical application in the food sector, and for this reason, PCR amplification is often preceded by an enrichment step. In the case of qPCR, it should be pointed out that after enrichment, the method from quantitative becomes qualitative, since no correlation between the number of cells at the end of the enrichment and those originally contained in the sample can be calculated. Some examples of conventional and quantitative amplification protocols for *L. monocytogenes* in food are reported in Table 2.

An inherent drawback with DNA amplification by PCR is the inability of the method to distinguish between live and dead cells. Since DNA is a very stable molecule, it persists long after the death of the microorganism, and it can be amplified. This consideration is particularly relevant for foodborne pathogens, since the presence of live or dead pathogenic microorganism in foods has a totally different significance. Considering also that food processing exploits bactericidal treatments (e.g., pasteurization and sterilization), it is common to find in foods DNA molecules generated from pathogen cell lysis. For this reason, it is important to correctly interpret the results obtained by DNA-based PCR. The possibility to differentiate live from dead cells in PCR protocols has been addressed by the researchers mainly in two ways: the use as target in the amplification of the RNA and the pretreatment of the sample with ethidium monoazide (EMA) or propidium monoazide (PMA). In the first case, since RNAs are molecules that are degraded immediately after cell death, a positive amplification correlates well with the presence of alive populations of the pathogenic bacteria in the food sample. In the second case, EMA and PMA are able to penetrate into damaged and dead cells, they bind to the DNA, and after a photosensibilization, they are able to provoke the hydrolysis of the molecule, which will not be amplified. These solutions are valuable alternatives to the classic DNA-based PCR approach; however, they are not frequently applied. Nevertheless, it should be pointed out that if the PCR amplification is able to detect specific targets of the pathogenic microorganism, independently from the fact that this is DNA from live or dead cells or RNA, it means that during the food chain, a contamination has occurred and this has to be taken into consideration and corrected.

Lastly, especially when environmental conditions influence the fitness and behavior of the pathogens, such as in the

presence of salt, or when the cells have to respond to several stresses such as disinfectants, starvation, and dry conditions, molecular methods represent good tools to properly detect them. As outlined earlier, it has been previously proven that *L. monocytogenes* undergoing stresses enters a VBNC state, which makes impossible its recovery by culture-dependent methods. The application of molecular methods can result in a better comprehension of the spread of a specific pathogen in the food chain, thereby allowing the implementation of corrective actions to eliminate or decrease the risk associated with its presence in the final product.

PCR is the most common technique used for *Listeria* spp. and *L. monocytogenes* nucleic acid amplification. Nevertheless, other techniques such as nucleic acid sequence-based amplification and the loop-mediated isothermal amplification have been developed. Both methods have the advantage of being carried out at a constant temperature, thereby avoiding the purchase of expensive equipment for the thermal cycling in PCR amplification.

The use of PCR-based methods in official routine analysis requires a validation. Generally, this includes a comparison with the current reference method using artificially and naturally contaminated food samples and an interlaboratory study. Validated protocols of PCR-based methods for the detection of *L. monocytogenes* in foods, such as raw milk, are available in the literature. Lastly, many commercial PCR kits available on the market are now validated according to certification bodies, such as AOAC, AFNOR, or NordVal.

Immuno-Based Methods

The high specificity of the antigen–antibody interaction has been exploited in food microbiology to develop specific methodologies for the detection and identification of foodborne pathogens. One of the main drawbacks of these methods is the low sensitivity, since a microbial load of about 10^5 cells per g or ml is necessary to produce a measurable signal. This

number is extremely high considering pathogenic microorganisms of food relevance, and it does not stand well against the limits of detection of the plate count (about 10^4 cells per g or ml) or molecular methods (10^2–10^3 cells per g or ml). Moreover, for some microorganisms, it is very complicated to find specific antibodies, without cross-reactions with other closely related species.

The antigen–antibody interaction in the field of food microbiology for the detection of *Listeria* spp. and *L. monocytogenes* has been used for the specific separation (and immunoconcentration) of the microorganism from enriched samples, to be then identified by molecular methods, or in the development of enzyme-linked immunosorbent assays (ELISAs), in which two specific antibodies are used and one of them is conjugated with an enzyme (often a peroxidase).

The Dynabeads are beads with a metal core, with *Listeria*-specific antibodies embedded in the polystyrene surface. As indicated earlier, Dynabeads can be used in enriched samples, in order to capture *Listeria* spp. After the separation, the beads can be streaked on a selective medium or subjected to DNA extraction followed by specific identification.

Regarding the ELISA, anti-*Listeria* antibodies are usually immobilized in a microtiter plate. The antibody blocks the target inside the well, allowing washes to remove non-specifically bound microorganisms, and it is used in combination with a second antibody that is linked to an enzyme. The addition of a chromogenic substrate, through the activity of the enzyme, is producing color, which can be evaluated visually or with a spectrophotometer. ELISA technique is characterized by a low sensitivity, as all the immuno-based methods, and positive signals are recorded above a threshold concentration of about 10^5–10^6 cells per g or ml. For this reason, an enrichment step is necessary that renders the assay qualitative.

Conclusions and Future Perspectives

Listeria spp. and *L. monocytogenes* detection has benefited from the implementation of molecular methods applied in food microbiology. Due to its low contamination level, methods of detection still rely on the use of enrichment broths, able to favor the growth of this microorganism and at the same time inhibit the microbiota associated to the specific food sample processed. The combination of culture-dependent and culture-independent methods has increased the possibility to detect this important foodborne pathogen, creating the prerequisites for better control in the food chain.

The 'omics' approaches can be considered as a valuable tool in order to better understand the physiology of the microorganism and as a consequence improve its control. Genomics, and more specifically metagenomics, can be used, for example, to detect specific signatures of *L. monocytogenes* in a food sample with a higher sensitivity compared to PCR, due to the number of sequences that the approach can read, while metatranscriptomics appears to be a powerful approach to understand the behavior of the pathogenic microorganism in terms of stress response, virulence, and survival during food processing and even when it is entering the human body. The information collected through the application of these modern approaches will have to be integrated in risk assessment models that have to properly take into account both intrastrain variability and differences in the microbial behavior.

Listeria Species and Subtyping

The Gram-positive *Listeria* genus of bacteria comprises motile, facultative, anaerobic, coccobacillary, non-spore-forming rods that are up to 2 μm in length. They are psychrotrophic or 'cold-tolerant' and are widely disseminated in the environment in relatively low numbers where they live as saprophytes in soil and vegetation. Currently, the *Listeria* genus is identified and designated into 15 species, and two of these, *Listeria monocytogenes* and *L. ivanovii*, are pathogenic primarily to humans and animals, respectively. Of these, *L. monocytogenes* is the most important pathogen that is a facultative intracellular organism and has attracted extensive research attention, not least because of its serious potential risk to human health. *L. ivanovii* shares facultative pathogen status, and while it is an important cause of disease in ruminants, there are only occasional reports of it infecting debilitated humans as an opportunistic pathogen. The other 13 described nonpathogenic species are *L. seeligeri*, *L. innocua*, *L. welshimeri*, *L. grayi*, *L. fleischmannii*, *L. marthii*, *L. rocourtiae*, *L. weihenstephanensis*, *L. floridensis*, *L. aquatica*, *L. cornellensis*, *L. riparia*, and *L. grandensis*.

The most studied member is *L. monocytogenes*, which is the most important pathogenic species. *L. monocytogenes* is remarkably adaptable and resilient. Other habitats identified for it include water, sewage, animal feeds (especially silage), farm, and food processing environments. Growth occurs over the range 4–45 °C but optimally at 30–37 °C, and biochemically, it is catalase-positive and oxidase-negative. Colonies on blood agar media after incubation for 24 h are small, smooth, and transparent and usually surrounded by a narrow zone of complete beta-hemolysis.

Commercially available biochemical test kits, Matrix assisted laser desorption/ionization - time-of-flight (MALDI-TOF) mass spectrometry, and various polymerase chain reaction (PCR) assays can be used to distinguish the *Listeria* species. Strain typing is performed using methods from molecular biology and involves, on the one hand, digestion of genome nucleic acid with restriction endonucleases or amplification of fragments followed by electrophoretic separation. These methods permit subtyping by generating fragment banding patterns by pulsed-field gel electrophoresis, ribotyping, amplified fragment length polymorphism, random amplified polymorphic DNA analysis, and repetitive extragenic palindromic sequence PCR. On the other hand, sequence-based subtyping, like multilocus sequence-based typing, multilocus variable tandem repeat analysis, multi-virulence-locus sequence typing, and microarrays, now plays an important role in determining the source of listeriosis outbreaks and is critical for the understanding of the natural history and transmission of the organism. Subtyping tests are now standardized internationally by the World Health Organization and the PulseNet International network.

Classification of *L. monocytogenes* has also benefited from comparative genomics and the organism now ranks among the most documented pathogens. Nevertheless, knowledge about subtype, natural history, and association with disease does not provide information about the virulence potential of *L. monocytogenes* isolates.

Seventeen serotypes of *L. monocytogenes* have been recognized based on somatic (O) and flagellar (H) antigens. These are identified alphanumerically. Whereas serotypes 1/2a, 1/2b, and 1/2c are the types most frequently isolated from food or the food production environment, more than 95% of human infections are associated with serotypes 1/2a, 1/2b, and 4b. Serotype 4b has been linked to international outbreaks, for example, those that have implicated coleslaw, soft cheese, pâté, and pork tongue (see in the succeeding text); serotype 1/2b has been linked to contaminated milk, rice salad, and imitation crabmeat products; and serotype 1/2a has frequently been linked to outbreaks stemming from food processing plants. Other serotypes have also been occasionally linked to sporadic cases, for example, 1/2c (Switzerland 2011–13, Spain 2009, Italy 2000–10).

L. monocytogenes has at least four distinct phylogenetic, evolutionary lineages. The lineages have different, but overlapping, ecological niches. Taken together, serotypes 1/2b, 3b, 4b, 4d, and 4e form a distinct evolutionary lineage, now recognized as lineage I. Lineage II comprises serotypes 1/2a, 1/2c, 3a, and 3c. Lineages III and IV comprise serotypes 4a and 4c. However, the latter ones are rare and predominantly identified in animals. Interestingly, the latter lineage serotypes are rarely isolated from foods or human patients. Characterization of *L. monocytogenes* isolates from listeriosis outbreaks has led to the suggestion that many of these outbreaks were caused by a small number of epidemic clones. The global transmission pathways and the true reservoirs of the *Listeria* species have not been yet defined.

Human Listeriosis

Listeriosis, infection with *L. monocytogenes*, is a relatively rare disease with an incidence rate of 0.26–0.32 reported infections per 100 000 habitants. However, it is one of the most serious foodborne diseases in humans. Listeriosis is associated with mild or severe, localized or generalized infections in most domestic animals and humans, particularly in temperate climates. *L. monocytogenes* was initially associated with septicemia and monocytosis in laboratory animals in 1926 following an epidemic infection among rabbits and guinea pigs. The name reflected the monocytosis observed. Meningitis in a human patient was first described in 1929.

However, it was not until the early 1980s that reports of *Listeria* isolates increased in the literature and a series of epidemic outbreaks in humans in North America and Europe thereafter established listeriosis as an important foodborne

infection. Until that time, listeriosis was considered a rare and sporadic disease. Since then, multiple large outbreaks have been reported internationally. Most cases of human listeriosis in adults are sporadic and likely go unreported, and this makes estimates of their incidence difficult. Besides sporadic illnesses, human listeriosis can also take the form of disease outbreaks following consumption of contaminated food, which is usually a particular food item.

In Europe and the United States, the hospitalization rate is estimated at over 95%. Once clinical infection is established, the overt form of listeriosis in humans is associated with a fatality rate of 25–30%. Outbreaks in humans often occur in urban environments in summer, and epidemics have been traced to foods of animal origin or fecally contaminated plant products, postprocess contamination of meats, or selective, prolonged growth of *L. monocytogenes* in refrigerated foods. Ready-to-eat foods are especially implicated. Preexisting gastrointestinal disease may be a risk factor for infection with *L. monocytogenes*.

Sourcing of epidemics is complicated by the relatively low incidence of *L. monocytogenes* and the long incubation period for the invasive forms of the infection, which has been cited to be up to 70 days, with a median of 8 days. A longer median incubation period of 27.5 days has been cited for pregnant women. While the infectious dose of the organism is not known, it may be as high as 1 million colony-forming units per gram of contaminated food. It may be considerably lower for susceptible individuals such as infants, pregnant women, the elderly, and immunocompromised people. Other likely variables influencing the infectious dose are strain virulence, susceptibility of the host, and the nature of the particular food matrix.

Original contaminated food sources are difficult to retrieve due to the perishable nature of food and the significant clinical incubation period. The actual level of original contamination is often never determined. However, exceptionally, an outbreak in central Europe occurred between June 2009 and February 2010, when 34 people became ill and eight of them died. The source of contamination was successfully traced epidemiologically and, by the concerted efforts of multidisciplinary specialists, to patient food purchase receipts from a Quargel cheese production site in Austria. Molecular typing was key to the identification. The outbreak could be traced to two specific *L. monocytogenes* serotype 1/2a clones, and for the first time, it has been possible to determine the contamination level of *L. monocytogenes* in the very cheese lots that caused the outbreak.

As an environmental organism, *L. monocytogenes* is capable of transition into a pathogen eliciting overt clinical disease following ingestion especially by susceptible consumers. These are typically infants, pregnant women, the elderly, debilitated and immunocompromised people, and particularly those with impaired T cell-mediated immunity. The latter include patients receiving immunosuppressive drug therapies, those undergoing hemodialysis, those with transplants, diabetics, human immunodeficiency virus (HIV) carriers, and drug abusers. This list may even be extended to include those receiving antacid drugs in that gastric acid may confer a degree of protection from ingested bacteria.

Infection with *L. monocytogenes* in humans causes a spectrum of illness, ranging from febrile gastroenteritis to outright life-threatening invasive disease, including bacteremia, sepsis, and meningoencephalitis.

Noninvasive Listeriosis in Adults

Self-limiting skin lesions in the form of papules on the hands and arms are occasionally observed in veterinarians and farmers following contact with ruminants infected with *L. monocytogenes*. Individuals not in high-risk groups may experience gastrointestinal discomfort, diarrhea, and fever with resolution of symptoms in 24 h following ingestion of the bacteria. This form of infection was described from an outbreak of gastroenteritis and fever due to consumption of infected chocolate milk at a picnic in Illinois, the United States, in 1997. None of the victims of the outbreak were in high-risk groups or subsequently showed signs of invasive listeriosis. Due to its transient nature, noninfectious listeriosis is likely to go underdiagnosed and unreported.

Invasive Listeriosis in Adults

Hematogenous spread of *L. monocytogenes* following oral ingestion can result in focal infections, which commonly involve the peritoneum, joints, endocardium, or eyes. This form of infection with *L. monocytogenes* is an important cause of bacterial sepsis, meningitis, or meningoencephalitis. The case fatality rate is ~30%.

Listeriosis during Pregnancy

Most cases of listeriosis during pregnancy occur in otherwise healthy women. Infection of pregnant women can lead to abortion, fetal death, or neonatal morbidity in the form of septicemia and meningitis. Pregnant women may be asymptomatic or present with nonspecific clinical symptoms. However, clinical cases can be life-threatening and typically present as septicemic or meningoencephalitis syndromes. Frequently, patients present with fever or flu-like illnesses lasting ~6 days. Pregnant women may be susceptible to infection with *L. monocytogenes* as their cellular immunity decreases secondary to increased progesterone secretion and the bacteria have a tropism for the uterus and placenta. The fetus becomes infected by transplacental transmission following maternal bacteremia. Women with multiple fetuses may be at increased risk of infection compared with singleton pregnancies, and listeriosis cases affecting pregnant women most frequently occur during the third trimester.

Neonatal Listeriosis

While maternal listeriosis often takes the form of a mild illness, neonatal infection is invariably serious and frequently fatal. Neonatal listeriosis can take early-onset or late-onset forms.

The early-onset form of neonatal listeriosis is acquired *in utero* and appears to result from aspiration of infected amniotic fluid, most probably as a result of transplacental infection. It results in illness at the time of birth or within the first week of life. Symptoms include septicemia, respiratory distress, and less frequently meningitis and *granulomatosis infantiseptica*, which is associated with disseminated abscesses or granulomas in various internal organs. The mortality rate for infected infants is ~20%, and this can increase to 50% when abortion and still births are taken into account.

Late-onset neonatal listeriosis frequently occurs during delivery of a full-term baby and can occur up to several weeks after birth. The route of infection is not well understood. Late-onset neonatal listeriosis can progress to meningoencephalitis and sepsis. The mortality rate has been cited at 10%, and a high number of surviving neonates develop severe and chronic neurological complications and blindness.

Diagnosis and Treatment

In all cases, diagnosis of human listeriosis infection with *L. monocytogenes* necessitates recovery of the bacteria from infected tissues, the blood, or the cerebrospinal fluid. There are no reliable serological tests. Fecal cultures are not informative as healthy individuals can be silent carriers of the bacteria.

Isolates of *L. monocytogenes* are susceptible to penicillins, aminoglycosides, trimethoprim, tetracycline, macrolides, and vancomycin, with reduced susceptibility or resistance to sulfamethoxazole, cephalosporins, and early quinolones. Aggressive antibiotic treatment is normally continued for at least 2 weeks. Longer treatment periods are recommended for neonatal infections and for immunocompromised patients with meningitis and bacteremia.

Pathogenesis

Emergence of *L. monocytogenes* as a foodborne pathogen in the 1980s also prompted substantial molecular biology research underlying its pathogenesis. Following ingestion of *L. monocytogenes* in contaminated food, passage into the gastrointestinal tract, and survival of gastric acid, translocation can occur directly by invasion of intestinal epithelial cells or indirectly by active penetration of M cells overlying Peyer's patches. Systemic spread occurs via the lymph and blood. From the intestines, it is disseminated to the mesenteric lymph nodes, spleen, and liver, and from there, *L. monocytogenes* can reach the brain and placenta.

Demonstration in the early 1960s that *L. monocytogenes* can survive and multiply in macrophages prompted its use in immunological research as a prototype intracellular parasite.

L. monocytogenes invades host cells, phagocytes, and nonphagocytes and replicates in the cytosol after phagosomal escape. In this way, *L. monocytogenes* is a classic example of a 'cytosol-adapted pathogen' that can readily escape from these macrophage phagosomes and replicate rapidly in the cytosol. Virulent strains are able to survive within cells by escaping from phagosomes before maturation to phagolysosomes.

The pathogenicities of *L. monocytogenes* and *L. ivanovii* are enabled by an ~9 kb virulence gene cluster that is also present in a modified form in *L. seeligeri*. This gene cluster appears to mediate the saprophyte-to-cytosolic parasite transition of *L. monocytogenes* through careful modulation of the activity of the transcriptional activator protein *prf*A.

Discovery of *L. monocytogenes*' hemolysin (listeriolysin) gene *hly* and elucidation of the key role that hemolysin plays in escape from destruction inside phagosomes, a prerequisite for intracellular proliferation, helped piece together its virulence strategies. Listeriolysin has also been proposed as a virulence factor that promotes encystment and supports survival of *L. monocytogenes* within ciliated protozoa.

Once within the cytoplasm, motility of the bacteria is facilitated by production of *act*A, an actin-polymerizing protein that promotes formation of taillike structures from host cellular microfilaments. These motile forms can then induce pseudopod-like projections on the cytoplasmic membrane, which enables them to be taken up by adjacent cells. By forming plasma membrane protrusions, *L. monocytogenes* can continuously avoid host defense mechanisms, and dissemination can occur via macrophages and the bloodstream. Due to this cycle, *L. monocytogenes* can move between host cells without being present in the extracellular environment. In this way, it escapes from the human T cell immune response. Since populations of *L. monocytogenes* can replicate in macrophage vacuoles, this has been anticipated as being important for the establishment of chronic infections.

Listeriosis and Food

It is now recognized that nearly all cases of human listeriosis are foodborne. Poor hygiene practices most likely increase the risk of *L. monocytogenes* persistence and survival in food processing environments and the risk of contamination from outside. Knowledge that *L. monocytogenes* is far more commonly associated with the digestive tracts of animals, especially silage-fed ruminants, than humans led to the association of food contamination with animal feces. Correspondingly, typical sources of ingestion are currently considered to be raw foods closely associated with their originating environments, such as unpasteurized milk and dairy products, fresh meat, smoked fish and other seafoods, and raw fruits and vegetables. Together with this association and the extraordinary viability of *L. monocytogenes* within wide temperature (−1.5 up to 45 °C) and pH ranges (4.4–9.4) and its ability to survive at high salt concentrations (up to 14%) and to form persistent biofilms, it poses a significant and ongoing challenge to the food industry. Due to these characteristics, *L. monocytogenes* is able to survive under adverse environmental conditions for long periods, which include persistence on food processing surfaces and equipment. Thus, food processing environments have emerged as one of the major, direct sources of *L. monocytogenes* found in human food.

High-risk foods generally have the potential for contamination and the potential to support growth of the bacteria to high numbers, require refrigeration, have an extended shelf life, and contain high numbers of bacteria at the time of consumption. This applies to ready-to-eat seafood, prepared raw vegetables, refrigerated cold meat, and dairy products.

Pasteurization and adequate cooking do kill *L. monocytogenes*. However, contamination may occur after cooking and before packaging. In conjunction with the long clinical incubation period, contaminated perishable food items are not likely to remain for investigation in the event of a listeriosis outbreak. Furthermore, the ease with which contaminated foods can now be transported internationally and the size of large-scale modern food production, combined with complex transnational retailing systems and consumer

expectations for food items with a long shelf life, add to the impediments to outbreak investigation.

Ready-to-eat meats and cheeses made from unpasteurized milk have been the most frequently identified vehicles implicated in outbreaks. Again, it is worth stressing that ready-to-eat foods, such as hotdogs and delicatessen meats, can be contaminated after cooking, before the packaging step.

Fruit and Vegetables

Raw vegetables can be vehicles for infection of consumers. A particular example of such contamination was seen in 1981 in Nova Scotia when the infection of 42 people was linked to the consumption of a coleslaw product. The cabbage used for the coleslaw was harvested from fields fertilized with sheep manure from a farm with a history of ovine listeriosis. There were 34 pregnancy-associated and 7 non-pregnancy-associated adult cases. Of infants born alive, 27% later died. This outbreak provided the first convincing evidence that listeriosis could be a foodborne disease and highlighted the potential for uncooked vegetables to be a source of infection.

More recently, in 2011, 147 people in 28 US federal states became ill after eating contaminated cantaloupes contaminated with *L. monocytogenes*, 33 people died. Whole cantaloupes produced by a single Colorado farm were linked to the outbreak. Unsanitary conditions identified in the processing facility operated at the farm are thought to have resulted in contamination of the cantaloupes with *L. monocytogenes*. This outbreak revealed that fresh produce could be associated with an outbreak.

Dairy Products

Pasteurized milk was implicated as the most likely vehicle for an outbreak in Massachusetts, the United States, in 1983, where 49 cases of listeriosis occurred and the case fatality reached 29%. However, most episodes of infection with dairy products have involved cheese. An outbreak in California in 1985 was associated with Mexican-style cheese; there were 142 cases and 48 fatalities. In Switzerland, between 1983 and 1987, 34 people died out of 122 cases of listeriosis associated with Vacherin Mont d'Or cheese. A blue mold cheese in Denmark between 1989 and 1990 was responsible for 26 cases and seven deaths. Contaminated Mexican-style cheese in the year 2000 in the US state of North Carolina resulted in 13 cases of listeriosis and five deaths. Butter was the vehicle in 25 cases in Finland in 1999 when six people died. In Quebec, Canada, in 2002, contaminated cheese made from unpasteurized milk resulted in 17 cases, but no reported deaths. In 2003, in Texas, the United States, Mexican-style cheese was again the vehicle associated with 12 cases. Finally, a large listeriosis outbreak occurred in Austria, Germany, and Czech Republic in 2009 and 2010. The outbreak was traced back to a traditional Austrian curd cheese called 'Quargel.' This outbreak accounted for 34 clinical cases and eight deaths.

Fish and Seafood

Ingestion of contaminated smoked fish and other seafoods has resulted in human listeriosis. While the prevalence of *L. monocytogenes* in raw fish is relatively low, ranging from 0% to 10%, significant contamination can arise when these products are handled, processed, or stored in conditions that favor growth of the pathogen. This has resulted in isolated cases of listeriosis and food recalls, associated with vacuum-packed graved and/or cold-smoked rainbow trout (Finland 1999–2000), imitation crab meat (Canada 1996), herring in oil (Germany 2010), and different smoked products like salmon or mussels.

Meat Products

In the United Kingdom, between 1987 and 1989, there were 366 cases of listeriosis associated with pâté; the exact number of deaths attributable to this outbreak is unknown. An outbreak in France in 1992 resulted in 279 cases and 85 deaths, which was associated with pork tongue in jelly. Also in France, in 1993, there were 38 cases and ten deaths associated with rilletts, a meat specialty similar to pâté. Hotdogs were implicated in a multistate outbreak in the United States between 1998 and 1999 involving 108 cases and 14 deaths. Again in France, between 1999 and 2000, rilletts were the vehicle for another outbreak of ten cases and three deaths. During the same period in France, 32 cases and ten deaths were associated again with pork tongue. In 2000, in the United States, contaminated ready-to-eat delicatessen turkey meat resulted in 30 cases and seven deaths. In 2002, a multistate outbreak in the United States, again attributed to ready-to-eat delicatessen turkey meat, resulted in 54 cases and eight deaths.

Food and Food Premise Monitoring

Minimizing cases of human listeriosis depends on improving our understanding of how to limit contamination of food with *L. monocytogenes*, which since the 1980s has become a major public health concern. The potential seriousness of listeriosis means that the presence of *L. monocytogenes* in foods has become intensively regulated by national and international authorities. The bacteria can enter the food chain at nearly every stage of production, and most incidences of food contamination can be traced to contamination of food processing facilities. Longitudinal studies have revealed that different types of facilities have a great diversity of strains in different foods. However, it is seldom clear how these strains come to contaminate premises.

Consequently, biosurveillance, early warning monitoring of foodstuffs, and the food processing environment for the presence of *L. monocytogenes* are of great importance. The monitoring involves numerous steps, which include frequent microbiological sampling strategies and incubation in enrichment broths, such as half and full Fraser broths, for various times, usually 24–48 h, followed by plating on a variety of selective and chromogenic agar media, such as Oxford, Palcam, and ALOA agars. These qualitative and quantitative microbiological methods are included in the standard method ISO 11290.

The accuracy of the quantification is very dependent on the food matrix involved. Some foods such as fat-rich cheeses are less amenable to dissolution in growth media than, for

example, lean meat samples, and plate counts can greatly underestimate actual *Listeria* counts in a food. New techniques to free viable bacteria from the food matrix of a variety of food types are undergoing development, and these are proving to make enumeration more specific and precise. The key word in this respect is sample preparation. The aim is to reduce the volume of the matrix, thereby conserving the target organisms. One such approach is *matrix lysis*, which reduces the 6.25–12.5 g of various foodstuffs to < 100 µl of bacterial pellet. Methods like this have the further advantage that the cells are alive and therefore suitable for both microbiological enrichment and molecular methods such as PCR.

PCR is particularly advantageous as it has the potential to detect nonviable organisms or viable but not culturable (VBNC) forms. However, a caveat is that PCR cannot distinguish between live and dead organisms. On the other hand, legislation dictates that detection is linked to growth of the bacteria as only living bacteria are considered as a risk. This undisputed the premise for official testing. Nevertheless, it is worth thinking about alternative methods. First, the whole microbiological identification process from sampling to confirmation can take several days; PCR is faster; second, VBNC forms are high risk as viability cannot be estimated; and third, one can argue that each *Listeria*, which is found in a food production plant, is an indication for a problem. Moreover, the detection limit of qPCR is as low as one DNA molecule per sample. This advantage together with the information, which is given by microbiological methods, indicates the combined use as preferable. This will generate the most output in terms of available information.

The widespread and resilient nature of *L. monocytogenes* in the food environment is particularly challenging from a public health perspective, and it may not even be realistic to expect its complete eradication from food processing establishments. While food producers are responsible for the safety of their products, to attain this goal, they must establish food safety programs. However, translating from a regulation to industrial practice can pose a huge burden on food business operators, who often run small enterprises lacking risk management capacities. The elements of an in-house monitoring system (sampling points and sample frequency) are not widely harmonized, and the extent of measures executed in many situations is limited by the financial resources available for quality assurance.

Control strategies include prevention of survival/growth of *L. monocytogenes* in niches from where foods can be contaminated, implementation of sampling programs to monitor the effectiveness of control measures, rapid response facility procedures for dealing with contamination, follow-up measures to ensure contamination has been removed, and ongoing short- and long-term monitoring practices to determine contamination trends.

Awareness of *L. monocytogenes*, monitoring practices, consumer education, and legislation have contributed to decreased incidences of listeriosis in most, but not all, industrialized countries. This includes implementation of hazard analysis and critical control point (HACCP) programs in food production and legislation requiring zero tolerance for *L. monocytogenes* in most countries for ready-to-eat foods that could support growth. Control measures now expected from public health agencies include development and maintenance of surveillance programs, rapid follow-up of listeriosis outbreaks, and enforcement of existing legislation. Consumers themselves are particularly advised to cook raw meats thoroughly; wash raw vegetables before eating; separate uncooked meats from vegetables, cooked foods, and ready-to-eat foods; consume only pasteurized dairy produce; and maintain clean hands and kitchen utensils following preparation of uncooked food.

Neglected Routes of Transmission

While studies suggest that the soil environment and farm animal produce remain key sources of contamination, growing awareness that wild and domestic animals, humans, and insects can be silent carriers of *L. monocytogenes* is necessitating a rethink as to how best to protect human health. True reservoirs of infection are elusive. In comparison to farm and rural environments, the urban environment has been poorly studied. However, there are suggestions that this can be influenced by both human silent carriers and transport of soil detritus on footwear by travelers.

Concluding Remarks

Since the relatively recent recognition of the human pathogenic potential of *L. monocytogenes*, it continues to emerge globally as a serious threat to human health. Despite the implementation of food processing hygiene measures, education programs, and legislation, its occasional presence in food at alarming levels remains an ongoing challenge to those tasked with the processing and preparation of foodstuffs. Possible explanations for the emergence of recent epidemics of listeriosis since the 1980s reflect major changes in food production, processing, and distribution, increased reliance on refrigeration, and changes in eating habits to reflect desires for ready-to-eat processed foods and changes in population dynamics reflecting aging populations and chronic diseases associated with immunopathies or the long-term use of certain medications. Improved techniques for continuous biosurveillance for the presence of *L. monocytogenes* in food processing facilities offer a certain reassurance to consumers and food businesses. However, intermittent outbreaks of human listeriosis continue to surprise and evoke legitimate public concern.

The Genus *Listeria*: General Features

Listeria is a gram-positive, rod-shaped, non-spore-forming bacterium that is widely distributed in the environment and is isolated primarily from soil, silage, water, foods, and food processing environments. It appears to maintain itself as saprophyte in decomposing plant materials, considered to be the natural habitat of *Listeria*. All known *Listeria* species grow in the presence of ambient oxygen, and those that have been characterized extensively have been shown to be facultative anaerobes (able to grow in the absence of oxygen) as well as facultative microaerophiles (preferring, but not requiring, reduced oxygen levels). The genus *Listeria* includes 15 species, nine of which have been only recently described (since 2009). Phylogenetic analysis suggests four distinct clades within the genus *Listeria*: clade I (*Listeria sensu stricto*) includes *L. monocytogenes* and five other species (the previously known species *L. innocua*, *L. welshimeri*, *L. seeligeri*, and *L. ivanovii* and the recently identified *L. marthii*); clade II consists of three recently described species (*L. fleischmannii*, *L. aquatica* sp. nov., and *L. floridensis* sp. nov.); clade III consists of five species, all recently identified (*L. rocourtiae*, *L. weihenstephanensis*, *L. cornellensis* sp. nov., *L. grandensis* sp. nov., and *L. riparia* sp. nov.); and clade IV contains the previously known species *L. grayi*. *Listeria* spp. from foods and food-related environments tend to be *L. monocytogenes*, *L. welshimeri*, *L. innocua*, and *L. seeligeri*, while the majority of the novel species recently identified were from other ecosystems (soils, water, and plants). Such trends suggest that additional novel species of *Listeria* will be identified as isolations of the organism from diverse ecosystems are more extensively pursued.

Within the genus *Listeria*, *L. monocytogenes* is the only species that is pathogenic to both humans and other vertebrates, while *L. ivanovii* is pathogenic only to ruminants.

L. Monocytogenes as Foodborne Pathogen

General Attributes of *L. Monocytogenes*

L. monocytogenes was first identified in 1924 by Murray, Webb, and Swann and named as *Bacterium monocytogenes* due to pronounced monocytosis observed in infected rabbits and guinea pigs. In 1929, *L. monocytogenes* was isolated for the first time from humans that had mononucleosis-like disease.

L. monocytogenes is a facultative intracellular pathogen with the ability to grow between 1 and 45 °C. Its ability to grow at low temperature qualifies it as a psychrotolerant and has important food implications. On blood agar, *L. monocytogenes* typically exhibits narrow beta-hemolytic zones, while pronounced hemolytic zones are produced by *L. ivanovii*. With the exception of *L. seeligeri*, nonpathogenic *Listeria* species are typically nonhemolytic (although occasional exceptions involving atypical strains have been reported). *L. monocytogenes* is motile via peritrichous flagella at low temperatures (up to ~28 °C) with motility repressed at 37 °C. Cold enrichment was earlier employed for isolation of *Listeria* from environmental samples. However, food safety interest in *L. monocytogenes* has promoted development of novel selective enrichment approaches and chromogenic media, greatly improving the sensitivity and speed of isolation of the pathogen.

Symptoms and Epidemiology of Listeriosis

L. monocytogenes is responsible for severe, systemic illness (listeriosis) with symptoms such as meningitis and meningoencephalitis with neurological symptoms, septicemia, abortions, and stillbirths. Although relatively uncommon, listeriosis remains a leading cause of death and hospitalizations due to foodborne illness in the United States. At high risk are pregnant women and their fetuses, neonates, the elderly, and immunocompromised patients. Mortality can be high (~21%, even under use of antibiotics). In addition to invasive listeriosis, febrile gastroenteritis without accompanying mortalities can occur in individuals without obvious risk factors. As in humans, in other vertebrates, invasive listeriosis is typically accompanied by neurological symptoms and stillbirths.

Even though 13 serotypes of *L. monocytogenes* are known, >96% of human listeriosis cases involve serotype 1/2a, 1/2b, and 4b. Two major genomic divisions (lineages) are represented among strains implicated in most human listeriosis: lineage I (serotypes 1/2b and 4b) and lineage II (serotype 1/2a). A small number of genetically related strains (epidemic clones) have been repeatedly involved in human listeriosis outbreaks. Animal listeriosis involves not only serotypes 1/2a, 1/2b, and 4b (also observed in human disease) but also strains of serotypes 4a and 4c (lineage III); the latter are uncommon in human listeriosis.

Foodborne Transmission of *L. Monocytogenes*

Although nosocomial infection of neonates and transmission through direct contact with animals has been reported, the primary transmission route of *L. monocytogenes* is foodborne. Processed, cold-stored, ready-to-eat foods are typically implicated in listeriosis with most outbreaks involving deli meats, soft (especially Mexican-style) cheese, and fresh produce. Soft cheese (especially Mexican-style) and fresh produce were the primary food categories associated with *L. monocytogenes* cases in the United States between 2009 and 2011.

Foods are typically contaminated via transfer of the pathogen from contaminated environmental sources and equipment. *L. monocytogenes* is killed following cooking or other thermal treatments. Risks occur with foods that are untreated or minimally treated (e.g., fresh produce), inadequately treated (e.g., soft cheeses made from raw milk), or subject to post-processing contamination and consumed without further

treatment. Risk levels depend on several factors, including temperature and duration of food storage, ability of *Listeria* to grow in or on a specific food (food composition, ingredients, other microbiota, etc.), and the virulence of the contaminating strain(s). In the United States, *L. monocytogenes* is considered an adulterant for ready-to-eat foods (to be consumed without further cooking or reheating), and 'zero tolerance' levels are enforced for such foods. In certain other countries, the presence of *L. monocytogenes* is permitted up to a certain threshold (not to exceed 100 viable cells per gram) in ready-to-eat foods that do not permit growth of the pathogen.

Survival and Growth in Foods

A number of stress tolerance attributes of *L. monocytogenes* provide advantages for its survival in foods. These include salt and acid tolerance and commonly involve regulation by the alternative sigma factor sigma B. Of special food safety relevance is the ability of *L. monocytogenes* to grow at refrigeration temperatures, as foods implicated in listeriosis commonly include cold-stored products (deli meats, soft cheeses, fresh produce, etc.). This has led to extensive research on the cold tolerance and cold shock response mechanisms of *L. monocytogenes*. One of the characterized cold survival mechanisms involves changes in cell membrane fatty acid composition. *L. monocytogenes* adapts to low temperatures by having shortened fatty acid chains and differentiation of the branching of the fatty acids from iso to anteiso, promoting cell membrane fluidity at low temperature. Another mechanism for survival at low temperatures is uptake of compatible solutes, such as glycine betaine and carnitine. *L. monocytogenes* accumulates glycine betaine and carnitine by acquiring these compounds from the growth media during its growth at low temperatures, and low-temperature growth is enhanced in the presence of these compatible solutes. RNA helicases critical for prevention of RNA misfolding at low temperature and for transcription initiation are also critical for the ability of *L. monocytogenes* to grow in the cold. In addition to low temperature, certain RNA helicases also impact responses to heat, alkali, oxidative stress, and ethanol.

Persistence in Food-Related Environments

L. monocytogenes strains of certain serotypes, for example, 1/2a, 1/2b, and 1/2c, tend to be more commonly isolated from food processing environments. Molecular subtyping has repeatedly revealed strains that persist in the same processing plant over many years, sometimes decades. It has been proposed that, depending on their access to specific harborage sites in the processing plants, all *L. monocytogenes* strains are capable of persistence. However, strains differ in a number of attributes that may impact their ability to persist in the environment, including biofilm forming potential, resistance to disinfectants, cold tolerance, and resistance to *Listeria*-specific viruses. For instance, strains of a major epidemic clone implicated in several outbreaks in the United States and elsewhere were resistant to all tested *Listeria*-specific viruses when grown at temperatures below 30 °C. The molecular ecology of *L. monocytogenes* in the food processing ecosystem remains poorly understood.

Prevention and Control of Food Contamination by *L. Monocytogenes*

To prevent contamination of foods by *L. monocytogenes* at the processing plants, effective cleaning and sanitation procedures must be employed. Food contact surfaces should be regularly tested for *L. monocytogenes*, and identification of positive samples should be followed by enhanced cleaning and sanitation. *Listeria* spp.-positive samples may suggest the simultaneous presence of *L. monocytogenes*.

Several food-level interventions can also inactivate *Listeria* and reduce or prevent contamination. Adequate heating of the food product will inactivate *Listeria* that may be present, and numerous other postprocessing treatments (high pressure, irradiation, etc.) have shown potential to reduce levels of viable *Listeria* in the food. Pasteurization of raw milk will inactivate *Listeria*, suggesting the need to pasteurize milk for soft cheese production. Refrigeration will reduce the rate of growth and freezing will prevent growth though *Listeria* may remain viable and grow further after thawing. Certain combinations of acid and salt will prevent growth, suggesting the need for modified formulations in manufacture of ready-to-eat meat products. Substantial research is investigating uses of GRAS antimicrobials such as nisin and essential oils against *Listeria*, alone or in combination with other ingredients and hurdles. Biological controls include *Listeria*-specific viruses (phages), which have been approved for use in ready-to-eat foods and other microbes with competitive exclusion potential against *Listeria*.

Virulence and Pathogenicity

Several key virulence factors including listeriolysin O (LLO), phospholipases, and ActA (mediating intracellular motility and actin polymerization) are clustered in one pathogenicity island (*Listeria* pathogenicity island 1 (LIPI-1)) on the chromosome of *L. monocytogenes*. These virulence genes are regulated by the regulatory protein, PrfA, encoded by a gene also harbored on LIPI-1. The genes are thermoregulated, being expressed at 37 °C but not below 30 °C. LLO is a cholesterol-dependent cytolysin and a pore-forming toxin. LLO binds to the cholesterol of the host cell membrane and causes the formation of pore. Several signals (such as pH and temperature) are important for the activity of LLO, restricting it to avoid lysis of the host cells. This is essential for the intracellular life cycle of *L. monocytogenes*, as damage to the host cell would cause cell death and *L. monocytogenes* would be exposed to the components of host immune system. LLO plays a crucial role in virulence of *L. monocytogenes* as it enables escape of the organism from phagosomal compartment of the host organism to its cytoplasm, where it multiplies (Figure 1). In contrast, LLO-deficient mutants are known to be nonhemolytic and avirulent in murine models. Additionally, two membrane-active phospholipase C enzymes (PI-PLC and PC-PLC) encoded by LIPI-1 genes are involved in escape of *L. monocytogenes* from the phagosome of the host cell to the host cytosol. The actin polymerization protein, ActA, of *L. monocytogenes* is another essential virulence factor as it facilitates intracellular motility of the organism upon escape from the phagosome and

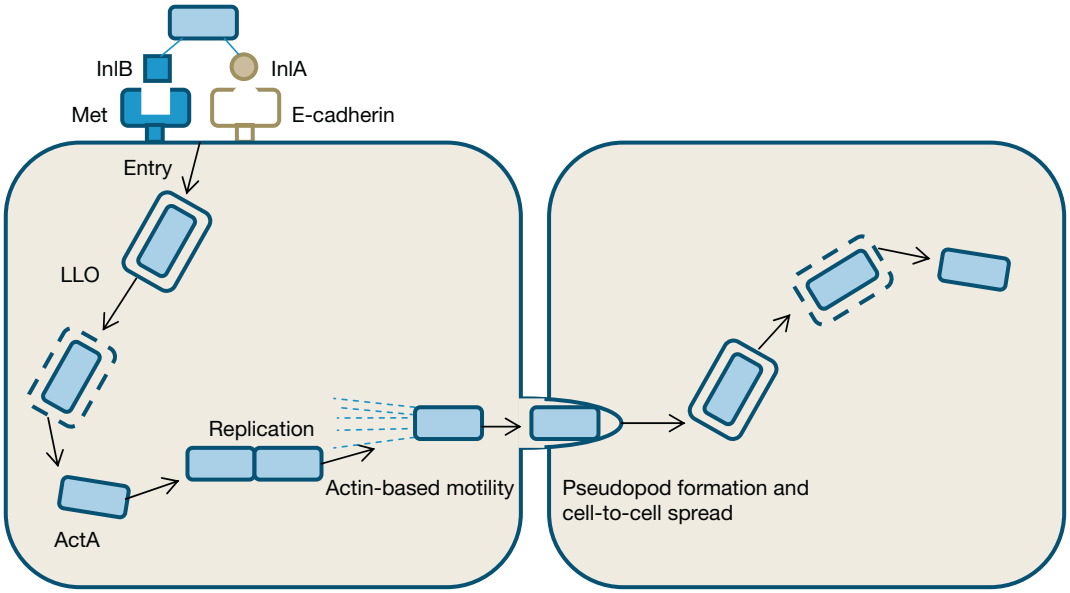

Figure 1 Invasion and cell-to-cell spread of *L. monocytogenes*. Reproduced from Tilney, L. G. and Portnoy, D. A. (1989). Actin filaments and the growth, movement, and spread of the intracellular bacterial parasite, *Listeria monocytogenes*. *Journal of Cell Biology* **109**, 1597–1608; Travier, L. and Lecuit, M. (2014). *Listeria monocytogenes* ActA: a new function for a 'classic' virulence factor. *Current Opinion in Microbiology* **17C**, 53–60.

cell-to-cell spread via membrane protrusions (pseudopods) that become engulfed by neighboring host cells, forming double-membrane *Listeria* phagosomes harboring the bacteria (Figure 1). Direct cell-to-cell spread is essential for survival of *L. monocytogenes* in the host as it minimizes recognition of the organism by the immune response components of the host. ActA allows intracellular motility of *L. monocytogenes* even without involvement of other bacterial factors such as flagella. ActA has recently been shown to have intriguing roles in aggregation of *Listeria* in the intestinal lumen and biofilm formation.

Numerous additional factors of *L. monocytogenes* with possible roles in virulence have been identified, encoded by genes outside of LIPI-1 but in certain cases also under PrfA control. Extensively characterized are invasion-associated proteins such as members of the internalin (Inl) family, especially InlA and InlB (Figure 1). InlA is anchored into the cell wall and is essential for invasion of intestinal epithelial cells. It is recognized by E-cadherin in cells from certain hosts (e.g., humans, guinea pigs, and gerbils), while E-cadherin from mouse cells fails to bind InlA due to a single amino acid substitution (glutamic acid instead of proline). Interestingly, a large fraction (~50%) of food and environmental strains of serotypes 1/2a, 1/2b, and 1/2c harbor premature stop codons in InlA, resulting in truncated InlA that fails to become anchored into the cell wall and in virulence attenuation in animal models; such truncated InlA is rare among clinical isolates.

Animal and Cell Culture Models Used for *L. Monocytogenes* Virulence Determination

Numerous cell culture models have been employed for analysis of *Listeria* invasion and cell-to-cell spread. As *L. monocytogenes* has the capability to pass the gastrointestinal barrier and reach the placenta and the central nervous system, it is especially important to characterize its virulence and persistence in animal models. Therefore, a variety of model systems have been used to study virulence of *L. monocytogenes*, including mice, guinea pigs, chick embryos, and zebrafish.

Murine models

Murine models have been most commonly employed for the characterization of virulence mechanisms of *L. monocytogenes*. Intravenous inoculations have been extensively used to compare virulence based on multiplication of *L. monocytogenes* in the liver and spleen. However, *L. monocytogenes* infections are typically foodborne and there is need for oral and intragastric infection models. Persistence and spread (gallbladder and brain of the host) of *L. monocytogenes* following oral infection via feeding of inoculated food samples in murine models have been reported. However, oral infections in murine models require high numbers of *L. monocytogenes* as inoculum and are poorly reproducible in terms of lethality to the host or breach of the gastrointestinal barrier. Murine models are effective for the characterization of T-cell response to intravenous infection of *L. monocytogenes* but cannot be readily used for the assessment of the role of internalin (InlA) as the murine E-cadherin (receptor for InlA) is unable to bind InlA due to a single amino acid substitution (proline in the E-cadherin of species that recognize InlA, e.g., humans and guinea pigs, vs. glutamic acid in the mouse). Mouse strains expressing either the human E-cadherin or a modified murine E-cadherin that recognizes InlA have been developed and extensively employed.

Guinea pig and gerbil models

In contrast to mice or rats, guinea pigs carry a functional E-cadherin receptor for InlA. This characteristic of guinea pigs makes them favorable to use as a model system for *in vivo* characterization of virulence of *L. monocytogenes*. Thus,

L. monocytogenes can be isolated from maternal and fetal tissues of pregnant guinea pigs that were inoculated by *L. monocytogenes* through the oral route as early as 2 days following inoculation. Yet, strain-specific differences in virulence of *L. monocytogenes* may be found using the intragastric guinea pig infection model system. Also, guinea pigs (as mice and rabbits) lack the receptor for another major invasion-associated determinant, InlB. Of the different rodent species tested, gerbils, which are also a natural host for *L. monocytogenes*, were the only species with receptors for both InlA and InlB and are being extensively employed as model systems.

Other animal models

The chick embryo model has been used for virulence assessments of different *L. monocytogenes* strains, with virulence corresponding to embryo mortality. Zebrafish larvae have been employed for real-time observations of interactions between macrophages and *L. monocytogenes*, administered into the larvae intravenously. *Galleria mellonella*, an insect model system, has been employed with *L. monocytogenes*. It is especially attractive as inoculated *Galleria mellonella* can survive at 37 °C, a temperature that permits expression of key virulence genes of *L. monocytogenes*. This model is also attractive due to low costs, ease of use, and the absence of animal care restrictions associated with vertebrate animals in research.

Conclusions

In this article, an overview of occurrence and key features of *Listeria* is presented. Numerous adaptive features of *Listeria*, including its ability to grow at low temperatures, to tolerate several other types of environmental stress, and to persist in biofilms, mediate its persistence in food processing environments and its capacity to contaminate foods. At the same time, *L. monocytogenes* has evolved numerous sophisticated adaptations mediating its ability to function as a facultative intracellular pathogen. Upon consumption of contaminated foods without further processing, *L. monocytogenes* can cause listeriosis, a serious, foodborne disease with symptoms such as stillbirths, septicemia, and meningitis and with high fatality rate. Complete genome sequencing and advances in other omics tools have markedly enhanced our understanding of *Listeria*'s environmental adaptations, virulence, and epidemiology.

Low-fat Foods: Types and Manufacture

MG O'Sullivan, School of Food and Nutritional Sciences, University College Cork, Cork, Ireland

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Organizations like the World Health Organization (WHO) are driving measures to reduce saturated fat content in foods by raising the consumers' awareness and setting guidelines around ingredient usage for companies. The prevalence of excess levels of adipose tissue buildup in the human body is widely recognized as a leading world health problem and is referred to as an obesity epidemic. The WHO found in 2008 that more than 1.4 billion adults, aged 20 and older, were overweight. Out of these overweight adults, 200 million men and nearly 300 million women were classified as obese. The WHO also found that more than 40 million children under the age of 5 were overweight in 2010.

Fat Replacers

Fat levels are very much on the agenda for the consumer when purchasing food, and food processors have endeavored to tackle the issue by the production of fat-reduced foods. However, fat also has some important sensory properties and contributes greatly to texture, mouthfeel, and satiety and assists in the sensation of lubricity in foods and overall flavor. It is thus very challenging for food processors to compensate for these qualities in fat-reduced food variants.

There are several ways in which reduced-fat foods may be produced. The first and simplest method is the partial reduction of fat through the use of technologies or alternative ingredients. This might include using baking instead of frying in the production of snack foods or the use of skimmed milk in yogurt production or leaner meat in a sausage formulation. The second method involves the replacement of fat with carbohydrate-, protein-, or lipid-based fat replacers that can be classified into either fat substitutes, fat mimetics, or bulking agents. Bulking agents are ingredients that increase the bulk of a food with minimal effects on sensory properties. Many of the carbohydrate fat mimetics are also bulking agents and include starch and cellulose-based components, as well as the polysaccharide mimetic polydextrose.

Fat Substitutes

Fat substitutes are materials that simulate the chemical and physical properties of fats and oils and can directly replace fat on a weight to weight basis. These materials can be produced by enzyme-modified oils and fats and can also be synthesized chemically. Fat substitutes quite often take on board the processing characteristics of conventional fats and can be used in baking and frying. Examples of common fat substitutes include fat-based sucrose polyesters such as olestra (Olean™), esterified propoxylated glycerol, fatty acid esters of sorbitol, and sorbitol anhydrides (Sorbestrin) (Table 1). One of the principal drawbacks of using olestra is that product labels must contain the warning 'This product contains olestra.' Olestra may cause abdominal cramping and loose stools. Olestra inhibits the absorption of some vitamins and other nutrients.

Fat Mimetics

Fat mimetics are compounds that simulate the sensory properties of fat and are often protein- or carbohydrate-based. Generally, they have a much lower calorific value compared to conventional fats and oils as they can bind relatively large volumes of water. For this reason, they can limit the processing characteristics of the reduced-fat foods they are incorporated into and, generally, cannot be used in products that are fried and carry water-soluble flavors. This issue can be partly resolved by the incorporation of emulsifying agents and more nonpolar or lipophilic flavoring compounds. Examples of common fat mimetics with generally recognized as safe status include carbohydrate-based compounds such as cellulose (Avicel™), starches (modified and dextrin), hydrocolloid gums (Slendid™), pectins, β-glucan, and inulin- or protein-based materials such as Simplesse® or Dairy-Lo® (Table 1). Simplesse® is a spray-dried, microparticulate protein powder used as a texturizer in many different foods such as dairy products (cheese, yogurt, and frozen desserts), margarine, salad dressings, sauces, and soups. Dairy-Lo® is a modified whey protein concentrate that can form a set matrix gel with heat and can hold the gel structure during shelf life and is quite often used as a fat replacer in cheese-based products.

Fluid gels offer a wide range of applications in reduced-fat food formulations. Gel-forming polysaccharides such as k-carrageenan, which form gels in the presence of water, can be used as fat replacers for emulsion-based, semisolid foods such as mayonnaise, margarine, custards, gravies, and pourable dressings. Hydrocolloids can form molecular gels through association of parts of the molecules forming 'junction zones.' Gel properties assist in the flavor release from gelled foods. Other common hydrocolloid food gelling agents include gelatin, starch, pectin, carrageenan, alginate, agar, celluloses, gellan gum, konjac, milk proteins, and soy proteins. Blends of the hydrocolloid κ-carrageenan and starch have also been widely adopted in the food industry as a texture enhancer for dairy products.

Meat Products

Researchers have been working on strategies to reduce animal fat usage in meat, and thus, this area has received considerable recent research focus on products such as frankfurters, breakfast sausage, beef patties, pork patties, bologna, and black and

Salatrim Acyl triglyceride molecule Energy density: 5 kcal g^{-1} *Functional properties*: emulsify, stabilize, texturize, lubricate, flavor carrier *Application*: cheese, dips, sauces, dairy desserts, confectionary	*Simplesse* Whey protein or white egg protein Energy density: 4 kcal g^{-1} *Functional properties*: stabilize, texturize *Application*: cheese, yogurt, dips, mayo, dairy spreads, desserts	*Starches*: corn, potato, tapioca, rice, maize, waxy maize Energy density: 4 kcal g^{-1} *Functional properties*: texturizer, water holding, thickening, gelling *Application*: processed meats, margarines, sauces, dressings, baked foods	*Methylcellulose* Energy density: 0 kcal g^{-1} *Functional properties*: texturizer *Application*: frozen desserts, powdered soups/sauces	*Guar*, *locust bean*, *xanthan* Energy density: 0 kcal g^{-1} *Functional properties*: retard staling in baked goods, retain moisture *Application*: bakery goods	*Maltodextrin* Hydrolyzed starch Energy density: 4 kcal g^{-1} *Functional properties*: water binding, imparts mouthfeel, body, viscosity *Application*: processed meats, dairy spreads, salad dressings, baked foods, frozen desserts
Caprenin Caprocaprylobehenic triglyceride molecule Energy density: 5 kcal g^{-1} *Functional properties*: emulsify, stabilize, texturize, lubricate, flavor carrier *Application*: candy, confectionary	*Trailblazer* White egg protein and xanthan gum Energy density: 4 kcal g^{-1} *Functional properties*: stabilize, texturize *Application*: dairy, soups, sauces, baked foods		*Microcrystalline cellulose* Energy density: 0 kcal g^{-1} *Functional properties*: stabilizer, texturizer, imparts mouthfeel *Application*: dairy, salad dressing, sauces desserts	*Carrageenan* Energy density: 0 kcal g^{-1} *Functional properties*: texturizer, imparts mouthfeel, viscosity *Application*: processed meats, yogurts, salad dressings, desserts, ice cream, chocolate	*Polydextrose* Energy density: 1 kcal g^{-1} *Functional properties*: texturizer, bulking agent *Application*: confectionary, spreads, salad dressings, baked foods, frozen desserts, sauces, toppings
Olestra (*Olean*) Sucrose polyester Energy density: 0 kcal g^{-1} *Functional properties*: texturize, lubricate, flavor carrier *Application*: reduced-fat snacks, potato chips				*Pectin* Energy density: 0 kcal g^{-1} *Functional properties*: texturizer, imparts mouthfeel, viscosity *Application*: sauces	*β-Glucan* Energy density: 1 kcal g^{-1} *Functional properties*: texturizer *Application*: baked foods
				Gum arabic Energy density: 0 kcal g^{-1} *Functional properties*: texturizer, imparts mouthfeel, viscosity *Application*: dressings	

white puddings. Overconsumption of meat and meat products has been linked with obesity, cancer, and cardiovascular diseases primarily due to the high amounts of sodium chloride and saturated fat present in processed products. However, fats and oils play vital functional and sensory roles in various food products and are important in processed meat for flavor development and satiety, having a large impact on eating quality as they interact with other ingredients and assist in developing texture and mouthfeel and provide a lubricating effect.

For meat, there are several methods to produce fat-reduced products such as using leaner meat, less fat and salt, and more

water, replacing parts of animal fat with plant oil, and the application of fat replacers.

One of the first methods of fat reduction in processed meat systems is the reduction of fat in formulations without replacement. This involves the sequential reduction of salt and fat in processed meats and has been demonstrated for a number of such products including beef patties, frankfurters, breakfast sausages, and black and white puddings. Sensory methods are used to identify the optimal formulations with different meat systems varying in their respective optimization criteria. Both salt reduction and fat reduction have been shown not to negatively impact on consumer acceptability in patties and sausages, while only fat reduction could be achieved in frankfurters without negative assessor feedback.

By replacing animal fat in processed meats with vegetable oils, the fatty acid profile can be nutritionally optimized as well as producing a lower-fat- and/or cholesterol-containing products. Unsaturated oils such as vegetable or fish oils have been used as a partial substitute to animal fat. Palm oil, palm stearin, cottonseed oil, hazelnut oil, and mixes of these oils have been used to increase the ratio of unsaturated to saturated fatty acids and maintain product quality in processed meats. Similarly, olive oil, linseed oil, fish oil, and konjac oil have also been used to produce products scored as acceptable in consumer trials.

As explained earlier in this article, fat replacers are categorized into fat substitutes and fat mimetics. Fat substitutes display a chemical structure close to fats, have similar physicochemical properties, and are either low in calorie or indigestible such as olestra, caprenin, and salatrim. By contrast, fat mimetics show distinctly different chemical structures from fat, are usually protein- and/or carbohydrate-based, and can be used to simulate some of the physicochemical attributes and eating qualities of fat such as mouthfeel, appearance, and viscosity. The use of fat replacers can drastically change the sensory profile of a meat product as over half the volatile compounds found in meat originate from the lipid fraction. The use of fat mimetics is, in general, more common, for example, a fat reduction of 46% can be achieved in salami, 60–83% in frankfurters, and 55% in beef patties using tapioca starch, oat fiber, maltodextrin, or milk protein.

Numerous studies have highlighted the benefits to human diets of high plant fiber intake on overall and digestive health through regular bowel movement. These include reduced risk of cancers, coronary heart disease, obesity, and diabetes. Essentially, fiber is a complex carbohydrate that can be incorporated into processed meat formulations as partial fat replacers and positively affect physicochemical properties of the resulting product by potentially improving water binding, texture, cooking loss, and texture quality of processed meats such as sausages, puddings, bologna, and meatballs. Hydrocolloids including polysaccharides and proteins can also be used as fat replacers in processed meat products to increase water binding and texture properties. Hydrocolloids, which thicken, gel, bind, and stabilize pH and emulsions are generally animal-based proteins such as gelatin, blood proteins, casein, or whey. Several researchers have reported the effectiveness of fat reduction using whey protein, soy protein, and surimi. As with oil incorporation, textural differences were detected in the finished product, but these changes did not have a negative impact on overall sensory acceptability.

Stabilizers, emulsifiers, or thickeners are added to meat to help maintain a uniform texture and a diverse range of polysaccharides are available on the market. These include celluloses (carboxymethyl cellulose), gums (guar, alginate, pectin, and locust bean), fibers (β-glucan), starches (corn, wheat, maize, potato, and tapioca, pea), and chitosan and xanthan derived from microorganisms. Starch can be added with either κ-carrageenan or locust bean gum to produce similar results in terms of texture as full-fat products. Cold-set binders are important to the meat industry as they can optimize the textural properties of a meat system, without the application of heat, thus keeping the meat product in its natural raw uncooked state. They also have applications in the replacement of salt and fat and the production of healthier processed meats. Examples of cold-set binders include nonthermal gelatin, alginate, and fibrin. Commercially available cold-set binding systems include Fibrimex™, alginate, and Activa™.

Dairy Products

Fat has an important sensory role in dairy products, contributing to both flavor and texture, and thus, technological difficulties can be encountered when levels are reduced. Cheeses like cheddar and mozzarella become firmer and more rubbery on removal of fat because of increasing protein content. Flavor is particularly affected as the fat/protein matrix changes and affects flavor perception deleteriously. Several studies have investigated the sensory optimization of reduced-fat cheese through the use of curd washing and incorporating adjunct cultures in cheddar cheese. The adjunct *Lactobacillus helveticus* in combination with *Leuconostoc cremoris*, *Lactococcus lactis* var. *diacetylactis*, and *Streptococcus thermophilus* can be used to produce 50% fat-reduced cheddar cheese with a higher preference score than for a similarly produced cheese manufactured without the use of the adjunct culture. However, the flavor profile of the end product is different from regular cheddar primarily because of the presence of burnt off-flavor notes. Fat mimetics have also been investigated in mozzarella cheese using two protein-based fat replacers (Simplesse® D100 and Dairy-Lo®) and two carbohydrate-based fat replacers (Stellar™ 100X and Novagel™ RCN-15).

Flavor optimization of reduced-fat cheddar cheese can also be achieved by removing the fat from normal-aged cheddar once the flavor had fully developed. According to sensory studies, this approach managed to retain the same flavor intensity as regular cheese, although the texture was quite different. It is also reported that reduced-fat emmental cheese made using a preprocessing routine involving homogenization of milk improved the sensory aspects and market position of these reduced-fat cheeses compared with full-fat emmental cheese made with the same process.

The protein-based fat replacers Dairy-Lo® and Simplesse® D-100 and the carbohydrate-based fat replacers Perfectamylgel MB and Satiagel ME4 have been investigated to determine the effects on the chemical, physical, and sensory attributes of low-fat, white-pickled cheese. These low-fat cheeses, produced by adding Dairy-Lo®, Perfectamylgel MB, and Satiagel ME4, were highly acceptable compared to the low-fat cheese manufactured without fat replacers. Also, differences between cheeses

made with Simplesse® D-100 and full-fat cheese or low-fat cheese manufactured without fat replacer, as found by the taste panel, were not detectable.

Fat is integral to the formation of the microstructure of ice cream, particularly aeration, as it stabilizes the air phase and freezing and is important as a carrier of lipophilic flavors and in their release during consumption. It is thus a difficult challenge for food processors to reduce the fat content of ice cream and maintain these fundamental qualities. Fat also increases the creamy flavor notes and mouth coating, in full-fat ice creams compared with low-fat ice cream. Generally, low-fat ice creams have lower flavor and texture ratings when measured by sensory analysis and can display textural defects like coarseness, iciness, crumbliness, shrinkage on storage, and reduced flavor release. Nonetheless, ice cream manufacturers have attempted to simulate the texture and flavor of fat-containing ice cream by adding bulking agents and concentrated milk components to fat-free formulations. Carbohydrate bulking agents, such as maltodextrin and polydextrose, are currently used in low-fat formulations because they produce minimal negative effects on ice cream production, shelf life, and price.

Inulin can also be used as a fat replacer in ice cream as it increases the viscosity and decreases the freezing point and produces a product with acceptable sensory properties. The protein-based fat replacers, Dairy-Lo® and Simplesse®, have been used to make both low-fat and nonfat ice creams. Simplesse® has been observed to be more similar to milk fat than Dairy-Lo® with respect to textural stability but was less similar in terms of thickness and mouth coating.

Confectionary Products

Fat and sugar cannot be easily replaced, especially in a complex food system such as biscuits. The fat mimetics, Oatrim and Z-Trim (both derived from oats), have been used in cookies and produced acceptable sensory characteristics at 50% fat replacement. The fat substitutes derived from pectin, gums, and oat bran (Slendid, Kel-Lire BK, and Trimchoice-5) have also been used to replace the fat in biscuit manufacture with the result that tenderness decreased as substitute use increased when biscuits were rated by the sensory panel. In a consumer location test, assessors rated the biscuits as moderately acceptable. Inulin (Raftiline, Orafti Active Food Ingredients, Oreye, France), Simplesse®, C*deLight (Cerestar, Brussels, Belgium), and polydextrose (Litesse (Pfizer, Inc., New York, NY, USA)) have been used for partial fat replacement and lactitol, sorbitol, and maltitol, for sugar replacement in low-fat, sugar-free cookies. Cookies prepared with Simplesse® had the least acceptable flavor, while cookies prepared with C*deLight were rated as the most acceptable by a sensory panel. Simplesse® has been used as an oil replacer in high-fiber muffins, which produced products with better stability toward batter refrigeration than full-fat muffins. These reduced-fat muffins were different from the freshly baked, full-fat control muffins, but they were still of comparable sensory quality. It has also been observed that Simplesse® does not affect full-fat taste when it replaced fat up to 93% in cakes, muffins, and brownies. Polydextrose (Litesse), acid-treated cornstarch (Stellar, A.E Staley, Decatur, IL), Slendid™, mono- and diglycerides, Simplesse®, and potato maltodextrin have been observed to replace 50% fat or over in chocolate chip cookies, but products had different flavor characteristics compared to full-fat control products.

Consumer studies have revealed that fat replacement with up to 15 g/100 g of inulin or hydroxypropyl methylcellulose provided acceptable biscuits, but higher replacement decreased overall acceptability. The replacement of up to 25% of shortening in crisp oatmeal cookies can be also achieved using polydextrose (Litesse) while maintaining physicochemical and sensory properties.

Salad Dressing and Sauces

Xanthan gum, as it forms weak gels, is often used in salad dressings. Polysaccharides (carrageenan, xanthan, pectins, etc.) are also incorporated into commercial salad dressing products, particularly those of low oil content as they stabilize the oil droplets and prevent creaming. Fat mimetics such as Simplesse® can be used as fat replacers and texturizers in margarines, salad dressings, sauces, and soups. Trailblazer can also be used as a texturizer in sauces and soups. Cooked starch may be incorporated into these products since starch gelatinization results in the release of polysaccharides, which act as emulsion stabilizers and thickeners. Corn, waxy maize, wheat, potato, tapioca, rice, and waxy rice starches can be used as fat mimetics in dressings, sauces, margarines, and spreads. Microcrystalline cellulose is used in reduced-fat salad dressings and maltodextrin has found applications in low-fat margarines, salad dressings, and sauces.

Introduction

There is a worldwide concern for the high dietary sodium intake, which, in most cases, considerably exceeds nutritional recommendations. High sodium intakes may have relevant consequences for consumers' health.

The main concerns as regards NaCl consumption is that high levels of sodium intake may be crucial for the development of hypertension and the age-related rise of blood pressure typically observed in modern society. It has been observed that NaCl is an important factor in the blood pressure regulation, which is usually associated to a type of lifestyle including also overweight and physical inactivity. There is also an increase in the risk of cardiovascular diseases (CVD) such as strokes, heart attacks, and heart failure. Elevated blood pressure has a high incidence in population of Western societies. For instance, it affects approximately one in three US adults, but another 78 million adults suffer from slightly elevated blood pressure, which can in turn lead to high blood pressure.

Apart from the adverse influence of high salt consumption on blood pressure, there are other evidences of diseases that can be negatively affected by salt. Such is the case of renal disease, hepatic affections, water retention, stomach cancer, and osteoporosis. An increasing evidence of the relationship between salt intake and obesity has also been reported.

All those negative effects of salt on health leads to the fact that salt reduction is very cost-effective apart from the evident health advantages.

The main source of sodium in the diet is in the form of sodium chloride, typically referred to as table salt, and its daily intake in Western societies is estimated to be within the range of 8–12 g day^{-1}, which is considered very high and, consequently, needs to be substantially reduced.

On a popular basis, it has been established that the consumption of more than 6 g NaCl/day/person is associated with an increase in blood pressure with age. Therefore, limitation of dietary sodium intake should be achieved by restricting daily salt (sodium chloride) intake to <5 g day^{-1}. Such recommendations are addressed to the general public. It is, however, generally recognized that those individuals, who are genetically salt-susceptible or suffering from hypertension, will particularly benefit from low-sodium diets. In such cases, the salt content should range between 1 and 3 g day^{-1}.

It has been observed that a reduction in the NaCl intake of 3 g day^{-1} results in blood pressure reduction of between 3.6–5.6 and 1.9–3.2 mmHg (systolic/diastolic) in persons with hypertension. Taking into account those values, it has been estimated that a reduction of 13% in cerebrovascular accident and 10% in CVDs could be achieved in the overall population with a NaCl reduction of 3 g day^{-1}. Further reductions could be achieved by further decreasing the NaCl intake.

Health authorities in most industrialized countries are trying to progressively reduce the salt content in foods by either instructing industry to add less salt to foods during processing or recommending consumers to add less salt during cooking.

This task is not easy to achieve due to the technological relevance of salt during processing and its effects in the final product quality, especially with respect to flavor enhancement. In fact, the effects of NaCl are so pronounced that its contribution to flavor, lower water activity, higher microbial stability, activation/inhibition of enzyme activity, increased water-holding capacity, protein solubility, and texture are difficult to substitute or replace. There are different approaches used in the reduction of salt in foods, and these are summarized in this manuscript.

Manufacture Strategies for Low-Salt Foods

Health institutions and agencies have assisted the food industry in selecting target foods where salt reduction is more of a priority on account of the reduction needed to achieve the desired salt intake reduction. Most dietary sodium comes from processed foods, prepackaged foods, and restaurant foods. Some of these targeted foods include meat products like bacon, ham, sausages, and meat pies; dairy products like cheese and butter; different types of breads, biscuits, crisps and snacks; sauces and dressings; and canned foods. The contribution of added salt during home cooking is quite low, and the natural occurrence of salt in foods is around 12%. It is also important to understand the mechanisms for taste perception and physiological controls, especially how the salt in the product interacts with and is perceived by the tongue. For instance, the use of salts with different sizes or shapes may maximize saltiness perception while using less salt. So, the strategies followed for salt reduction in foods are as follows:

Sodium Reduction

The easiest way to reduce the salt content in food products is simply through the reduction of added salt during processing. This means that ingredient formulations are modified to contain less salt. If brine is used in the manufacturing process, either the amount of salt in the injected brine or the duration of brining may be reduced. If salt is incorporated by rubbing on the outer surface of the food, as in the case of some muscle foods like dry-cured ham, the reduction may be achieved by reducing the salting time as less salt penetrates into the product. However, one limitation to using this approach, in addition to the shelf-life of the food, is that you must have a clear understanding of what the consumer will and will not accept in terms of salt reduction for each specific product. Therefore, attempting to provide a single salt concentration reduction strategy will not work in reality.

The main concern in reducing salt in processed food products is related to the preservation action of salt and consequently to food safety. When salt is reduced, the water activity of food increases if the moisture content is maintained

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00431-1

at original levels in the product formulation, and thus, an increase in the rate of spoilage reactions occurs. Consequently, alternative preserving techniques may be necessary to ensure the safety of food, such as the following:

- Use of other solutes that can contribute to reduce the water activity of food, such as polyols or sugars
- Use of nonthermal preserving techniques, such as high pressure or electric pulses
- Addition of preservatives that enables the control of microbial growth
- Use of hurdle technology (combination of packaging, low or high temperatures, modifying acidity, and redox potential, among other factors)

As highlighted previously, the influence of salt reduction on the sensory perception of food is also an issue of major concern, and the final product could achieve sensory properties that preclude it from consumption by consumers. Sometimes, it is possible to add products that can hinder the taste and flavor changes as a consequence of salt reduction, such as the addition of natural acids, spices, flavorings, and yeast hydrolysates. Some products that have been used in this manner are pepper, onion, garlic, tomato, sweet pepper, basil, parsley, thyme, celery, lime, chili, nettle, rosemary, smoke flavoring, curry, coriander, and lemon.

There are other aspects that are influenced due to the reduction of sodium content, such as enzyme activity, water-holding capacity, protein solubility, and texture that can be influenced to such an extent that it becomes impossible to further reduce salt in products.

For example, salt reduction in dry-cured ham results in an increased enzymatic activity, mainly through the presence of endopeptidases, which can result in an excessive breakdown of myofibrillar proteins, thereby leading to an excessive softness.

Sodium Replacement

When direct NaCl reduction is not a feasible alternative due to technological or sensory constraints, sodium replacement can constitute a valid alternative. So, NaCl can be partially or totally replaced by other edible salts that do not contain sodium. The most commonly used salts in this strategy are potassium chloride and potassium lactate. Other salt forms that have been examined for suitability of use are magnesium chloride, calcium chloride, potassium citrate, and potassium acetate, among others. Those salts can be used alone or in combination.

The use of salts targeted at replacing sodium in food has some factors that must be taken into account. The first factor that must be considered is the different solubility of each salt, which makes the control of the salting process difficult; the formed brine on food surface, when using dry salting, can have a different concentration than the used salt mixture. Additionally, the pH of the brine can change dramatically depending on the salt mixture, which can in turn affect the water-holding capacity and other quality and safety aspects of the product. In the same sense, it has to be considered that the salt diffusion inside the food product depends on each ion type present. Some studies have demonstrated that the diffusion rate is higher in monovalent ions than with divalent ions. This implies that the salt composition inside the salted food can differ to a great extent from the salt composition present in dry salt or brine.

Another effect related with sodium replacement is the capability of each salt type used to reduce water activity, which, as pointed out previously, can affect the safety status of the salted product. This is another major issue of public health concern that has to be considered.

Apart from those effects, the use of other salt mixtures can influence food texture and color, flavor, enzyme activity, or antimicrobial activity. This implies that the processing conditions must be adapted to the new salt formulation and/or other compounds must be added to the food in order to compensate for the new effects generated by the use of these salts. One of the most undesirable effects related with the use of non-sodium-containing salts are the off-flavors associated with their use, and these have been described as unpleasant in taste, with bitter or metallic aftertaste, especially when potassium, magnesium or calcium chlorides are used. Therefore, masking agents can be used to reduce these unpleasant tastes, such as pepper, onion, garlic, tomato, sweet pepper, basil, parsley, thyme, celery, lime, chili, nettle, rosemary, smoke flavoring, curry, coriander, and lemon.

National Plans for Salt Reduction in Foods

The National Salt Reduction Initiative (NSRI) was launched by New York City, and its main aim was to encourage food manufacturers and chain restaurants to voluntarily achieve effective sodium reductions in the United States. It was planned to reduce 25% sodium in the food supply by 2018 and reduce population sodium intake by 20% within the same time period.

In most countries, national health authorities are recommending that the food industry in the respective jurisdictions reduce the amount of salt formulated during food processing. To date, Finland has achieved a 30% reduction in salt intake, while in the United Kingdom, the Consensus Action on Salt and Health (CASH) and the UK Department of Health reached an agreement to achieve 20–30% reduction in the salt content of processed foods that can be bought in supermarkets. Similar actions are being taken in other European countries.

Current Regulations on Labeling of Foods with Reduced/Low Salt Content

There are regulations about the terminology that can be applied to packaging labels when claiming salt reduction or low salt content in foods. In the European Union, Regulation EC 1924/2006 on nutrition and health claims on foods described the terms that may be used in claims for foods with low salt content. So, this regulation distinguishes the following types of claims depending on the degree of sodium content: low in sodium/salt for <0.12 g of sodium, or the equivalent value for salt, per 100 g or per 100 ml; very low in sodium/salt for <0.04 g of sodium, or the equivalent value for salt, per 100 g or per 100 ml; sodium/salt-free for <0.005 g of sodium, or the equivalent value for salt, per 100 g; and reduced

sodium/salt for at least 25% less sodium, or the equivalent value for salt, than in the original food product.

In the United States, the Nutrition Facts Label lists the percent daily value (%DV) of sodium in one serving of a food, which is based on 100% of the recommended amount of sodium, which is < 2400 mg day^{-1}.

The FDA *Food Labeling Guide* stipulates the terms in respect of sodium that can be labeled in the package: salt/sodium-free for < 5 mg of sodium per serving, very low sodium for 35 mg of sodium or less per serving, low sodium for 140 mg of sodium or less per serving, reduced sodium for at least 25% less sodium than in the original product, light in sodium or lightly salted for at least 50% less sodium than the regular product, and no-salt-added or unsalted when no salt is added during processing, but this does not mean necessarily sodium-free making necessary to check the Nutrition Facts Label to be sure. When the food exceeds 480 mg of sodium per serving but other health claims are made (e.g., low in fat), then a disclosure statement is required.

Introduction

Functional foods are attracting more interest at the consumer level due to the potential to provide health benefits. Proteins sourced from plants are considered to be valuable ingredients in the preparation of functional foods by food industry. In recent times, lupine (*Lupinus* spp.) a legume crop has been investigated for its health benefits in relation to its high protein and fiber contents. Lupine-enriched foods increase satiety and reduce energy intake, decrease blood pressure, and decrease blood glucose and cholesterol levels. The lupine seed proteins have been considered to be the main contributor to these claimed health benefits. The other reported bioactivities of lupine protein include plasma cholesterol- and triglyceride-lowering effects, antihypertensive properties, and angiotensin-converting enzyme inhibitory activity.

Lupine has been used as a green manure since early Greek times and as a cultivated crop plant for more than 3000 years. There is evidence of lupine consumption in human food since early Egyptian times. The Mediterranean region and South America are considered the ancient homes of this crop; it was gradually introduced into Europe to improve soil health.

Evolution of *Lupinus*

In the family Fabaceae, *Lupinus* L. is a large genus consisting of herbaceous, soft-woody shrubs and small tree species. Herbaceous lupines include 200–500 annual and perennial species that are mainly used as grain crops. The diversified species of lupine are grouped as Old World and New World species. The New World species compose >90% of the total species that are distributed from Alaska to South Argentina and Chile. The Old World species include 13 lupine species from the Mediterranean and African regions, which are annual, herbaceous, and large-seeded. Three Old World species (*L. albus* L. (white), *L. angustifolius* L. (narrow-leafed lupine/Australian sweet lupine), and *L. luteus* L. (yellow)) and one New World species (*L. mutabilis* (bitter)) are cultivated as crops for human consumption (Figure 1). Some other species are used as green manure, forage, and ornamentals and for land stabilization.

Lupines represent a group of species characterized by a diverse geographic distribution and morphological and chromosomal polymorphisms, which potentially have large variation in seed protein levels. During the last 50 years, systematic and taxonomic relationship studies among lupine species were with particular emphasis on Old World species mainly because of the limited number of species and economic interest as fodder, food, and N-fixing crops. Based on seed coat texture, Old World species had been categorized as either smooth- or rough-seeded species, which generally agrees with chemotaxonomic and morphological relationships among the species. The five smooth-seeded species are further categorized in four sections: *Albi*, *Micranthi*, *Angustifoli*, and *Lutei*. Six or seven species have been identified

Figure 1 Commonly cultivated lupine species: *Lupinus angustifolius* (narrow-leafed lupine or blue lupine or Australian sweet lupine), *L. albus* (white lupine), *L. luteus* (yellow lupine), and *L. mutabilis* (pearl lupine).

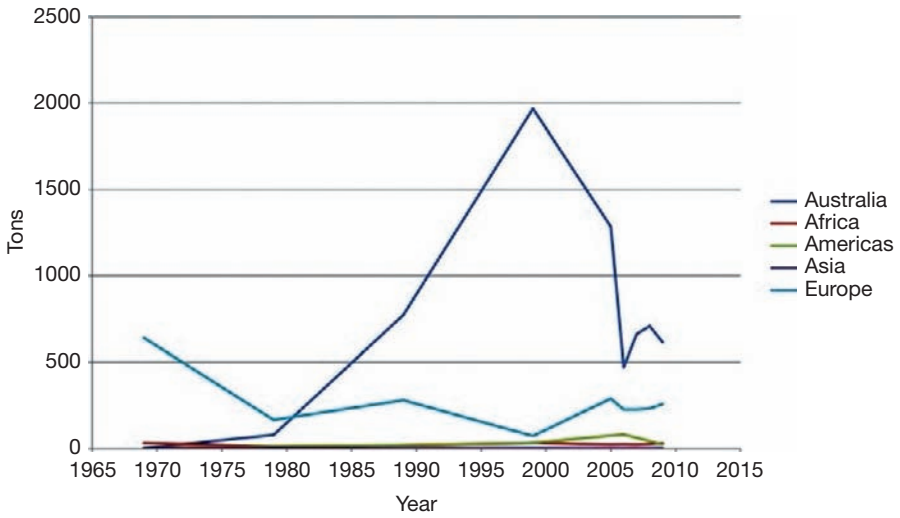

Figure 2 Production of lupine in various years from 1969 to 2009 by continent. Prepared based on the data obtained from FAOSTAT database (2011). FAO in http://faostat.fao.org/site/567/DesktopDefault.aspx.

as rough-seeded with higher interspecies resemblance and typical scabrous, tuberculate testa, which is unique to the genus.

In contrast, New World lupines comprise hundreds of annual and perennial species, which makes phylogenetic relationships very complex within this genus. New World lupine species are mainly distributed in South and North America. For North American species, 18 groups have been categorized comprising ~200 species, although >1700 names have been proposed for New World *Lupinus*. New World lupines are reported as largely polymorphic species by floristic investigations. The complexity of this genus may come from its high morphological, breeding, and ecogeographic diversity and the lack of clear diagnostic characters to distinguish species. Although a number of groups and complexes are already recognized, some groups are roughly circumscribed, which may be valuable for further modern analyses.

Current Production

Lupine occupied 2.7% of world pulse production (tonnes) in 2009. In the last three decades, Australia has been the largest lupine producer, capturing approximately 70% of the world's production (Figure 2). The other major producers are European countries. Blue lupine (*L. angustifolius*) is mostly cultivated in Australia, while white (*L. albus*) and yellow (*L. luteus*) lupines are traditionally cultivated in Europe and South America. In African and Mediterranean countries such as Morocco, South Africa, Syria, and Egypt, mainly *L. albus* and *L. luteus* are grown. Bitter *L. mutabilis* is still cultivated in some parts of Ecuador, Peru, and Bolivia.

In Australia, the state of Western Australia produces roughly 70% of the country's total followed by South Australia, New South Wales (NSW), and Victoria. The lupine industries in Western Australia and South Australia are dominated by *L. angustifolius*. The world's largest lupine-breeding program has been based in Western Australia since the 1960s and includes a goal to improve cultivars suitable for human consumption.

Consumption

A major part of the global lupine production is used by stock-feed manufacturers. Consumption by ruminants (cows and sheep) is the most significant, followed by pigs and poultry. Lupine has been increasingly used as a feed source in the aquaculture industry in recent years.

Although lupine is largely used as animal and fish feed, it has been used as a human food since ancient times. Different communities in the world have traditional methods of producing lupine-enriched food. Most commonly, lupine seeds are first soaked in water to remove most of the alkaloids, followed by cooking or toasting. With the improvement of nutritional science and equipment in food industries, lupine is now being considered for many food preparations such as bread, cookies, cake, pasta, noodles, muffins, and drinks. Although about 4% of global production is currently consumed as human food, it has been reported that ~500 000 tonnes of lupine-enriched food product is consumed annually in the EU, mainly through inclusion of lupine flour in wheat-based baked goods.

Composition of Lupine Grain

Nutritional Value of Lupine

Oilseeds and legumes are the most commonly consumed crops due to their high protein, mineral, and vitamin contents. Among the legumes, soybean is one of the most important for its nutritional properties and desirable functionality. However, lupine is an excellent alternative to soybean or any other legume due to its high protein content, low starch and lipid contents, and high dietary fiber (nonstarch polysaccharide). Analyses of nutritional values of sweet lupine (Figure 3) have shown that the bioavailability of the constituents is comparable to those of processed soybeans.

Amino Acid Composition of Proteins

Lupine seeds contain approximately 40% protein (by weight). Seed proteins occupy a key position in the interests of nutritionists, not only for their nutritional role but also for a

number of other beneficial effects for the human body like cholesterol-lowering effect and enzymatic activities.

Lupine represents an important source of proteins for human beings (Table 1), with a biological value of 91% compared to egg proteins. Storage globulins, which make up the bulk of the protein of legume seeds, contain more than the adequate levels of most of the essential amino acids and make this group a convenient protein source. For example, lupine proteins contain high levels of lysine, an amino acid that is underrepresented in cereals generally.

(2015) The role of protein in weight loss and maintenance. *American Journal of Clinical Nutrition* 101 (Suppl):1320S–1329S.

Fiber

A significant nutritional component of lupine seed is its high fiber content, which has health benefits for human consumption. Lupine kernel fiber (LKF) is a novel insoluble nondigestible carbohydrate that also has value as a fat replacer. It is beneficial for bowel health and the digestive system. LKF is primarily insoluble but is similar to pectin, a soluble fiber, in its chemical structure. LKF also appears to have an unusually high water-binding capacity and viscosity compared with other insoluble fibers, indicating the potential to induce physiological effects more characteristic of soluble fibers, such as lowering glycemic response.

Other than the direct consumption of LKF in lupine flour, kernel fiber can also be manufactured from dehulled lupine seeds after extraction of protein, lipid, and soluble carbohydrate fractions. This fiber, in the form of a pale-colored powder with bland flavor, can be used to boost the dietary fiber content of baked goods while maintaining high levels of consumer acceptability.

Minerals

See Table 2.

Antinutritional Factors

Like some other grain legumes, lupine has antinutritional components (Table 3). Some of these, such as alkaloids, are generally toxic to humans and have an adverse effect on taste. In the developed/modern varieties of lupine, these components have been reduced to tolerable levels. For example, Australian sweet lupine is considered suitable for human consumption since it has low levels of bitter-tasting and potentially toxic alkaloids compared with wild species. The risk level of alkaloid content of lupine for human consumption is >0.012 on a dry weight basis, whereas most of the cultivars of narrow-leafed lupine have alkaloid between 0.004% and 0.02%. Furthermore, lectins and protease inhibitors, which can reduce protein digestibility,

are found at lower levels in lupine than in many other legumes. However, some of the protease inhibitors of lupine have now been positively reevaluated considering the impending utilization of their biological behavior in pharmacological and medical applications. For example, an inhibitor, belonging to the Bowman–Birk inhibitor family, has been isolated from *Lupinus albus* L. having the ability to prevent or suppress carcinogen-induced transformation.

Protein Diversity in Lupine

Generally, the proteins of legume seeds are the storage type, mostly located in storage vacuoles of cotyledonary tissues, and their main role is to supply nitrogen and carbon to the emerging plantlet. With the advancement of proteomic and food technologies, seed proteins are considered significant components for the human diet for their nutritional value and health benefits including hypolipidemic, hypoglycemic, hypotensive, anticarcinogenic, and antiobesity effects. At the same time, they have been investigated for adverse effects on human health such as food intolerance, allergies, and inhibition of endogenous hydrolytic enzymes.

Types of Lupine Seed Proteins

Lupine seeds have two types of proteins, namely, albumin and globulins. Their quantitative ratio is approximately 1:9. Other minor fractions of proteins include prolamins. Albumins are the functional proteins of lupine seed, which are largely metabolic enzymes, linked to the storage role of the seed cotyledon. Globulins comprise a number of protein molecules, which are the salt-soluble storage proteins of seeds.

The first separation of lupine seed protein was carried out in 1975 that differentiated lupine proteins into four main fractions, namely, α-, β-, γ-, and δ-conglutins, on the basis of their electrophoretic mobility. Further separations of lupine protein showed the extreme heterogeneity of the different protein fractions. The α-conglutin fit into the 'legumin-like' or 11S globulin family. This protein group consists of hexamers of disulfide-linked subunits. The β-conglutins are referred to as 'vicilin-like' or 7S globulins. These are trimeric proteins with monomers. In addition to these main protein types, lupine seed proteins contain considerable amounts (5–6%) of γ-conglutin, a basic 7S protein consisting of two heterogeneous disulfide-linked subunits, and a monomeric low-molecular-weight protein similar to other 2S albumins, named δ-conglutin.

Genetic and Proteomic Variations at Species Level

Differences in basic genetic components among lupine species were demonstrated by several cytological studies. The New World lupines' predominant chromosome number is $2n = 48$ with a basic chromosome number of $x = 6$. In contrast, Old World lupines have a series of basic chromosome numbers from $x = 5$, 6 (or 9), 7, 8, 13 at different ploidy levels. Intense selection/evolution in changeable environments is considered as the reason for recent changes in chromosome number of lupine species. Among the smooth-seeded Old World lupines, *L. angustifolius* has lower chromosome numbers ($2n = 40$) compared with *L. albus* ($2n = 50$), *L. micranthus*, *L. luteus*, and *L. hispanicus* ($2n = 52$).

DNA-based analyses have revealed extensive genetic diversity among different lupine species clearly separating the Old World from the New World species. Seed protein studies also reported substantial variation among Old World lupine species and found that heterogeneous smooth-seeded lupines were distantly related to rather homogeneous rough-seeded lupines. The phylogenic analysis based on matrix-assisted laser desorption/ionization time-of-flight (MALDI/TOF) clustered the Old World smooth- and rough-seeded and New World lupine species separately, in broad agreement with clustering based on morphological characters, life history, and cytogenetic and DNA polymorphism. Interestingly, two New

World lupine species *L. mutabilis* Lindl. and *L. succulentus* were grouped into the smooth-seeded Old World group.

Genetic and Proteomic Variations at Cultivar Level

There has been considerable effort to increase the genetic diversity of lupines by crossing breeding lines with diverse wild germplasm. An obvious, substantial genetic diversity among different accessions/cultivars within the same species has been developed, and considerable proteomic differences have been revealed accordingly. The genetic diversity of *L. angustifolius* appears to be larger than *L. luteus* and *L. albus* due to the domestication of this crop in places far from the naturally distributed areas. Characterization of morphological and molecular diversity of *L. angustifolius* revealed considerable genetic differences among cultivars. For example, DNA-based fingerprinting found substantial genetic variation among the cultivars of *L. angustifolius*. Two-dimensional gel electrophoresis revealed seed globulin differences among three varieties each of *L. albus* and *L. angustifolius*. Variation in grain protein content among wild accessions has been reported from under 32% (dry matter basis) to almost 43%. In contrast, grain protein content of cultivars ranged from 32% ('Belara') to 35% ('Coromup'). Thus, the lupine-breeding program at the Department of Agriculture and Food Western Australia (DAFWA) has set the target to increase protein content by initially crossing wild accessions with current varieties. DAFWA has released 25 cultivars of *L. angustifolius* since the 1960s. Recently, a qualitative variation of proteins among 25 Australian cultivars of *L. angustifolius* using MALDI/TOF showed that a pairwise distance between the cultivars ranged 15–50% indicating considerable proteomic variation across the cultivars.

Allergenicity of Lupine Proteins

Considering the increasing and potential use of lupine in food preparation, allergenicity of this grain is a significant issue that needs to be addressed. Since many legume crops, particularly peanut and soybean, have some allergic effect, it is not unexpected that this might also be the case for lupine. A small proportion (<1%) of the world population is allergic to lupine proteins. Allergic reactions to lupine have been reported either as primary lupine allergy or as a result of cross-reactivity to other legumes, especially peanut. Furthermore, lupine flour is a cause of occupational IgE-mediated allergy. A number of studies have reported on lupine globulins that comprise the bulk of lupine proteins as IgE-binding molecules. The overall pattern of lupine allergenicity is similar to that of soybean, peanut, and other edible legume seeds. Like other legumes, the allergic reaction to lupine is of concern, particularly with regard to healthy lupine-enriched bread.

Although the proteins responsible for lupine allergic reaction have not been fully characterized, the basic subunits of α-conglutin (legumin-like, 11S), β-conglutin (vicilin-like, 7S), γ-conglutin (7S), and δ-conglutin (2S-albumin) appear to be responsible for the allergic reactivity. Characterization of the lupine allergic proteins may elucidate their role as cross-reactive and unique lupine allergens. β-Conglutin was reported as the major allergen of *L. angustifolius* named as 'Lup an 1,' whereas α-conglutin was reported as the predominant allergen in *L. albus*. On the other hand, γ-conglutin was suggested as the IgE-binding component of lupine protein in both *L. angustifolius* and *L. albus*. These differences in lupine allergic reaction might be due to the genotypic variation of proteins. Differential expression of some allergic proteins has been identified among four cultivars of *L. angustifolius*.

More defined information on lupine seed protein allergenicity is crucial for the continued adoption of this legume grain in the food industry.

Use of Lupine Proteins in Food

As lupine has been used in different communities as a human food for a long time, there are unique processing and food preparation methods for different product purposes. In modern food technologies, the most common use of lupine in human food is as flour in confectionary and baked products such as bread, crackers, biscuits, noodles, and pasta.

In addition to its direct use as flour, lupine seed derivatives including protein isolates and protein concentrates are used for various food preparations such as drinks, yogurt, sauces, and infant formula. To remove the bitter-tasting alkaloids, which limit the use of lupine in the human diet, protein isolates or concentrates may be an alternative choice for food preparation since alkaloids are water-soluble and removed during the preparation of protein isolates. The use of plant protein isolates in foods as functional ingredients, to improve the nutritional quality of products or for economic reasons, is increasing in modern food production. Lupine protein isolate is useful as a food ingredient for changing the emulsifying capacity and improving the texture of food. However, due to incomplete recovery of proteins by isoelectric precipitation, a technology commonly used in industry, the protein quality of isoelectrically precipitated lupine protein isolate is lower than that of lupine flour from which it was extracted.

It is worth noting that, for bread preparation, gluten (normally present in wheat) plays a vital role in baking by forming long chains of gluten networks, which help to retain gas. Lupine does not contain gluten, and for this reason, lupine is mixed with wheat when utilized in the baking process.

Effect of Adding Lupine Flour to Wheat on Food Properties

The nutritional attributes of food in relation to the impact on biochemical and physiological processes of the human body are now considered key quality features of grains. For example, wheat flour has moderate protein content (11.4 g/100 g) and is low in lysine, an essential amino acid (2.4 g/100 g).

Physical properties

Physical properties of dough and bread were noticeably different when a considerable amount of wheat flour was substituted with lupine flour. The addition of lupine flour tends to improve baked products' flavor and often color and also increases its shelf life. Bread firmness, product volume, and water absorption significantly increased with the addition of lupine flour, which can be considered a positive change for bread quality. Although sensory value decreased after the addition of lupine flour, the products are considered

acceptable. On a negative note, dough development time increased and dough strength decreased, as proteins from lupine obstruct the interconnection of the wheat gluten matrix and ultimately affect the bread texture.

The particular breadmaking properties of wheat flour are recognized mainly by the ability of its gluten proteins to provide viscoelasticity by forming a gluten network when mixed with water. When a portion of wheat flour is supplemented by other flours rich in proteins (e.g., lupine), the added protein molecules interact with the gluten network in both direct and indirect ways: directly by cross-linking with gluten proteins and indirectly through the water availability of wheat gluten proteins. Reduction of gluten networks leads to weakening of dough elasticity. However, an optimum proportion of lupine flour (between 5% and 10%) permits dough elasticity to remain in an acceptable range.

Enriched health attributes

The high fiber content of lupine seed makes it particularly significant for the human diet. Lupine–wheat bread is rich in fiber, improving bowel health and keeping the digestive system smooth. It also helps to reduce fat and energy intake.

The inhibitory effect of foods on appetite – the satiating power of foods – has recently been acknowledged by nutritionists to be vital for planning low-energy/weight-loss diets. High-protein diets are more satiating than high-carbohydrate diets and high-fiber diets are more satiating than low-fiber diets. As a result, foods enriched in protein, fiber, or both have the potential to increase satiety and reduce energy intake. From this point of view, lupine-enriched bread is attracting attention due to the increased protein and fiber levels and the associated positive contribution to reducing obesity.

Available evidence also suggests that substitution of refined carbohydrates in the diet with protein and fiber may benefit blood pressure. This means that lupine-enriched bread has the potential to control blood pressure and cardiovascular disease. Lupine-enriched bread also decreases blood glucose and cholesterol levels, which benefits controlling diabetes. Proteins play key roles in the health benefits, for example, glucose-lowering effect of lupine γ-conglutin.

Wheat Seed Proteins and Interaction with Lupine Proteins in Mixture

The direct way of interaction between lupine and wheat protein (while a portion of wheat flour is supplemented by lupine) is cross-linking between lupine and gluten proteins. During dough preparation, different ingredients such as oxidizing agents, salts, and water are added that promote and affect the formation of protein cross-links.

Research on lupine–wheat flour interaction is limited to physical and chemical properties and sensory evaluation of baked bread. However, it has been reported recently that the two major subgroups of conglutins showed very different solubilities after the baking process indicating different levels of interaction with gluten protein. Most of the α-conglutins were readily extracted from the lupine–wheat bread even at low-salt and nonreducing/nondenaturing extraction conditions. In contrast, most of the β-conglutins lost extractability suggesting that they were trapped in the bread gluten matrix. On the other hand, a number of wheat proteins observed in wheat bread became unextractable from lupine–wheat bread. The higher thermal stability of α-conglutins compared with β-conglutins is speculated to account for this difference.

Conclusion

Lupine-enriched food is a relatively new health-food source, in which consumer awareness and acceptance are still low. An efficient way to bring lupine-associated health benefits to consumers is to add lupine flour to a widely consumed food product such as bread.

Magnesium – An Essential Mineral

Magnesium Functions

Magnesium (Mg^{2+}) is an essential mineral because it cannot be synthesized and is essential for a vast number of body functions and cellular processes. Hence, it must be obtained from dietary sources. Magnesium is the second most abundant intracellular cation after potassium. It is fundamental to the function of adenosine triphosphate, acts as cofactor of more than 300 enzymes, stabilizes proteins and membranes, is necessary for nucleic acid synthesis, and interacts with some cell receptors, like *N*-methyl-D-aspartate receptor. Magnesium involvement in ion fluxes regulation is mandatory for extra/intracellular ion balance. Indeed, magnesium is central for the control of sodium and potassium transport across cell membranes. In addition, because of its antagonistic action on calcium fluxes, magnesium is considered as 'nature's calcium channel blocker.' Therefore, alterations of magnesium concentration lead to a variety of disturbances at the cellular level that may translate to severe dysfunctions and diseases.

Magnesium in the Body and Its Homeostasis

In an adult male, the total body magnesium is approximately 24 g. More than 60% resides in bones, while about 25% is in the muscles where magnesium plays an important role in contraction. Magnesium is predominantly intracellular. Indeed, only 1% of magnesium is in the blood, 55% of which is ionized and biologically active, while 30% is bound to proteins and 15% is complexed to citrate, bicarbonate, ATP, and phosphate. Magnesium is fundamental for cell functions and, consequently, its homeostasis is tightly regulated. The main contributors to whole body magnesium homeostasis are intestinal absorption, kidney reabsorption, and bone stores of magnesium.

Magnesium is absorbed in all parts of the intestine. However, its absorption is maximal in the distal jejunum and ileum. There are two modes of magnesium absorption: passive paracellular – unsaturable mechanism, which is driven by an electrochemical gradient, and active transcellular – saturable absorption mediated by transporters. In healthy subjects, 30–50% of the ingested magnesium is usually absorbed. Because the major part of magnesium in the intestine is absorbed via the paracellular pathway, the amount of magnesium in foods is the main determinant of the quantity absorbed. Active absorption appears to play an important role when magnesium intake is low or in the case of deficiency. Hence, lower magnesium supply results in higher efficacy of its absorption (higher fractional absorption).

Systemic magnesium homeostasis is largely based on its renal handling via filtration–reabsorption processes. Of the 2000–2500 mg of magnesium filtered daily by the glomeruli, about 95% is reabsorbed in the kidney, mainly in the thick ascending limb of the loop of Henle. Magnesium reabsorption depends upon its concentration in the blood. Under conditions of magnesium deficiency, reabsorption in the loop of Henle is significantly increased, while, when magnesium is in excess, its urinary excretion increases. This is the reason why high magnesium intake does not usually result in a marked hypermagnesemia.

Bones are an important reserve of magnesium. About 35% of skeletal Mg is located in the cortical bone either on the surface of apatite or in the hydration shell around the crystals. This is exchangeable magnesium useful to maintain physiological extracellular concentrations. The rest of bone Mg is incorporated into bone crystals and released upon bone resorption. Most magnesium deficiencies are acquired and may result from insufficient intake, altered absorption, and gastrointestinal or renal losses. Several rare monogenic disorders with marked abnormalities in magnesium homeostasis have been identified (including Gitelman, Bartter, and hypomagnesemia syndromes) and permitted to identify several genes involved in magnesium metabolism. However, at present, the data on the impact of gene polymorphism on magnesium status in the general population is limited.

Magnesium Intake

Dietary Recommendations

Several guidelines of recommendations for magnesium intake have been emitted by various countries or organizations (France, Germany, Germany, UK, Nordic countries, WHO/FAO). As an example, Table 1 presents recommended dietary allowances (RDA) provided by Food and Nutrition Board Institute of Medicine National Academy of Sciences U.S. The term of RDA is used to represent the average daily dietary intake that is sufficient to meet the nutrient requirements of

Table 1 Recommended dietary allowances (RDAs) for magnesium (mg) provided in the dietary reference intakes (DRIs) developed by the Food and Nutrition Board at the Institute of Medicine of the National Academies

Age	*Male*	*Female*	*Pregnancy*	*Lactation*
Birth to 6 months	30[a]	30[a]		
7–12 months	75[a]	75[a]		
1–3 years	80	80		
4–8 years	130	130		
9–13 years	240	240		
14–18 years	410	360	400	360
19–30 years	400	310	350	310
31–50 years	420	320	360	320
51+ years	420	320		

[a]Adequate intake (AI).

Dietary reference intakes for calcium, phosphorus, magnesium, vitamin D, and fluoride. Washington, DC: National Academy Press.

nearly all (97–98%) individuals in a life stage and gender group. In fact, RDAs are the estimated average requirements (EAR) + 2 SD. When evidence is insufficient to develop an RDA an adequate intake (AI) is established at a level assumed to ensure nutritional adequacy. The RDA values vary by age, sex, and physiological condition (such as pregnancy, lactation, etc.) and are provided for each of these specific situations. Similarities, but also discrepancies, exist between the various guidelines on RDA (EAR, reference nutrient intakes (RNI)) for magnesium. This is due to the scarcity of studies permitting to precisely estimate allowances. As an example, the RDA for 31–50 years old men and women are 429 mg (EAR 350 mg) and 320 mg (EAR 265 mg) of magnesium/day, respectively. French guidelines (ANC – Les apports nutritionnels conseillés pour la population française; AFSSA, 2000) with 6 mg of magnesium/kg body weight/day are similar to U.S. RDA. RNIs in the United Kingdom for adult men and women are 300 and 270 mg of magnesium/day, respectively. However, FAO/WHO guidelines (2001) consider these values overestimated, and then RNIs for the adults are 4 mg of magnesium/kg body weight/day.

Several dietary surveys point to the inadequate magnesium intake in large parts of the populations of western countries. National Health and Nutrition Examination Survey (NHANES) of 2005–06 found that nearly one-half of Americans (aged 1 year and over) had inadequate intakes of magnesium. This inadequacy was more important in 14–18 year olds and in adults over 71 years. More recently, published results from a prospective cohort study on 73 684 postmenopausal women enrolled in the Women's Health Initiative observational study also indicate an important proportion of women consuming less magnesium than RDA. In France, magnesium intake in subjects from the SU.VI.MAX cohort (35–60-year-old women and 45–60-year-old men) published in 1997, was lower than RDA in 77% of women and 72% of men; 23% of women and 18% of men consumed less than two-thirds of these RDA.

Table 2 Magnesium content in selected foods

Food	*Magnesium (mg/100 g)*
Bread (with cereals and grains)	181
Rye bread	110
Bread (standard baguette)	20
Rice (complete, cooked)	50
Rice (white, cooked)	11
Almonds (with skin)	231
Hazelnuts	88
Spinach (cooked)	53
Bean (white, cooked)	60
Lentils (cooked)	35
Split peas (cooked)	20
Potatoes (cooked)	17
Chicken (roasted)	25
Fish (cooked)	27
Pizza (cheese)	22
Milk	11
Yogurt	12
Cheese (white)	11

Dietary Sources of Magnesium

Food and water

Magnesium is fairly ubiquitous in commonly available foods. Nevertheless, some foods are of particular interest for magnesium supply because of their abundance in magnesium. Green vegetables have a high content of magnesium because magnesium is the central atom of chlorophyll's porphyrin ring. Also, grains, nuts, beans, peas, seeds, cocoa, and connected products are rich in magnesium. From the nutritional point of view, not only magnesium content of specific foods should be considered, but also their processing, their matrix (presence of other components), and the eating habits of consumers (such as Western diet, severe dietary restriction, some athletes' diets), all factors that may affect magnesium content and intake. The refining of the wheat grain, leading to remove magnesium-rich bran and germ from the grain, results in important loss of magnesium. Consequently, white refined flour is poor in magnesium. As an example, there is a marked difference between magnesium content in wheat white bread and whole-wheat bread. Similarly, other refined products such as sugar and oil are totally depleted of magnesium. Food processing, industrial as well as household, may result in significant losses of magnesium. This is particularly important when vegetables are cooked in boiling water and cooking water is discarded. The U.S. Department of Agriculture's (USDA's) Nutrient Database and the French food composition table CIQUAL (ANSES) provide a comprehensive list of foods and their content in magnesium. Table 2 illustrates magnesium content in selected foods.

In nutrition, not only the content of magnesium in foods should be considered, but also food servings and caloric density of foods. Vegetables are of high nutritional interest with regard to magnesium, especially in Western nutrition, because they are abundant in magnesium and low in calories.

Water, either tap or bottled, can be an important source of magnesium. In general, water with adequate magnesium content is an interesting magnesium source because of the zero calories supply and good magnesium absorption. However, magnesium concentration depends upon the water sources. Some waters are rich but many others are poor in magnesium, to the point of approaching the composition of distilled water. Different studies have shown that variations in magnesium levels in drinking water between different areas correlate with the incidence of various diseases. Following, are a few examples. A large epidemiological study in Taiwan has shown the significant protective effect of magnesium from drinking water on the risk of cerebrovascular disease. Research performed in Sweden has demonstrated that magnesium in drinking water is an important protective factor for death from acute myocardial infarction. Recently, magnesium levels in drinking water have been linked to the incidence of hip fracture for both men and women. It is therefore important for the consumers to be worried about mineral content of the consumed water.

Effect of dietary components on magnesium absorption and status

Dietary components may affect magnesium absorption and/or magnesium excretion, thus influencing body magnesium status. The quantity of ingested magnesium and its solubility are major determinants of the quantity of the absorbed magnesium in the intestine. Therefore, diet components positively or negatively affecting its solubility may favor or reduce its absorption.

Because of the phytate content, the negative role of fibers and fiber-rich diets on magnesium absorption was extensively debated. However, in the standard western diet, this negative effect seems overemphasized. In fact, the whole diet rich in vegetables as a source of fibers, is also a substantial source of magnesium. In addition, fiber fermentation in the large bowel improves magnesium absorption in this part of the digestive tract. Within nutritional conditions, an increase of calcium and of vitamin D intakes does not significantly affect magnesium absorption.

High protein intake may affect both magnesium absorption and excretion. Low protein intake may negatively affect magnesium absorption while high protein intake may increase its urinary excretion. This last effect is of particular interest with regard to the Western diet, which, *per se*, is rather deficient of magnesium. In fact, the Western diet, which is usually rich in animal proteins and low in fruits and green vegetables, leads to a chronic, low-grade metabolic acidosis. This metabolic alteration considerably affects magnesium homeostasis. In particular, renal magnesium reabsorption is reduced, thereby resulting in their increased urinary excretion. It could be anticipated that this effect on urinary magnesium losses may be amplified in elderly subjects and in diabetics whose renal function is impaired.

It is well established that chronic alcohol consumption affects whole body magnesium homeostasis. Indeed, magnesium deficiency is frequent in chronic alcohol abusers. This is due to general malnutrition, intestinal malabsorption and renal dysfunction leading to magnesium urinary loss, all typical features of people with alcohol dependence. In addition, ethanol impairs magnesium transport and homeostasis in brain, brain vessels, liver, skeletal muscle, and heart.

Dietary supplements

A large variety of magnesium supplements is available. The most customary are magnesium chloride, oxide, and several organic salts (citrate, aspartate, pidolate, gluconate, lactate, etc.). The main determinant of the absorption of these different forms is their solubility. Frequently, in supplements, magnesium is associated with vitamin B6. Routinely, within nutritionally relevant doses, magnesium supplementation does not provoke significant adverse effect in healthy subjects. This is due to the renal intervention in regulating magnesemia so that magnesium in excess is excreted in the urine. Therefore, magnesium supplementation should be restricted in subjects with kidney dysfunctions characterized by an excess of magnesium excretion. Most commonly, magnesium supplementation with high doses may have laxative effects because of the osmotic activity of unabsorbed salts in the intestine and the stimulation of gastric motility. A tolerable Upper Intake level of magnesium for adults from supplements (without magnesium present in food and beverages) has been fixed by the U.S. Food and Nutrition Board at 350 mg/day and the EU Scientific Committee for Food at 250 mg/day.

Magnesium Status Assessment

The assessment of magnesium status is still a challenge for the physicians and for clinical laboratories. Only a marginal part, less than 1%, of magnesium is in the blood, and therefore it is not representative of overall magnesium levels. Thus, it is comprehensible that laboratory assessment of magnesium status is problematic because it is difficult to perform measures reflecting the tissue/cell content of magnesium. The conciliation between an easy obtained sample, rapid and robust laboratory test, and the parameter representative for intracellular magnesium is extremely difficult to reach. Current clinical laboratory tests are almost limited to total serum (or plasma), ionized serum (or plasma) magnesium concentration, and, seldom, 24 h urinary excretion of magnesium (Table 3).

Table 3 Laboratory approaches to assess magnesium status

Clinical laboratory available assessments
– Total serum magnesium concentration
– Serum ionized magnesium concentration
– Twenty-four hour excretion of Mg in urine
Assessments used for research purposes
– Total and free red blood cell magnesium concentration
– Leucocyte, platelets, buccal cell magnesium
– Magnesium retention test (intravenous or oral magnesium challenge)
– Tissue magnesium (muscle, bone)
– Electron probe for total magnesium in tissue (x-ray spectrometry)
– NMR for magnesium in tissue
– Stable Isotope studies (balance, body pool size and in vitro blood load test)
– Fluorescent probes (flow cytometry and fluorescence spectroscopy)

Total serum (or plasma) magnesium concentration is so far the most widely measured parameter for magnesium status assessment, because it is rather easy to perform and inexpensive. NHANES I study defines the reference interval value for U.S. adult population between (central 95th percentile) 0.75 mmol l^{-1} and 0.955 mmol l^{-1} with a mean concentration of 0.85 mmol $^{-1}$. Even if it is admitted that magnesium serum concentration reflects magnesium status, the current laboratory assessment of deficiency is difficult due to the heterogeneity of serum magnesium values. Therefore, serum magnesium may reflect a severe magnesium deficiency, but it is not a sufficient discriminant of latent chronic deficiency. In addition, serum and erythrocyte magnesium concentrations have been shown to have a heritable component with heritability estimates of ~30%. Recent advances in molecular genetics permitted to identify a variety of genes implicated in magnesium transport mechanism. However, the potential impact of genetics in the context of low magnesium status in the general population is still poorly known.

Apart from the above discussed markers, other various approaches have been used to determine magnesium status, but they are mostly restricted to research purposes. The aim of these techniques is to obtain information as accurate as possible about the amounts of intracellular magnesium which better reflect body stores. Therefore, a range of studies has evaluated blood cell magnesium, mainly in erythrocytes, and to a lesser extent, in leukocytes and platelets. Only a few reports concerned the determination of tissue magnesium (bone, muscle).

An important challenge in the assessment of magnesium status is to evaluate whole body magnesium stores. Currently, this measurement could be achieved through the magnesium retention test, which evaluates urinary magnesium excretion after intravenous or oral magnesium loading. This test is presently considered the gold test for magnesium evaluation. An advent of stable isotopes of magnesium permits to evaluate the exchangeable magnesium pool size. However, at present the number of performed studies is scarce. It should be stressed that, at the moment, there is no clearly validated candidate to serve as indirect biomarker of magnesium (not related to direct magnesium determination).

Magnesium in Health and Disease

Magnesium deficiency may lead to characteristic neuromuscular and cardiac clinical symptoms. However, severe magnesium deficiency is rare, and subclinical latent deficiency mostly occurs with nonspecific symptoms (muscle contractions, weakness, fatigue, digestive troubles). This subclinical, chronic deficiency may contribute to various dysfunctions and diseases (see below). As we discussed, it is difficult to make a diagnosis of this deficiency by the assessment of serum magnesium. However, population studies have shown an important occurrence of hypomagnesemia (values below 0.75 mmol l^{-1}) in Western countries. For example, in Germany, the study of 16 000 individuals from an unselected population indicates that, with the lower limit set of magnesemia at 0.76 mmol l^{-1}, the frequency of hypomagnesemia was estimated about 14.5% of the population. Several studies suggest high frequency of hypomagnesaemia in latent magnesium deficiency prone populations, especially, as discussed earlier, those with metabolic syndrome and type II diabetes. Other population groups are also prone to magnesium deficiency due to lower intake or to magnesium losses, that is, chronic alcohol abusers, individuals with gastrointestinal and kidney diseases, diabetics, elderly, and people treated with some medicines like diuretics, aminoglycosides, and cisplatin, among others.

Epidemiological studies stress the need to pay more attention to magnesium intake, often low in healthy populations. Magnesium intake below RDA does not mean that subjects are magnesium deficient, but supports increased risk of chronic latent magnesium deficiency in large numbers of people.

It is by controlling many cellular and molecular functions that magnesium participates in the maintenance of tissue and systemic homeostasis, from neuromuscular conduction to bone integrity, from the regulation of blood pressure to glucose and lipid metabolism. Consequently, it is unsurprising that chronic latent magnesium deficiency is a contributing factor to several common chronic diseases which exact a high toll in terms of morbidity and mortality, such as diabetes, metabolic syndrome, osteoporosis, hypertension, Alzheimer's, and cardiovascular diseases. Magnesium deficiency promotes inflammation and oxidative stress, known to act as partners in crime in the pathogenesis of all these diseases. It is relevant to note that a low magnesium status associates with increased chronic inflammatory stress, partly generated by excess free radicals, which is alleviated by augmenting magnesium intake. An issue that has been overlooked until now is relative to the altered ratio magnesium/calcium. Since Mg^{2+} is an antagonist of Ca^{2+}, when deficient it cannot properly counterbalance Ca^{2+} signaling, and this impairs the tightly tuned complex mechanisms regulating cell and tissue homeostasis, thus leading to disease.

Let us begin our overview through data linking magnesium deficiency to insulin resistance and type II diabetes. Magnesium participates to the regulation of glucose metabolism since it is important for pancreatic β-cells proliferation and function; it is required for tyrosine kinase activity and for insulin signaling. Magnesium also directly affects the activity of GLUT4 which uptakes glucose in peripheral tissues. Another relevant issue is that inflammatory cytokines, which are produced in excess when magnesium is deficient, reduce the sensitivity to insulin. Several studies have associated type II diabetes with hypomagnesemia. In particular, magnesium deficiency is linked to the development and severity of the disease. Supplemental magnesium improves glucose and insulin metabolism both in healthy and in diabetic adults, and higher magnesium intake lowers the risk of progression to diabetes in insulin resistant individuals. Insulin resistance is one of the hallmarks of the metabolic syndrome, a disease of modern times which is defined also by the presence of hypertension, dyslipidemia, and obesity. Hypomagnesemia is often detected in patients with metabolic syndrome and a high intake of magnesium decreases the risk of this syndrome in a dose-dependent fashion. To this purpose, it is noteworthy that hypomagnesemia is linked also to hypertension and dyslipidemia, thus suggesting that hypomagnesemia is a master contributor to this disorder.

With regard to the regulation of blood pressure, magnesium regulates vascular tone mainly by antagonizing calcium channels in smooth muscle cells, thus reducing vascular resistance.

Most patients with hypertension are hypomagnesemic and magnesium supplementation determines a clinically significant reduction of diastolic and systolic blood pressure. In particular, it is dietary magnesium that shows the strongest inverse correlation with blood pressure.

Magnesium deficiency is implicated in promoting atherosclerosis, an inflammatory disease which is initiated by and progresses in the context of hypercholesterolemia. In experimental models, magnesium deprivation activates inflammation and causes hyperlipemia, thus accelerating and exacerbating atherogenesis. In humans, an inverse association exists between magnesium intake and C-reactive protein level, a marker of systemic inflammation and a known risk factor for cardiovascular diseases. In addition, magnesium deficiency induces a pro-atherogenic lipid profile because it decreases HDL and increases total serum cholesterol, LDL and triglycerides. In the light of epidemiological and experimental studies, magnesium deficiency is also emerging as an inducer of endothelial dysfunction, an early and pivotal event in atherogenesis. Accordingly, an inverse relationship between serum magnesium and development of coronary artery disease has been described. Hypomagnesemia has also been linked to increased intima-media thickness and the risk of carotid plaques. Oral magnesium supplementation exerts favorable effects by increasing HDL, decreasing markers of systemic inflammation, and reverting endothelial dysfunction in patients with ischemic heart disease. It is possible to conclude that correcting and maintaining magnesium homeostasis prevents and retards atherogenesis directly by acting on the endothelium and indirectly by controlling major risk factors such as hypertension, dyslipidemia, and diabetes.

Since magnesium is fundamental in controlling synapse density and plasticity, it is noteworthy that magnesium levels are reduced in the serum and in the brain of patients with moderate to severe Alzheimer's disease. Magnesium supplementation facilitates learning and ameliorates cognitive impairment. These beneficial effects might be explained in the light of studies in an Alzheimer's disease mouse model showing that magnesium reduces Aβ plaques and prevents synapse loss and memory decline.

Mainly the kidneys but also the intestines are protagonists in maintaining magnesium homeostasis by acting through a complex network of transporters. Bone is a co-star, because it stores about 60% of total magnesium and functions as a reservoir of exchangeable magnesium. Indeed, the levels of bone surface magnesium are related to serum magnesium. When deficient, magnesium is mobilized from the surface of the bone to buffer hypomagnesemia, thus leading, in the long run, to osteopenia and osteoporosis. Mg is also important for bone integrity since it acts directly on bone cells by regulating the interplay between osteoclasts and osteoblasts, and indirectly by affecting the homeostasis of the two master regulators of calcium homeostasis, that is, parathyroid hormone and 1,25 (OH)2-vitamin D. Indeed, lower magnesium intake is associated with lower bone mass density of the hip and whole body, and a correct magnesium intake can ameliorate this condition. Since a winning strategy to prevent osteoporosis is to build healthy bones starting early, from childhood, it is relevant to recall that pre-adolescent dietary intake of magnesium positively relates to bone mass density in Caucasian girls.

Memory decline, Alzheimer's disease, atherosclerosis, insulin resistance and osteoporosis are all age-related disorders. A link between low magnesium and aging has been described and, in turn, aging itself is a risk factor for developing a magnesium deficit, thus creating a vicious circle that drives the clinical patterns observed in aging. Aging is an important medical, social, and economic topic of interest in industrialized countries where the number of elderly citizens is rapidly growing. Therefore, correcting nutritional intakes of magnesium might be an easy solution for healthier aging and for reducing the impact of age-related diseases.

A last issue is about magnesium intake and tumors. Epidemiological studies indicate magnesium deficiency as a risk factor for some types of neoplasia, among which breast, colon, prostate, liver, esophageal, and ovarian cancers. It is therefore feasible to propose a contribution of altered magnesium homeostasis to tumorigenesis, partly because magnesium deficiency promotes inflammation and oxidative stress, both involved in cancer. It should also be noted that hypomagnesemia frequently occurs in oncologic patients. This seems to be due to the fact that tumor cells are avid for the cation and tend to accumulate magnesium. To further complicate the picture, radiotherapy and chemotherapy influence magnesium homeostasis through different mechanisms and cause magnesium deficiency. Although it is still debated whether or not to supplement magnesium in oncologic patients, magnesium is emerging as a chemopreventive agent that might contribute to the fight against cancer.

Conclusions

A tight control of magnesium homeostasis is fundamental for health. However, diet is not the only determinant since differences in magnesium handling on a genetic basis have been reported. In the last years, hereditary single-gene mutations resulting in hypomagnesemia have been described, thus leading to the identification of several molecular players participating to magnesium homeostasis. New hints about the relevance of magnesium to maintain health and prevent diseases will derive from nutrigenomics and nutrigenetics. Recently, magnesium supplementation has been shown to differently modulate gene expression and proteomic profile in overweight healthy individuals. The possibility of individuating the effects of nutrients on gene expression will lead to personalized food-based recommendations on the basis of the genotype. Nutrigenetics evaluates the effects of genetic variation on the relation between nutrients and health. In the case of magnesium, by single nucleotide polymorphisms, six different genomic regions were individuated that contain variants reproducibly associated with hypomagnesemia.

These results will change our outlook on the complex mechanisms involved in magnesium absorption and distribution and will allow new interpretations of interventional studies.

Introduction

In the last 150 years, heat treatment became as a common practice in the food industry. Treatments such as sterilization or baking improve the organoleptic and health properties of heat-treated foods. Many different chemical reactions take place during heating and storage of foods, giving rise to the formation of new compounds that affect the final characteristics of foodstuffs and consumer acceptability. Some of these transformations include a complex set of reactions known as non-enzymatic browning (NEB), leading to the formation of brown colors without the intervention of enzymes. Among them, the Maillard reaction (MR) is the most ubiquitous due to its ability to develop in a large range of temperatures, water activity, presence–absence of oxygen, etc. Therefore, the MR development is desirable in foods like coffee or bread, where specific color and aroma are expected. Contrary, in foods like milk or fruit juices, the MR is avoided due to the formation of strange colors and aromas as well as nutritional decrease. To do so, the food industry establishes different processing standards and control measures aiming at decrease the extension of the MR.

The Chemistry Behind the MR

General Pathways

The MR is a complex net of chain chemical reactions responsible for the aroma, color, and taste of many thermally treated foods. It is favored under the absence of oxygen – although its presence does not avoid its development – neutral–basic pH, low/intermediate water activity, and mild heating conditions. The MR was first described in 1912 by the French chemist Louis Camille Maillard, who described the reaction between glycine and glucose, producing a yellow-pale color in water solution. In 1953, Hodge proposed a scheme (Figure 1) currently considered the most appropriate to describe this reaction.

(a) The first step of the MR consists of the nucleophilic condensation of a carbonyl group with an amino group and, after dehydration, an unstable *Schiff base* is formed, which is transformed rapidly into an N-substituted-glycosylamine or imine known as Schiff base for either glucose or fructose (Figure 2). This reaction is reversible because in a strong acidic medium, the sugar and the amino acid can be regenerated. The amino group can be a free amino acid, the side chain of an amino acid (like lysine) incorporated in a protein or the amino group of the last amino acid in each protein. In the case of the carbonyl groups, they are usually reducing sugars, although they can be also carbonyl compounds from the intermediate stages of the MR and/or lipid oxidation.

(b) The next step consists of the irreversible rearrangement of the N-substituted glycosylamine. As a result of the hydroxyl group present in the α-position, the imines (Schiff base) can rearrange via the 1,2-eneaminols corresponding to the 1,2-enediol (Figure 3). When the molecule is an N-substituted-aldosylamine, by means of the *Amadori rearrangement*, the 1-amino-1-deoxy-2-ketose is formed (the Amadori compound). However, when the starting product is an N-substituted-ketosylamine, a 2-amino-2-deoxy-2-ketose is formed by means of the *Heyns rearrangement* (the Heyns compound). The Amadori products are more stable than the parent Schiff base, being the first MR compounds that can be measured in foods. The reason for such partial stability compared with imines is explained by their cyclic molecular structure: imines can be converted to the cyclic hemiaminal, which is unstable because they mutarotate very easily. However, the Amadori rearrangement leads to a furanose, which, as a hemiacetal, has a stability to mutarotation comparable with that of carbohydrates.

(c) The Amadori and Heyns products are decomposed, depending on the pH and temperature of the medium, giving rise to the formation of different intermediate compounds responsible for the final aroma and color of heated foods. Different osuloses – named *1-, 3-, or 4-deoxyosone* and *reductones* – are formed, which again decompose and react in the intermediate steps of the MR. The formation of deoxyosones is accomplished at pH ranging from 4 to 7. The Amarodi product 1-amino-1-deoxy-2-ketose can be converted to 2,3-eneminol as well as 1,2-eneaminol, which decomposes to form the subsequent deoxyosone (Figure 4). Water elimination from the 1,2-eneaminol and hydrolysis of the imine cation gives 3-deoxyosone. The 2,3-eneaminol has two different β-elimination options: the elimination of the amino acid by a retro-Michael reaction with formation of 1-deoxyosone and water elimination at carbon 4 of the 2,3-eneminol with the formation of 4-deoxyosone.

Further decomposition of 3-deoxyosones at low pH, through 1,2-enolization, gives rise to the final formation of *furanic compounds* like 5-hydroxymethylfurfural (HMF) and furfural from hexoses and pentoses, respectively. A 2,3-enolization takes place at basic pH, generating pyrroles and pyranones. The reductones so formed can be dehydrated again to form dehydroreductones, which form polymers by reacting with amino groups at the advanced stages of the MR.

(d) The Amadori compounds can be split into different *fission products*, such as acetal or acetaldehyde.

(e) The interaction of amino acids with dicarbonyl compounds, like dehydroreductones or fission products, is known as the *Strecker degradation* and implies the loss of amino acids in foods. As a result of this degradation pathway, new aldehydes with one carbon atom less – lost as

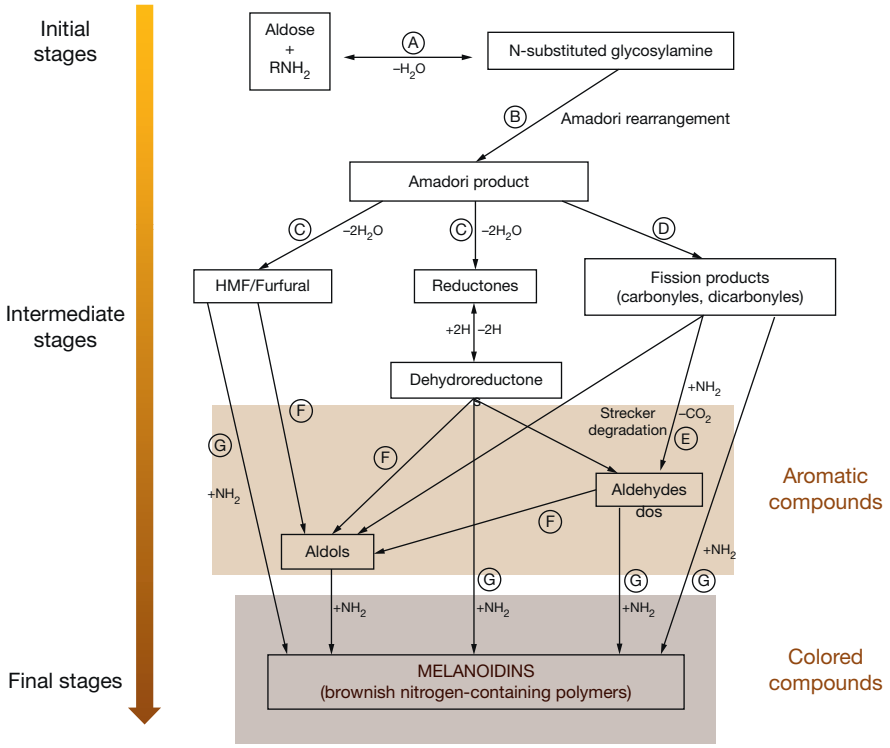

Figure 1 The Maillard reaction.

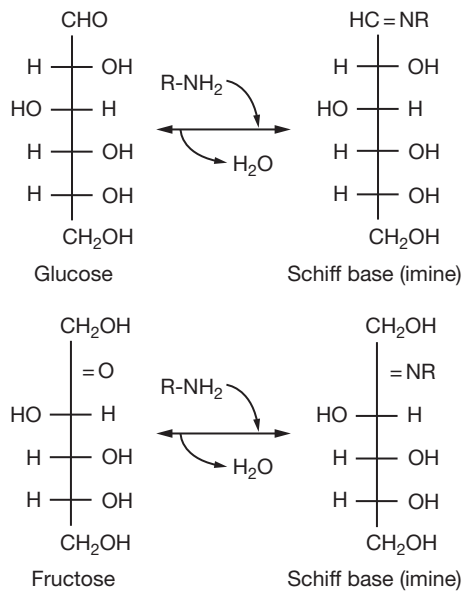

Figure 2 The formation of Schiff base from glucose and fructose.

CO_2 – are formed. It occurs in foods at higher concentrations of free amino acids and under more drastic reaction conditions (high temperature or under pressure). The aldehydes so formed (i.e., methional, phenylacetaldehyde, and 3-methylbutanal) have a very high aroma potential, depending on the amino acid degraded.

The next steps (f and g) are known as the advanced steps of the MR, where two different classes of compounds are formed: melanoidins and volatile aromatic compounds.

(f) *Volatile aromatic compounds* are formed directly from the Amadori compounds and do not need the mediation of free amino groups. However, a 1% of the total volatile compounds produced are formed by the reaction of 2-deoxyglucose with amino acids. As in the case of the Strecker degradation, many different chemical odorants are formed, like pyrazines, pyrroles, thiazoles, and thiophenes. For example, alkylpyrazines are the main flavors of roasted meat, while boiled meat gives rise to other products like 2,4,5-trimethyl-3-thiazoline.

(g) *Melanoidins* are brown polymeric anionic compounds produced by means of the condensation of aminated products of the intermediate stages of the MR such as N-substituted pyrroles, N-substituted 2-formylpyrroles, and 2-furaldehyde. Melanoidins have a wide molecular weight and different absorbance spectra. When formed from a carbohydrate backbone (coffee, balsamic vinegar, etc.), they are known as melanosaccharides, but if the melanoidin core is formed by a protein (i.e., bakery products), they are known as melanoproteins.

The MR has an initial induction period necessary to obtain enough the Amadori and Heyns products to start the intermediate stages of the reaction. The cascade of complex reactions that follows the formation of these initial intermediates means that the MR is not a classical chemical reaction. Rather, it represents a series of consecutive and parallel reactions that occur in the same reaction pool to produce a complex matrix of reactions. The propagation of the MR is best described by the formation and interaction of the so-called chemical pools

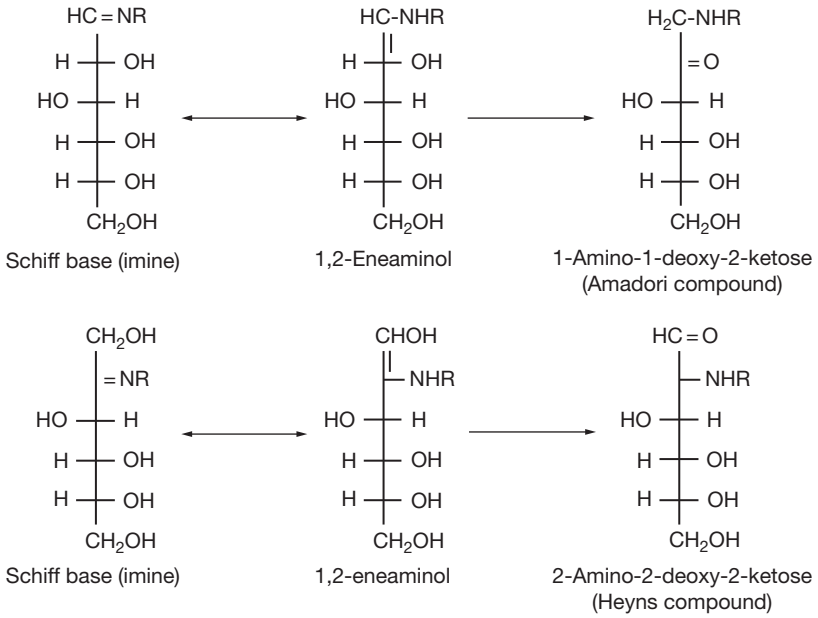

Figure 3 The formation of the Amadori and Heyns compounds.

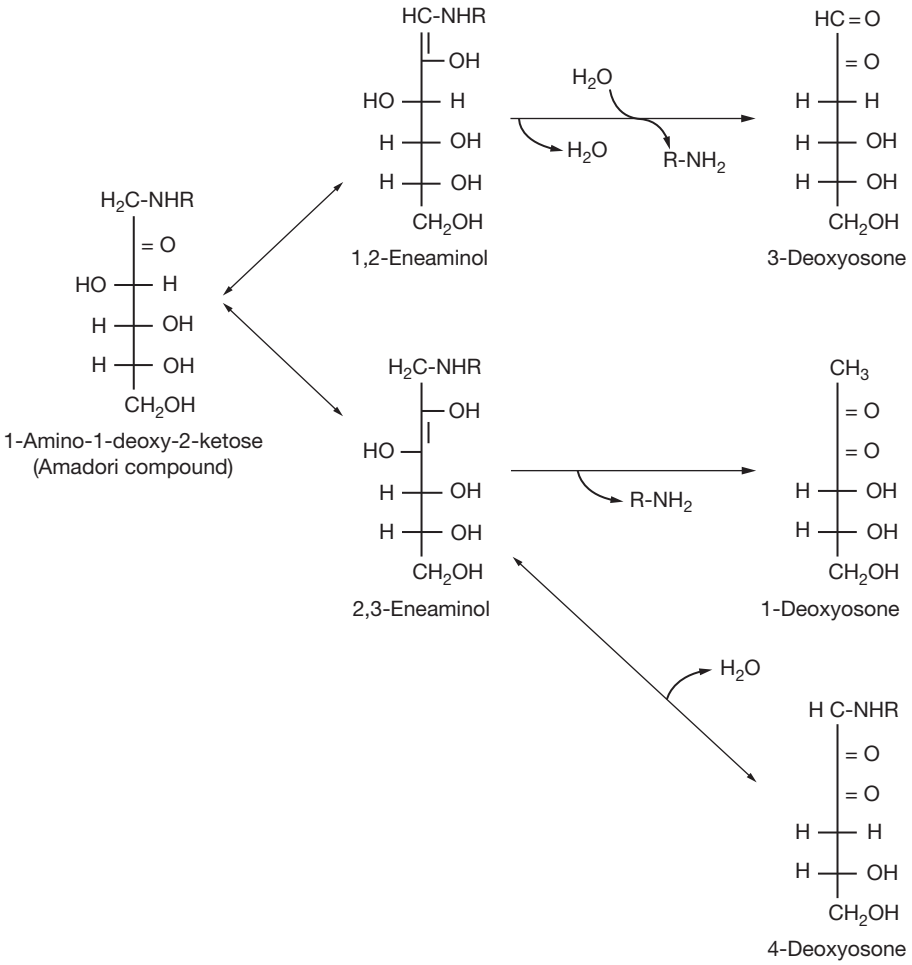

Figure 4 The formation of deoxyosones.

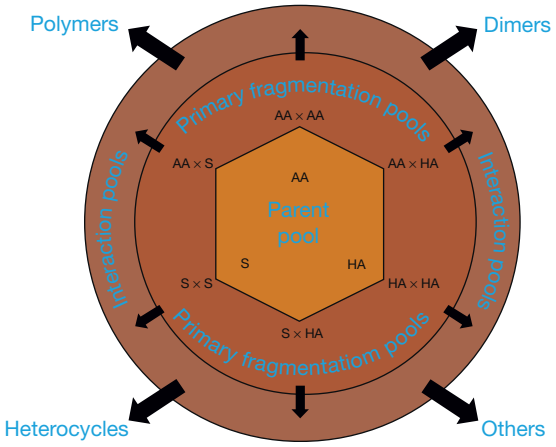

Figure 5 The pool theory of the Maillard reaction.

generated from specific precursors, theory stated in 1997 by Prof. Yaylayan. The intermediates produced during the initial phase of the MR arise from three well-defined main precursors: sugars (S), amino acids (AA), and the Heyns or Amadori products (HA) (Figure 5). This parent pool ($S \times AA \times HA$) will determine the pathway of the MR under specific conditions. In addition, each principal precursor can generate its own specific fragmentation products, being the collection of products arising from a single precursor or from interacting different precursors termed as pool:

- Amino acid fragmentation pool (AA): amino acids, amines, carboxylic acids, alkanes, etc.
- Sugar fragmentation pool (S): C_1 fragments (formaldehyde, formic acid, etc.), C_2 fragments (glyoxal, acetic acid, etc.), C_3 fragments (glyceraldehyde, hydroxyacetone, etc.), C_4 fragments (tetroses, 2,3-butanedione, 2-hydroxybutanal, etc.), C_5 fragments (pentoses, pentuloses, furans, etc.), and C_6 fragments (hexoses, pyranones, glucosones, deoxyglucosones, etc.)
- The Heyns and Amadori fragmentation pool (HA): amino acid–propanone, amino acid–propanal, amino acid–butanones, amino acid–pentadiuloses, amino acid–hexadiuloses, etc.

Each pool consists of either stable products and reactive intermediates that can rapidly undergo interactions either within a pool or with components of other pools or polymerize, resulting in 'interaction pools' (intermediate MR products (MRPs)) that give rise to 'final' compounds such as polymers, heterocycles, or other compounds.

Connection with Other Chemical Reactions

As stated earlier, the MR comprises different well-defined pathways, although most of them share different substrates and compounds formed with other common chemical reactions found in foods such as ascorbic acid degradation, caramelization, and lipid oxidation. Therefore, the development of one of these chemical reactions may lead to a higher development of another one.

In the case of the *degradation of ascorbic acid*, different compounds like furfural or reductones are formed, which take part in the Strecker degradation. In the case of *caramelization*, the enolization reactions can produce more aldoses to increase the development of the MR, as the hydrolysis of oligosaccharides to produce monosaccharides. In addition, the formation of osuloses or heterocyclic compounds – such as HMF – also increases the speed of the MR.

Lipid oxidation products are able to modify the MR by promoting the reaction or by reacting with some intermediates and producing compounds different to those commonly formed in the absence of lipids, for example, the development of aroma in cooked meat mediated not only by Strecker degradation aromatic compounds but also by different aldehydes produced during lipid oxidation and the reaction of the amino group of the polar head of phospholipids with carbohydrates or other carbonyl compounds. There are also common intermediates in both lipid oxidation and MR pathways. Both reactions produce carbonyl compounds, some of which are identical when starting from both lipids and carbohydrates. Thus, two dicarbonyl compounds, namely, glyoxal and methylglyoxal, are produced from both oxidized lipids and carbohydrates. These compounds have a special interest due to their high reactivity, promoting the development of the MR. In addition to carbonyl compounds, many other volatile (pyrroles) and nonvolatile (N-substituted hydroxyalkylpyrroles) compounds are also produced in both reactions. The formation of N-substituted hydroxyalkylpyrroles has a special interest because they are key compounds in the development of browning due to the MR and lipid oxidation.

Variables of the MR

The development of the MR depends on many different physical (temperature and heating time) and chemical parameters (pH, water activity, and substrates) that should be kept under control.

Substrates

The substrates involved in the MR are carbonyl groups – particularly from reducing sugars – and amino groups from amino acids and proteins. Carbonyl groups coming from fat oxidation also contribute, although to a lesser extent. Although the MR is an isomolecular reaction taking place between a sugar and an amino acid, the loss of sugars is always greater than that of amino acids due to the coexisting caramelization reactions.

Low-molecular-weight (LMW) *carbohydrates* are more reactive than higher-molecular-weight (HMW) ones due to reduced steric hindrance. Thus, standardized concentrations of sugars produce lysine losses coming from 16% for disaccharides, 42% for hexoses, and 60% for pentoses. The reactivity of sugars is also proportional to the amount of open form. In isomers, the stereochemical configuration determines the reactivity. Therefore, the general degree of browning of sugars decreases in the following order:

1. Pentoses: ribose > xylose > arabinose
2. Hexoses: galactose > mannose and glucose > fructose
3. Disaccharides: maltose ≥ lactose

However, it should be taken into account that the reactivity of sugars is not absolute and depends also on the state and nature

of the proteins with which they react. For example, raffinose destroys six times more lysine with lactalbumin than with globulins, while pentoses and hexoses have a similar reactivity with both proteins.

Other molecules with carbonyl groups formed by the Strecker degradation (formaldehyde, acetal, and propional) or those produced during the degradation of the Amadori compounds (furfural and hydroxymethylfurfural) can react with the amino groups, and the reaction starts again. Thus, in foods like cheese or fruit juices, whose composition includes such kind of MRPs, the MR can develop without the involvement of sugars.

All *proteins*, except the insoluble keratin, can react with sugars. The α-amino acids, which form the peptide bond with the subsequent carbonyl group, are inaccessible during heat treatments, unlike the terminal amino acids and those having a second amino group, such as lysine. In casein, the amount of free ε-amino groups is 50 times higher than the amount of the free α-amino group, so that the loss of lysine via the ε-group is the most serious nutritional consequence. For example, when a mixture of casein and glucose is heated, the destruction of histidine accounts for 17%, arginine for 22%, and lysine for 46%. Browning intensity is proportional to the concentration of lysine in feed protein. Thus, milk proteins turn brown faster than soy proteins and these faster than cereals proteins.

In the case of free basic *amino acids*, they react with sugars at a rate markedly higher than other amino acids but are the stereochemical configurations that determine their behavior. Thus, it has been established a classification of amino acids according to the degree of browning they produce:

- Amino acids producing high browning: lysine, glycine, tryptophan, and tyrosine
- Amino acids producing an intermediate degree of browning: proline, leucine, isoleucine, alanine, hydroxyproline, phenylalanine, methionine, valine, glutamic acid, and asparagine
- Amino acids producing a low degree of browning: histidine, threonine, aspartic acid, arginine, glutamic acid, and cysteine

pH

The effects of pH are complex, as each stage of the MR has an optimum pH: at pH <3, the browning is low and increases with increasing pH to a maximum of 10. At pH greater than 10, the decrease of protons required for catalysis of the Amadori and Heyns restructuring may be the cause of the decline of this reaction. The reactivity of the amino group is higher when the amino acid is in anionic form and this value depends on the acid–base character of the amino acid: For acidic amino acids (aspartic and glutamic acids), the anionic form occurs at pH 3, but for basic amino acids (lysine and arginine), a pH of 10 is required.

Taking into account this behavior, the initial pH of the product and the buffer capacity of the system influence the type and intensity of the MR. Then, foods can be divided in three groups depending on their pH and reactivity:

- *Foods with a pH between 6 and 8* (milk, eggs, cereals, and meat) where conditions are favorable to the MR: a decrease in pH can reduce browning during dehydration but adversely modifies the organoleptic characteristics.
- *Intermediate pH foods* (canned vegetables, fermented foods, honey, sauces, and soups) in which the MR and degradation of ascorbic acid can occur simultaneously.
- *Foods with a pH between 2.5 and 3.5* (acidic juices and fruit concentrates): these products are poor in amino acids and the MR occurs very weakly. Ascorbic acid degradation and caramelization of sugars are responsible for browning.

Water Activity

The intensity of the MR depends on the amount of water present in the foodstuff. The maximum activity is obtained at 50–70% relative humidity (10–15% water in the product or water activity of 0.67–0.70). Higher moisture decreases the rate of the MR and it is believed to not exist in the absence of water. Such kinetic is explained as follows: At very low water content, the diffusion of chemical species is decreased; the addition or increase of water content facilitates the diffusion of the reactants and increases the rate of browning. However, with higher amounts of water, the concentrations of reactive substances in solution decrease and the rate of reaction decreases. Typically, it is during the dehydration process when the risk of browning is higher, particularly at the stage of the process in which the water content is below 20% and the temperature is high, as in the final stages of milk dehydration.

Temperature and Time

The MR occurs at both room temperature (storage of many products) and high temperature (sterilization processes) and gives rise to the loss of amino groups due to the time/temperature pairing. Thus, equivalent losses are obtained during a high-intensity short-time heating than during a weak treatment for a long time period. For example, the same lysine loss is observed in a mixture of α-lactalbumin and lactose after 4 h of heating at 96 °C than after 4 days at 55 °C.

The activation energy values of the MR range from 10 to 160 kJ mol^{-1}. Depending on such activation energy and the energy supplied during heat treatment, one step of the MR or others are favored. As an example, Table 1 shows how different amino acids react with the same single sugar to produce different aromas depending of the heating temperature.

Nutritional Consequences of the MR

The MR have a high impact not only on the sensory properties of foods but also on their final composition, due to the decrease of nutritionally relevant substrates (such as essential amino

Table 1 Effect of temperature over the development of aromas in the MR

Amino acid	*100 °C*	*120 °C*	*180 °C*
Leucine	Sweet chocolate	Bread crust	Burnt cheese
Threonine	Chocolate	Wheat	Burnt
Valine	Rye bread	Bread crust	Chocolate-penetrating

acids), inhibition of various enzymes needed for the digestion of food, and the development of new compounds with both healthy (antioxidant activity) and harmful (acrylamide, heterocyclic amines, etc.) properties. It is evident that most of the effects refer to isolated foods, but little is known about the total intake of these compounds in the population or the overall nutritional and physiological effects of their consumption. This situation should be investigated for a better understanding of the positive and negative aspects of the intake of MRPs, especially because the current eating habits of young people comprise the intake of large amounts of snacks and fast food, which are foods plenty of MRPs.

Negative Effects

Loss of essential amino acids

The MR reduces the nutritional value of foods by decreasing the bioavailability of the essential amino acids. This reduction occurs even if no changes are observed in the color and flavor of food and is a consequence of amino acid consumption as the MR develops. Lysine is the most affected amino acid, although others like sulfur amino acids, tryptophan, and histidine are also decreased. The Schiff base formed in the first stage of the reaction is still nutritionally available as amino acid, while the Amadori compound is not. Only 5–15% of the *N*-ε-fructose-lysine can be used as a source of lysine, while the remaining 90% is metabolized by the gut microbiota thanks to the presence of an amadoriase enzyme.

Effect on digestive enzymes

The MR produces changes in the protein structure that prevent the action of digestive peptidases in the proximity of the cross-links. In this sense, *in vivo* assays on glycated proteins show a decrease in their digestibility, while *in vitro* digestions show a larger release of small peptides than free amino acids. Besides, it has been observed also that some components of the MR can inhibit the activity of certain digestive *proteases*. LMW compounds formed during the MR can inhibit the activity of trypsin, carboxypeptidases A and B, aminopeptidase N, and the glycine–leucine cytosolic dipeptidase, while dipeptidyl dipeptidase IV is not affected. In fact, it has been demonstrated that certain MRPs can even decrease nitrogen uptake from non-glycated proteins. Intestinal *disaccharidases* may also be affected. LMW MRP products are *in vitro* inhibitors of lactase, invertase, maltase, and trehalase at concentrations of 5–10 mg ml^{-1}. Other HMW compounds cause also inhibition at concentrations of 1.4–2.8 mg ml^{-1}. Quantitatively only the latter appear to be important in the reduction of enzyme activity.

Effect on vitamins

The influence exerted of MRPs on vitamins is not fully understood. Some MRPs can react with and destroy vitamins. As an example, losses of thiamine and pyridoxal have been demonstrated during the storage of milk powder for 9 weeks at 60 °C. Thiamine has an amino group and vitamin B6 an aldehyde group that can theoretically participate in the MR. Other vitamins affected are B1, B6, B12, and pantothenic acid, while nicotinic acid and biotin are relatively insensitive.

The destruction of the ascorbic acid in foods is closely related to the MR (see section '**Connection with Other Chemical Reactions**'). Dehydroascorbic acid reacts via the MR with the amino compounds of foods to form red and brown pigments. However, the nutritional loss of vitamin C by the MR is negligible; in the usual conditions of storage and processing, most of the ascorbic acid is destroyed before the MR became predominant.

Effect on minerals

The products of the MR also interfere with the absorption and metabolism of minerals. Melanoidins, the final polymeric brown pigments formed in the MR, have usually a net negative charge, responsible for the chelation of mineral cations such as Fe^{3+} and Cu^{2+}, leading to a final decrease on mineral absorption. It has been proposed that minerals are chelated through replacement of H^{+} ions within the melanoidin structure. Thus, the rank order of affinity for complexing the different minerals could be as follows:

$$Mg > Ca = Cu > Zn$$

The presence of MRPs decreases not only the absorption of minerals but also their excretion rate and deposition within the human body. The consumption of diets rich in MRPs gives rise to an increased renal excretion of calcium, iron, and zinc. In addition, there is a depletion on calcium content in bone and its deposition in other nonusual organs such as the bladder. In addition, the metal complexing capacity of MRPs could explain some effects such as inhibition of metalloenzymes (carboxypeptidases A and B) as stated earlier.

Development of substances with mutagenic and/or carcinogenic activity

Heat treatment is very common as a source of new compounds with pleasant colors and flavors. However, there is a concomitant formation of different compounds with toxic properties, reducing the biological value of food. These chemicals are known as processing contaminants, compounds that were not present in the fresh food, and its genesis is directly related to the technological process. Most of these compounds are associated with mutagenic, teratogenic, or carcinogenic activities in living organisms and therefore should be evaluated and, if necessary, controlled by the appropriate food safety agencies. As examples, heterocyclic amines, polycyclic aromatic hydrocarbons (e.g., benzopyrene), *N*-nitrosamines, monochloropropanediols (e.g., 3-MCPD), furan, acrylamide, and hydroxymethylfurfural are important processing contaminants, which are detailed in other chapters.

Positive Effects

Antioxidant activity

One of the positive features of the MR is its antioxidant action, as some MRPs, like melanoidins, have antioxidant properties. Its antioxidant activity is particularly interesting since they are formed naturally in the food during processing or storage. The mechanism of the antioxidant activity of these MRPs is not well understood, but is believed to be based on the ability to trap positively charged electrophilic species, elimination of oxygen radicals, and/or chelation of metals to form inactive complexes. *In vivo* antioxidant activity has been found to be exerted

in cell cultures, animal models, and human beings. For example, digested coffee melanoidins protected human hepatocytes HepG2 under oxidative stress. In human beings, coffee melanoidins increase the antioxidant activity of plasma up to a 7%, shortly after consumption, and protects human lymphocytes against DNA damage induced by ROS.

Antimutagenic effect

Reference should also be made to the antimutagenic effect of Maillard compounds, either by chemical or enzymatic modification or by inducing its suppressive effect on DNA alterations stimulated by mutagenic agents. For example, melanoidins can modify the activity of phase I and phase II enzymes at the liver, which performs a chemopreventive activity due to the processing of xenobiotics in order to be excreted in urine. In addition, *N*-methylpyridinium, a known MRP produced during coffee roasting, has been identified as the key compound in coffee brews modulating phase II glutathione *S*-transferase and induction of Nrf2 gene transcription, a transcription factor in the nucleus responsible for the antioxidant and detoxifying enzymes. Other types of enzymatic systems modulated by melanoidins are matrix metalloproteases, endopeptidases that allow tumor growth and metastasis. In addition, melanoidins can bind LMW harmful compounds like acrylamide. The nucleophilic amino groups of amino acids from the protein core of melanoidins react with acrylamide by a Michael addition reaction.

Antimicrobial action

Certain products of the MR exert an antimicrobial action. The first assays showed that 20 different bacterial genera diminishing or inhibiting their growth in the presence of MRPs originated in different ways. In subsequent trials, it has been found that melanoidins present in foods such as beer, cookies, and coffee have bacteriostatic and bactericidal actions, depending on their concentration in the foodstuff. This antimicrobial activity is shown with different types of bacteria, either Gram+ or Gram− such as the species *Staphylococcus aureus* and *Escherichia coli*. The mechanism of action by which melanoidins exert bactericidal action is related to the ability of melanoidins to chelate the Mg^{2+} ions present in the outer bacterial membrane, which is finally disrupted. The bacteriostatic activity is performed by iron chelation, which is an essential cofactor for the biochemical metabolism in bacteria.

Antiallergic character

Some intermediates of the MR have antiallergic action, such as the Schiff base formed during the first step of the reaction. This is supported by some experiments that showed a reduction on antigenicity and allergenic response of those foods rich in protein and carbohydrates heated under mild conditions. However, it should also be noted that such reactions are able to introduce new antigenic determinants in dietary proteins.

Food Processing and Prevention of the MR

Processes such as roasting, baking, and frying rely on favorable effects of the MR such as the development of pleasant colors and flavors. However, during pasteurization, sterilization, or drying, the occurrence of the MR is unfavorable. The main challenge in the food industry is therefore the specific design, optimization, and control of the aforementioned processes for the production of food with the desired quality and stability. All the parameters listed in the section of variables of the MR can be manipulated in the daily laboratory work with model systems in order to make the reaction rate controllable. However, given the chemical complexity presented by foods in a real environment, it is only possible to moderately modify the rate of the MR. Reducing the pH, temperature, and water activity significantly inhibits reaction, but sometimes, it is technically and economically impossible to achieve that.

One of the most common ways to control browning reactions consists of the addition of sulfite, metabisulfite, or sulfur dioxide. These compounds react with carbonyl compounds and Schiff bases to give highly stable sulfonates. Then, sulfites fix many reactive intermediates of the MR, extending the induction period and delaying the onset of browning. However, changes in the laws of different countries, caused by the adverse effects of sulfites, have hampered the use of sulfites, causing the search for alternatives. Sulfur amino acids can prevent browning in various food products like fruit juices, being *N*-acetyl-L-cysteine and others – SH-containing compounds – as effective as sodium bisulfite in decreasing the rate of browning. The addition of glutamic or aspartic acid also causes a decrease in browning. This effect may be associated with the stability of the Amadori compounds so formed with glutamic or aspartic acids, as the rate of the MR is lower with such Amadori compounds.

Another way to control the development of the MR is the removal of substrates from food. For example, during the preparation of dried eggs, glucose is usually oxidized to gluconic acid by the enzyme glucose oxidase to gluconic acid or removed by fermentation. In the case of potatoes, storage for 2 weeks at a 20 °C decreases the amount of reducing sugars, giving rise to a lower production of acrylamide during potato frying. Furthermore, the conversion of the amino group in the amide function by the activity of transglutaminase enzymes can preclude the first stages of the MR.

For those foods where the inactivation of pathogenic and spoilage microorganisms and enzymes is developed by means of thermal processes, a minimal treatment temperature and a corresponding holding time are required. Thus, a suitable method of control the extension of the MR is to reduce the thermal load to which a product is exposed during processing. As a general rule, it is desirable to work with low-intensity thermal treatments and to store foods at moderate temperatures in order to not to exceed the MR activation energy. The reduction of processing times for heating to a final temperature and cooling is possible by improving the heat transfer or by applying alternative thermal technologies such as direct steam injection and ohmic heating. These new alternatives avoid temperature gradients and heat transfer limitations. In addition, preservation of food can be achieved also by nonthermal based on alternative inactivation mechanisms. Pulsed electric field processing and high hydrostatic pressure treatments work at reduced treatment temperatures, avoiding the occurrence of heat-induced product changes.

Contrary, the occurrence of the MR is desired to a certain extent in foods like bread of baked meat where the formation

of color and flavor is expected on the surface of the food. As an example, the application of emerging technologies such as infrared heating allows the achievement of a pleasant surface color and flavor while reducing the total thermal process intensity. Compounds such as malonate, phenylacetone, tertiary amine salts, acetic acid, and boron trifluoride can also be added in order to catalyze the MR and Amadori rearrangement. Another possibility is the addition of MR substrates such as milk proteins or beaten egg to the surface of baked dough, a common practice in the bakery industry.

Conclusions

The MR is a ubiquitous reaction taking place in heat-treated foods and also those foods stored during long time at room temperature. The development of the MR is desired in products where a brown color and a special aroma are expected, such as coffee, bread, and meat. Contrary, many efforts have been done by the food industry in order to limit the extension of the MR in foods like milk or fruit juices, where brown colors denote a low-quality product. In addition to this, the MR is responsible for a decreased nutritional value in many foods and the development of harmful compounds as well. Furthermore, the MR shares different biochemical pathways with other common reactions such as lipid oxidation, caramelization, and ascorbic acid degradation. Therefore, a fine-tuning of the MR alone is complicate under a technological point of view. Currently, the knowledge of the shared chemical pathways of these reactions constitutes the basis for obtaining new foods with healthier and tasteful properties.

Introduction

Maize (*Zea mays* L.) is the leading grain in the world with an annual production of more than 1 billion tons in 2013, and it constitutes staple foods for large groups of people in Latin America, Africa, and Asia. Maize production has increased the most because of its greater adaptation to different ecological systems and strong demand for bioethanol and animal feed and for the production of sweeteners and other nonfood industrial products (i.e., biodegradable packaging materials). The genetic modification of maize (*Bt* maize) is partially responsible for record productions observed in the past 10 years. According to the FAO, 54%, 19%, 13.8%, and 14% were used for feed, food manufacture, direct food, and bioethanol, respectively. Maize is used for the production of numerous indigenous foods, maize meals, flours, grits, starches, sweeteners, cooking oils, breads, tortillas, breakfast foods, snacks, bioethanol, and alcoholic beverages. Processed maize products are manufactured from raw materials obtained from three major industries: dry milling, wet milling, and nixtamalization (Figure 1). Dry millers produce an array of products widely used by the breakfast cereal, snack, baking, and brewing industries (Figure 2). Most of the prime starch obtained from wet millers (Figure 3) is enzymatically converted into maltodextrin, maltose, glucose, and high-fructose syrups (Figure 4). The nixtamalization industry generates fresh or dry masa flours, which are further converted into table tortillas and lime-cooked snacks such as corn and tortilla chips.

The Americas and particularly Mexico are the cradle of maize, the most adapted cereal to different ecosystems. The most accepted position of the maize origin is that teosinte is the ancestor because of the free and frequent hybridization of teosinte and maize in nature; they own the same chromosomic number ($2n = 20$), and cultivars shared several anatomical traits including analogous morphological pollen features. The Mesoamericans created maize by transforming a tiny two-rowed ear of teosinte of about 5 cm long into the more than 300 races known today. After the Spaniards conquered Mexico, maize was taken to Europe and then quickly disseminated into Asia and Africa. Today, maize is planted in all continents under different climatic conditions and agrosystems. Open-pollinated varieties are generally planted in developing countries while high yielding and *Bt* hybrids in developed countries. Among commercial cereals, maize is the only one that has the male or staminate and female or pistillate flowers separated.

Maize is a crop with a remarkable genetic variability, and it is classed according to the form of the caryopses into dent and flint or corneous and subclassed according to color into white or yellow. Most of the maize planted worldwide is yellow dent (Table 1), which is the preferred by the feed, bioethanol, breakfast cereal, snack, and starch processors. The use of white dent maize is growing because it is preferred for tortilla and related snack production. Nutritionally, maize is considered as an excellent source of calories due to its high starch content (between 65% and 70% starch) and an adequate source of insoluble dietary fiber. Most maizes contain between 8.5% and 11% protein, which is considered intermediate in terms of essential amino acid balance. The maize proteins lack sufficient levels of lysine and tryptophan to sustain infant growth. The supplementation of maize foods with legumes, eggs, and other animal proteins greatly enhances protein quality and levels of micronutrients. Nutrient composition of maize is reported in Table 3.

However, many specialty genotypes such as popcorn, waxy, high-amylose or amylomaize, sweet, blue and other pigmented, Cuzco, and quality protein are planted for specific uses (Table 1).

Traditional Foods

Regular and specialty types are widely consumed in numerous forms in Latin America, Asia, Africa, and the Balkans. White dent maize is generally preferred for foods because it favors the final color of processed foods, but yellow types are preferred in China, Brazil, Argentina, Italy, and some other countries. Most traditional foods are produced from kernels that are milled into whole wheat or refined grits, meals, or flours.

The use of immature maize on the cob is practiced worldwide. Maize cobs with or without husks are boiled in water or cooked over a fire and then flavored with salt, cream, butter, margarine, and other sauces. In most areas, regular maize is used as green maize. In Latin America, maize is additionally processed into tortillas, arepas, couscous, polenta, porridges, and gruels. The traditional method to convert maize into tortillas was developed by ancient Mesoamericans. In the traditional process, maize is lime-cooked in clay pots over a fire followed by overnight steeping. The alkaline-cooked kernels named *nixtamal* are ground into a dough or *masa* with a stone grinder. Pieces of *masa* are hand-molded into disks, which are baked on a hot griddle to yield tortillas. Industrially produced tortillas are mainly used as wraps to prepare tacos that hold different types of fillings (beans, various meats, cheeses, eggs, and vegetables). Tacos are the symbol of the Mexican cuisine and are known and consumed worldwide. Many other nixtamalized foods such as *tamales*, *atole*, and *pozol* are produced from *masa*.

Arepas, the national maize bread of Venezuela and Colombia, are traditionally produced from white grits or meals that are moistened, cooked in water, and ground to a dough. The dough is hand-shaped into flat disks that are baked on each side on a griddle. Arepas are stuffed with various types of meats, cheeses, butter, jellies, and other fillings. Stuffed arepas are also fried to produce *hallaquitas* or *empanadas*. Large Venezuelan plants commercially manufacture instant arepa flours that require only hot water to produce the dough. Briefly, grits

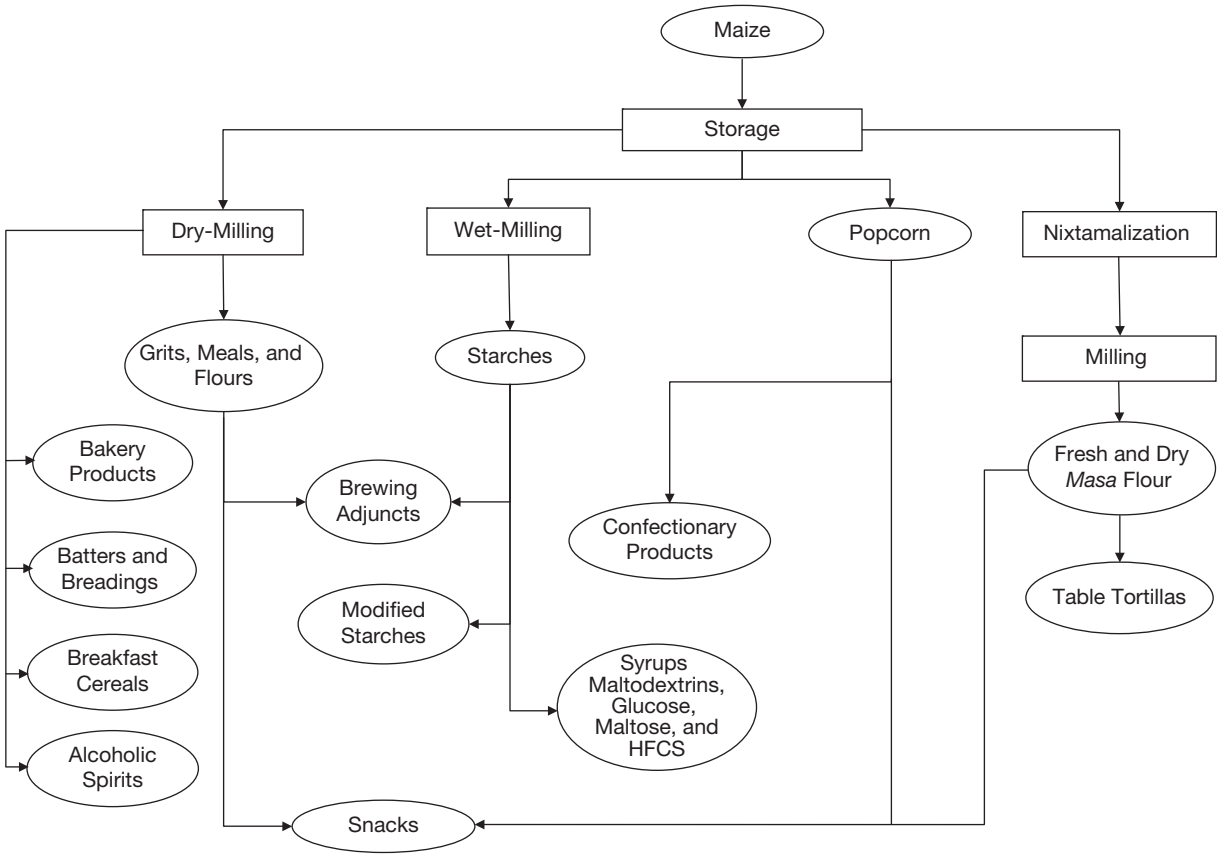

Figure 1 General flowchart of the postharvest management and processing of maize for human foods.

Nixtamalized products from maize.

are cooked and then passed through flaking rolls to gelatinize the starch. The flakes are dried and ground into flour to meet a certain particle size distribution. With precooked flour, arepas can be prepared in approximately 30 min instead of 12–24 h required by the traditional process.

Maize is also used for the production of many traditional beverages still widely consumed worldwide. Chicha is a prehispanic sacred fermented beverage prepared in Peru and Bolivia in which ground maize is first treated with amylases from germinated maize or saliva and then naturally fermented. Other alcoholic beverages such as tesguino, pito, talla, and other related opaque beers are still traditionally consumed in Africa and Mexico.

In Africa and Asia, maize is generally dry-milled into grits, meals, and flours for the production of flat breads, unfermented and fermented porridges, steamed foods (couscous), and alcoholic or nonalcoholic beverages. Many of the traditional foods are produced from fermented or sprouted kernels. Tô, pap, nshima, and sadza are popular maize porridges widely consumed in Africa.

Industrial Processing of Maize for Foods

Most of the maize is first industrially processed by dry milling, wet milling, or nixtamalization. Dry-milling manufactures refined endosperm fractions of varying particle sizes (grits, meal, and flour), germ for oil, and sometimes dietary fiber ingredients (Figure 2). Starch and refined dry-milled products are mainly used for the production of breakfast cereals, snacks, sweeteners, lager beers, and fuel or potable ethanol. Wet millers (Figure 3) produce relatively pure starch, protein, fiber, and germ, whereas the nixtamalization industry produces dry masa flours, tortillas, and related snacks that are increasing rapidly in popularity in many countries around the globe.

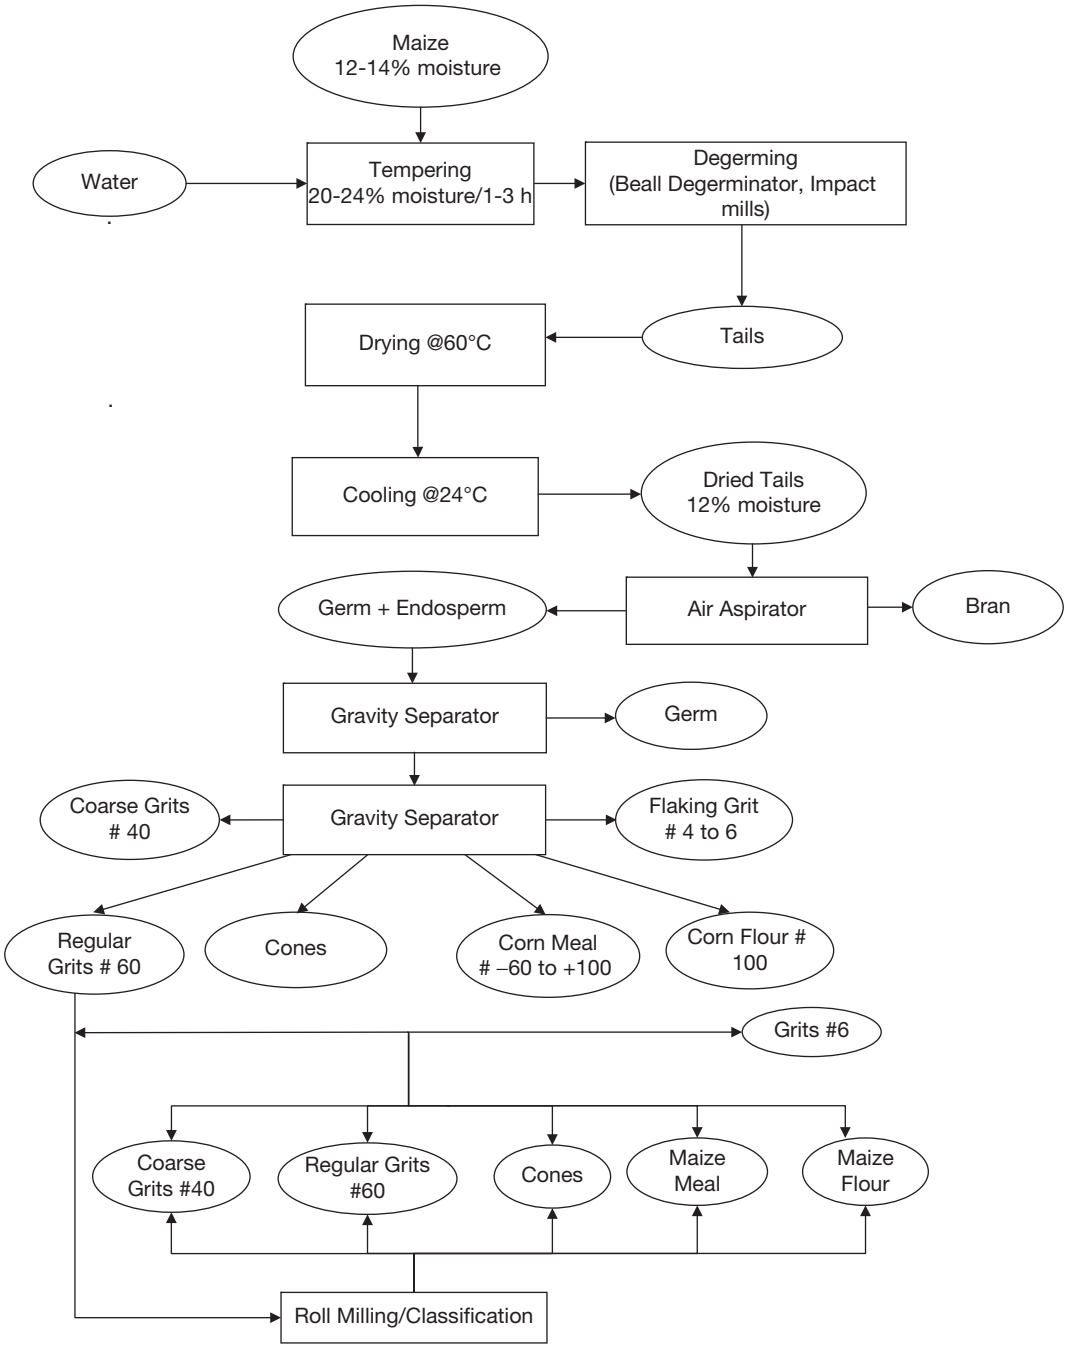

Figure 2 Flowchart of the degerming–tempering dry-milling process of maize.

Food Uses of Dry-Milled Fractions

Endosperm products from dry milling, ranging from large grits to flour, are widely used by brewers and snack food and breakfast cereal processors (Table 2). Flaking grits are large (the United States, 3.5–6 mesh sieves) endosperm particles obtained after degerming. These large pieces of endosperm are used to produce corn flakes still considered the most popular ready-to-eat breakfast cereal worldwide. The traditional cornflake process starts when yellow flaking grits are pressure-cooked (1 kg cm^{-2}) in rotary cookers for 1–2 h with syrup, sugar, nondiastatic malt, salt, and water. The cooked grits are delumped and partially dehydrated to about 20% moisture. Then, the grits are equilibrated, flaked through a pair of counterrotating rollers, and toasted in order to develop the crisp texture, brown-golden color, and the characteristic flavor. Sugar-coated flakes are made by the same process, but the sweetener is sprayed onto the flakes immediately after toasting. Cornflakes can also be made from meal or grits that are extruded into third-generation half products or pellets.

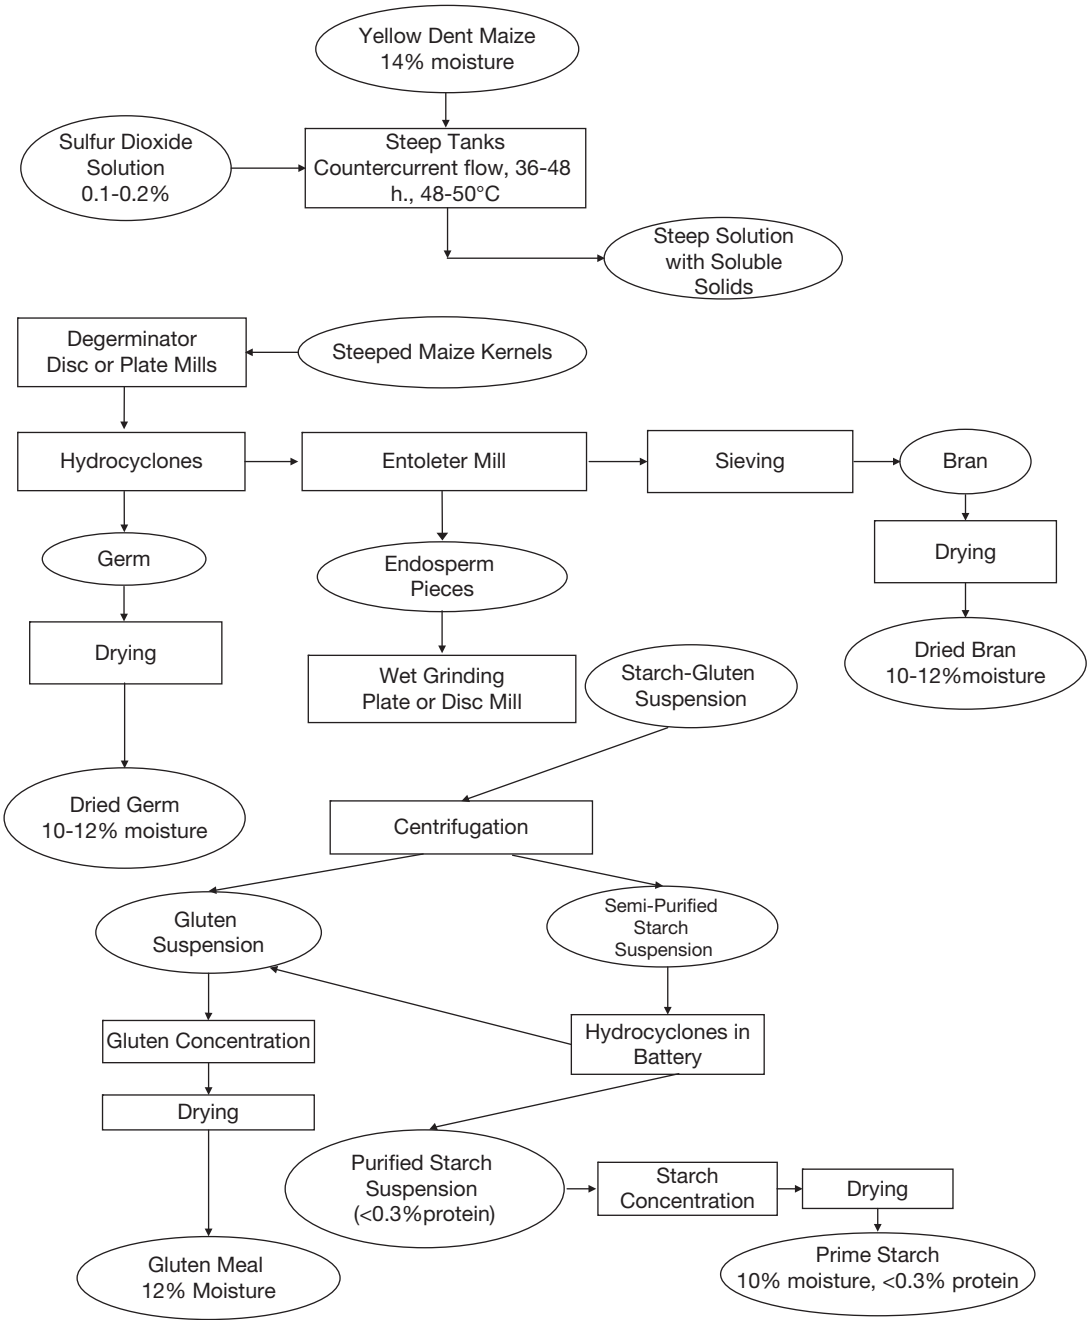

Figure 3 Flowchart of the sulfur dioxide wet-milling process for the production of maize starch.

Corn grits are low in fiber and contain less than 1% oil (Table 3). Grits of various granulations are extensively utilized by the snack, breakfast cereal, and brewing industries. In many countries around the globe (the United States, Italy, and Argentina), cooked white or yellow maize grits are consumed as a side dish. Instant or precooked maize grits, which require only 5 min cooking, are popular.

Traditionally, the brewing industry has been the largest user of grits because they are a cheap source of fermentable carbohydrates. Whole ground or refined grits are also utilized to produce alcoholic beverages. Straight bourbon whiskey is obtained from distillation of a fermented mash containing at least 51% maize in the United States.

Refined milled fractions from maize alone or in combination with other cereals and ingredients are often used in ready-to-eat breakfast and snack foods. Grits, meals, or flours are cooked to gelatinize the starch, denature the protein, and produce a pregelatinized dough, which can be formed into flakes, shreds, puffs, or collets. Extruded gun-puffed cereals are still one of the most popular types of ready-to-eat breakfast cereals. The puffing gun is charged with equilibrated collets, sealed, and heated to increase the pressure to 10.5–14 kg cm^{-2}.

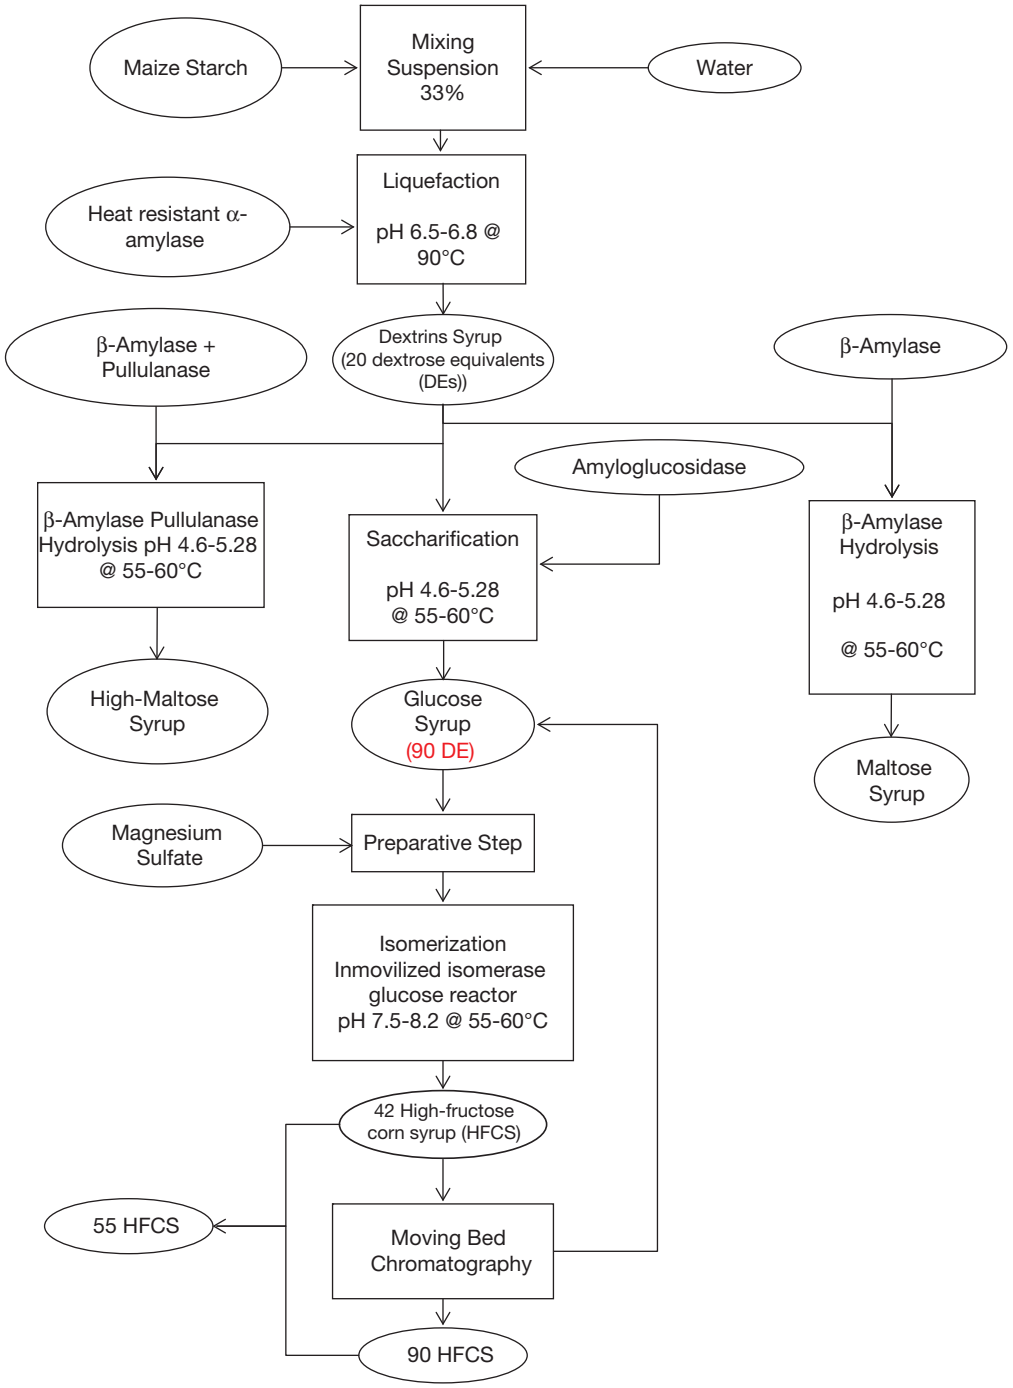

Figure 4 General scheme followed for the production of maize syrups.

The pressure is suddenly released and the material puffs and explodes from the gun. The degree of puffing varies according to temperature and pressure and commonly varies from 10 to 16 times. Products that require less expansion are generally oven-puffed. This process yields products with a three- to fourfold expansion.

Corn meal or grits are processed through extrusion cooking and puffing to produce snacks such as curls, puffs, and balls. Extrudate expansion is closely related to product texture and is affected by the viscoelastic nature of the material and the amount of moisture in the material flowing through the extruder die assembly. The extrudates are baked or fried, flavored, and packaged to produce the final ready-to-eat item. Pellets or half products are usually manufactured using a combination of two extruders. The first extruder cooks the raw ingredients while the second cools, forms, and sizes the extrudate into dense pellets, which are dried, stored, and then baked or fried into the third-generation snacks. Baked collets are crisp

Table 1 Characteristics and food uses of different types of maizes

Type of maize	*Food uses*
Feed grade yellow maizes	These are the most popular types grown in the world. The high yielding yellow dent maizes with soft-textured endosperms are widely used as feed and for the production of first-generation bioethanol and refined starch
Food grade yellow and white maizes	These types have improved processing efficiency in dry milling, nixtamalization, and snack food processing plants. These maizes have high test weight and density
Quality protein maize (QPM)	QPM has the opaque-2 gene that is combined with modifier genes that significantly improve the hardness and agronomic performance of the crop. These types contain about twice the amount of lysine and tryptophan compared to their regular counterparts. Both yellow and white QPM open-pollinated varieties and hybrids are being used in Brazil, Mexico, Ghana, and other countries. Harder QPMs are suited for dry milling and alkaline cooking
Popcorn	Special kind of flint or corneous maize. Hybrids or varieties with high proportions of translucent or vitreous endosperm give higher expansion rates. Expansion volume is the most critical quality factor for popcorns. Most commercial popcorn has a 35- to 40-fold expansion. The pericarp or bran of the kernel contributes directly in the popping mechanism by serving as a pressure vessel enclosing the endosperm. Popped corn with a spherical shape is called mushroom or ball type and is preferred in the confection industry. The butterfly-type popcorn has a higher expansion, lower apparent bulk density, and better mouthfeel and therefore is preferred for on premises popping
Blue maize	Most blue maizes have a soft or floury endosperm texture that generally grow in long ears (8–12 rows). The aleurone layer contains the anthocyanins that impart the blue coloration. Blue corn is used to produce traditional foods in Mexico and other parts of America and especially for the production of organic flours and foods such as tortillas and chips. These colored genotypes contain higher levels of flavonoids that are an excellent source of antioxidants
Sweet maize	Sweet maize types have recessive genes (sugary 1 or 2 and su1 or 2) that cause an alteration in the endosperm that results in higher levels of soluble sugars and reduced levels of starch in the kernel. Sweet-corn hybrids have been developed specifically for the canning industry or for consumption on the cob
Baby maize	Special varieties that are grown and shucked immediately after pollination when the ears are about 5 cm long. These small ears are used as pickles and other tasty snacks in salad bars. Most of the baby corn used is produced in Thailand and exported to Europe and North America
Waxy maize	Waxy maize is named for the somewhat waxy appearance of the kernel. Waxy maize starch is composed entirely of amylopectin. It is utilized mainly by the wet-milling industry. Waxy starch has a higher hot viscosity and produces softer, more stable, and clearer gels due to its lower retrogradation. It also has a higher freeze–thaw stability
High-amylose maize	Also named amylomaize. Expresses high quantities of linear amylose because of the recessive *ae* gene located in chromosome 5. Most genotypes contain amylose from 37% to 65%. The amylomaize starch has potential for the paper, textile, corrugating, and adhesive industries. The high-amylose starch produces rigid opaque gels with potential for the confectionery industry and as a thickener in various puddings and processed foods
Cuzco/cacahuacintle maize	Cuzco maizes come from eight-rowed ears that produce the largest known dent kernels. Cuzco corn grows at high altitudes and produces white kernels with soft endosperm texture and bland flavor. Cuzco kernels are mainly used to manufacture Cornnuts™ and Cacahuacintle kernels for hominy and *pozole* production

Maize starch and syrup.

with a light and crunchy texture. Deep-fat-fried collets are crisp with smoother texture due to the uptake of the oil.

Corn meals and flours are commonly used to produce an assortment of chemically leavened baked and fried products such as corn bread, muffins, pancakes, sticks, fritters, and hush puppies (Table 2). Most maize bread formulations contain wheat flour, chemical leavening agents, sugar, salt, milk powder, and other ingredients. Maize does not have functional gluten so wheat flour is included to give the dough more

Corn flakes, the most popular breakfast cereal sold worldwide.

Popcorn, one of the most popular snack foods worldwide.

elasticity and hence produce a more aerated product. Composite flours of maize and wheat are also frequently used to produce batter and breadings.

Food Uses of Starch

More than 90% of the commercial starch is from maize due to the low cost of the grain, high starch content, and high value of the coproducts. The industrial wet-milling process of maize is detailed in Figure 3. In this process, yellow dent maize kernels are steeped in a sulfur dioxide solution for about 2 days in order to disrupt the protein matrix that entraps starch granules. Then, the wet kernels are degermed and ground to free the starch, which is separated from the gluten via centrifugation and use of hydrocyclones. The resulting dehydrated prime starch contains less than 0.3% protein. The refined starch is channeled to various food industries to be used as additive or enzymatically hydrolyzed into various types of syrups. The main types of products obtained are dextrins, maltose, glucose, and fructose syrups (Figure 4). In addition, the by-products are highly utilized by the feed and oil-crushing industries. The bran is generally used to feed domestic animals, although some is finely ground to produce high dietary fiber foods. The germ is demanded by oil mills to produce the refined oil and defatted protein meal. Corn oil is widely used as cooking oil because of its stability and high levels of polyunsaturated fatty acids.

Corn Syrups

In 2014, nearly 20 million metric tons of maize was converted into syrups in the United States. About 64% of this production was transformed into high-fructose syrups (HFCSs). The production and utilization of syrups have increased during the past decades because the soft drink industries prefer to use sweeteners instead of crystallized sugar. Maize sweeteners are preferred over sucrose because they quickly dissolve in water and are easier to incorporate into soft drinks. The HFCSs containing 90% fructose impart 1.7 times more sweetness than sucrose at equivalent concentrations.

The various types of syrups are manufactured from acid hydrolysis or preferably after enzymatic conversions. The industrial production of amylolytic enzymes allowed the production of better-quality low-dextrose-equivalent (DE) syrups and the production of glucose syrups with high DE or sweetness. The industry evolved with the commercial availability of heat-stable α-amylase and amyloglucosidase that could transform practically all the starch into glucose. The greatest technological developments were the utilization of immobilized glucose isomerase and the continuous separation of glucose and fructose by moving bed chromatography (Figure 4).

Low-DE Syrups (Maltodextrins)

The low-DE or maltodextrin-rich syrups are industrially produced by acid hydrolysis or by α-amylase conversion. These syrups are the easiest to manufacture and are the first step for the production of maltose, glucose, and HFCS. The acid hydrolysis is performed in 35–40% starch suspensions using a 0.02–0.2 N hydrochloric solution in a pressurized reactor. This technology is now limited because it can yield undesirable compounds such as methylfurfural, formic acid, and/or off-flavors and off-colors. The most popular way to convert starch into dextrins is via the utilization of α-amylases. Nowadays, heat-stable α-amylases are used because they require shorter incubation. Their optimum activity is achieved at pH of 6.5 and temperature of 90–100 °C. These syrups with 10–20 DE are very viscous, rich in dextrins, and low in sweetness; therefore, they are mainly used as thickeners. Dextrin syrups are alternatively used as substrate for cyclodextrin production. These cyclic oligosaccharides are composed of six, seven, or eight glucose units linked by α-(1–4) linkages to form α-, β-, or γ-cyclodextrins, respectively. Cyclodextrins are used to enhance chemical stability and reduce volatility of complexed molecules and mask undesirable odors and flavors.

Table 2 Principal food uses of refined maize dry-milled fractions

Type of dry-milled fraction	*Particle size of US mesh sieve*	*Major food uses*
Flaking grits	3.5–6	Used for the production of breakfast cereals such as corn flakes and corn pops. In Brazil, flaking grits are used to produce a traditional food named *canjica*
Coarse grits	10–14	Used for the production of extruded breakfast cereals (i.e., extruded flakes and puffs) and second-generation (i.e., puffs) and third-generation (i.e., pellets) snacks
Medium grits	14–28	Used as brewing adjuncts and for the production of extruded breakfast cereals (i.e., extruded flakes and puffs) and second-generation (i.e., puffs) and third-generation (i.e., pellets) snacks
Fine grits	50–75	Used as brewing adjuncts and raw material for the production of maize porridges and for the production of extruded breakfast cereals (i.e., extruded flakes and puffs) and second-generation (i.e., puffs) and third-generation (pellets) snacks
Cones	50–80	Used as raw material for the production of corn bread, extruded, breakfast cereals (i.e., Cheerios™) and second-generation (i.e., puffs) and third-generation (i.e., pellets) snacks
Meal	50–75	Used for the production of breadings and batters and maize-based bakery items (pancakes, muffins, biscuits, waffles, and corn bread)
Flour	−75	Used for the production of breadings and batters, thickening agents, baby foods, meat extenders, and maize-based bakery items (pancakes, muffins, biscuits, waffles, and corn bread)

USDA (2014) – http://ndb.nal.usda.gov/.

Maltose Syrups

Regular and high-maltose corn syrups are manufactured starting with a low-DE syrup that is treated with β-amylase or a combination of pullulanase and β-amylase (Figure 3). β-Amylase activity is optimized at pH of 5 and temperature of 55 °C. The utilization of only β-amylase yields syrups with 50–55% maltose, while the use of pullulanase and β-amylase results in syrups with about 80% maltose. Maltose syrups are extensively used as flavorings for breakfast cereals, beverages, and ice creams.

Glucose Syrups

For the production of 90 DE glucose syrups, low-DE syrups are treated with amyloglucosidase or saccharifying enzyme at pH of 4.6–5.2 and a temperature of 55–60 °C (Figure 4). The syrup is refined and clarified through columns of activated carbon and ionic resins with the aim of removing minerals, pigments, soluble protein, fat, and enzyme-resistant starch. Glucose syrups are utilized as sweeteners for soft drinks and baking formulations and as a source of fermentable carbohydrates for light beers, alcohol production, and yeast-leavened bakery items. Crystallized dextrose can be produced by concentrating the syrup to 75% solids, adding glucose, and gradually cooling to drop the temperature to 20–30 °C for several days.

High-Fructose Corn Syrups

HFCSs are manufactured starting from 90 DE glucose syrup that is further treated with immobilized glucose isomerase (Figure 4). The refined glucose syrup is deaerated and treated with magnesium sulfate so as to assure oxygen removal and the

sequestration of calcium that lowers enzyme activity. There are three major types of HFCS: 42, 55, and 90. The 55 and 90 HFCSs are produced from the 42 HFCS. The 42 HFCS is industrially produced by passing glucose syrup through a reactor with glucose isomerase. The optimum operating conditions are pH of 7.5–8.2 and temperature of 55–60 °C. The glucose syrup flow rate is controlled to convert 42–45% of the glucose into fructose. The 90 HFCS is obtained after separating fructose and glucose in a moving bed chromatography system that produces two syrups with about 90% of each type of sugar (Figure 4). The 55 HFCS, which is analogous to crystallized sugar, is manufactured by mixing 42 and 90 HFCSs. The 90 HFCS has approximately 1.7 times more sweetness than crystallized sugar. HFCSs are used as substitutes of table sugar especially in soft drinks.

Food Uses of Nixtamalized Products

Three basic types of products are industrially produced from lime-cooked maize: table tortillas, corn chips, and tortilla chips. Corn and tortilla chips are primarily produced and consumed in developed countries, where they have an important share within the salted snack food market.

Nixtamalized traditional foods.

Table Tortillas

Tortillas and masa products constitute the staple food for large populations in Mexico and Central America. Tortillas are produced using traditional and industrial processes. The industrial production of tortillas is labor-intensive and requires considerable equipment. Frying has expanded the market for *masa*-based foods because the final product has excellent organoleptic properties and a long shelf life. The two most popular snacks, tortilla and corn chips, are usually made from coarsely ground fresh *masa* or *masa* flours. Corn chips are produced directly from *masa* and contain more oil than tortilla chips. Tortilla chips are baked similarly to tortillas before frying. Corn and tortilla chips are often salted and flavored immediately after frying. Most popular flavorings include nacho cheese, hot/spicy, barbecue, lemon salt, and jalapeño. Special processes to produce baked low-fat tortilla chips that combine air impingement, infrared, and microwaves have been developed.

Introduction

Malnutrition does not always imply hunger or famine, which is the first association that typically comes to mind. It is manifest in many forms, ranging from hunger to obesity, and can be defined in terms of undernutrition, overnutrition, and micronutrient deficiencies. Simply put, malnutrition is caused by excessive intakes, insufficient food consumption, and inadequate utilization of nutrients provided by foods ingested. On the one hand, insufficient intakes often result from precarious circumstances and inequalities existing at the level of economic resources, education, access to food and safe drinking water, adequate health care, and sanitary living conditions. On the other hand, excessive intake of foods high in saturated fats and sugars and industrially processed and refined foods accompanied by decreased physical activity has led to increased obesity and cardiovascular diseases.

The face of malnutrition is changing the manner in which it presents in some form or another in nearly all countries. There is currently a global pandemic of overweight and obesity. Simultaneously, the burden of disease in low- and middle-income countries is rapidly changing from communicable to noncommunicable illnesses. Yet micronutrient deficiencies are still an issue as seen in the rates of anemia and wasting, which have not changed substantially for more than 20 years. The World Health Organization (WHO) estimates that at least one-third of the world's population is affected by micronutrient malnutrition and that, in 2008, more than 1.4 billion adults over the age of 20 were overweight. In effect, no country is free of malnutrition, and many households, communities, and regions struggle with all of these forms of malnutrition at the same time. Countries are confronted with the burden of complex, overlapping, and interrelated malnutrition problems, with a combination of stunting in children under 5 years of age, anemia in women of reproductive age, and adult overweight and obesity being the most common. Less than 20 countries have only one of these manifestations of malnutrition at problematic levels in nationally representative survey data. These different conditions are connected not only at a physiological level but also at a resource and political level. As obesity is dealt with in other articles, this article will focus on malnutrition in terms of undernutrition and micronutrient deficiencies.

Definitions for the Discussion of Malnutrition

For clarity, several definitions are presented so as to better understand the context of malnutrition and how to distinguish its various forms.

Malnutrition

Malnutrition is defined as an abnormal physiological condition caused by inadequate, unbalanced, or excessive consumption of macronutrients, micronutrients, or both. Malnutrition includes undernutrition and overnutrition as well as micronutrient deficiencies.

Overnourishment

Overnourishment is defined as food and beverage intake that is continuously in excess of dietary energy requirements.

Overnutrition

Overnutrition is a result of excessive food intake relative to dietary nutrient requirements.

Overweight and Obesity

These comprise body weight that is above normal for height as a result of an excessive accumulation of fat. It is usually a manifestation of overnourishment and/or sedentary lifestyles and a lack of physical activity. Overweight is defined as a body mass index (BMI) of more than 25 kg m^{-2}, but <30 kg m^{-2}. Obesity is defined as a BMI of 30 kg m^{-2} or more.

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00439-6

Protein–Energy Malnutrition

Protein–energy malnutrition (PEM) is a classic medical terminology referring to a group of related disorders that include marasmus, kwashiorkor, and intermediate states of marasmus–kwashiorkor. This name implied that malnutrition is a deficiency of protein or energy and it is, as for other specific deficiencies, suggested that treatment should consist of proteins or energy. Textbooks usually went on to say that marasmus (extreme thinness) was due to a lack of energy and kwashiorkor (edematous malnutrition) was the result of a lack of proteins. This has now been proved incorrect due to the role of deficient intakes of essential micronutrients needed for growth and tissue renovation. Marasmus can occur with excess energy if no nutrients are ingested and kwashiorkor can become manifest even with excess protein in the diet.

Stunting

Stunting is also known as linear growth retardation, and it is defined as low height for age, reflecting a past episode or episodes of chronic undernutrition.

Undernourishment

Undernourishment is a state, lasting for at least 1 year, of inability to acquire enough food, defined as a level of food intake insufficient to meet dietary energy requirements.

Undernutrition

Undernutrition is the outcome of undernourishment, poor absorption, and poor biological use (bioavailability) of nutrients consumed as a result of repeated infectious/parasitic diseases, alone or in combination. It includes being underweight for one's age, too short for one's age (stunted), dangerously thin for one's height (wasted), and deficient in vitamins and minerals (micronutrient malnutrition).

Underweight

Underweight is defined as low weight for age in children and a BMI of <18.5 kg m^{-2} in adults, reflecting a current condition resulting from inadequate food intake, past episodes of undernutrition, or poor health conditions.

Wasting

Wasting is defined as low weight for height and is generally the result of weight loss associated with a recent period of acute hunger/starvation or disease.

Malnutrition and Mortality

The recent 2013 *Lancet* Series on Maternal and Child Nutrition highlights that undernutrition, including fetal growth restriction, suboptimum breastfeeding, stunting, wasting, and deficiencies of vitamin A, iodine, and zinc, causes 3.1 million deaths annually in children younger than 5 years. This represented a staggering 45% of the total child deaths in 2011. As part of this total, the combined distribution of suboptimum breastfeeding and fetal growth restriction in the neonatal period resulted in 1.3 million deaths or 19% of all deaths of children younger than 5 years. There is clear evidence about the importance of undernutrition as a predisposing factor of an increased risk of becoming ill or dying and as an antecedent condition of structural and functional limitation. During the acute stage of severe undernutrition, the greater susceptibility of the child to infectious disease is undoubtedly of major clinical significance and has important consequences for child mortality.

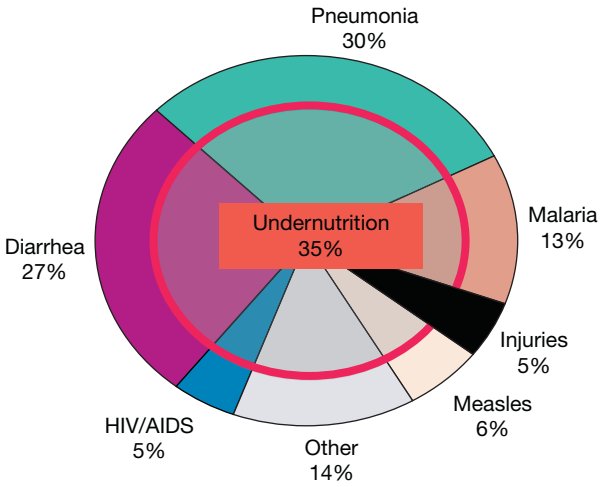

Figure 1 Undernutrition-related risk of death associated with specific diseases. UNICEF emergency nutrition network training course adapting *Lancet* 2008 data.

Figure 1 shows the contribution of different childhood illnesses on child mortality based on data from the 2008 *Lancet* Series on Maternal and Child Nutrition. As depicted, pneumonia (30%) and diarrhea (27%) comprise over 50% of childhood deaths. The area within the red circle represents the percentage of deaths due to the child being undernourished. Children with severe, moderate, or even mild undernutrition have a higher risk of mortality from these childhood illnesses than a well-nourished child. As such, undernutrition constitutes an underlying cause for most childhood deaths associated with severe infections.

Nutrition and Sustainable Development

The first International Conference on Nutrition held in Rome in 1992 called for a global commitment to address the problem of malnutrition. The Millennium Development Goals (MDGs) established in 2000 included the target of reducing the prevalence of underweight children and thus established an accountability mechanism to ensure global action. With the publication of the 2008 *Lancet* Series Maternal and Child Nutrition, the evidence base for effective actions to address malnutrition in these target populations was provided. However, in spite of the advances made to decrease hunger and achieve poverty goals and targets, much remains to be done.

Table 1 How investing in nutrition is critical to achieving the MDGs

Goal	*Nutrition effect*
Goal 1: Eradicate extreme poverty and hunger	Undernutrition erodes human capital through irreversible and intergenerational effects on cognitive and physical development
Goal 2: Achieve universal primary education	Undernutrition affects the chances that a child will go to school, stay in school, and perform well
Goal 3: Promote gender equality and empower women	Anti-female biases in access to food, health, and care resources may result in undernutrition, possibly reducing women's access to assets Addressing undernutrition empowers women more than men
Goal 4: Reduce child mortality	Undernutrition is directly or indirectly associated with most child deaths, and it is the main contributor to the burden of disease in the developing world
Goal 5: Improve maternal health	Maternal health is compromised by undernutrition, which is associated with most major risk factors for maternal mortality. Maternal stunting and iron and iodine deficiencies are common problems
Goal 6: Combat HIV/AIDS, malaria, and other diseases	Undernutrition may increase risk of HIV transmission, compromise antiretroviral therapy, and hasten the onset of full-blown AIDS and premature death. It increases the chances of tuberculosis infection, resulting in disease, and it also reduces malarial survival rates

Source: World Bank. (2006). *Repositioning nutrition as central to development. A strategy for large-scale action*. Washington, DC: The World Bank.

Across the globe, 805 million people are still suffering from chronic dietary energy insufficiency, 162 million children are stunted, 51 million children are wasted, and there are over two billion people who suffer from one or more micronutrient deficiencies.

Now that the end point of the MDGs is nearing, sustainable development has taken center stage as the prevailing priority post-2015. The role of nutrition emerges as the ideal example of a sustainable development objective. Table 1 shows the impact that undernutrition has on six of the eight MDGs.

Human and Economic Costs

Improving nutrition contributes to productivity, economic development, and poverty reduction by improving physical work capacity, cognitive development, school performance, and health by reducing disease and mortality. As demonstrated in the Copenhagen Consensus Center, who works with the world's top economists to research and publish the best solutions to global challenges, investing in nutrition is critical, as poor nutrition perpetuates the cycle of poverty and malnutrition through three main courses: (1) direct losses in productivity from poor physical status and losses caused by disease linked with malnutrition, (2) indirect losses from poor cognitive development and losses in schooling, and (3) losses caused by increased health-care costs. The economic costs of malnutrition are steep, amounting to several billion dollars a year in terms of lost gross domestic product.

Since early childhood offers a special window of opportunity to improve nutrition, the bulk of the investment needs to be targeted between prepregnancy and two years of age. Economic studies show that every dollar spent on nutrition in the first 1000 days of a child's life (fetus to age two) can give an average savings of $45 and in some cases as much as $166 (Figure 2).

SUN framework

In April 2010, a policy brief – Scaling Up Nutrition: A Framework for Action (SUN) – was released at joint meetings of the World Bank and the International Monetary Fund. It was a collective effort stimulated by the publication in January 2008 of the aforementioned *Lancet* Series on Maternal and Child Nutrition. The series encouraged an emphasis on the 1000-day window from the start of pregnancy to a child's second birthday, with interventions that both were cost-effective and yielded high returns for cognitive development, individual adult income, and economic growth.

The SUN Movement, which started in September 2010, is the most important symbol of the increased interest in nutrition. By 2014, the movement has grown to include more than 50 countries that are committed to the scale-up of direct nutrition interventions and the advancement of nutrition-sensitive development, including 21 of the 34 highest burden countries, in which 41% of the global burden of child stunting is located.

Undernutrition

Types of Malnutrition

Undernutrition is the outcome of undernourishment, poor absorption, and infectious/parasitic diseases, alone or in combination.

Undernutrition is a physical condition characterized by a nutritional disorder resulting from insufficient food intake (undernourishment) and/or poor absorption and poor biological use (bioavailability) of nutrients consumed as a result of repeated infectious disease, alone or in combination. It encompasses being underweight for one's age, too short for one's age (stunted), dangerously thin for one's height (wasted), and deficient (status and function) in vitamins and minerals (micronutrient malnutrition). Although the terms malnutrition and undernutrition are often used interchangeably, the first is more extensive in scope. In this article, both are used, but not interchangeably. Indeed, malnutrition is a nutritional disorder that can manifest itself in distinct forms:

(a) *Overnutrition*: a result of excessive food intake relative to dietary nutrient requirements. Previously more prevalent in developed countries, but now also appearing in countries with emerging economies.
(b) *Undernutrition*: as previously defined in the text. It is worth noting that different organizations have distinct definitions for this term. Some refer to it as an insufficient intake of nutrients to sustain a state in which the physical

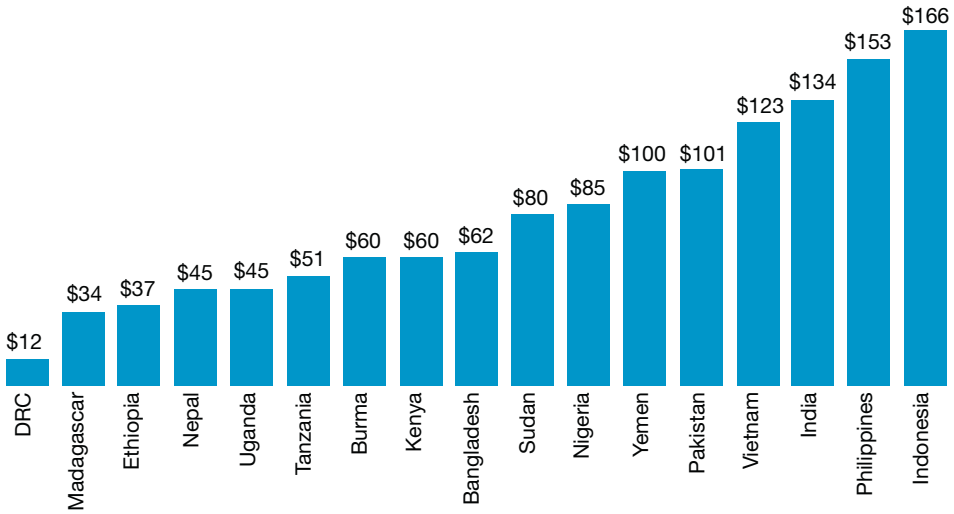

Figure 2 Reducing stunting: benefit for every dollar spent by country (discount rate = 3%, final working age = 50). Copenhagen Consensus Data.

function of an individual is impaired to the point where he or she can no longer maintain adequate bodily performance processes such as growth, pregnancy, lactation, physical work, and resisting and recovering from disease.

(c) *Secondary undernutrition*: not caused by diet but rather by diseases or pathological conditions (diarrhea, infections, measles, intestinal parasites, etc.) that prevent the body from absorbing ingested nutrients.

(d) *Micronutrient deficiency*: when essential micronutrients such as vitamins, minerals, or both are not present in adequate amounts in the diet.

The last three are common in developing countries in which varieties of undernutrition, also known as moderate acute malnutrition (MAM) or severe acute malnutrition (SAM), are the most relevant. These three situations, and especially undernutrition, are often referred to colloquially as hunger. In a given place and time, it undergoes a process of deterioration that is accompanied by other factors (impoverishment, epidemics, and often an increase in mortality), the situation turns into a famine. Undernutrition affects all age groups, but some are particularly vulnerable, mainly children (especially those between 6 months and five years, after weaning), the elderly, and pregnant and lactating women.

Currently, undernutrition is a problem that affects developing and industrialized countries, and in both cases, the most economically disadvantaged are those that are most affected. In developed countries, obesity is rapidly extending, especially among the poorest segments of the population, bringing with it an epidemic of nutrition-related noncommunicable diseases (NCDs) such as diabetes and cardiovascular disease, which increase health-care costs and reduce productivity. In developing countries, although undernutrition and micronutrient deficiencies continue to be very widespread, the swiftly spreading problem of obesity is also a burden. Currently, it is common to find underweight children and obese adults within the same household, in both developed and developing countries.

Manipulating market dynamics and prices fail to address the problem of undernutrition when families have no money to buy enough food or pay for health-care expenses. Advocacy linked to human rights and equity should be considered, as well as other initiatives related to income generation, thus justifying government intervention to support those families in need. However, undernutrition also occurs in many families with adequate economic resources, as people do not always know which foods or feeding practices are best for themselves or for their children, in which inadequate marketing practices from industry play a part. It may also be difficult for parents to know whether their children are starting to suffer from undernutrition as growth deficits and micronutrient deficiencies are not easily detected without previous training or education on the topic.

Table 2 shows the main problems of undernutrition throughout the life cycle.

Causes of undernutrition

The fundamental causes of undernutrition and mortality quite often fall outside the nutrition sector and are associated with each country's levels of potential resources (e.g., energy, geography, and climate), as well as with all the factors that condition their use, such as management of the population density in relation to the resources available, poverty, social inequalities, the side effects of growth-oriented macroeconomic policies on structural adjustment, and the migration to cities.

The classification of these causal chains can be simplified into three broad categories:

(a) *Food insecurity*: This includes problems of food production or supply at the national, regional, or household level, as well as problems of families and communities in accessing sufficient amounts of safe and nutritious food for normal growth and development and an active and healthy life. It may be caused by the unavailability of food, insufficient purchasing power, inappropriate distribution, or inadequate use of food at the household level. Food insecurity may be chronic, seasonal, or transitory and may be induced by a myriad of factors including agricultural and trade policies, wars, famine, and climate change, among others.

(b) *Poor conditions of health and sanitation*: The aspects of environmental hygiene include the supply of safe drinking

Table 2 Undernutrition throughout the life cycle, according to disorder and main consequences

Life cycle stage	*Nutrition disorder*	*Main consequences*
Embryo/fetus	• Intrauterine growth retardation • Iodine deficiency disorders • Lack of folate	• Low birth weight • Prematurity • Incomplete nervous system development • Stillbirth
Neonate (newborn)	• Low birth weight • Iodine deficiency disorders	• Growth retardation/failure to thrive/deafness • Delayed cognitive development • Anemia
Infants and children	• Protein energy malnutrition • Iodine deficiency disorders • Vitamin A deficiency • Iron deficiency anemia	• Chronic undernutrition • Delayed physical and cognitive development • Increased risk of infections • Blindness • Anemia
Adolescents	• Protein energy malnutrition • Iodine deficiency disorders • Vitamin A deficiency • Iron deficiency anemia	• Delayed growth spurt • Stunting • Delayed intellectual development • Goiter • Increased risk of infections • Blindness • Anemia • Inadequate bone mineralization
Pregnant and breastfeeding women	• Protein energy malnutrition • Iodine deficiency disorders • Vitamin A deficiency • Iron deficiency anemia • Folate deficiency • Calcium deficiency	• Inadequate prenatal weight gain • Maternal anemia • Increased maternal mortality risk • Increased risk of infection • Night blindness • Increased risk of fetal mortality • Low birth weight
Adults	• Protein energy malnutrition • Iodine deficiency disorders • Obesity • Nutrition-related diseases	• Thinness • Permanent fatigue • Obesity • Cardiac disease • Diabetes • Cancer • Arterial hypertension/myocardial infarct • Anemia
Elderly	• Protein energy malnutrition • Iodine deficiency disorders • Obesity • Osteoporosis • Nutrition-related diseases	• Obesity • Vertebral and hip fractures • Cardiovascular disease • Diabetes • Cancer • Cognitive impairment

water and food products, sanitation of the environment in all its forms, and hygienic practices of the population. Health aspects address the areas of infectious and parasitic diseases, on the one hand, and the systems and utilization of health care, on the other.

(c) *Inappropriate care and feeding practices*: The concept of the provision of care and feeding practices refers both to care at the household level and to the broader aspects of solidarity and social protection at the community or national level. Thus, it encompasses the full range of maternal and child care, with mothers and children constituting the principal at-risk groups. In general, it refers to the attitudes and practices of the members of the household or community toward the most vulnerable members in their social sphere (i.e., available time, food distribution, and emotional and material support), as well as the educational level of the caregivers (Figure 3).

The United Nations Children's Fund (UNICEF) conceptual framework, which the Nutrition Community has been using for programming over the past three decades, identifies three levels of causes of undernutrition: immediate, underlying, and basic. It schematically illustrates the multifactorial and interconnected causes that usually form the conceptual basis of 'nutrition security,' in other words, achieving good nutritional status through the control of the different determinants of undernutrition, with particular attention to the underlying causes. This analysis must be, however, more specifically tailored to each local situation, as well as the selection of

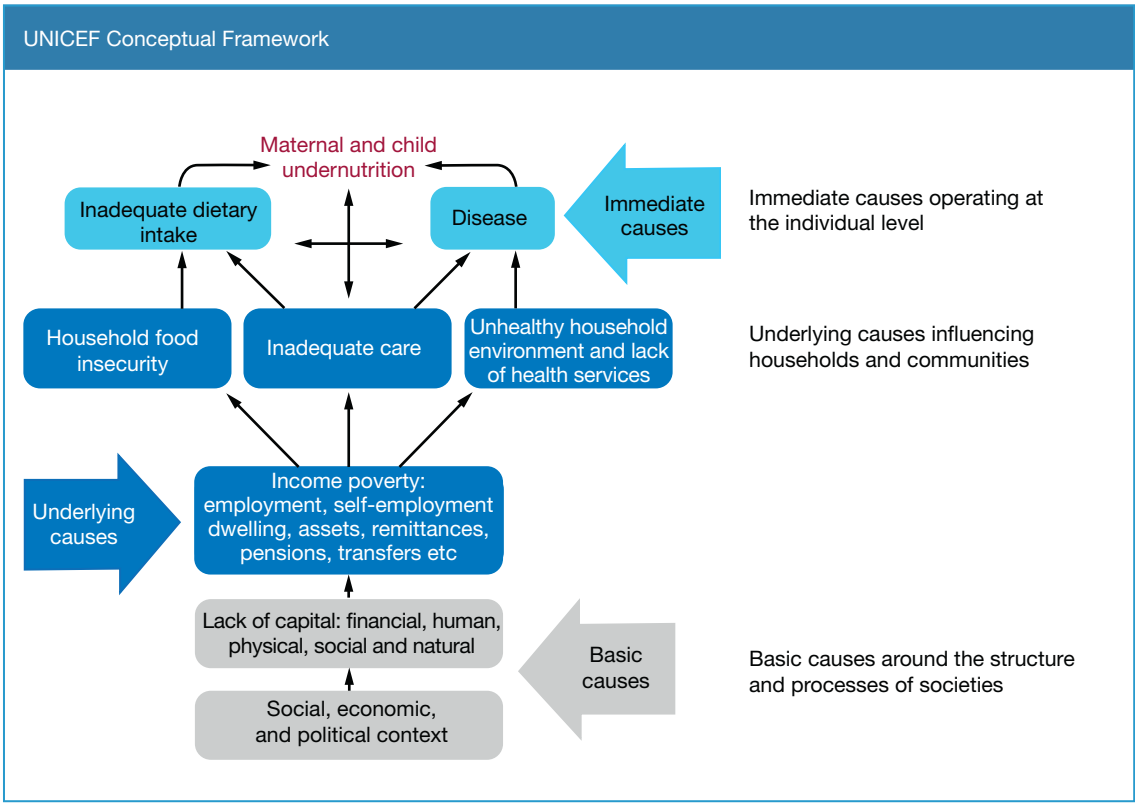

Figure 3 Conceptual framework of the causes of undernutrition. UNICEF (2011).

Box 1 Why does undernutrition occur in food-secure households?

- Pregnant and breastfeeding women have inadequate intakes of calories and protein, and infections – such as sexually transmitted diseases – if left untreated can cause low birth weight and insufficient rest.
- Mothers lack sufficient time to care for small children or for themselves.
- Mothers of newborns discard their colostrum, or first milk, which contains substances that strengthen the immune system of the child.
- In many cases, instead of exclusively breastfeeding, mothers of babies younger than 6 months give them foods other than breast milk, which constitutes the best source of nutrients and protection against infectious and chronic diseases.
- Caregivers wait too long to start giving weaning foods.
- Caregivers give children under two too little food or foods with low-energy content.
- Although foods are available, there is inadequate distribution within the household, usually at the expense of women and young children whose diets are often times insufficient in proteins or micronutrients.
- Children's caregivers do not follow recommendations for feeding when the child has diarrhea or fever, or shortly thereafter.
- Due to a lack of hygiene on the part of caregivers, foods become contaminated with bacteria or parasites.

Source: World Bank 2006

appropriate indicators corresponding to the distinct causal levels and to each determinant.

As we have seen and contrary to popular belief, undernutrition/malnutrition is not simply a result of food insecurity. Many children from environments that are food secure and from families with economic resources are below the normal weight or have short stature (stunting), due to inappropriate infant feeding and care, poor access to health-care services, or inadequate sanitation. As shown in Box 1, the World Bank in 2006 has outlined a scenario for the occurrence of undernutrition even in households that do not meet the criteria of food-insecure.

In many countries where undernutrition is widespread, food production is not the limiting factor, with the exception of famine cases. The most important factors are as follows: firstly, insufficient knowledge about the benefits of exclusive breastfeeding, complementary feeding practices, and the function of micronutrients and, secondly, the lack of time a woman has to adequately care for their babies or for themselves during pregnancy. The most pernicious effects of undernutrition occur during pregnancy and the first 2 years of life, and the consequences of such early damage to health, brain development, intelligence, and possibilities of benefiting from education and productivity are largely irreversible. There is evidence suggesting that obesity and NCDs such as cardiovascular disease and diabetes may also have their origins in early childhood. As such, some have criticized the classification of malnutrition into undernutrition and overnutrition as being simplistic due to the interrelationship between the two.

Causal Determinants

Biological and Dietary Factors

Maternal undernutrition can result in intrauterine undernutrition and low birth weight, among others. Insufficient food intake to allow for compensatory growth that could offset this situation brings about the onset of SAM in early life stages.

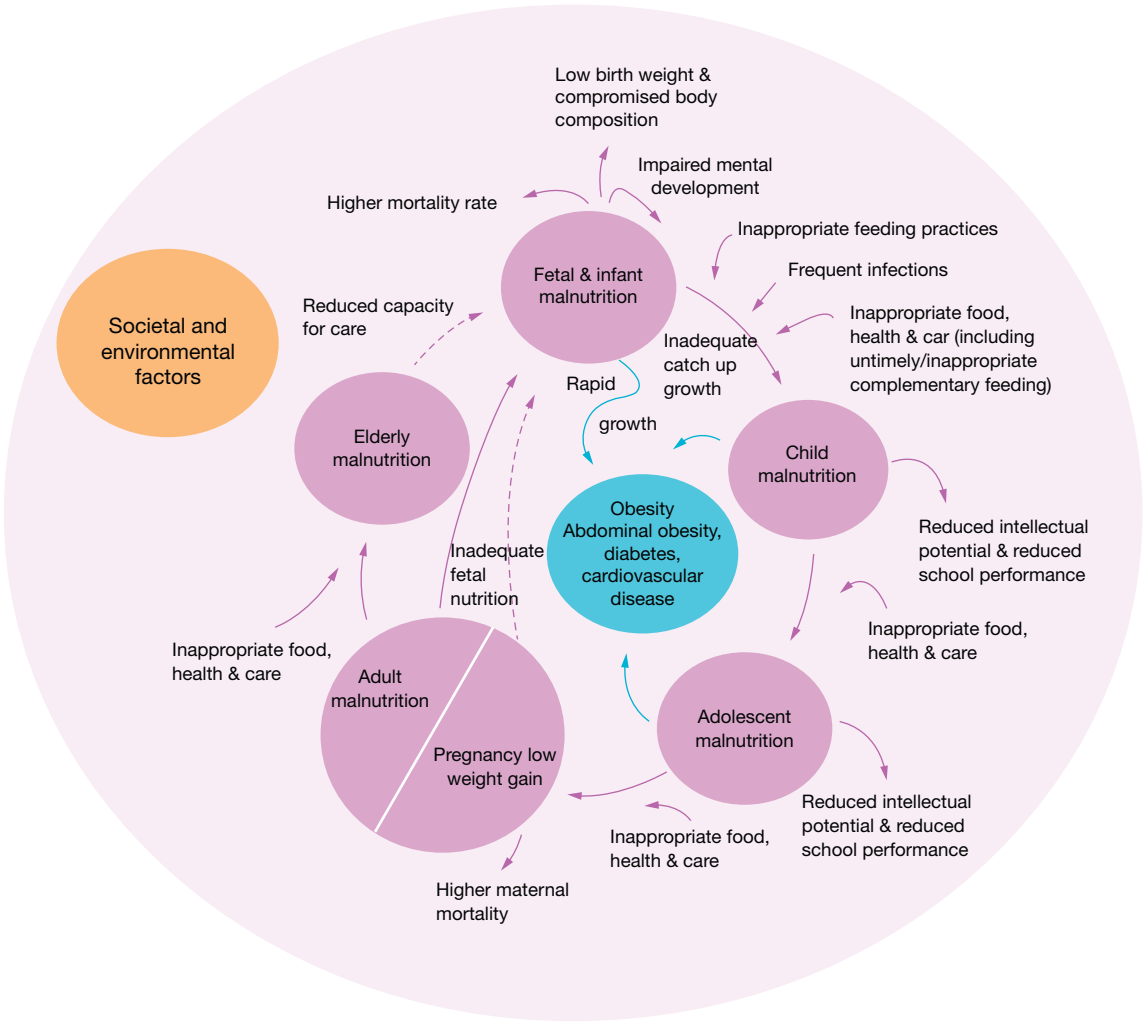

Figure 4 Life course: The proposed causal links of malnutrition. Reproduced from Darnton-Hill, I., Nishida, C. and James, W. P. T. (2004). A life course approach to diet, nutrition and the prevention of chronic diseases. *Public Health Nutrition* **7**(1A), 101–121.

Figure 4 shows the vicious circle of undernutrition. When a woman who is undernourished during pregnancy does not improve her nutritional status, the newborn presents with low birth weight. If that child is inadequately fed, it grows up being undernourished; and if the poor diet continues, the child will become an undernourished adult. If female, when this undernourished woman becomes pregnant, she will give birth to an undernourished infant, perhaps with difficulty through a narrowed pelvis, and the cycle is perpetuated.

Socioeconomic Factors

Poverty is often associated with undernutrition due to reduced access to food, unsanitary living conditions, overcrowding, and inadequate child care. Lack of knowledge leads to poor child care practices, misconceptions about the use of various foods, inadequate feeding practices during illness, and inadequate distribution of food among family members. The reduction in the initiation and duration of breastfeeding, combined with inadequate weaning practices, is also associated with high rates of childhood undernutrition.

Social problems, such as the physical and emotional abuse of children, maternal deprivation, neglect of the elderly, alcoholism, and drug addiction, can lead to the onset of undernutrition. Moreover, cultural and social practices that impose taboos and prohibit given foods, certain diet fads, and the precarious conditions that characterize the migration from traditional rural areas to urban poverty zones also contribute to the development of undernutrition (Figure 5).

Environmental Factors

Overcrowded housing and poor sanitation favor the emergence of frequent infections and infectious disease outbreaks such as Ebola. Natural disasters, such as droughts or floods, and human-induced disasters, such as wars and forced migration, produce sudden, prolonged, or cyclical food shortages and can produce undernutrition in large population groups. New studies have brought to light the impact of global climate change, which is projected to reduce future crop yields and thus threaten food security and eliminate much of the improvement in child undernutrition levels

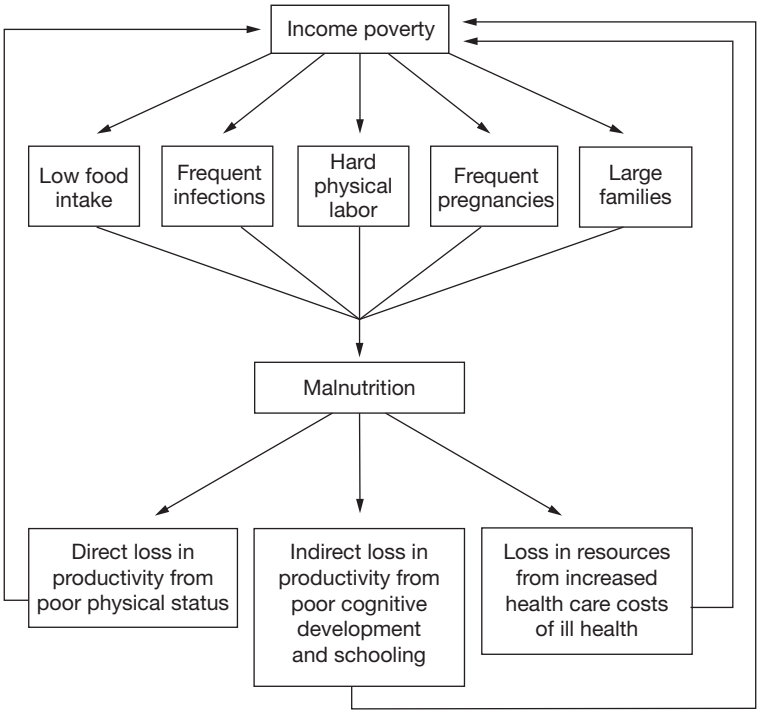

Figure 5 Vicious cycle of poverty and malnutrition. Reproduced from World Bank (2006). *Repositioning nutrition as central to development. A strategy for large-scale action*. Washington, DC: The World Bank.

that would occur with no climate change. Simon Lloyd's research estimated that climate change would lead to a relative increase in moderate stunting of 1–29% in 2050 compared with a future without climate change. This study also predicted that climate change would have a greater impact on severe stunting rates, projected to increase from 23% (central sub-Saharan Africa) to 62% (South Asia). Moreover, losses would be exacerbated by the additional loss of food postharvest due to bad storage conditions as well as inadequate systems of food distribution, thus also contributing to the development of undernutrition, even after periods of agricultural abundance.

Epidemiology

The 2014 FAO estimates indicate that global undernutrition rates continue their downward trend. About 805 million people were estimated to be chronically undernourished in 2012–14, a reduction of more than 100 million over the last decade and of 209 million since 1990–92.

Nonetheless, worldwide, approximately one in every nine people still suffers from insufficient food intakes to maintain an active and healthy life. The majority of these undernourished people live in developing countries, where an estimated 791 million were chronically hungry (undernourished) in 2012–14. Although developing countries have also shown the most improvements in the last two decades – reducing the overall number of undernourished people by 203 million since 1990–92 – around one of eight people in these regions (13.5% of the overall population) remains chronically underfed. Figure 6 compares the numbers and proportion of undernourished people by region. The MDG hunger target aims to halve the *proportion* of undernourished people, whereas that of the World Food Summit (WFS) was more ambitious – to halve the *number* of undernourished people by 2015. Meeting the MDG hunger target seems to be within reach, but not that of the WFS.

As depicted in Figure 6, despite the progress in developing regions as a whole, significant differences are seen across regions. East Asia and Southeast Asia have already met the MDG hunger target. The same is true for Latin America and the Caribbean, whereas the Caucasus and Central Asia are projected to reach the MDG objective by the end of 2015. Latin America and the Caribbean are also expected to reach the more ambitious WFS goal. In contrast, sub-Saharan Africa and South and West Asia have not shown sufficient progress to achieve the MDG target. Sub-Saharan Africa has become home to more than a quarter of the world's undernourished people, owing to an increase of 38 million in the number of hungry people since 1990–92.

According to UNICEF data, worldwide, 99 million children under 5 years old were underweight in 2013, two-thirds of which lived in Asia and around one-third in Africa. Underweight prevalence continues to decline, but at a slow pace. Between 1990 and 2013, it decreased from 25% to 15% of the under-five population worldwide. If current trends continue, the MDG 1 target (halving the 1990 underweight prevalence by 2015 at the global level) will not be met. Three regions have already met or exceeded the target: East Asia and the Pacific, Latin America and the Caribbean, and Central and eastern Europe and the Commonwealth of Independent States (CEE/CIS). Africa has experienced the smallest relative decrease, with underweight prevalence of 17% in 2013, down from 23% in 1990; Asia reduced underweight prevalence during the same period from 32% to 18% and in Latin America and the Caribbean from 8% to 3%.

	Number (*millions*)		Regional share (%)	
	1990–92	2012–14	1990–92	2012–14
A Developed regions	20	15	2.0	1.8
B Southern Asia	292	276	28.8	34.3
C Sub-Saharan Africa	176	214	17.3	26.6
D Eastern Asia	295	161	29.1	20.0
E South-Eastern Asia	138	64	13.6	7.9
F Latin America and the Caribbean	69	37	6.8	4.6

J Oceania	1	1	0.1	0.2
Total	1015	805	100	100

Figure 6 The changing distribution of hunger in the world: numbers and shares of undernourished people by region, 1990–92 and 2012–14. Reproduced from FAO (2014).

In children under 5 years of age, 15% were classified as being underweight, and an additional 8% suffered from SAM/undernutrition. Sixty percent of all cases with acute undernutrition are found in just ten countries. A total of 32 countries account for 10% or more of children under 5 years with SAM of the type that requires urgent treatment and for which WHO has developed community- and clinic-based protocols.

UNICEF data show that, in early childhood, there are no substantial differences in nutritional status based on gender. However, this changes dramatically during adolescence, in which a greater propensity of females presents with undernutrition and anemia. In this light, India, Bangladesh, Niger, and Senegal show the highest rates of adolescent females with a BMI falling below the recommended levels. Additionally, the majority of girls marry before the age of 18, which exposes them to high-risk pregnancies and the risk of increased maternal and infant mortality rates.

Severe Acute Malnutrition

SAM was previously known as PEM, or protein–calorie malnutrition, and is an important nutritional condition in developing countries due to its high prevalence and its association with high rates of infant mortality, changes in growth and development, and decreased ability to work, altogether leading to inadequate social and economic development.

SAM occurs when the diet does not provide sufficient protein, energy substrates (calories), or both, to satisfy the body's nutritional needs. It is usually also associated with a deficiency of vitamins and minerals and essential micronutrients needed for growth and tissue renovation. The term SAM includes severe clinical syndromes of kwashiorkor (edema), marasmus (without edema), marasmic–kwashiorkor (edema and the combination of chronic energy deficiency and chronic or acute protein deficiency), and mild and moderate cases that are much more numerous than severe forms. The term 'malnutrition' is generally used in common vernacular to refer to SAM.

SAM may be of primary or secondary origin. Primary SAM is caused by inadequate nutrient intake. Secondary SAM results from disorders or drugs that interfere with nutrient use, such as cases of diseases accompanied by low food intake, inadequate nutrient absorption or utilization, increased nutritional requirements, increased nutrient losses, or any or all of these factors. Although SAM is mainly an issue in early childhood, it may also occur in older children and adults, particularly the elderly. This article focuses on primary SAM of gradual onset, with predominance of metabolic disorders and clinical features of protein and energy deficiency.

Physiopathology and Reductive Adaptation

The body tends to maintain a dynamic balance in energy intake through a series of physiological mechanisms. When there are long periods of energy and/or protein restriction, the body gradually adapts to this restriction in order to maintain an adequate functional state within the margin that the limited nutrient supply allows.

Nutrient reductive adaptation represents the phenomenon that the body undertakes in order to survive two synergistic assaults, the lack of nutrients and frequent infections. It does so by modifying normal biological patterns and creating new homeostatic conditions. SAM progresses gradually and thus allows for the following series of metabolic adjustments that result in a reduction in nutrient requirements and a nutritional balance compatible with lower availability of cellular nutrients. If at this point the nutrient supply continues to be increasingly lower than that accepted by the body in its adaptive state, death ensues. However, although in the majority of cases, this nutrient supply is low, it is not sufficient to cause death and the individual is capable of living in an adaptive state with decreased intake.

Mobilization and Energy Expenditure

Energy expenditure falls rapidly after the reduction of caloric intake; this explains the diminished periods of play and physical activity observed, as well as longer periods of rest and less physical work. When the decrease in energy expenditure cannot compensate for insufficient intake, body fat reserves are mobilized and the adipose tissue and body weight decrease. Lean body mass is reduced at a lower rate as a result of muscle protein catabolism, which increases the amino acid pool. As the energy deficiency becomes more serious, subcutaneous fat is significantly reduced and the catabolism of proteins leads to muscle wasting. Visceral proteins are preserved for a longer period of time.

Protein Metabolism

The lack of dietary proteins reduces protein synthesis. Reductive adaptations allow for preserving structural proteins and maintaining essential functions that depend on proteins. This leads to enzymatic changes that favor the degradation of muscle protein, the reduction of hepatic protein synthesis, and the mobilization of energy substrates from fat deposits. When the nonessential tissue proteins are depleted, visceral organ proteins are employed and death may be imminent if nutritional therapy is not initiated.

Protein half-life increases, the rate of albumin synthesis decreases, and albumin is transferred from extravascular to intravascular reserves to maintain adequate levels of circulating albumin in light of their reduced synthesis. Adaptive mechanisms fail when protein depletion is very severe and their concentration in serum decreases. Secondary reduction of intravascular oncotic pressure and leakage of fluid into the extravascular space contribute to the formation of edema in kwashiorkor.

Endocrine Changes

There is a reduction in the activity of hormones involved in the increase of body reserves, elevation of metabolism, and nonvital functions related to growth, such as insulin, somatomedin (or insulin-like growth factor), thyroid hormones, and gonadotropins.

The activity of glucocorticoids is normal or elevated, which favors the functional catabolism of the hypothalamus–pituitary axis, whereas the adrenal medulla is kept normal, which allows for adequate endocrine and metabolic responses under conditions of stress. Some researchers have postulated that the evolution of MAM into kwashiorkor or marasmus (SAM) may be due, in part, to differences in the adrenocortical response. A better response would make it possible to more efficiently maintain visceral protein integrity, thus resulting in marasmus, which is associated with improved adaptation.

Hematology and Oxygen Transport

The decrease in hemoglobin concentration and red blood cells that is observed in almost all serious cases of SAM constitutes an adaptive phenomenon related, at least in part, to tissue oxygen requirements. The decrease in lean body mass and lower physical activity levels in patients with undernutrition also lessen the demand for oxygen. The simultaneous decrease of amino acids provided in the diet results in a decrease in hematopoietic activity, as amino acids are reserved for the synthesis of other more necessary proteins. As tissues receive enough oxygen, this response should be considered as an adaptive mechanism and not as a 'functional' form of anemia. When the synthesis of the tissue, lean body mass, and physical activity improve with diet therapy, the demand for oxygen increases and it becomes necessary to accelerate hematopoiesis. If there is a lack of sufficient iron, folic acid, and vitamin B_2, functional anemia with secondary tissue hypoxia will appear.

Other Physiological and Metabolic Changes

Not all of the pathophysiological changes in SAM lead to beneficial life-preserving reductive adjustments. Certain functions are affected and some nutrient reserves decrease, making it more likely that the undernourished patient will undergo alterations with serious repercussions.

Cardiovascular and renal functions

Cardiac output, heart rate, and blood pressure decrease and central circulation takes on greater importance than peripheral circulation. Cardiovascular reflexes are altered and cause postural hypotension and decrease in venous return. The main form of hemodynamic compensation is tachycardia without increasing the ejection volume rate. Both the renal plasma flow and glomerular filtration rate may decrease because of the reduced cardiac output, while apparently, the ability to excrete liquids and concentrate and acidify urine remains intact.

Immune system

The main effects observed in SAM seem to affect T lymphocytes and the complement system. The number of lymphocytes that originate in the thymus gland is drastically reduced and the gland atrophies. Furthermore, the depletion of T lymphocytes in the spleen and lymph nodes is observed. In SAM, the production of various complement components decreases. These deficiencies can account for the great propensity to sepsis by gram-negative bacteria. As a consequence, such changes lead to increased susceptibility to infections and to severe complications. There is a well-known link between undernutrition and increased risk of infection as depicted in Figure 7.

Electrolytes

Total body potassium decreases due to the reduction in muscle proteins and the loss of potassium from the intracellular compartment. The low action of insulin and the decreased energy within the cell reduce the availability of ATP and phosphocreatine. This leads to the entrance of sodium and water into the cell, with consequent intracellular overhydration.

Gastrointestinal functions

The absorption of lipids and disaccharides may become altered and the velocity of glucose absorption decreases in severe protein deficiency. Moreover, reduced production of gastric, pancreatic, and biliary substances occurs. These changes further affect altered absorptive function brought on by diarrhea and perhaps also by irregular bowel motility and

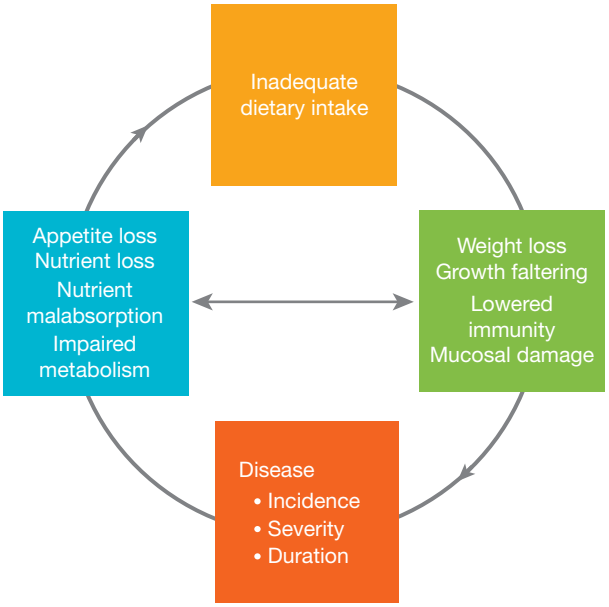

Figure 7 Relationship between undernutrition and infection. Reproduced from East, Central, and Southern African Health Community (ECSA-HC), Food and Nutrition Technical Assistance Project (FANTA), and LINKAGES Project (2008). *Nutrition and HIV/AIDS: a training manual for nurses and midwives*. Arusha, Tanzania: ECSA-HC.

gastrointestinal bacterial overgrowth. Diarrhea increases malabsorption and can further aggravate compromised nutritional status.

Central and peripheral nervous system

Patients who present with SAM at an early age may have decreased cerebral growth, nerve myelination, neurotransmitter production, and nerve conduction velocity. It is still not clear what the long-term functional implications are of these alterations and they have not been associated with subsequent behavior or level of intelligence.

Rupture of Adaptive Responses

When the cells and tissues of affected patients fail to obtain sufficient energy for proper functioning, a series of compensatory mechanisms are produced including hypoglycemia, hypothermia, altered circulatory and renal functions, acidosis, coma, and death. These events can take place rapidly, within a matter of hours.

Infections may cause serious metabolic disorders due to an increase in protein catabolism and loss of nitrogen, mobilization of nitrogen metabolism to acute-phase protein synthesis, alterations in energy metabolism, and/or production of free radicals.

Clinical Manifestations and Classification

Mild and MAM

Its main clinical feature is weight loss with notable thinning accompanied by a reduction in subcutaneous adipose tissue. WHO/UNICEF defines MAM as a weight for age between −3 and −2 *z*-scores below the median of the WHO Child Growth Standards (see section on '**Anthropometric Indicators for Measuring Malnutrition**' in this article). The criteria for mid-upper arm circumference (MUAC) measurements are having an MUAC from 115 to <125 mm. MAM can be due to a low weight for height (wasting) or a low height for age (stunting) or to a combination of both. Similarly, moderate wasting and stunting are defined as a weight for height and height for age, respectively, between −3 and −2 *z*-scores.

MAM affects many children in poor countries. Children with moderate malnutrition are at increased risk of mortality and MAM is associated with a high number of nutrition-related deaths. If some of these moderately malnourished children do not receive adequate support, they may progress toward SAM (severe wasting and/or edema) or severe stunting (height for age less than −3 *z*-scores), which are both life-threatening conditions.

Children with mild to moderate malnutrition tend to be more sedentary and participate less frequently in games and activities that require some degree of physical exertion. Older children and adolescents may show a reduction in their ability to perform strenuous physical work for prolonged periods. Other nonspecific manifestations include pallor, apathy, shortened attention span (particularly in school settings), and frequent episodes of diarrhea. Clinical lab tests do not contribute to the diagnosis of mild or moderate malnutrition.

Severe Acute Malnutrition

In addition to clinical manifestations, the dietary and clinical histories of the patient are important for diagnosis. Marasmus is usually associated with food shortages, prolonged semi-starvation, premature weaning, and extended time intervals between the administration of foods to infants and young children. Kwashiorkor is often associated with low-protein intake, late weaning with inadequate complementary feeding practices, and current or recent episodes of diarrhea or measles. Various bouts of infectious diseases and chronic or recurrent diarrhea occur frequently. WHO/UNICEF classification of SAM is based on presenting with weight for height (W/H) < −3 SD or MUAC <115 mm or edema, any of which is accompanied by complications such as lack of appetite, fever ≥38.5 °C, hypothermia ≤35.5 °C, vomiting, or severe dehydration.

Wasting refers to children that are too thin for their height and is a common manifestation of SAM. The WHO global nutrition target on wasting is to reach or maintain levels below 5% by 2025. Weighted quartiles (in populations of stunting in children under 5 years of age) based on 119 countries with data between 2005 and 2012 show that 9 countries with wasting rates ≥15.7% (3rd quartile) total more than 55% of the global estimated number of wasted children (Bangladesh, Chad, Djibouti, India, Niger, Papua New Guinea, South Sudan, Sudan, and Timor-Leste). Given that wasting rates can change rapidly, the composition of the list countries with very high wasting levels is also extremely variable.

Marasmus

Marked muscle wasting and the extreme reduction of subcutaneous fat in cases with severe nonedematous SAM present with

Figure 8 Nutritional marasmus with severe wasting. Reproduced from Latham, M. C. (2002) Human nutrition in developing countries. FAO (ed.), *Food and nutrition series — number 29*. Rome: United Nations Food and Agriculture Organization.

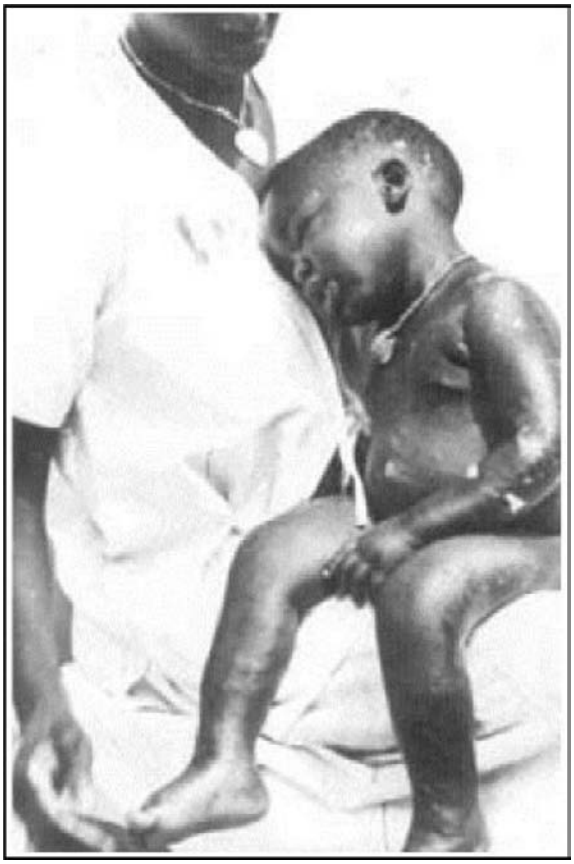

Figure 9 Kwashiorkor. Reproduced from Latham, M. C. (2002) Human nutrition in developing countries. FAO (ed.), *Food and nutrition series — number 29*. Rome: United Nations Food and Agriculture Organization.

a 'skin and bones' appearance. Children with marasmus frequently have 60% or less of the expected weight for height and suffer from short stature. Their hair tends to be dry, thin, and dull and at times lacking in quantity (Figure 8).

Children with marasmus often show complications such as acute gastroenteritis, dehydration, respiratory infections, and eye lesions due to hypovitaminosis A. Systemic infections can lead to septic shock or disseminated intravascular coagulation syndrome with high mortality rates. Obtaining a medical history plays an important role for the differential diagnosis of SAM secondary to AIDS, tuberculosis, cancer, and other debilitating diseases.

Kwashiorkor

The main feature is mild edema, being palpable without pain and usually presenting in the feet, ankles, and legs but, in severe cases, possibly extending to the perineum, upper extremities, and the face. Many patients have pellagroid skin lesions at the edema sites and in areas of pressure or frequent irritation. The skin can be erythematous and shiny in the regions of edema, alternating with areas showing dry, hyperkeratosis, and hyperpigmentation that tend to converge. Where the epidermis becomes dark and dry, it splits open when stretched to reveal pale areas between the cracks ('lacquered flaky paint' and 'crazy pavement dermatosis'), leaving exposed tissues that become infected easily. Subcutaneous fat tends to be preserved, and there may be some degree of muscle wasting. Weight loss, after correcting for edema, is usually not as severe as in marasmus. Children may have short or normal stature, depending on the length of the current episode and their nutritional history (Figure 9).

The hair is dry, brittle, and dull and can be pulled out easily without causing pain. Curly hair becomes straight and pigmentation changes usually acquiring a brownish, reddish, or yellow-white tone. Patients who alternately undergo periods of very poor and relatively good intakes of protein may present with alternating bands of depigmented and normal hair.

Patients have the same complications as described for marasmus cases, but diarrhea and respiratory and skin infections are more frequent and severe. Apart from diarrhea, they frequently present with anorexia and postprandial vomiting. These general conditions improve as nutrition therapy progresses, without specific treatment for gastrointestinal disorders. Kwashiorkor cases may have infections without fever, tachycardia, shortness of breath, or leukocytosis, making diagnosis difficult. The most frequent causes of death are pulmonary edema with bronchopneumonia, gastroenteritis, septicemia, and electrolyte disturbances. A differential diagnosis of other conditions that cause hypoproteinemia and edema should be carried out, as well as secondary undernutrition due to alterations in metabolism and protein absorption.

Marasmic–Kwashiorkor

This form of edematous SAM combines the clinical features of marasmus and kwashiorkor. The major manifestations are the edema of kwashiorkor with or without skin lesions accompanied by the muscle wasting and subcutaneous fat reduction characteristic of marasmus. In the initial stages of treatment, once the edema is resolved, the patient acquires an appearance that is very similar to the child with marasmus. The patient's biochemical profile is characteristic of kwashiorkor and marasmus but the alterations due to severe protein deficiency are those that predominate.

Long-Term Consequences

Studies assessing cognitive development indicate that there is a close interrelationship between undernutrition and intellectual development. In recent years, progress has been made for improved recovery of neurological development in severely undernourished infants when they are systematically stimulated as part of their treatment. Augmented deterioration observed in severely undernourished children is mostly due to electrolyte imbalance, gastrointestinal disorders, cardiovascular or kidney insufficiency, and compromised immune function to combat infections. The psychological alterations can also be profound. Severe anorexia, apathy, and irritability make the child difficult to feed and handle, making prognosis more precarious.

In general, death is secondary to bronchopneumonia, gram-negative septicemia, severe infections, and acute cardiovascular, hepatic, and renal failure. The signs and symptoms of severe vitamin and mineral deficiencies may also be of critical importance and may become manifest during early rehabilitation if an adequate supply of these nutrients is not provided. The clinical picture may be complicated by a severe folate, thiamin, and niacin deficiency with or without associated acute deficiency of potassium, sodium, and magnesium as well as chronic deficiency of iron, zinc, copper, and chromium.

Chronic Undernutrition

A child who suffers from chronic undernutrition experiences delay in his or her growth. This growth retardation is measured by comparing the height of the child with the standard recommended for their age. It indicates a lack of the necessary nutrients over an extended period of time and, thus, the increased risk of becoming ill and the subsequent effects of these events on the physical and intellectual development of the child. Chronic undernutrition, although a problem of greater magnitude in terms of the number of children affected, has up until recently received less attention than more acute forms of undernutrition.

Stunting

Chronic undernutrition is reflected in stunting, the indicator measuring length/height for age and is defined as having a length-/height-for-age *z*-score that is more than two standard deviations (SD) below the age–sex median for a well-nourished reference population. Stunting is a largely irreversible outcome of chronic inadequate nutrition and repeated bouts of infection during the first 1000 days of a child's life. Almost all stunting takes place in the first 1000 days after conception.

Specifically, factors that impact on stunted growth and development include poor maternal nutrition and health, inadequate infant and young child feeding practices (non-exclusive breastfeeding and complementary feeding that is limited in quantity, quality, and variety), and infection. Special importance is placed on maternal nutritional and health status before, during, and after pregnancy, which determines a child's early growth and development, beginning in the womb. Maternal contributors to stunting include inadequate nutrition during pregnancy leading to low birth weight, maternal short stature, short birth spacing, and adolescent pregnancy. The latter impairs nutrient availability to the fetus due to the competing demands of the adolescent mother's own growth.

Stunting has long-term effects on individuals and societies, including diminished cognitive and physical development, reduced productive capacity and poor health, and an increased risk of degenerative diseases such as diabetes. In fact, stunted children who experience rapid weight gain after 2 years of age show an increased risk of becoming overweight or obese later in life, thus increasing the risk of coronary heart disease, stroke, hypertension, and type 2 diabetes onsets. As for the economic impact, the World Bank estimates show that a 1% loss in adult height due to childhood stunting is associated with a 1.4% loss in economic productivity.

The Role of Fetal Growth Restriction

The most common definition of intrauterine growth restriction is a fetal weight that is below the 10th percentile for gestational age as determined through an ultrasound. This can also be called small for gestational age (SGA) or fetal growth restriction. New findings in the 2013 *Lancet* series highlight the impact of SGA on attributable neonatal deaths. Thirty-two million babies were born SGA, and about 800 000 neonatal deaths and 400 000 postneonatal infant deaths could be attributed to the increased risk associated with having fetal growth restriction. These new data contradict the widespread assumption that SGA infants, as compared to preterm babies, are not at a substantially increased risk of mortality. Additionally, infants who are SGA have an increased risk of growth faltering in the first 2 years of life. Causes of childhood growth faltering are multifactorial, but fetal growth restriction might be an important contributor to stunting and wasting in children. The 2013 *Lancet* Series on Maternal and Child Nutrition demonstrated that about 20% of childhood stunting could have its origins in the fetal period, as shown by being born SGA. As such, there is now impetus to focus attention on preventing SGA by scaling up prenatal nutrition interventions. In 2010, 32.4 million babies were born SGA, with 27% of all births occurring in low- and middle-income countries (LMIC). Figure 10 shows the prevalence of SGA by UN LMIC regions with higher rates occurring in Asia and Africa.

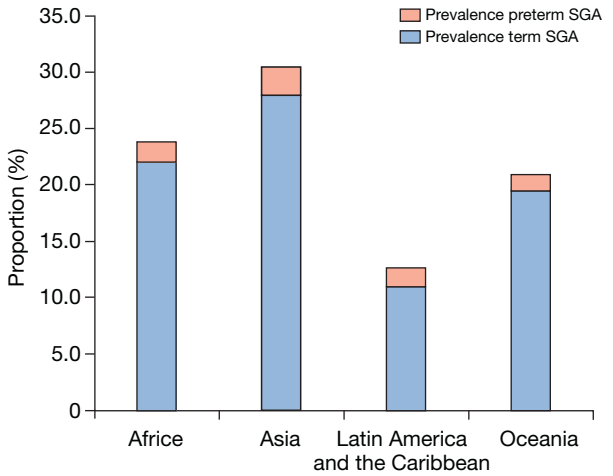

Figure 10 Prevalence of small-for-gestational-age births, by UN regions. Reproduced from Black, R. E., Victora, C. G., Walker, S. P., et al. (2013). Maternal and child undernutrition and overweight in low-income and middle-income countries. *The Lancet* **382**, 427–451.

Epidemiology

Stunting remains widespread in LMIC. Robert Black's analysis estimated that in 2011, 165 million children in LMIC were stunted. East and West Africa and south-central Asia have the highest prevalence estimates in UN subregions with 42% (East Africa) and 36% (West Africa and south-central Asia). There has been a dramatic reduction in the prevalence of stunting in Asia, from 49% in 1990 to 28% in 2010, nearly halving the number of stunted children from 190 to 100 million. Nevertheless, the majority of those stunted remain in Asia, with India being the country having the largest number of stunted children under 5 years of age – about 61.7 million. The stunting prevalence in Africa has stagnated at about 40% since 1990 and accounts for the second largest regional share of world stunting, a share that is increasing.

Eighty percent of stunted children live in 24 countries. Six of the 10 countries (India, China, Nigeria, Pakistan, Indonesia, Bangladesh, Ethiopia, the Democratic Republic of the Congo, the Philippines, and the United Republic of Tanzania – from highest to lowest number of cases) that contribute most to the total figure are in Asia – Bangladesh, China, the Philippines, India, Indonesia, and Pakistan – partly due to the high population reported for these countries. To summarize, Figure 11 depicts the regional trends of malnutrition in children under 5 years of age, showing data for stunting, underweight, wasting, and overweight.

Anthropometric Indicators for Measuring Malnutrition

Several measures and anthropometric indices are used to diagnose and classify malnutrition. The choice of a measure or index of choice will depend on its simplicity, accuracy, and sensitivity, as well as the availability of instruments to make measurements and the existence of reference standards for interpreting the results. In clinical practice, the utilization of reference growth charts for weight, height, and BMI for age and weight for height is common in the pediatric population. Growth charts consist of a series of percentile curves that illustrate the distribution of selected body measurements in children. The reference standards for anthropometric measurements presented in this article are those used in 2010 WHO's Nutrition Landscape Information System (NLiS), a comprehensive data collection system that compiles nutrition-related indicators in standardized form.

Malnutrition in Children

The measurement of weight and height is used for the calculation of indicators such as 'weight for age,' 'height for age,' 'weight for height,' and BMI (BMI = weight in kg/height squared in meters). Other anthropometric measures employed are the measurements of arm circumference and head circumference. In statistical terms, it is more appropriate to use SD ('*z*-scores') or percentiles to evaluate differences between the patient and the reference standard. This is the preferred expression for anthropometric indicators in surveys. It is the difference between the value for an individual and the median value of the reference population for the same age or height, divided by the SD of the reference population. In other words, by applying *z*-scores, one can describe how far a child's weight is from the median weight of a child at the same height in the reference value.

Underweight, stunting, and wasting

These indicators are used to measure nutritional disorders resulting in undernutrition (assessed from underweight, wasting, and stunting) and overweight. Child growth is globally acknowledged as an important indicator of nutritional status and health in populations. The percentage of children with a low height for age (stunting) reflects the accumulated effects of undernutrition and infections since and even preceding birth. Thus, it can be interpreted as an indication of poor environmental conditions or long-term restriction of a child's potential to grow. The percentage of children who have low weight for age (underweight) can reflect 'wasting' (i.e., low weight for height), indicating acute weight loss, 'stunting,' or both. As such, 'underweight' is a composite indicator and may therefore be difficult to interpret.

Definitions used

- Underweight (thinness): weight for age less than −2 SD of the WHO Child Growth Standards median (severe underweight: less than −3 SD)
- Stunting (short for age): height for age less than −2 SD of the WHO Child Growth Standards median (severely stunted: less than −3 SD for length/height for age) (children under 2 are usually measured lying down (recumbent length), and those over 2, standing height is taken)
- Wasting: weight for length/weight for height less than −2 SD of the WHO Child Growth Standards median (severe wasting less than −3 SD for weight for length/weight for height or BMI for age)
- Overweight: weight for height greater than +2 SD of the WHO Child Growth Standards median

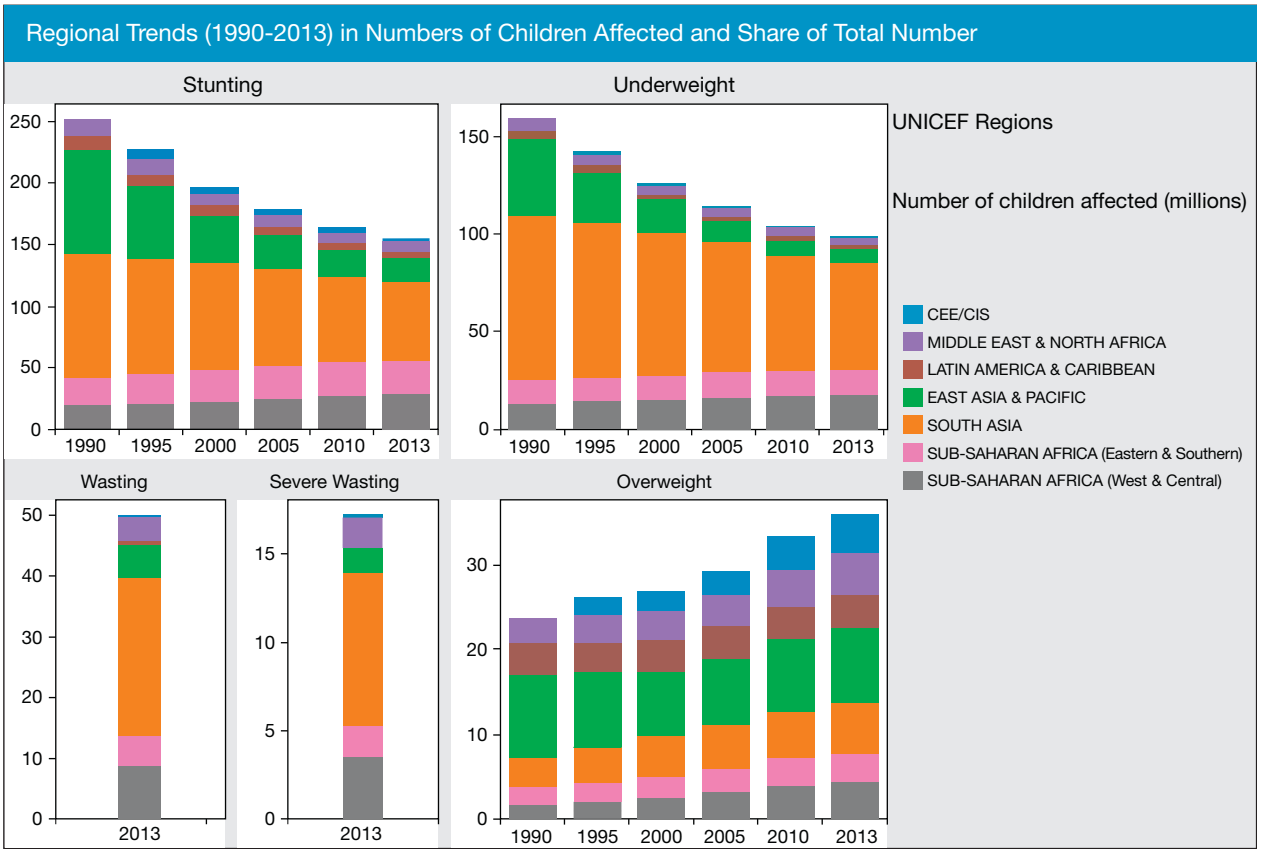

Figure 11 Regional trends (1990–2013) of malnutrition in children under 5 years old. The UNICEF-WHO-World Bank Child Nutrition Interactive Dashboard.

Interpretation

Underweight: As weight is easy to assess, this has been the most widely collected indicator. Evidence has shown that the mortality risk of children who are even mildly underweight has increased, and severely underweight children are at even greater risk.

Stunting: Children who suffer from growth retardation as a result of poor diets or recurrent infections tend to be at greater risk for illness and death. Stunting is the result of long-term nutritional deprivation and often results in delayed mental development, poor school performance, and reduced intellectual capacity. This in turn affects economic productivity at the national level. Women of short stature are at greater risk for obstetric complications because of a smaller pelvis. Small women are at greater risk of delivering an infant with low birth weight, contributing to the intergenerational cycle of malnutrition, as infants of low birth weight or retarded intrauterine growth tend be smaller as adults.

Wasting: Wasting in children reflects acute undernutrition, usually as a consequence of insufficient food intake or a high incidence of infectious and parasitic diseases, especially diarrhea. In addition, it is associated with an impaired immune system functioning and can lead to increased susceptibility, severity, and duration of infectious diseases as well as increased mortality risk. In the WHO protocols for SAM management, MUAC is also assessed, along with the presence or absence of edema.

Overweight/obesity: Childhood obesity is linked with a higher probability of obesity as an adult, which can result in a variety of disabilities and pathologies, such as diabetes and cardiovascular diseases.

Malnutrition in Adults

The values for BMI are age-independent for adult populations and are similar for both males and females. However, differences in BMI may not correspond to the same degree of fatness in different populations as there may be variations in body proportions.

Moderate and severe thinness, underweight, overweight, and obesity

- BMI <17.0 kg m^{-2} indicates moderate and severe thinness
- BMI <18.5 kg m^{-2} indicates underweight
- BMI 18.5–24.9 kg m^{-2} indicates normal weight
- BMI ≥ 25.0 kg m^{-2} indicates overweight
- BMI ≥ 30.0 kg m^{-2} indicates obesity

Moderate and severe thinness: A BMI <17.0 kg m^{-2} indicates moderate and severe thinness in adult populations. This has been associated with increases in illness in adults studied in three continents, and this is considered a reasonable further limit to choose as a cutoff point for moderate risk. A BMI <16.0 kg m^{-2} is associated with a markedly increased risk for ill health, poor physical performance, lethargy, and even death; as such, this cutoff point is considered a valid extreme limit.

Underweight: The cutoff point of 18.5 kg m^{-2} for underweight in both genders has less scientific validity as a cutoff point for moderate and severe thinness but is considered a reasonable value for use pending further comprehensive studies. The proportion of the population with a low BMI that is considered a public health problem is closely linked to the resources available for correcting the problem, the stability of the environment, and government priorities. Approximately 3–5% of a healthy adult population have BMIs <18.5 kg m^{-2}.

Micronutrient Malnutrition

Micronutrient Deficiencies

More than 2 billion people are deficient in micronutrients such as vitamin A, iodine, iron, and zinc. Malnutrition due to the lack of vitamins and minerals (micronutrients) can make its appearance in a variety of ways. Fatigue, reduced learning capacity, and impaired immunity are just a few examples. These nutrients are called micronutrients since the body requires them in small amounts for growth, development, and health maintenance. The combination of different ecological factors such as climate; low production, availability, and consumption of certain micronutrient-rich foods; cultural patterns that limit the consumption of given foods; and poverty-induced food restrictions contributes to mapping a specific region's particular micronutrient and health profile. In regions with a high prevalence of undernutrition, associated micronutrient deficiencies occur, which contribute to the symptoms that appear. Or they may remain in an asymptomatic subclinical phase, without apparent clinical expression, thus giving rise to the expression 'hidden hunger.' This expresses the phenomenon of a chronic lack of vitamins and minerals that often have no visible warning signs, such that those affected by it may not even be aware of it. Yet it nevertheless brings about significant negative health consequences.

Unlike many other impediments to social and economic development, micronutrient deficiencies can be reduced with relatively inexpensive investments in public health, agriculture, and education. The technology exists to solve many of these deficiency states. However, they persist for various reasons, including the lack of awareness among policy-makers on the importance of resolving the issues, as well as the lack of knowledge by program planners about their consequences and the strategies available to combat them.

In recent decades, the research community, governments, development agencies, and nongovernmental organizations (NGOs) have made considerable progress in identifying the population groups that have the greatest risk of micronutrient deficiencies and in developing programs for short-term improvement of given deficiencies. These strategies focus on improving access, availability, and consumption of foods rich in vitamins and minerals. The benefits of these food-based strategies are that they not only address improving the intake of certain nutrients but also enhance the overall situation in terms of food and health. Since 1985, FAO has actively participated in the definition and implementation of programs to reduce micronutrient deficiency diseases. FAO strongly supports the promotion of producing and consuming micronutrient-rich foods as a sustainable solution to the problem of micronutrient deficits. Globally, the three micronutrients having the greatest repercussions for public health are vitamin A, iron, and iodine, which will be the focus of this article. Other deficiencies of relevance also exist, such as of folate, zinc, and calcium, and the reader is referred to the supplementary materials for more information on these topics.

Vitamin A Deficiency

Vitamin A deficiency (VAD) most frequently occurs in young children. A child who lacks this vitamin is more susceptible to the negative effects of infections, which will be more severe and will increase the risk of mortality. Deficient intakes increase the risk of blindness. It also leads to alterations in the skin, mouth, stomach, and the respiratory system. Vitamin A supplementation reduces the risk of death from measles. It is estimated that in populations with this problem, administering vitamin A can reduce infant mortality due to measles by 50% and mortality from diarrhea by 40%. The overall risk of infant mortality can be reduced by 23%. Interventions that provided the basis for these data included programs of food enrichment and oral supplementation.

As seen in Figure 12, WHO shows regional data on the proportions of preschool-age children with biochemical VAD, as indicated by a serum retinol concentration <0.70 μmol l^{-1}. In all developing countries, an estimated 163 million children have VAD (by low serum retinol), with a prevalence of around 30%. South-central Asia (which includes India) has the highest prevalence with the greatest number of children (two-thirds of affected children) and pregnant women and, along with Central and West Africa, has a prevalence of more than 40%. South and Central America and the Caribbean have the lowest prevalences, near 10%.

Vitamin A (also called retinol, for one of its chemical forms) is essential for normal vision, growth and development, the maintenance of epithelial integrity (the layer of cells that make up the lining of internal and external body surfaces), immunity, and reproduction. VAD occurs when organic reserves of the micronutrient drop below the level that allows for the maintenance of proper physiological functioning, generally as a result of insufficient intake of foods containing this vitamin. The integrity of the epithelial barriers (part of natural immunity and physical barriers against microorganisms such as the skin and mucous membranes) and immune response, itself, is the first to be affected, followed by visual functioning. As a result of the body's compromised defenses, the frequency and severity of infections increase and there is a greater risk of mortality, especially in children. Moreover, anemia and the dryness of the skin (hyperkeratosis) constitute other extraocular manifestations of VAD.

The eye lesions caused by the lack of vitamin A are known as xerophthalmia and are characterized by progressive dryness, opacity, and weakening of the cornea. The first manifestation is the appearance of night blindness (hemeralopia), which is evident in children when they stop playing or start tripping over objects within the home at sundown. Ocular lesions in the conjunctiva and cornea are easily visible when Bitot's spots appear (small grayish foamy triangular deposits on the conjunctiva). At this stage, the eye disorder is still reversible, but without treatment, it progresses to corneal necrosis (disintegration), which results in permanent blindness.

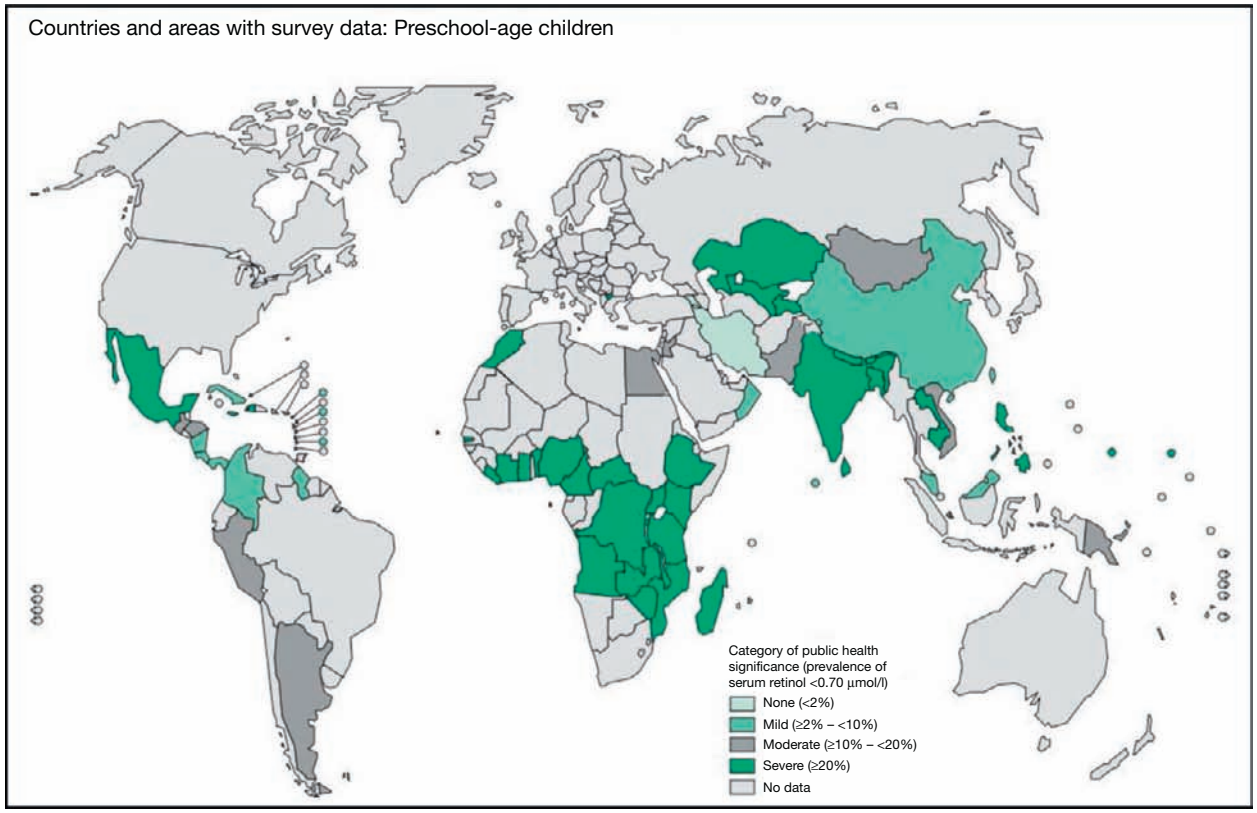

Figure 12 Global prevalence of preschool-age children with biochemical VAD. Reproduced from WHO (2009). *Global prevalence of vitamin A deficiency in populations at risk 1995–2005. WHO global database on vitamin A deficiency*. Geneva: World Health Organization.

Table 3 Global anemia prevalence and number of individuals affected

	Prevalence of anemia		*Population affected*	
Population group	*Percent*	*95% CI*	*Number (millions)*	*95% CI*
Preschool-age children	47.4	45.7–49.1	293	283–303
School-age children	25.4	19.9–30.9	305	238–371
Pregnant women	41.8	39.9–43.8	56	54–59
Nonpregnant women	30.2	28.7–31.6	468	446–491
Men	12.7	8.6–16.9	260	175–345
Elderly	23.9	18.3–29.4	164	126–202

Source: de Benoist, B., et al. (eds.) (2008). *Worldwide prevalence of anaemia 1993–2005. WHO global database on anaemia*. Geneva: World Health Organization.

Different strategies exist to prevent VAD. The three main ones consist of the administration of vitamin A (normally in capsule form), food fortification with the vitamin, and food-based enhancement by providing access to foods that contain this nutrient. Each strategy has its advantages and disadvantages, but a combination of approaches may result in even greater efficacy for program interventions.

Iron-Deficiency Anemia

The lack of iron is the most common nutrient deficiency in the world and mainly affects children and women of reproductive age. The resulting anemia significantly contributes to maternal and neonatal mortality. Anemia reduces resistance to diseases and weakens children's learning capacity and physical vigor while it significantly increases the risk of maternal mortality during childbirth. As seen in Table 3, globally, anemia affects 1.62 billion people, which corresponds to around 24.8% of the population worldwide. The highest prevalence is in preschool-age children (47.4%), and the lowest prevalence is seen in men (12.7%). However, the population group with the greatest number of individuals affected is that of nonpregnant women (468.4 million).

Anemia is a disease caused by the decrease in the amount of hemoglobin in the red cells of the blood. Hemoglobin is composed of a protein attached to an iron molecule and is the

component of red blood cells that carries oxygen from the lungs to the tissues. There are different causes of anemia, the most common of which is iron-deficiency anemia. The lack of other nutrients such as folate (or folic acid), protein, and vitamin B_{12} can also contribute to the onset of anemia. Ascorbic acid (vitamin C), vitamin E, copper, and pyridoxine (vitamin B_6) are also necessary for the production of red blood cells. It is worth noting that VAD is also associated with anemia.

Unlike other micronutrient deficiency diseases, iron deficiency anemia is also common in industrialized countries, although it is of a greater magnitude in developing countries. Food sources of iron are principally of animal origin (known as heme iron), such as liver, red meat, fish, and meat products. The plant sources of iron (called nonheme iron) are found in legumes, dark-green leafy vegetables, nuts, and seeds, but the body has greater difficulty in assimilating this type of iron. The total amount of iron in the diet is not the only factor that determines the development of anemia. Nonheme iron from plant foods is better absorbed when taken with certain foods (vitamin C-rich fruits and vegetables) to favor its absorption. Yet other foods (such as raw egg yolk and tea) impede its absorption. In addition, iron losses can result from a variety of conditions, of which one stands out in many tropical countries – parasitic infections, caused by intestinal helminths. Schistosomiasis, a parasitic disease that affects genitourinary or intestinal blood vessels, is also an important cause of blood loss, and consequently iron, via urine or fecal matter. Moreover, malaria is also a major cause of anemia, although in this case, it is not related to the loss of iron, but to the destruction of red blood cells by the disease process.

As the body manages iron very effectively, the daily nutritional requirement of this mineral in healthy men and postmenopausal women is quite low. However, women of childbearing age must replace iron lost during menstruation and at childbirth and should meet their increased need for iron arising from pregnancy and lactation. Children have relatively high iron requirements, not only derived from an increase in body size but also augmented blood volume. Anemia in children is associated with reduced development of cognitive capacity, increased learning problems, and difficulties in concentrating in and out of school, as well as decreased ability to perform physical work and a reduction in appetite and growth.

Anemia is particularly hazardous for pregnant women, as it significantly increases the risk of death during childbirth as a result of hemorrhages. In addition, anemia is associated with preterm births and low-birth-weight infants. The principal clinical manifestations common to almost all types of anemia are tiredness, weakness, fatigue, shortness of breath after exertion, dizziness, headaches, palpitations, and pale mucous membranes. Reduced resistance to infection is another sign of anemia. Severe anemia, which is rare, can progress to heart failure and in some cases death. The signs and symptoms, at least in the early stages of anemia, are discrete and not at all severe, which often results in the disease being ignored or neglected.

Iron-deficiency anemia is relatively easy and inexpensive to treat via the administration of oral iron supplements, which usually also incorporate folate. People with iron-deficiency anemia due to poor diets should be advised to eat more fresh fruits and vegetables at meal times. These foods contain vitamin C, which facilitates the absorption of iron content coming from cereals, tubers, legumes, nuts, and seeds. In addition, fruits and vegetables contain folate and a variety of vitamins and minerals. To the extent possible, the anemic patient should be encouraged to consume, even in very small quantities, foods rich in heme iron, such as meat, especially liver or kidneys. The iron in breast milk is well absorbed, especially when compared to that found in cow's milk, infant formula, or common milk powder. As such, the protection, support, and promotion of breastfeeding are strategies for preventing iron deficiency in infants during exclusive breastfeeding and for maintaining adequate iron intake when complementary foods are introduced. Moreover, as breastfeeding delays the onset of menstruation, the nursing mother is protected from blood loss, thus enhancing iron status.

Iodine-Deficiency Disorders

Iodine-deficient diets can result in various diseases, including endemic goiter and cretinism. Iodine is an essential component for the synthesis of thyroid hormones, which have an important role in the regulation of metabolism, sustaining normal growth and intellectual development. The synthesis of these hormones occurs in the thyroid gland, located at the bottom of the neck and invisible under normal conditions. The most common discernible manifestation of the lack of iodine in the diet is endemic goiter. The neck swells in response to the substantial enlarged size of the thyroid gland as it attempts to increase hormone production.

On the one hand, a less important cause of goiter is the consumption of foods considered to be goitrogenic (suppress the function of the thyroid gland by interfering with iodine uptake), rapeseed, cabbage, mustard seeds, and especially cassava, which is the staple food in different regions of Africa. On the other hand, cretinism, which in its acute form includes mental retardation, deaf–muteness, short stature, and other defects, is due to a diet devoid of iodine consumed by the mother during pregnancy.

Endemic goiter and cretinism are the obvious components of iodine-deficiency disorders (IDDs). These abnormalities can be diagnosed with relative ease by health professionals without the use of laboratory or other medical tests. However, other harmful consequences caused by iodine deficiency are not easily detected. These include less visible enlargement of the thyroid gland, different degrees of mental retardation, poor growth in children, and a greater incidence of spontaneous abortions and stillbirths. In areas with a high prevalence of iodine deficiency, many children are unable to fully develop their intellectual potential due to poor school performance and to a lower IQ as compared to similar groups without iodine deficiency. This is detrimental not only to the affected children but also to the development of the country insofar as human resource potential and productivity are diminished (**Figure 13**).

Unlike nutrients such as iron, calcium, and vitamins, iodine is a nutrient that is not naturally occurring in given foods. Rather, it is present in the soil and is ingested through foods that have been cultivated in it. The food produced in endemic iodine-deficient areas will never be able to provide enough iodine for the population and livestock that consume it. Iodine

deficiency is due to unequal distribution of this micronutrient in the soil covering the land's surface area.

Ocean water contains adequate amounts of iodine, and therefore, people living close to the sea and those who eat saltwater fish and marine products tend to have sufficient iodine. However, these foods are not accessible to all and the mere fact of living in coastal regions does not necessarily guarantee sufficient intake levels of this nutrient. Soil in the mountain ranges of the Himalayas, the Alps, and the Andes are prone to be deficient in iodine content. Many other parts of the world also have soils with scarce iodine levels, such as vast regions of Central Africa. Figure 14 shows the global impact of IDDs.

Figure 13 Children with goiter in Tanzania's Ukinga mountains. Reproduced from Latham, M. C. (2002) Human nutrition in developing countries. FAO (ed.), *Food and nutrition series — number 29*. Rome: United Nations Food and Agriculture Organization.

Of the three key micronutrients with most relevance for malnutrition (iodine, iron, and vitamin A), IDDs are the easiest to control. Iodine is a vital nutrient that is required in small quantities. An adult does not need more than 100–200 μg of iodine per day. The main measure to control IDD has been via the iodization (iodine fortification) of salt (or other basic staples such as bread), which is a simple and relatively cheap method that does not change salt's appearance or taste.

Malnutrition and Sustainable Diets

In 2012, FAO defined sustainable diets as those diets with low environmental impacts that contribute to food and nutrition security and to healthy life for present and future generations. Sustainable diets are protective and respectful of biodiversity and ecosystems, culturally acceptable, accessible, economically fair, and affordable, as well as nutritionally adequate, safe, and healthy, while optimizing natural and human resources. This same organization estimated that of a total of 300 000 flowering-plant species, 10 000 plant species have been used

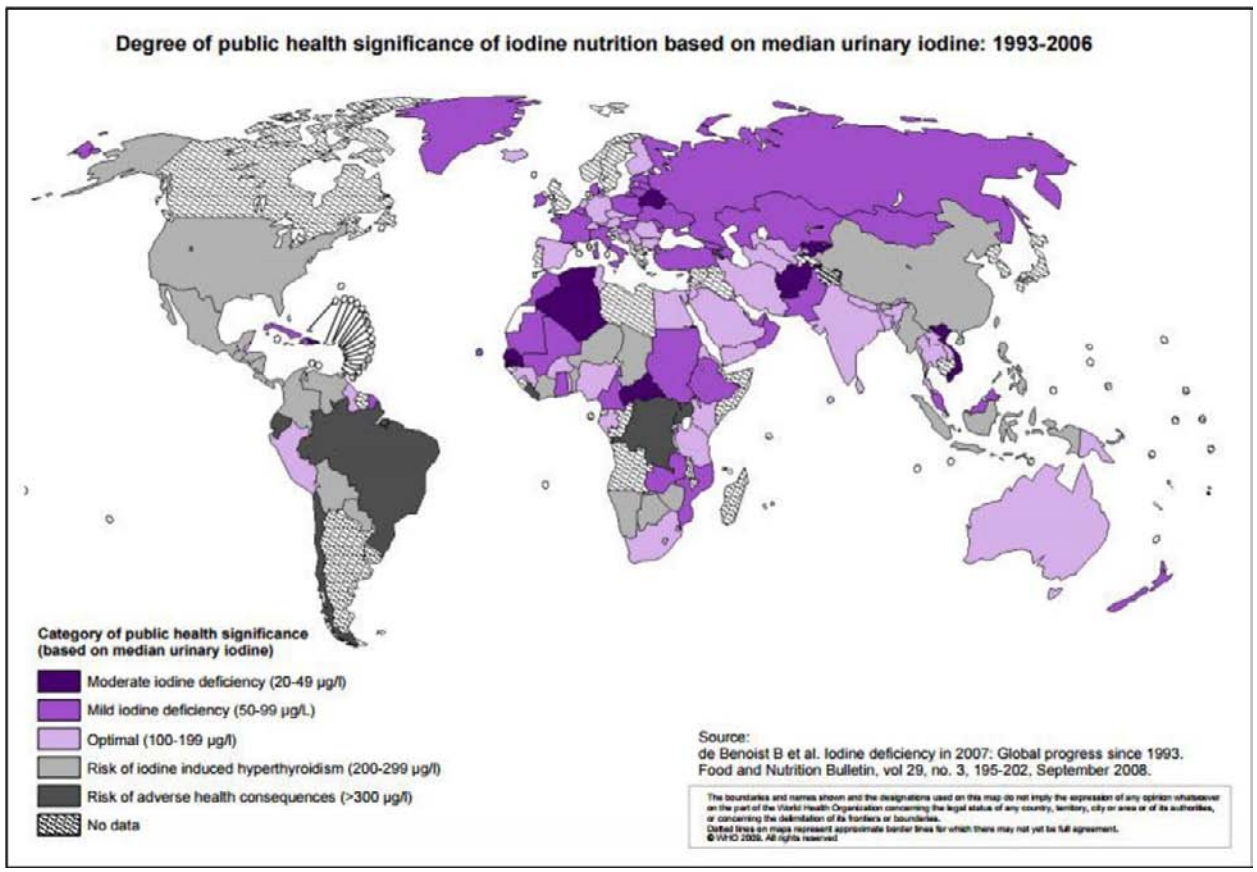

Figure 14 Global iodine public health significance.

for human food since the origin of agriculture. Out of these, only a mere 150–200 species have been commercially cultivated, with rice, wheat, maize, and potato flour supplying 50% of the world's food energy needs and with 30 crops providing 90% of the world's food energy intake.

The intensification of agricultural systems, poverty, population demands, urbanization, and changes in lifestyle have altered food production and consumption in ways that profoundly affect diets, resulting in an overall reduction in seasonality and concentration of staple food sources. What is more, the disturbing speed of biodiversity loss and ecosystem degradation accompanied by climate change and resource extraction, and the negative impact of this on farming systems, livelihoods, and health, make a convincing case for re-examining food systems from an environmentally sustainable and public health perspective.

Helping people and families to follow a sustainable diet is also a major objective of the Cooperative for Childhood Nutrition (CONIN). CONIN, founded in Chile in 1975, has worked for the recovery of children from 0 to 3 years who present with primary or secondary undernutrition. Since 1993, this project has been extended to the province of Mendoza, Argentina, as the CONIN Foundation, where this initiative was consolidated and extended by creating Undernutrition Prevention Centres in many Latin American countries. In these centers, health prevention and promotion strategies are developed with a focus on sustainability and empowerment. The challenge continues to develop preventive programs that involve educating and impelling the family to modify its lifestyle in order to improve its health and its education. CONIN serves as an example of how investing in human capital early in life will optimize and sustain the growth and socioeconomic development of children, families, and communities, thus contributing to break the intergenerational transmission of poverty and undernutrition.

The Centre for Nutrition Recovery and Education (CREN), administered by the Nutrition Without Borders (NWB), an NGO, in Gambia, provides another example of integrated sustainable actions carried out at the community level. Following the WHO, UNICEF, and NaNA (the Gambian National Nutrition Agency) malnutrition protocols, NWB regularly conducts community screenings supported by local counterparts (NaNA) to detect severe cases of undernutrition (SAM), which are referred to CRENs for clinic-based treatment. The moderate cases of undernutrition are treated in the community, where actions to improve dietary quality and quantity are reinforced by the implantation of NWB-supervised community-run vegetable gardens, which form part of NWB's strategy to reduce undernutrition. NWB has implemented a complementary agricultural project to support the promotion of sustainable farming, encouraging and training the inhabitants of selected villages in the catchment area ($\sim$50 000 individuals) about the cultivation and consumption of local plants with higher nutritional content (such as *Moringa* and millet). CRENs also have an on-site vegetable garden where mothers of children under treatment also participate and learn about food preparation, conservation, and hygiene as part of the strategy to prevent recurrent cases of undernutrition in the community.

The UN's Zero Hunger Challenge aims for all food systems to be sustainable. Current food production and consumption patterns contribute to biodiversity loss, put pressure on natural resources, and provoke greenhouse gas emissions and excessive agrochemical inputs, particularly in developed countries. Industrialized regions are living beyond the Earth's capacity, yet their food systems are too often considered as role models for developing countries. Food systems – in both developed and developing countries – need to be restructured and take into account social, environmental, and public health impacts. Agriculture policies and programs have concentrated so far on commodities and value chains. There is a need for policy-makers to move beyond the current focus on commodity goods and instead implement actions centered on whole diets and food systems. Biodiversity offers a wealth of untapped potential for livelihoods, health, nutrition, and environments. Interdisciplinary collaboration is needed if global efforts are to tackle malnutrition, NCDs, and the impact of food on climate change, water, and biodiversity. In order to be sustainable, it is essential that diets be healthy, compatible with sustainable management of natural resources and social equity. As has been done with nutrition, the time has come to advocate for making sustainable food production central to development.

Conclusions

In the last two decades, the world has undergone profound changes. Over 800 million are hungry and 2 billion lack essential micronutrients, while 2 billion are overweight and prone to diet-related diseases. The burden of malnutrition presents itself in multiple, complex, and connected ways and countries need concentrated action at the policy, health-system, and community levels. For this reason, in 2012, the World Health Assembly Resolution 65.6 endorsed a comprehensive implementation plan on maternal, infant, and young child nutrition, which specified a set of six global interrelated nutrition targets for the year 2025 with the aim to (1) achieve a 40% reduction in the number of children under 5 years of age who are stunted, (2) achieve a 50% reduction of anemia in women of reproductive age, (3) achieve a 30% reduction in low birth weight, (4) ensure that there is no increase in childhood overweight, (5) increase the rate of exclusive breastfeeding in the first 6 months up to at least 50%, and (6) reduce and maintain childhood wasting to $<$5%. It is evident that although there are clear measurable comprehensive targets to help us focus our efforts in combating malnutrition, the remaining challenges are many. For this purpose, it is necessary to strive for sustained political commitment and cooperation among the many stakeholders concerned, both public and private, in and out of the field of nutrition. Governments, international partners, civil society, NGOs, and the private sector have a key role in the creation of healthy environments and conditions for affordable, accessible, and sustainable healthy dietary choices for communities and especially for those most at risk of malnutrition in all its forms.

Introduction

In theory, deficiencies and excesses occur with respect to strictly essential, conditionally essential, and beneficial nutrients. For the purposes of this article, the concept of deficiency or excess will be restricted to the setting of status; this relates to the nutrients within the body. One cannot rely on dietary intake to be a reliable proxy for nutrient status. Aside from the vagaries of evaluating habitual intake of nutrients, consumption of a nutrient above or below the recommended levels is a poor predictor of the nutrient status within the body. It is recognized, however, that assessment of status is not readily or validly performed for all nutrients. Individuals can often adapt to intakes below the recommendations by augmenting uptake efficiency or reducing turnover. Conversely, in the face of an excessive dietary offering, adaptations to reduce absorption or increase excretion can allow the individual to maintain normative status.

The Spectrum of Malnutrition

Defining and characterizing 'malnutrition' is not straightforward. The most important may be that it is varied and spans a spectrum from deficits below the normative level to excesses above the norm. An important paradigm shift emphasized in the writings of Prof Ricardo Uauy is to be concerned with 'malnutrition in all of its forms'; that means a focus on both *under-* and *over*nutrition in individuals, within households, and across societies. It has specificity for the macro- or micronutrient nutrients in question, and the total dietary energy (derived for a collective of the macronutrients of carbohydrate, fat, protein, and at times alcohol) is to be included in the malnutrition spectrum. There is also a gradient of degree. This can be partitioned as *subclinical* (diagnosable by way of laboratory testing, but not clinically evident) or *clinical* (presenting with detectable signs and/or symptoms). Within the latter category, there is further differentiation into mild, moderate, and severe for deficits in weight and stature. For micronutrients, this gradation often takes on the language of 'marginal' or 'deficient' in the parlance of vitamin B complex or 'insufficient' or 'deficient,' as for vitamin D.

The Principles of Assessment of Malnutrition

The public health or clinical address of malnutrition in all of its forms would presuppose the availability of diagnostic tools to determine when a deficit or excess of nutrients exists. One could begin with an analogy to banking. How much is a satisfactory reserve of assets and what is a precarious deficit from borrowing? Information could easily be assessed by banking statement sheets. As with all other aspects of nutrition, this objective is fraught with caveats and difficulties, and the analogy of financial assets and liabilities quickly breaks down in practice. This is nutrient-specific and can be further seen in a perusal of the relevant chapters in this encyclopedia.

Clinical malnutrition, by definition, has its associated signs, symptoms, measurements, and imaging. A skilled practitioner, familiar with the symptoms and physical manifestations, should be able to recognize manifestations consistent with under- or overnutrition states. Few manifestations are pathognomonic for a nutritional origin, however. When clinical deficiency of protein, essential fatty acids, or micronutrient is suspected, further laboratory testing or a therapeutic trial with the nutrient in question may be needed for conclusive diagnosis.

Subclinical deficiencies and excesses are far more elusive to detection. They require a high level of suspicion, from history or circumstances, to invoke an investigation. Thereafter, they must rely on diagnostic tests based on amounts of the nutrient in the body or functional responses to nutrient deficiency that are in no way completely sensitive or specific.

Assessment is relevant to both individuals, to trigger individual therapeutic action, and to populations, to trigger public health action. A limited number of routine biomarkers are reliable for defining the nutritional status of an individual across the entire spectrum from deficient, to depleted, to normative, to excessive, to toxic. One such marker is serum ferritin as an indicator of total-body iron reserves, a caveat, however, that concurrent inflammation must not be present, or this will distort the assessment. Circulating retinol concentrations will not discriminate the same gradient for vitamin A status in an individual, as there is homeostatic regulation of levels across a wide range of total-body vitamin A stores. As a screening tool for the assessment of a population, the standard of >20% of the under-5-year-old segment having a circulating retinol concentration $<20\ \mu g\ dl^{-1}$ can be used as an indication of hypovitaminosis A risk and a trigger for public health action, but it does not confirm the adequacy or inadequacy of any given subject in the representative national sample. To assess an individual with any degree of graded reflection of actual vitamin A reserves generally requires total-body dilution studies with exogenous, stable isotope-labeled tracer retinol; this test is too expensive and cumbersome for wide-scale use but can be used in monitoring of public health interventions.

Furthermore, not all nutrients have a pool or storage reserve of nutrients that can be called upon in the absence of a dietary supply. Clearly, iron and vitamin A, the previous, do have storage in tissues. Along with some other vitamins and minerals, these storable nutrients are called by Golden as type I nutrients (Table 1) and lend themselves to assessment through biomarkers of body reserves. For another series of nutrients outlined in Table 1, however, there are no tissue-storage reserves, so-called type II nutrients. The stress of underconsumption leads to a regulatory reaction by increased retention, shutting down to the degree possible the excretion of

Table 1 The concept of type I and type II nutrients as derived from the formulation of Michael Golden

Type I nutrients
All of the 13 vitamins, calcium, choline, chromium, copper, essential fatty acids, fluoride, iodine, iron, manganese, molybdenum, selenium
Comments: Have accessible storage pools/reserves in specific tissues. Humans continue to grow despite deficiency, often further depleting stores. Diagnostic biomarkers of circulating concentrations or tissue levels are often responsive to status and potentially useful in status assessment
Type II nutrients
Nitrogen, essential amino acids, magnesium, potassium, phosphorus, sodium, sulfur, zinc
Comments: Do not have accessible storage pools/reserves in specific tissues. Cessation of growth is an early response to deficiency, as one mechanism for retention. Diagnostic biomarkers of circulating concentrations or tissue levels are often homeostatically regulated and are relatively unresponsive to change in status

the nutrient. Zinc is a classic member of this group, and circulating zinc is a relatively poor biomarker of status. In young individuals, part of the conservation mechanism is a loss of appetite (acute anorexia) and a cessation of growth (growth arrest). Both are clear manifestations in human zinc deficiency and in the depletion of the companion type II nutrients. Evidence for reduced excretion can often be used as a diagnostic test for this class of nutrients. However, because of the absence of a storage pool, the quantity of the nutrient in urine, stool, or saliva is really an indicator of the level of recent dietary intake.

In both clinical medicine and public health epidemiology and programs, it is prudent to support the actions with efforts to assess the initial and posttreatment or postintervention status of the patient or population, respectively. This must be done, however, with a consciousness of the challenges and limitations in the reliability of biomarkers and diagnostic tests to reflect the true nutritional status with respect to the nutrient(s) of interest.

Prevention of Malnutrition

Although not the sole predictor and determinant, nutritional status depends heavily on the supply of nutrients; therefore, the first principle of preventing malnutrition begins with the assurance of an adequate diet. In the absence of disease, dysfunction, or adverse environmental conditions, habitually consuming at or above the recommendations for one's sex, age, and physiological (reproductive) condition (e.g., pregnancy or lactation) should be a safeguard against deficiency. Conversely, restricting nutrient intakes to below the upper tolerable intake limits (UL) should generally prevent excessive deposition of or exposure to those nutrients that can be harmful in excess. This framework for prevention, based on the assumption of good health, however, is fraught with caveats.

The first consideration is ignorance in the populace regarding exactly how close their intakes are to the upper or lower boundaries of recommended intake. Few people know how much a person of their age and sex should be consuming of the total dietary energy or the gamut of nutrients. Even if this information was generalized and socialized, however, knowing how many nutrients are in the food makes selecting an adequate intake a virtual impossibility. Commercially processed foods provide some indication of their nutrient content on the labels; but this only relates to nutrients providing a certain percentage of the 'daily value' needs; moreover, it is not presented in an expression useful to the average consumer. When it comes to unprocessed or lightly processed items such as foods of animal origin (meat, foul, fish, eggs, and dairy), produce (fruits, vegetables, roots and tubers, and herbs), and nonpackaged bakery goods, only a food-composition table can provide reliable nutrient-content information.

The most useful datum would be the total dietary energy. In Western industrialized countries, the concern would be for an *excess* of calories. In situations in the low-income world of natural disasters, war and social turmoil, and/or climate change and famine, a *deficit* of calories is the concern. See chapters on obesity and famine. This would be followed in priority by knowledge on the consumption of sodium (salt and monosodium glutamate) and successively on sugars, cholesterol, and saturated fats.

For micronutrients (vitamins and minerals) and other beneficial nutrients (essential fatty acids, fiber, and polyphenols), the popular adage of 'consume a balanced diet' makes a positive contribution. The connotation of 'balanced,' as well as an operational definition, however, is critically important for program and policy discussion. To prevent malnutrition, a diet maximizing food variety, which is having a large number of different food and beverage items consumed, should be followed. It should likewise be of high dietary diversity, which is with balanced representation of all of the principle food groups (meat and eggs; milk and dairy products; fruits; legumes and vegetables; and cereals and tubers). There are a number of challenges to these broad, preventive recommendations, especially for the less affluent segments of any society. These include the year-round availability, affordability, and quality of the items in the food supply.

No matter how balanced the diet, an adequate intake of iodine and fluoride cannot be assured. This is likely to depend on the iodization and fluoridation of salt or the iodine fortification of bread or the enhanced fluoride content of the drinking water.

Micronutrient epidemiology tells us that insufficient intakes of bioavailable forms of specific nutrients will predispose to endemic deficiencies. Among the candidate nutrients for inadequacy in low- and middle-income societies and among the poor of affluent societies are vitamins D and A and folate, along with iron and zinc. Problems with vitamin D and iron, moreover, will not be unknown even among the affluent. Omega-3 fatty acids, vitamins B_{12} and E, and selenium are micronutrients with greater geographic specificity in their deficiencies. In free-living populations, however, nutritional deficiencies or excesses of vitamin K, thiamine, niacin, vitamin B_6, pantothenic acid, biotin, copper, manganese, and chromium are unlikely to occur. Specific diseases, surgeries, medications, or chronic parenteral feeding can predispose to occasional occurrence of manifest deficiencies of the latter group of nutrients.

On the side of overnutrition, a series of actions aimed at consumer education, improving access to healthful foods, suppressing consumption of items of higher energy density, and

stimulating exercise in recreational activities, are available. Further detail is presented in other chapters.

Food Fortification for Prevention of Undernutrition

When dietary intakes are shown to be low by survey evidence or when nutrient deficiencies are endemic, food fortification policies and programs can be initiated. The conventional approach is to find a staple food item that is widely consumed across all social strata and age groups in a precarious population. Salt, table sugar, cooking oil, and flours are the most commonly identified staples. Based on an assessment of the dietary gap and the level of habitual consumption across the society, a specific addition of the nutrient is made during processing. Among the advantages of fortification are the lack of need for any change in behavior and the relative low cost. The concerns of fortification are problems at both ends of the spectrum: on the one hand, insufficient intake or nutrient bioavailability, which may lead to poor effectiveness in its impact on nutrient deficiency and, on the other hand, the risk of excessive intake for the segment of the population with the highest consumption of the fortified foods.

Two other elements of fortification are worthy of mention. Food manufacturers have voluntarily added fortificant nutrients to their products as a value-added gesture; this is known as 'market-driven' fortification. Folic acid, iron, zinc, and vitamin C are most commonly added. When combined with a mandatory national fortification programs, excess intakes in the high-consumer sectors can be exacerbated. Biofortification is a novel approach in which the intrinsic content of nutrients in foods can be increased by genetic approaches, either hybridization or genetic modification. This extends the vehicles of micronutrients from grains to legumes, tubers, fruits, and vegetables.

Periodic Supplementation for Prevention of Undernutrition

Periodic supplementation is an approach much more targeted to specific groups within an at-risk population than fortification. The target groups often considered most vulnerable to undernutrition, namely, children under 5 years old, pregnant and lactating mothers, and women of reproductive age, are often the groups included in national nutrition surveys.

The threshold for initiation of a supplementation program is generally the documentation of a certain prevalence of deficient biomarkers, for example, >20% for low retinol or >40% for anemia. Alternatively, folic acid supplementation can be targeted only to fertile-age women at risk of pregnancy to prevent neural tube defects, whereas a 10-day course of oral zinc is triggered by a prior episode of diarrhea or pneumonia. Interestingly, with the exception of iron and folic acid for anemia, the outcomes are not really supporting nutritional status. Rather, they seek to prevent specific conditions: child mortality with vitamin A, birth defects with folic acid, and recurrent infections with zinc.

Periodic supplementation is restricted to a specific period of the life span (vitamin A and folic acid) or a certain specific time interval for the recipient (iron and zinc). If the dosage is correct, hazards of excessive exposure are minimal. Overdosage with a vitamin A syrup has been documented in India, and high-dose iron supplements represent a hazard for poisoning if inadvertently consumed by young children. The disadvantages include the need for a conscious behavior change and for the logistics for distribution, which can require a substantial investment of public funds. Combinations of supplementation and fortification programs occur in some settings, notably for vitamin A and folic acid, which increases the chances for excessive exposure in dual recipients.

Health and Sanitation Interventions for Prevention of Undernutrition

Nutrients are poorly absorbed, poorly retained, and underutilized in the presence of intestinal or systemic diseases caused by microbes and parasites endemic to low-income countries. Indeed, just lack of general sanitation, safe potable water, and organic and inorganic contaminants in the environment can adversely affect nutrient metabolism, even with an adequate dietary intake. These programs of immunizations, periodic deparasitizing, environmental hygiene, pure drinking water, hand washing, household ventilation, suppression of mycotoxin, etc., can lead to better absorption, retention, and utilization of nutrients in the diet, thereby preventing malnutrition.

Breast Feeding in Preventing Malnutrition

The World Health Organization recommends exclusive breast feeding for the first six months of an infant's life. This permits the exceptions of medicinal or nutrient drops and oral rehydration therapy (ORT). As a lesser option, WHO defines predominant breast feeding (PBF) as the aforementioned exceptions along with pure water, juices, and ritual fluids. Mixed feeding, which is the offering of infant formula or any semisolid or solid food, before the seventh month of age is dissuaded in early child feeding recommendations. Once complementary feeding is introduced after 6 months, partial breast feeding is to be encouraged for as long as it is mutually desirable to both elements of the dyad.

EBF, and to a lesser extent PBF, can be considered as an important – if not consummate – measure for the prevention of both undernutrition in the short term (the first half of infancy) and overnutrition during infancy and potentially throughout the course of life. Human milk has the energy density to satisfy both caloric and hydration needs as governed by the hunger and thirst of the infant. Prevention of most forms of undernutrition is virtually assured in EBF as breast milk is close to being nutritionally complete. Commercial breast-milk substitutes may – or may not – be as nutritionally complete, and bottle formulas present the risk of overfeeding and nutrient imbalance. EBF has two admitted vulnerabilities in covering infant nutrient requirements: iron and vitamin D. Iron drops are often recommended as part of EBF. The vitamin D problem is particularly notable in darkly pigmented mothers; vitamin D supplement to the mother or in drops for the infant can cover the latter situation.

Breast milk can protect infant nutrition in additional ways. As secreted from the breast, it can be hygienic as no other beverage offered to the young infant; this avoids nutrient wasting diarrheal episodes. Human milk has immunologic properties that support the resistance to pathogen of the infant. Its high lactose content and blend of oligosaccharides support a

fecal microbial flora that supports colonic health and appropriate stool consistency and regularity.

Energy balance as 'not too much, not too little,' that is, appropriate growth velocity for length and proportional weight gain, is easily achieved with EBF and PBF as the modes of early infant feeding. Although the studies are not all totally consistent, for the longer term into childhood and later life, a history of extensive breast feeding is associated with lower risk of overweight and obesity. Geographic variation in the outcomes of such studies could be related to the overall background rates of excess weight.

Management of Malnutrition

When prevention efforts have been absent or incompletely responsive to societal or individual conditions, cases of malnutrition – of deficit or excess – are destined to occur. Whether they are epidemic or sporadic determines the overall strategy and the tactical address for the deficiencies and excesses. When multiple nutrient problems are society-wide, the concepts of therapy and prevention will blur over the long term.

Principles of Nutritional Therapy

When a deficiency is detected in the clinical setting, its reversal will almost inevitably require the application of supplementary nutrients, as either nutrient supplements, fortified foods, or nutrient-rich food sources. Historically, foods were the source of therapeutic nutrients. Scurvy has been cured with citric fruits, beriberi with brewer's yeast, and the vitamin B_{12} deficiency of pernicious anemia with beef liver. Cod liver oil has been the treatment for both vitamin D-deficiency rickets and vitamin A-deficiency night blindness for decades. Insofar as pharmaceutical chemistry provides pure forms of most organic micronutrients through extraction or synthesis, fortification or supplementation interventions have emerged as the modalities of choice.

For overnutrition and nutrient overload, the first principle is to adjust the diet or identify the exposure that is introducing more nutrient into the body than can be removed at a comparable rate. In the case of micronutrients, it might involve suspending a supplementation regimen or reduce the intake of heavily fortified foods. When overnutrition relates to energy, therapy involves reduction in total caloric intake combined with regimens of enhanced physical activity that enhanced expenditure of energy. In severe cases, medicines (which block macronutrient absorption, enhance urinary glucose excretion, or accelerate oxidative metabolism) and surgery (which restricts the gastric volume) can be important adjuncts in the treatment of obesity.

Some important caveats exist regarding when to treat malnutrition, how aggressively to treat, or even when to defer intervention. At one end of the spectrum is the situation of ocular xerophthalmia in severe vitamin A deficiency. Since this poses a risk of visual impairment or blindness, multiple high doses of vitamin A are warranted immediately upon diagnosis. A specific manifestation of severe thiamine deficiency, Wernicke's encephalopathy, is also a medical emergency risking death, and it is to be treated by immediate injection of high-dose thiamine. At the other end of the spectrum are situations in which aggressive therapy is contraindicated and repletion with the nutrient in question should be graded or even deferred. It was observed that feeding high amounts of energy and protein to survivors of World War II concentration camps had a high mortality. The lesson was relearned in the instances of kwashiorkor (edematous protein–energy malnutrition) and anorexia nervosa. Acute compartment shifts in circulating volume and in cellular fluxes of potassium and phosphate can lead to fatal consequences from vascular collapse or cardiac arrhythmias. Iron supplementation in malaria-endemic areas may do more harm than good until measures against malaria transmission are assured.

Nutritional deficiencies have been somewhat arbitrarily divided into the categories of primary and secondary. The concept from the late Prof. Victor Herbet can provide guidance in this regard (Table 2). The first cause of insufficient intake constitutes the primary form, and the remaining causes generally comprise the secondary forms.

Treatment of Primary Deficiency

If a nutritional deficiency is due simply to a lack of intake or of low dietary bioavailability, therapy with a supplemental dose is indicated for rapid restoration. Primary undernutrition is most commonly the result of adverse social, economic, or environmental conditions. It is common in famine, drought, warfare, and refugee situations. Voluntary resistance, such as hunger striking, is a cause of primary deficiency. Iatrogenic causes of primary deficiency cannot be overlooked. Physicians and dieticians can recommend a dietary regimen that, when adhered to, produces deficient intakes of protein or certain micronutrients. Early in the era of intravenous (parenteral) nutrition, primary deficiencies of trace elements were produced due to the lack of recognition of their essentiality.

The pockets of chronically poor and food fads and taboos have a role in primary undernutrition in high-income countries. Without the income to purchase a quality diet, food selection may include enough food to supply needed calories but with 'empty calories' in terms of essential nutrients. Macrobiotic and fruitarian diets have been associated with protein and micronutrient deficiencies as have strict vegan regimens. Vitamins D and B_{12} and omega-3 essential fatty acids are among the commonly deficient nutrients with fads or taboos.

A plan to prevent recurrence for the patient should be developed and implemented even as acute treatment of primary undernutrition is under way. If dietary imbalance is the underlying cause of low intake, adding a rich food source is the prophylactic action of choice. Food culture, prohibitive pricing, or scarce availability may thwart any food-based

Table 2 The six possible causes of nutrient deficiency (modified after the concepts of Victor Herbert)

Reduced consumption
Impaired absorption
Increased excretion
Impaired utilization
Enhanced destruction
Increased requirements

route with natural foods. An appropriately fortified food might be the next best food-based solution, providing that the same impediments do not apply. Finally, daily or weekly supplementation with the problem nutrient(s) would be the recourse.

De facto primary undernutrition can occur in the context of adequate energy intake when the intrinsic bioavailability of a nutrient is affected. A curiosity example of this was for people who consumed high quantities of raw eggs, which contain an antinutritional protein called avidin. Avidin tightly binds biotin from the diet and could theoretically reduce biotin nutriture. A more practical concern, however, is that of the bioavailability of iron and zinc from unrefined grains, seeds, and legumes. These are the bases for the maize-based diets of Meso-America and the whole-grain wheat-flour diets of the Middle East. In absence of sufficient fat in the meals, active vitamin A cannot be converted from provitamin A carotenes. Thus, persons with plant-based diets can develop hypovitaminosis A despite the orange and green fruits and vegetables in their customary fare.

Finally, in suspected 'primary' nutrient deficiency, practitioners need to consider – and rule out – occult secondary causes to the extent that diagnostic resources permit. For example, a young woman may be anemic and have a proved deficit of bioavailable iron in her diet. However, her excessive menstrual bleeding, representing a secondary aggravating condition and a treatable condition, may be overlooked in the evaluation.

Treatment and Management of Secondary Deficiency

A primary lack of food intake can also be secondary to pathological conditions. Anorexia nervosa and bulimia, or even psychic depression or adolescents' 'fear of fatness,' are psychological origins of diminished oral intake. Hyperemesis gravidarum, the excessive nausea and vomiting of pregnancy, would also fit this category. Thereafter, the framework of Herbert (Table 2) provides guidance. Obviously, pathological conditions from the mouth through the small intestine in the alimentary tract can compromise the digestion and/or absorption of nutrients. Among these are certain intestinal parasites. Metabolic and renal conditions, as well as fever, are the primary factors that reduce retention of nutrients and lead to their excessive wastage in the urine. In certain acute and chronic intestinal diseases, however, excessive loss of nutrients can occur via the bile or intestinal secretions. Excessive destruction of vitamin C occurs in tobacco users, and poorly absorbed antibiotics can interfere with recovery of vitamin K and biotin from our own intestines. Inflammatory conditions and lead exposure can interfere with the utilization of iron to make red blood cells.

When nutritional deficiency is clearly secondary to a primary medical condition, attempts should be made to palliate or eradicate the underlying problem. Even though it is possible, with sufficiently intense supplementation, to overcome iron deficiency anemia in hookworm-infected individuals, without eradicating the parasites, treatment with antiparasitic medications and prevention of recurrence are worth pursuing as well. This can reduce the iron dosage and make the iron treatment self-limited. With a condition such as cystic fibrosis, however, supplementation with fat-soluble vitamins will not only be needed to treat the initial deficiency; maintenance therapy will be required throughout the patient's lifetime. Zinc therapy will correct deficiency symptoms in acrodermatitis enteropathica, a zinc-absorption disorder; thereafter, continued treatment will permanently suppress all clinical manifestations of the disease.

Admonitions for Nutritional Therapy

Just as fortification of staple foods can lead to excess accumulation of nutrients, as in the case of vitamin A fortification of sugar in Central America, the chronic use of nutrient supplements runs a similar risk. Correspondingly, weight-loss diets, medications, and surgery are all associated with potential adverse consequences. Monitoring the body weight and nutritional status of any patient undergoing nutritional therapy is essential, and their regimens should be continuously adjusted accordingly. In situations of primary deficiency, the goal is weaning from overt therapy to a diet-based maintenance of good nutritional health. With secondary deficiencies, the need for supplements may fluctuate with remissions or exacerbations of the primary affliction conditioning the nutritional deficiency.

Conclusions

The prevention of malnutrition should begin with a prudent, balanced, and nutritionally adequate diet; measures to protect against nutrient wasting, recurrent illnesses, and environmental stress; and a personal regimen of modest physical activity. Programs of food fortification or periodic supplementation may be required when dietary and/or environmental issues cannot be resolved. Primary deficiency states should be addressed by nutritional supplementation and the recovery consolidated by dietary and social measures. Secondary deficiencies require a judicious combination of attention to ameliorating the inciting condition and restoring nutritional status of the patient.

Introduction

Manganese (Mn) is a hard, silvery white metal, brittle, easy to oxidize, and difficult to fuse, with a melting point of 1244 °C. It is found in soil, water, and plants, being the 12th most abundant element in the Earth's crust. Mn is mainly mined in Australia and South Africa and is commonly used in the metallurgical industry, especially iron, aluminum, and steel production. It is also used in the oil industry as an octane enhancer and engine antiknock agent, as well as in the battery industry.

Mn is abundant in the Earth's crust and is absorbed by plants and deposited in oceans, and rivers. The highest levels of Mn in food products are found in seafood, and these levels are region-dependent. Some plants, such as nuts, pumpkins, beans, and cloves, contain relatively high levels of Mn. Mn is common in the human diet and is absorbed by the gut and distributed to all organs and metabolized and excreted predominately in the bile and feces. Intracellularly, Mn serves as a cofactor for multiple enzymes and is incorporated into numerous proteins. Excessive consumption of dietary Mn may lead to its increased accumulation, and within the central nervous system (CNS), it may target dopaminergic (DAergic) neurons.

In the general population, enteral intake of Mn is <5 mg Mn/kg (with a range of 0.9–10 mg Mn/day). Human studies defined the no observed adverse effects levels in adult subjects at 11 mg day^{-1} from food sources. The National Academy of Sciences (2001) established an adequate intake (AI) in adult men and women at 2.3 and 1.8 mg Mn/day, respectively. AIs for newborn (<6 months of age) infants are approximately 3 μg day^{-1}, while AIs increase to 600 μg day^{-1} in children 7–12 months of age. Children between 1–3 and 4–8 years of age require a daily intake of ~1.2 and 1.5 mg Mn/day, respectively. There are multiple sources of Mn in the diet as discussed later.

Manganese in Food Sources

Numerous studies have focused on nutritional contents in food products, including their metal content. Mn is found in different food products, and its consumption may be altered by dietary components. Major sources of Mn intake include seafood, grains, rice, and nuts. Meat products from pork, chicken, lamb, and beef contain small and variable amounts of Mn. Higher levels of Mn intake are more frequently encountered in vegetarian and ovo-lacto vegetarian adults. Mn content may considerably vary in relation to the vegetable species, Mn levels, and pH in the soil, to name a few.

As mentioned earlier, Mn levels are relatively high in cereals; however, in other food staples, such as soy-made tofu, seafood, and meat, Mn may be present at even higher concentrations (see Table 1). The *açaí* berry, a Brazilian fruit, can contain ~6 mg Mn/100 g. This represents a high level of Mn compared to other sources, such as cooked rice (0.46 mg/100 g). Furthermore, a popular tea consumed in the southern Brazil and surrounding countries, such as Paraguay, Argentina, and Uruguay, named 'chimarrao' (*Ilex paraguariensis*), contains Mn levels that vary between 2.3 and 1069 mg l^{-1}, dependent upon the location of the harvested plants.

Assessment of Manganese Status

A range of techniques have been used for metallic specie determination including inductively coupled plasma optical emission spectrometry, inductively coupled plasma mass spectrometry, and flame atomic absorption spectrometry (FAAS). However, the Mn levels and sample properties should dictate the choice for the appropriate method. Low-Mn-concentration issues may be suppressed by using a separation or preconcentration procedure before the detection. While FAAS is extensively used for Mn quantification in food products, this is not the best method in wine samples, given alcohol's content of ethanol, sugars, and other organic compounds.

Mn Availability, Absorption, and Metabolism

Mn Absorption

Mn absorption occurs predominantly through the pulmonary or gastrointestinal tract. Oral Mn absorption is affected by several factors, such as the quantity of carbohydrate or iron (Fe) consumed. Mn absorption by the lung occurs largely in occupational cohorts exposed to this metal, such as welders, miners, alloy, and battery production workers.

In relation to Mn absorption from food products and drinking water, according to the World Health Organization's (WHO) Environmental Health Criteria, healthy adults should consume a daily average of 3.6 mg Mn, considering a gastrointestinal absorption rate approximating 3–5%. This equates to systemic Mn absorption of approximately 180 μg Mn/day.

Mn homeostasis is governed predominantly by excretion, which is rapid and efficient. In a normal adult, oral Mn absorption is ~3–5% of an ingested dose. When dietary Mn levels are high, adaptive changes include reduced GI absorption, enhanced Mn liver metabolism, and increased biliary and pancreatic excretion of Mn. Additional factors such as Fe, phytate, ascorbic acid, and other minerals can influence Mn

Table 1 Mn content in different food products

Food product	*Amount of Mn in 100 g portion (mg)*
Mussels	6.8
Açaí berry	6.16
Hazelnuts	5.6
Pumpkin seeds	4.5
Whole-wheat bread	2.1
Bovine meat	1.5
Tofu	1.2
Lima beans	1.3
Spinach	0.9
Damascus (fruit)	21

uptake and retention. Dietary Fe ion competes with Mn, decreasing GI absorption. Conversely, low Fe levels represent a risk for increased GI Mn absorption.

Mn body distribution and elimination

The total Mn content of a 70 kg man is ~12–20 mg, and it is distributed in all tissues throughout the body (Table 2). The highest Mn concentrations are found in the liver; Mn is mostly eliminated via the bile in the feces (>90%). Very little Mn is excreted in urine and sweat.

Blood–Brain Barrier and Cellular Mn Uptake

Mn in the environment exists in various chemical forms including 11 oxidation states (Mn^{2+}, Mn^{3+}, Mn^{4+}, Mn^{6+}, Mn^{7+}, and others), salts (sulfate and gluconate), and chelates (aspartate, fumarate, and succinate). However, within the human body, Mn largely exists only in two Mn oxidation states (Mn^{2+} and Mn^{3+}).

Mn^{2+} transporters

As mentioned earlier, absorption and accumulation of Mn and Fe are mediated via shared transporters. Fe has a strong influence on Mn homeostasis. Both metals can be transported by the divalent metal transporter-1 (DMT-1) including across the blood–brain barrier (BBB). DMT-1 functions as a hydrogen ion symporter, transporting one hydrogen ion and one divalent cation in the same direction. DMT-1 belongs to a large family of metal transporters, which are responsible for the transport of other divalent metals ions, including Fe, zinc (Zn), cobalt (Co), copper (Cu), and cadmium (Cd). Deletion of the DMT-1 gene results in reduced tissue levels of both Mn and Fe. Notably, DMT-1 is widespread in the brain and highly concentrated in DAergic neurons and the nasal epithelium.

Other important Mn^{2+} carriers are the zinc transporters, ZIP-8 and ZIP-14. These transporters function as Mn-bicarbonate symporters, carrying one HCO_3^- ion and one divalent Mn cation across the membrane. Although ZIP-8 and ZIP-14 are expressed in brain capillaries, it has yet to be proved that they are functional at the BBB.

Mn^{2+} can also be carried by Mn-citrate transporters; however, the relevance of these carriers has not yet been fully elucidated. Hip14 and the product of the park9 gene are novel putative Mn transporters. The choline transporter also has high affinity for Mn^{2+} relative to the other metals (Cd and Al) and may potentially function as a Mn transporter.

The cytoplasmic Fe exporter, ferroportin (Fpn), and SLC30A10 (solute carrier family 30, member 10) function as the predominant Mn exporters.

Table 2 Mn distribution in the human organs

Human tissues	*Approximate values of Mn (mg kg^{-1} wet weight)*
Liver	2.05
Pancreas	1.18
Kidneys	0.9
Intestine	0.35
Heart	0.32
Brain	0.3
Lung	0.22

Mn^{3+} transporters

The one known transporter of trivalent Mn (Mn^{3+}) is the transferrin receptor (TfR): TfR is the major cellular receptor for Tf-bound Fe^{3+}, but since Tf can also bind trivalent Mn, TfR can also mediate its transport. This protein carries Mn^{3+} into the cell with subsequent endocytic reduction of Mn^{3+} to Mn^{2+} and ensuing transport via DMT-1 into the cytosol.

Mn Uptake in Various Cellular Organelles

Mitochondria, the Golgi apparatus, and nuclei store the majority of intracellular Mn. Mitochondria in the basal ganglia accumulate the highest Mn concentration, predominantly via the Ca^{2+} uniporter channel. Efflux of mitochondrial Mn^{2+} is mediated preferentially through an active, but slow, Na^+-independent mechanism. This slow Mn efflux accounts for the net accumulation of Mn in the mitochondria and its protracted half-life. In the Golgi apparatus, a P-type pump, referred to as SPCA1, serves as a Mn/Ca pump. GPP130, another Golgi apparatus-related protein, rapidly traffics from the Golgi apparatus to lysosomes where it is degraded. The degradation of GPP130 occurs in response to increased intra-Golgi Mn levels.

Other mechanisms that regulate Mn homeostasis and detoxification remain largely unknown. It is likely that optimal tissue Mn levels are maintained by multiple Mn transporters, both importers and exporters.

Effects of Mn on Human Health

Mn Deficiency

The requirement for Mn varies throughout the life span and based on gender. Mn levels are higher in women of childbearing age than in men and rise during pregnancy, in both the mother and the fetus. Cellular energy, immune function, digestion, reproduction, bone growth, and blood clotting require optimal Mn concentrations. Mn plays an important role as a cofactor of numerous enzymatic reactions, controlling optimal levels of amino acids, lipids, proteins, and carbohydrates. Mn is inherent to antioxidant enzymes, such as superoxide

dismutase, and it activates glycosyltransferase, an essential step in bone and connective tissue growth.

Mn deficiency, though rare, causes poor bone formation and skeletal abnormalities, compromised growth, decreased fertility and birth defects, abnormal glucose tolerance, and altered lipid and carbohydrate metabolism. Suboptimal Mn status may occur in humans with osteoporosis or exocrine pancreatic insufficiency and children with Perthes' disease or phenylketonuria. Mn deficiency has also been associated with reduction in body and liver weights, total plasma protein, high density lipoprotein (HDL) cholesterol, and apolipoprotein E protein (present in HDL). Mn deficiency also leads to decreased triglyceride synthesis, reinforcing the role of Mn in lipid, protein, and carbohydrate metabolism.

Mn Toxicity

Mn may cause adverse hematologic, endocrine, male reproductive, nephrotoxic, or hepatotoxic effects, but its predominant target is the CNS. Mn neurotoxicity has been primarily observed in occupational cohorts, where the potential for chronic exposure exists. The predominant route of exposure in occupational settings is via inhalation of Mn-laden dust derived from welding, mining, smelting, or battery manufacturing. The neurological effects of Mn result in muscle weakness, limb tremor, whispering speech, salivation, and postural changes, all of which are collectively referred as 'manganism.' These effects are commonly preceded by neuropsychiatric disturbances.

The cellular and molecular mechanism(s) underlying the neurotoxicity of Mn remains to be fully understood. Mn impacts many biological functions, dependent upon dosage, chemical form (oxidation state), routes and duration of exposure, and the sex and age of the exposed individual.

Mechanisms of Mn toxicity

Alzheimer type II astrocytosis

Astrocytes are specialized glial cell present in the CNS. These cells play many critical physiological roles, all of which are essential for optimal neuronal activity. Astrocytes have the ability to concentrate Mn to levels 50-fold higher than the surrounding media, representing the major homeostatic regulator and storage site for Mn in the brain. Such preferential accumulation renders astrocytes potentially the most vulnerable neural cell to Mn toxicity. Primate models of Mn toxicity have been associated with pathological alterations in astrocytes, known as the *Alzheimer type II astrocytosis*. Moreover, Mn accumulation in astrocytes has been shown to alter glutamate (Glu) homeostasis and to elicit excitatory neurotoxicity, as astrocytes are critical for the removal of synaptic Glu.

Mitochondrial dysfunction

Mn accumulation in mitochondria can inhibit the electron transfer chain. Such effects result in a diminished ATP production, leading to increased leakage of electrons and increased superoxide ($O_2^{\bullet -}$) production, thereby causing cellular collapse. Excessive Mn uptake in astrocytes and subsequent mitochondrial accumulation of this metal may compromise energy metabolism, augment oxidative damage, and impair astrocytic–neuronal communication, thus leading to alterations in excitatory and inhibitory control and contributing to the subsequent development of secondary Glu-mediated toxicity.

Once inside the mitochondria, Mn can inhibit the enzymatic complexes of the mitochondrial electron transport chain, notably complexes I and II. Remarkably, mitochondrial complex II is a key mediator of Mn^{2+}-induced hydrogen peroxide production. In addition, it has been shown that Mn^{2+} can bind to ATP, reducing its availability.

Mn has also been reported to alter Ca^{2+} homeostasis in the mitochondria by inhibiting its efflux, thus increasing its levels in this organelle. As a consequence, oxidative stress generated by high Mn concentrations leads to the induction of mitochondrial permeability transition (MPT), a Ca^{2+}-dependent process, characterized by the opening of the MPT pore in the inner mitochondrial membrane. Ca^{2+}-mediated MPT opening leads to the activation of the Bcl-2 family of proteins, especially Bax/Bac, culminating with the release of *cytochrome c* (*Cyt c*). *Cyt c*, via the ERK pathway, activates the cysteine protease, caspase-3, an executioner protein, which is responsible for mediating apoptosis, chromatin condensation, and DNA fragmentation.

Endoplasmic reticulum stress

Endoplasmic reticulum (ER) stress is caused as a result of the accumulation of excessive unfolded protein response, leading to apoptosis. The ER is important for the synthesis, proper folding, posttranslational modification, and transport of nascent proteins. Thus, the presence of a protein overload in the ER results in ER stress. ER stress is inherent to Mn-induced neurotoxicity. Mn induces ER stress via activation of pancreatic ER kinase RNA signaling pathway. Mn exposure induces the ER stress genes glucose-regulated protein 94 and C/EBP homologous protein and increases the phosphorylation of the eukaryotic translation initiation factor 2a. These effects are accompanied by the activation of the ER-resident enzyme caspase-12 and caspase-3. Notably, the Mn-induced responses are enhanced by Fe depletion.

Mn-induced alterations in neurotransmitter systems

DAergic system Excessive Mn accumulation may cause symptoms similar to those observed in Parkinson's disease; thus, special attention has been directed to its effects on the DAergic system. Chronic exposure to Mn is associated with nigrostriatal DAergic neurodegeneration. Nevertheless, the effect of Mn on striatal dopamine (DA) levels remains controversial.

Both Mn^{2+} and Mn^{3+} react with DA via the Fenton reaction, catalyzing its autooxidation and generating reactive species, thereby contributing to oxidative damage. However, it is noteworthy that neither Mn^{2+} nor Mn^{3+} can directly generate hydroxyl radicals from hydrogen peroxide and/or superoxide via the Fenton-type or Haber–Weiss-type reactions. Hence, Mn-induced DA autooxidation is a complex process involving several steps in which semiquinone and aminochrome, L-cysteine, or copper (Cu) and NAD(P)H are implicated. Possible mechanisms underlying semiquinone- and aminochrome-induced damage in Mn-induced neurodegenerative process may therefore include NADH or NADPH depletion, inactivation of enzymes by oxidizing thiol groups or

essential amino acids, formation of reactive oxygen species, and lipid peroxidation.

Effects of Mn on glutamatergic system Mn accumulation produces symptoms consistent with an excitotoxic mechanism. Glu is the most abundant excitatory neurotransmitter, and it plays several major roles in normal brain function. Glu excitotoxicity is associated with an excessive amount of Glu in the extracellular space, which can lead to a cascade of downstream degenerative processes. Excess Glu is removed by cellular uptake, which is mediated by Glu transport proteins, such as glutamate–aspartate transporter (GLAST) and the glutamate 1 transporter (GLT1); both are particularly abundant in astrocytes.

Mn exposure can decrease the ability of astrocytes to remove synaptic Glu, thereby increasing its excitotoxicity. Decrease in GLAST and GLT1 expression and activity has been documented in Mn-exposed astrocytes. In addition, the distribution of Glu is highly sensitive to changes in energy supply. Thus, mitochondrial dysfunction must be considered as a key mechanism in mediating Mn-induced Glu dyshomeostasis. Furthermore, Mn-induced reactive oxygen species generation may directly inhibit Glu uptake, effectively increasing extracellular Glu concentrations.

Effects of Mn on the GABAergic system GABA (γ-aminobutyric acid) is the main inhibitory neurotransmitter. Previous data have been pointed that the GABAergic system is affected by exposure to Mn, and, there is a temporal factor that contributes to these effects. Mn augments GABA content in the caudate nucleus and increases its release. In cell culture models, striatal GABAergic neurons are more vulnerable to Mn relative to mesencephalic DAergic neurons. Other studies have shown decreased pallidal GABA concentration in response to Mn exposure. It has yet to be determined which is the primary effect of Mn on GABAergic systems.

Effects of Mn on the cholinergic system The cholinergic system, which is involved in emotions, cognition, and/or locomotion, consists of acetylcholine (Ach)-secreting neurons and associated glia. Neurotoxicants targeting the cholinergic system lead to excessive extracellular Ach levels due to hyperproduction or limited degradation, consequently leading to hyperresponsiveness to Ach, oxidative stress, and cell death.

A number of cholinergic synaptic mechanisms are putative targets for Mn activity, such as presynaptic choline uptake, quantal release of Ach into the synaptic cleft, postsynaptic binding of Ach to receptors, and its synaptic degradation by acetylcholinesterase. Moreover, Mn influences astrocytic choline transport and astrocytic Ach-binding proteins. Thus, the symptoms associated with the early psychotic phase of manganism, also called 'manganese madness,' may be attributed to an impairment of the septohippocampal cholinergic system, which is involved in both the physiological and the behavioral responses to stress.

Conclusions

The ubiquitous presence of Mn in food products and drinking water assures its optimal absorption and function in regulating cellular metabolism and homeostasis. Mn is important for optimal development, growth, and antioxidant system and energetic metabolic pathways. However, the intake of this essential metal must be tightly regulated, since high levels of intracellular Mn may cause mitochondrial dysfunction, lipid peroxidation, and alterations in neurotransmitter systems, just to name a few.

Mangoes

AC Matheyambath, J Subramanian, and G Paliyath, University of Guelph, Guelph, ON, Canada

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Mango (*Mangifera indica* L.) is one of the most relished and important tropical fruits consumed in fresh or processed form globally. Mango products such as canned slices, puree, nectar, pickles, and chutney experienced worldwide popularity and also gained an increasing importance in US and European markets. Mango has been listed at the top of the super fruit list because of their health-promoting properties. India is the world's largest mango producer, followed by China, Thailand, Indonesia, Pakistan, Mexico, and Brazil. Commercial processing of mango into juice, nectar, pulp, puree, fruit leather, and jam produces 35–60% waste consisting of peel, kernel, and cull fruit. Most mangoes are consumed uncooked as a dessert fruit, the rest of them being processed into various products, such as nectar, juice powder, dried mangoes, canned mango slices in syrup, chutneys, and pickles, among others. One of its most processed forms is pulp, which is further used for manufacturing finished products such as juice, nectar, fruit drink, jam, and squash.

There are over one thousand different cultivars of mangoes growing worldwide, and mangoes are considered to be one of the most widely eaten fruits. Mango is known to be an excellent source of nutrients and vitamins such as ascorbic acid, thiamine, riboflavin, niacin, and ß-carotene. Mangoes are also high in phytochemicals. Epidemiological evidences suggest that a diet rich in fruits and vegetables provide health benefits by preventing the development of chronic diseases such as cardiovascular diseases and cancer. These health beneficial effects are due to the presence of various bioactive compounds that are present in mango fruits, and these compounds are shown to exhibit antioxidant, antiallergenic, antiatherogenic, anti-inflammatory, antimicrobial, and antithrombotic effects. Several studies have reported that *Mangifera* species are rich in dietary fiber and phytochemicals in all their parts, which play an important role as antioxidants.

Mango as a Fruit

The common English term 'mango' and the botanical name '*Mangifera indica* L.' originate from the ancient Tamil name 'manga.' The *Mangifera indica* belongs to the family Anacardiaceae that consists of 64 genera, mostly of trees and shrubs, some of which are poisonous. Mango is one of the oldest tropical fruits and has been cultivated for over 4000 years, originating apparently in the Indo-Burma region. Mango fruit is one of the most popular, nutritionally rich fruits with unique flavor, fragrance, taste, and health-promoting qualities, often labeled as a 'super fruit.' Mango is a tree cultivated in many tropical regions, and now, its farming is distributed widely across the world in many continents.

Mango comes in different shapes and sizes depending upon cultivar types. Internally, its flesh is juicy and orange–yellow in color with numerous soft fibrils radiating from its centrally placed nearly flat, oval-shaped stone (enveloping a single large kidney-shaped seed). Its flavor is pleasant and rich, and it tastes sweet with mild tartness. Mango fruit is a large fleshy drupe containing edible mesocarp of varying thickness. It varies in size, shape, color, and flavor. The exocarp (peel) is thick and glandular. The mesocarp (pulp) can be fibrous or fiber-free with flavor ranging from turpentine to sweet. The mesocarp provides edible pulp, which is firm containing a sweet, well-flavored juice. The endocarp is woody, thick, and fibrous, forming a thick, tough, leathery glandular covering of the seed, termed as husk. The seed is exalbuminous. It is solitary, large and flat, and ovoid oblong and is surrounded by the endocarp at maturity. The testa is thin and papery. The outer skin is smooth and is green in unripe mangoes but turns into golden yellow, crimson red, yellow, or orange–red when ripened depending upon the cultivar type.

There are around a thousand varieties of mango available all over the world, which includes Ataulfo, Haden, Keitt, Kent, Edward, Palmer, Manila, Kesar, and many more exotic delicacies. Apart from numerous seedling varieties, more than a thousand vegetatively propagated mango cultivars have been reported. Most of these have originated as chance seedlings selected earlier and further maintained asexually. Majority of these cultivars is of Indian origin, and representation from other parts of the world is limited in number.

Mango: Production Scenario

Mango is one of the most important tropical fruit crops in the world and is ranked fifth in production among major fruit crops. Mangoes are produced in over 90 countries worldwide. FAO estimates that the mango harvest will be around 28 million tons in 2014, that is, 35% of the production of the world's tropical fruit. Asia accounts for approximately 77% of global mango production, and the Americas and Africa account for approximately 13% and 9%, respectively. Mango has a long history of cultivation, and its cultivation has recently expanded to countries in temperate zones by use of protected cultivation. Most of the major mango-producing countries like India, China, Thailand, Indonesia, Pakistan, the Philippines, and Bangladesh are located in Asia; however, the cultivation has spread to countries such as Mexico, Brazil, Madagascar, Tanzania, Dominican Republic, Haiti, Brazil, and Australia.

Currently, only 3% of the world production of mango is traded globally. Trade centers for mango in the world can be divided into three regional areas: Asia, which trades mainly with the Middle East; Africa, which exports to the European market; and Latin America, which supplies to the American and European markets. The two major import markets are the United States and Europe. The mango market has grown considerably over the last 30 years. Latin American countries have made the most of this dynamism by increasing their supply. In

the last 10 years, it has grown in volume by 38% in the United States and doubled in Europe. The highest levels of consumption are in Asia, followed by Latin America, Africa, and Australia. In Asia, unripe mangoes are especially popular, while in the West, ripe mangoes are mainly eaten. The United States and the European Union have increased their import share.

The most popular export mango cultivars are Kent, Tommy Atkins, Haden, and Keitt, which have fruits with a red blush and that are fiberless, firmer, and more suited for long-distance transportation than other types of cultivars. The green cultivars, such as Ataulfo and Amélie, are now widely accepted in the international market. Other cultivars gaining popularity in the international market are Alphonso, Dudhpeda, Kesar, Sindhu, Pairi, Desi, Chaunsa, Langra, and Katchamita. There is also evidence that the processed mango fruit market is increasing. Processed fruit products include mango juice, pickled mangoes, mango chutney, mango pulp, mango paste, mango puree, dried mango fruit, mango slices in brine, and mango flour. India is the main exporter of processed mangoes, followed by Pakistan, Brazil, and Zimbabwe. Major importers include the United Arab Emirates, Saudi Arabia, Kuwait, the United States, the United Kingdom, and Canada.

Mango: Consumption Pattern

Mango is an important component of the diet in many less developed countries in the subtropics and tropics. Mango fruit is valued because of its excellent flavor, attractive fragrance, delicious taste, and health-giving properties. Before 1970, mangoes were not famous to consumers outside the tropics, and the trade involving fresh fruit was nonexistent. In the subsequent years, a rapid expansion of mango production into nontraditional areas resulted in the mango trade becoming well established. Mango industry has provided livelihood opportunities to its growers and those involved in its marketing channel. Creation of essential infrastructure for preservation, cold storage, refrigerated transportation, rapid transit, grading, processing, packaging, and quality control is the important aspect, which needs more attention. The international market is becoming more competitive, and other mango-producing countries are also entering the market.

As mango is a seasonal fruit, mango fruit is processed and used at almost every stage of its growth. The range of products includes products derived from both raw and ripe fruit. Mango and mango products are experiencing worldwide popularity and also gained increasing importance in the market. Therefore, processing and product development are an important factor in mango marketing. Mangoes are processed at two stages of maturity. Green fruit is used to make chutney, pickles, curries, and dehydrated products. Ripe mangoes are processed as canned and frozen slices, puree, juices, nectar, and various dried products. Mango juice, nectar, and squash are some of the important beverages prepared on a commercial scale. The pulp was extracted from fully ripe fruits, canned and used for preparing nectars and juice. Mango-based carbonated beverages and wines are also available in the market. Production of fruit juice powder has important role in food processing industry in recent years because of several advantages. Dried mango powder is a good adjunct in ice cream, bakery, and confectionery industry. The pulp of the sour and seedling varieties is traditionally sun-dried for use as flavoring ingredients especially in Indian food preparations.

The mango processing industry faces many problems related with its industrialization and market expansion. The high number of varieties with their various attributes affects the quality and uniformity of processed products. A lack of simple, reliable methods for determining the stage of maturity of varieties for processing also affects the quality of the finished products. A significant problem in developing mechanized equipment is the large number of varieties available and their different sizes and shapes. There is, however, a considerable export potential to developed countries, but in these countries, the processed mango products must compete with the market for established processed fruits.

Nutritional Value of Mango

The mango fruit is an important part of human nutrition in several parts of the world. Mango is used as food in all stages of its development. During the ripening process, the fruit is initially acidic, astringent, and rich in ascorbic acid. Mango fruit contains amino acids, carbohydrates, fatty acids, minerals, organic acids, proteins, and vitamins (Table 1). The fruit flesh of ripe mango contains about 15% sugar. Sugars present in mango comprise sucrose, glucose, fructose, and maltose. Sucrose is the principal sugar in ripe mango. Sucrose content of ripe fruit of three important cultivars, namely, Alphonso, Pairie, and Totapuri, ranges from 11% to 20%. Free sugars including glucose, fructose, and sucrose generally increase during ripening. Mango fruit contains 0.5–1.0% protein on a fresh weight basis. The presence of amino acids including the essential ones such as lysine, leucine, cysteine, valine, arginine, phenylalanine, and methionine in fruits of various cultivars has been recorded. Total lipid content in seven commercial mango cultivars ranged from 0.26% to 0.67% at harvest.

Mango fruit is particularly a rich source of vitamin C. Raw mango contains more vitamin C than that of ripe or fully ripe mango. Literature reports indicate great variation in ascorbic acid contents, ranging from 9.79 to 186 mg per 100 g of mango flesh. Daily consumption of mango fruits by population groups of all life stages can meet the recommended dietary

Table 1 Food value of mango (100 g fresh fruit)

Component	*Content*
Calories	62.10–63.70
Moisture	78.90–82.80 g
Protein	0.36–0.40 g
Fat	0.30–0.53 g
Carbohydrates	16.20–17.18 g
Fiber	0.85–1.06 g
Ash	0.34–0.52 g
Calcium	6.10–12.80 g
Phosphorus	5.50–17.90 g
Iron	0.20–0.63 g

Source: Morton, J. (1987). Mango. In: Julia F. Morton (eds.) *Fruits of warm climates*. Miami, FL: Florida Flair Books, pp. 221–239.

requirements of vitamins A and C. Mangoes differ in their ascorbic acid content because of genotype variations, climatic factors, agricultural practices, and ripening stage.

Fruit acidity is mainly due to the presence of malic and citric acids. The presence of folic acid (3.6 mg/100 g), vitamin B1 (35–63 mg/100 g), and vitamin B2 (37–73 mg/100 g) in mango has been reported. Mango also contains the B vitamins thiamine and riboflavin (0.08 mg) and niacin (0.09 mg) per 100 g of ripe mango. The vitamin A equivalent in mango ranges between 1000 and 6000 IU. β-Carotene was found to account for 60% of total carotenoids in mango. It was found that mevalonic acid, a precursor of carotenoids, increased progressively during the ripening of mangoes. Mango consumption is very important for some populations in tropical regions, where the deficiency of vitamin A constitutes a public health problem. A study using an *in vitro* model indicated that there are varietal differences in the content and bioavailability of β-carotene from mango. Ash content decreased during fruit development with some increase near maturity, while crude fiber remained constant. Studies on mango flesh showed that a high proportion of the fiber fraction consists of pectin, and its content in the peel is also quite high. The US Department of Agriculture (USDA) Nutrient Database indicates α-tocopherol content of 1.12 mg/100 g. Alpha-tocopherol is the only detectable tocopherol in seven mango cultivars examined. 'Haden' and 'Tommy Atkins' mangoes had the highest amounts (380 and 470 μg/100 g, respectively), with 200–250 μg/l00 g in the other cultivars.

Mango is known for its medicinal properties at both raw and ripe stages. The unripe fruit is astringent and a stimulant tonic. The acid content in the green mango increases the secretion of bile and has a role in intestinal absorption. Ripe mangoes are highly beneficial in the treatment of night blindness. Ripe mango is antiscorbutic, diuretic, laxative, and mildly astringent. In Ayurvedic system, mango is considered to increase seven body 'elements' called *dhatus*, namely, food, juice, blood, flesh, fat, bone marrow, and semen.

Bioactive Compounds in Mango and Its Health Benefits

Mangoes are found to be rich in bioactive compounds such as polyphenolics, carotenoids, vitamins, and dietary fibers and have many of the pharmacological properties attributed due to the presence of these bioactive compounds in them. The presence of gallic acid, *m*-digallic acid, *m*-trigallic acid, gallotannin, quercetin, isoquercetin, mangiferin, and ellagic acid was reported in mango fruit. Digallic acid seemed to undergo a small degree of polymerization, whereas quercetin and isoquercetin disappeared during ripening. Another type of polyphenols found in mango fruit is alkylresorcinols, which are predominantly found in unripe fruit and decrease in quantity during ripening. Reports suggest that the phytochemical content of mango pulp consists of gallic acid, mangiferin, quercetin glycosides, and many identified and uncharacterized hydrolyzable tannins. Other compounds in smaller concentrations include *p*-OH-benzoic acid, *m*-coumaric acid, *p*-coumaric acid, and ferulic acid. In most mango varieties, free gallic acid, 3,4,5-trihydroxybenzoic acid, is the predominant compound present and has been shown to possess a high antioxidant capacity with numerous implications to overall human health.

The major polyphenols in mango in terms of antioxidative capacity and/or quantity are mangiferin, catechins, quercetin, kaempferol, rhamnetin, anthocyanins, gallic and ellagic acids, propyl and methyl gallate, benzoic acid, and protocatechuic acid. Nutraceutical and pharmaceutical significance of mangiferin, which is a special polyphenol in mango, has been extensively demonstrated and continues to attract much attention especially in its potential to combat degenerative diseases such as cardiovascular diseases and cancer. The amount of the different polyphenolic compounds in mango varies from part to part. Mango polyphenols acts mainly as antioxidants, preventing DNA damage and many degenerative diseases. Bioactive compounds found in mangoes, just as in other plants and herbs, have been shown to have possible health benefits with antioxidative, anticarcinogenic, antiatherosclerotic, antimutagenic, and angiogenesis-inhibitory activities.

Polyphenolic Compounds

Polyphenols are a large family of natural compounds that are secondary metabolites and are derivatives of the pentose phosphate, shikimate, and phenylpropanoid pathways in plant. Phenolic compounds exhibit a wide range of beneficial properties to health, such as antiallergenic, anti-inflammatory, antimicrobial, antioxidant, antithrombotic, cardioprotective, and vasodilatory effects. The main classes of polyphenols are defined according to the nature of their carbon skeleton, and they are phenolic acids, flavonoids, stilbenes, and lignans.

Mangiferin, gallic acids (*m*-digallic and *m*-trigallic acids), gallotannins, quercetin, isoquercetin, ellagic acid, and β-glucogallin are among the polyphenolic compounds already identified in the mango pulp. Gallic acid (6.9 mg kg^{-1}) and mangiferin (4.4 mg kg^{-1}) have been identified as the major polyphenol present in mango fruits and pulp, followed by *p*-OH-benzoic acid, *m*-coumaric acid, *p*-coumaric acid, and ferulic acid. In a polyphenol screening of 20 mango varieties, gallotannins represent the major components of unripe fruits and seeds. Gallic acid is the substrate of polyphenol oxidase in the fruit pulp, whereas ellagic acid is the predominant substrate in mango peel.

Mangiferin (C 2-β-D-glucopyranosyl-1,3,6,7-tetrahydroxyxanthone) is a xanthone, and xanthones are some of the most potent antioxidants known and sometimes unofficially referred to as 'super antioxidants.' Mangiferin, generally called C-glucosyl xanthone, is widely distributed in higher plants, and it is a pharmacologically active phytochemical and a natural polyphenolic antioxidant present in the bark, fruits, roots, and leaves of *M. indica* Linn. It has been found to exhibit a wide range of pharmacological effects including antioxidant, anticancer, antimicrobial, antiatherosclerotic, antiallergenic, anti-inflammatory, analgesic, and immunomodulatory, among many others. Mangiferin also inhibited body weight gain in experimental rats and can be used in food products for special dietary needs for obese people. Mangiferin protects erythrocytes and RBCs from reactive oxygen species production, thus contributing to integrity and functionality of these cells. It was reported that mangiferin inhibits the glucosidase enzymes sucrase, isomaltase, and maltase from rats, which are involved in the digestion of carbohydrates into simple sugars in the gut leading to delay or inhibition of carbohydrate breakdown and

subsequent slower glucose absorption from the intestine. Mangiferin was found to significantly reduce plasma total cholesterol, triglycerides, and LDL-C associated with a concomitant increase in HDL-C levels and a decrease in atherogenic index in diabetic rats indicating its potential antihyperlipidemic and antiatherogenic activity.

Flavonoids can be divided into several classes according to the degree of oxidation and substitution of the benzopyran ring, including flavones, flavanones, flavonols, flavanols, isoflavones, anthocyanins, and proanthocyanidins. Mangoes are a rich source of flavonoids and xanthones such as mangiferin, catechins, quercetin, kaempferol, rhamnetin, flavonol, and xanthone. Quercetin and isoquercetin are reported in mango pulp, and quercetin, kaempferol, rhamnetin, mangiferin, mangiferin gallate, isomangiferin, and isomangiferin gallate can be found in peels. Other flavonoids found in mango include fisetin and astragalin (kaempferol-3-glucoside). The skin of mango variety Haden is reported to contain peonidin-3-galactoside. Catechins is a group of flavonoid including (−)-epicatechin, (−)-epigallocatechin, (−)-epicatechin gallate, and (+)-gallocatechin. Several epidemiological and *in vitro* studies suggest that catechins have beneficial effects on human health due to their free radical-scavenging and antioxidant activities. The major flavonoids identified in mangoes are quercetin and related glycosides in mango pulps, with the predominant flavonol glycoside, namely, quercetin 3-galactoside (22.1 mg kg^{-1}), followed by quercetin 3-glucoside (16.0 mg kg^{-1}), quercetin 3-arabinoside (5.0 mg kg^{-1}), and quercetin aglycone (3.5 mg kg^{-1}). Peels of the cultivar Tommy Atkins contained a large number of flavonol O-glycosides and xanthone C-glycosides including isomangiferin, mangiferin gallate, isomangiferin gallate, quercetin 3-O-diglycoside, quercetin 3-O-galactoside, quercetin 3-O-glucoside, quercetin 3-O-xyloside, quercetin 3-O-arabinopyranoside, quercetin 3-O-arabinofuranoside, quercetin 3-O-rhamnoside, kaempferol 3-O-glucoside, rhamnetin 3-O-galactoside, rhamnetin 3-O-glucoside, quercetin (aglycone), mangiferin, isomangiferin, mangiferin gallate, and isomangiferin gallate.

A wide range of biological activities, including antibacterial, antithrombotic, vasodilatory, anti-inflammatory, and anticarcinogenic effects mediated by different mechanisms, are associated with flavonoids. Studies have shown biological effects of quercetin on inhibition of protein kinases, DNA topoisomerases, and regulation of gene expression. There is consistent evidence from these studies that quercetin may reduce the risk of cancer. Quercetin may also provide a promising approach for treatment of Alzheimer's disease and other oxidative stress-related neurodegenerative diseases. A population study showed that higher intakes of kaempferol tended to lower ischemic heart disease mortality and the incidence of cerebrovascular disease.

Phenolic acids such as caffeic acid and gallic acid are the most well-absorbed polyphenolics, followed by catechins, flavanones, and quercetin glucosides. Mango gallotannins most likely are not absorbed in the small intestine and might reach the colon where they are transformed into low-molecular-weight galloyl glycosides derivatives by bacterial action. Polyphenolics such as the proanthocyanidins, the galloylated tea catechins, and the anthocyanins are not absorbed well in the GIT. These polyphenolics are extensively metabolized by the colonic microflora into a wide array of low-molecular-weight polyphenolic breakdown products.

Carotenoids in Mango

The mango fruit is a rich source of carotenoids, and some of them are identified as β-carotene (all-*trans*), β-cryptoxthanin (all-*trans* and *cis*), zeaxanthin (all-*trans*), luteoxanthin isomers, violaxanthin (all-*trans* and *cis*), and neoxanthin (all-*trans* and *cis*). Carotenoids are responsible for the yellow–orange color of mango mesocarp. Beta-carotene is generally the predominant carotenoid in mango pulps, comprising 48–84% of the total carotenoids. During mango fruit ripening, carotenoid levels increase, and ripe fruits are tenfold richer in carotene than partially ripe fruit, while unripe green mangoes contain only trace amounts. Mevalonic acid, a precursor of carotenoids, increases progressively during mango ripening. Variation in carotenoid content in mango is mainly due to several factors such as cultivar, geography, climate, storage/processing conditions, and analytic procedures employed.

The absorption of these carotenoids is influenced by many factors. In the case of carotenoids, they are absorbed at the level of the mucous of the duodenum by the mechanism of passive diffusion. The principal factor limiting the bioavailability of carotenoids in foods is its liberation from the food matrices where they are enclosed and dissolved in lipid droplets. In fruits, carotenoids are found in the chromoplast, hence limiting their liberation during digestion. It is better to transform the fruits (juice or fresh slices) before consumption. The quantity and quality of food lipids constitute a primordial factor affecting bioavailability of carotenoids. Transportation of carotenoids and their products of hydrolysis from the intestines to the blood vessels and liver is assured by lipoproteins rich in triglycerides.

Conclusions

Mango is a fruit with high nutritional value providing human diet with calories, fiber, vitamins, and minerals. Mangoes could also serve as a rich source of bioactive compounds such as polyphenols and carotenoids (Table 2). Bioactive compounds present in fruits and vegetables are receiving increased attention due to their health-promoting benefits including protection against cardiovascular diseases and cancer. The major polyphenols in the mango in terms of antioxidative capacity and/or quantity are mangiferin, catechins, quercetin, kaempferol, rhamnetin, anthocyanins, gallic and ellagic acids, propyl and methyl gallate, benzoic acid, and protocatechuic acid. The nutraceutical and pharmaceutical significance of mangiferin, which is a special polyphenol in the mango, has been drawing much attention especially in its potential to combat degenerative diseases such as heart diseases and cancer. The amounts of the different polyphenolic compounds in mango vary from part to part (pulp, peel, seed, bark, leaf, and flower) with most polyphenols being found in all the parts. Being a very popular plant, especially within the tropics and owing to its uniqueness in taste and flavor, mango could be a readily available source of dietary polyphenols with great antioxidative potential that will help to manage degenerative diseases such as cancer, atherosclerosis, diabetes, and obesity.

Table 2 Bioactive compounds in mango

Bioactive compounds in mango
Phenolic acids
Gallic acid (*m*-digallic and *m*-trigallic acids), benzoic acid, 3,4-dihydroxybenzoic acid, *p*-OH-benzoic acid, *m*-coumaric acid, *p*-coumaric acid, ferulic acid, ellagic acid
Flavanoids
Mangiferin, mangiferin gallate, isomangiferin, isomangiferin gallate
Quercetin, isoquercetin, quercetin 3-galactoside, quercetin 3-glucoside, quercetin 3-arabinoside, quercetin aglycone, quercetin 3-O-diglycoside, quercetin 3-O-galactoside, quercetin 3-O-glucoside, quercetin 3-O-xyloside, quercetin 3-O-arabinopyranoside, quercetin 3-O-arabinofuranoside, quercetin 3-O-rhamnoside

Margarine: Composition and Analysis

MD Guillén, ML Ibargoitia, and P Sopelana, University of the Basque Country (UPV/EHU), Vitoria, Spain

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Since its development as a butter substitute by the end of the nineteenth century, margarine has become a highly versatile product due to the advances in technology and the great variation in composition that it can exhibit. Margarine manufacture technology enables the production of very varied products that can satisfy the needs and requirements of different segments of the population. This has contributed to an increase in margarine consumer demand over time. Thus, in 2012, the world production of margarine amounted to 9.4 million tons.

Definition and Types of Margarines

Strictly speaking, margarine is a water-in-oil (W/O) emulsion derived from vegetable and/or animal fats, with a fat content of between 80% and 90% and a milk fat content of no more than 3%. The emulsion remains solid at 20 °C. Other W/O emulsions with a fat content of 39–41% may be designated as minarine or halvarine, according to the Codex Stan 256-2007. In addition to these two kinds of emulsions, there are others with fat contents outside the limits mentioned, which could be described as fat spreads. In spite of these clear differences in relation to the fat content of the different kinds of products and in order to simplify matters, this article will use the term 'margarine' in a general way, regardless of fat content. Table 1 shows the different kinds of margarines and related products and their denominations according to their fat content. Moreover, depending on their composition and texture, they have been described as hard, soft, and semisoft margarines.

Margarine Manufacture Process

Margarine manufacture involves the blend of a lipidic and an aqueous phase in order to obtain a W/O emulsion with a fat percentage of at least 80%. Apart from 80% of fat, the rest is usually skim milk, whey, or a water solution containing salt and flavors.

Preparation of the fatty raw material

One of the main requirements of the margarine lipidic fraction is that it provides an appropriate texture to the final product; this will depend both on the fat composition and on its physical structure. The type of fats used for margarine manufacture can be very varied, including vegetable oils with different unsaturation degrees, marine oils, solid fats of either vegetable or animal origin, and their mixtures. Some of these fats are usually subjected to specific treatments aimed at achieving the desired characteristics in the final product.

In the beginning, partial hydrogenation of liquid vegetable oils was the technology used for margarine production. This process, which involves the addition of hydrogen gas in the presence of a suitable catalyst, raises the melting point of the oil by saturation of double bonds, providing a firmer consistency. However, partial hydrogenation can produce *trans* isomers of fatty acids (FAs), which have been related to harmful effects on human health. In an attempt to reduce the levels of *trans* isomers in margarine, other strategies and technologies, such as the introduction of some modifications in the hydrogenation process, have been developed. These include hydrogenation in critical fluids, pressure-controlled hydrogenation, the use of novel catalysts, and conditions known to suppress *trans* FA formation including low temperatures, high pressures, and increased catalyst loadings. Even so, it could be said that the most widely used technology to avoid the occurrence of *trans* isomers in margarine is interesterification, which results in an exchange of acyl groups in the glycerol backbone either of the same triglyceride (TG) or of different TGs. This does not change the unsaturation degree of the fat but causes a modification in the fat physical properties that enables the obtention of fat with suitable melting point and crystallization behavior. The reaction can be catalyzed by sodium methoxide (chemical interesterification) or by lipases (enzymatic interesterification), each process having specific technological conditions. Carrying out this type of reactions usually requires the use of fully hydrogenated oil or of another type of solid fat such as palm stearin together with an unsaturated liquid oil.

Another possibility to produce the lipid-based stock for margarine manufacture is to blend different oils (hydrogenated or not), each with specific melting characteristics. However, it is sometimes necessary to include in the mixture harder components, like stearin.

Description of the process

Margarine production includes the following steps:

- Blending of the suitable fats with other oil-soluble components such as emulsifiers (lecithin, mono- and diglycerides, or a combination of them), oil-soluble vitamins, and colorants (β-carotene and annatto).
- Preparation of the aqueous fraction by mixing different water-soluble components. These include milk or water with salt and flavors such as diacetyl or starter distillate.
- Mixing of both the lipidic and the aqueous phases to form the W/O emulsion at temperatures around 50–60 °C.
- Pasteurization of the emulsion at temperatures around 70–86 °C.
- Chilling to 15–25 °C in a scraped-surface heat exchanger while undergoing vigorous agitation and kneading (plasticizing). This makes an extremely fine dispersion of the water phase in the fat phase possible.
- Solidification of the margarine before extrusion to the packaging line.

Table 1 Kinds of margarines and related products according to their fat content (Council Regulation (EC) No. 1234/2007)

Denomination	*Fat content (%)*
Margarine	≥80 to <90
Fat spreads X %	>62 to <80
Three-quarter fat margarine	≥60 to ≤62
Fat spreads X %	>41 to <60
Half-fat margarine[a]	≥39 to ≤41
Fat spreads X %	<39

[a]Corresponding to minarine or halvarine in Codex Stan 256-2007.

Margarine Composition

Factors Influencing Margarine Composition

Two main factors influence margarine composition: the raw material from which it comes from and the conditions under which its processing takes place.

The raw material can vary a great deal. Vegetable oils such as soybean, sunflower, canola, palm kernel, palm, corn, cottonseed, safflower, coconut, and olive, among others, have been used for margarine production. They can be either totally or partially hydrogenated or not hydrogenated at all. This wide range of raw materials is one of the reasons for the great variability observed in margarine composition.

The processing method in margarine manufacture has a decisive influence on its composition, especially on its unsaturation degree and on its content in unsaturated acyl groups with *trans* configuration. However, when the processing involves enzymatic interesterification instead of partial hydrogenation, the *trans* isomer content is considerably reduced and may even reach zero.

Margarine Components

Triglycerides

These are the main margarine components. The nature of their acyl groups and the position of these in the glyceryl backbone define the properties and physical characteristics of margarine, such as melting and crystallization temperatures, which in turn affect its textural properties. TG composition also influences margarine behavior during processing and storage, as well as its effects on nutrition and health.

Many different acyl groups have been found in margarine TG, with a chain length usually ranging from eight to twenty four carbon atoms and with different unsaturation degrees. Among these, *cis* isomers predominate over *trans* isomers while acyl groups having an even number of carbon atoms predominate over odd chain acyl groups.

Over the years, different compositional parameters have been described as being important for margarine quality and safety. Factors taken into account have included polyunsaturated (P), linoleic (L), saturated (S), and *trans* (*t*) acyl groups content, as well as such ratios as P/S, P/(S+*t*), L/*t*, and omega-6/omega-3 ($\omega-6/\omega-3$). The values considered optimal for each one of these parameters have changed over time, as knowledge of their importance has advanced.

Table 2 shows the ranges in percentage by weight of each one of the FAs in different studies. A wide range of acyl group compositions in margarines can be observed from this table. This reflects the variety of fat sources and processing methods used for their production.

Palmitic acyl groups (C16) are the most abundant of the S groups, whereas the major monounsaturated (M) groups are those with 18 carbon atoms. Of the P acyl groups, the diunsaturated are found in the highest proportions, with triunsaturated acyl group content being much lower. The widest diversity can be found in the S group, with acyl group chain lengths between 14 and 22 carbon atoms. In addition, acyl groups with fewer than 14 carbon atoms and with 24 carbon atoms have also been found in some margarines. The presence of long-chain acyl groups has been related to the use of fish oils for margarine production.

As Table 2 shows, most *trans* unsaturation is found in the monoene fraction, especially in octadecenoic acyl groups. In general, higher *trans* contents have been reported for hard-type margarines than for soft margarines. Broadly speaking, a decrease in the *trans* content of margarine has been observed over the years.

Minor margarine components

Apart from TG, other minor components can be found in margarine. Some of them are naturally present in the fats used for margarine production but their concentrations can get bigger by external addition. Others can be exclusively added during manufacture. The Codex Stan 256-2007 establishes which type of substances can be added and their maximum use level. Vitamins A, D, and E constitute an exception, since these are regulated by national legislations. The most common are the following:

- Mono- and diglycerides

  These components can be present in margarine derived either from the vegetable oils used in its manufacture or as a consequence of hydrolytic reactions during processing and/or storage. They can also be added to margarine due to their emulsifying properties.
- Free fatty acids (FFAs)

  Although there is very little information about the occurrence of FFA in margarine, mean values below 0.5% have been found in margarines prepared both from hydrogenated fats and from fractionated or interesterified fats. These values are considered comparable to those usually found in refined vegetable oils.
- Carotenes and vitamin A (retinol)

  Both carotenes and vitamin A are present in many of the fats used in margarine manufacture. Moreover, in some cases, they are added for their coloring, antioxidant, nutritional, and healthy properties. Vitamin A is usually added as palmitate or acetate esters.

  Although there is little information about carotene and/or vitamin A content of margarine, concentrations of carotene ranging from 0.1 to 1.3 mg $100\,g^{-1}$ have been reported. In margarines declared as being colored with β-carotene or carotene, the concentration of total carotenes ranges between 0.3 and 0.9 mg $100\,g^{-1}$. However, this value can decrease to 0.2 mg $100\,g^{-1}$ in margarines colored with carrot extract and in those with no colorant declared.

- Tocopherols and tocotrienols

  Tocopherols are well-known natural antioxidants and they are present in margarine coming from the vegetable oils used in its manufacture. Of them, α-tocopherol deserves special attention from the nutritional point of view. Tocopherols can also be added externally with the aim of improving both the nutritional properties and the oxidative stability of margarine.

  The tocopherol content of margarine can vary widely due to the very different compositions of the fats/oils used in its manufacture. As an example, margarines produced from corn, sunflower, and cottonseed oils have been reported to have higher α-tocopherol levels than those obtained from soybean oil. Moreover, the vegetable source has also an influence on the relative proportions of the different tocopherol isomers. α-Tocopherol concentrations with values between 0.3 and 44.62 mg 100 g^{-1} have been found in margarines from different countries.

  Tocotrienols, also important due to their nutritional value and to their antioxidant activity, are always in lower concentrations than tocopherols. It is worth noting that margarines made from palm oil can be expected to be among the richest in tocotrienols, since this oil is especially rich in this type of components.
- Vitamin D

  There is very little information concerning the occurrence of vitamin D in margarine. The presence of this vitamin results from its addition in the form of ergocalciferol (D_2) or cholecalciferol (D_3). The values reported for vitamin D_3 content range from 1.08 to 3.9 IU (international units; 1 IU = 25 ng) g^{-1}, exceeding the labeling claims in some cases.
- Vitamin K_1 (phylloquinone)

  Some oils used for margarine manufacture, such as soybean or canola oil, contain significant amounts of vitamin K_1. For this reason, it is present in certain margarines whose consumption could contribute to the dietary intake of this vitamin. Different contents of vitamin K_1 have been found depending on the type of margarine, with a concentration ranging from 4 to 161 μg 100 g^{-1}. In general, hard margarines have been found to contain lower levels of vitamin K_1 than soft ones, when comparing products with similar fat levels and similar oil sources.
- Phytosterols

  The phytosterols that are usually present in margarines come from the vegetable oils used in their manufacture, although in low concentrations. However, certain oils such as rapeseed or corn oils are especially rich in sterols; in fact, higher sterol contents have been observed in margarines obtained from these sources.

  These compounds can also be added in significant proportions (7.5–8%) to some margarines, because of their interest as functional food ingredients, which are able to lower blood cholesterol levels. In this case, they are added in the form of FA phytosteryl or phytostanyl esters, to improve their solubility.

  As in the case of tocopherols, the amounts of sterols in margarines can be very variable. Of these, β-sitosterol has been found to be among the most abundant, in concentrations ranging from 5.4 to 412.9 mg 100 g^{-1}, followed by campesterol (2.0–106.3 mg 100 g^{-1}) and stigmasterol (1.6–60.9 mg 100 g^{-1}).
- Minerals

  There is very little information about the mineral content of margarine. Sodium and potassium appear to be the most abundant, in concentrations ranging between 13.2 and 9870 μg g^{-1} and between 58.2 and 1140 μg g^{-1}, respectively, followed by calcium, magnesium, and iron. Some of these are important from the sensory point of view. They include sodium, responsible for a salty taste, or potassium, related to bitter notes. Others, such as iron, can favor oxidation and thus the formation of compounds responsible for both unpleasant flavors and toxic effects. Other elements such as zinc and manganese are in lower concentrations, with values between 0.38 and 2.71 μg g^{-1} for the former and between 0.12 and 0.59 μg g^{-1} for the latter.

  With regard to the elements that can be toxic in high concentrations, the small amount of existing data reveals that cadmium seems to be the most abundant, with concentrations ranging between 0.02 and 3.66 μg g^{-1}, whereas the mean contents of lead and arsenic do not exceed the maximum of 0.1 mg kg^{-1} established for them in the Codex Alimentarius. Variable concentrations of nickel, used as catalyst in margarine manufacture, have also been observed in a few margarines, up to 1.70 μg g^{-1}.
- Gelatin

  This is sometimes used in margarines with a low fat content, to improve the stability of the emulsion. It has been observed that the addition of gelatin to the aqueous phase of margarine at 0.02% increases the firmness of the product. This enables the addition of 25% more water, when compared to margarine with no gelatin.
- Other components

  In addition to the earlier-mentioned, other components such as sugars, proteins, and different types of additives can also be found in margarine. Apart from the additives already mentioned in the text (carotenes, tocopherols, and emulsifiers such as mono- and diglycerides), acidity regulators, antifoaming agents, synthetic antioxidants such as BHA and BHT, coloring agents such as bixin-based annatto extracts, preservatives such as sorbates, stabilizers, thickeners, and flavorings can also be used. Among these latter, lactones can be cited, as they have been added to some margarines in order to give them a buttery flavor.

Composition of Margarines and Effects on Health

A high content in polyunsaturated *cis* acyl groups and a content of both saturated and *trans* acyl groups as low as possible have been considered desirable from the health point of view for a long time. In fact, S acyl groups in dietary lipids have been held responsible for certain cardiovascular diseases. However, more recent studies have shown that there was insufficient scientific evidence to support this negative opinion of these groups.

As far as *trans* groups are concerned, nutritional studies have suggested a direct relationship between this type of acyl groups and the risk of heart disease, since they increase low-density lipoprotein (LDL) and reduce high-density lipoprotein (HDL) cholesterol levels. In spite of this, nowadays, there are no regulations to control *trans* group content in margarine in a general way, although some organisms such as the World Health Organization (WHO) or the International Margarine Association of the Countries of Europe (IMACE) have given

recommendations aiming at reducing the occurrence of *trans* isomers in margarine. Moreover, some countries have established legal limits for this type of acyl groups, resulting in an effective decrease in the *trans* group content of margarine.

In relation to polyunsaturated acyl groups, certain values of the $\omega-6/\omega-3$ ratio have been considered optimal from the point of view of health, and great efforts have been made to produce margarines with such an acyl group profile. However, this optimal value has changed over time. It should be pointed out that there has been a recent tendency to reduce the $\omega-6$ acyl group content in fat foods and to increase the content in $\omega-3$ because of the beneficial effects attributed to the latter.

As a consequence of the current interest in the development of functional foods whose goal is to improve consumer health, there is a growing trend toward enriching margarine with bioactive compounds.

Therefore, margarines enriched in $\omega-3$ acyl groups are available on the market due to the beneficial cardiovascular effects attributed to these groups. As a result, fish oils and vegetable oils rich in $\omega-3$ acyl groups, such as camelina oil, have been used to this aim. Likewise, the enrichment of margarines with specific acyl groups considered bioactive, like pinolenic, a tri-unsaturated acyl group present in pine nut oil, has also been carried out. However, it should be noted that margarines with high levels of P acyl groups are highly susceptible to oxidation; therefore, special care should be taken in their use when thermal treatments are involved, because toxic compounds can be easily formed upon the degradation of this type of acyl groups.

The effects of phytosterol and phytostanol consumption on lowering cholesterol levels seem to be well established; for this reason, margarines with significant levels of these compounds have received wide consumer acceptance. Phytostanols could have an advantage over phytosterols in view of their lesser tendency toward to oxidation.

In an attempt to help prevent iodine deficiency, the possibility of obtaining iodine-fortified margarine, with a content of 1 μg iodine g^{-1} product, from iodine-fortified sunflower oil has been studied. This could contribute in part to eradicating this deficiency, which can affect both physical development and intellectual development.

Analysis of Margarine

Many efforts have been dedicated to the analysis of margarine components, especially to the nature and content of acyl groups. The methodologies and analytic techniques used have evolved over the years alongside technological improvements and the development of new and more accurate techniques.

Analysis of the TGs

The technique used for the determination of the TG profile of margarine is high-performance liquid chromatography (HPLC) coupled either to an evaporative light-scattering detector or to an atmospheric pressure chemical ionization mass spectrometer (APCI-MS) detector. Before HPLC analysis, the TG fraction can be isolated by column chromatography on silica gel using a mixture of petroleum ether and diethyl ether as eluent.

In addition to HPLC, ^{13}C nuclear magnetic resonance (^{13}C NMR) has also been used for the study of the TG composition of margarines and the distribution of acyl groups in the glycerol structure.

Determination of the Different Types of Acyl Groups

The most usual way to study margarine acyl groups is to perform an alkaline TG hydrolysis in methanol, either directly on the margarine sample or after solvent extraction of the lipidic fraction, followed by the transformation of FAs in the corresponding methyl esters (FAME).

Once the FAME are obtained, they can be analyzed directly by gas chromatography using either flame ionization detector (GC-FID) or mass spectrometry (GC-MS) detector. Over the years, several kinds of columns have been used for this technique with the aim to achieve an optimal separation of *cis* and *trans* isomers; the best results have been obtained by using high-polar columns of great length (100 m). However, with this methodology, the separation of *trans* and *cis* C18:1 isomers cannot be totally obtained, especially when the concentration of the *trans* isomers is higher than the 5%.

Other methodologies involve an additional isolation step by means of thin-layer chromatography (TLC) with silica gel containing silver nitrate (Ag-TLC) before the GC analysis. This technique enables the separation of FAME into fractions differing in the number and geometric configuration of the double bonds. The subsequent GC analysis of each of the fractions makes identification of the different geometric and positional isomers present in the margarine fat possible. However, this methodology is lengthy and not suitable for routine analysis.

As an alternative to the combined procedure of Ag-TLC and GC, a method based on GC-FID and infrared spectrophotometry has also been used, leading to equivalent results. This latter method was recommended for samples with >5% *trans* unsaturation.

HPLC has also been used by some authors for the determination of acyl groups in margarine. However, although some advantages over GC have been identified, HPLC has been little employed for margarine acyl group analysis.

In addition to the previously mentioned techniques, ^{13}C NMR provides information regarding the composition and nature of the acyl chains present in margarine TG. Likewise, ^{1}H NMR has also been proved to be very useful in determining the composition in acyl groups of margarine samples, in only a few minutes and with minimal or no sample pretreatment. The spectral signals from which the different types of acyl groups can be determined are shown in Figure 1.

Determination of the Unsaturation Degree

The total content of double bonds in margarines has also been subject of analysis. Total double bonds can be determined by chemical methods by means of the so-called iodine index or by easier methods involving spectroscopic techniques such as Fourier transform infrared spectroscopy (FTIR) or ^{1}H NMR.

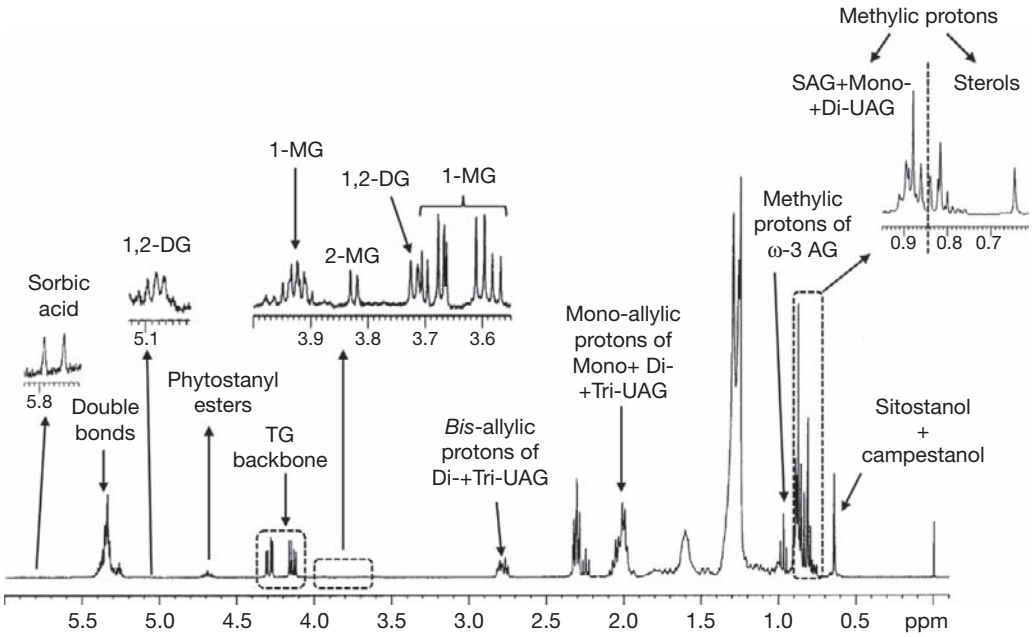

Figure 1 ^{1}H NMR spectrum of the lipidic fraction of a margarine enriched in phytostanyl esters. AGs, acyl groups; UAGs, unsaturated acyl groups; SAGs, saturated acyl groups; MGs, monoglycerides; DGs, diglycerides.

Specific Determination of *trans* Unsaturation

The most common methodology for the determination of the *trans* unsaturation degree of margarines is based on FTIR, it being possible either to use attenuated total reflectance or not. The advantage of this technique in relation to chromatography is that it does not require either fractionation or special sample preparation or chemical modifications of the sample. The band of *trans* double bonds appears near 966 cm^{-1}. This determination has also been carried out by means of optothermal window.

Another spectroscopic technique used for the determination of the *trans* unsaturation in margarine is ^{13}C NMR.

Mono- and Diglycerides

The analysis of mono- and diglycerides in margarine has received very little attention. One of the techniques used for this purpose is HPLC. Monoglyceride determination can be carried out after derivatization with 3,5-dinitrobenzoyl chloride using a ultraviolet (UV) detector or without any sample pretreatment by using a glyceride-selective postcolumn reactor detector.

Both mono- and diglycerides can also be determined by ^{1}H NMR. This technique allows the detection and even quantification of 1- and 2-monoglycerides, as well as of 1,2- and 1,3-diglycerides, simultaneously with the determination of the different kinds of acyl groups. The spectral signals from which the different types of mono- and diglycerides can be determined are shown in Figure 1.

Fatty Acids

This is usually carried out by the methods used to determine this kind of compounds in other fat-containing foods such as vegetable edible oils.

Carotenes and Vitamin A

The analysis of these compounds has been carried out by means of different methodologies and techniques. UV spectrophotometry has been used to determine carotenes and vitamin A after previous extraction of the unsaponifiable matter, separation, isolation, and purification of both kinds of compounds. As saponification can degrade these compounds, there has been a tendency in recent years to avoid this step and carry out the determination directly in a hexane extract of the margarine sample. Carotene absorption occurs near 450 nm and that of vitamin A near 325 nm.

Another method used to determine these compounds is HPLC with two UV detectors connected in series to detect both carotenes and vitamin A simultaneously. This method is faster than the previously mentioned since the isolation and purification steps are carried out by this technique automatically. With HPLC, the determination of these compounds can also be achieved directly from a margarine hexane extract, avoiding the saponification stage.

The isolation step can also be carried out by gel permeation chromatography, directly on the margarine sample dissolved in methylene chloride, followed by nonaqueous reverse-phase (RP) HPLC.

More recently, and with the same aim of avoiding saponification, photoacoustic spectroscopy and optothermal window, two rapid and extremely simple techniques, have also been applied to the analysis of total carotenes in margarines with satisfactory results.

It should be taken into account that, with the exception of HPLC methods, these methodologies without either saponification or an isolation step only give information about total carotenes.

Tocopherols and Tocotrienols

The determination of this type of components usually involves a first step of alkaline saponification. Next, the unsaponifiable material is extracted with an appropriate organic solvent such as hexane. The analysis of tocopherols can be performed either by GC, after derivatization to trimethylsilyl ethers, or by HPLC. This latter technique is the most commonly used to this aim, being the fluorescence (FL) (excitation wavelength set at 290 nm and emission wavelength at 330 nm) preferable to the UV detector.

Given that tocopherols are very prone to oxidative degradation, it is recommended to perform saponification in darkness and in a nitrogen atmosphere or in the presence of an antioxidant such as ascorbic acid or pyrogallol. In order to avoid the saponification step, the determination of tocopherols has also been achieved directly from a margarine hexane extract by HPLC with FL detector.

The direct determination of tocopherols from the margarine hexane extract has been also carried out by using an online coupling of both chromatographic techniques HPLC-FL and GC-FID in order to avoid interfering compounds.

In addition to tocopherols, the determination of tocotrienols may also be of interest. The determination of these latter can be carried out by using some of the earlier-mentioned techniques simultaneously with that of tocopherols.

Vitamin D

As in the case of other liposoluble vitamins, the methodology for vitamin D determination includes an initial alkaline saponification of the margarine sample and extraction of the unsaponifiable material with an organic solvent like hexane. HPLC is usually used for the subsequent isolation of vitamin D fraction, which is finally injected to another RP-HPLC system for the separation and quantification of vitamins D_2 and D_3 with a UV detector at 264/265 nm.

An automatic method to simultaneously determine liposoluble vitamins (A, D_3, and E) has been also used. The margarine samples were dissolved in an aqueous micellar medium and directly subjected to an online sample treatment that included alkaline hydrolysis and solid-phase extraction (SPE). This system was coupled to liquid chromatography with amperometric detection.

Vitamin K_1

The methodology employed in the determination of this vitamin is based on HPLC analysis. This can be carried out after enzymatic digestion or after direct extraction with hexane and subsequent purification either by semipreparative HPLC or by SPE on a silica column. Quantification is performed by RP-HPLC equipped with a dual-electrode electrochemical detector or with FL.

Phytosterols and Phytostanols and/or Their Esters

Margarine can contain phytosterols, phytostanols, and esters of these compounds. The total determination of all of them requires alkaline hydrolysis, extraction with an organic solvent like diethyl ether, and a cleanup step using SPE or TLC. The analysis of the isolated compounds is done by GC previous derivatization to trimethylsilyl ethers. Although FID has been sometimes used, MS detectors are the most commonly used nowadays.

Recently, analytic methodologies have been developed to determine phytosteryl and phytostanyl esters in enriched margarines. They are based on RP-HPLC/MS analysis with different types of ionization, such as APCI and electrospray ionization. The sample preparation steps differ from some methodologies to others, ranging from a minimal sample pretreatment to the use of SPE cartridges for the isolation of steryl esters from a hexane extract of the margarine sample.

Some of the sterols present in margarine can also be determined by ^{1}H NMR. Among these, brassicasterol, β-sitosterol+campesterol, stigmastanol, or Δ7-avenasterol can be mentioned. It is worth noting that this determination can be carried out simultaneously with that of the several kinds of acyl groups, mono- and diglycerides. Some of the spectral signals corresponding to phytosterols and/or phytostanols are shown in Figure 1.

Minerals

The first step in determining minerals in margarine involves the release of the several elements from the fat matrix, which can be achieved by several methods. Afterward, the determination of each element can be carried out by different techniques, some of which involve sample emulsification. The most frequently used are atomic absorption spectrometry and inductively coupled plasma optical emission spectrometry. With the first technique, flame atomic absorption spectrometry is usually used to determine those elements that are in greater concentrations, whereas graphite furnace atomic absorption spectrometry is chosen for those elements whose concentrations are expected to be much lower.

The determination of the isolated elements can also be achieved by ion chromatography (IC), either with a conductivity detector or with a variable-wavelength UV–vis detector, depending on the element. In addition, electrochemical methods such as differential pulse anodic (or cathodic) stripping voltammetry and galvanostatic stripping chronopotentiometry have also been used for the analysis of minerals in margarine; these have shown a good agreement with the results obtained by IC. Finally, it is worth commenting on that instrumental neutron activation analysis also enables the measurement of a large number of trace elements in margarine, with minimal sample handling and processing.

Other Components

The analysis of some of the additives used in margarine manufacture, such as benzoic or sorbic acid, together with acids such as formic, lactic, citric, acetic, and butyric can be carried out by means of ^{1}H NMR, from the margarine polar fraction. The spectral signals corresponding to sorbic acid are shown in Figure 1.

Introduction

Food science concerns the physical–chemical nature of foodstuff and its evolution due to storage, handling, and processing. In a broader meaning, food science also embraces all those aspects that are related to nutrition, including the knowledge of how human body transforms foods and how foods impact on human health.

The definition of the parameters that concur to the global perspective of food science is an extremely challenging task. From an analytic point of view, foods are heterogeneous mixtures of very different classes of compounds and reflect the complexity of the animal or vegetal organism(s) from which they derive. Therefore, the enormous heterogeneity of almost all food matrices, which often derives from complex biochemical systems (for instance, milk or fermented foods), complicates the detection of all the components that occur in concentrations spanned over several orders of magnitude. Generally speaking, the impact of the various constituents on human health is not necessarily correlated to their amounts, considering that a bacterial or an algal toxin can be harmful to health even at ppb–ppt concentrations. Also, the variety of technological practices applied to process raw materials in order to get the final product multiplies the variables for the analytic definition of food quality. A food product is the result of concomitant and/or consecutive physical and chemical processes: thermal treatments or cooking, spray drying, extrusion, gel or dough formation, chemical or enzymatic hydrolysis, cross-linking, and oxidation, just to mention a few, all of which induce deep and different structural changes to the food constituents.

The development of 'omic' sciences (from genomics to transcriptomics, proteomics, glycomics, lipidomics, and metabolomics) has introduced integrated high-throughput approaches to address the understanding of the biochemical systems and of their dynamic evolution. When applied to the field of food and health, 'omic' sciences are delineating a global approach, which is inclusively referred to as foodomics. In the development of the advanced foodomic platforms, mass spectrometry (MS) techniques have assumed an unquestionable 'core' position because of their potential of providing comprehensive biomolecular profiles, or at least multiplexed snapshots for the various classes of biomolecules.

The ultimate aim of foodomics is the sustainable production of high-quality and safe foods for improving human health and well-being. Here, we critically survey the achievements and the potentiality of MS applied to foodomics through selected recent research outcomes.

MS: Platform and Instruments

MS has its roots in the chemical and physical studies regarding the nature of the matter at the end of the nineteenth century, in particular in the pioneering work of Sir J. J. Thomson (1856–1940). Long remained a pure tool of physicists, MS has gradually emerged as an invaluable analytic technology that offers an elevated informative level, unparalleled sensitivity and specificity, high-throughput, and extreme versatility. Rather than a discipline positioned between physics and chemistry, MS is nowadays considered a self-standing branch of science and technology, whose application field is the production, study, and characterization of gas-phase ions. The evolution of MS and the technological advances have supported the building of progressively more sophisticated mass spectrometers.

MS data are recorded as 'mass spectra,' which are two-dimensional (2-D) graphs displaying ion intensity versus the mass-over-charge (m/z) ratio. The accurate measurement of the m/z enables the access to a unique characteristic of the molecules, that is, their molecular weight. Often combined with data generated by the fragmentation of selected molecules ('hard' ionization techniques or MS/MS experiments), this information allows to identify or structurally characterize (or contributes to this aim) the components of a mixture. Today, MS embraces any array or analytic tool able to analyze the m/z of ions produced or introduced within a mass spectrometer. The basic parts of a mass spectrometer are the ion source (in which ions are generated), the ion analyzer (where ions are separated and their m/z ratio determined with high accuracy), and the ion detector.

Since their introduction, more than 50 years ago, commercial MS instruments, substantially electron impact ionization (EI) and chemical ionization (CI) ion sources with quadrupole (Q) analyzers, have been successfully applied to the analysis of small organic molecules such as, in the case of foods, hazardous contaminants, including pesticides, halogenated hydrocarbons, dioxins, bisphenol, and bacterial metabolites in food matrices such as vegetables, milk, and fish. More importantly, the quite easy combination of EI and CI with high-resolution separation techniques such as gas chromatography-mass spectrometry (GC-MS) soon provided a handful of analytic tools to face qualitative and quantitative aspects of food composition, safety, and nutritional quality. Also, in different configurations, for example, EI and CI ion sources coupled to Q, ion trap (IT), time-of-flight (TOF) analyzers, hyphenated GC-MS remains one of the most powerful approaches in food metabolomics and metabonomics, allowing fast and accurate tracking of metabolite patterns indicative of food quality and preservation over time. One recent example is the detection of the distinctive volatile signature of meat spoilage bacteria.

However, at that stage, determining the largest part of the constituents of a food was still precluded, because GC-MS methods were only able to analyze volatile compounds with a mass not exceeding 1 kDa. This gap was bridged in the early 1980s, by the introduction of 'soft' ionization techniques, such as fast atom bombardment, and then by the electrospray

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00448-7

ionization (ESI) and matrix-assisted laser desorption/ionization (MALDI), which allowed to measure nonvolatile, high-molecular-mass molecules. In 2002, John Fenn and Koichi Tanaka were awarded the Nobel Prize in Chemistry for the pioneering application of ESI and MALDI, respectively, to measure the molecular weight of large proteins and (bio)polymers. For the first time, it was possible to measure with high accuracy the molecular weight of intact (poly)peptides, proteins, polysaccharides, and complex lipids, covering the whole range of the food constituents. ESI and MALDI are the two techniques most commonly used for MS. Thanks to the availability of these techniques, MS-based food and nutrition proteomics is now capable to address a wide range of analytic questions, which include issues related to food quality and safety, certification and traceability of (typical) products, and definition of the structure/function relationship of food proteins and peptides.

As for GC-MS, the easy combination of ESI with liquid chromatography (LC) separation allowed the analysis of complex mixtures, such as those occurring in most food matrices. This high-throughput approach to molecular characterization also relies on the high resolving power of the LC-MS/MS systems, which include several configurations of quadrupole time-of-flight (Q-TOF) hybrid analyzers, TOF/TOF, Fourier transform ion cyclotron resonance (FT-ICR), and the most recent Orbitrap instruments. Besides the introduction of the soft ionization sources, other key advances have contributed to set the stage for the success of MS applied to the omic sciences: (i) the development of microscale capillary reversed-phase LC, (ii) the introduction of nanoelectrospray sources enabling the continuous interfacing of capillary chromatography with high-sensitivity mass spectrometers, and (iii) the development of computer algorithms to correlate MS and MS/MS data to database entries.

Biological MS in combination with separation methods and with statistical and bioinformatics tools is today the key analytic technique that the recently established 'omic' technologies such as proteomics ad metabolomics rely on.

For quantitative purposes, an essential issue in food analysis, the isotope dilution technique, relying on the use of standards labeled with heavy stable isotopes (^{2}H, ^{13}C, etc.) allows accurate measurement of trace analytes even in the presence of complex matrices. The addition of a stable isotope-labeled internal standard at the beginning of the extraction enables the control of possible variation (for instance, partial loss of the compound of interest) that can occur during sample preparation. An internal standard should ideally be an isotope-labeled analog that displays similar behavior (extraction, chromatography, ionization, and ion suppression/enhancement) as the monitored analyte. These approaches require specific methods to be developed and validated for each analyte or class of compounds, as well as analytic instruments/analyzers able to provide the necessary stability and reproducibility among chromatographic analysis. The most widely used systems are triple quadrupole (QqQ) instruments, which exhibit a relatively ample linear dynamic range, and IT, whereas the recently introduced triple TOF is expected to probably ensure maximum performance in quantitative proteomics. In foodomic studies, for instance, in the detection of harmful protein components (allergens, toxins from pathogens, and antinutritionals) or for adulterated foods, monitoring of a whole target protein is surrogated by the analysis of short peptides contained within the protein sequence ('proteotypic peptides'). These peptides are more easily detected than the parent protein. The targeted monitoring of mass and transitions of selected 'proteotypic peptides' overcomes the bias due the presence of a large number of dominant components. According to the absolute quantification (AQUA) workflow, once proteotypic peptides are chosen, it is possible to synthetize copies of them, which are labeled with isotopes to one or more amino acid positions in order to shift molecular mass, without influencing retention time and ionization properties. Protein samples after tryptic hydrolysis are spiked with known amounts of standard AQUA peptides and both native and surrogate peptides are monitored by LC-MS operating in multiple reaction monitoring (MRM) mode. The absolute amount of peptide(s) is determined by the ratio of the ion intensities of AQUA peptide and its native cognate.

MS to Food and Health

Application of MS to food science has a long and outstanding history. From the beginning, MS-based techniques have rapidly evolved for the determination of quality, authenticity, functionality, and safety issues.

Food Proteomics

In the proteomic approach, the entire protein/peptide repertory of a food product can be explored by using MS-based methodologies following a high-resolution electrophoretic or chromatographic separation step.

The MS-based proteomic workflows can be performed through two fundamental analytic strategies: the bottom-up or the top-down approaches. In the bottom-up workflow, the protein identity is inferred by the MS/MS sequencing of proteolytically generated peptides (peptide-centric proteomics). In top-down proteomics, intact protein ions undergo gas-phase fragmentation for MS analysis. Proteins are identified or even partly sequenced through the assignment of fragmentation patterns that are generally predictable. The separation requirements and the type of MS instrumentation differ between the two methodologies. The original bottom-up strategy is accomplished by the combination of 2-D gel electrophoresis (2-DE) separation combined with MALDI-TOF MS or LC tandem MS (MS/MS) of peptides arisen from in-gel proteolytic digestion (e.g., with trypsin) and database search (peptide mass fingerprinting, PMF). The 2-DE approach allows to resolve very complex proteomes, but it is time-consuming and suffers from several pitfalls, primarily including the limited dynamic range.

An advanced bottom-up approach referred to as shotgun or multidimensional protein identification technology is increasingly adopted. This methodology relies on the mono or 2-D HPLC separation and online ESI-MS/MS analysis of the peptides generated from the proteolysis of the whole protein fraction, and it is performed with high resolving power instruments. In spite of the enhanced sample complexity due to a multiplying of the components in the hydrolyzate (each

protein produces a variable number of peptides), peptides are separated and analyzed by MS at much higher sensitivity and accuracy than proteins. Improved peptide-centric pipelines for deep expression proteomics can be exploited to characterize posttranslational and process-induced modifications of proteins too. Overcoming many of the 2-DE gel-based analysis, the shotgun approach allowed, for instance, to characterize hundreds of minor proteins in human milk, which are potentially implied in numerous biological functions. Although the cutting-edge shotgun techniques are not broadly available yet, time seems mature for achieving unbiased, complete, and ubiquitous characterization of whole proteomes. In the near future, these techniques will be applied to deliver deeper knowledge of food systems, their changes, and their influence on the physiology of human body.

One of the major drawbacks of the gel-free approach is that the information on the intact protein is lost, which implicates that information on the protein integrity is usually not available. This limitation can be important in the case of fermented foods (yogurt, cheese, and sausage), where proteins undergo extensive proteolysis. In cases such as these, unhydrolyzed proteins and peptides require a previous prefractionating step and separate analysis workflows.

Food Metabolomics

Similar to proteomics, the metabolomics workflow implies the combined use of advanced analytic techniques (mainly omic tools) and bioinformatics methods to recover relevant information.

Foods are constituted by an enormous variety of compounds, both intrinsically present and generated by technological processes, which are responsible for the quality (texture, flavor, odor, color, and shelf life) and nutritional value (vitamins, antioxidants, and nutrients) of the final product. Therefore, a food and its nutritional quality can be fully defined in terms of the metabolic profile of the material concerned at a particular time (metabolome).

Metabolomics aims to the characterization of the repertory of small (<1500 Da) molecules of a biological system. The asset of metabolites in a food is the result of the specific metabolic pathways of the organism(s) and of the modifications induced by processing or by interaction with other components. Well beyond the cataloging of the food components, metabolomics, combined with *in vitro* assays, cell models, or *in vivo* interventional studies, is also increasingly used to assess, under a molecular profile, the impact of specific dietary components on human health (metabonomics). Shifting nutritional status assessments to an 'omic-oriented' nutritional phenotyped perspective is providing insights into the relationship between diet and health (nutrigenomics).

In food technology, metabolomics and metabolome profiling is increasingly used for many purposes, among which are (i) tracing the evolution of a product from 'the farm to fork,' (ii) evaluating the microbial action (both desired and detrimental) on food quality, (iii) monitoring the evolution of functional and bioactive compounds, and (iv) assessing the impact of technological treatments (physical, chemical, enzymatic) on the development of rheological and sensory characteristics.

Analytic tools of metabolomics are based on traditional GC-MS and LC-MS, aside from different approaches based on the nuclear magnetic resonance (NMR). GC-MS analysis, also in its 2-D version (GC × GC-MS), has been extensively used in metabolomics because of its high separation efficiency and the easy interfacing of GC with MS. It can be used to analyze a wide range of volatile and chemically derivatized semivolatile compounds. However, sensitive and specific LC-MS methods, which do not require derivatization of polar/nonvolatile metabolites, are often replacing GC-MS. A recent introduction into the field of metabonomics is ultraperformance liquid chromatography (UPLC) systems, with narrow columns either monolithic or packed with 'core-shell' or small diameter particles, coupled to MS/MS instruments. Compared with HPLC-MS system, the UPLC-MS system has very short run time, higher sensitivity and resolution, and signal-to-noise ratio that could be increased by fivefold.

NMR and MS are considered complementary in metabolomics. Although MS often requires cleanup or prefractionation steps, it is more sensitive than NMR, enabling the detection of much less abundant components. Mass measurement with high-accuracy MS (e.g., Orbitrap or FT-ICR MS), especially when coupled with downstream MS/MS or MS^n data, and database interrogation is successful in most of cases for the identification of the common metabolites. Several authors have proposed the use of direct infusion of nonfractionated extracts in very high-accuracy mass spectrometers (typically <1–2 ppm) to obtain metabolic profiles without previous chromatographic step.

A present limitation of food metabolomics relates to our current inadequacy to structurally characterize the vast majority of metabolites in a complex foodstuff. The lack of available reference standards for many of the food metabolites (particularly the myriad of plant secondary metabolites) is a challenge that can be somehow tackled with the MS-based 'untargeted' metabolomic approach. Untargeted metabolomic comparison between wild-type and genetically modified soybeans has been recently exploited to assess the perturbation in the metabolic asset induced by gene modifications with the aim of supporting the safety and the bioequivalence with respect to conventional crops. Targeted modes of data acquisition (generally relying on the single/multiple ion monitoring, SRM/MRM) are designed to monitor by MS preselected compounds with higher sensitivity and specificity. Targeted experiments are conveniently carried out in second instance, after the untargeted 'discovery-driven' profiling. The general metabolomic approaches and strategies that also apply to foods are schematized in **Figure 1**. Among several others, the website www.metabolomicssociety.org provides a compendium of metabolomic online resources and tools.

Lipidomics and glycomics concern the definition of the global array of specific metabolite classes, that is, oligosaccharides and lipids, respectively. In consideration of the relevance of these compounds in biological systems, lipidomics and glycomics are emerging as standing alone 'omics' from the wider melting pot of metabolomics. Food lipidomics and glycomics are now relevant issues in food science and nutritional research, and several examples taken from the recent literature exemplify the nontrivial MS-assisted transition from component-oriented traditional analysis of lipids or sugars to the respective omic perspective.

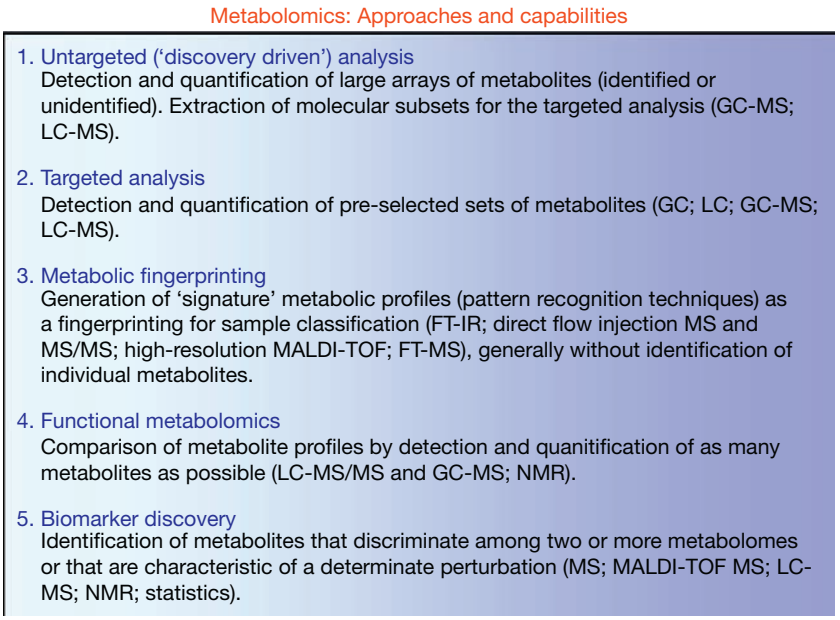

Figure 1 List of metabolomics that also applies to food analysis. The most commonly used analytic strategies are indicated for the various approaches.

Due to a relatively less heterogeneous class of compounds, if compared to the whole metabolome, lipidomic analyses have been often performed by direct infusion into MS instruments (shotgun lipidomics). For instance, a very fast shotgun lipidomic strategy has been applied to the characterization of the lipids in fisheries, finalized to the species differentiation. The determination of the acylglycerol fraction is particularly relevant for foods. Detailed composition and fingerprinting profiles have been obtained for several vegetable oils by LC-ESI-MS. Because of the minimal sample handling required and short analysis time, MALDI-TOF-MS is increasingly used to profile food phospholipids and neutral lipids. For instance, phospholipids and triacylglycerols (TAGs) from hen egg yolk have recently been profiled by MALDI-TOF-MS. When tested for assessing cocoa butter authenticity, MALDI-MS delivered information comparable to GC even in quantitative terms. Very complex lipid mixtures, such as those of TAGs and modified acylglycerols in thermo-oxidized vegetable oils, have been profiled by MALDI-TOF-MS with emphasis on the detection of potentially harmful neoformed compounds.

Regarding glycomics, carbohydrates are present in foods in very different forms, ranging from free saccharides to polymers or to glycoconjugates. In consideration of the large spectrum of physiological actions of dietary oligosaccharides, food glycomics is gaining a rising interest. Particularly interesting is the characterization of bioactive oligosaccharides from both human and bovine milk. In foods, both N- and O-linked glycoproteins can affect not only the technological properties of proteins but also the digestibility and the potential allergenicity. Multistage MS has become one of the most powerful and versatile techniques for the structural characterization of the glycan moieties of glycoproteins and of glycoconjugates in general. Due the complexity of the glycan fractions, direct MS analysis is sometimes not sufficient for a complete profiling. Thus, high-resolution strategies based on hydrophilic interaction or porous graphitized carbon LC are crucial for carrying out accurate online MS analysis of oligosaccharides.

Also in the case of metabolomics, and hence lipidomics and glycomics, the use of robust bioinformatic tools is crucial to convert the MS-generated datasets in useful information. Several lists of lipidomic and glycomic resources are available in the Internet (e.g., www.lipidmaps.org; www.functionalglycomics.org).

Food Composition and Safety

MS in food science is aimed to define the entire and detailed composition of raw materials and ingredients, as well as their modification throughout the production process, to correctly evaluate food quality and safety aspects. The frontier of analytic chemistry for food safety is represented by the development of multiclass, multiresidual techniques to simultaneously monitor the presence of substances belonging to different chemical groups in a sample.

Among contaminants along the food chain, algal toxins produced by cyanobacteria in water reservoirs are a special concern. The occurrence of toxin-producing blooms in freshwaters has been implicated in several animal and human poisoning outbreaks worldwide. The analysis of algal toxins is therefore of growing interest for water surveillance authorities. MALDI-TOF-MS and ESI-Q-TOF-MS/MS have been useful for fast screening and quantitative determination, as well as for structural characterization of known and unknown toxin structures (untargeted analysis). MS analysis has been then extended to the setup of a method for quantitative determination of microcystins in food integrators for human and animal nutrition, as well as to the analysis of biological fluids in patients to diagnose toxin poisoning. In this way, qualitative

and quantitative information can be obtained to monitor rivers, lakes, and water reservoirs and to improve current knowledge on algal contamination in the food, feed, and drinking water chain and also to detect protein marker to discover the use of unsafe water in fish and seafood aquaculture.

Also, CE-MS has been proposed as a methodology to study proteins (phycobiliproteins) from the edible microalga like *Spirulina platensis*, which is a natural source of functional ingredients. Reliable and reproducible CE-MS analysis of the main proteins found in this microalga has been reported. It was demonstrated that both analyzers, CE-IT-MS and CE-TOF-MS, allowed the characterization of these proteins with coherent results.

One of the most urgent issues in food science is the fast and accurate detection of ingredients used in food preparations. Although most of them are not harmful for the great majority of consumers, they can be highly toxic for allergic or sensitive subjects. MS analysis has also provided important outcomes in the field of food authentication, in accordance with the comprehensive system of food and feed traceability established by the European Food Safety Authority in order to ensure food safety. This issue, particularly pressing in the case of protected denomination of origin (PDO) products, also requires efficient traceability systems, to ensure the authenticity of the raw materials and the correct application of the procedures throughout the productive processes and during distribution. For many food matrices, markers can be found in the protein fraction, which closely reflects the nature and the structural changes induced by technological processes of production.

Several MS-based procedures have been developed to authenticate ingredients in dairy products. A case example is represented by milk powders, widely used as ingredients by dairy, bakery, and meat industry to improve nutritional and rheological properties and for animal feedings. The EU subsides the use of milk powder in compound feeding stuffs. Recent reports of adulterated milk powders by the addition of lower value plant proteins (wheat, soy, pea, and other legumes) caused alarm as their presence is not revealed by official reference methods. For these reasons, a sensitive identification method was developed based on LC-ESI-Q-TOF-MS/MS analysis of tryptic proteotypic peptides specific for the storage proteins of each vegetal matrix (soy glycinin and conglycinin, pea legumin, and vicilin).

Several MS strategies, relying on both MALDI- and ESI-based monitoring of species-specific target proteins of derived peptides, also enable the detection of adulterating cheaper bovine milk to other ruminants' milk used in the manufacture of PDO cheese. Another exemplary case is the analysis of gluten residues in declared gluten-free foods and beverages, exploited by several studies. In the assessment of meat and fish genuineness and in foodborne bacterial identification, MS-based profiling of strain-specific gene products has the capability to substitute or complement other available strategies, such as the multiplex PCR assay.

A food product is in general the result of a series of physical and chemical processes including heat treatments, all of which induce deep structural changes in the food constituents. Food components, especially proteins, encrypt information distinctive of the identity and history of a product. Modifications induced by thermal treatments include deamidation of glutamine residues, formation of nonnatural amino acids, and nonenzymatic glycosylation caused by heat treatments. Several markers of heat treatments have been identified and used to set up procedures either to monitor the correctness of the treatment on food matrices (milk, soy, juices, and jams) or to detect the fraudulent addition of prohibited ingredients in PDO products. For instance, lysinoalanine, an unnatural amino acid, has been proposed as a LC-MS quantifiable marker to demonstrate either excessive heat treatments or the addition of heated milks/milk powders to fresh milks destined to cheesemaking.

Heat treatment is applied not only to ensure microbiological food safety but also to inactivate antinutritional components such as lectin phytohemagglutinin (PHA) present in raw legumes, including bean, pea, and soy, where lectin level is 1–10 g kg^{-1}, implying a possible risk for health in processed food. The most common methods of inactivation use heat treatment in boiling water or by extrusion. Inaccurate heat treatments of legumes have caused severe poisoning outbreaks in restaurants or refectories. Furthermore, commercial protein concentrates of common beans (*Phaseolus vulgaris*) are also the most used ingredients for production of dietary supplements to control body overweight in obesity (starch blockers and weight blockers). MS-based strategies have been developed to set up novel proteomic and glycomic methods for lectin structural and functional definition and to monitor the structural changes (proteolysis, oxidation, and sugar changes) in raw and in industrially treated products. In this way, possibly combined with the enrichment with affinity chromatography, they constitute the basis to allow for either the structural or quantitative analysis of PHAs in food samples.

Food Allergy and Digestion

Food allergy is an increasingly important issue for food safety, as the prevalence of the immune-mediated reaction to foods is steadily increasing. This is making the detection of allergens of primary importance for both food industry and consumers. MS strategies for *de novo* sequencing combined with the serum IgE recognition of allergens from animal (milk, fish, and crustaceans) or plant (cereals, legumes, and tree nuts) foods are leading to the identification of several previously uncharacterized 'type I' food allergens, even in cases when the genome of the injuring species is not fully sequenced.

Due to the concerns related to the food allergy in infants, to a relatively high incidence of cow's milk allergy, and to the very large use as ingredients in a countless variety of food preparations, one of the main targets of investigation is milk proteins (either casein or whey proteins). MS procedures to detect milk proteins in biscuits and baked goods have been proposed, using casein peptides as markers. In comparison with ELISA, the reference screening method showed good agreements between the two approaches.

These data demonstrate that the MS approach is promising in complementing or even replacing the ELISA methods currently used to discover the occurrence of trace allergens in foods and also in beverage. A recent study performed on a significant number of beers produced with different brewing systems compared quantitative ELISA results with those obtained by nano-LC-ESI-QqQ-MS/MS analysis of target

peptides. The analytic response was superior for the latter approach, in terms of either sensitivity or, most importantly, specificity. Indeed, the MS approach does not depend on the antibody affinity, and it is only marginally affected by matrix effects. Furthermore, while ELISA is targeted for a single allergen, the MS-based approach is potentially multiplexed, allowing the multiallergen detection in a single run.

The shotgun proteomic approach also expands the dynamic range of the detectable allergens. This could be not a particular advantage for the characterization of allergens, because these are generally proteins abundant in the food matrix. However, it is the most effective strategy to monitor 'hidden' allergens or cross contaminating species that occur in traces. Hidden allergens are those proteins whose presence is not immediately suspected in a food. This is the case of milk, soy, and gluten proteins used in wine as clarifying agents. MS analysis after selective enrichment by use of combinatorial peptide ligands, as well as shotgun MS analysis, revealed the unsuspected occurrence of allergenic proteins, which could be quantified by selection of target 'probe' peptides.

These encouraging results are now pushing the development and diffusion of automated allergen detection and quantification methods at low-ppm levels fully based on MS analysis and commercialized by MS instrument producers to this purpose. Initial sample preparation stages have been simplified for rapid and easy handling. Reliable allergen quantification (1 ppm) is based on the monitoring of the MRM transition of proteotypic peptides using the MRM-initiated detection. The derived method for allergen detection is already finding applications in food control companies and agencies in the analysis of major allergens in processed foods as it is advantageous on ELISA tests. Importantly, MS has been entrusted the task of challenging the issue of (food) allergen standardization that is related to diagnosis and treatment of allergies besides the analytic aspect of the identification and quantification of allergens.

With rare exceptions, 'type I' food allergens are proteins particularly stable to gastrointestinal digestion. Protein stability is dramatically affected by processing; thus, the digestibility of food proteins requires to be evaluated case by case. The MS-based procedures appear at the moment as those exclusively practicable for a suitable characterization of the 'digestome,' that is the pool of proteins/peptides surviving *in vitro* or *in vivo* digestion models of dietary proteins, in order to predict their immunogenic potential. MALDI-TOF and HPLC-ESI-Q-TOF-MS/MS analyses have allowed to identify the digestion-stable domains of wheat prolamins that elicit celiac disease and the potential epitopes of β-lactoglobulin that survive all the digestion compartments of a complete *in vitro* model and are able to cross a cell model of the intestinal epithelium.

The full elucidation of the 'kinetics' and 'dynamics' of nutrients in human body is one of the next goals of food science, and MS-based technologies will undoubtedly play a pivotal role for its achievement.

Conclusion

Food and nutrition play a crucial role in health as well as in the development of several diseases. MS-based omics are already assisting multiple aspects of the food chain (agriculture, food production, food safety, and quality assurance), are delivering economic benefits and improving aspects of human nutrition and health. By dissecting the food proteome and metabolome in their constituents, using the new technologies, specific markers are being identified to trace the complete productive processes from raw materials to end products, and structure/function links can be clarified for the design of novel functional foods. Quantitative analysis of food components and contaminants provided by MS is ensuring control of crucial food quality and safety aspects.

In analogy with the recently introduced concept of systems biology, according to which a biological system has to be regarded in its entirety considering the spatiotemporal integration of the metabolic networks, the global approach of 'foodomics' relocates the subject of the investigation in food sciences in order to access to a higher information level. Foods are in general complex dynamic biomolecular systems; the interactions among the constituents are a key aspect for determining its technological, sensory, and functional properties. Furthermore, the impact of foods on human physiology is often the result of synergistic (or on the contrary antagonistic) activity due to more than a single component. The intake of active ingredients elicits in turn complex biological responses that for many traits remain to be elucidated. It is clear, in such a scenario, that integrated multi-omic approaches will be the next step forward for progressing in food science, for understanding what foods do to human body, and for designing novel health-promoting food products. The parallel pillars of the individual -omic datasets have to sustain an orthogonal (and transversal) superior block of knowledge that is represented by foodomics (Figure 2). The new 'meta-omic' platform defined as 'nutrigenomics' aims to acquire an integrated viewpoint of the -omic datasets from interacting nutrients, host, and microorganisms, with the ultimate objective of a

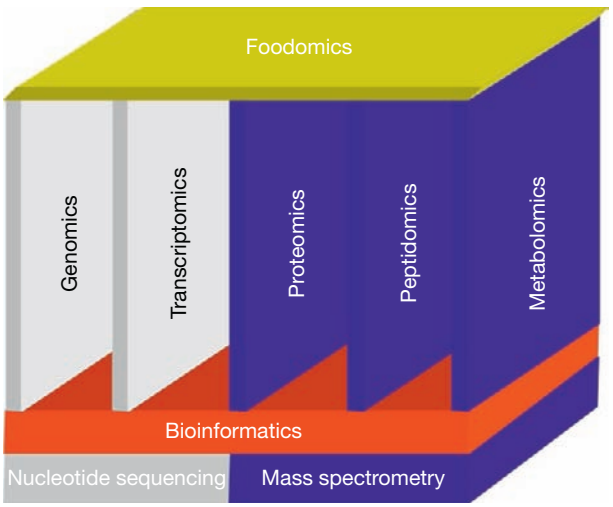

Figure 2 Foodomics, regarded as a transversal superior level of information in food science, is sustained by the '-omic' platforms, many of which relying on mass spectrometry. The foodomic block further integrates with the dataset acquired from food effects on host and from interaction with microbiota, in the 'meta-omic' perspective of 'nutrigenomics.'

functional personalized nutrition. At the status, it seems impossible to imagine meta- or multi-omic achievements lacking the 'core' role of MS, because several among the 'omic pillars' firmly reside on the MS ground.

Introduction to Mass Spectrometry

Mass spectrometry (MS) is a powerful analytic technique used to quantify known materials, to identify unknown compounds within a sample, and to elucidate the structure and chemical properties of different molecules. The complete process involves the conversion of the sample into gaseous ions, with or without fragmentation, which are then characterized by their mass-to-charge (m/z) ratios and relative abundances. MS depends upon chemical reactions in the gas phase where sample molecules form ionic and neutral species.

A mass spectrometer generates multiple ions from the sample under investigation; it then separates them according to their specific m/z ratio and then records the relative abundance of each ion type. The instrument consists of three major components: the ion source for producing gaseous ions from the substance being studied, the mass analyzer for resolving the ions into their characteristic mass components according to their m/z ratio, and the detector system for detecting the ions and recording the relative abundance of each of the resolved ionic species (conversion dynode with secondary electron multiplier, multichannel plate). A general scheme of a mass spectrometer is shown in Figure 1. A sample introduction system is necessary to admit the samples to the ion source while maintaining the high vacuum requirements of the technique. Mass spectrometers are instruments of high complexity and are operated by special software that controls the instrument and acquires, manipulates, and reports data.

MS represents the biggest share in the analytic industry in annual investment and sector growth and lately also on publications and citations. This is also reflected in the analytic applications in food sciences as shown in Figure 2 where the numbers of publications are plotted for different analytic techniques. The prominence of MS is evident in view of its faster growth in contrast to other techniques.

Ionization Methods

Many ionization methods are available and each has its own advantages and limitations. The ionization method to be used depends on the type of sample under investigation and the mass spectrometer available. The most common modes of ionization are electron impact (EI), chemical ionization (CI), fast atom bombardment (FAB), matrix-assisted laser desorption ionization (MALDI), electrospray ionization (ESI), atmospheric pressure chemical ionization (APCI), and atmospheric pressure photoionization (APPI).

EI is widely used for relatively volatile samples that are insensitive to heat and have relatively low molecular weight. A beam of electrons passes through a gas-phase sample and collides with neutral analyte molecules (M) to produce a positively charged ion or a fragment ion. Generally, electrons with energies of 70 eV are used. The spectra, usually containing many fragment-ion peaks, are useful for structural characterization and identification. CI is applied to similar samples and analytes and is used to enhance the abundance of the molecular ion that permits the calculation of the molecular mass of a compound. Ionization begins when a reagent gas is ionized by EI and then subsequently reacts with analyte molecules to produce analyte ions. CI is a lower-energy alternative to EI that provides simpler mass spectra with reduced fragmentation. These ionization techniques are widely applied to gas chromatography separation techniques coupled to mass spectrometry (GC–MS).

FAB is a softer ionization method than EI. The target is bombarded with a fast atom beam (4–10 KeV argon or xenon) that desorb molecular-like ions and fragments from the analyte. The spectrum often contains peaks from the matrix, a few fragments, and a peak for a protonated or deprotonated sample molecule. FAB-MS is used to obtain the molecular weight of sensitive, nonvolatile compounds but is prone to suppression effects due to the high chemical background.

In MALDI, the analyte is dissolved in a solution containing an excess of a matrix that has a chromophore that absorbs at laser wavelength. A small amount of this solution is placed on the laser target. The matrix absorbs energy from the laser pulse and produces plasma that results in vaporization and ionization of analyte molecules. MALDI is used to quantify or determine the molecular weight of peptides, proteins, oligonucleotides, and other compounds of biological or synthetic origin. The amount of sample needed is very low (pmoles or less). MALDI is ideally coupled to time-of-flight (TOF) mass analyzers. Lately, MALDI is also coupled to orbitrap analyzers with applications (among others) on MS imaging.

The most common ionization methods utilized with liquid chromatography–mass spectrometry (LC–MS) include ESI, APCI, and APPI. In ESI, a solution is nebulized under atmospheric pressure and exposed to a high electric field (3–5 kV), which creates a charge on the surface of the sample droplets. Droplets rapidly become smaller through solvent vaporization and produce molecular ions. ESI is extremely useful for accurate mass measurement and for producing multiple-charged ions to high-molecular-mass substances (i.e., proteins, nucleotides, and polymers). In APCI, a corona discharge electrode is used to ionize the analyte in the atmospheric pressure region. The gas-phase ionization in APCI is more effective than ESI for analyzing less-polar species. ESI and APCI can be considered as complementary methods. The ionization process in APPI is initiated by photons emitted by a discharge lamp (typically krypton, 10 eV), which ionizes nonpolar analyte molecules, while ionization is rather selective. The utilization of combined ESI/APCI or ESI/APPI ion sources facilitates

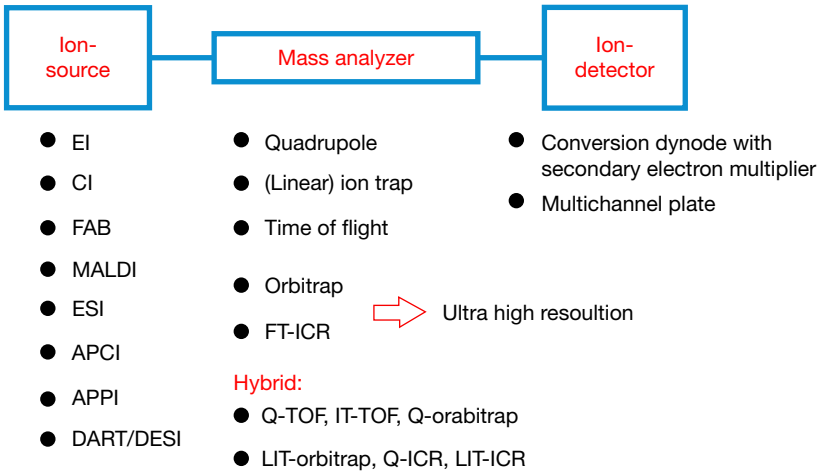

Figure 1 General scheme of a mass spectrometer.

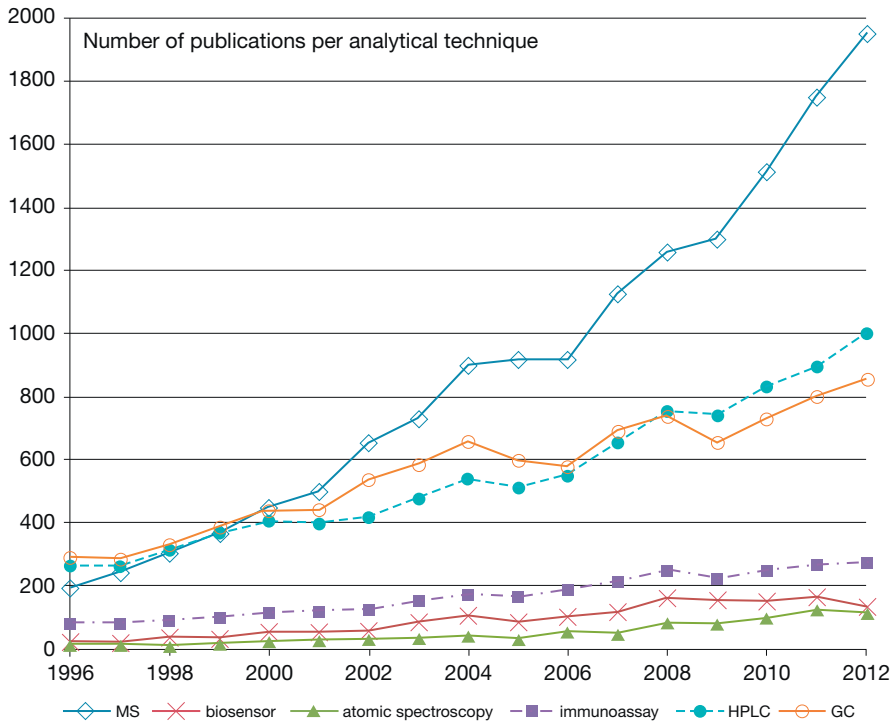

Figure 2 Plot of the numbers of publications per year and analytic technique. Search was made in Scopus in July 2013 using the terms food and the analytic technique depicted (gas chromatography, mass spectrometry, and so forth).

simultaneous detection of both polar and nonpolar analytes, which is useful for high-throughput biological screening to increase the analytic coverage of the method. Figure 3 represents the relative use of individual atmospheric pressure ionization techniques (ESI, APCI, and APPI) in LC–MS papers based on the Web of Science search from 2012.

Mass Analyzers

The main function of the mass analyzer is to separate, or resolve, the ions formed in the ionization source according to their m/z ratios. There are a number of mass analyzers currently available, the better known of which include quadrupoles (Qs), TOF analyzers, ion traps (ITs), Fourier transform ion cyclotron resonance (FT-ICR), and orbitrap configurations. These mass analyzers are characterized by different features, including the m/z range that can be covered, the mass accuracy, and the achievable mass resolution. The compatibility of different analyzers with different ionization methods varies. Table 1 gives an outlook of some of the most fundamental characteristics of the common mass analyzers.

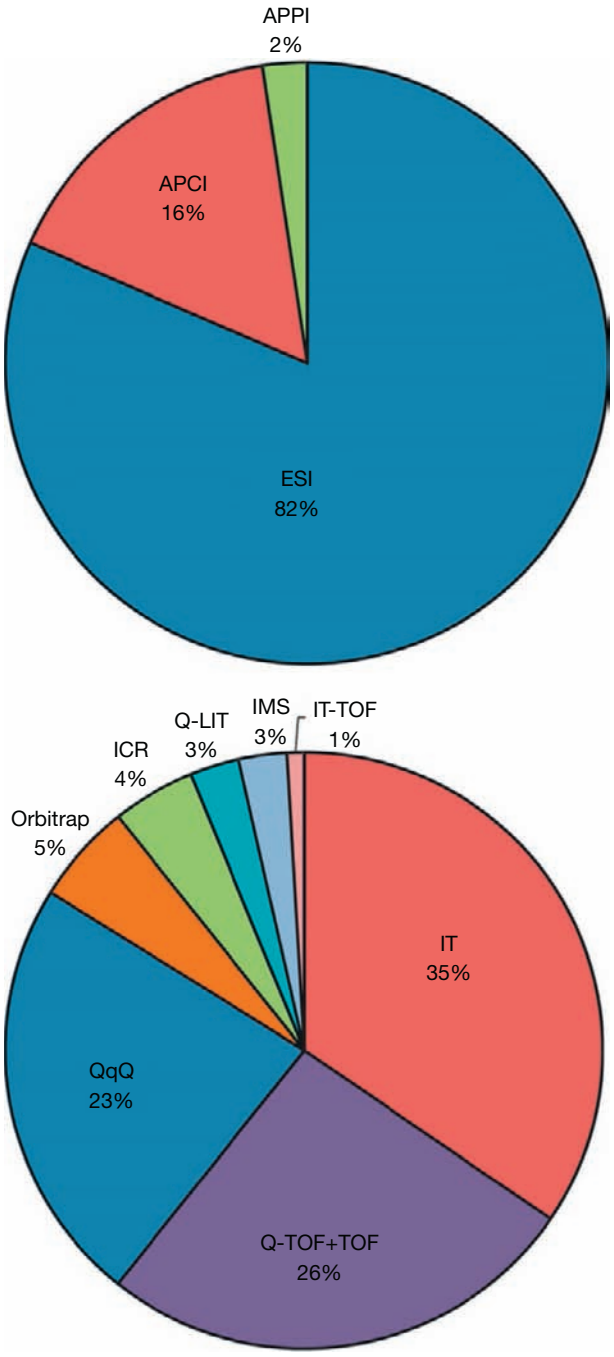

Figure 3 Relative use of individual atmospheric pressure ionization techniques and types of mass analyzers in LC–MS papers based on the Web of Science search from 2012. Reproduced from Holcapek, M., Jirásko, R. and Lísa, M. (2012). Recent developments in liquid chromatography–mass spectrometry and related techniques. *Journal of Chromatography A* **1259**, 3–15, with permission from Elsevier.

Quadrupole

The quadrupole mass analyzer is the simplest, most affordable, and robust mass spectrometer. The limitations of quadrupole analyzers are the low resolution (<3000), poor mass accuracy (>100 ppm), and limited mass range (typically up to 3000 amu). Quadrupoles are easily coupled to GC–MS or LC–MS due to their rather low vacuum requirements and high scanning speeds. As a result, quadrupoles are the most frequently used mass analyzers. Quadrupoles (also termed Q analyzer) consist of four parallel rods that function as electrodes: positive and negative terminals of a direct current (DC) source. Variable radiofrequency alternating current (AC) potentials are applied to each pair of electrodes. Ions accelerated between the rods are resolved by modulating the AC/DC potentials. Quadrupole MS are the workhorse of life sciences and the instruments of choice for a huge number of analyses. Most manufactures offer a number of different configurations that in the case of triple quadrupole MS/MS instruments offer increasing sensitivities (typically up to an order of magnitude) but with the corresponding economic cost.

Ion trap

ITs have distinct advantages over the quadrupole, as it is capable of tandem mass spectrometric experiments up to MS^n, thus offering unparalleled potential for the identification of unknowns and *de novo* structure elucidation. Upon introduction into the IT, ions are trapped by the AC voltage applied to the ring electrode. Then, they are cooled to the middle of the trap due to the presence of helium as dampening gas. Then, selective instability scanning is performed, manipulating the voltages so that ions are ejected toward the detector in the order of increasing m/z ratio. Linear ion traps (LITs) have a higher ion capacity, resulting in increased linear dynamic range in quantitative analysis. The resolution of ITs is slightly higher in comparison with quadrupoles.

Time of flight

TOF-MS is based on the fact that ions with the same energy but different masses travel with different velocities. Basically, ions formed by a short ionization event are accelerated by an electrostatic field obtaining the same kinetic energy and then travel over a drift path to the detector. The lighter ions arrive before the heavier ones and a mass spectrum is recorded. Measuring the flight time for each ion allows for the determination of their m/z ratios. Advantages of TOF mass analyzers include their simplicity, ruggedness, high scan speed, a virtually unlimited mass range, and a higher resolution compared with Q and IT mass analyzers. However, TOF mass analyzers suffer from limitations in resolution, related to the relatively large distribution in flight times among identical ions.

Orbitrap-MS and FT-ICR-MS

Fourier transform instruments such as ICR or orbitrap provide much higher resolution and mass accuracy compared with other mass analyzers. Orbitrap is basically an electrostatic IT: Ions are trapped and then they travel in circular motion before being ejected according to their m/z values. The orbitrap technology has rapidly emerged in the last years, improving performance and reaching mass resolutions higher than 240 000, with mass accuracies lower than 1 ppm (internal calibration). Orbitrap-based mass spectrometers are widely used in all major applications of life science such as proteomics, metabolomics, and environmental, food, and safety analysis. Orbitraps are interfaced not only to LC but also to ambient real-time ionization methods.

Table 1 Characteristics of the most common mass analyzers

	Quadrupole	*Ion trap*	*Time of flight*	*Orbitrap*	*FT-ICR*
m/z range (amu)	Up to 3000	Up to 20 000	Virtually no limit	Up to 6000	Up to 30 000
Mass accuracy	>100 ppm	<30 ppm	5–100 ppm	<1–2 ppm	<0.6 ppm
Mass resolution (FWHM)	<3000	<5000	5000–40 000	>240 000	2.5×10^6
Scanning rate	0.5–4 Hz	1–10 Hz	20–200 Hz	0.3 Hz	1 Hz
Quantification	Good–very good	Poor	Medium–good	Medium	Medium
Handling	Easy	Easy	Easy–medium	Medium	Demanding
Cost (k€)	<150	<150	<250	<500	<1000

The FT-ICR mass analyzer is an extraordinary instrument, considering its extremely high price, large size, extremely high vacuum needs, resolution (which could be higher than 10^6), and mass accuracy (routinely <1 ppm with external calibration or even lower with internal calibration). Recently, a Q-ICR was introduced achieving a mass resolution up to 2.5×10^6 with a mass accuracy < 0.6 ppm. Ions are placed in a very strong magnetic field (5–14 T), which causes them to move in circular paths. Ions are trapped by the magnetic field, and next, wide-band frequency excitation is performed. The ion motion induces an AC image current. The image current is recorded and is Fourier-transformed to produce mass spectra. FT-MS instruments offer the strongest potential for the identification of unknown analytes. FT-MS can be coupled to LC, but it should be kept in mind that such devices are typically operated only by highly trained personnel.

Tandem Mass Spectrometry

Tandem mass spectrometers (MS/MS) are instruments that have more than one analyzer and so can be used for structural and sequencing studies. In MS/MS, the ion of interest is selected in the first analyzer and collided with inert gas atoms in a collision cell, and the produced fragments are separated by a second analyzer. Two, three, and four analyzers can be incorporated into commercially available tandem instruments. Analyzers are not (necessarily) of the same type, in which case the instrument is called a hybrid mass spectrometer. Common tandem mass spectrometers include those of the triple-stage quadrupole (QqQ) ITs. Popular hybrid configurations include combinations of TOF, orbitrap, and ICR with Q or LIT as the first mass analyzer (Q-TOF, IT-TOF, Q-orbitrap, LIT-orbitrap, Q-ICR, and LIT-ICR). The common parameters that evaluate the overall performance of such mass spectrometers are the resolving power, mass accuracy, sensitivity, acquisition speed, linear dynamic range, and price. QqQ provides higher sensitivity compared to other mass analyzers and better linear dynamic ranges, followed by the IT and TOF mass analyzer configurations. High resolving power is obtained by TOF mass analyzers and ultrahigh resolving power by orbitrap and ICR mass analyzers, but the latest suffer from limitations in the dynamic range. As one of the most important tasks in analytical chemistry is sample throughput, high-speed separation techniques are applied to increase efficiency. The use of small particle size at ultrahigh pressures in LC requires high acquisition speed for these mass spectrometers. The fastest mass analyzer within common speeds between 10 and 50 Hz is the TOF mass analyzer, with the Q-TOF combination achieving up to 100 Hz.

Real-Time Analysis Mass Spectrometry

Direct analysis without sample preparation is an ultimate goal in analytical chemistry. In the last years, several approaches have been introduced for direct analysis to MS with limited sample preparation and without the use of chromatographic separation. Real-time analysis mass spectrometry techniques allow a direct, online measure of volatile organic compounds (VOCs) or semivolatile organic compounds (SVOCs). These configurations increase sample throughput but may still suffer from ion suppression, caused by matrix interferences, thus hindering analyte quantitation.

Popular ambient ionization techniques include direct analysis in real time (DART) and desorption electrospray ionization (DESI).

DART/DESI Source

DART ion source can analyze gases, liquids, solids, and materials on surfaces. DART is an APCI-like ionization technique. Helium or nitrogen is used for producing ionizing plasma. The gas flows through a chamber where an electric discharge (corona discharge) produces ions, electrons, and excited-state (metastable) atoms and molecules that generate protonated gaseous water clusters in ambient air. The water clusters exchange protons with the sample, giving rise to positive ions. In negative ion mode, oxygen water clusters are deemed responsible for ionization. DART has been used to analyze a wide range of analytes including drugs, pesticides, toxic materials, inks, dyes, spices, beverages, and fatty acids.

In DESI, a mixture of liquid similar to LC mobile phases is used to provide a spray. DESI provides soft ionization desorbing ions directly from animal or plant tissue or biological materials. Desorbed ions can be analyzed by atmospheric pressure ionization mass spectrometers. The working species in DESI appears to be the charged droplets or desolvated solvent ions generated in the electrospray process. DESI generates secondary ions directly from the surface of the material of interest.

Proton Transfer Reaction-Mass Spectrometry

Proton transfer reaction-mass spectrometry (PTR-MS) is based on efficient implementation of soft CI combined to the swarm technique of the flow tube and flow drift tube. The generation of precursor reagent ions and CI of VOCs are individually controlled and spatially separated processes. This leads to constant and well-defined conditions, enabling quantitative determinations without the use of gas standards. Briefly, the sample

gas is continuously introduced into a drift tube where it is mixed with a very intense pure (>99.8%) beam of H_3O^+ ions. VOCs with proton affinities higher than water are ionized by proton transfer from H_3O^+, pass through the mass analyzer (a Q in the early version), and are detected as ion counts per second. Since most of the constituents of normal air (i.e., O_2, N_2, Ar, and CO_2) have proton affinity lower than water, normal air is used as buffer without interferences. Recent introduction of TOF-MS brought significant improvements in mass accuracy and dynamic range. The first applications of PTR-TOF-MS in food science focussed on the study of milk storage conditions on the VOCs profile of Trentingrana cheese and the monitoring of VOC evolution during lactic acid fermentation of milk. PTR-TOF-MS was recently proposed as a novel tool for fruit metabolomics analysis due to its high-throughput capabilities. PTR-MS facilitates direct online monitoring of fast processes that cannot be followed by other techniques (e.g., GC), for example, monitoring of flavor release during eating. Analytic capabilities of the technique have been, now, extended by the coupling with a switchable reagent ion system (H_3O^+, O_2^+, NO^+, Kr^+, or Xe^+) that allows for virtually all volatile substances to be detected in real time.

Hyphenated Technologies

GC–MS in Food Analysis

GC–MS combines the features of GC with those of MS. GC can separate compounds and MS can provide specific, sensitive detection and structural information. As a result, GC–MS is considered a 'gold standard' for substance identification and the method of choice, the method required by the regulatory authorities for a wide number of analyses of high significance such as the analysis of pharmaceuticals/drugs of abuse, steroids and hormones, contaminants, and other analytes.

A major advantage of GC over other separation methods (e.g., LC) is its simplicity and higher separation power.

Food products are usually complex matrices made of organic or inorganic substances that consist of essential body nutrients, such as carbohydrates, fats, proteins, vitamins, or minerals. Furthermore, different sources of contaminants such as pesticides, environmental pollutants, natural toxins, veterinary drugs, and packaging materials can taint foodstuffs. GC–MS is extensively used for the analysis of such complex matrices. GC–MS is the method of choice for the VOC analysis and for routine qualitative and/or quantitative determination of components such as fatty acids, sterols, alcohols, oils, and low-mass carbohydrates and for the detection and quantification of a large number of contaminants. MS is ideally coupled to GC, for example, GC is the 'classical' method for the determination of fatty acid composition, but only the coupling with MS, allowing the identification of the number of double bonds, can provide peak assignment and compound identification.

Depending on the scope of the analysis, different GC–MS solutions are nowadays available. GC–MS following derivatization is used in the quantification of several food constituents such as carbohydrates or phenolic acids in fruits and vegetables. For the detection and quantification of target compounds in complex matrices at trace levels, GC coupled to triple quadrupole MS is a very powerful instrument providing greater selectivity and sensitivity than single quad rupole MS. The system provided higher selectivity, resulting to less interference from coeluting compounds and matrix and consequently a better signal-to-noise (S/N) ratio, allowing quantitation with lower limits. Furthermore, MS/MS instruments facilitate the development of multiresidue analysis of pesticides. Nowadays, in a single GC run, it is possible to analyze hundreds of trace compounds in food products such as environmental contaminants or pesticides.

Comprehensive two-dimensional GC (GC × GC) coupled to TOF-MS facilitates the analysis of very complex matrix, that is, components of essential oils, residual pesticides, or contaminants in food products. In GC × GC, compounds are separated on two columns of different selectivities connected in series by a modulation device. The modulator continuously collects small fractions of the effluent from the first column that are quickly transferred to the second column. GC x GC provides much higher peak capacity, better separation power, and enhanced sensitivity. TOF-MS provides high data acquisition speed suitable to GC x GC even though high-speed Qs are nowadays available. Recent applications in food-related topics include the investigation of the impact of malolactic fermentation on the volatile composition of Pinotage wines and the analysis of VOCs in cacao beans and its quality control.

LC–MS/MS in Food Analysis

The combination of LC with MS/MS is currently the most popular technique applied for the analysis of contaminants (veterinary drugs, growth promoters, mycotoxins, organic contaminants, and pesticides) and nutrients (vitamins, flavonoids, amino acids, terpenoids, and saponins) in food.

The most common MS/MS mass analyzers are QqQ, Q-TOF, and QqLIT using APCI, ESI, and APPI ionization techniques, covering a very wide applicability range (molecules of different properties such as polarity or molecular weight). APPI ionization overcame the difficulty in analyzing nonpolar compounds such as vitamins (carotenoids) that represent essential ingredients. Despite their broad applications, the quantification of some contaminants can present limitations in the selection of an adequate number of transition ions (at least 2 for the unambiguous confirmation of the analyte) and in the number of analytes detected (often reaching numbers than 150 compounds). High-resolution mass spectrometers (HRMSs) (QqTOF and LIT-orbitrap) gave the opportunity to overcome such restrictions, providing unlimited number of analytes acquired with fragmentation patterns, together with accurate mass measurements of product ions. Figure 3 shows the relative use of types of mass analyzers in LC–MS papers based on the Web of Science search from 2012. LC-HRMS full-scan modes allowed the development of multigeneric extraction procedures in the determination of hundreds of pesticides, pharmaceuticals, veterinary drugs, and growth promoters in various animal foods and feeding stuff. Figure 4 shows a representative extracted ion chromatogram of a spiked pig feed sample containing veterinary drugs with LC-ESI-orbitrap technology. HRMS data (full-scan mode) offer also the potential for revisiting data at later stages to evaluate the presence of new analytes not known at the time of

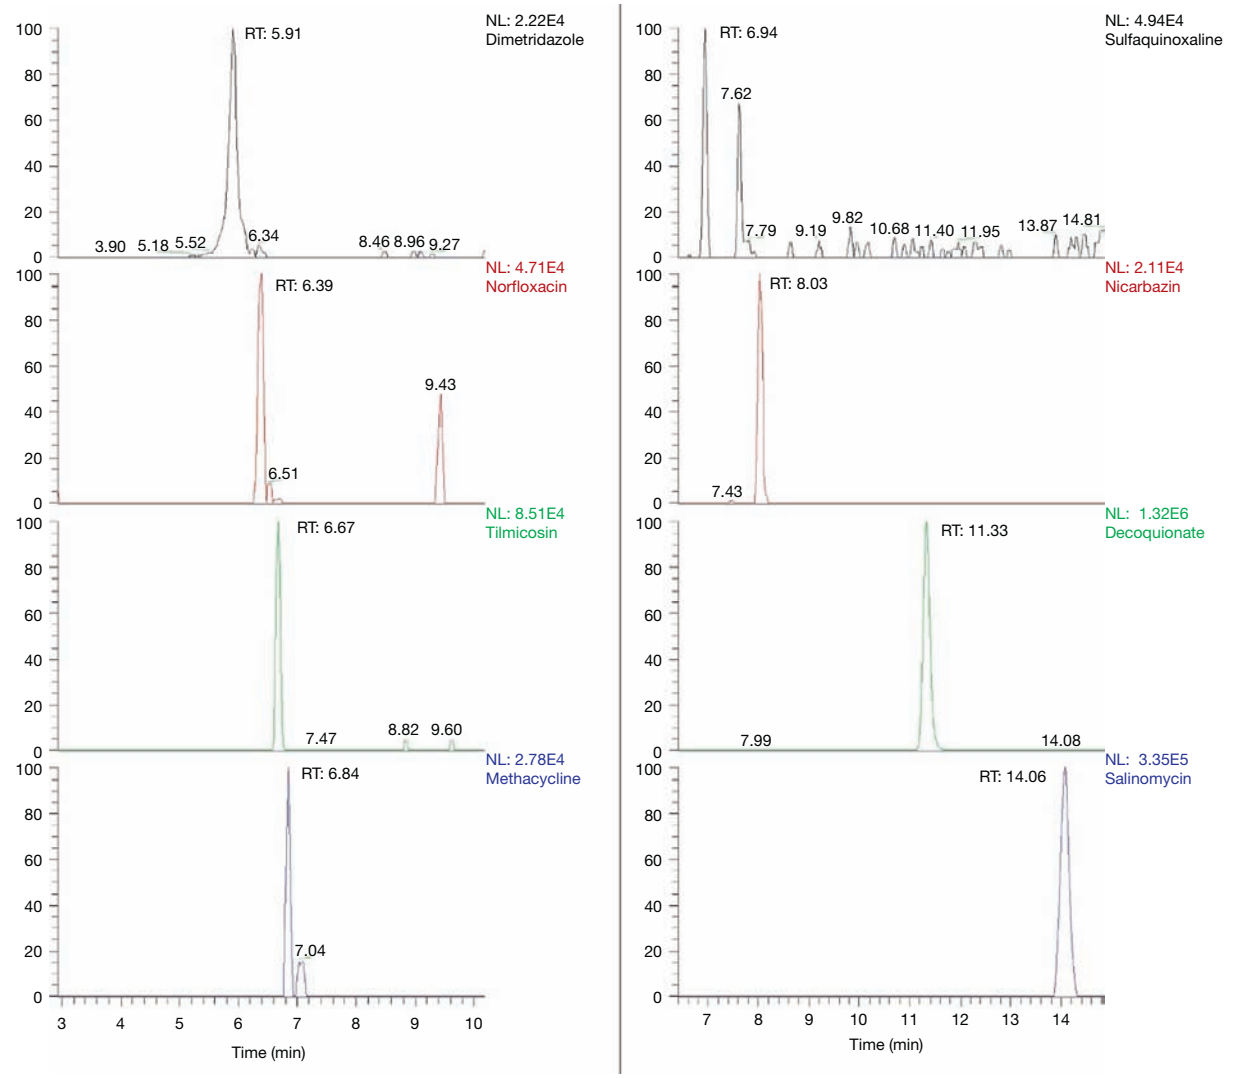

Figure 4 Representative extracted ion chromatogram of a spiked pig feed sample containing dimetridazole (RT: 5.91), norfloxacin (RT: 6.39), tilmicosin (RT: 6.67), methacycline (RT: 6.84), sulfaquinoxaline (RT: 6.94), nicarbazin (RT: 8.03), decoquinate (RT: 11.33), and salinomycin (RT: 14.06) at a concentration of 50 μg kg^{-1} (LC-ESI-orbitrap, mass extraction window of 5 ppm). Reproduced from Kaklamanos, G., Vincent, U. and von Holst, C. (2013). Analysis of antimicrobial agents in pig feed by liquid chromatography coupled to orbitrap mass spectrometry. *Journal of Chromatography A* **1293**, 60–74, with permission from Elsevier.

data acquisition, and its use is now advocated in fields such as sports antidoping control.

Technological improvements in LC promote fast separations without compromising the resolution and the separation efficiency (sub-2 μm particle-packed columns, monolithic LC columns, and fused-core columns). Such improvements in combination with improvements in fast acquisition rates of MS (QqTOF) have broadened the application field to more complex matrices. The improved resolution of ultrahigh-pressure LC can facilitate the separation of isomers, such as growth promoters, mycotoxins, and industrial contaminants in food and biological samples. Monolithic LC columns offer the potential of using high flow rates in conventional column lengths without increase of the back pressure. Monolithic LC columns have found application in food analysis, such as aflatoxins, methylxanthines, and antibiotics in foodstuffs. Core–shell materials result to faster mass transfer and less peak broadening with 'conventional' back pressure. The technology is new, but applications have been developed for the determination of organophosphorous compounds, bisphenol A, and chlorinated compounds in foodstuff.

Multidimensional LC (LC × LC) has given solutions for the separation of complex mixtures (such as natural phenols, peptides, proteins, and oligosaccharides) in food and beverages. Online LC × LC analysis is achieved by automatic transfer of the selected fraction of the analytes from the first column to a second column, which functions in a different separation mechanism. Multidimensional LC can be implemented in a number of ways and can be tailored to the requirements of particular sample types, achieving unparalleled separation power.

A topic of high significance for the health of food consumers is seen in the analysis of food allergens such as milk,

egg, wheat, tree nuts, soybeans, peanuts, fish, and shellfish food products. The topic was till recently dominated by immunoassays. MS offers high selectivity, sensitivity, and unambiguous analysis of proteins and peptides. The high resolving power and mass accuracy of LC-HRMS spectrometry (QqTOF, LIT-orbitrap, and Q-orbitrap) have opened the way for the explanation of the mechanism of action of allergenic proteins and peptides, capturing fragmentation patterns, facilitating their structural elucidation.

In the same line, powerful MS analytic platforms have also boosted the field of natural products and metabolite identification. Medical plants contain hundreds of chemical constituents. The identification and determination of the bioactive constituents are necessary in order to successfully evaluate the efficacy, safety, and quality of phytomedicines and traditional medicaments.

Nontargeted Analysis: Metabolomics Analysis

The metabolome can be described as the total content of small molecules in the analyzed sample: a biofluid, a cell, or an organ. Metabolomics include analysis toward the identification and quantitative determination of all small molecules present in the sample. The potential of metabolomics is on the correlation of concentration patterns with different pathophysiological conditions, genetic variation, or other factors or properties of the analyzed samples.

Metabolomics require the application of the highest level of analytical chemistry, advanced statistical analysis (typically multivariate statistics), solid knowledge of the biochemistry of the system under investigation, and finally expertise in the specific applied sciences of interest: agricultural, environmental, life, or other sciences. Metabolomics utilize information-rich spectroscopic techniques: NMR spectroscopy and MS coupled to chromatographic separations (LC or GC). The following section describes (in short) the application of MS technologies in food sciences.

MS-Based Metabolomics Studies in Food Sciences

In food sciences, metabolomics have found application toward various aims from gathering new biochemical knowledge to more applied/practical endeavors such as the traceability and determination of origin, breeding, and species improvement and the development of advanced methods for controlling and monitoring sensory properties. Furthermore, metabolomics hold great promise in nutritional studies either independently or as part of greater nutriomics studies where metabolomics are combined with genomics or transcriptomics findings.

MS has become the major analytic technology in metabolomics and in omics research in general. MS provides the necessary high sensitivity and high resolving power in order to detect the myriads of molecules present in the sample.

GC–MS-based food metabolomics provided the ground for the first applications of metabolomics. GC–MS has reached a high maturity state already for several years and, despite its limitations (i.e., restricted to small molecular weight $<$350 amu), is a very powerful technique. The advantages of GC–MS are its high sensitivity, wide dynamic linearity ranges, and high resolving power and the fact that it can provide analyte identities due to the existence of high-quality spectral databases, for example, NIST and Agilent Fiehn. GC–MS is typically applied following a dual derivatization scheme that first applies reaction with methoxyamine to cover carbonyl moieties and then applies silylation to cover the active hydrogen atoms (OH, NH_2, and COOH moieties). Derivatization is a dynamic organic reaction so preparations and parameter control should be thorough.

Data treatment in GC–MS metabolomics can follow two routes: The first route is to extract data with bespoke software that can perform deconvolution, analyte identification, signal normalization, peak alignment, and a number of related functions that would lead to the formation of peak table. This peak table is imported for multivariate statistical analysis that will reveal significant signals. Then, efforts are put to identify the compounds that generate the signals. In the second route, analytes are first identified by comparing retention times and EI spectra with data from libraries, and then statistical analysis is performed in a very 'light' peak table aiming to identify biomarkers.

LC–MS is the analytic method with the widest applicability and the biggest increase in annual budget (instruments and consumables). The applicability and potential of MS-based metabolomics in food sciences are immense. MS metabolic profiling can provide solid trustworthy results on a single instrumental configuration (from one injection or from one analyst) on a huge variety of substances of high importance such as biogenic amines, amino acids, organic acids, sugars, and secondary metabolites (carotenoids, flavonoids, terpenes, and so forth). This practically means that instead of resorting to ten or more different instruments, analytic conditions, and software and reporting schemes to cover, for example, 160 analytes of interest, one can now obtain this information from a single injection in one instrument. Such evolutions not only improve productivity but also improve the quality of the results, eliminating potential sources of error while augmenting the potential for standardization and protocol harmonization.

Conclusions and Perspectives

MS is now the 'biggest player' in the arena of analytic technologies and is expected to maintain its dominance for many years. The number of practitioners and installed instruments increases globally. The great versatility and utility of the technique is seen in the various different tasks that are undertaken and resolved using MS. MS can be as simple so that it can be considered as undemanding as a typical chromatography detector (in fact, new MS instruments occupy the same laboratory space with a UV detector); at the same time, ultrahigh-resolution hybrid instruments cost close to 10^7€ require very highly trained personnel and provide gigabytes of data and unparalleled wealth of information. Instrument developers invest heavily on the improvement of their products' performance and introduce new instruments with a pace unprecedented for other analytic techniques in order to cover the needs of an ever-expanding market. MS is now applied by a variety of scientists from analytical chemists to biologists, biochemists,

toxicologists, pharmacologist, forensic scientists, and many others. Especially in the field of food and nutritional sciences, MS is increasingly applied as an indispensable method for (among others) quality and safety assurance, determination of nutrients, or monitoring of sensory properties and product origin. Developments in miniaturization, quality of reporting, and data management software are also needed to help the analyst in handling data and improving productivity. Apart from developments in ion physics/chemistry and hardware, developments in the software could be seen as the crucial factor for the growth of the sector.

Mayonnaise

WG Morley, Group Head of Technical Innovation, 2 Sisters Food Group, Birmingham, UK

© 2016 Elsevier Ltd. All rights reserved.

Introduction and Origins

Mayonnaise is an emulsion of oil droplets in water, a so-called oil-in-water (O/W) emulsion. Such emulsions are characterized by the presence of a dispersed phase of oil and oil-based ingredients, an emulsifier or combination of emulsifiers, and a continuous phase of water and water-based ingredients. The oil-based ingredients may be soluble or suspended in oil; likewise, the water-based ingredients may be soluble or dispersed in water. In mayonnaise, the emulsifier is typically egg-based, and the water phase typically contains vinegar.

O/W emulsions are prepared by simply blending an oil phase into a water phase in the presence of an emulsifier. Mayonnaise typically has a thick and spoonable texture that is derived from the viscosity of the water phase and/or the high dispersed oil content. The oil droplets in mayonnaise are typically of the order of 5 μm in diameter, resulting from a combination of the egg-based emulsifier and the manufacturing equipment. A light micrograph of a mayonnaise product is given in Figure 1, clearly showing a multiplicity of dispersed oil droplets (image courtesy K. Groves, Leatherhead Food Research).

Mayonnaise is believed to have originated in the mid-eighteenth century when the original concept was brought back to France in 1756 from Mahón, a city on Minorca. It was created for a victory banquet to celebrate the capture of Mahón by forces under Louis François Armand de Vignerot du Plessis, duc de Richelieu (1696–1788), a marshal of France and a grandnephew of Cardinal Richelieu. The new sauce, made with olive oil instead of cream, was named Mahónnaise in honor of the victory. The word evolved to mayonnaise, probably deriving from the old French words for egg yolk and to stir or blend, *moyen* and *manier*. Later on, the French chef Marie Antoine Carême (1784–1833) lightened the original recipe by blending the vegetable oil and egg yolk into an emulsion. This product, presumably containing water as part of the emulsion, became the basis for the mayonnaise product that we know today.

Perhaps, the first and most well-known commercial product was introduced by Richard Hellmann in the early twentieth century. Hellmann emigrated to New York City from Germany in 1903, and in 1905, he opened a delicatessen, selling salads that contained his wife's recipe for mayonnaise. Customer demand was such that Hellmann began selling the mayonnaise itself, in the 'wooden boats' that were used for weighing butter. The mayonnaise ultimately made it into jars, and in 1912, the label incorporated a 'blue ribbon' design to identify the preferred recipe. The blue ribbon survives to this day. Hellmann's mayonnaise is now owned by Unilever and is produced and consumed worldwide.

Types

Compositional Standards

Products sold as 'mayonnaise' are manufactured, distributed, and sold worldwide. The compositional standards vary widely, but there appears to be common agreement regarding the key components, namely, vegetable oil, acidifying agent, and egg components. These ingredient types will be described in section 'Key Ingredients.' The compositional standards tend to refer to a minimum content of fat or vegetable oil, with occasional references to the levels of the other key components.

In Europe, the Codex standard 168 for mayonnaise from 1989 quotes a minimum total fat content of 78.5% and a minimum 'technically pure' egg yolk content of 6%. However, this does not appear in the 2014 list of Codex standards but may still be considered to be a reference point for what tends to be known as 'real' mayonnaise; see succeeding text.

In the United States, the FDA 'Requirements for Specific Standardized Food Dressings and Flavorings,' Sec. 169.140 from 2013, quotes a minimum vegetable oil content of 65%, one or both of acetic acid (minimum 2.5%, from vinegar) and citric acid (minimum 2.5%, from lemon and/or lime juice), and egg yolk-containing ingredients.

In South Africa, Government Notice No. R. 92 of 1986 quotes a minimum vegetable oil content of 52%, together with an acidifying agent and 'egg or modified milk protein.'

In addition to the vegetable oil, acidifying agent, and egg components, there are a number of optional ingredients in all of the compositional standards, some of which are described in section 'Key Ingredients.'

Real Mayonnaise

Real mayonnaise tends to comply with the Codex compositional standard for mayonnaise, specifically the minimum fat and egg contents of 78.5% and 6%, respectively. For example, in the United Kingdom, Hellmann's Real Mayonnaise contains 79.1% fat (77% vegetable oil) and 8% egg and egg yolk.

Full-Fat Mayonnaise

Full-fat mayonnaise typically contains in the region 65–75% fat, although fat contents outside of this range are known. For example, Sainsbury's Mayonnaise in the United Kingdom contains 78% rapeseed oil, and Calvé Mayonaise in the Netherlands contains 70 g fat per 100 ml (approximately 66% w/w). The products with the lower fat contents in this category tend to include one or more thickening agents in the formulation in order to provide the desired thick and spoonable texture. The Calvé product, for example, contains xanthan gum.

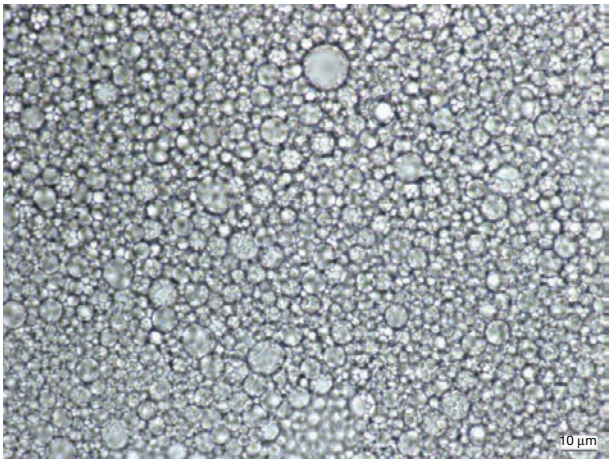

Figure 1 Light micrograph of full-fat mayonnaise.

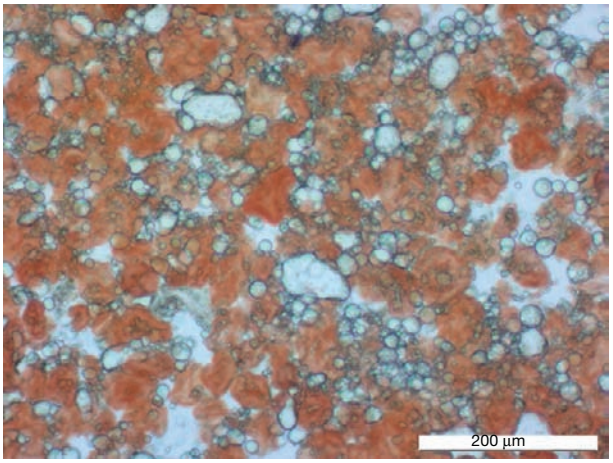

Figure 2 Light micrograph of light mayonnaise.

Confusingly, the 'Basics' mayonnaise from Sainsbury's in the United Kingdom contains only 25% rapeseed oil, presumably in an attempt to provide a low-cost option by replacing much of the oil with water. In this case, the texture has been maintained by the addition of modified maize starch, xanthan gum, and guar gum.

Light Mayonnaise

There are a multiplicity of 'reduced-fat' and 'light' mayonnaise products on the market, and they typically contain in the region 20–30% fat, although fat contents outside of this range are known. For example, in the United Kingdom, Hellmann's Light Mayonnaise contains 28% vegetable oil, and Sainsbury's Reduced Fat Mayonnaise contains 26% rapeseed oil. Both products contain modified maize starch and xanthan gum (also guar gum in Hellmann's) in order to provide the desired thick and spoonable texture. This combination of thickening agents is very common in dressing products generally.

Because of the reduced levels of fat, light mayonnaise requires lower levels of egg-based ingredients for emulsification. The Hellmann's and Sainsbury's products contain 4.2% egg and egg yolk and 3% egg yolk, respectively.

The microstructure of such products comprises a combination of an O/W emulsion as for full-fat and 'real' mayonnaise and a modified starch gel. It is likely that the starch gel dominates the texture with the emulsified oil droplets merely filling the structure. A light micrograph of a light mayonnaise is given in Figure 2, showing swollen starch granules (stained brown in iodine solution) and dispersed oil droplets (image courtesy K. Groves, Leatherhead Food Research).

Extra Light Mayonnaise

Extra light mayonnaise typically contains less than 10% fat. In the United Kingdom, Hellmann's Extra Light Mayonnaise contains 3% fat, with citrus fibers in addition to modified maize starch and xanthan gum being used to provide the desired thick and spoonable texture. Although hardly required for emulsification, the product contains 4% egg and egg yolk. The microstructure of extra light mayonnaise comprises a thickened starch-based water phase with a small amount of emulsified oil droplets.

Other Mayonnaise Types

Apart from the main types of mayonnaise products described earlier, there are a number of flavor variants, including garlic, lemon, and chili, as well more specialized types such as organic and egg-free. Egg-free mayonnaise contains alternative emulsification agents such as soya or pea protein.

Key Ingredients

Oils

The main types of vegetable oils that are used in mayonnaise products are rapeseed, sunflower, and soybean. These oils are all liquid at room temperature and can easily be emulsified at ambient temperature or above, depending on the required processing methodology. They tend to support omega-3 claims for the mayonnaise, depending on the levels applied. Sunflower oil can form waxes at chill temperatures, leading to cloudiness and possibly emulsion instability. It is therefore often 'winterized' to remove the waxes for use in mayonnaise.

Olive oil is applied at relatively low levels in olive oil mayonnaise. At higher levels, it can tend to impart a bitter taste, is relatively expensive, and can form waxes at lower temperatures, especially in the case of the extra-virgin grades. For example, in the United Kingdom, extra-virgin olive oil mayonnaise from Waitrose contains 5% extra-virgin olive oil.

Egg Ingredients

Egg-based ingredients are used in all mayonnaise products primarily for the emulsification of the vegetable oils. The phospholipids and to some degree the proteins impart the emulsification ability of yolk. Egg yolk can also contribute color and flavor at the appropriate levels. The egg-based ingredients are generally egg yolk or a blend of whole egg and egg yolk. They are pasteurized and supplied in either liquid or frozen form.

The ingredients contain salt as part of the preservation system, for example, egg yolk '92-8' comprises 92% egg yolk and 8% salt. An alternative system is '92-7-1,' which comprises 92% egg yolk, 7% salt, and 1% potassium sorbate. Egg yolk powder is also used in some products.

Whole egg tends to be applied in products for which the egg white component contributes to the structuring of the water phase, resulting in a more spoonable-type texture. For the viscous products, egg yolk alone is used.

Modified egg yolk is applied in many products. In this case, the egg yolk has been treated with the phospholipase A2 enzyme to improve the emulsification capability and generally result in a firmer mayonnaise. Crucially, the enzyme-treated egg yolk has improved temperature stability and so can be applied in 'hot' manufacturing processes without 'scrambling.'

In mayonnaise manufacture, it is generally considered preferable to keep the egg and acids apart for as long as possible. This is due to acid damage, which can reduce the emulsification capability of the egg yolk and result in a thinner product. For this reason, the vinegar tends to be added as late as possible during the manufacturing process.

The application level for egg ingredients is determined by compositional standards legislation in some markets as described in section 'Types.' In practical terms, the appropriate ratio of egg to oil for acceptable emulsification is generally 1:10 for liquid egg ingredients or 1:20 for egg yolk powder.

Vinegars and Acetic Acid

Acetic acid, in the form of vinegar, is the main acidulant applied in mayonnaise products. Acetic acid is a weak acid and the undissociated form is especially suitable as it contributes significantly to the preservation and is a key factor in stability models such as CIMSCEE (Comité des Industries des Mayonnaises et Sauces Condimentaires de la Communauté Économique Européenne). Acetic acid is mostly undissociated at the pH values normally associated with mayonnaise products, typically in the range 3.5–4.5 and ideally less than pH 4.

The dissociated acid contributes to the reduction in pH, another key factor in stability models such as CIMSCEE.

Spirit vinegar is used widely in mayonnaise products because it is colorless and contributes little to the flavor (apart from the acid taste). It is typically supplied at a strength of 12% acetic acid in water but both 10% and 14% are common. The higher levels are preferable for transportation cost reasons.

Wine vinegars, both red and white, are also extensively used, as is balsamic vinegar in specialized products. In the latter case, the strength is usually 5% acetic acid in water, but this is generally not an issue as lower levels are used.

Occasionally, chemically synthesized, food-grade acetic acid is used in addition to the vinegar. This is likely to be for cost and manufacturing efficiency reasons.

Thickeners

A wide range of water-based gelling and thickening agents are used in mayonnaise products with the most common being modified starch, xanthan gum, and combinations of these. Guar gum, locust bean gum, carrageenan, and gelatin are also applied. The modified starch may be a preswelled cold-soluble version for products that are manufactured and filled under ambient conditions or a standard cook-up version for pasteurized products. Of the range of modified starches, the most useful tend to be those that are the most resistant to shear damage through the colloid mill emulsification devices. Accordingly, they require significant heat and shear energy in order to fully swell the granules and achieve full functionality.

The new generation of 'clean-label' starches and flours does not yet appear to be widely used in mayonnaise products, presumably because they are not sufficiently robust for the typical equipment and manufacturing processes.

Gelling and thickening agents are primarily applied in order to compensate for the loss of texture due to fat reduction at total fat levels of around 70% and below. Accordingly, there has been significant research to develop specific blends in order to match the product quality of the full-fat versions. The emergence of citrus fiber as a 'clean-label' thickening agent is an example of innovation in ingredients in this area.

Other Ingredients

Apart from the obvious flavoring ingredients such as garlic and chili, there are a huge number of other ingredients that are widely used in mayonnaise products. This section is not exhaustive in describing these.

Apart from vinegar and acetic acid, citric acid in the form of lemon or lime juice is used both for the flavor contribution and for pH reduction. Citric acid does not have the preservation capability of acetic acid. Then, there are around 23 or so acids that are approved according to EU legislation as given in Table 1. These acids are added in order to achieve a reduction in pH, and accordingly, strong acids that readily dissociate are used. Phosphoric acid is an example of such an acid. Such acids however are relatively rare in comparison with citric acid and especially acetic acid.

Mustard is applied in some products mainly for flavoring reasons. The proteins and phospholipids in mustard contribute to emulsification but are much less effective in this regard than egg yolk. The mustard may be added as the liquid product itself or as mustard flour. Some mayonnaise products do not contain mustard but instead contain a mustard flavoring in the form of AITC (allyl isothiocyanate), the pungent component of mustard, dissolved in oil.

Table 1 Acids permitted for use in foods in Europe

Sorbic acid	E200	Phosphoric acid	E338
Benzoic acid	E210	Metatartaric acid	E353
Acetic acid	E260	Adipic acid	E355
Lactic acid	E270	Succinic acid	E363
Propionic acid	E280	Alginic acid	E400
Boric acid	E284	Hydrochloric acid	E507
Malic acid	E296	Sulfuric acid	E513
Fumaric acid	E297	Gluconic acid	E574
Ascorbic acid	E300	Glutamic acid	E620
Erythorbic acid	E315	Guanylic acid	E626
Citric acid	E330	Inosinic acid	E630
Tartaric acid	E334		

Salt is another component of mayonnaise that plays a role in stability models due to its functionality as a preservative. It is added as a component of the egg ingredient and may also be added directly as a separate ingredient. Salt also makes an important contribution to the taste of many mayonnaise products. A key challenge in the current environment of salt reduction is achieving the necessary preservation at the lower fat levels. As the water content is increased, so the ingredients in the water phase contributing to the microbiological safety and stability have to increase too. This includes both vinegar and salt. Developing lower fat mayonnaise products that do not taste too sour or contain too much salt in comparison with the full-fat equivalents can be very difficult. This topic will be discussed further in section '**Health Effects of Mayonnaise**.'

Sugar (sucrose) is applied in some mayonnaise products albeit at relatively low levels. It plays a role in preservation and contributes to the texture as well as the sweetness. Other sugars such as glucose and fructose, especially glucose/fructose syrup, are also used. Often, this is in combination with sugar for cost and manufacturing efficiency reasons. The current trend for sugar reduction may not be as significant for mayonnaise as for other food and beverage products because the starting levels are generally much lower and the major calorific contribution is from the fat.

Milk powder is sometimes added at low levels to impart some dairy-type flavoring notes. The small amount of protein added may make a small contribution to the emulsification of the oil phase.

The main types of coloring agents used in mayonnaise products are paprika extract, beta-carotene, and titanium dioxide. Most products are pale yellow or off-white in color and contain one of these coloring agents in order to compensate for differences in oil droplet size and color intensity of the main ingredients such as egg yolk. Titanium dioxide tends to be used for products with a relatively inefficient emulsification process, lower fat content, or larger oil droplet size, and that would otherwise result in a dull white appearance.

In addition to the key elements for preservation, namely, acetic acid, pH, salt, and pasteurization, chemical preservatives are occasionally used. The main preservative applied in mayonnaise products tends to be potassium sorbate, specifically to control the growth of spoilage organisms. These are often considered to be introduced during packaging; therefore, hot filling is another effective decontamination mechanism. Accordingly, potassium sorbate is mostly applied in products that are filled under ambient conditions.

The usage of unsaturated oils means that mayonnaise is prone to the development of rancidity through oxidation. Indeed, this is the critical quality deterioration mechanism and the main determinant of shelf life. Steps are usually taken during manufacture and filling to reduce the inclusion of oxygen, with vacuum emulsification and steam capping, for example, and the consumer advice to store the product in the fridge after opening also prolongs the life from a quality as well as a spoilage perspective. Even with these actions, rancidity can develop relatively quickly and the use of antioxidants is recommended. The antioxidant that tends to be applied in mayonnaise products is calcium disodium ethylenediaminetetraacetic acid.

Sources and Production of Mayonnaise

Introduction

Mayonnaise is manufactured worldwide in factories ranging from a few kilograms per day to several tonnes per hour. In its simplest form, the equipment is fairly straightforward, comprising blending, emulsification, and filling. The higher-fat products do not always require pasteurization as the vinegar and salt levels can control the microbiological status of the water phase, thus simplifying the manufacturing further. Accordingly, there are many artisanal producers of specialty mayonnaise products, selling their products through local outlets.

Emulsification

The colloid mill is the method of choice for the manufacture of mayonnaise, and many types are available, including both batch and continuous systems. They work on the rotor and stator principle with high shear forces generated that can effectively reduce the oil droplet size of even the most viscous products. The pumping action ensures that the shear forces are distributed evenly throughout the sample, but care has to be taken that particulates and other sensitive ingredients are not damaged too much. Pilot-scale colloid mills are available and have the advantage over many other unit operations in that they tend to be reasonably predictable in scale-up from pilot to factory production.

Colloid mills are especially suitable for mayonnaise due to the high viscosities that are required, but a number of other emulsification devices may be applicable in specific cases. The key task is to reduce the mean oil droplet diameter to ideally around 3–5 μm, and this can also be achieved using high-pressure homogenizers, high-shear mixers, membrane devices such as those supplied by Micropore Technologies, and the recently reported magnetohydrodynamic dispersion device. As in all manufacturing operations, the key task is to select the most appropriate equipment for the desired product quality and production efficiency reasons. This may require a combination of unit operations, including storage tanks for intermediate and finished products.

Emulsification processes tend to be more predicable when a preemulsification step is included. Working on the 'rubbish in, rubbish out' principle, an initial high-shear mixing step to produce a crude emulsion with a consistent mean oil droplet diameter means that a single pass through the colloid mill may be sufficient to achieve the required consistency. As part of a rigorous quality assurance scheme, monitoring the properties of the preemulsion, with appropriate control measures, is essential.

In section '**Key Ingredients**,' the challenges in selecting the most appropriate starch ingredient for the application were described. The colloid mill step can be especially damaging to the integrity of swollen starch granules; therefore, highly robust modified starches are mostly applied. These not only will be more stable to the high-shear emulsification step but also are more difficult to cook up in the first place, requiring more heat and shear energy than other grades. It is therefore essential to monitor the status of the starch granules in the

finished product and to ensure compatibility between the starch and the process, especially if a change is made. Pregelled starches are also available but tend to have more limited use in mayonnaise products due to the generally reduced robustness when compared to the cook-up versions.

Batch and Continuous Processing

Mayonnaise products are manufacturing using three basic types of process, namely, batch, continuous, and batch–continuous.

Batch processing is probably the simplest and involves the manufacture of individual batches of product in a suitable vessel and subsequent direct filling. The batch vessel ranges in size from 50 to 500 kg or more, incorporates ingredient addition and product evacuation, and operates under a vacuum to reduce the incorporation of air. A high-shear impeller generates a suitable preemulsion and the product circulates through a colloid mill device at the bottom of the vessel via a return loop back into the vessel. The mayonnaise is circulated and emulsified until the appropriate product quality has been achieved. The vessel is temperature-controlled via a jacket for either high- or low-temperature processing steps. Batch processing requires careful control and consistency of the ingredient addition and key timings in order to achieve acceptable product quality for each of the batches.

Continuous processing takes the liquid ingredient streams and combines them in a continuous manner immediately before emulsification. There may be four or six different streams and the challenge is to ensure a constant flow rate of each such that the final mayonnaise has the correct composition. In practice, this can often be difficult as the quantities of the ingredient streams may differ widely, and they may have differing viscosities. For example, in the case of full-fat mayonnaise, the quantity of oil will be much greater than any of the other ingredient streams, and for light mayonnaise, the starch/water stream will have the highest viscosity. Particular difficulties are likely to be encountered with extra light mayonnaise with a very low oil content and a very viscous starch/water stream.

Batch–continuous processing combines the two approaches in order to achieve a consistent quality product at a high throughput. In this case, relatively small batches, say, 250 kg, of preemulsion are produced and then pumped into intermediate storage tanks. This achieves a consistent feed for the subsequent colloid mill final emulsification step. The combined preemulsion batches are then processed on a continuous basis through the colloid mill and then to the filler. This combination of consistent preemulsion and long run time for the colloid mill means that the final mayonnaise product is optimized for quality and manufacturing efficiency. This methodology can be applied to all kind of products with varying levels and viscosities of the ingredient streams.

Ingredient Streams

As with all products, mayonnaise manufacture requires the addition of the ingredients in a consistent and predictable manner. In the batch process, this will involve the simple and direct addition of the ingredients in their standard liquid or powder form. However, even in this case, and certainly in the continuous and batch–continuous processes, the preparation of liquid ingredients streams may be appropriate. These are based on solutions or dispersions in oil or water and will include one or more of the following.

The starch may be added either as a cold water slurry or as a gelatinized dispersion. In the latter case, the starch/water mixture will have been heated to swell the starch granules and then maintained at a high temperature or cooled prior to adding as an ingredient stream. Other minor components such as salt, sugar, and preservative may also be added at this stage.

The remaining aqueous ingredients may be added as a separate stream. This includes any other thickening agents such as xanthan gum, salt, and sugar if not added with the starch, preservative, and antioxidant. Again, this could be a slurry, dispersion, or solution of the ingredients in water. The lemon juice, mustard, and any acids, apart from the vinegar, may be added at this stage.

The bulk oil or oils will be added as an ingredient stream. This may be simply the rapeseed oil or sunflower oil, or a blend if this is applied, or with a small amount of olive oil for this type of product. The bulk oils will generally be stored in bulk tanks and may be chilled or have nitrogen blankets in order to reduce the amount of oxidation.

The oil ingredient stream includes all of the minor oil-soluble ingredients such as the colors and flavors, together with an appropriate amount of the bulk oil in order to balance the quantities and ensure consistent addition rates of these components.

The vinegar or blend of vinegars is added as a separate ingredient stream. As stated previously, the vinegar is often added as the last ingredient stream in order to reduce the impact on the functionality of the egg ingredients for emulsification. In some manufacturing processes, the addition of the vinegar assists in the cooling of the water phase streams that have been heated for pasteurization or starch cooking.

The egg ingredients are added as a separate stream at an early part of the process in order to achieve efficient emulsification before many of the other ingredients, such as the vinegar, are added. The egg ingredients tend to be supplied in bulk containers under chilled conditions, can separate somewhat during storage, and have a limited shelf life. As stated previously, they are also always pasteurized and contain salt.

Hot and Ambient Processing and Filling

Depending on the microbiological status of the ingredients and of the finished product, the mayonnaise product may be processed under ambient conditions or with heat, and ambient- or hot-filled.

Ambient processing is reserved for those products in which the microbiology is controlled by the formulation itself. The high-fat products tend to have a small number of ingredients that are considered to be a relatively low microbiological risk, such as salt and sugar, meaning that heat treatment for decontamination is not necessary.

Hot processing is applied to those products in which the formulation cannot control the microbiology without further interventions. There are likely to be a larger number of ingredients that pose a higher level of microbiological risk, and

pasteurization is required in order to achieve the appropriate microbiological status. Hot processing is also required in order to activate the cook-up starches that are used in most mayonnaise products containing 70% fat and below.

Ambient filling is reserved for those products in which the packaging does not pose an enhanced microbiological risk. Either the packaging has been decontaminated in a previous step or the microbiology is controlled by the product. The product itself may have been ambient- or hot-processed according to the criteria described earlier. In addition, the products are likely to contain potassium sorbate as a preservative.

Hot filling is primarily applied as a mechanism for decontaminating the packaging and ensuring acceptable microbiological status. It is most often conveniently combined with hot processing, thus avoiding the need to cool the product before filling.

Patterns of Consumption of Mayonnaise

Sauce Market

Mayonnaise may be considered to be part of the global sauce category although the various market reports tend to differ in the subdivision below this level, making comparisons difficult. For example, sauces may be divided into 'cold' and 'hot,' mainly according to the host food, so cold sauces include mayonnaise, ketchup, barbecue sauces, salad dressings, and mustard and are characterized by a long open shelf life of at least 4 weeks under chilled conditions. Hot sauces then include cooking sauces for casseroles and stir-fries, with a relatively short open shelf life of a few days under chilled conditions.

A global food markets report on sauces from Leatherhead Food Research in 2010 defined sauces as follows:

- Cooking sauces (wet and dried (including soy sauce in China))
- Accompaniment sauces (e.g., ketchup)
- Mayonnaise and salad dressings
- Other sauces (e.g., mustard, vinegar, soy (excluding China), and other sauces)

In this context, the global sauce market amounted to more than 30.2 million tonnes in volume terms in 2008, with value sales in excess of USD 67.4 billion. The mayonnaise and salad dressing sector was the second largest, comprising around 26% global market value.

Mayonnaise Consumption

The global leader in the consumption of mayonnaise is Russia at about 5.1 kg per capita in 2013, over three times the amount for the United Kingdom (1.6 kg) and five times the amount for Germany (1.0 kg). Overall, the top 10 is dominated by eastern European countries as shown in Table 2.

The United States and Canada do not make the top 10 but nevertheless consume 1.9 kg per capita. This amounts to around USD 2 billion worth of mayonnaise in the United States. Within this, low-fat mayonnaise has doubled in size in the United States since 2005 and is now worth over USD 500 million.

Table 2 Global league table of mayonnaise consumption

Availability, Absorption, and Metabolism

The nutritional characteristics of mayonnaise are dominated by those of the component oils, which are present at relatively high levels, from 20% in light or reduced-fat mayonnaise to 80% in full-fat and 'real' mayonnaise. The component oil in a mayonnaise product is usually rapeseed oil, sunflower oil, or soybean oil, as discussed in section '**Key Ingredients**,' with the occasional use of olive oil in appropriate products.

The bioavailability, absorption, and metabolism of the common vegetable oils used in mayonnaise products are described in the relevant chapters of this encyclopedia. There are no known aspects that apply to mayonnaise over and above those of the component oils. It is possible however that future nutritional studies may take into account the water-continuous basis of this product type, and the presence of other components such as salt and acid, to determine whether the bioavailability, absorption, and metabolism of the oil may be enhanced.

Health Effects of Mayonnaise

Introduction

The impact of mayonnaise products on dietary health extends beyond the bioavailability, absorption, and metabolism of the component oils as described in section '**Availability, Absorption, and Metabolism**.' Of particular concern is the fat content that can be as high as 80% and is generally around 30% even for the light and reduced-fat versions. Therefore, the potential solutions for reducing the fat level while maintaining product quality are of interest. In a similar vein, there are moves to reduce the salt and sugar levels, although in these cases, the challenge is around preservation as well as product quality. And finally, the presence of common allergens means that the 'free-from' agenda is relevant too.

Omega-3

Mayonnaise products contain omega-3 and omega-6 fatty acids from the component oils. As stated in section '**Key Ingredients**,' the oil component is usually rapeseed oil, sunflower oil, or soybean oil, and the fatty acid compositions of these oils are described in the relevant chapter of this encyclopedia. In the United Kingdom, Hellmann's Real Mayonnaise and Hellmann's Light Mayonnaise both claim to be 'a good natural

source of omega-3,' containing 8.4 g/100 g and 2.6 g/100 g, respectively, of omega-3 fatty acids 'from plant sources.' They also contain 16.8 g/100 g and 6.1 g/100 g, respectively, of omega-6 fatty acids.

Other mayonnaise products such as the one from Sainsbury's in the United Kingdom give a breakdown of the saturates, monounsaturates, and polyunsaturates, but do not quote the levels of omega-3 or omega-6 fatty acids.

Allergens

The nature and composition of mayonnaise products are such that they tend to contain some of the components that require labeling as allergens. Chief among these is egg, the emulsifying agent present in all except the egg-free versions.

Mustard is the next most popular allergen with many mayonnaise products containing this as an ingredient mainly for flavoring reasons. Some products such as Hellmann's mayonnaise in the United Kingdom contain mustard flavoring but not mustard itself. The mustard flavoring tends to be AITC in oil, as described in section 'Key Ingredients,' and as such is not protein-based as are all allergens apart from sulfite/sulfur dioxide. However, as a precaution and to guard against adverse reactions to AITC, mustard allergen labeling tends to be carried out.

Other allergens may be present depending on the mayonnaise formulation, for example, dairy when milk powders are used for flavoring reasons.

Fat Reduction

Full-fat and 'real' mayonnaise can contain 75–80% fat and may therefore be considered to be unhealthy as part of the obesity agenda. A single portion or tablespoon of mayonnaise (15 ml/14 g) can contain 11 g fat, and for this reason, the light and reduced-fat versions are important for some sectors of the population.

As described in sections 'Types' and 'Key Ingredients,' fat reduction in mayonnaise products has been successfully achieved using a range of gelling and thickening agents such as modified starch and the emerging ingredients such as citrus fiber. The extra light products containing as little as 3% fat have demonstrated that acceptable thick and spoonable textures can be achieved using these ingredients. However, such compositions, especially the highly viscous water phases, can present significant problems during manufacturing. An alternative approach that is especially suitable for liquid, water-based systems is that of water-in-oil-in-water (WOW) double emulsions.

WOW emulsions have been studied for many years for their ability to reduce the fat contents of water-continuous emulsions by 'hiding' some additional water inside the oil droplets as a second emulsion. Figure 3 is a light micrograph of a WOW emulsion, clearly showing the internal water droplets (image courtesy K. Groves, Leatherhead Food Research). WOW emulsions are prepared by firstly emulsifying the internal water phase into the oil using a highly lipophilic emulsifier. Polyglycerol polyricinoleate, PGPR (E476), is especially suitable for this purpose although lecithins have also been used. This water-in-oil emulsion is then emulsified into the external water phase using an egg ingredient such as egg yolk as the emulsifier. In this way, an emulsion has been created in which the internal water phase is considered to be part of the oil, increasing the effective oil content.

Various studies have been carried out to demonstrate the fat-reducing capability of WOW double emulsions. A project at Leatherhead Food Research involved the reduction of the fat content of a mayonnaise-type sauce by 20% using WOW double emulsion technology. The resulting emulsions were characterized using rheology and sensory analysis and found to be similar to the full-fat equivalent products prepared as standard O/W emulsions. Figures 4 and 5 clearly demonstrate these effects. WOW double emulsion technology therefore appears to be a potential alternative to the use of gelling and thickening agents for mayonnaise products containing around 70% fat or less. The potential challenges to this appear to be the requirement to use PGPR as an additional emulsifier and the requirement for two emulsification steps.

Salt and Sugar Reduction

Salt and sugar reduction activities in foods and beverages have mainly focused on gradual reductions and the use of alternative ingredients. In the case of salt, this has mostly been potassium chloride, and for sugar, a combination of ingredients for sweetness and texture. There are many options available

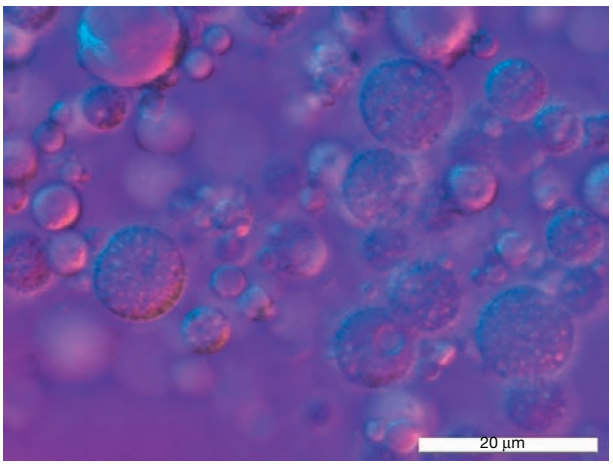

Figure 3 Light micrograph of WOW emulsion.

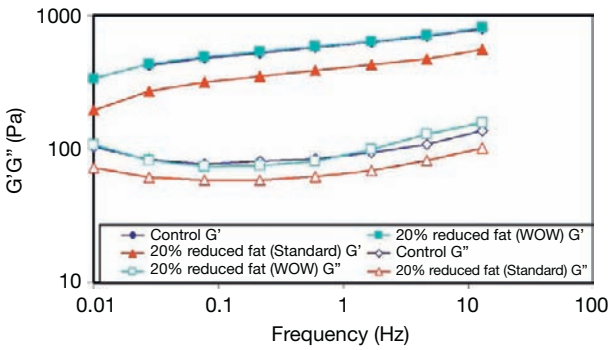

Figure 4 Rheology of emulsions.

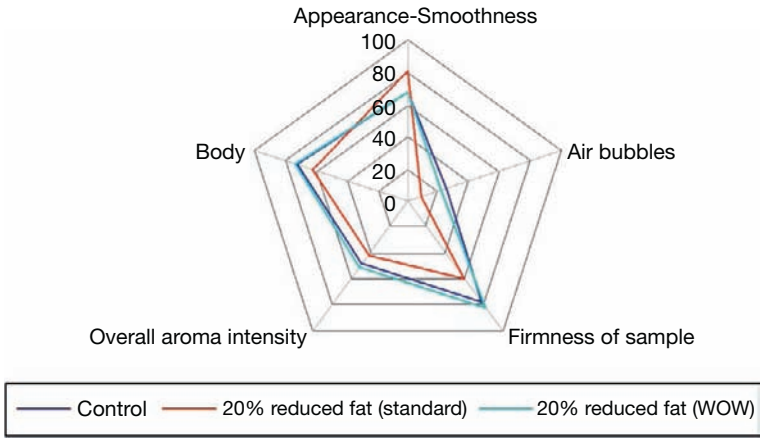

Figure 5 Sensory properties of emulsions.

although in general terms, these have not been applied significantly in mayonnaise products. As stated previously, salt is important for preservation, so care must be taken in reduction or replacement exercises. Sugar, when used, is generally at relatively low levels and contributes little to the calorific value in comparison with the fat.

WOW double emulsions have also been studied for the capability to reduce salt levels in thickened water-based foods. In this case, the technology relies on the internal and external water phases being of differing compositions, specifically the majority, if not all of the salt being present in the external water. The hypothesis is that the internal water is swallowed without being detected in the mouth; therefore, it does not need to contain any salt. A study reported in 2010 incorporated all of the salt in the external phase of a thickened soup-type WOW emulsion, with sensory assessments of the resulting saltiness. It was demonstrated that a salt reduction of 10% could be achieved with acceptable sensory performance. A potential challenge in the application of this technology in mayonnaise products appears to be the preservation of the internal water phase, although a balancing of the acetic acid and pH levels between the two water phases would assist in this.

As for salt reduction, it is possible that WOW emulsion technology could be used for sugar reduction, although there do not appear to be any reported studies. This is a potential area for future research.

Meat: Conversion of Muscle into Meat

R Warner, The University of Melbourne, Parkville, VIC, Australia

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Transformation of muscle to meat involves biochemical and metabolic processes induced by the animals' tissues in an attempt to retain homeostatic control. The size, extent, and timing of these responses postharvest can significantly affect the development of meat quality. In order to understand the influence of postharvest biochemistry on the structure of the muscle and consequent effects on quality, a brief review of muscle structure is required. Also, in order to understand postharvest muscle biochemistry, an appreciation of the importance of the contribution of energy management is required. Postharvest biochemistry of muscle has profound influences on muscle structure, with consequent effects on consumer acceptability and quality. Aberrations in meat quality are usually a result of a divergence from normal muscle biochemistry, due to variations in the genetics of the animal, stress preharvest, or chilling and freezing of the muscle. These aberrations in meat quality are discussed.

Muscle Structure and Fibers

Skeletal muscle is the largest tissue of most animal species and is composed of whole muscles, usually attached to bone by a tough inextensible connective tissue called epimysium. Muscles are subdivided into muscle bundles, which are surrounded by a connective tissue called perimysium (see Figure 1). Muscle bundles contain a number of muscle cells (also called muscle fibers), which are surrounded by a connective tissue called endomysium. Endomysium, perimysium, and epimysium are composed primarily of the protein collagen.

Muscle cells, when viewed longitudinally in the microscope, have a striped appearance due to alternating dark and light bands, which arise from the arrangement of myofibrils within the muscle cell. Individual myofibrils have these alternating dark and light bands and all myofibrils are in register and aligned within a muscle cell; hence, the striated appearance is evident at the level of the muscle cell and the myofibril and also when the myofilaments are viewed under electron micrographs (Figure 2). Thick and thin filaments, which comprise the myofilaments, are composed primarily of the proteins myosin and actin, respectively, and the light band of the sarcomere is the portion where only thin filaments are present and the dark band is where both thick and thin filaments are present. Other proteins associated with the thick and thin filaments include titin, nebulin, tropomyosin and troponin and are structural or regulatory in function. The thick and thin filaments are bounded by a z-line at each end, which is composed of the protein α-actinin, and a sarcomere is composed of two z-lines, with a pale band of thin filaments at either end, next to the z-line, or a dark band of thick and thin filaments in the middle. The unit of contraction is the sarcomere, and *in vivo* and postharvest contractions are a result of thick and thin filaments sliding past each other and attaching, which is termed the 'sliding filament theory' of contraction. *In vivo*, the presence of adenosine triphosphate (ATP) allows the myosin head on the thick filament to detach and relax from its bound state to actin. Postharvest, contraction, and shortening can occur in the sarcomeres and myofibrils, but once ATP is depleted, 'myosins' bond to actin remains as actomyosin, and rigor mortis is the result, with stiff and inextensible muscles.

An important point to make is that all muscles are not homogeneous. Muscles differ in their ratio of fiber types (slow, red, oxidative vs. fast, white, and glycolytic), their length, their width, and also their biochemistry and chemical composition. They also go into rigor at different times, and within a muscle, fibers can vary in the rate at which they go into rigor mortis. The effect of temperature on metabolic processes and on the rate of conversion of muscle to meat is also very important. Postharvest, carcasses are usually transferred into coolers within 30–60 min. But the rate of chilling can vary and the depth of the muscle and the weight of the carcass influence the rate of temperature decline in any muscle. This is exemplified in the difference in the temperature at different depths in muscles postharvest, as shown in Figure 3.

Process of Rigor Mortis

The process of rigor mortis is one of the recognizable signs of death as a result of the chemical changes in the muscles, causing the musculature to lose extensibility and become stiff. Figure 4 shows the changes that occur postharvest, using a pig carcass as an example. Synthesis of ATP is initially by creatine phosphate (CP) but later by glycogenolysis and glycolysis. CP usually drops to low levels within 1–2 h postharvest. Once CP levels drop to 75% of initial levels, ATP starts to decline. As CP disappears, Pi increases in the cell postharvest, and lactate accumulates concomitantly with increasing hydrogen ion (H^+) concentration. Once ATP reaches low levels, the extensibility of the muscles starts to approach 0% of its original, the pH approaches the final pH, and lactic acid reaches its final concentration of 5–6 μmol g^{-1} of tissue (in a well-fed, rested animal). Rigor mortis is defined by the decline of ATP to zero, 0% extensibility, an ultimate pH that is reached, and the production of lactic acid that has plateaued.

Metabolism and Biochemistry

The energy balance and biochemical reactions in muscle fibers that ensue postharvest, and end in rigor mortis, are complex and still being studied. The excellent reviews given in the suggested reading list give comprehensive information on this important topic.

In the living animal, ATP is formed through glycolysis and in the oxidative phosphorylation pathway and oxygen is

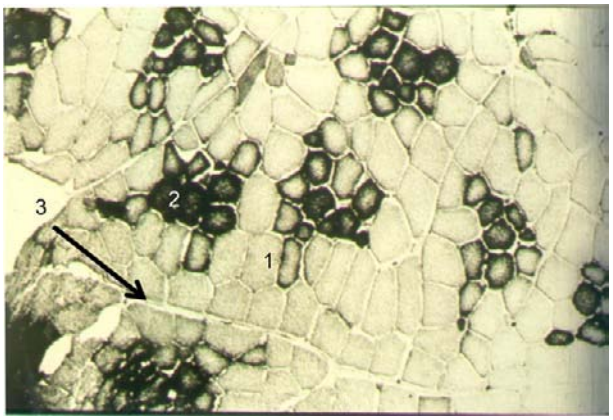

Figure 1 A cross section through a porcine longissimus muscle, with staining for succinate dehydrogenase, which differentiates between oxidative and nonoxidative fibers. 1 = fast twitch glycolytic or oxidative fiber, 2 = slow twitch oxidative fiber, 3 = a gap between muscle bundles where perimysial connective tissue exists. This cross section shows the characteristic groupings of the fiber types in porcine muscle, with oxidative fibers clustered together in a muscle bundle, surrounded by glycolytic fibers. The glycolytic and oxidative fibers are about 100 and 50 μm in diameter, respectively.

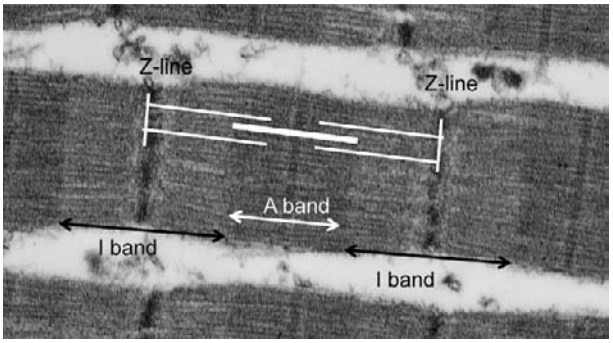

Figure 2 Transmission electron micrograph of a longitudinal view of muscle. The banding pattern is explained by the position of the thick and thin filaments. The I-band contains thin filaments and is bisected by the z-line. The A-band contains thick and thin filaments. The white lines show the thick and thin filaments and z-line, stylized to assist in understanding the structure. The sarcomere spans from one z-line to the next and is ~1.8 μm.

available to cells via the bloodstream. Energy-rich compounds, such as ATP, are used to maintain homeostasis in cells including steady state of reactions to produce heat and keep body temperature constant. Energy is stored in the cells as glycogen, lipid, and CP. After harvesting of an animal, the blood supply stops, leading to anoxia throughout the organs and tissues. Anoxia of skeletal muscle results in dramatic changes in the metabolism and biochemistry both *in vivo* and postharvest. Furthermore, the loss of blood supply postharvest means that the muscles can no longer maintain body temperature and the temperature drops. These changes in skeletal muscle postharvest involve the conversion of muscle into meat and are associated with biochemical and structural changes, which determine the meat quality parameters of tenderness, juiciness, flavor, and shelf life.

The postharvest muscle cell attempts to maintain its ATP levels, as ATP is required for metabolic reactions and ion transport. ATP is split at about 0.5–0.65 μmol g^{-1} of muscle/min at 38 °C and the enzyme with the greatest demand for ATP is the myosin ATPase. In resting muscle, myosin is not bound to actin and ATP splitting is inhibited by millimolar concentrations of Mg^{2+}. A slow hydrolysis of ATP to ADP and Pi occurs and as myosin is 20–30% of the total protein in muscle, myosin ATPase accounts for the majority of ATP splitting in resting and postharvest muscle. The effect of temperature on ATP turnover is very similar to the effect of temperature on myosin ATPase activity, giving evidence for their dependence. When cytosolic Ca^{2+} increases from $<10^{-8}$ M to 10^{-6}–10^{-5} M, myosin ATPase activity is stimulated 300–500-fold. This increase in Ca^{2+} occurs not only during contraction but also during rigor mortis development. The Ca^{2+}-ATPase pumps Ca^{2+} back into the sarcoplasmic reticulum, and as membranes become leaky postharvest, ATP is broken down to support this and other active ion transport pumps such as the mitochondrial ATPase, the sarcolemmal Na^+, K^+-ATPase, and sarcolemmal Ca^{2+}-ATPase.

ATP is not only generated during glycolysis but also consumed, as shown in Figure 5. Thus, ADP is required in order for glycolysis to continue. Glycogen is the main storage unit of carbohydrate in muscle and is equivalent to starch in plant cells. Glucose-6-phosphate can be formed from glucose, a reaction catalyzed by hexokinase (see Figure 5), but very little of this reaction occurs in postharvest muscle. Glycogen is hydrolyzed to glucose-1-P by glycogen phosphorylase and the compounds are then sequentially broken down to lactate, in postharvest anaerobic muscle. The accumulation of H^+ from lactate and ATP hydrolysis account for the pH decline in muscle postharvest. The sequence of enzymatic steps in glycolysis postharvest is shown in Figure 5, and ATP is generated in two steps after fructose 1,6-bisphosphate, generating 4 ATP per glycogen–glucose molecule (as one 6-carbon molecule is split into two 3-carbon molecules). Also and importantly, ATP is consumed in two reactions prior to fructose-1,6-bisphosphate. Thus, only three ATP are generated from the conversion of a glucose-1-P molecule to lactate. This process is called anaerobic glycolysis and, in the living animal, is recognized to be very inefficient and can only be used in short bursts when demand for energy is high, such as sprinting. In the living animal, the lactate produced from anaerobic glycolysis is transported out of the muscle, via the blood to the liver, where it is reconverted to glucose. Postharvest, in the absence of circulating blood, it remains as a waste product and causes the decline in pH. The hydrolysis of nucleotides (ATP, ADP, AMP, and IMP) also generates hydrogen ions (and Pi) (see Figure 6); thus, recent literature has pointed out that the pH decline postharvest is due to hydrogen ions accumulating not only from lactic acid but also from nucleotide hydrolysis. In order for glycolysis to proceed, ADP is required by the steps involving the enzymes phosphoglycerate kinase and pyruvate kinase.

The postharvest contribution of creatine kinase- and adenylate kinase-catalyzed reactions to ATP production is shown in Figure 6, as well as the interconversion and degradation of high-energy phosphates.

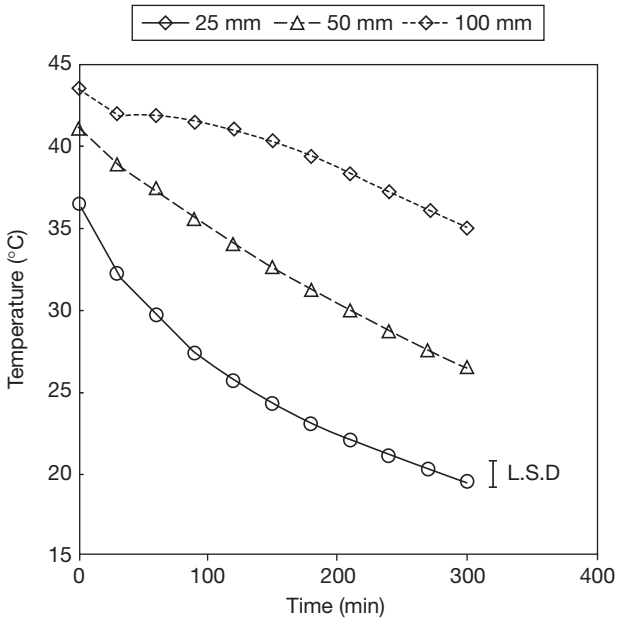

Figure 3 The temperature (°C) of the fascial seam between the *M. semimembranosus* and *M. semitendinosus*, in a beef carcass, at depths of 25, 50, and 100 mm from the surface. (Values are means. LSD represents the average least significant difference ($P < 0.05$) for comparing different means for different depths and different times. Differences between means that are greater than the LSD are significantly different.) Reproduced from Jacob, R. H., Beatty, D. T. and Warner, R. D. (2014). Figure 4 Chemical and physical changes in muscle postharvest. The pattern shown is typical for pig muscle undergoing normal postharvest metabolism. Abbreviations: ATP, adenosine triphosphate; CP, creatine phosphate; LA, lactic acid; Ext, extensibility. Reproduced from Greaser, M. L. (2001). Postmortem muscle chemistry. In: Hui, Y. H., Nip, W.-K., Rogers, R. W. and Young, O. A. (eds.) *Meat science and applications*, pp. 21–37. New York: Marcel Dekker.

Before glycolysis starts postharvest, creatine phosphate (CP) maintains the ATP concentration according to the reaction

$$CP + ADP + H^+ \rightarrow ATP + \text{creatine}$$

Thus, creatine phosphate acts as a short-term ATP buffer and amounts to 20–30 mmol kg^{-1} in resting muscle. Thus, in the initial period 0–30 min postslaughter, there is no fall in pH and ATP levels remain constant, as CP is supplying ATP (see Figures 4 and 6). CP is quickly exhausted, and as the demand for ATP continues, glycolysis proceeds and the reactions shown in Figure 5 ensue.

The net equation can be simplified as

$$\text{Glucose (from glycogen)} + 3\ ADP + 3Pi + 3H^+ \rightarrow 3\ ATP + 2\ \text{lactate} + 3H^+$$

As can be seen in Figure 5, this is an oversimplification as it is a complex series of steps with enzymes catalyzing each reaction. The enzyme phosphofructokinase is seen as a key regulator of the rate of glycolysis, and it has recently been

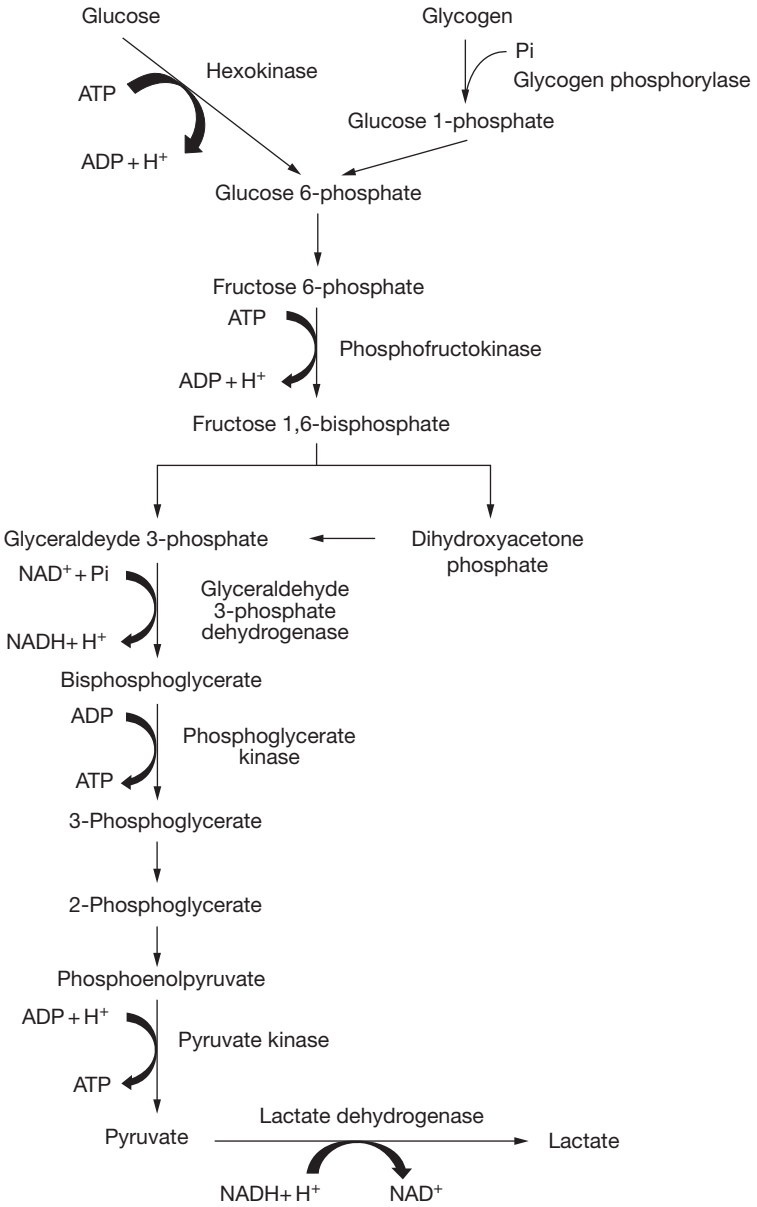

Figure 5 The glycogenolytic/glycolytic pathway. Glucose or glycogen is metabolized via glycolysis. Under anaerobic conditions, the final product, pyruvate, is converted to lactate. H^+ are released during the early steps when ATP is 'invested' as well as in the reaction catalyzed by glyceraldehyde 3-phosphate dehydrogenase; H^+ are consumed during the ATP-harvesting step catalyzed by pyruvate kinase and in the production of lactate. Reproduced from Scheffler, T. L., Park, S. and Gerrard, D. E. (2011). Lessons to learn about postmortem metabolism using the AMPK [gamma] 3R200Q mutation in the pig. *Meat Science* **89**, 244–250.

conclusively shown that this enzyme fails below pH 5.5, thus causing the cessation of glycolysis. Previously, it was thought that the loss of adenosine dinucleotides to the IMP form was the cause of glycolysis cessation at pH < 5.5.

Finally, glycolysis is driven by the demand by ATPases for ATP (Figure 6). The main ATPase-consuming ATP postharvest is the myosin ATPase, but the ATPases in the sarcolemma and mitochondria also contribute. The hydrolysis of ATP by these ATPases generates H^+ ions as shown in Figures 6 and 7. The consumption of ATP by mitochondria postharvest has recently been discussed as 'mitochondrial treason' and is considered to contribute to postmortem pH decline and biochemistry.

Changes in Muscle Structure That Impact on Meat Quality

The extent and rate of pH fall are influenced by biochemical events pre- and postharvest, which have their action on structural components in muscle cells and the associated connective tissue. The influence of rate and extent of pH fall on protein denaturation, myofilament lattice spacing, and the shrinkage in muscle cells is fundamental in determining the quality of raw meat. Furthermore, the influence of the extent of pH fall (ultimate pH) on muscle structure is a fundamental mechanism behind many genes associated with quality.

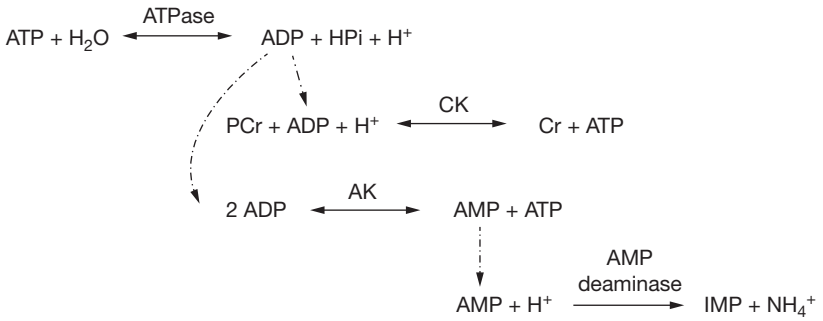

Figure 6 Contribution of creatine kinase (CK)- and adenylate kinase (AK)-catalyzed reactions to ATP production. Creatine phosphate is labeled as PCr (phosphocreatine) in this diagram. AMP is deaminated to inosine monophosphate (IMP) to preserve high ATP/ADP and free energy of ATP hydrolysis. H^+ are released by ATP hydrolysis, and H^+ are consumed by the CK and AMP deaminase reactions. Reproduced from Scheffler, T. L., Park, S. and Gerrard, D. E. (2011). Lessons to learn about postmortem metabolism using the AMPK [gamma] 3R200Q mutation in the pig. *Meat Science* **89**, 244–250.

Prerigor and postrigor changes in tenderness of ovine longissimus muscle. *Journal of Animal Science* **72**(5), 1232–1238.

Water-Holding Capacity

Postrigor muscle is about 75% water, with up to 87% of the volume of the muscle cell being myofibrils, which contain the majority of the water. Hence, any changes in the length or the diameter of the myofibril impact on water loss from the myofibril, and hence the muscle cell, and eventually the meat. The decline in muscle pH postharvest associated with the glycolysis and onset of rigor mortis results in a fall in pH from about 7.0 to about 5.5, in a muscle of 'normal' quality. As the pH drops, it comes closer to the isoelectric point (the point at which the molecules carry a net zero charge) of the muscle proteins (~5.0–5.1), resulting in a reduction in negative charge between the myofilaments, and these myofilaments can then approach each other more closely. As the myofilaments approach each other, with a consequent shrinkage in the diameter of the myofibril, less water is held in the myofibrillar structure and the water moves to the intracellular space, and subsequently to the extracellular space, and then is lost from the muscle structure as drip, with associated reduction in water-holding capacity (Figure 7(a)). In addition, if myosin is denatured postharvest, due to conditions of fast pH fall at high muscle temperatures (e.g., pale, soft and exudative (PSE), or heat shortening; see in the succeeding text), the myosin head shrinks and draws the thin filament in more closely, causing a shrinkage in the myofibril diameter and further water loss. Finally, if the sarcomeres within the myofibril shorten, causing a reduction in the length of the myofibril, as may occur due to heat shortening, rigor shortening, or cold shortening (see in the succeeding text), this will also cause loss of water from the structure and reduced water-holding capacity of the muscle.

Tenderness

In the prerigor period, muscle is quite tender, due to a lack of cold, heat or rigor shortening. As rigor commences (see 'Rigor Shortening' section), the sarcomeres shorten and transverse shrinkage of the myofibril occurs, and this is associated with an increase in toughness (Figure 7(b)). The reduction in myofilament lattice spacing in the myofibrils increases the interdigitation between actin and myosin, increases the protein in a defined area, and thus impacts on measured tenderness. It is also likely that there is reduced access of proteases to the

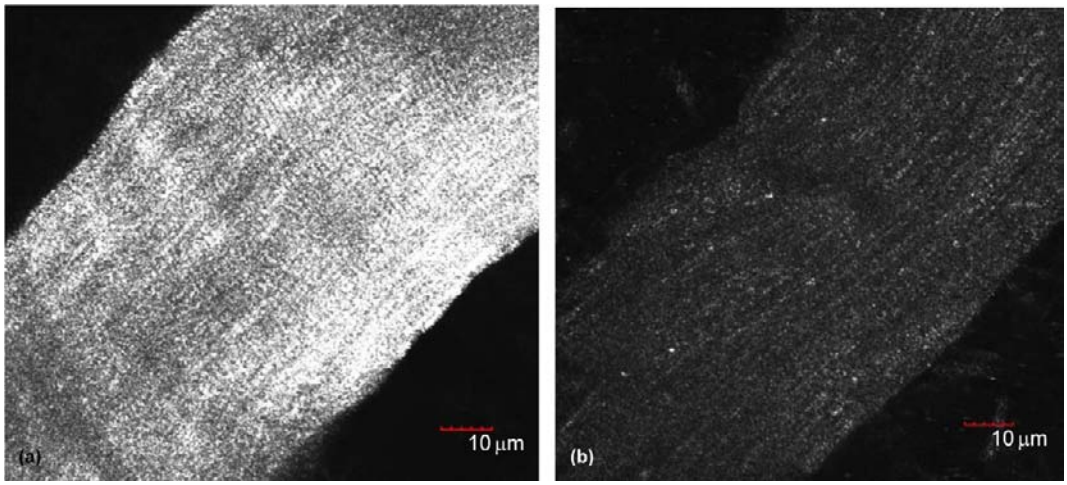

Figure 8 Reflection confocal scanning microscopy images of a muscle fiber from beef *longissimus lumborum* from (a) a low ultimate pH muscle, pH = 5.4 and (b) a high ultimate pH muscle, pH = 6.4. Reproduced from Hughes, J. M., Oiseth, S. K., Purslow, P. P. and Warner, R. D. (2014). A structural approach to understanding the interactions between colour, water-holding capacity, and tenderness. *Meat Science* **98**(3), 520–532.

myofibrillar proteins, due to the reduced spacing. Proteases are the enzymes that are associated with the degradation of myofibrillar proteins and associated improved tenderness. Thus, the toughness in meat postharvest due to rigor shortening is most likely due to increased protein density and reduced access of proteases to meat protein substrate.

Color

As the pH declines from 7.0 to 5.5, there is an increase in light scattering within the structure of a muscle cell, which can be seen when viewed under confocal microscopy (Figure 8). This increase in scattering is associated with an increase in paleness of the meat surface and is one explanation for why the meat surface appears paler, as the pH declines from 7.0 to 5.4. Thus, the meat surface is pale in a low ultimate pH muscle (pH = 5.4–5.7) and dark in a high ultimate pH muscle (pH > 5.8) (Figure 8). Thus, prerigor meat will also appear dark until the pH has fallen from 7.0 to 5.5, as a consequence of glycolysis. Apart from scattering, the other reason that the meat surface appears dark in a muscle of high pH is because the pigment myoglobin, which is the main pigment in meat, is predominantly in the dark purple-red reduced deoxymyoglobin state. In meat of low pH, the predominant form of myoglobin in the surface is the bright-red oxymyoglobin, which has an O_2 bound to the iron atom in the center of the protein.

Aberrations in Meat Quality

Final meat quality is in part a result of the change in muscle temperature and pH in the prerigor period, prior to the onset of rigor mortis. Quality traits that are influenced by the rate and extent of decline in temperature and pH are tenderness, water-holding capacity, shelf life, bacterial growth, and color.

PSE or weepy, pale meat is a consequence of increased rate of early postharvest glycolysis and is associated with elevated muscle temperature and fast pH decline. This phenomenon is similar to what some describe as heat shortening or high rigor temperature meat. The occurrence of high prerigor temperature accompanied by a faster than normal pH decline in muscle causes denaturation of sarcoplasmic and myofibrillar proteins, with consequent negative effects on all quality traits. These negative effects include the occurrence of unacceptably pale meat, high water loss, variable tenderness, and increased susceptibility to oxidation and consequent reduced shelf life. The cause of PSE is attributed to stress at slaughter, particularly in stress-susceptible pigs, such as those carrying the halothane gene or RYR1 gene. Electrical stunning of pigs, or the application of electric prodders to animals, can also cause an increased occurrence of PSE in pigs. PSE also occurs in turkey and poultry muscles. Recently, pale, weepy (PSE-like) meat has been found in the muscles of beef and sheep carcases and, in cattle, is attributed to grain feeding beyond 70 days and the use of electrical stimulation at the immobilizer, hide puller, and bleeding points on the processing floor. For sheep carcases, the limited data suggest it is due to the excessive use of electrical stimulation on the carcass. In pigs, poultry, and turkey, PSE is defined by a muscle pH at 45 min postslaughter <5.8–6.0. In cattle and sheep, PSE-like is defined by a muscle that has a temperature $>35\,^{\circ}C$ when the pH drops below 6.0 (Figure 9).

High ultimate pH meat is called dark firm dry or dark-cutting and is defined by the ultimate pH of the muscle being >5.8–6.0. The high ultimate pH is high due to a low concentration of muscle glycogen at slaughter; thus, insufficient glycolysis occurs to generate lactic acid and hydrogen ions. The critical level of muscle glycogen in order to achieve an ultimate pH <5.8 is about 40–60 $\mu mol\,g^{-1}$ of tissue. There is usually about 80–150 μmol of glycogen per gram of tissue in the muscles of a healthy well-fed animal. The excess glycogen remains in the muscle as residual glycogen, once glycolysis ceases. Muscle glycogen levels are usually high if the animals are on an increasing weight trajectory prior to dispatch for slaughter. Time-off feed in pigs and stress encountered preslaughter, by any animals, can deplete muscle glycogen stores and result in high ultimate pH meat. Meat of a high ultimate pH is dark in color and has variable tenderness and reduced shelf life, as it tends to exhibit 'greening' in the vacuum bag.

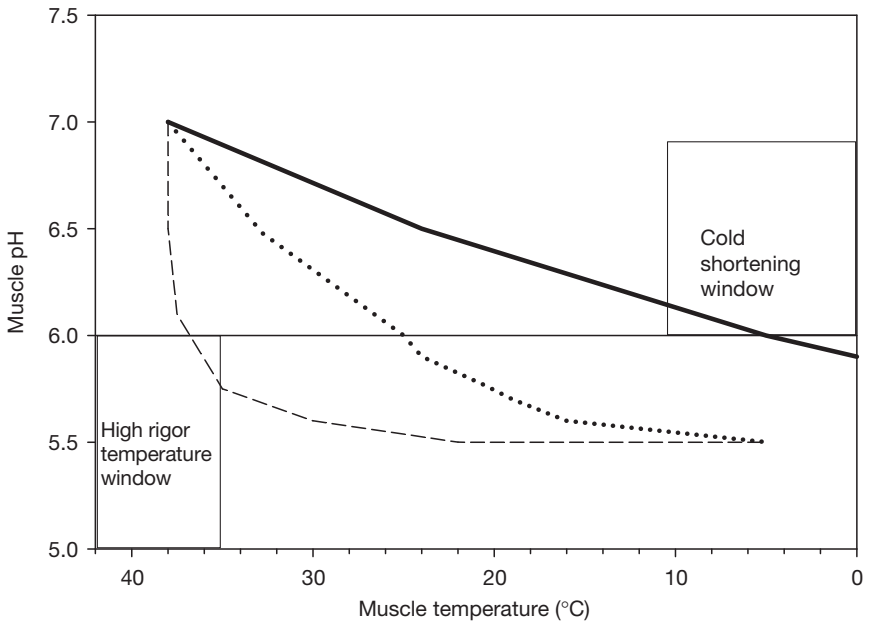

Figure 9 The pH temperature window used by Meat Standards Australia to optimize the decline in muscle pH relative to the temperature of the muscle in beef. The dotted line represents an optimal rate of decline, the solid line a cold shortening, and the dashed line, a high rigor temperature scenario. The regions to avoid for assurance of quality meat are the cold shortening region and the high rigor temperature region. Reproduced from Gutzke, D. A., Franks, P., Hopkins, D. L. and Warner, R. D. (2014). Why is muscle metabolism important for red meat quality? An industry perspective. *Animal Production Science* **54**, iii–iv.

Cold Shortening

Cold shortening is dependent on the cooling rate of a muscle and generally occurs if the muscle temperature drops below 10 °C while the muscle is still in the prerigor state (pH > 6.0; Figure 9). The underlying mechanism appears to be the inability of the sarcoplasmic reticulum and mitochondria to bind and sequester calcium at temperatures <10 °C, which causes an excess of calcium in the intracellular space, causing contraction. The maximum amount of shortening occurs close to the freezing point of meat. Adequate ATP levels need to be present for cold shortening to occur. The result of cold shortening is shorter sarcomeres and tough meat. In hot-boned muscles free of the physical restraint of the carcass, excess shortening >40% can occur, which produces meat that is more tender. This appears to be due to the myofilaments driving through the z-line and severely disrupting the muscle structure, increasing the tenderness. Cold shortening can be prevented by the application of electrical stimulation to the carcass. Care must be taken for beef and sheep carcasses as excessive stimulation can lead to the quality problem of pale, weepy meat (see in the preceding text). Electrical stimulation is not recommended for pig carcasses due to the likelihood of inducing PSE.

Thaw Rigor

This occurs if muscle has been frozen while still in the prerigor state. Thaw rigor or thaw contracture occurs upon thawing of the muscle. It is characterized by massive shortening, excessive drip loss from the muscle structure, and very tough meat. The mechanism is similar to cold shortening except that massive levels of calcium flood the intracellular space, causing very rapid glycolysis and pH drop. Because of the phenomenon of thaw shortening, it is not recommended to freeze prerigor meat.

Rigor Shortening

Unrestrained muscle generally shortens by up to 30% as it goes into rigor mortis. This shortening is temperature-dependent and is higher at 40 °C than at 15 °C. If muscle is restrained from shortening during rigor mortis, it develops weak tension, which can be measured using a rigorometer (measures the development in tension during the onset of rigor mortis). The force that develops is either due to a rise in cytoplasmic calcium, as ATP disappears (and can no longer pump calcium back into organelles), or because of the activation of contraction when the myosin heads bind to actin. Rigor shortening can be prevented by the application prerigor of a stretch to muscles. 'Tenderstretch' or 'aitch-bone' hanging has been implemented in some processing plants around the world, as this method stretches most muscles in the hindquarter and also has some effects on the loin muscle. The disadvantages of utilizing these methods include the time and labor involved in rehanging the carcass, the increased space required in chillers, and the change in the shape of the primal cuts.

Introduction

Meat and meat products are an important group of nutritionally dense foods, which are widely consumed all over the world and as such are of great environmental and socioeconomic importance. Modern consumers are increasingly demanding meats that are safe, are of good eating quality, are nutritious, and are produced through sustainable farming practices. Thus, it is an ongoing challenge for the meat industry to produce high-value table cuts of consistent good quality, and so eating quality and preservation are major issues in that respect. This article provides basic information on the main factors determining the eating quality of meat and offers a review of the technologies used to preserve meat.

Eating Quality of Meat

Meat quality is a multidimensional concept that plays a major role in product marketability. The way in which it is perceived by consumers, and hence their preferences and the degree of acceptability, is influenced by various factors (Figure 1), mainly relating to (a) the intrinsic properties of the product, (b) consumer characteristics, and (c) the sociocultural environment. The sensory perspective is an essential part of meat quality, including appearance aspects considered at the point of sale (color, marbling, drip, etc.) and those considered at the table, which come under the general heading of eating quality. Eating quality combines sensory aspects like appearance, tenderness, juiciness, flavor, and overall palatability, and they are the most important characteristics by which consumers judge meat quality. Of these, tenderness is arguably the most important factor, determining eating satisfaction, and, hence, poses the greatest challenge in terms of acceptability of meat purchased by consumers. A thorough understanding of the most important factors influencing meat eating quality is imperative in order to produce a consistent product that meets consumer expectations. This knowledge can be used in the industry to produce a more consistent product in terms of enhanced eating quality.

Factors Affecting Meat Eating Quality

Eating quality (especially tenderness and flavor) at the consumer level is of paramount importance for the industry in order to remain competitive in the marketplace. The eating quality of meat is a result of complex interactions between the biological traits of the live animal and biochemical processes that occur *postmortem* as muscle is converted to meat (Figure 2). The variability in eating meat quality stems from several factors that arise throughout the production chain, and so in order to guarantee a particular and consistent meat eating quality (limiting this variability), global programs have been pursued to assess the effectiveness of meat production systems and develop a tool (quality assurance strategies) conducive to a detailed understanding of the factors that interact to determine (and assure) the eating quality of meat. These factors are mainly related to animal type, preslaughter handling, *postmortem* processing (including storage), and consumer intervention (cooking) (Figure 2).

Biological and preslaughter factors

There are major preslaughter factors that are known to influence the eating quality of meat (Figure 2). Firstly, there are what might be called 'intrinsic muscle characteristics,' which refer to a set of particular attributes associated with the animal in question and which will affect not only the quality of the meat but also how suitable it is for processing; these are determined by biological factors relating to species, breed, sex, etc., physiological aspects (genetic background, stress responses, etc.), and production practice (feeding, finishing weight, age at slaughter, etc.). These characteristics may be classified as (a) anatomical and histological, for example, the fiber type (red and white, with mechanical, biochemical, structural, and functional differences) with varying degrees of susceptibility to cold shortening, presence of fat cover affecting chilling rates and weight loss, or muscle location, again affecting chilling rates and the degree of sarcomere shortening; (b) chemical composition (proteins, lipids, glucogen, etc.), influencing, inter alia, postmortem biochemical processes; and (c) physical properties, relevant in thermal processes (cooling and heating), and affecting technological processes (e.g., preservation methods).

Preslaughter treatments, such as those involved in transport, reception, lairage, etc. produce a number of changes (stress response and glucogen depletion), which alters metabolic response and causes various types of glycolysis (ultimate pH). Some of these have undesirable effects, for instance, the kind of rapid, intense glycolysis that results in pale, soft, exudative (PSE) muscle or slow and limited, which results in a dark, firm, dry (DFD) muscle. The effect of preslaughter treatments on *postmortem* events has major impacts on various quality attributes, such as color, texture, and shelf life. Regardless of the biological and physiological aspects of the animals, both these situations can be avoided or restricted by good management practices in farming, transport, and lairage.

Postmortem factors and treatments

Following slaughter, the carcass undergoes a number of physiological, biophysical, and biochemical changes through which muscle becomes meat. These processes go through various stages, which have considerable impact on the quality, technological suitability, and stability of the meat (Figure 2). The consequences of *postmortem* treatments are generally more serious than those deriving from livestock rearing. When the animal dies, the blood flow ceases, oxygen ceases to reach the muscle, and glycolysis becomes anaerobic. At the same

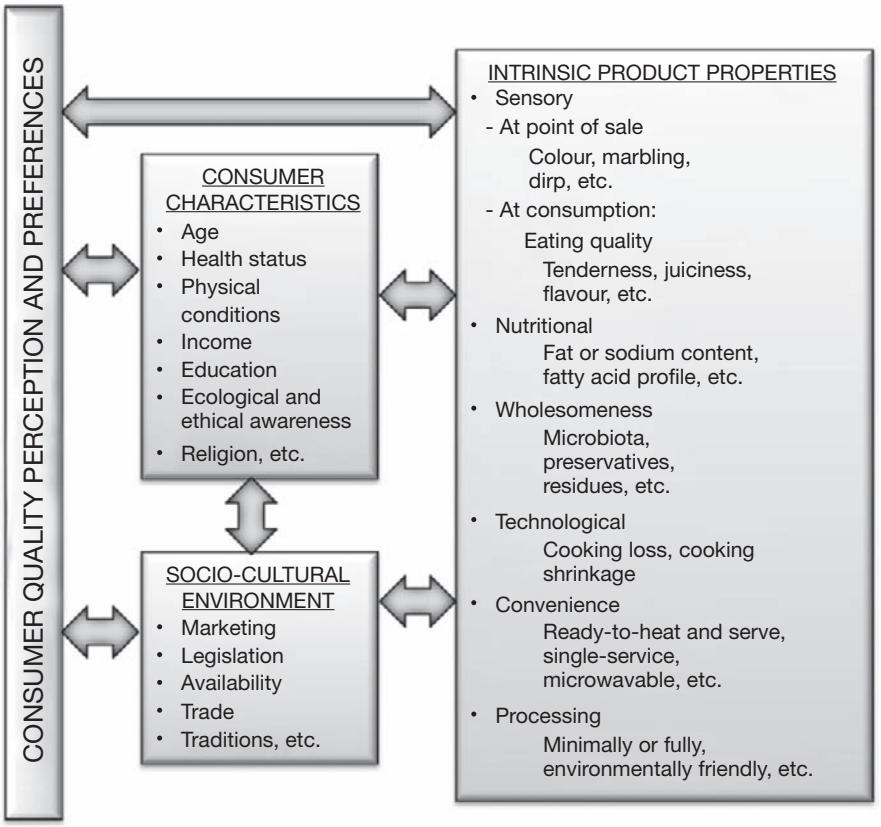

Figure 1 Eating quality in the context of factors affecting consumer meat quality perception and preferences.

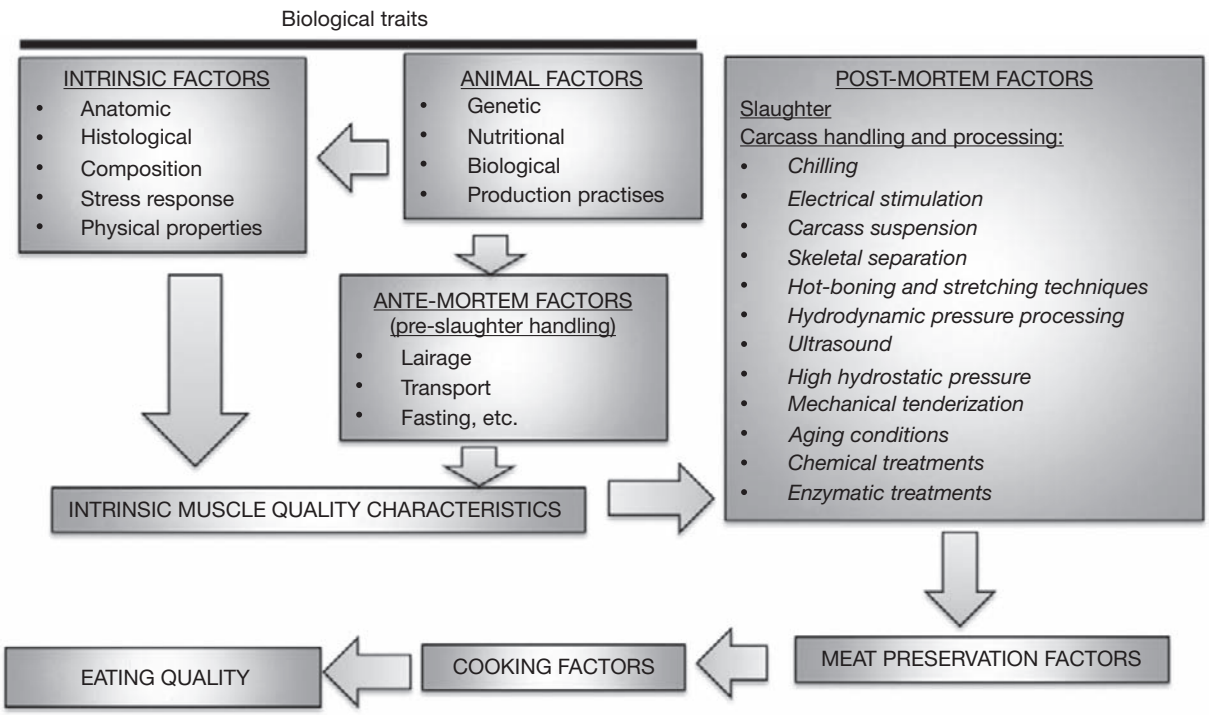

Figure 2 Production, processing, and consumer factors, which affect the eating quality of meat.

time, there are a buildup of lactic acid and a drop in pH (until the energy store is depleted or until the glycolysis enzyme is inactivated). As levels of adenosine triphosphate (ATP) decline, actin–myosin bonds form, producing actomyosin and causing shortening of the sarcomere, so that *rigor mortis* gradually sets in. The rate of these processes is influenced by intrinsic factors, which vary from one animal to another and in some cases from one muscle to another in the same animal, and also by extrinsic factors including the tension on the muscle and above all the temperature at which *rigor* sets in. The extent of shortening of the muscle fiber during the onset of *rigor* is influenced by the temperature at which the *postmortem* processes take place. This means that a poor adjustment may cause cold shortening and thaw rigor, resulting in a considerable decline in the eating quality of meat, which will be tough even after cooking. Meat quality is also considerably affected by the type of glycolysis, which can range from moderate, characterized by a gradual drop in pH, to types that result in PSE or DFD muscle (given the link between ultimate pH and tenderness).

Various *postmortem* treatments have been assayed to improve the eating quality of meat by influencing biochemical and structural events (**Figure 2**). These are based on strategies to (a) optimize the temperature/biochemistry postmortem relationship, (b) increase the tension on the muscle during the onset of rigor mortis, (c) promote processes conducive to maturation, and (d) induce structural damage in certain muscle components (contractile system and connective tissue). Based on their mode of action, these *postmortem* interventions can be classified in three main categories (physical, chemical, and enzymatic).

Carcass chilling conditions

Postslaughter chilling conditions are crucial for meat eating quality and safety. For purposes of shelf life and food safety, carcasses should be chilled as quickly as possible; however, chilling conditions can influence *postmortem* biochemical processes (*rigor*) and hence eating quality. Since cold shortening occurs when the muscle temperature drops below 10 °C while the muscles still contain sufficient energy (at pH > 6.0) to allow muscle contraction and the degree of sarcomere shortening is lower when rigor takes place at temperatures over 10 °C (generally lowest between 14 °C and 20 °C), 'high-temperature conditioning (slow or delayed chilling rates)' has been proposed to improve eating qualities (especially tenderness and flavor). However, depending on how it is carried out, this procedure can pose problems in terms of both economy (high weight loss, need for more storage space, etc.) and health/hygiene (greater microbial growth). 'Very fast chilling,' consisting of reducing the temperature to −1 °C after 5 h *postmortem* throughout its mass, has many potential benefits, including the production of tender meat, which can be attributed to two mechanisms: (a) the outer surface of the muscle may be frozen and act as a straitjacket to prevent cold shortening and (b) the intense cold releases bound calcium so that tenderizing enzymes are stimulated. However, this approach has some limitations: The carcass must be intact and a high degree of control and automation is required.

Electrical stimulation

This consists in passing an electric current through the muscle mass of the freshly slaughtered animal, producing a large number of muscle contractions in a short space of time. This speeds up postmortem glycolysis (rapid decline in pH), so that higher chilling rates can immediately be applied to reduce the risk of cold shortening and thaw rigor. Electrical stimulation (ES) generally makes the meat more tender by preventing excessive muscle shortening during rigor and enhancing proteolysis (release of Ca ions) and physical disruption of muscle structures. Moreover, rapid chilling reduces weight loss and microbial growth while allowing added savings in space and time. There are many forms of ES applications, ranging in magnitude of voltage, current, frequency of pulses, and waveforms. Low-voltage (<150 V) stimulation is performed with simple, low-cost equipment and requires little in the way of safety measures, although it must be done immediately after slaughter. High voltage (300–1000 V) is applied at the end of the deskinning chain and requires more safety precautions. While ES of beef and lamb carcasses is widely used to prevent cold shortening, with beneficial effects on tenderness, in the case of pigs, ES accelerates the rate of pH decline, resulting in increased frequency of PSE.

Carcass suspension

One means of avoiding toughening due to muscle shortening during rigor is to hang the carcass in such a way that there is maximum tension on the muscles and they cannot shorten during rigor, thus increasing the sarcomere length and tenderness. One method that has been proposed for this purpose is tenderstretching. This new technique entails a change from the normal ways of hanging carcasses to stretch the higher commercial cuts (tenderizing effects depending on the muscle location on the carcass); the carcass is hung from the pelvic bone (obturator foramen or aitchbone) rather than from the Achilles tendon in the traditional way. The backbone in a tenderstretch carcass is straight, and so there is tension on the loin muscle, which prevents it from shortening during *rigor*. In addition, the tenderstretch leg hangs in a more natural position and there is tension on most muscles so that shortening cannot occur.

Skeletal separation

Severance of the vertebral column prior to chilling can increase carcass and sarcomere lengths and improve the tenderness of beef meat cuts. In view of this, a process known as Tendercut™ has been developed, consisting of making cuts (prerigor carcass) in the skeleton at specific locations on the m. longissimus in order to achieve stretching without the need to alter the carcass suspension. In addition to breaking the vertebrae at the 12/13th rib junction, all tissues surrounding the loin are cut, so that it is the only the dorsal component that is holding the forequarter to the hindquarter. This method has proved effective in improving tenderness in the loin and the round muscle.

Hot-boning muscle/stretching techniques

Hot boning of meat consists in separating the muscles from the carcass when in prerigor. This technique has many economic advantages including reduced chiller space requirements,

quicker meat turnover in the abattoir, lower chilling costs, and reduced weight loss. However, it also has a major limitation in that removing the muscle from its skeletal anchors before *rigor* increases muscle toughness as compared with cold-boned muscles (*postrigor* carcass removing). Various different techniques for artificial restraint of hot-boned muscles have been developed; among them are the Tenderbound (Pi-Vac Elasto-Pack) system and SmartStretch™ technology, which wraps hot-boned *prerigor* muscles to prevent muscle contraction and shortening during *rigor*, thus producing a tenderizing effect. The main advantage of these systems is that they are very flexible and can be applied to any targeted muscle.

Hydrodynamic pressure processing

Hydrodynamic pressure, also known as hydrodyne, is a meat tenderizing technology that involves underwater detonation of a high-energy explosive in a containment vessel to generate a shockwave pressure front at velocities exceeding the speed of sound. A sudden increase in pressure is exerted on the meat, disrupting the structural integrity of the muscle and connective tissue. Although significant tenderization has been documented, this approach has a number of technological limitations. Subsequently, alternative methods of producing shockwaves have been developed. One such is the TenderClass Process in which a shock wave is electrically generated by creating a high-voltage arc across two electrodes immersed in non-compressible fluid, preferably water.

Ultrasound

Ultrasound treatment has been proposed as an alternative technology for modifying properties of meat and meat products, including tenderization. Although ultrasound has been shown to induce some structural changes in muscle and activation of proteolytic systems, reports on the effects on meat tenderness have been inconsistent. This may be related to differences in the application conditions (acoustic parameters, ultrasound systems, type of muscle, etc.). Generally speaking, only high-intensity treatments seem to be capable of producing a significant tenderizing effect.

High-pressure processing (HPP)

High pressure is useful for food processing and preservation thanks to its effects on food constituents. HPP has been used to tenderize meat, but the effect depends on various factors; among them are the pressure level applied, temperature, processing time, and rigor state of the meat. High pressure (<200 MPa) can tenderize meat when applied in prerigor, but it has no marked effect on postrigor meat at low temperature (<30 °C). HPP treatment of postrigor meat has been found to improve tenderness, but only when applied at higher temperatures (40–60 °C). The effect of pressure may be the result of dissociation of myofibrillar components through denaturation and/or the release of various cathepsins from lysosomal structures leading to an increase in proteolytic activity. Although undesirable meat color changes (browning) are a limitation (>300 MPa), there are ongoing studies aimed at preventing color changes in the pressurization of frozen meat. Other possible advantages of HHP treatment of frozen hot-boned meat include prevention of shortening caused by thaw rigor and enhancement of overall tenderness.

Mechanical tenderization

This technique consists in inserting (manually or by means of an automated system) a set of needles or blades (spaced at a given intervals of distance) in *postrigor* meat cuts. Penetration produces partial destruction of connective tissue and severance of muscle fibers, which weakens the meat structure and, thereby, enhances the tenderness of the meat. This method, which can be applied more than once depending on the type of cut and the level of tenderization required, has the advantage of achieving instant tenderization without the need of holding time, exposure to relatively high temperatures, or the addition of nonmeat components.

Aging conditions

After rigor, the muscle undergoes a series of gradual, complex changes, which tend to improve eating quality. The mechanism through which this occurs is mainly associated with the breakdown of muscle structural proteins by endogenous enzymes. Since the aging process depends on many factors (type of muscle, pH, chilling conditions, aging temperature and time, etc.), different conditions such as wet (boned vacuum-packed) or dry (boned non-vacuum-packed) meat aging have been assayed to optimize its impact on eating quality of meat. Aging, for appropriate periods of time and under appropriate storage conditions, greatly improves meat tenderness. Besides effective tenderizing conditions, economic factors and the risk of meat spoilage are also factors to be taken into account.

Chemical treatments

Infusion, marination, and injection with salts of calcium (e.g., chloride, lactate, ascorbate, or carbonate), sodium (e.g., chloride, acetate, citrate, or ascorbate), phosphate, or some commercial preparations have all been used to improve the tenderization of meat. The effect is achieved through the physical weakening of muscle structures (myofibers and perimysial connective tissue) or through the activation of proteolysis. However, these effects are frequently accompanied by undesirable changes in other eating quality factors (particularly flavor).

Enzymatic treatments

Exogenous proteases from tropical plants (e.g., ficin, bromelain, and papain) or of bacterial, fungal (e.g., collagenase or aspartic protease), or animal (porcine pancreatin) origin have been used (by marination or injection) to tenderize meat, although with some effect on flavor. These enzymes act on myofibrillar proteins and connective tissues to various degrees to produce a more fragmented and disintegrated structure.

Cooking

Most meat and meat-based products are cooked before being eaten. The cooking process not only destroys microorganisms but also develops sensory properties, which are specific to the cooked product. The rise in temperature during cooking produces dramatic changes in the meat structure, the most striking being protein denaturation/coagulation, muscle fiber shrinkage, water loss (expelled from the meat matrix by protein denaturation and shrinkage of muscle structures), changes in

color, a warmed-over flavor, etc. The nature and extent of these changes, which considerably influence the final eating quality of meat (Figure 2), depend on factors – the temperature on the surface of the meat, the temperature profile through the meat, and the mode of heat transfer – associated with common cooking techniques (roasting, grilling, frying, boiling, and microwaving). Meat characteristics (e.g., type of meat, cuts, and composition) also affect the consequence of the cooking process.

Cooking causes denaturation of the myofibrillar components, which results in toughening. Conversely, it can also promote structural alterations and solubilization of collagen, which makes the meat more tender. Optimum meat tenderness occurs between 55 and 65 °C, although this varies with a number of factors, among them being collagen content. Muscles with high collagen content require higher temperatures (>75 °C) to bring the collagen to a soluble, gelatinized state and, thus, achieve softening. Color is influenced not only by meat composition (e.g., hemoprotein content) but also by the heating process and end point temperature (browning with increasing temperature). Thermal treatment induces changes in various components of meat (e.g., amino acids, carbohydrates, and fats), producing various types of compounds; among them are Maillard reaction products, which contributes to the flavor of cooked meat. Loss of juices is one of the key factors influencing the quality of cooked meat. If water loss is too high, the meat will become tough and fibrous, while keeping water loss to a minimum will produce juicier cooked meat. An increase in the end point temperature will cause a decline in juiciness.

Also, cooking has a considerable effect on the nutritional properties of meat (loss of fats, water-soluble compounds, and temperature-sensitive components), improving digestibility while at the same time favoring reactions between compounds inherent in meat, yielding genotoxic substances (e.g., polycyclic aromatic hydrocarbons and heterocyclic aromatic amines).

Preservation

Because of its composition, meat is a highly perishable product, and therefore, to preserve it, a number of measures need to be applied to delay or prevent microbiological, chemical, and physical alterations that adversely affect its quality (including eating quality; Figure 2), shorten its shelf life, and render it unfit for consumption. Of all the types of deterioration undergone by fresh meat, microbial spoilage is the most important in that it normally precedes all the other types and can render the meat harmful to health in the event that the microorganisms include pathogenic species or compounds have formed that are toxic to humans. There are a variety of procedures (physical, chemical, and microbial) that can be used to preserve meat (Table 1). While some methods (e.g., chilling, irradiation, and high hydrostatic pressure) serve to retain the original characteristics of the product, others (curing, drying, fermentation, etc.) cause desirable changes in quality attributes, contributing to products' diversification.

Table 1 Meat preservation methods

Physical methods
Low temperature: chilling, superchilling, freezing/thawing; high temperature: heating, canning; drying; irradiation; high pressure; luminic pulses; packaging: overwrap, modified and controlled atmosphere, active and intelligent systems
Chemical methods
Curing; smoking; chemical preservatives: ozone, organic acids, sulfites, etc.
Microbiological methods
Fermentation; biopreservation: natural or controlled microflora
Hurdle technologies
Superimposing of effects by combination of hurdles (e.g., temperature, a_w, acidity, redox potential, preservatives, pressure, radiation, or competitive flora)

Physical Methods

Refrigeration

Refrigeration of meat and meat products serves two basic purposes: to preserve the initial quality at the time of consumption and to keep them at temperatures that propitiate certain processes, some of which play a decisive role in the characteristic eating quality attributes of the product (texture, appearance, flavor, odor, etc.). Among these, for example, are early *postmortem* events, the maturation of sausages, and the curing of ham. The preservative effect of low temperatures essentially derives from the fact that they slow down the chemical and enzymatic reactions that cause spoilage, and they prevent microbial growth. The quality of refrigerated meat is highly dependent on maintenance of the cold chain, meaning the series of successive steps in the low-temperature retailing of meat. This includes processes in the abattoir, transport, cold storage, sale and display cabinets, etc., and also domestic refrigerators. The refrigeration process may consist of either chilling (short-term) or freezing (medium- and long-term) depending on the desired storage life.

Chilling

Chilling generally means a process embracing the reduction of the carcass temperature immediately after slaughter to appropriate temperatures for storage, without the formation of ice crystals in its structure, and also maintenance of the temperature (and other parameters) at an appropriate level throughout storage. Rapid carcass chilling reduces microbial growth, increases product yield (reduces weight loss from evaporation and also pulverization of water during air spray chilling), and reduces infrastructure requirements (less space and less chilling facilities needed). It is essential to properly control early and fast chilling and early postmortem events; otherwise, the eating quality of the meat may be adversely affected (e.g., by cold shortening). Chilling takes place in various kinds of facilities (cold rooms, cells, or tunnels) basically using air as the chilling medium (water immersion or spraying is also used for poultry).

Once it is chilled, the meat must be kept in optimum storage conditions (controlling factors such as temperature and relative humidity of chilling cabinets) to preserve quality and improve stability. The meat inevitably undergoes changes

of various kinds depending on the raw material, the processing, and the conditions of chilling treatment and storage. Some of these factors improve eating quality (aging process), while others – physical (weight loss by evaporation and exudation), chemical (color changes), and microbiological – promote spoilage. This is generally the key limiting factor in chilling storage of meat. Various chilling adjunct strategies have been used to prolong storage life.

Superchilling has been suggested for preserving meats. With this technology, the temperature of the product is lowered to 1 or 2 °C below the initial freezing point. This has several major advantages: maintenance of food freshness, maintenance of high food quality, inhibition or suppression of most microbial activity, and increased shelf life.

Freezing/thawing

Freezing is an excellent means of preserving the original characteristics of the meats practically intact for a considerable period of time. The effect derives both from the reduction of temperature and from the reduction of water activity, as most of the water is turned to ice. The effectiveness of freezing in preserving meat and meat products quality and prolonging its useful storage life depends on a number of factors: (a) product characteristics (inherent characteristics, *rigor* state, prior chilling process, use of packaging, etc.), (b) freezing process and storage (moment and rate of freezing, storage temperature and duration, etc.), and (c) thawing conditions. The method most commonly used to freeze carcasses is air blast. Plate contact or cryogenic fluid freezing methods are not used so much for meat and then generally only for technological and/or financial reasons. The freezing rate and the procedure selected depend on the processing conditions (rate and air temperature) and also on the product characteristics (size, shape, fattiness, thermal properties, etc.).

Freezing prolongs the shelf life of meat, but a number of cumulative and irreversible changes take place as storage time progresses, and these compromise the final quality. The most significant changes that can occur arise from processes whose origin may be physical (e.g., ice recrystallization and sublimation), biochemical (ATP degradation), or chemical (e.g., lipid oxidation, protein denaturation, and color changes), and they may cause not only weight loss but also undesirable alterations to the sensory characteristics and technological suitability of the meat.

Thawing in inappropriate conditions can promote more spoilage than in the freezing stage, as well as being slower and harder to control. Meat is generally air-thawed, but thawing can also be performed in water, under vacuum or high pressure, or electrically (resistance, dielectric, microwave, etc.), depending on the characteristics (shape, size, electrical properties, type of packaging, etc.) of the product, the target market, and the economic considerations. In some cases, the meat only requires tempering, which entails raising the temperature to a point (below freezing) suitable for a given processing step.

Heat processing methods

There are two broad types of heat treatment: preconsumption cooking to promote a desirable texture, flavor, and color and render meat products more palatable and appetizing for the consumers and production of pasteurized (heating) or commercially sterile (canning) products by reducing the microbial content to prolong shelf life and eliminate potential food poisoning agents. Thermal treatment consists in placing the products in cooking vessels, which contain hot water, steam, or a mixture of both. Radiant (e.g., dielectric or ohmic) heating offers interesting possibilities, although these are limited in the case of meat-based applications and generally have to be combined with other techniques. Pasteurized products generally reach an internal temperature of 71 °C (kills most microorganisms and the product must be refrigerated), while sterile meats are heated to 121 °C so that all microorganisms are killed and products are shelf-stable. After thermal treatment, the product must be chilled as quickly as possible to avoid overcooking. The intensity of thermal treatment can be defined in terms of a value of F_0 (between 1 and 10 for most canned meats). Important to note is the time–temperature relationship in the impact on inactivation of microorganisms and on the sensory quality of the product. Sous-vide cooking of vacuum-packed meats at relatively low temperatures and long cooking times have emerged as popular techniques to provide foods of superior sensory quality with a longer shelf life as compared with conventional technologies.

Drying

Drying is probably one of the oldest methods of food preservation. It is a process in which water is removed (generally by evaporation), lowering the water activity (a_w) in the meat and thus inhibiting microbial growth. Meat may be dried for the sole purpose of dehydrating fresh meat for longer storage, but it may also be one of the various processing steps during the manufacture of specific meat products (curing or fermentation). Meat drying is a simple but efficient procedure. Dried meat can be stored at ambient temperatures for many months. Drying causes numerous physical (e.g., shrinkage, shape alteration, and texture modification) and chemical (e.g., increased concentrations of protein, fat, etc. and greater susceptibility to oxidation of lipids) changes that affect the eating quality of meat.

Irradiation

Irradiation is one of the most efficient intervention strategies to reduce or eliminate pathogens in meat products. It is a physical process that exposes meat to an ionizing radiation (accelerated electrons and γ- and x-rays), which create ions or free radicals from atoms. These molecular species can fragment or destroy the DNA of microorganisms, killing the pathogens present in a meat matrix. International organizations (e.g., FAO and WHO) recommend a maximum dosage of 10 kGy. This technology enables the meat industry to obtain non-heat-treated products essentially free of pathogenic food-borne bacteria, which can be processed in the package due to the high penetrative ability of γ-rays, avoiding further contamination and with lower energy consumption. The adverse effect of irradiation on the wholesomeness and quality of meat products is very low compared to some other preservation methods; however, it does have some drawbacks such as color changes and/or production of off-flavors.

High-pressure processing

In addition to meat tenderization (previously described), HPP (100–1000 MPa) has been used for preservation. HHP renders

food more stable and safer due to its ability to reduce the number of spoilage and pathogenic microorganisms and to inactivate certain food enzymes. The effectiveness of HHP for microbial control depends on factors such as the process parameters, pressure level, temperature, and exposure time, as well as intrinsic factors in the food itself, such as pH, strain and growth stage of microorganisms, and the meat matrix. The undesirable effect of HHP on fresh meat color can adversely affect consumer preference at the point of sale, whereas it is not perceptible when the product is served after cooking. There are numerous meat products where HHP is used to prolong shelf life (e.g., cured products) to which this limitation does not apply.

Pulsed light

This is a nonthermal technology for food preservation, which consists in the application of short- (10^{-3}–10^{2} ms) broad-spectrum (200–1000 nm) light pulses. Its antimicrobial effect derives mainly from the UV-C component (200–290 nm) emitted in each pulse, which prevents cell replication. In solid foods, decontamination takes place on the surface because little light penetrates, and so the technology has been assayed on ready-to-eat meat products.

Packaging

Packaging consists in surrounding or wrapping meat and meat products with suitable material to protect them against deteriorative effects, including physical, chemical, sensory, and microbiological (pathogenicity) changes. Variables that influence shelf life properties of packaged meat and meat products are product type, gas mixture, package and headspace, packaging equipment, storage temperature, and additives. There are currently many meat packaging systems, each with different attributes and applications. These systems range from overwrap packaging for short-term chilled storage and/or retail display to a diversity of protective atmospheres such as specific modified atmosphere, controlled atmosphere packaging systems, and vacuum packaging for longer-term chilled storage and/or display. The last few years have seen the introduction of new approaches such as active and intelligent packaging systems for use in meat and meat products. Active packaging refers to the incorporation of additives in packaging systems in order to maintain or enhance meat product quality and shelf life. Active packaging systems may include oxygen scavengers, carbon dioxide scavengers and emitters, moisture control agents, and antimicrobial packaging technologies. Intelligent packaging systems monitor the condition of packaged foods to give information regarding the quality of the packaged food during transport and storage.

Chemical Methods

Curing

Meat curing practice involves the addition of sodium and/or potassium chloride, sodium nitrite, and other ingredients (e.g., erythorbate, polyphosphates, and seasoning) to raw meats. Curing is used in the manufacture of meat products in varying conditions of structural breakdown (from comminuted meat to whole pieces) and thermal treatment (raw and cooked), following various strategies (dry, brine, tumbling, and injection). In the past, when refrigeration was not commonly available, curing was mainly used to prolong the storage life of whole pieces of muscle utilizing the preservative effects of common salt (removal of moisture and reduction of water activity) and sodium nitrite. Today, this aspect is not so important as there are more efficient meat preservation methods and curing is now mainly used to achieve characteristic eating quality and to inhibit growth of *Clostridium botulinum*. Cured-raw meats need to be kept in controlled conditions throughout processing, when fermentation and ripening take place simultaneously with drying in order to achieve the desired palatability. In the case of cured-cooked meats, after the curing process, a specific heat treatment is applied (>60 °C) to induce stability and achieve the desired palatability. One new procedure for cured meat products that has been attracting interest is indirect addition of nitrate or nitrite, in the form of natural or alternative curing (e.g., nitrate-rich ingredients).

Smoking

Smoking is a technique whereby meat is exposed directly to wood smoke (or more recently liquid smoke) for purposes of preservation, appearance, and flavor. These are the effects of a combination of heat, drying (decrease of a_w), and the antibacterial and antioxidant action of components of smoke particles. All of them act to prolong the shelf life of the product, although the preservative effect varies with the intensity of the smoking. This procedure is used in combination with others (drying and curing) and in low-temperature conditions.

Chemical preservatives and natural extracts

Various different chemical compounds have been used in meat processing to inhibit, retard, or prevent the activity and growth of spoilage and pathogenic microorganisms. Their chief purposes are to prolong the shelf life of foodstuffs by protecting them against deterioration caused by microorganisms and to enhance their safety. Various chemical preservatives and application conditions (e.g., additives and carcass rinses) have been used depending on the type of product. These include ozone, carbon dioxide, organic acids (e.g., lactic, acetic, propionic, citric, sorbic, and benzoic acids and the methyl and ethyl esters of 4-hydroxybenzoic acid – parabens – or their salts and benzoic acid), sulfur dioxide and sulfites, and nitrates and nitrites (see section 'Curing'). Antioxidants (synthetic or natural) are used to retard lipid oxidation. Recently, natural compounds such as plant extracts, essential oils, chitosan, and some proteins (lysozyme and lactoferrin), with antimicrobial or antioxidant properties, have been used.

Microbiological Methods

Fermentation

Fermented meats have traditionally been produced all around the world. They are generally made with chopped or minced meat and fat, mixed with salt, seasoning, and spices, stuffed into a casing, and then ripened and dried, or in some cases smoked. There are many types of sausages responding to various factors (geographic, environmental, technological, etc.). These may be classified according to various criteria, such as acidity, particle size, diameter and type of casing, degree of drying, and type of starter cultures. Their main

characteristics – shelf life and eating quality (specific flavor, texture, and color) – are determined by a combination of acidulation (generation of lactic acid by lactic acid bacteria from natural contamination or well-defined starter cultures) and the lowering of a_w by the action of salt and drying. The interrelated microbiological, biochemical, and physicochemical changes that take place during meat fermentation are affected by the ingredients used, the processing technology, and the microbiota. While dry sausages take a long time to ripen, depending on the intensity of dry, semidry sausages ferment rapidly at high temperatures, and the drying step may even be omitted.

Biopreservation

Biopreservation is based on the use of natural or controlled microbiota (such as lactic acid bacteria) or antimicrobial natural products (such as lactic acid and bacteriocins) to extend the shelf life and enhance the safety of food products by reducing or eliminating microbial spoilage. Bacteriocins (nisin is the best known) are a heterogeneous group of antibacterial proteins that vary in spectrum of activity, mode of action, molecular weight, genetic origin, and biochemical properties.

Hurdle Technologies

As has been stressed throughout this article, generally, most meat preservation strategies (although analyzed separately) combine various technologies, factors, and/or agents in order to maximize the preservative effect. This superimposing of effects, known as the 'hurdle concept,' consists in an appropriate combination of barriers or hurdles (e.g., temperature, a_w, acidity, redox potential, preservatives, pressure, radiation, or competitive flora) to improve the microbial stability and the sensory quality of meat and meat products.

Introduction

The consumption of meat from wild and domesticated animals is evident throughout human history. Archaeological evidence supports the consumption of meat from wild animals beginning about 500 000 BC and from domesticated animals since about 7000 BC. It is thought that sheep were among the first domesticated animals (*c.*7000 BC), followed by cattle (*c.*5000 BC) and pigs (*c.*2500 BC). Progression of domestication from free breeding to breeding in captivity and, lastly, selective breeding to promote desirable characteristics has resulted in the meat consumed today. Developments in refrigeration, processing, packaging, integration, and transportation as well as increased relative wealth have allowed for the worldwide availability and consumption of meat. The efficient production of meat enhances the nutritional quality of the food supply and promotes global food security.

Sources and Production

Meat sources vary throughout the world. Pork, beef including veal, poultry, lamb/mutton, and goat meats are the most commonly consumed; however, regional variations exist. According to availability or local custom, rabbit, deer (venison), horse, camel, and other mammals often serve as sources of meat. Currently, pig stocks lead the world's meat production with China and the United States producing more than half (55%) of the world's pork (Tables 1 and 2). The United States is the largest producer of beef cattle, accounting for 19% of global production, followed by Brazil with 14% of global production. The United States, China, and Brazil are also the top producers of chicken, representing 19%, 14%, and 13% of global production, respectively. The United States is the largest producer of turkey, providing almost half (48%) the global production.

The production of livestock for food is increasing driven by a shift toward the inclusion of more animal products in the diet. In Asia, where the bulk of increase in the world population has occurred over the last decade, consumption of meat has increased an estimated 3% annually. The rapid growth in meat production has been primarily the result of increased demand for poultry with beef, buffalo, and pork production remaining relatively stable as shown in Figure 1. According to the Food and Agricultural Association (FAO) Statistical Yearbook 2013, a change in the composition of livestock production has been occurring since the 1960s. Growth of global beef production has gradually declined from almost 2% per year in the 1960s to $<1\%$ per year in the early 2000s. Pig production has undergone a greater decline, from a growth rate of 4% per year to 0.8% per year during the same time period, while poultry stocks continue to grow at a rate of $\sim 3\%$ per year. However, China and Oceania are exceptions to the trend in red meat production elsewhere. Pig stocks in China have shown a significant increase from 36.8 million tons in 2000 to 49.4 million tons in 2011, representing an increase of over 34% during the 11-year period. In Oceania countries, the percentage of total livestock produced – specifically cattle and buffalo – has increased from 11.8% in 2000 to 14.4% in 2011 (Figure 2).

Several production systems contribute to the availability of meat around the world. No single production system best fits all livestock or the availability and security needs for food across different world regions and communities. Productions systems vary on a continuum from those that rely on livestock grazing and consumption of feed sources not readily consumed by humans to those occupying limited land, which rely, at least in part, on feed sources common to the human diet. Over 60% of the world's poultry meat and eggs are produced in so-called 'landless' production systems, which is not surprising, as poultry require limited space due to their size. As monogastric animals, poultry consume a diet containing food sources that also contribute nutrients to the human diet. In contrast, over 70% of the world's beef was produced using a mixed system including grazing and, as ruminant animals, consumption of crop residues and concentrates not otherwise edible for humans.

Patterns of Consumption and Related Nutrient Intake

Consumption Patterns

Globally, estimates of meat consumption often rely on FAO balance sheets or similar. These data are not derived from direct intake/consumption measurements, but rather are based on production and disappearance of available food from the food supply. As such, loss due to trimming, cooking, waste, and spoilage is not captured and can inflate the estimate of meat consumption on a per capita basis. Conversion factors aimed at limiting the inflation caused by these inedible aspects have resulted in as much as a 100 g difference between adjusted and unadjusted daily intake estimates for meat consumption. Food consumption estimates based on disappearance-type data are, therefore, best described as 'average apparent consumption.' Based on FAO food balance data for developed countries, the average apparent consumption of meat ranges from 225 to 330 g day^{-1} including ~ 110 g red meat. Recommended levels for total meat intake range from 65 to 250 g daily of meat and meat alternatives. As such, red meat consumption appears to be within recommended levels in most developed countries. In contrast, average apparent meat consumption in the least developed nations is roughly 40 g per capita/day, the bulk of it as poultry and beef. Interestingly, in the decade spanning 2001–11, average estimated meat intake in the least

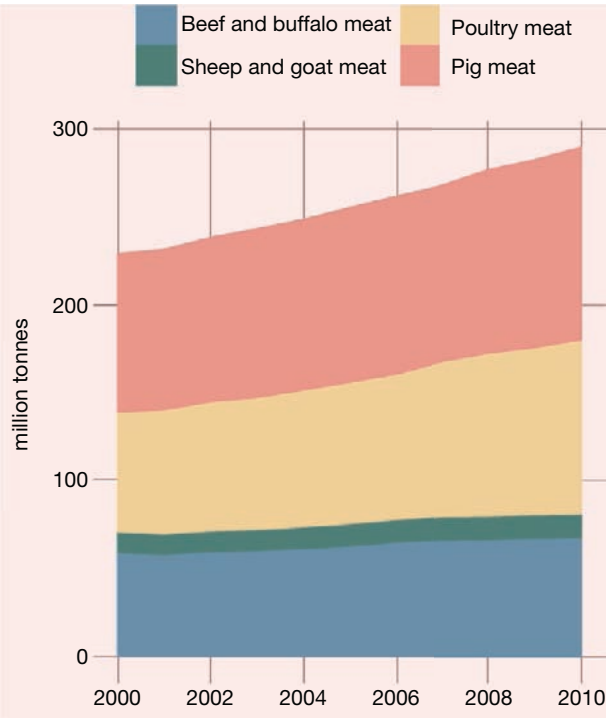
developed nations grew by 10 g daily. A global trend in increased meat consumption is predicted with estimates suggesting that production will need to increase to 470 million metric tons by 2050 to meet worldwide demand.

In addition to estimations of meat consumption based on balance sheet data, large national dietary surveys are also important to the understanding of meat consumption. In the United States, for example, the National Health and Nutrition Examination Survey (NHANES) has collected nutrition-related data since 1971 and contributes to the understanding of dietary intake patterns. NHANES examines how meat is consumed (main dish or as a component of a recipe) and collects demographic data allowing consumption patterns to be examined based on age, income, ethnicity, education, and geographic location, providing detailed information rather than balance sheets. However, these survey data may be collected using food frequency questionnaires or food diaries over



FAO Statistical Yearbook 2013 (FAOStat); FAO endorsement is not implied

Figure 1 World meat production (2000–10).

a limited period of time or even a single day. Such cross-sectional data, which often rely on recall, provide only a snapshot of evidence making assumptions regarding continuous intake difficult. While it is interesting to understand the use of meat in various composite foods, it is also difficult to disaggregate such data to obtain a clear picture of meat consumption. Thus, determining meat consumption patterns is complicated, and observations made regarding population consumption patterns must be made with caution to avoid conclusions that meat consumption is insufficient or in excess.

Research publications, particularly observational studies of dietary patterns, often group meats into broad categories including 'meat,' 'red meat,' 'processed meat,' 'red and processed meat,' 'poultry,' and 'white meat.' The term 'meat' is most commonly used to describe all muscle meat excluding fish, but this is far from standardized. Generally, the terms 'red meat' and 'red and processed meat' represent meat from beef including veal, pork, and lamb regardless of whether it is fresh or processed, but often, these terms are undefined by the researchers reporting them. The broad and inconsistent grouping of meat within dietary patterns complicates our understanding of how meat is commonly consumed and limits our understanding of nutrients contributed to the food supply by individual types of meat. The term 'processed meat' often reflects a combination of red and poultry-based products but the type of processed meat is rarely, if ever, reported. Processing of meat for products such as sausage, bacon, and deli meats adds sodium, spices/flavorings, and preservatives that can change the nutrient profile. Reformulations of processed meat products over the past decade to include a lower sodium and fat content makes earlier observational data regarding

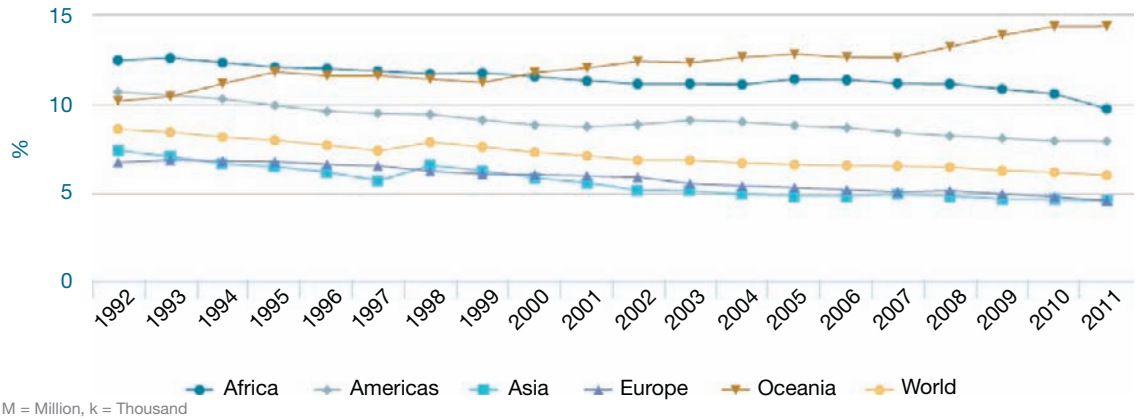


Figure 2 Trend of cattle and buffaloes as percent of total livestock produced 1992–2011. FAO, Statistics Division (FAOSTAT), http://faostat.fao.org.

nutrient intake and related health effects of processed meat of questionable relevance today.

Lipids

Worldwide data indicate that more than half (55%) of total dietary fat comes from vegetable products although the distribution of fat from plant- versus animal-based products varies from region to region. Global disappearance data suggest that, in the meat category, pork is the biggest contributor to total fat in the diet followed by poultry and beef. Change in production practices over several decades has led to a leaner supply of red meat. Driven largely by changes in breeding and retail trimming of external fat, it is estimated that in the United States, for example, the estimated amount of total fat available in the food supply from beef has been reduced by 44% (from 13% to 7%) since the 1970s. A similar experience is reported in the production of red meat in the United Kingdom with just over 20 years of change in animal husbandry resulting in 30% less carcass fat in pork, 15% in beef, and 10% in lamb.

Regardless of origin, meat fat predominantly contributes monounsaturated fatty acids (MUFA) to the diet (Table 3). MUFA are also derived from vegetable oils, nuts, and seeds. Olive oil, rich in MUFA, is the cooking oil used primarily in the Mediterranean dietary pattern, which is associated with decreased risk of many noncommunicable diseases. Oleic acid is the most common MUFA in meat.

Saturated fat (SFA) is the second most predominant fatty acid class supplied by meat. While SFA has traditionally been viewed as a major dietary contributor to coronary heart disease (CHD), not all SFAs are created equal with some contributing more than others to increased blood lipids associated with CHD risk. Also worth noting is, over the last decade, a growing body of research that has shown that blood lipids may be influenced as much by dietary carbohydrate as it is SFA. Generally speaking, shorter-chain SFAs (4–12 carbon chains), often found in high-fat dairy products, and refined carbohydrate-based food and snacks with added fats and sugars, have a more pronounced effect on blood lipids than longer-chain SFAs. In fact, stearic acid (18:0), as demonstrated by decades of data from randomized controlled trials (RCTs) and observational studies, is neutral in regard to its effect on total and low-density lipoprotein (LDL) cholesterol, and it appears to promote higher levels of high-density lipoprotein (HDL) cholesterol. Compared to vegetable oils, grains, nuts, and seeds, meat fat is low in the essential polyunsaturated fatty acids (PUFAs), linoleic acid (LA; 18:2 $n-6$), and alpha-linolenic acid (ALA; 18:3 $n-3$), although both lean and dark meat poultry contain higher PUFA content than red meat (Table 3). PUFAs supply essential fatty acids that cannot be made by the human body and, thus, viewed as healthy fatty acids often being recommended as replacements for SFA in the diet. Whereas meat contributes a relatively small amount of PUFA to the diet, meat is a good source of the long-chain omega-6 PUFA, arachidonic acid (ARA). ARA along with the long-chain omega-3 fatty acid ($n-3$ LCPUFA) docosahexaenoic acid, found mainly in fish, is important in the diet of infants and young children to promote growth and nervous system development.

Interest in manipulation of the PUFA content of meat has been a popular area of research. Generally speaking, the ability to modify the PUFA content of meat through changes in animal feeding practices is far more successful in monogastric animals than ruminant animals. Dietary PUFAs ingested by poultry and swine (monogastric) are reflected directly in the resulting nutritional content of meat and eggs. Dietary PUFAs ingested by ruminant animals, however, are transformed by rumen microflora in a process called biohydrogenation. Biohydrogenation saturates dietary PUFA resulting in very little 'bypass' of dietary PUFA for deposition in the resulting meat. Particular interest in increasing the $n-3$ LCPUFA content of meat and eggs stems from the limited supply of these fatty acids in populations that are landlocked or do not commonly consume fish. Grass/pasture feeding of cattle is often promoted as a means to increase $n-3$ LCPUFA in beef, but plants contain no preformed $n-3$ LCPUFA. Little of the $n-3$ LCPUFA precursor found in plants, ALA, escapes rumen biohydrogenation to be further metabolized to $n-3$ LCPUFA. Research to encapsulate or enable dietary $n-3$ LCPUFA to bypass the rumen has been successful but makes only modest PUFA contributions to the diet compared with naturally PUFA-rich foods. While beef from grass-finished cattle tends to have a slighter higher level of total $n-3$ PUFA, research has shown that beef from both grain- or grass-finished cattle can make a modest

Table 3 Select lipid contributions of meat

	100 g cooked portion (lean, skinless, and boneless)							
Lipid type	*Beef*	*Pork*	*Lamb*	*Chicken breast*	*Chicken thigh*	*Turkey breast*	*Turkey thigh*	*Lipid characteristics and functions*
Total fat (g)	9.28	9.21	9.52	3.17	8.15	2.08	6.04	Concentrated energy source important for health: supplies essential fatty acids; spares protein; carries fat-soluble vitamins; insulates tissues and organs for protection and regulation of body temperature. Enhances food flavor, texture, and color
Saturated fat (g)	3.54	3.09	3.40	0.99	2.31	0.59	1.81	Fatty acids containing no double bonds; generally solid at room temperature. Some saturated fatty acids increase total and LDL cholesterol when consumed in excess
Palmitic acid	2.11	1.92	1.83	0.70	1.75	0.37	1.18	
Stearic acid	1.14	1.00	1.17	0.24	0.48	0.18	0.51	
Monounsaturated fat (g)	3.90	3.91	4.17	1.21	3.36	0.63	2.06	Fatty acids containing one double bond; type of fat also found in olive and avocado oils; generally liquid at room temperature. Reduces LDL and total cholesterol when used to replace excess saturated fat
Oleic acid	3.55[a]	1.44[b]	3.86[a]	1.03[b]	2.79[b]	0.54[b]	1.77[b]	
Polyunsaturated fat (g)	0.32	0.86	0.62	0.76	1.70	0.53	1.66	Fatty acids containing two or more double bonds; type of fat also found in vegetable seed oils; liquid at room temperature. Provides omega-6 and omega-3 fatty acids essential for health. Reduces LDL and total cholesterol when used to replace excess saturated fat
Cholesterol (mg)	86	84	92	104	133	80	128	Critical component of cell membranes in all animal tissues; not present in plant products. Precursor to steroid hormones and vitamin D; essential in brain cell function

contribution to $n-3$ LCPUFA intake goals. Conjugated linoleic acid (CLA) is a metabolic end product of the rumen biohydrogenation of LA and accumulates in the fat and muscle of ruminant animals. Health benefits attributed to CLA include reduced biomarkers of CHD and changes in various cancer-related outcomes in animal models and cell lines. However, clinical trials with CLA have shown that intakes to achieve these benefits are typically associated with supplemental levels, averaging 5 g daily; a 100 g serving of meat may provide only 20 mg.

Finally, like all animal products, meat is a source of dietary cholesterol. While cholesterol is often viewed as responsible for increased risk of CHD, cholesterol is actually a critical component of cell membranes and essential for brain function. Regardless of meat source, cholesterol averages 80–130 mg per 100 g serving. One large chicken egg provides almost all the daily reference value for cholesterol, while several servings of meat must be consumed to accomplish the same.

Protein

It is estimated that ~40% of the world's protein intake (79 g/capita/day) is derived from animal products (31 g/capita/day). Protein intake worldwide has increased by roughly 15% since 1992, but only 5% of this increase has been from animal products. Of the worldwide total protein derived specifically from meat, dairy, and eggs, ~45% (14.2 g/capita/day) is contributed by meat. More specifically, in the most developed nations, it is estimated that 35 g of daily available protein is derived from meat, while in the least developed countries, about 6 g of available daily protein is sourced from meat.

The proportion and profile of the essential amino acids, and the true ileal digestibility of each essential amino acid, determine the quality of protein. Animal proteins contribute a near complete profile of dietary essential amino acids and are classified as of high biological value, while those lacking in essential amino acids, such as most plant-based proteins, are classified as incomplete or of low biological value. The protein digestibility-corrected amino acid score (PDCAAS) has long been used to determine the value of various proteins in the human diet. The PDCAAS score considers both the ability of a protein to supply essential amino acids and the ability of humans to digest that protein. Proteins are given a score on a continuum from 0 to 1.0 with protein from whole wheat and wheat gluten considered of poor value (0.25 and 0.42 PDCAAS

scores, respectively) and milk, egg, and soy protein providing the highest value with a score of 1.0. It is acknowledged, however, that PDCAAS often overestimates dietary protein quality, particularly for lower-quality proteins. PDCAAS relies on fecal digestibility, evaluating amino acids remaining at the end of the colon from various food sources. Overestimation occurs because, once present in the colon, amino acids are no longer available for absorption. PDCAAS also underestimates the quality of animal proteins because values are truncated at 1 and most animal proteins would be expected to score well over 1. Consequently, FAO has endorsed a newer scoring method, digestible indispensable amino acid score (DIAAS). DIAAS gives a more accurate assessment of digestion and absorption based on ileal digestibility (i.e., amino acids available from the small intestine). So, while milk and soy score 1.0 for protein quality using PDCAAS, based on DIAAS methodology, they would score 139 and 102, respectively. The amino acid content of meat varies depending on collagen content, with those cuts containing more collagen containing less essential amino acids. DIAAS data for all meat sources or cuts are not yet available, but a recent estimate indicates a DIAAS score of 131 for beef.

Protein/Energy Ratio

Caloric deficit in developing countries contributes to diseases of malnutrition. Caloric excess in developed countries contributes to weight gain and obesity and the various chronic diseases caused by excess body weight. It is estimated that about 10% of the world's caloric intake comes from protein, whereas more than 20% comes from more calorically dense fat. Globally, consumption of meat and offals contributes approximately 17% of the dietary energy supply or about 225 kcal/capita/day. Because plant-based proteins are often low in SFA, they are promoted as an alternative to animal-based proteins. However, the caloric cost of about 1 day's intake of protein from a range of plant-based sources is five times higher than if derived from lean meat. Studies designed to promote and maintain weight loss in overweight and obese adults indicate that proteins derived from lean red meat, poultry, or fish all support healthy body weight.

Current research further suggests that protein-based foods are more satiating compared to carbohydrate-based foods. This evidence indicates that shifting the macronutrient mix to favor a higher percentage of calories from protein (doubling on average) is associated with higher satiation and preservation of lean mass. For overweight or obese individuals, higher protein weight loss diets have also been shown to sustain weight loss more effectively than carbohydrate-rich diets.

Micronutrients

Meat not only has a favorable protein to energy ratio but also is nutrient-dense. A serving of meat (100 g) is a concentrated source of the trace minerals iron, zinc, and selenium. Red meat or dark poultry meat supplies up to 20% of adult daily requirements for iron. Beef is the richest source of zinc followed by lamb with beef providing up to 45% of zinc requirements (Table 4). All meat provides at least 30% of average selenium requirements with pork being the most significant, providing over half the recommended daily intake. The trace minerals available from meat are highly bioavailable compared with those from plants. While plant foods can supply similar quantities of iron per 100 g serving (Table 4), the bioavailability of iron from these foods is limited. Heme iron, present in meat, is more bioavailable than nonheme iron, present in plants. The absorption rate of iron from a meat-containing meal averages approximately 25% but can range from 10% to 40% depending on the iron status of an individual, the calcium content of the meal, and how the food was prepared with higher cooking temperatures decreasing heme iron absorption. In contrast, the absorption of nonheme iron is at most half that of heme iron ranging from 5% to 12% and influenced by the presence of pro- and antinutrient factors, such as ascorbic acid and phytates, respectively, as well as the iron status of the individual. Like iron, zinc is abundant in the diets of those regularly consuming meat, but limited in largely plant-based diets. In grains, the majority of zinc is located in the germ and bran portion, and up to 80% of zinc is lost during milling. Furthermore, while plants can contain similar amounts of zinc per serving as lean poultry, the presence of phytates limits its absorption. Selenium content of foods varies largely across geographic locations and is related to environmental and agricultural factors such as selenium content of soil and fertilizer. These factors influence directly the content of cereal grains, animal feeds, and resulting meat products. Generally speaking, however, meat is a more significant source of selenium than plant-based foods.

Meat is also a key source of B vitamins. Vitamin B_{12} is only found in animal products, and thus, individuals adhering to a diet free from animal products are at risk for developing a deficiency. Beef liver is one of the best sources of B_{12} providing more than ten times recommended intakes in a 100 g serving. Meat from cattle and sheep can provide up to half the recommended intake per serving (Table 4). Pork is notable as a particularly rich source of thiamine, second only to the yeast extract spread vegemite. Unrefined grains are also a source of thiamine, but processing removes a considerable amount, meaning reliance on polished rice as a dietary staple can contribute to the development of thiamin deficiency disease (i.e., beriberi). Poultry meat and pork are also leading meat sources of vitamin B_6 and niacin.

Health Effects

Growth and Development

The transitional stage from 6 to 12 months, when infants are introduced to complementary foods (solid or liquid), is viewed as a particularly vulnerable and dangerous period for development of diseases of malnutrition, including stunting and wasting, starvation, and a predisposition to chronic noncommunicable disease later in life. Iron deficiency anemia is the most common nutrient deficiency in the world, affecting growth and development of infants and young children as well as pregnancy outcomes. Zinc deficiency is widespread in developing countries and related to increased risk of morbidity and mortality from diarrhea, pneumonia, and malaria, particularly among infants and children. First weaning foods in most countries are low-fat, carbohydrate-rich grain-based products

Table 4 Select nutrient contributions of meat

		100 g cooked portion (lean, skinless, boneless)								
Nutrient	*NRV-R*[a]	*Beef*	*Pork*	*Lamb*	*Chicken breast*	*Chicken thigh*	*Turkey breast*	*Turkey thigh*	*Pinto beans*	*Nutrient function*
Macronutrient										
Protein (g) (%NRV-R)	50	29.88 (59.8)	27.51 (55.0)	28.22 (56.4)	30.54 (61.1)	24.76 (49.5)	30.13 (60.3)	27.71 (55.4)	9.01 (18.0)	Supplies essential amino acids required for: normal growth, immune function; and, tissue protein synthesis including immunoglobulins, enzymes, hormones. Maintains fluid and pH balance; provides energy
Minerals										
Iron (mg) (%NRV-R)	14	2.99 (21.4)	1.00 (7.1)	2.05 (14.6)	0.45 (3.2)	1.13 (8.1)	0.71 (5.1)	1.43 (10.2)	2.09 (14.9)	Component of: hemoglobin and myoglobin to carry oxygen; hormones and enzymes including those needed for cell respiration
Phosphorus (mg)	NE[b]	231	231	210	258	230	230	212	147	Component of: bones and teeth; nucleic acids and phospholipids; enzymes involved in energy metabolism. Intracellular buffer
Potassium (mg)	NE[b]	355	357	344	391	269	249	227	436	Participates in the regulation of acid–base balance and osmotic pressure of body fluids. Impacts blood pressure and muscle contraction, especially cardiac muscle
Selenium (μg)	NE[b]	21.3	44.2	26.1	28.4	27.1	30.2	31.4	6.2	Component of antioxidant systems, which aid vitamin E and fatty acid metabolism and tissue respiration
Zinc (mg) (%NRV-R)	15	6.78 (45.2)	2.90 (19.3)	5.27 (35.1)	0.90 (6.0)	1.92 (12.8)	1.72 (11.5)	3.51 (23.4)	0.98 (6.5)	Component of antioxidant enzyme systems. Essential for insulin formation and function
Vitamins										
Thiamin (mg) (% NRV-R)	1.2	0.090 (7.5)	0.672 (56.0)	0.100 (8.3)	0.107 (8.9)	0.096 (8.0)	0.035 (2.9)	0.060 (5.0)	0.193 (16.1)	Component of enzyme required for metabolism of carbohydrates, fat, and branched-chain amino acids
Riboflavin (mg) (% NRV-R)	1.2	0.240 (20.0)	0.311 (25.9)	0.280 (23.3)	0.213 (17.75)	0.218 (18.2)	0.205 (17.1)	0.375 (31.3)	0.062 (5.2)	Component of enzymes involved in tissue respiration and hydrogen ion transport
Niacin (mg) (%NRV-R)	15[c]	4.000 (26.7)	6.503 (43.4)	6.320 (42.1)	12.133 (80.9)	6.208 (41.4)	11.750 (78.3)	6.685 (44.6)	0.318 (2.1)	Component of enzyme required for oxidation of carbohydrate and fat. Required for glycogen and fatty acid production
Vitamin B_6 (mg) (% NRV-R)	1.3	0.350 (26.9)	0.577 (44.4)	0.160 (12.3)	1.157 (89.0)	0.462 (35.5)	0.807 (62.1)	0.438 (33.7)	0.229 (17.6)	Component of enzymes needed for: synthesis and breakdown of amino acids, glycogen, and unsaturated fatty acids; production of niacin from tryptophan
Vitamin B_{12} (μg) (% NRV-R)	2.4	2.64 (110.0)	0.68 (28.3)	2.61 (108.8)	0.21 (8.8)	0.42 (17.5)	0.39 (16.3)	1.65 (68.8)	0.000 (0.0)	Essential for biosynthesis of nucleic acids and nucleoproteins. Required for maturation of red blood cells. Closely linked with folate metabolism
Choline (mg)	NE[b]	114	65	NR[d]	NR[d]	72	84	96	35	Component of acetylcholine and phospholipids involved in cell communications and nutrient metabolism

that provide limited amounts of key micronutrients, fatty acids, or high-quality protein. In many developing regions, plant-based foods remain as staples throughout the first years of life at the expense of animal products and, thus, limit intake of key nutrients such as iron, zinc, and $n-6$ and $n-3$ LCPUFA. Because of the nutrient density of meat, and similar nutrient profile to human milk, small amounts of meat can dramatically improve the nutritional status of children during development. Consumption of meat 1–3 times a week among older infants has been shown to reduce the incidence of stunting by 36% and wasting by half. However, estimates suggest that consumption of meat on a regular basis may be as low as 10% for infants and 20% for young children in developing countries.

Sarcopenia

Middle-aged and older adults often experience a gradual loss of muscle mass and function known as sarcopenia. Stressors such as illness and injury resulting in bed rest or decreased activity often hasten its progression. While many factors contribute to the development of sarcopenia, diet, specifically protein intake, is an important consideration. The type, amount, and timing of protein intake throughout the day are all factors for dietary strategies to reduce the risk of sarcopenia. Evidence suggests that a range of protein intakes, often higher than commonly recommended (0.8 g kg^{-1} body weight), may be necessary to support optimal health. The protein intake of older adults is often skewed with most consumed as plant-based protein during the evening meal. Current research suggests that 25–30 g of high-quality protein at each meal improves postprandial muscle protein synthesis and performing exercise in proximity to protein intake further enhances muscle anabolism. Further, the high leucine content of meat and dairy supports muscle protein synthesis.

Cancer

It is estimated that about a third of cancer-related deaths may be due to lifestyle factors such as diet, physical activity, and obesity. While maintaining a healthy body weight through balanced nutrition and adequate physical activity consistently lowers cancer risk, evidence for individual dietary components, as related to cancer, is much less clear. For example, increased fruit and vegetable consumption is commonly advised to reduce cancer risk, but research since the mid-1990s has weakened the scientific evidence and is now described by expert panels to be somewhat less impressive. Similarly, research aiming to identify an independent effect of meat and/or red meat on cancer has also been inconsistent. Studies reporting positive associations between red meat and cancer are often confounded by an unhealthy lifestyle including smoking, higher body weights, and inadequate physical activity. Meat, particularly red meat, has often been associated with a 'Western' dietary pattern characterized by high intakes of animal products, refined sugars, and fats, which collectively are thought to contribute to an increased risk of various chronic diseases. Certain assumptions often underpin the conclusions drawn from dietary pattern data, in particular the assumption that all foods in a food group are created equal and, therefore, all equally contribute to health outcomes attributed to various patterns. Disentangling the independent effects of individual foods on health outcomes is a substantial challenge.

Heart Disease

Early research examining dietary patterns and risk of developing chronic disease determined a relationship between excess dietary fat intake and development of cardiovascular disease. High animal fat intake, particularly from red meat, was marked as a culprit in raised blood total and LDL cholesterol levels. Resulting nutrition recommendations often encouraged reduced consumption of red meat and/or consumption of lean meats as a means of controlling blood cholesterol levels and, thereby, reduced risk of disease. However, more recent data from high-quality RCTs have demonstrated that diets designed to reduce CHD risk are as successful at achieving target blood lipid levels (i.e., total cholesterol, LDL, HDL cholesterol, and triglycerides) and may be easier to adhere to long term, if they contain sufficient protein from lean red meat.

Conclusion

In developed counties, meat contributes significantly to daily protein and micronutrient intakes, but as a source of dietary fat, its positive role in the diet has been confounded by dietary patterns associated with caloric excess in developing countries. Meat consumption has been a fundamental component of the human diet throughout history. Today, global demand for meat continues to increase. A substantial contributor of high-quality protein and essential micronutrients, meat intake has an important role in nourishing humans.

Meat: Structure

R Hamill and C Botineştean, Teagasc, Food Research Centre, Ashtown, Dublin, Ireland

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Meat is the mostly widely used term to describe the edible part of animal tissues and any processed products prepared from these tissues. The term 'meat' not only refers to the skeletal muscle, adjacent fat, and other tissues but also can be used to refer to other edible tissues such as offals. Meat is a highly prized food commodity that provides many nutrients essential for human health.

In general, meats are classified by the source of provenance (type/species of animal), as follows:

- Red meat corresponds to mammal meat.
- White meat corresponds to fowl meat.
- Seafood corresponds to fish and shellfish meat.
- Game represents the meat from animals that are not commonly domesticated.

In general, beef refers to the meat from cattle, veal from calves, pork from pigs, lamb from young sheep, and mutton from sheep older than 2 years.

Meat is a very complex food product that can be affected by both *antemortem* and *postmortem* factors. The structure, composition, and characteristics of meat are highly linked with the structure of the living muscle. Contractile proteins and connective tissue as components of the muscle can thus influence the quality of the final product. Knowledge of the structure and composition of the muscle, as well as the process of its conversion to meat, is very important for the characterization and appreciation of the quality of meat.

Meat: Structure

The muscle consists of contractile cells or fibers that are largely composed of contractile protein complexes (termed myofibrillar proteins). The connective tissue surrounds and supports the muscle cells. The muscle has three layers of connective tissue, as presented in Figure 1: endomysium, perimysium, and epimysium.

The connective tissue is involved in the 'background toughness' and the myofibrillar proteins are involved in the 'myofibrillar toughness.' The toughness of meat is highly related to the sarcomere length in terms of interaction between actin and myosin proteins from the muscle. Knowledge of the muscle function, force generation/transmission, and the associations between the structures is very important for the interpretation and understanding of the properties of meat.

The muscle cells in red meat include the following components:

- The sarcolemma, also called myolemma, plasmalemma, and plasma (cell) membrane, is the double-layered membrane inside the endomysium, the tissue that completely surrounds each fiber and defines the limits of the muscle cell. The sarcolemma displays the typical characteristics of eukaryotic cell membranes. The sarcolemma provides a barrier between extra- and intracellular components, whose properties are defined largely by the lipids (especially phospholipids) in its composition.
- The sarcoplasm is the cytoplasm of the muscle fiber, populated mostly by myofibrils, and contains organelles (mitochondrion, lysosomes, nuclei, Golgi apparatus, and ribosomes), enzymes, and other substances (glycogen and lipid droplets), which are essential components for normal cellular metabolic activity.
- The sarcoplasmic reticulum stores and releases available calcium and surrounds myofibrils. The sarcoplasmic reticulum and T-tubules as components of intracellular membrane form a system that transports a neural impulse to the inner part of the muscle cells controlling the processes of relaxation and contraction.
- The sarcolemmal cytoskeletal proteins can be classified into
  - myofibrillar proteins (α-actinin, nebulin, titin, and desmin) and
  - sarcolemmal proteins (vinculin, integrins, talin, paxillin, dystrophin, and glycoprotein complex).
- The myofibrillar proteins that form the contractile system represent ~80% of the muscle cell volume. From all the muscle cell components, myofibrillar proteins are the most important in the proteolytic process that involves changes in meat tenderization during *postmortem* storage.

Myofibrils are characterized by light bands, which are isotropic, named I-bands, and dark bands, which are anisotropic, called A-bands. I-bands have at their center dark lines, called Z-lines or Z-disks (the contractile system represents the component located between two adjacent Z-disks). At the center of the A-bands is a light zone – the H-zone, characterized by the H-line. The A-band consists of thick filaments (mainly myosin) and the I-band consists of thin filaments (mainly actin).

The Thick Filament. The most predominant myofibrillar protein of the thick filament is *myosin* (approximately 45% of myofibrillar protein). Myosin is a structural protein, an asymmetrical molecule, consisting of six polypeptide units, and has an elongated rod-shaped structure; at the end of the myosin is a thickened area, called the head region; the thin region, named the tail of the molecule, consists of two polypeptides in a coiled α-helix. Myosin presents two globular heads at one end (double-headed molecule). It also possesses an ATPase activity; the double-headed regions bind and hydrolyze ATP to ADP. The myosin filament has a cylindrical shape and the center of the A-band contains the rod region of myosin (free of the globular double heads) – this region is named the pseudo H-zone.

The Thin Filament is composed of three important myofibrillar proteins: actin, tropomyosin, and troponin. The thin filament (visible in the I-band) has two coiled strands of

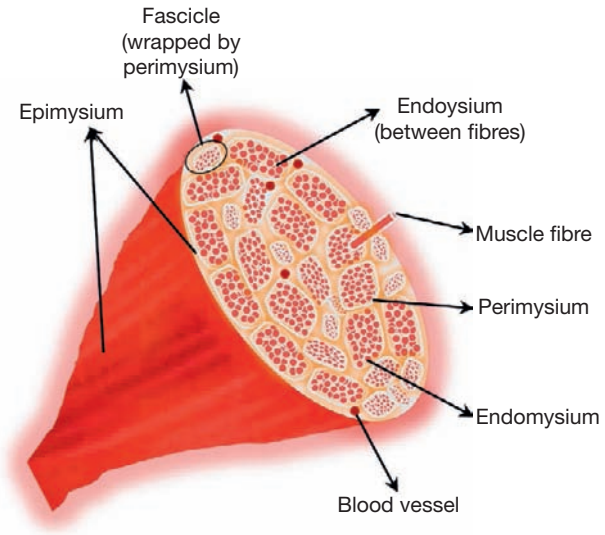

Figure 1 Structure of the skeletal muscle.

polymerized actin fibrous molecules (*F-actin*) that wrap around each other, creating a double-helix structure, a thin filament appearing like a four-stranded rope. Since actin is the protein with the highest concentration in thin filaments, it is usually referred to as actin filaments.

Actin molecules represent ~20% of the myofibrillar proteins. Tropomyosin consists of two polypeptide chains that associate to form a coiled helix (α-helical structure). It has been reported that tropomyosin is located in the groove of the coiled actin, characterized by two different units, having different molecular weights, called α-tropomyosin and β-tropomyosin.

Troponin is an asymmetrical protein and has three fractions:

- Troponin T is characterized by the fact that it is bound to troponin subunits C and I and links in the I-band the troponin and tropomyosin molecule.
- Troponin C binds to troponin I and troponin T, is responsible for the process of forming the complex troponin–tropomyosin–actin (calcium complex), and is the Ca^{2+} receptor that controls its regulation – in terms of muscle contraction.
- Troponin I represents the inhibitory fraction, interacting between actin and myosin in the relax stage, and also binds tightly to troponin C and actin (the presence of calcium ions represents a favorable situation) and binds slightly to tropomyosin/troponin T.
- Each *F-actin* filament is anchored in a Z-disk that consists mainly of actin. The Z-disk consists of thin filaments – Z-filaments –that are connected with actin filaments.

α-Actin is the major component of the Z-line being an integral part of Z-line. Desmin is another important constituent of the Z-disk and presents in the periphery of Z-disk. Since it connects many components of the cytoplasm, desmin has a very important role.

Muscle Contraction

Muscle contraction refers to the voluntary contraction of thick filaments (which contain myosin) and thin filaments (which contain actin). The process of hydrolysis of ATP is considered an energy provider; the movement of the actin filament over the myosin filament leads to the formation of the actomyosin protein complex, characteristic of muscle contraction (as presented in Figure 2).

The crossbridge can be classified as weak or strong, in terms of the nucleotide status of myosin. Strong crossbridges can be found in rigor muscles and contracting muscles (stiff/inflexible muscles), while weak crossbridges can be found in relaxed muscles (extensible muscles). Troponin and tropomyosin are involved in the regulation of the interaction between myosin and actin. Tropomyosin is a flexible protein, whose position fluctuates on the surface of the thin actin-containing filament. The contraction of a skeletal muscle cell starts with the activation in the motor cortex of the brain using a signal of a potential action in a motor neuron that leads to the release of acetylcholine. A membrane depolarization process then takes place, followed by calcium release into the cytosol creating a higher calcium concentration there. Once strong crossbridges are formed, the sarcomere shortens, the force is transmitted to the tendon and bone, and the crossbridge cycle is completed.

The relaxation process implies repolarization, that is, the removal of acetylcholine from synaptic cleft and the release of cytosolic calcium, which leads to a decrease of calcium concentration in the cytosol.

Voluntary muscular contractions can be classified according to the changes that can occur in their length or in terms of the force levels, as follows:

- Concentric contraction: The force generated is sufficient to overcome the resistance, being characterized by the process of muscle shortening.
- Eccentric contraction: The force generated is insufficient to overcome the external load on the muscle, being characterized by the process of lengthening of the muscle fibers.
- Isometric contraction: There are no changes in the length of the muscle.
- Isotonic contraction: This is characterized by the fact that despite a change in muscle length, the tension in the muscle remains constant.
- Isovelocity or isokinetic contraction: This is characterized by the fact that the muscle contraction velocity remains constant, while force is allowed to vary.

Theory of Contraction: Sliding Filaments

Figure 2 presents the formation of a crossbridge and the process of how the muscle uses energy to break the crossbridge:

- In the first stage, myosin attaches to actin; in this stage, the myosin head presents the highest energy configuration. ADP and P_i remain bound to myosin.
- The second stage is characterized by the orientation of the myosin head on the actin, sliding thorough the thin filament, and resumes the tightly bound rigor state; the power stroke is initiated by the release of P_i.
- During the third stage of crossbridge formation, a molecule of ATP is attached to the myosin head; the result of this is the detachment of the crossbridge.
- The fourth stage is characterized by the hydrolysis of ATP, the formation of ADP and P_i; as a result, the process of formation of another crossbridge can begin.

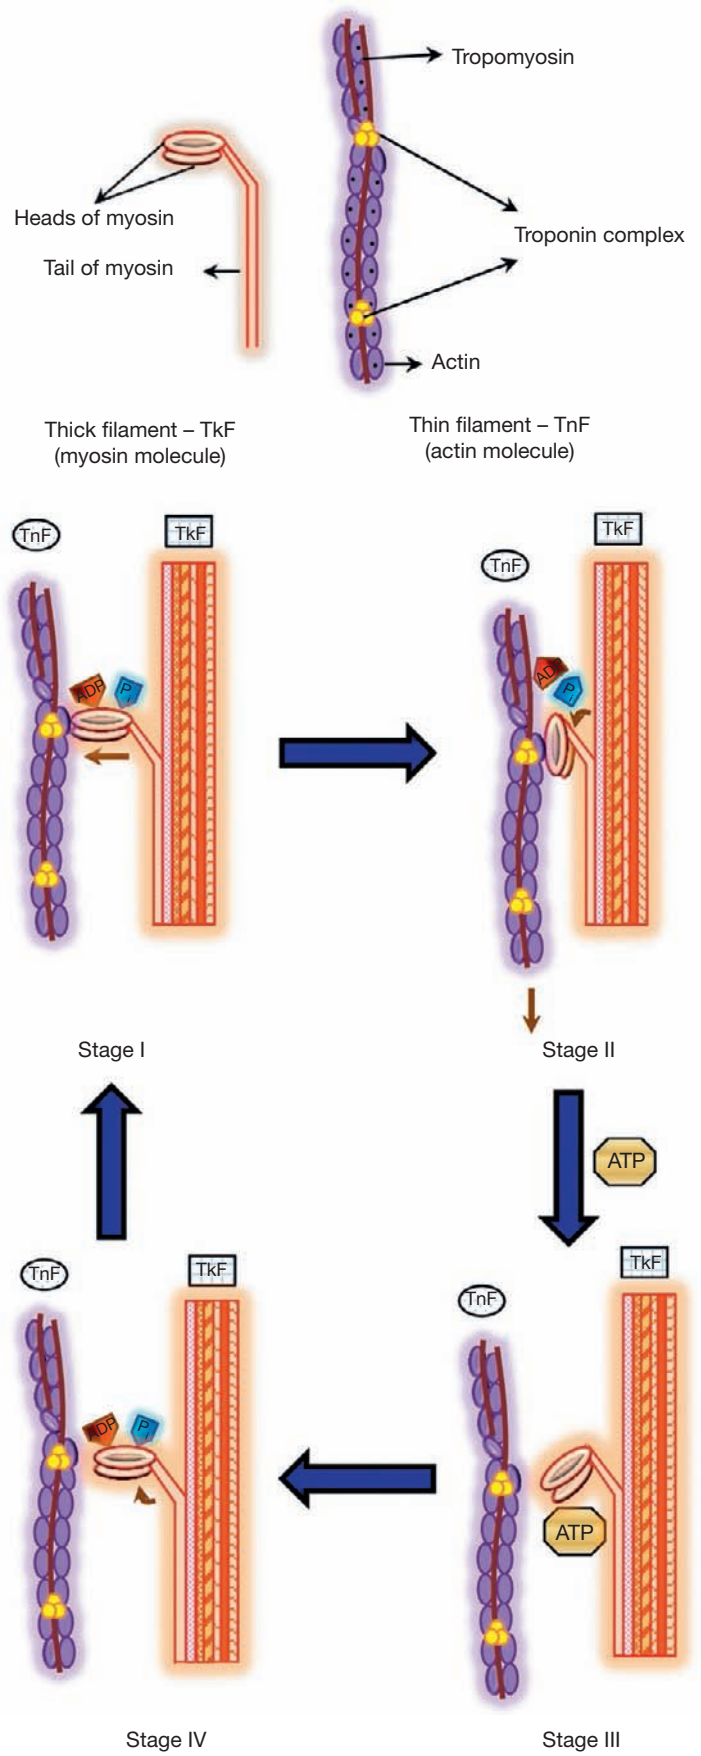

Figure 2 The stages of crossbridge cycle formation during muscle contraction.

Postmortem Changes in Meat: Conversion of Muscle to Meat

In the conversion of prerigor to postrigor muscle, the ATP concentration drops very low, the concentration of crossbridges becomes high and the calcium level becomes low – preventing the relaxation of the muscle. If no ATP is available, the thick and thin filaments remain bound together. The intrinsic metabolic process that is responsible for restoring ATP will stop functioning once the animal dies. The rigor state is characterized by the fixation of the actomyosin structure, which is very important in the process of conversion of muscle into meat (via glycolysis). During the process of conversion from muscle to meat, several chemical and structural changes occur that have a high impact on the quality and functionality of the meat. The most important changes that take place during slaughter and processing are the following:

- Declining pH due to the accumulation of lactic acid (meat is becoming more acidic leading to a reduced water-holding capacity)
- Increasing ionic strength (the sarcoplasmic reticulum loses the ability to sequester calcium)
- Changes in the redox potential
- Decreases of the energy levels
- Color changes
- The rigor bonds (crossbridges between actin and myosin cause rigor mortis process in the muscle or muscle rigidity, a process that reduces the tenderness of the meat)

To improve meat palatability in terms of flavor and tenderness, meat is stored for a period of time at refrigerated temperature – this period of time is named aging. During the aging process, meat tenderness increases – in terms of the myofibrillar component, for example, a decrease in the intensity of Z-lines can be observed in the meat structure under microscopy.

Meat tenderness increases slightly during the first 3–4 days of aging. Some of the *postmortem* changes occur due to some specific proteolytic enzymes from the lysosomes called cathepsins. Also involved in *postmortem* changes, especially in the tenderization that occurs during the aging process, is the calpain system. It has been reported that calpains degrade myofibrillar proteins including titin, nebulin, desmin, and TnT and greatly contribute to the process of *postmortem* tenderization. Collagen molecules also have a very important role in defining meat tenderness. The proteolysis of collagen *postmortem* is very low, and intermolecular crossbridges are not degraded. Collagen will hydrolyze to form gelatin, if heated in the presence of moisture. One important collagen crossbridge is pyridinoline, which is specific to older animals, is heat-stabile, and is nonreducible. The improvement of tenderness that occurs during *postmortem* changes is therefore due mainly to proteolytic degradation of the myofibrillar proteins and the toughness associated with collagen level and cross-linking in *postmortem* meat, termed 'background toughness.'

Meat flavor is strongly associated with the protein and fat content and their status. The breakdown of protein and fat (proteolysis and lipolysis) produces flavor compounds including acetaldehyde, hypoxanthine, hydrogen sulfide, and xanthine, which combine to define the complex flavor of aged meat.

Meat: Composition

Nutrients are chemical compounds or environmental substances that are used for energy and growth and for an organism's physiological functions, so they can be:

- energy providers (carbohydrates, proteins, and lipids),
- growth promoters (proteins, lipids, vitamins, minerals, and water),
- physiological function regulators (carbohydrate, proteins, lipids, vitamins, minerals, and water).

Depending on the amount needed, nutrients can be classified as macronutrients (proteins, carbohydrates, and lipids) and micronutrients (vitamins and minerals).

Each macronutrient provides energy, expressed in calories. In terms of energy, proteins and carbohydrates provide 4 calories per gram and lipids 9 calories per gram.

The main chemical components of meat tissue are water (moisture), proteins, lipids, carbohydrates, and inorganic matter. Factors that can have variable influence on the chemical composition of meat include species, breed, genetics, gender, nutrition, chronological and physiological maturity at harvest, weight at slaughter, muscle or cut of meat, preslaughter conditions, *perimortem* conditions, and *postmortem* processing. The composition of meats largely depends on the lean to fat ratio, in terms of providing energy and high nutritional value proteins.

Water/Moisture

The principal constituent of meat is water. In living muscle tissues, the water content can reach up to 80% of the total mass.

The water in the muscle can be present within and/or between the myofibrils, between the myofibrils and sarcolemma, between muscle cells, and between groups of muscle cells. In terms of location, water is present in muscles in three phases: bound water, immobilized water, and free water. In the process of conversion of muscle to meat, the formation of lactic acid leads to a reduction of the pH value in the meat. When the pH value is close to the pH value of muscle proteins, especially myosin, then the positively and negatively charged groups (components of the protein) will be attracted to each other. This means that the concentration of water attracted and bonded to muscle proteins will be reduced. Myofibrillar proteins therefore play an important role in defining how much moisture is retained by meat *postmortem*, termed the meat's water-holding capacity.

Protein

Proteins comprise long peptide chains of amino acids, encoded by DNA, and meats are very good sources of high-quality proteins. Muscles contain ~30% protein with a high biological value. Skeletal muscle tissue proteins can be generally classified according to their physiological function:

- Myofibrillar (contractile)
- Sarcoplasmic (metabolic)
- Stromal (connective or support)

Protein concentration in the muscle, and therefore meat, can vary with muscle fiber type, maturity, species, sex, and muscle type.

The color of meat is a very important parameter that can influence the purchasing decisions of consumers. Myoglobin is the pigment in meat largely responsible for its color and is composed of a protein moiety (globin) and a heme prosthetic group. Myoglobin is the most important iron- and oxygen-binding protein of the muscle.

The polypeptide structure of globin, consists of eight helical segments positioned around the heme moiety. Myoglobin contains an iron atom that can exist in two forms: oxidized and reduced, Fe^{2+} (ferrous form) and Fe^{3+} (ferric form), respectively.

In fresh meat, myoglobin can be found in four redox forms:

- Deoxymyoglobin (Fe^{2+}, when iron binds with water) – interior of raw meat
- Oxymyoglobin (Fe^{2+}, when iron binds with oxygen) – surface of meat in air
- Metmyoglobin (Fe^{3+}, when iron binds with hydroxide)
- Carboxymyoglobin (Fe^{2+}, when iron binds with carbon monoxide)

The formation of metmyoglobin – which causes a specific brown coloration in meat – is the result of the oxidation of Fe^{2+} (ferrous form) to Fe^{3+} (ferric form). Metmyoglobin is a physiologically inactive compound, incapable of binding oxygen.

On average, 40% of the amino acids in meat protein are termed 'essential' – these types of amino acids cannot be synthesized in the body and have to be supplied by the diet.

The essential amino acid composition of the proteins of the most important/principle types of meat is presented in Table 1.

Lipids/Fat/Triacylglycerols

The fat present between the bundles of muscle fibers within the meat is termed marbling and it contributes to the juiciness and flavor of meat. The degree of marbling in meat is a very important parameter that can also impact the firmness of meat.

Animal adipose tissue or simply fat is composed mainly of adipocytes (fat cells) and also contains stromal vascular fractions, connective and nerve tissues, and immune cells.

Fat can be present in meat as:

- intermuscular fat (the fat located between the muscles),
- intramuscular fat (the fat located within the muscles),
- subcutaneous fat (the fat located under the skin).

The main role of the adipose tissue is to store energy, through the lipid components. Due to the fact that it produces resistin and leptin hormones, the adipose tissue represents an endocrine organ that is a highly active component and is involved in coordinating various biological processes like the metabolism of energy and immune and neuroendocrine functions.

Lipids (fats) are energy-dense macronutrients, producing 2.25 times more energy compared to proteins or carbohydrates. The components of the animal adipose tissue are important in the solubilization and transportation processes for fat-soluble vitamins (A, D, E, and K).

Most of the fat is present as glycerol esters, but it also exists as cholesterol, phospholipids, and fatty acid esters. Neutral lipids represent >90%, 10% being represented by sterol esters (e.g., cholesterol) and phospholipids (phosphatidylethanolamine, or cephalin), phosphatidylserine, and phosphatidylcholine, or lecithin.

Table 2 presents the chemical structures for some representative compounds in the animal adipose tissue, with a high impact on human health. The chemical structure of phospholipid (as shown in Table 3) is very similar to the structure of triacylglycerol – phospholipids have a phosphoric acid inserted between the glycerol ester bond and the fatty acid that corresponds to position R3.

Triglycerides can be classified into:

- simple (all attached fatty acids are identical),
- mixed (two or more attached fatty acids are different).

Fatty acids can be classified as

- saturated (containing no double bonds between carbon atoms),
- monounsaturated (containing one double bond between two carbon atoms),
- polyunsaturated (containing two or more double bonds in the carbon chain).

Fat is present in organisms around vital organs, subcutaneously, inter-/intramuscularly. The adipose tissue is dynamic and is constantly being stored or mobilized. Fatty acids can be synthesized by animals in the liver and adipose tissue starting from carbohydrates and proteins. It has been reported that *trans*-fatty acids have been involved and implicated in contributing to coronary heart disease, increasing low-density lipoprotein cholesterol, and in decreasing high-density lipoprotein cholesterol. Palmitic acid is the fatty acid with the highest concentration for meat samples (beef, pork, and lamb), as shown in Table 2.

Carbohydrates

Glycogen is the most predominant carbohydrate present in animal tissue; it is a multibranched polysaccharide, the principal storage form of glucose, formed by linear chains of α-D-glucose molecules linked by α-1,4- and α-1,6-glycosidic bonds. The amount of glycogen present in muscle tissues at slaughtering is very important due to the fact that it has a direct impact on the final color, texture, firmness, water holding capacity (WHC), emulsifying capacity, and shelf life of the meat. Glycolysis is the catalytic process of degradation of glucose; glycolysis means 'splitting sugars,' the process of converting glucose in two molecules of sugars containing three atoms of carbon each. The glycolytic process can occur with or without oxygen, and the components that result in the end of the process are two molecules of ATP (free energy), two molecules of pyruvic acid, and two molecules of NADH (high-energy electrons).

Since the content of glycogen available in the muscle is transformed into lactic acid *postmortem*, few carbohydrates are present in meat at the time of consumption. Once death occurs and circulation ceases, no oxygen is accessible to the muscle, ATP is not produced via the mitochondria, and this leads to a

Table 1 Essential amino acid composition of fresh meats from different species, expressed as % of crude protein

		Concentration of crude protein (%)

switch in muscle metabolism to anaerobic glycolysis. Until the muscle enters rigor *postmortem*, the lactate concentration continually increases, while the glycogen concentration decreases, accompanied by a decline in the pH value. Where glycogen is depleted *premortem*, anaerobic glycolysis *postmortem* is limited, and this leads to meat that is dark, firm, and dry (DFD) with a poor shelf life. DFD is more common in beef, compared with pork. Pale, soft, and exudative (PSE) meat is more common in pork and represents the result of a rapid decrease in the pH value coincident with a high muscle temperature. PSE meat presents abnormal properties in terms of water-holding capacity, color, texture, and consistency, and as a result, meat becomes unappealing for consumers. Genetic conditions and stress level that could occur around the time of slaughter have an important impact on the PSE meat.

Apart from glycogen, there are two other important carbohydrates present in animal muscle tissue: glycosaminoglycans and proteoglycans.

Glycosaminoglycans are linear heteropolysaccharides, formed by repeating disaccharide unit that contain either of two modified sugars, *N*-acetylgalactosamine (GalNAc) or *N*-acetylglucosamine (GlcNAc), and a uronic acid (glucuronate or iduronate).

Proteoglycans are complex compounds that are formed by a core protein and one/more covalently attached chains of glycosaminoglycan.

Micronutrients in Meat

Minerals (inorganic matter)

Meats – without referring to any particular species – contain ~1% minerals. It is very well known that iron is the main nutrient that is associated with meat, but meat is a valuable source of many other micronutrients such as vitamin D, vitamin B complex, zinc, and selenium. Meats have a relatively high content of iron, zinc, phosphorous, and a low level of calcium, iodine, and magnesium.

Iron is present in meats in two forms: heme and nonheme. Heme iron represents ~50% of the total iron available in meat and it is readily absorbed because it is found naturally in the composition of hemoglobin and myoglobin (porphyrin ring). Liver contains twice as much iron as muscle meats.

Because iron is very important in the formation of hemoglobin in red blood cells, a deficiency caused by a lower bioavailability of iron can lead to anemia, defective psychomotor development in infants, impaired educational performance of children in school, adverse perinatal outcome in pregnancy, and generally a diminished work capacity, which are all associated with iron deficiency. Nonheme iron absorption is inhibited by phytate, oxalate, and other minerals (zinc, calcium, and copper) and is enhanced by vitamin C.

Meat is a valuable source of *zinc*. Meat/meat products can supply 30% of the total zinc intake, and it has a high bioavailability. Zinc from other food products is poorly absorbed. Zinc is an important cofactor in the functioning or composition of more than 200 enzymes and is involved in growth, healing, gene expression, brain maturation, cognitive development, and reproduction. Zinc deficiency can cause dwarfism.

Selenium is a micronutrient that acts as cofactor in the reduction of some specific antioxidant enzymes, such as glutathione peroxidases and thioredoxin reductase. Selenium is a component of glutathione peroxidase, a highly important enzyme that inactivates toxic hydrogen peroxide and hydroperoxides. Due to its role in this process, selenium can be considered an essential antioxidant nutrient.

Even though meat contains a relatively low concentration of selenium (as shown in Table 4), organ meats (e.g., kidney and liver) are considered valuable sources of selenium.

Selenium deficiency can cause various chronic diseases, such as cancer, diabetes, tuberculosis, and coronary heart disease.

Table 4 Mineral and vitamin composition of muscle meat (pork, beef, and lamb) (concentration expressed per 100 g of lean meat)

Micronutrient	*Pork*	*Beef*	*Lamb*	*RDI*[a]
Vitamin B_1 (mg)	0.48	0.04	0.12	1.5
Vitamin B_2 (mg)	0.18	0.18	0.23	1.7
Vitamin B_3 (mg)	6.61	5.0	5.2	20
Vitamin B_5 (mg)	0.69	0.35	0.74	10
Vitamin B_6 (μg)	0.68	0.52	0.10	2
Vitamin B_{12} (μg)	0.53	2.5	0.96	6
Iron (mg)	0.63	1.8	2.0	18
Calcium (mg)	19	4.5	7.2	1000
Zinc (mg)	1.77	4.6	4.5	15
Magnesium (mg)	25	25	28	400
Sodium (mg)	55	51	69	460–920
Potassium (mg)	343	363	344	2800–3800
Phosphorus	209	215	194	1000
Selenium (μg)	35.9	17	14	70

[a]Reference Daily Intake/Recommended Daily Intake (RDI) represents the daily intake concentration of a nutrient, considered to be sufficient to meet the requirements of 97–98% of healthy individuals. It has been used in the country where it has been developed, the United States, and in other countries.

Vitamin D (cholecalciferol)

Vitamin D is an essential component in the process of bone growth and tooth development, being involved in the process of absorption and metabolism of calcium and phosphorus. The main source of vitamin D is sunlight. The process of synthesis of vitamin D starts with the oxidation of cholesterol from food or bile to provitamin D_3 (7-dehydrocholesterol) that is transported to the skin, mainly the epidermis. UVB rays converts 7-dehydrocholesterol, which lies in the skin, to cholecalciferol.

The process continues with the hydroxylation of cholecalciferol to calcidiol (25-hydroxyvitamin D_3 ($25OHD_3$); liver) and to calcitriol (1,25-dihydroxyvitamin D_3 ($1,25OHD_3$); kidney), compounds that stimulate the process of calcium absorption. Research reports indicated that $25OHD_3$ (active metabolite synthesized in the liver) is five times more active than cholecalciferol, while $1,25OHD_3$ (active metabolite synthesized in the kidney) is 25 times more potent than vitamin D_3. So, in the calculation of concentration of vitamin D_3 in meat, the levels of $25OHD_3$ and $1,25OHD_3$ are also very important.

A serious deficiency of vitamin D can lead to the occurrence of osteomalacia, rickets, bone loss, and osteoporotic fractures. Rickets is characterized by imperfect calcification, softening, and distortion of the bones, typically resulting in bow legs.

Vitamin D is also protective against various diseases: diabetes, tuberculosis, muscle weakness, coronary heart disease, and different types of cancer.

Despite the fact that it can be synthesized in the body, many people in northern regions do not get enough sunlight exposure and thus are at risk of vitamin D deficiency. Research has indicated that lean red meat is a valuable source of vitamin D and is present in meat in a highly absorbable form. Because vitamin D is a fat-soluble vitamin, higher quantities are found in meat with high levels of fat, compared with lean meat.

Vitamin B complex

Meat is a very important and relevant source of vitamin B, which are water-soluble vitamins, so the lean meat contains

higher amounts than meat fat does. Because they are temperature-sensitive, some losses of vitamin B occur during thermal processing, depending on the cooking temperature and method.

Vitamin B_1 (*thiamine*) It is an antineuritic factor and is present in meats, particularly in pork. Pork is actually the richest meat sources of thiamine (0.91 mg/100 g), compared with beef (0.04 mg) or lamb (0.12 mg). Vitamin B_1 is a cofactor for enzymes involved in the processes of converting lipids and carbohydrates to energy. Vitamin B_1 regulates the appetite process and the functions of the nervous system, promotes growth, and is very important for normal functioning of nerve tissue.

Vitamin B_2 (*riboflavin*) It is usually known as vitamin G and is a cofactor for enzymes involved in citric acid cycle (Krebs cycle), which is the key pathway in which carbohydrates, fats, and protein are metabolized, supplying energy to the organism. A deficiency of riboflavin reduces appetite, can cause anemia, and also impairs the conversion of tryptophan to niacin.

Vitamin B_3 (*nicotinic acid*) It is an essential human nutrient that has two sources in the diet: nicotinic acid (vitamin) and tryptophan (amino acid). Meat is considered the richest food source of vitamin B_3, and more than half of the niacin available from meat is provided by tryptophan. A high deficiency of dietary nicotinic acid causes pellagra – a disease characterized by diarrhea, dermatitis, and dementia, as well as hyperpigmentation, thickening of the skin, inflammation of the mouth and tongue associated with digestive disturbances, delirium, etc.

Vitamin B_5 (*pantothenic acid*) It has an important role in the metabolism of fats, being involved in energy production and sustaining the synthesis of steroid hormones. Organisms require vitamin B_5 to synthesize and metabolize fats, carbohydrates, and proteins and to synthesize coenzyme A. Pantothenic acid is an anti-gray hair factor.

Vitamin B_6 (*pyridoxine*) Meat is a valuable source of pyridoxine. Even though vitamin B_6 is also present in plants, it cannot be absorbed from some vegetables because of the abundance of glycosides that act as inhibitors to absorption. Vitamin B_6 also plays a role in red blood cell formation and converts fat to energy, contributing to supplying the body with fuel.

Vitamin B_{12} (*cobalamin*) It is produced as a result of bacterial fermentation in the gut and is an important parameter in the process of red blood cell formation and also in maintaining a normal central nervous system. A deficiency of vitamin B can favor the occurrence of megaloblastic anemia. It is recommended that vegans and vegetarians take supplements of vitamin B_{12}, since it has an exclusively animal origin. Elderly people have a very low capacity to absorb dietary vitamin B_{12}.

Mediterranean Diet

A Trichopoulou, Hellenic Health Foundation, Athens, Greece
E Vasilopoulou, Medical School, University of Athens, Athens, Greece

© 2016 Elsevier Ltd. All rights reserved.

Definition

The traditional Mediterranean diet (MD) is the diet prevailing until the early 1960s in the olive tree-growing areas of the Mediterranean basin. Until then and in spite of frequent violent disruptions, daily life and dietary habits in the Mediterranean region remained largely unchanged, and populations still applied simple and time-honored nutritional approaches. In the 1960s, however, the food industrial revolution, which was gradually expanding in Europe after the Second World War, finally reached the Southern European countries causing a serious disruption in the traditional dietary pattern of the Mediterranean populations.

The traditional MD is the heritage of millennia of exchanges of people, cultures, and foods of the countries around the Mediterranean basin. The succession of different dominant population groups introduced and/or contributed to the diffusion of different crops and foods. Some plants, like the olive tree, wheat, and the grapevine, have apparently been in this area since antiquity. Other plants, however, such as orange and lemon trees, as well as tomatoes, eggplants, corn, rice, and potatoes, were imported at different time periods. All of these, however, have found their way into the MD, which reflects a balanced ecosystem supported by the benevolent climate of this region.

The MD implies a common dietary pattern in Mediterranean countries; however, there are differences in the dietary patterns of the Mediterranean populations due to regional, cultural, and religious factors. However, in all of them, olive oil occupies a central position. It is therefore legitimate to consider these diets as variants of a single entity, the MD, which refers to dietary patterns found in olive-growing areas of the Mediterranean region until the 1960s. The traditional MD is characterized by high consumption of olive oil, vegetables, legumes, fruits, and unrefined cereals; regular but moderate wine intake, mostly during meals unless prohibited for religious purposes; moderate to high consumption of fish; low consumption of meat; and low to moderate intake of dairy products.

The word diet derives from the ancient Greek word 'diaita,' which implies equilibrium and lifestyle. Therefore, the traditional MD is more than just a diet; it is a whole lifestyle pattern with physical activity playing an integral role. This healthy lifestyle is also the consequence of the availability of local agricultural products, related to the geographic and climatic Mediterranean environment. A life-affirming aspect of the Mediterranean food culture is the central role of conviviality: the pleasure of sharing food with others and of celebrating communal culinary traditions and life at large. A notable point is wine consumption, which, except when prohibited on religious grounds, has been consumed in moderation in Mediterranean countries, almost always during meals and as a rule in the company of friends – the ancient Greek word 'symposium' means drinking in company, but with a connotation of intellectual interchange.

The MD was acknowledged by UNESCO in 2010 as an intangible cultural heritage with the following description:

> The Mediterranean diet constitutes a set of skills, knowledge, practices and traditions ranging from the landscape to the table, including the crops, harvesting, fishing, conservation, processing, preparation and, particularly, consumption of food. The Mediterranean diet is characterized by a nutritional model that has remained constant over time and space, consisting mainly of olive oil, cereals, fresh or dried fruit and vegetables, a moderate amount of fish, dairy and meat, and many condiments and spices, all accompanied by wine or infusions, always respecting beliefs of each community. However, the Mediterranean diet encompasses more than just food. It promotes social interaction, since communal meals are the cornerstone of social customs and festive events.

The traditional MD reflects as much the benign climate and the flora of the area, as the culture and the hardship of the people who were mostly responsible for the formulation of this diet.

Pictorial Presentation

The healthy traditional Mediterranean dietary pattern was popularized through a traditional Mediterranean diet pyramid (MDP) representation, which graphically highlights the foods to be consumed on a daily or weekly basis or less frequently. Throughout the years, various MDPs have been designed for different Mediterranean populations, tailored to their variable food habits.

After the recognition of the MD as an intangible cultural heritage of humanity, scientists have presented a consensual communication tool for the general public, health professionals, and other stakeholders. This is a pyramid with which scientists hope to contribute to a better adherence to this healthy dietary pattern and its way of life in the Mediterranean area countries and elsewhere. This graphic representation (Figure 1) provides guidance for the selection of foods, indicating the relative proportions and consumption frequency of servings of the various food groups.

Plant-origin foods are situated at the base of the pyramid. They provide key nutrients and fibers that contribute to general well-being, satiety, and the maintenance of a balanced diet and thus should be consumed in higher quantities and frequencies. This pyramid follows a standard pattern: at the base, foods that should sustain the diet and, at the upper levels, foods to be eaten in moderate to low amounts, such as those of animal origin and/or rich in sugars and saturated fats. Moreover, lifestyle elements characteristic of the Mediterranean way of life

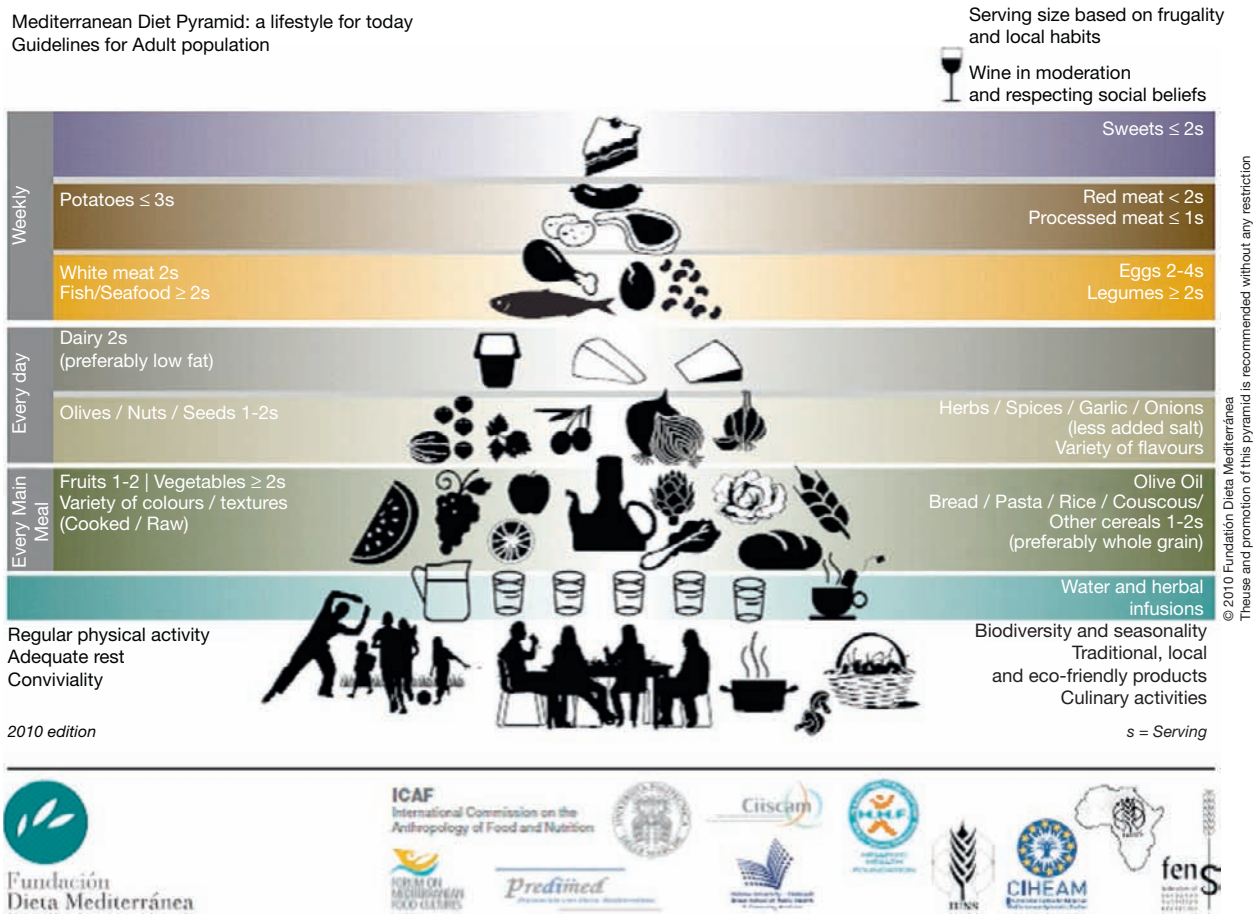

Figure 1 The new Mediterranean diet pyramid. Reproduced from Bach-Faig, A., Berry, M.E., Lairon, D., et al. (2011). Mediterranean diet pyramid today. Science and cultural updates. *Public Health Nutrition* **14**, 2274–2284.

are incorporated in the graphic design. So, it is about not only prioritizing some food groups from others but also paying attention to the way of selecting, cooking, and eating in addition to pointing to the composition and number of servings per meals. A balanced composition of the main meals should include vegetables and legumes (immersed on or cooked with olive oil) and fruits and whole-grain cereals, complemented with relatively lower intakes of dairy products and protein sources.

The MDP was conceived as a simplified main frame in order to be adapted to the different country-specific variations related to the various geographic, socioeconomic, and cultural contexts of the contemporary Mediterranean lifestyle. It addresses the healthy adult population and should be adapted to specific requirements in the case of children, pregnant women, and particular health circumstances.

In this graphic representation of the MD culture and lifestyle, elements are taken into account, such as conviviality, culinary activities, physical activity, and adequate rest, along with proportion and frequency recommendations of food consumption. These elements are stressed without omitting other items associated with the production, selection, processing, and consumption of foods, such as seasonality, biodiversity, and traditional, local, and eco-friendly products.

Health Effects

The MD addresses the paradox that although the people living in Mediterranean countries tend to consume relatively high amounts of total lipids, they have far lower rates of cardiovascular diseases than people in countries where similar levels of total lipid consumption are found. This implies that it may be the types of lipids consumed rather than the amount that adversely affect health, highlighting the beneficial role of extra virgin olive oil, generally consumed in Mediterranean countries. The MD was first considered in the pioneer Seven Countries Study as a low-saturated lipid diet that was conveying protection against coronary heart disease by lowering plasma cholesterol levels (the distinction between high-density lipoprotein cholesterol and low-density lipoprotein cholesterol was not known at that time). Over the years, however, the emphasis has shifted away from the low saturated lipid content of this diet towards its high content of olive oil and its overall composition. Moreover, the study of the MD expanded beyond its effects on coronary heart disease, to include possible effects on cancer occurrence and total mortality.

The MD is widely considered as a healthy dietary pattern, and a greater adherence to the MD has been associated with significant improvements in health and longevity. In 1995, a 9-fold

score was introduced to evaluate the adherence to the traditional MD, allowing the study of its possible health effects. The MD is characterized by high intake of (i) vegetables, (ii) legumes, (iii) fruits and nuts, (iv) minimally processed cereals, (v) moderately high intake of fish, (vi) high intake of monounsaturated lipids coupled with low intake of saturated fat, (vii) low-to-moderate intake of dairies, (viii) low intake of meat products, and (ix) regular but moderate intake of wine during meals. Adherence to a Mediterranean dietary pattern has been measured using this score with components reflecting intake of each dietary factor. The health beneficial components that are mostly consumed in the traditional MD (vegetables, legumes, fruits and nuts, wholegrain cereals, fish, and olive oil, as reflected in the ratio of monounsaturated-to-saturated lipids) were indexed positively, while the components less consumed and more typical of the Western-industrialized world (meat and dairy products) were negatively indexed. Several score variants have since been introduced and used in observational and some intervention studies to assess the relationship between conformity with the MD and various health outcomes, including total mortality, incidence of or mortality from coronary heart disease and stroke, and incidence of or mortality from cancer overall and from specific cancer sites. Indeed, numerous studies confirmed that closer adherence to the traditional MD is consistently associated with a markedly reduced risk of cardiovascular events and mortality, with a lower incidence of the metabolic syndrome and type 2 diabetes and certain types of cancer, and, eventually, increased longevity.

The diet that the Mediterranean populations developed many years ago, without any scientific input, appears to meet current dietary recommendations. Adherence to the MD may also provide the consumer with an adequate overall micronutrient supply including inorganic constituents, vitamins, and phytochemicals, thus meeting requirements for optimal health and functioning. Phytochemicals represent a common element in the typical foods of the MD, and an antioxidant action provides a plausible explanation for some of the health benefits. The variety and amount of phytochemicals taken with the consumption of primary and composite foods of the MD may provide better antiatherogenic properties than single phytochemicals.

Several studies, undertaken in both Mediterranean and other countries, have documented the superiority of the traditional MD, as an integral entity, in the prevention and supportive treatment of coronary heart disease, the prevention of certain malignant neoplasms, and, eventually, longevity and quality of life. The realization that the traditional MD is conducive to health and longevity went through several stages but reached a momentum during the last decade, following three scientific developments. In brief, these developments were the recognition that refined carbohydrates are inferior to unrefined ones, the documentation of the superiority of olive oil among the frequently used added lipids, and the successful operationalization of the traditional MD.

In conclusion, a diet that adheres to the principles of the traditional Mediterranean one is associated with better health and longer survival. Two elements distinguish the MD from other prudent diets. It stresses the pattern rather than individual components and provides no restriction on lipid intake, so long as lipids are not saturated and are preferably in the form of olive oil.

Sustainability and Mediterranean Traditional Foods

The MD has been acknowledged by the Food and Agriculture Organization of the United Nations (FAO) as an example of a sustainable diet in which nutrition, biodiversity, local food production, and local culture are closely interconnected.

> According to FAO:
>
> Sustainable Diets are those diets with low environmental impacts which contribute to food and nutrition security and to healthy life for present and future generations. Sustainable diets are protective and respectful of biodiversity and ecosystems, culturally acceptable, accessible, economically fair and affordable; nutritionally adequate, safe and health; while optimizing natural and human resources.

The traditional MD is considered as sustainable because it is inextricably linked to biodiversity: It includes a variety of food practices and food preparation techniques; its main food groups are beneficial to health; it reflects an adherence to culture and traditions; it instigates respect for seasonality; it contains foods less demanding in primary energy and has limited environmental impact, due to low consumption of animal products; and it involves pastoralism, with a favorable impact on carbon sequestration, as well as meat quality.

It is important to preserve the cultural heritage of the MD as an outstanding resource of sustainable development as it contributes to promoting local production and consumption, encourages sustainable agriculture, and safeguards landscapes. Sustainable food combines environmental conservation and community development through social and economic processes.

Based on a variety of diverse local foods, which are integral to the Mediterranean environment, the MD is still an underexplored resource for biodiversity and nutrition, in the context of food and nutrition security in the region. More than just a dietary pattern, it is a potential model for effective sustainable development in the Mediterranean basin. Environmental sustainability and biodiversity may also benefit from the perpetuation of Mediterranean traditional foods, which are generally prepared with local products.

Traditional foods are footprints of the past in the contemporary life of many population groups. Traditional foods reflect cultural inheritance and impose their imprints on the respective dietary patterns. The longevity associated with the MD could be partly attributed to Mediterranean traditional foods, which this diet incorporates. 'Traditional' characterize foods that have long been used by smaller or broader local societal groups, and their recipes have been perpetuated from generation to generation by word of mouth or in writing.

Traditional foods, apart from being vehicles of our culture, may also possess health qualities, since tradition rarely honors foods that are not palatable and healthy. Beneficial effects can be attributed to traditional foods that incorporate the knowledge and wisdom of past generations who, living under difficult conditions, have learned how to optimize use of locally

available ingredients in order to produce palatable foods and recipes with potential to preserve and improve human health.

Traditional foods are generally perceived as foods with beneficial properties, due also to their naturalness and local preparation, implying lack of massive industrial processing. To consider food products as traditional in a more systematic context, it is important to look at the traditionality of the raw materials, the formulation in terms of ingredients, total composition, and methods of production and/or processing. In early 2005, the EuroFIR scientific working group on traditional foods recognizing the lack, at the time, of a definition for traditional foods established a definition of the term 'traditional' in order to classify traditional foods in European food composition databases. The EuroFIR definition of traditional foods was later acknowledged by FAO. According to the EuroFIR definition,

'*Traditional*' means conforming to established practice or specifications prior to the Second World War. '*Traditional food*' is a food of a specific feature or features, which distinguish it clearly from other similar products of the same category in terms of the use of '*traditional ingredients*' (raw materials or primary products) or '*traditional composition*' or '*traditional type of production and/or processing method*.'

The selected time limit 'prior to the Second World War' implies 'prior to the era of mass food production,' and it delineates the period when populations still applied simple and time-honored approaches. This is before the introduction of technological innovations has substantially altered the food production processes. This food industrial revolution appeared earlier in Northern European countries than Southern European countries. Under this perspective, the time limit of the EuroFIR definition could be expressed as 'prior to the 1960s' when referring exclusively to European Mediterranean countries.

Mediterranean traditional foods are often rich sources of nutrients and bioactive compounds. Many of them have a high potential of meeting micronutrient requirements, while a great number of Mediterranean traditional foods have a high potential for nutrient function claims that fall within the scope of the recent European Commission regulation on nutrition and health claims made on foods.

Traditional foods, notably those from the Mediterranean area, have earned a reputation for their nutritional quality and should, therefore, be protected and supported. The MD is currently appreciated for its low environmental impact. It is considered as a model among the world's diets. Indeed, the MD not only does offer considerable health benefits but also respects the environment.

Microscopy: Light Microscopy and Histochemical Methods

E Jean-Marie, Université de Lyon, Lyon, France; Université Catholique de Lyon, Lyon, France; E.P.H.E., Lyon, France

© 2016 Elsevier Ltd. All rights reserved.

Techniques of microscopy are frequently used to understand the structure of both healthy and sick tissues and organs. More particularly, they are used for studying the digestive tract and aid the understanding of its physiology. These methods are used in medical research and in clinical studies in order to appreciate diseases in different organs such as the liver and more especially in different parts of the digestive tract (esophagus, stomach, and intestine). Methods used in microscopy are diversified and their principles are based upon chemical and physical principles.

A Brief History of Microscopy

The anatomy of animals and plants has been known for a long time. Representations of animals with very precise details have been discovered on cave walls. During several centuries, the observations were done with the naked eye only. In the seventeenth century, the invention of the microscope introduced a revolution in the methods of observation and permitted the discovery of the smallest living beings. The inventor of the microscope is not precisely known. Galileo (1564–1642) wrote that he used a 'telescope' to observe the smallest particles. Janssen (1588–1631) probably used a microscope. Hooke (1635–1703) built a microscope and observed cavities on a piece of cork he called 'cells.' Anton van Leeuwenhoek (1632–1723) also built and improved microscopes with which he observed pieces of plants, sperm (called worms), and pond water in which he found small organisms.

Microscopy then became more and more successful. Histology developed with fixation and embedding and staining allowing the understanding of tissue organization. The cell theory was developed in 1839 by Schleiden (1804–81) and Schwann (1810–82) explaining that each living organism is constituted by cells, and the theory was completed in 1858 by Virchow (1821–1902) who said that each cell came from another cell.

After the use of dyes to differentiate the parts of tissues, giving a general view, the methods of histochemistry based upon biochemical methods were adapted to histology in the first part of the twentieth century. Later, immunohistology used the antigen–antibody reaction in order to detect the precise molecules directly on the tissues. To date, the use of *in situ* hybridization permits the appreciation of the structure of DNA or the expression of genes (mRNAs). Automatic methods allow image analysis and quantification with the help of a computer.

The Light Microscope

The principle of the light microscope is based upon the image obtained after a light is crossed through a thin sample and submitted to a system of lenses. So, a light microscope consists of an optical system with a tube with lenses on each tip: the 'ocular' near the eye and the 'objective' near the sample. Generally, several objectives are available to perform small (4 or 10×), medium (40 or 50×), or high (100×) magnifications. In this last case, it is necessary to dump the objective into special oil in order to obtain a refractive index compatible with high magnifications. To obtain total magnification, one must multiply the magnification of objective with the ocular's one (generally 10×); so with an ocular with a magnification of 10× and an objective with a magnification of 50×, the result is 500×. A system producing light is situated under the preparation. The sample is placed on a stage and the lenses can be adjusted in order to obtain a sharp image of the object. A condenser under the sample is used to modify the light intensity and the contrast of the image (Figure 1).

The magnification is directly linked to resolution or resolving power defined as the smallest distance between two points at which they can be separately observed. Resolution is given by the formula:

$$d = 0.61\,\lambda/n\sin\alpha$$

where d is the resolution, λ the wavelength of light source, n the refractory index of the medium (air or oil), and α the aperture of beam.

Light microscopes are often equipped with a camera that can be linked to a computer in order to obtain photography or to perform image analysis.

In fluorescent microscopes, a steam lamp of mercury is used. In epifluorescence microscopes, the illumination is done over the object, exciting fluorescent dyes on the sections; consequently, a fluorescent light is emitted. Filters are used to choose the good wavelength in order to obtain the fluorescent image.

General Principles of Histology

To perform a histological study, tissues and cells must be submitted to a series of operations: fixation, dehydration, clarification, impregnation, embedding, sectioning, adhesion of sections on a slide, staining, dehydration, and mounting. Each step differs according to the nature of the results expected, tissue studied, and the technique used.

Tissue Fixation

All biological material can be visualized: histological sections, smears, karyotypes, and monolayer or suspension cell cultures. Fixation allows tissues to conserve a state as close as possible to the living one. But fixation must also allow the visualization of components by histological or histochemical methods. So, this process must preserve the tissue morphology in a recognizable

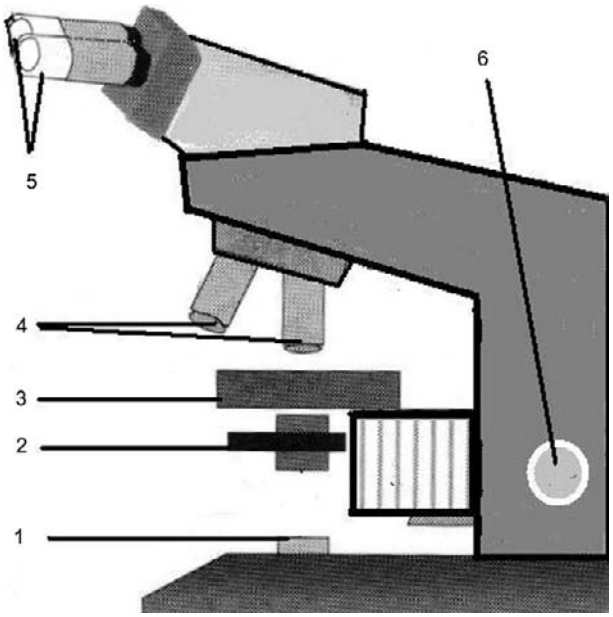

Figure 1 A light microscope; 1, light source; 2, condenser; 3, stage; 4, objective lenses; 5, ocular lenses; 6, screw used to focus.

form, without eliminating the components, and the fixative must not react with the atomic groups that will be used to visualize the structure.

Simple fixatives are constituted of only one molecule (i.e., ethanol or formalin). Composed fixatives are constituted by a mixture of simple fixatives. Some fixatives are denaturant of proteins, giving a reticulated aspect to the cytoplasm. Others are not denaturant and permit a homogeneous aspect of the cytoplasm. The effects of several simple fixatives are additive and fixative mixtures are most often used. The duration of fixation must be adapted to the thickness of the piece, and it is well variable: 24–48 h with Bouin's fluid, 4 h with Carnoy's fluid, and indefinitely with formalin.

Some methods are based on physical principles: fixation by cold between −20 °C and −40 °C and sections obtained with a freezing microtome (or cryotome). Cryodessication and freezing–dissolution combine several physical properties. It is often useful to store preserved tissues in holding fluids such as ethanol 70%, formalin, or butanol.

Embedding

Paraffin Embedding

Paraffin is hydrophobic, constituted of carbon and hydrogen with no functional group that can react with tissue molecules. Tissues are first dehydrated and immersed in a substance in which paraffin is soluble, such as toluene, xylene, or warm butanol. After this operation, tissue can become transparent. Tissue is then immersed for several hours in liquid paraffin maintained at a temperature between 50 and 65 °C, the fusion temperatures of paraffin used for histology. Then, it is immersed into liquid paraffin at room temperature in order to harden. When paraffin is solid, the organ can be cut with a microtome.

Other Embedding

Paraffin is not the alone means used for embedding. Paraplast, a mixture of paraffin and synthetic carbohydrates, is often used to obtain thinner sections than what are obtained with paraffin. Celloidin embedding has been widely used to study organs comprising both hard and smooth structures. Gelatin and resin embedding are also used.

Not only was resin embedding used primarily for electron microscopy, but also it can be used for light microscope. Blocks are particularly hard, allowing one to obtain semithin sections (0.5–1 μm) and to increase the precision of images. Epon and araldite are resins frequently used.

Histological study of calcified tissues can be done from decalcified preparations. Methyl methacrylate can be used to embed bones without decalcification, a useful method to appreciate osteoporosis.

Sections

Paraffin Sections

Paraffin blocks are put on the stage of a vertical microtome with a pair of clamps. The block is submitted to a vertical up-and-down motion. When it goes down, a section usually 5 μm thick is cut by a steel razor. The block then goes up behind the blade. Sections can be directly taken from the blade with a brush. Generally, the microtome movement is manipulated by hand but some microtomes are automatic. Horizontal microtomes can also be used.

Frozen Sections

Frozen sections are sometimes useful to detect lipids, for histoenzymology or immunohistology. They are obtained by the use of a cryotome, which is a vertical microtome installed in a cryostat that is a cooled chamber. The tissue is frozen and directly embedded in a wax that becomes solid at low temperatures. Sections are obtained like with a classic microtome for paraffin sections.

Adhesion of Sections

Several methods can be used to stick the paraffin sections on slides: sections can be stuck with water, glycerin, albumin, and gelatinous water or on gelatinized slides. Plastic wax sections are adhered with water. It is also possible to put the sections on distilled water and then water evaporates on a warming stage. Frozen sections are recovered directly from the blade by apposition of the slide, which has been refrigerated.

Staining

Before staining, paraffin must be eliminated from sections. Dewaxing is done with a solvent. But dyes being usually in water solution, sections must be rehydrated by putting slides in baths containing decreasing degrees of ethanol and finally water.

Dyes

Staining is a complex phenomenon concerned by chemical and physical factors, often not precisely known. Dyes are chemical substances able to permanently stain a tissue. Competition between dyes and blinding of one dye by another are also used.

A dye is a molecule with two chemical groups: the chromophore giving the color and the auxochrome required to fix the dye molecules on the tissue. Chromogens are colored because they possess a chromophore but they do not possess an auxochrome, and so, they cannot fix themselves on the tissues. If there is no auxochrome, a mordant, usually an aluminum salt, can be used to allow the fixation of the staining substance on the tissue. The tissue can be first submitted to the action of this molecule and then to the staining substance, or the mordant can be added to the staining solution. Lysochromes are dissolved into lipids that are stained.

In classic histology, there are acidic or basic dyes. But this terminology is not linked to the pH of the dye solution. Basic dyes are nuclear and acidic dyes are cytoplasmic (but cytoplasm can also be stained by acidic dye).

Dyes for Nucleus

Nuclear staining is performed with dyes having an animal or vegetal origin or being obtained by organic synthesis. They are not used in histochemistry for their mode of action is not well known and cannot be controlled.

Carmine, the only dye with an animal origin, was the first one used in histology. The staining molecule is carminic acid characterized by kinonic groups that are chromophores. Carmine is obtained by treating dry body extracts of a female Mexican cochineal with iron alum. Carmine is often replaced with azocarmine, a synthetic molecule.

Hematoxylin is extracted from *Haematoxylum campechianum*, a South American tree. It is not a dye by itself but hematein, its oxidation product with a kinonic group, presents chromophoric qualities. Therefore, hematoxylin must be oxidized before use. Hematein, which does not possess an auxochrome group, has no affinity for tissues and it is necessary to use a mordant, generally an aluminum salt, giving hemalum. Words 'hemalum,' 'hematein,' and 'hematoxylin' are often used interchangeably. Nuclear fast red is a synthetic dye.

Staining of Connective Tissue

The connective tissue is characterized by several cells synthesizing a matrix composed of a fundamental substance containing several molecules such as proteoglycans and several fibers such as collagen fibers; reticulin fibers, which are single fibers of collagen; and elastic fibers. In some organs , such as large arteries, elastic fibers are associated to form blades. Loose connective tissue, cartilage, and bone can be distinguished according to the nature of the fundamental substance, fibers, and cells.

In loose connective tissues, fibroblasts and fibrocytes synthesize both fundamental substance and fibers. Mastocytes synthesize some proteoglycans. Plasmocytes are characterized by the disposition of chromatin in a 'wheel-rays' fashion; they are migrating cells belonging to the immune system. Several macrophages and leucocytes are also found. Adipocytes stocking fats are grouped together but are separated from each other with fundamental substance and fibers. In the cartilage, chondroblasts and chondrocytes synthesize the fundamental substance containing chondroitin sulfuric acid and chondroitin sulfate salts. In the bone, fundamental substance contains calcium salts and more particularly hydroxyapatite giving the hardness to the bone. Osteoblasts and osteocytes are implicated in bone dynamics; osteoclasts are cells with several nuclei, devoted to the reduction of the bony matrix.

Methods used to visualize connective tissue concern essentially the fundamental substance and fibers. It is possible to stain fundamental substance with several dyes used in bichromic or trichromic reactions, giving a staining reaction with the connective tissue. In hemalum–eosin staining, the connective tissue is stained by eosin. Collagen is mainly composed of proteins and can be visualized in several manners. It is possible to use both acidophilic character and permeability of collagen fibers to visualize them on histological sections. In common methods such as hemalum–phloxine–saffron, saffron dissolved in ethanol gives a yellow coloration to collagen fibers (Figure 1). Methods using phosphomolybdic acid and/or aniline are based on fast green or aniline blue. In Masson's trichrome, azan staining, or still van Gieson's method, visualization is based upon the competition between two acidic dyes. Argyrophily (capacity to reduce silver salts) can give a staining of reticulin fibers, which are single fibers of collagen. Elastic fibers can be specifically visualized with orcein or paraldehyde fuchsin.

Stainings Often Used

With hemalum eosin, the nucleus is dark blue or brown-stained, while the acidophilic cytoplasm is pinkish. Some secretions such as the mucous of the stomach wall remain uncolored. Hemalum eosin staining yields quick results and it is very often used, but it is not sufficiently selective to visualize tissue components with a high precision.

Hemalum–phloxine–saffron method uses hemalum as a nuclear dye and phloxine as a cytoplasm one. Saffron is collagen-specific. The nuclei are blue-stained; the cytoplasm, muscle fibers, and red blood cells are red; and collagen is yellow. This staining is a standard method in pathological anatomy in several countries (Figure 2).

Trichrome

Masson's trichrome is a classical method of visualization with several variants. The nuclear dye can be Masson's hemalum or several hematoxylin solutions. The cytoplasmic dye is fuchsine. An aniline-derived dye allows the differentiation of collagen fibers (Figure 3). The nuclei are brownish blue; the cytoplasm is red; secretions are red or green; and the muscles and collagen fibers are green-stained if fast green or sulfo green (in Masson–Goldner's variant) is used and blue if aniline blue is used. This staining method yields good results for morphological studies because the different parts of the tissue are very well contrasted.

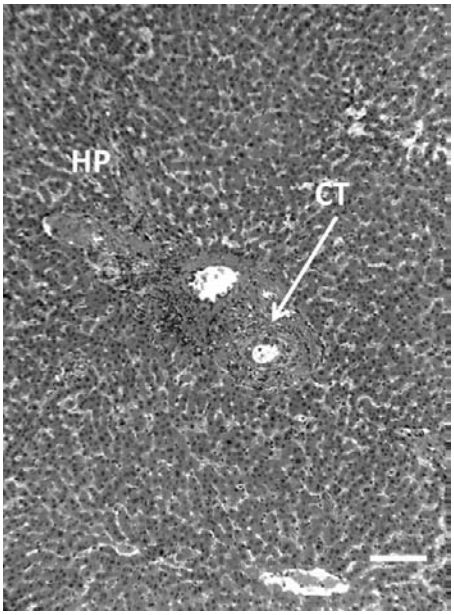

Figure 2 Section of liver stained with hematoxylin–phloxine–saffron; HP, hepatic parenchyma; CT, connective tissue. Bar = 100 μm.

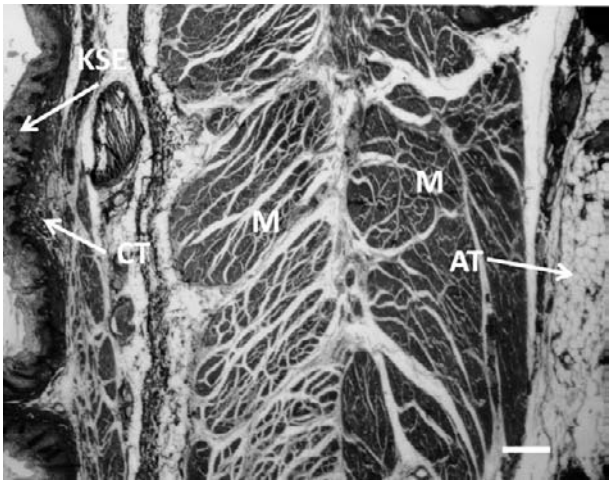

Figure 3 Section of amphibian skin stained with Masson's trichrome; KSE, keratinized stratified epithelium; CT, connective tissue; M, muscles; AT, adipose tissue. Bar = 100 μm.

Other trichromes are available, particularly Prenant's triple staining, Ramon y Cajal's trichrome, and Herlant's tetrachroma, or still one-time trichrome can be good methods for morphological studies. Cleveland and Wolfe's staining is useful to study the pituitary cells (Figure 4).

Staining with Azoic Dyes

Azocarmine and aniline are at the base of these types of staining. They allow several histological structures, particularly the chromatin repartition, to be visualized with great precision. After staining with Heidenhain's azan or Romeis's azan, the nuclei and certain cytoplasms are red-stained; other cytoplasms are yellow or gray. Collagen is blue-stained. Secretions can be different in function of their nature. Acid mucopolysaccharides are blue-stained. The nuclei are very well stained. If the protocol is well done, all details of chromatin can be observed.

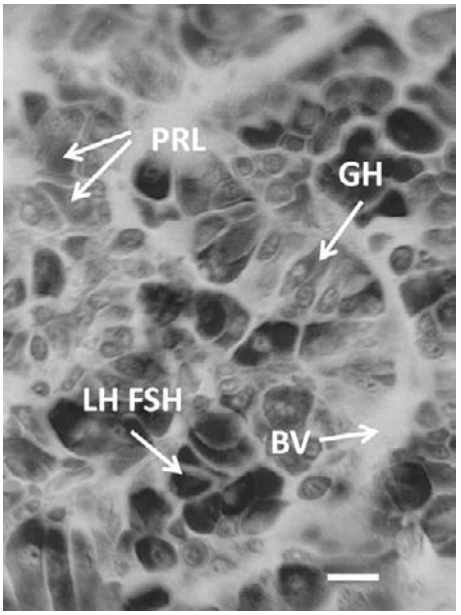

Figure 4 Staining of a section of amphibian pituitary with Cleveland and Wolfe's staining. BV, blood vessel; GH, somatotropic cells; LH–FSH, gonadotropic hormones; PRL, lactotropic cell. Bar = 5 μm.

Mounting Sections

After staining or histochemical reaction, sections are generally dehydrated and mounted with a hydrophobic medium. When staining can disappear after dehydration, a hydrophilic medium is directly used.

Histochemical Methods

The purpose of histochemistry is to visualize *in situ* the chemical components of cell and tissue structures. Sections are obtained according to the method previously described. Then, tissue components are visualized with several reactions based upon physical and histochemical properties. The reaction between the tissue or cell molecule and dye is known. The use of control methods allows to accurately measure if the staining obtained is specific.

Fixation

Fixatives used for histochemical investigations may be the classic fixatives described but it is indispensable to know if the fixative does not prevent the visualization of the researched molecule.

Characterization of the Chemical Nature of Structures

The visualization of the chemical nature of cell and tissue substances requires the use of chemical or physical methods. Two types of chemical methods can be used. The first allows visualization of a peculiar atom or atomic group. The second is used to visualize an atomic group that can belong to several different substances. Several methods based upon physical properties are also useful such as solubility, extraction, microincineration, and the use of polarized light.

Basophilic Staining

Basophilic components of tissues react with basic dyes. Acidophilic staining occurs when tissues react with an acidic dye. A basic dye is a salt, the cation of which is colored and not the anion. It is the contrary for an acidic dye. So, in basophilic staining, a colored cation reacts with the tissue, which becomes colored. In acidophilic staining, a colored anion reacts with the tissue, which becomes stained.

Metachromasy

A metachromatic dye visualizes a tissue by staining it with a color that is different from the color of the diluted dye solution. Variations of concentration or temperature modify the color of an aqueous solution of metachromatic dye. For example, solutions of toluidine blue are blue-colored at the concentrations usually used and become purple if concentration increases; the solution remains blue at high temperature but becomes red at low temperature. The color change is called metachromasy; the cell or tissue element is called the chromotrope. Chromotropic substances are mainly acidic mucopolysaccharides, nucleic acids, and silica particles.

Visualization or Reductive Groups

Several types of reactions based upon reductive properties of numerous substances are used for their detection. Reductive substances can act on ammonium silver nitrate to yield a black precipitate of reduced silver. In this argentaffin reaction, the tissue substance is the reagent. Other reactions are based on the visualization of an argentophilic tissue component by silver deposition. These reactions are silver impregnations, but they are not histochemical for the tissue does not react as a reagent. These silver impregnations are frequently used to visualize the nucleolus organizer (AgNOR method).Reductive groups can be visualized with other reducing reactions.

Visualization of Carbonyl Groups

Carbonyl groups are characteristic of aldehyde and ketone, and their visualization mainly groups several reactions used to visualize DNA with Feulgen and Rossenbeck's reaction or carbohydrates with periodic acid–Schiff (PAS) reaction.

Histochemistry of Carbohydrates

Carbohydrates are constituted with carbon, several hydroxyl chemical groups, and aldehyde or ketone groups. They are used for storage and distribution of energy. Fixation of tissues depends on the type of carbohydrate researched. Usually, classical fixators can be used.

Periodic Acid–Schiff

Carbohydrates are oxidized with periodic acid to give aldehyde functions that react with Schiff's reagent (sometimes called faded fuchsin) that gives a red staining to the sections (Figures 5 and 6). If glycogen is researched, its identification needs comparison between section with a normal reaction and sections that have been submitted to an enzymatic digestion with amylase. For other molecules, it is necessary to control the carbohydrate nature of PAS-positive substances and to submit sections to acetylation followed by saponification.

Acidic Carbohydrates Detection

These molecules, which are abundant in the intestine, possess carboxylic or sulfate acidic functions (Figure 7). They are metachromatic; they can also be visualized with alcian blue at different pH or with combined reactions such as alcian blue–PAS and alcian blue–alcian yellow at different pH.

Histochemistry of Proteins

For thirty years, immunohistochemical methods became the main means used to visualize proteins, so the classical methods were often abandoned. Nevertheless, some of these methods

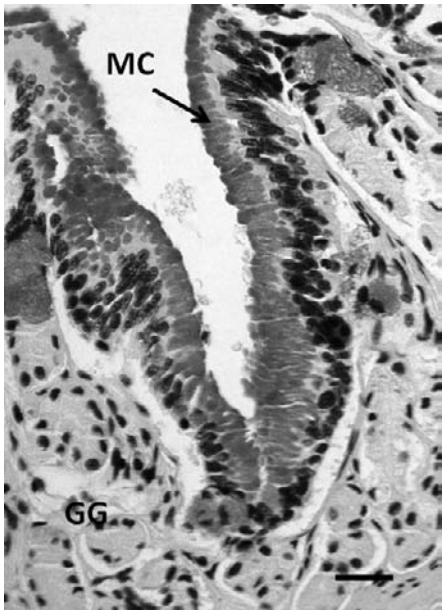

Figure 5 Visualization of mucous cells with PAS reaction on a section of amphibian stomach. MC, mucus cells; GG, gastric glands. Bar = 30 μm.

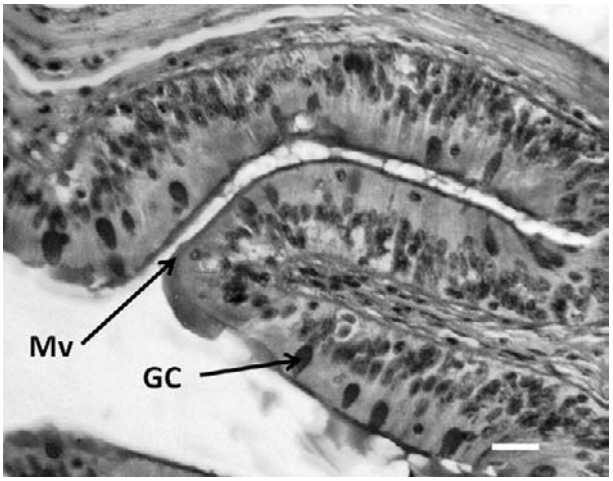

Figure 6 Visualization of PAS-positive goblet cells and mucus on the surface of amphibian intestine wall. GC, goblet cell; Mv, microvilli. Bar = 30 μm.

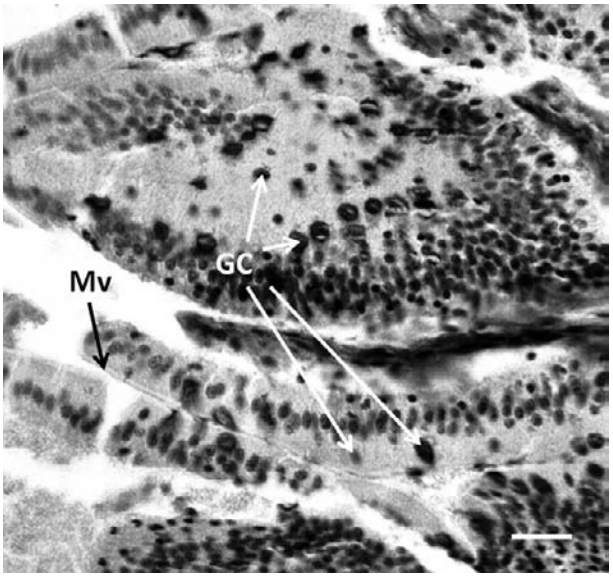

Figure 7 Visualization of goblet cells and mucus with alcian blue on the surface of amphibian intestine wall. GC, goblet cells; Mv, microvilli. Bar = 30 μm.

remain useful. All the current fixatives can be used to detect proteins, but it is always possible that the reactive functions of proteins can be modified with fixative action.

A lot of dyes used in classic histology, like eosin, phloxine, orange G, or Coomassie brilliant blue, can be considered as protein-specific. Danielli's tetrazoreaction is based on a double reaction. The first one consists of the combination of the tissue with a diazonium salt. The product is then combined with a naphthol (fast blue B or H acid), giving an intense brown color. Chloramine-T–Schiff method is based upon the oxidative deamination with the production of aldehydes that re-stained with Schiff's reagent. With ninhydrin–Schiff method, free amino acids are oxidized to give aldehydes that are visualized with Schiff's reagent.

Visualization of sulfhydryl proteins is based on the detection of thiols (R S H) and thioether (R S S R′). They can be useful in visualizing normal or pathological keratins, methionine, cysteine, and cystine particularly well distributed in the skin and rodent esophagus and cardia. Chevremont and Fredéric's method is based upon the reduction of ferricyanide with –SH groups giving a blue-colored ferric ferrocyanide also called 'Prussian blue.' With Barnett and Seligman's method, staining with D D D (2, 2′ dihydroxy-6, 6′ dinaphthyl disulfide) gives a blue staining of -SH chemical groups.

Histochemistry of Lipids

Lipids are fat components entering in the composition of cell membranes, they have storage and structural functions, and some of them are hormones. Lipids are stocked into adipocytes and they can be particularly abundant in hepatocytes in pathological liver.

Fixation and Tissue Preparation

Homophasic lipids are hydrophobic and physically isolated looking like droplets into the cytoplasm. Heterophasic lipids are associated with other components, giving them some hydrophilic properties.

A lot of lipids are soluble in organic solvents, so the use of organic and paraffin embedding is not possible. Consequently, if embedding is necessary, lipids must become insoluble with the use of chrome salt; frozen section can also be prepared. Contrarily, masked lipids are strongly bound to other molecules such as proteins or polysaccharides and must be demasked with the use of organic solvents, acids, proteolytic enzymes, and salt solutions.

Visualization

Physical methods such as polarization microscope can be used to study lipids. Staining methods for lipids with lysochromes such as red oil or Sudan black are often used. Nile blue sulfate allows the visualization of both neutral lipids that are pinkish-stained and acidic ones that are blue-stained. Osmium tetroxide can be used to visualize the unsaturated lipids.

Staining of Pigments

Some pigments, such as melanin, are observed in healthy and pathological tissues (the skin and liver); others are found in several pathological cases only. They can be visualized by direct observation or autofluorescence. Solubility in several solvents and whitening in oxidizing reagents are also used to characterize pigments. Several staining methods are also used. Melanin can be visualized by the reduction of a silver salt.

Staining of Biogenic Amines

Biogenic amines (adrenalin, noradrenalin, dopamine, serotonin, and histamine), implicated in various manners in the

organism, are secreted by endocrine cells such as enterochromaffin cells of the intestine or parietal cells of the stomach. Biogenic amines can also be used such as neurotransmitter. Staining method based on chromaffinity with the use of a mixture of potassium dichromate and potassium chromate gives a brown color to these cells.

Mineral Detection

Mineral elements are implicated in several ways: membrane polarization, nerve influx, intercellular cement, coenzyme factors, and contractility of the muscle. Minerals are important at low concentration, but an increased concentration can become lethal for the organism. So the presence of an increased amount of mineral elements can be the sign of a pathological state of the tissue.

General Principles of Mineral Visualization

Fixative must not bring mineral elements and not dissolve mineral elements out of sections. Microincineration is a technique consisting of burning the tissue, obtaining a spodogram on which only mineral elements are conserved such as ashes. With general staining methods, mineral elements can be visualized with colored reactions based on metal substitution, formation of colored lacquers, formation of complexes, and reactions of conversion. Several physical methods can be also used.

Visualization of Iron with Perls' Method

This method is used to detect iron in pathological organs such as the pancreas. The reaction is based upon a combination of potassium ferrocyanide, hydrochloric ferrocyanide, and iron of the tissue. Ferric iron appears blue-stained.

Visualization of Calcium: Stoelzner's Method

A heavy metal is substituted to calcium and then it precipitates to give a sulfide. Components containing calcium are black-stained. Results must be compared with decalcified sections.

Detection of Nucleic Acids

Structure of Nucleic Acids

DNA is characterized by a sugar, deoxyribose, associated to a nitrogenous base (a deoxynucleoside) and a molecule of phosphoric acid. Nucleoside and phosphate constitute a deoxyribonucleotide. Puric bases are adenine and guanine; pyrimidic bases are cytosine and thymine. The molecular structure of DNA is that of a double helix, composed of two molecular chains that are linked by nitrogenous bases. Adenine is always bound to thymine and cytosine to guanine. The histones, which are basic proteins, are bound to DNA contributing to its stability. RNA is characterized by a ribose associated with one nitrogenous base (ribonucleoside) and a phosphoric group. Ribonucleoside and phosphoric group constitute a ribonucleotide. Adenine is linked to uracil and guanine to cytosine.

Methods of Detection

Four types of methods can be performed to visualize nucleic acids. Detection of bases with ultraviolet spectrography (Caspersson's spectrophotometric method) and detection of pentose with tetrahydrofluorone are not frequently used. The detection of phosphoric acid can be performed with the use of basic dyes such as gallocyanin, methyl green for DNA, and pyronine for RNA or with Pappenheim–Unna's staining, that is, a combination of both these two stainings. Controls with RNase must be performed. Detection of the protein part can be performed with Danielli's tetrazoreaction after benzoylation or acetylation.

The Feulgen and Rossenbeck nuclear reaction consists of submitting DNA to an acidic hydrolysis that exclusively reacts with puric bases and deoxyribose binding, releasing aldehydes that are stained by Feulgen's reagent. The duration of the hydrolysis, depends on the nature of the fixative. Acidic fluids must be avoided for they induce the beginning of hydrolysis, and if hydrolysis is too strong, DNA degradation will continue, finishing with a total degradation of its molecule. It is possible to realize a Feulgen and Rossenbeck reaction on tissues preserved with very different fixatives, but it is necessary to modulate the duration of the hydrochloric acid action. Other methods based on the same principle can replace the original reaction. The difference is mainly linked to the methods used to visualize aldehydes such as thionine–SO_2 and azure A–SO_2, reacting like Schiff reagent. Silver salts can be reduced by the reducing group of aldehyde and metal silver deposits. The Feulgen and Rossenbeck method allows quantification.

Fluorescent Methods

Nucleic acids can be visualized by the use of fluorochromes. Intercalating fluorescent dyes such as orange acridine, ethidium chloride or bromide, and coriphosphine O are fixed between the two DNA strands or within a RNA loop. Feulgen–Schiff-like fluorescent dyes such as acriflavine or auromicine can be used on aldehyde functions obtained after DNA acidic hydrolysis. Fluorescent dyes react with specific base pairs. DAPI, DIPI, and Hoechst 33258 or Hoechst 33342 are intercalated between adenine and thymine. Chromomycin A3, mithramycin, or olivemycin intercalates between guanine and cytosine. Fluorescent staining is stoichiometric so quantification is possible. Visualization of X chromosome can be performed with quinacrine mustard on smears.

Enzyme Histochemistry or Histoenzymology

Enzyme histochemistry is used to demonstrate the activity of enzymes present on tissues. The visualization is based on the action of the enzyme on a specific substrate. Following this reaction, an insoluble product develops providing the location of enzyme. If the product is not stained, a metal precipitation technique or coupling with azoic dye and tetrazolium salt can be performed. Several types of enzymes can be visualized with these methods: alkaline phosphatase, acid phosphatase, ATPase, glucose-6-phosphatase, cholinesterase, acetyl cholinesterase, β-galactosidase, peroxidase, etc.

Preparation of the Tissue

Fixation

The choice of the fixative must be related to the enzyme searched. Activity of some enzymes such as phosphatases and hydrolytic enzymes can be correctly visualized after formaldehyde fixation. Yet an overfixation or exposition to high temperatures must be avoided. The enzyme histochemical reactions are often performed on frozen tissues avoiding inactivation by fixatives; the transfer in ethanol, which can alter the enzyme; and temperature used to melt paraffin, which can inhibit enzymatic activity. Nevertheless, for some enzymes, the paraffin with low melting point can be used.

Factors Influencing the Reaction

Enzymes can be inactivated by fixation or embedding and several factors could influence the success of the enzymatic reaction. The buffered medium must be at an optimal pH allowing the enzyme reaction; the substrate should be soluble in water or in the buffer solution.

Controls

Controls are necessary to monitor the success and the specificity of the reaction. Some mammal tissues can be used as positive controls.

Example: Alkaline Phosphatase

The activity of this enzyme can be visualized in the intestine by the use of Gomori's calcium method. Paraffin sections are incubated in a medium containing β-glycerophosphate salt; the product, phosphate, is captured with nitrate cobalt and then with ammonium sulfide. The presence of enzyme is finally visualized with a dark brownish precipitate. Alkaline phosphatase can also be visualized with sodium naphthyl phosphate and appears reddish.

Immunohistochemistry and *In Situ* Hybridization

The immunohistology is based upon both principles of immunology and histology. It is based upon a reaction between an antigen (corresponding to the researched molecule) and an antibody, a reagent prepared in an animal species. The tissue must be preserved in order to permit the reaction. Fixatives must not prevent the reaction, so they must not react with the functions used for the immunoreaction. In direct immunohistological method, a specific antibody of the researched component tagged with a fluorochrome or a molecule that can be stained is applied on the section. Finally, the researched molecule becomes labeled. In the indirect method, the first antibody prepared in the species 1 (e.g., a goat) is specific of the molecule researched. This antibody is then coupled to a second one, which can be visualized, prepared in a second species (e.g., a rabbit) directed against proteins of species in which the first one has been prepared (the goat). Finally, the molecule researched is visualized.

Visualization can be obtained with a fluorochrome, an enzyme whose activity has been revealed with a histoenzymology reaction. Several methods of amplification exist in order to ameliorate the visualization of the molecule researched.

Several cautions must be considered. It is essential to control specificity of the reaction and of the antibody.

In situ hybridization is a method used to visualize mRNAs in order to appreciate gene expression or to visualize the presence of genes in DNA to appreciate several displacements of genes in chromosomes. Methods of visualization resemble immunohistological ones.

Introduction

Milk is a nutritious food. Raw milk from healthy cows is supposed to contain relatively few bacteria. Drinking of raw milk of healthy cows reduces the health risk but it is highly perishable. In history, mankind has made various attempts to preserve and concentrate milk so as to extend its shelf life. Marco Polo in the thirteenth century reported that soldiers of Kublai Khan carried a dried milk on excursions. The belief is that part of the fat was removed from the milk before drying and dehydration was accomplished by solar heating. The first usable commercial production of milk powder (MP) was invented by the Russian chemist M. Dirchoff in 1832. In 1850, Birdseye concentrated milk with added sugar until a solid was obtained. In 1855, T. S. Grimwade filed a patent on process of drying of milk, though William Newton had patented a vacuum-drying process as early as 1837. The real beginning of the concentrated and dried dairy product industry began in the nineteenth century when Nicolas Appert, a French inventor, described his procedure for concentrating and drying milk. In 1909, Nicolas Appert developed dried milk in tablet form by air-drying of milk solids concentrated to a 'dough' consistency. During the second half of the nineteenth century, attempts were made to produce a dried milk, which involved the addition of other dry products to concentrated milk. Sugar, cereal products, and sodas, singly or in combinations, were added.

The MP is a perfect solution to those who lack immediate access to adequate refrigeration facilities. MP results from extracting water content out of milk. The main purpose of converting milk into MP is to convert the liquid perishable raw material to a product that can be stored without substantial loss of quality, preferably for some years. The MP has various applications in confectionaries, bakeries, infant formulas, nutritional foods, etc.

Production of MP has become an increasingly important segment of the dairy industry, which is expected to grow further because of its features such as better keeping quality, less storage space, and lower transportation costs, which result in attractive economics and convenience during industrial and domestic formulation of composite foods. Nonfat dry milk serves the same purpose for milk solids-not-fat that traditionally butter has done for milk fat. The ultimate aim of the industry is to obtain dry products, which if recombined with water give little or no evidence of detrimental change compared to the original liquid product. Various names have been applied to the same dry milk product. For example, nonfat dry milk also has been called skim MP (SMP), dried skim milk, nonfat dry milk solids, and dehydrated skim milk. Dry whole milk, dry cream, dry buttermilk, and others frequently are called dried or powdered whole milk, according to their identities.

Today, MP is usually made by spray-drying. Alternatively, the milk can be dried by drum (roller)-drying and freeze-drying. Freeze-drying preserves almost all the nutrients in milk but it is very expensive.

China, the United States, and France are the major markets for dried milk products. New Zealand is the largest exporter of MP. Even though the United States, Australia, Argentina, and European regions are the largest producers of MP, they do not fall in to the category of largest exporters. The United Kingdom, Germany, the Netherlands, and Brazil are the major importers of the MP.

Definition and Composition

The internationally agreed definition of the MP is "milk products which can be obtained by the partial removal of water from milk. The fat and/or protein content of the milk may have been adjusted, only to comply with the compositional requirements in Section 3 of Codex Standard, by the addition and/or withdrawal of milk constituents in such a way as not to alter the whey protein to casein ratio of the milk being adjusted."

The standard specifies that only milk and cream are permitted as raw materials for MP. However, the protein content of the powder may be decreased by addition of lactose or increased by addition of skim milk or partially skim milk or by addition of the retentate or permeate obtained from the treatment of milk by ultrafiltration (UF). The standard also lists other permitted additives from within the following groups: stabilizers, emulsifiers, acidity regulators, anticaking agents, and antioxidants. No other additives are sanctioned. Standards are also provided for thresholds for contaminants, production hygiene, and product labeling. The composition of different types of powder is depicted in Table 1.

Technology of MP Manufacture

The MPs are dairy products from which the water has been removed to the greatest extent possible, thus creating hurdles in the growth of microorganisms. Production of MP consists of the processing steps like reception, clarification, cooling and storage, standardization, heat treatment, evaporation, homogenization, drying, and packaging as shown in Figure 1.

Raw milk plays an important role in deciding the quality of MP. Milk should be of high chemical, sensory, and bacteriological quality. At reception point, chemical and bacteriological tests are carried out before selection of raw milk. High microbial load in raw milk adversely affects the solubility of MP. After reception, the milk may be clarified or treated in

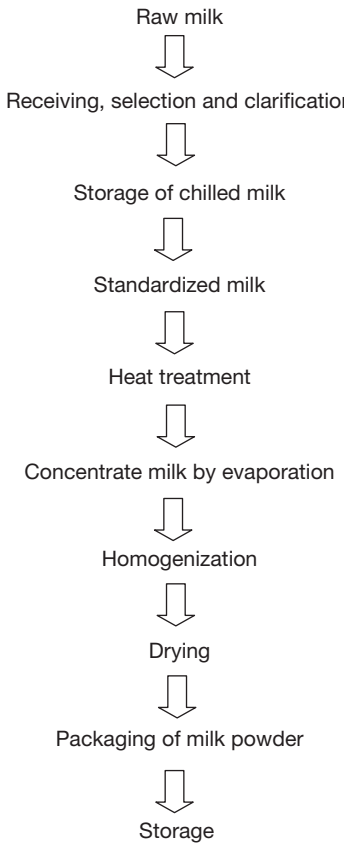

Figure 1 Generalized scheme for production of milk powder.

bactofuge to reduce the contamination by particulate matter and bacteria. Nowadays, microfiltration technique is used for manufacture of low-heat powders with very low bacterial loads. To avoid subsequent growth of psychotropic bacteria, clarified milk is stored under refrigeration until it ultimately heat-treated. Raw milk is standardized by adding calculated amount of skim milk or cream. Standardization of the protein content involves addition of either permeate from the UF of skim milk or retentate to reduce protein content, or retentate is added to increase the protein content.

The heat treatments eliminate all the pathogenic organisms. It also destroys saprophytic microorganisms, inactivates lipases, and activates SH groups of β-lactoglobulin, thus increasing resistance to autoxidation during storage. Milk is concentrated prior to drying; usually, a continuous multiple effect evaporator is used. The concentrate is not always homogenized, especially in the case of spray-dried powders. Homogenization of concentrated milk increases its viscosity, which leads to coarse droplets during atomization. The concentrated milk is generally dried by roller-drying or spray-drying method.

There have been attempts to develop completely new drying methods. However, only spray-drying and roller-drying methods are used for industrial production of MP. In the case of roller-drying, concentrated milk comes in direct contact with the hot drum surface, resulting in some irreversible changes such as caramelization of lactose, Maillard's browning, and denaturation of proteins, which decrease the solubility of the powder.

Spray-drying in the dairy industry dates back to around 1800, but it was not until 1850 that it became possible in major scale to dry milk. All processes, however, required addition of sugar, sulfuric acid, or alkali, so that the end product could not be considered pure. One of the first spray-drying patents was applied for in 1901 by the German Mr. Stauf, who sprayed the milk by nozzles into a chamber with warm air. The first real breakthrough, however, was in the United States in 1913, when the American Mr. Grey and the Dane Mr. Jensen developed a nozzle spray dryer and started to produce and sell drying installations on a commercial scale. The first rotary atomizer was developed by the German Mr. Kraus in 1912, but not until 1933, when the Danish engineer Mr. Nyrop filed his world patent, which was the real breakthrough of atomization. The basis for the modern MP industry, formed by these pioneers, has led to new developments, and the spray-drying equipment installed nowadays is in most cases very sophisticated and involves a highly technical and technological design. The feed is pumped from the product feed tank to the atomizing device, located in the air disperser at the top of the drying chamber. The drying air is drawn from the atmosphere via a filter by a supply fan and is passed through the air heater to the air disperser. The atomized droplets meet the hot air and the evaporation takes place, while cooling of the air happens simultaneously. After the spray is dried in the drying chamber, the majority of the dried product falls to the bottom of the chamber and enters a pneumatic conveying and cooling system. The fines, which are the particles with a small diameter, will remain in the air, and it is therefore necessary to pass the air through cyclones to separate them. The fines leave the cyclone at the bottom via a locking device and enter the

pneumatic system, too. The air passes from the cyclone to the atmosphere via the exhaust fan. The two fractions of powder are collected in the pneumatic system for conveying and cooling and are passed through a cyclone for separation, after which they are bagged off. The instrumentation comprises indication of the temperature of the inlet and outlet air, as well as automatic control of the inlet temperature by altering the steam pressure and amount of oil or gas to the air heater and automatic control of the outlet temperature by altering the amount of feed pumped to the atomizing device. The spray-drying process has become a highly acceptable method for drying milk. After drying, it is essential to cool the powder immediately to a temperature below the melting point of fat to maintain better flavor, body characteristics, and long shelf life.

The production of SMP slightly differs from the whole MP (WMP). Pasteurization is the most intensive heat treatment by low-temperature method to achieve the minimal detrimental heat-induced changes like serum protein denaturation. Homogenization is omitted and the milk can be concentrated to higher solid contents. Sometimes, vitamin A preparations are added by dry mixing. SMP is susceptible to humidity and heat-induced changes, which can intensify the adverse effect on the powder quality; therefore, it must be promptly cooled.

Powder should be packed in suitable containers that protect it from moisture, air, light, etc. Common wrappings are paper, multilayer boxes or bags with a polyethylene layer inside, metal barrels with polyethylene bags inside, or tins covered with aluminum foil at the contact surface. When planning the quantity of wrapping material, it is necessary to consider the bulk density of the product, because it is highly affected by processing parameters and techniques. When the product is intended for long storage, it is packaged in an atmosphere of inert gas, mostly nitrogen, or in a partial vacuum (4.0–5.3 KPa) to avoid oxidative changes of fat and other components. Properly produced and packed milk power, with low oxygen content, is stored at ambient temperature.

Instantization

Instant MP has better reconstitution properties than other MPs. The instantization process patented by Peebles significantly improved the quality and economical aspects of the drying technology. The principal purpose of instantizing is to improve the rate and completeness of reconstitutability of MP. The aim of spray-drying process is to produce particles with a big surface/mass ratio. The reconstitution of small particles of powder in water is, however, difficult and requires intensive mixing for their dispersion. One of the major objectives of new innovations in the area of spray- and fluid bed-drying is to produce instant powder by effecting agglomeration. Agglomeration provides the structure of porous aggregates, which disperse readily and quickly without vigorous agitation to produce stable reconstituted milk. The properties of dried products improved positively by the instantizing process include wettability, penetrability, sinkability, dispersibility, and dissolvability. The process permits a better equilibrium among these variables. An effective agglomeration is achieved by either rewet or straight-through methods: the rewet process, where the instantization is carried out after the powder is obtained in dry form, and the 'straight-through' process, where instantization is accomplished during drying.

Dry MP is the starting material for the rewetting procedure. The powder is dispersed in the wetting chamber and gains a water content of 5–10%, causing powder particle agglomeration. The agglomerated product is transferred to the vibrating fluid bed dryer and cooler, where it is redried in a hot air stream at 90–120 °C and immediately cooled to approximately 10 °C. The final product from the fluid bed dryer has a water content <4% (2–4%). Hot air, blown upward through the fine perforated plate of the fluid bed dryer, 'fluidizes' the powder and carries the smallest powder particles or fines to the cyclone, where separation takes place. The air is discharged into the atmosphere after heat and solids have been recovered and the fines are returned to the start of the process. Instantization process is complicated in the case of WMP as the surface of particles is covered with milk fat layer. Free fat forms a hydrophobic layer on the particle surfaces, impregnating them and decreasing their water-binding capability. In order to prevent this and improve the recombination properties, powder particles are lecithinated by adding lecithin mixed with butter oil during instantization. In this process, the powder is dried in two stages and the fines are recirculated to the wet zone. The lecithinated powder should be cooled and packed in a suitable material to protect the agglomerates from breaking down.

Properties of MP

The important properties of MP are particle size, shape and surface density, flowability, dissolution, insolubility, and whey protein nitrogen (WPN) index. These properties decide the quality and the suitability of MP in specific applications.

Particle Size

Particle size is an important physical property of MP and can relate to its appearance, reconstitution, and flow characteristics. Particle size in MP can affect powder reconstitution properties. Difference in particle size can lead to stratification of the powder with the higher solids concentrated at the top, which will affect reconstitution of the dry product. Wettability and dispersibility of MP can also be influenced by particle size. Dispersibility decreases as percentage of fine particles below 90 μm increases. Flowability also depends on particle size and shape. Large particles tend to flow more easily than smaller particles. Shape and size of the particles will affect the closeness of the particle pack, which in turn will affect the powder bulk density. The particle of MP generally consists of a continuous mass of amorphous lactose and other low-molar-mass components in which fat globules, casein micelles, and serum proteins are embedded. The particles also contain vacuoles of occluded air where particle surfaces are not in contact. The surface of spray-dried particles not only is usually smooth but also may be wrinkled. Conditions such as higher inlet air temperature and larger temperature differences between the hot air and powder particles may contribute to wrinkles. The presence of particles of different morphology in the same sample can be attributed to the different drying conditions to which the individual particles were exposed. Particle size can be

influenced by the milk characteristics, processing conditions, and the type of equipment used in the drying process. Atomization parameters influence product shape and size distribution of powder particles making it possible to control powder particle size. A spray-dried particle using centrifugal atomization will give a larger particle than the pressure nozzle atomization. Spray-dried powder particles usually are spherical with diameters in the range of 10–250 μm. Rapid dispersion requires a particle size of approximately 150–200 μm diameter. The particles in agglomerated MP are larger and irregular in shape and contain very few separate small particles. Agglomeration causes an increase in the amount of air incorporated between the powder particles. The air is replaced by water during reconstitution. Hence, the agglomerates are readily dispersed and dissolve quickly.

Density

Bulk density is a very complex product property for MP and is of great importance for economical and functional reasons. High bulk density is desirable for reducing shipping and packaging costs. On the other hand, low bulk density, as seen in agglomerated products, influences other powder properties such as flowability and instant characteristics. Bulk density is the weight of a volume unit of powder and is usually expressed in g/cm^3, kg/m^3, or g/100 ml. Bulk density is usually determined by measuring the volume of 100 g of powder in a 250 ml graduated cylinder after exposure to compaction by standardized tapping. The bulk density of nonfat dry milk has a wide range, from 0.18 to 1.25 $g\,ml^{-1}$. Regular spray-dried nonfat dry milk is approximately 0.50–0.60 $g\,ml^{-1}$, while roller-dried nonfat dry milk is 0.30–0.50 $g\,ml^{-1}$. The bulk density of the final powder is a result of particle density (occluded air and density of the solids) and the interstitial air. Bulk density can be influenced by many different factors, which include density of the solids, amount of air entrapped in the particles (occluded air) or the particle density, and amount of interstitial air (air between the particles). Occluded air is one of the most important factors for controlling bulk density.

Flowability

Flowability is the ability of a powder to flow freely without forming lumps or aggregates. It can be measured as the time necessary for a given volume of powder to leave a rotary drum. Flowability depends upon particle size and shape, density, and electrical charge. Larger particles flow more easily than smaller particles with a diameter of <90 μm. Flowability can considerably be improved by adding some inert very fine powders such as SiO_2, Na–Al–silicate, or $Ca_3\ (PO_4)_2$. Such additions are applied, for instance, in MP for coffee machines.

Dissolution

When dissolving MP in water, it is dispersed, implying that the powder particles will become fully wetted, which may take some time. Subsequently, the soluble components dissolve, and the colloidal particles (fat globules and casein micelles) become dispersed in the solution. This will take several minutes. Generally, a small part does not dissolve. After a solution is obtained, it may take about a day before its composition, especially the salt distribution, has more or less reached equilibrium. This process may be accelerated by heating the reconstituted milk to 50–60 °C and then cooling it again.

Insolubility

Insolubility can be estimated in various ways. The powder is dissolved in water under standardized conditions (concentration, temperature, and duration and intensity of stirring) and centrifuged. The supernatant is removed and replaced by water and is centrifuged again before reading the volume of insoluble residue. The result is called the insolubility index. In WMP, aggregates of coagulated protein with entrapped milk fat globules may float to the surface; the quantity involved usually is more than the sediment. Hence, the insolubility found closely depends on the method used.

Whey Protein Nitrogen Index

It measures the amount of heat treatment the powder has received during processing. Whey proteins are denatured or altered by heat. The test measures the amount of undenatured whey protein present in the powder. After application of low centrifugal forces under specified conditions, a high value indicates that the whey proteins are more soluble and product is therefore more soluble. WPN is expressed as milligram (mg) undenatured WPN per gram of nonfat MP with a moisture content of 3.16%. Casein and the heat-denatured whey proteins are removed by filtration after precipitation of the reconstituted milk with NaCl. The filtrate contains all undenatured whey proteins. By adding HCl, the proteins denature and develop turbidity depending on the concentration of the whey proteins. The turbidity is measured as percentage transmittance, in a spectrophotometer at a wavelength of 420 nm. By using the standard curve, this reading can be converted directly into milligram undenatured whey protein N/g powder (WPN).

Sensory Evaluation of MP

In order to determine the temperature sensitivity of a reaction, a Q10 model is often employed. This describes how much faster a reaction will go if the product is held at temperatures differing by 10 °C; Q10 models can be used to predict quality and nutrient loss, as well as shelf life of a product.

MPs, particularly SMP, are manufactured in large quantities in the flush season and subsequently used in lean period in reconstituted form to maintain milk supply. It has become an important export commodity. MP has been graded on the basis of bacterial, physicochemical, reconstitutional (i.e., when the powder is dispensed in water to prepare reconstituted milk), and organoleptic properties. These properties are basic elements of quality specifications. During drying, care should be taken to preserve the natural properties of the original raw milk. Evaluation of MP on the basis of its sensory characteristics plays an important role toward its consumer acceptance.

Desirable Attributes and Defects in MPs

Whole Milk Powder

Upon rehydration, WMP should have clean, rich, sweet, fresh, and pleasant flavor. Sensory defects may be due to use of either poor quality ingredients, manufacturing conditions, drying method, or abusive storage conditions. The development of storage-based defects in WMP is most difficult to control. This relatively rapid onset of off-flavors in WMP is primarily a function of the generation of lipid oxidation products. The product should be free-flowing to some extent with absence of lumps. The presence of hard lumps is a serious defect in WMP. The color of WMP depending on the source of fat varies from white to deep yellow. Tactile properties of WMP vary with the method of manufacture, degree of concentration, particle size, and porosity after drying. Spray-dried WMP may be extremely fine and uniform throughout, but two powder defects that may occasionally be noted are lumpy and caked. Some common quality defects encountered in WMP and their characteristics are the following.

Flavor defects

1. *Stale*: This is a characteristic age defect associated with protein. This defect closely resembles the musty flavor common to casein. This defect is observed in MP after storage for 9 months. When the defect is intense, it may be accompanied by a darkening of the product.
2. *Rancid*: Rancid WMP has bitter, soapy, unclean taste, which is persistent after the sample has been chewed up and spit out. The reason may be insufficient temperature used for fore warming and the lipase enzyme that remains active and causes rancidity.
3. *Oxidized/tallow*: It is the most troublesome flavor defect of WMP. Many factors are responsible for the development of this defect such as temperature, light, moisture, acidity, metallic salts, condensation, and type of packaging.
4. *Scorched*: This flavor is produced in products that have been subjected to excessive heat during the drying stage or have been permitted to remain in the drying chamber for too long period of time. It is usually accompanied by a large number of scorched specks in the product and sometimes by a dark discoloration typical of overheating.

Body and texture defects

1. *Lumpy*: A lumpy powder lacks homogeneity. This defect is found frequently in the spray process product. Lump formation is due to insufficient drying, dripping from spray nozzles, or exposure to moisture-laden air. Hard lumps ranging in size from a grain of wheat upward may be interspersed throughout.
2. *Caked*: Usually, this defect is not observed in WMP, but when it does occur, the product loses its powdery consistency and becomes a rock-like solid. When the mass is broken up, it remains in chunks, thus failing to return to the original powder state. This defect is serious since such milk solids have lost their sales value for human consumption.

Color defects

Normal dry whole milk is light yellow in color but varies reasonably with the color in the fat from a creamy white to a deep yellow:

1. *Browned or darkened*: When the defect is present, the normal creamy color has been replaced by a distinct brown. The defect is usually associated with an old, stale flavor.
2. *Scorched*: Discoloration due to browning of the milk solids is usually associated with the roller process. The powder may vary from light to dark brown.
3. *Lack of uniformity*: This defect may be due to either partial discoloration after packaging or partial scorching during the manufacturing.

Skim Milk Powder

The flavor of good quality SMP, when reconstituted, should be similar to that of fresh skim milk, that is, normally a flat taste because of practically no fat in it. Otherwise, the flavor is clean, sweet, and pleasant and may have a slightly cooked or heated perception. The common flavor defects of SMP are stale/storage, neutralizer, oxidized, and scorched. Instant SMP is usually quite granular, the product pours readily somewhat like that of corn meal. SMP prepared by spray-drying process is very fine, light, and dusty and has flow characteristics similar to the flow of corn meal. Scorched off-flavor is developed due to exposure of MP to abnormally high heat during processing. Cake formation is the most frequently occurring defect related to texture of SMP. Sometimes, the defect is so serious that the product looks as hard as a rock. The color of SMP should be uniform and showing complete absence of foreign specks, scorched particles, and browning. The product should have a creamy white or light yellow color.

Introduction

Milk is nutritious, appetizing, and nature's perfect food (except vitamin C, copper, and iron) and is recommended by nutritionists for development of sound body and consumed by all sectors of people. People suffering from lactose intolerance and old age are unable to digest milk, but can easily digest fermented foods like yogurt (as lactic acid bacteria converts lactose into lactic acid). Demand for milk was greater in developed countries as compared to developing countries, but the gap has narrowed due to an increase in urbanization, population, and consumption. Total production of milk up to 20 July 2014 was 5339.4 million liters, which is exhibiting an increasing trend from the previous year. Pasteurized milk and ultra-high temperature (UHT) milk market share in 2014 increased to 83.7% and 6.9% (in volume), respectively, as compared to 81.9% and 5.2% in 2013. India is the largest producer of milk with a total volume of 121.8 million tons followed by the United States and China.

One of the disadvantages associated with heating of milk is destruction of nutrients like water-soluble vitamins, but technological advancement and research have made it possible to prepare fortified milk or milk with added supplements. Milk is a perishable commodity, and being rich in nutrients it acts as the perfect substrate for growth of microflora, and to reduce this, different thermal and nonthermal techniques are implemented. Thermal treatments are the common techniques used for extending the shelf life of milk, for example pasteurization, sterilization, and UHT, but loss of nutrients is a concern associated with these treatments. Nonthermal treatments like high-pressure processing (HPP), pulse electric field, ultrasonication, and irradiation are also explored to process milk to minimize the loss of nutrients as compared to thermal treatment. Postprocess contamination is a major factor that can affect the shelf life of milk, and to maintain the product, safe packaging plays an important role when the milk and milk products are stored at refrigeration or ambient temperature. Aseptic packaging of milk when used in combination with high temperature can considerably extend shelf life of milk for more than 6 months at room temperature.

Types of Products

With judicious preservation technique and by harnessing the potential of milk into different types of products, milk could be made available year-round in those sectors where it is not being produced or during the lean season. Different types of liquid milk include pasteurized milk, sterilized milk, homogenized milk, and special milk. Special milk includes whole milk, standardized milk, soft curd milk, flavored milk, vitaminized/irradiated milk, fermented milk (natural buttermilk, cultured buttermilk, acidophilus milk, kumis, and kefir), reconstituted/rehydrated milk, recombined milk, soya milk, toned, double toned milk, filled milk, and imitation milk that are generally pasteurized or UHT treated (Figure 1). Standardized milk, toned and double toned are those milks in which standardization of fat and solid not fat (SNF) content are done by addition or removal of cream. Fermented milks are categorized depending on inoculation of different cultures of bacteria for example *Lactobacillus bulgaricus*, *Streptococcus thermophilus*, and *Streptococcus lactis*. Flavored milk is prepared by incorporated flavors like chocolate, strawberry, mango, butterscotch, and vanilla along with fruit pulps, cocoa powder, sugar, permitted color, and stabilizers followed by sterilization/UHT treatment. Milk products available in the market include cream, butter, butter oil, ice cream, cheese, powdered milk, and condensed milk. Manufacturing of milk products varies worldwide as a consequence of traditional practices, different dietary habits, and social, cultural, and religious dissimilarities. Market milk is available in different packaging materials including glass containers, PET (polyethylene terephthalate) bottles, tetra packs, and high-density polyethylene (HDPE) laminate pouches. In the dairy market, liquid milk (54%) occupies the largest segment followed by ghee, yogurt, and whiteners 14%, 8%, and 4%, respectively.

Collection and Storage of Raw Milk

Previously milk was collected by small-scale dairies directly from nearby farms so there was no critical requirement of chilling centers. However, with an increase in distance between collection and processing, large dairy processing units required chilling centers, as on many occasions it took 3 days for transportation from distant places. Milk can be collected directly from producers, through cooperative societies, or by the chilling centers. If the processing plant or dairy is near a village/town, then farmers individually can contact processors on a daily basis. Sometimes a middleman is also involved for transporting raw milk from villagers to the dairy using cans on rickshaw, bike, and so on. A cooperative society is formed by a group of persons at the village level. They do not ensure to take milk on daily basis and can deny on various grounds.

The milk is procured either on a weight or a volume basis, and payment is made on the basis of percentage of fat, SNF, and other quality attributes. Generally cans, insulated tankers, trucks, or rail tankers are used as a means to transport milk to a processing plant. At a chilling center the milk is usually stored at a temperature below 5 °C in insulated tanks/silos, and the cooling of milk can be achieved by implementing techniques like can immersion, in-can cooling, rotor freeze, bulk milk cooler, plate chiller, tubular cooler, brine cooling, and ice cooling. Milk storage

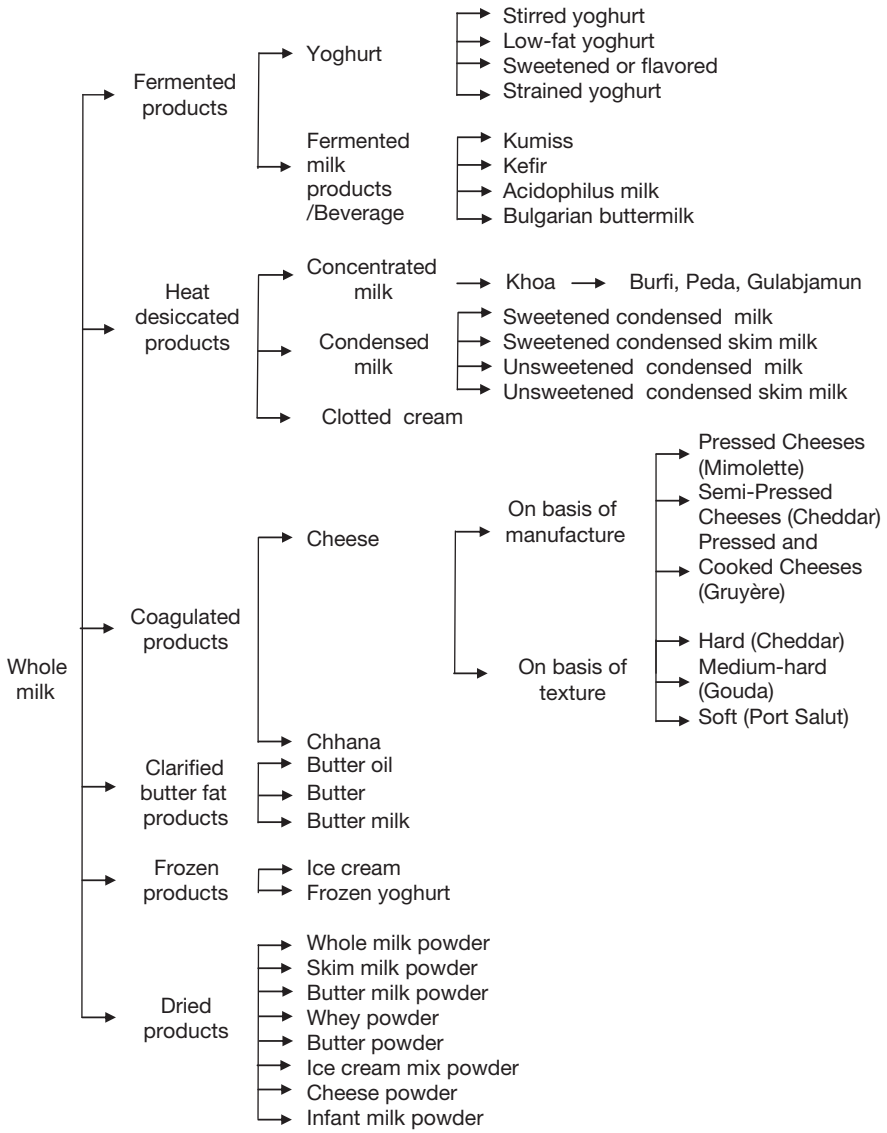

Figure 1 Milk and milk products.

temperature is generally kept low, as it will minimize the bacterial growth and thereby avoid milk spoilage, which is very high if the milk is stored at 30–40 °C, as it is the optimum growth temperature for most of the microorganisms present in milk.

Quality assessment is the foremost requirement as soon as the milk is received. It includes a platform test like organoleptic (taste, smell, and visual), temperature, clot on boiling (COB), sediment test, neutralizer test, and alcohol-alizarin test, which are performed on the dock itself and are indicators of the quality of the milk. Based on the results of platform tests, a decision is taken to accept or reject the milk. After acceptance of the milk, tests are further conducted in a laboratory that will include determination of fat, SNF, acidity, methylene blue reduction test (MBRT), microbial counts (direct microscopic, standard plate count, and presumptive coliform test), and tests for adulterants that ensure the quality of raw milk. Milk is further pumped into large storage insulated tanks (silos) in which milk is stored at temperature less than 4 °C until it is further pasteurized or sterilized, depending on the requirement.

Standardization

Standardization involves adjustment of the fat/SNF content of milk, or a milk product, by addition of cream or skim milk as appropriate to obtain a given fat/SNF content. Generally raw milk is standardized before processing, and it also depends on regulatory authorities, as standardization is not allowed in some countries. Depending on scale of automation in the dairy, either direct inline or batch standardization can be carried out. Milk products that are utilized for adjusting fat in milk include cream, butter oil, and whole milk powder, and for increasing the SNF content skim milk powder is often used.

Preservation Techniques

Because milk is a rich source of nutrients, it is susceptible to growth of microorganisms if not processed or stored at a low temperature. Second, to meet the demand of the urban population and to supply the milk in the lean season, milk needs to

be dried and stored in the flush season. With the growing demand for milk and milk products and changing lifestyles, it is necessary to increase the shelf life of the milk not only by days or months but up to years while maintaining the nutrients present. Extension of shelf life can be achieved by implementing one of these techniques: lowering the temperature (chilling, freezing), heat treatment (pasteurization, sterilization, UHT), removal of moisture by concentrating (evaporation, drying, sweetening, or salting), modified atmosphere (removal of oxygen), or microfluidization and cold pasteurization techniques (HPP, pulse electric field, oscillating magnetic field and irradiation; Figure 2).

Pasteurization

Louis Pasteur in 1860 demonstrated that heat treatment (50–60 °C) killed most of the spoilage microorganisms in fruit juices. In the case of milk, pasteurization means treating every particle of milk with a time–temperature combination effective to destroy bacteria (*Mycobacterium tuberculosis*, *Coxiellaburnetii* and *Listeria monocytogenes* as indicator) without altering nutritional status, as well as color and flavor. At the industrial level batch pasteurization or low temperature for longer time (LTLT) and high temperature for short time (HTST) are carried out at 63 °C for 30 min and 72 °C for 15 s, respectively, which is immediately followed by cooling to 5 °C or below. LTLT involves a water jacketed vat, waterspray, or a coil vat pasteurizer. LTLT has benefit of low equipment cost, but the energy and labor requirement is high compared to HTST. LTLT impairs creaming properties due to excessive agitation that leads to churning. The HTST pasteurizer provides a continuous flow of milk, occupies less floor area, uses automation (clean-in-place [CIP] cleaning), and requires low operating cost (effective regeneration). Other time–temperature combinations are 89, 90, 94, and100 °C for 1, 0.5, 0.1, and 0.01 s, respectively (US code of federal regulation). Regeneration allows heating of incoming milk and cooling of outgoing milk, where 80% of pasteurization temperature is achieved and 94–95% of heat from the outgoing milk is recovered.

In HTST, plates are generally used for exchanging the heat and are made of stainless steel (SS type 320) of 0.8–2.0 gauge with a gap of 2.5–4.0 mm between two consecutive plates. Apart from the fact that copper has an excellent heat transferring capacity of 218 BTU h^{-1} ft^{-1} F^{-1} as compared to stainless steel (10 BTU h^{-1} ft^{-1} F^{-1}), it is not used in fabrication of plates as it may produce off flavor by catalyzing the oxidation of milk fat. The heating medium used for heating of milk may be steam or hot water, and for cooling of milk, glycol, brine, water, or ice water can be used. Capacity of the dairy plant using plate heat exchanger can be as high as 1 00 000 L h^{-1}, which can be adjusted by increasing or decreasing the size of

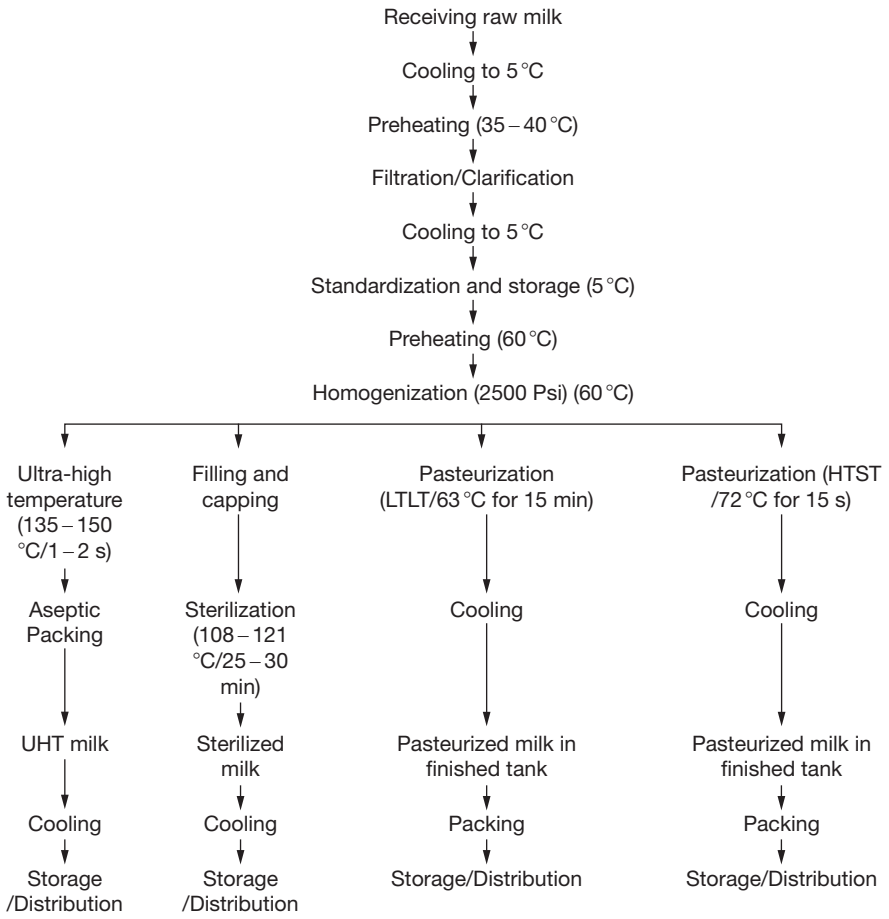

Figure 2 A flowsheet for the manufacture of pasteurized liquid milk, sterilized milk, and UHT milk.

the plate and the number of plates. In the plate heat exchanger, the heat of the pasteurized milk is utilized to warm the incoming cold milk that is simultaneously precooled. This in turn saves the cost of heating and refrigeration, and this capacity of the plate exchanger is called regenerative heat exchange or, more commonly, heat recovery. The regeneration section is divided into different subsections with the help of a block, and these blocks are further connected to processes like homogenization, clarification, microfiltration, and separation. Shell and tube heat exchangers are used for pasteurization of highly viscous products like cream, and an added advantage of shell and tube heat exchanger over plate heat exchanger is of low maintenance.

UHT

UHT processing of milk involves heating milk in a continuous process to temperatures higher than 135 °C for a few seconds, cooling rapidly, and aseptically packaging in the milk into sterile containers. UHT treatment must be sufficient to produce a commercially sterile product in which bacterial growth will not occur under normal storage conditions, but not severe enough to cause chemical changes that result in an unacceptable flavor, color, and nutritive loss. In general, the heating should be equivalent to a minimum of 9 log reduction of thermophilic spores (referred to as a B^* value, >1) and a maximum reduction of 3% in the level of thiamine (referred to as a C^* value, <1). UHT was invented in 1960, and UHT-treated milk was commercially available in 1970 with an objective to reduce nutritional loss caused by in-container sterilization. UHT-treated milk is generally packed in paperboard made of six different layers. A polyethylene layer is used for sealing in the milk and also acts as a moisture barrier; aluminum foil acts as an oxygen barrier and protects from off-flavors and light. UHT-treated and aseptically packed milk can have a long shelf life extending up to 6 or even 9 months without any preservatives at ambient temperature. The disadvantage associated with UHT treatment of milk is that in many instances the milk appears to have a cooked taste with a slight to dark brown color that may be due to Maillard browning. Development of sulfurous flavor is also associated with UHT milk, which is developed on thermal treatment as a result of unfolding of whey proteins. Milk with a high preprocessing microbial count is more susceptible to gel formation than milk with a low count. Microorganisms that produce heat-stable enzymes cause the most serious gelation problems. Longer refrigeration times prior to sterilization allow increased growth of psychotropic microorganisms and concomitant production of heat-stable enzymes, especially proteinases and lipases.

Two main types of UHT processes are used commercially: direct heating, in which milk comes into direct contact with the heating medium, that is, steam; and indirect heating, in which the heating medium, steam or superheated water, is separated from the milk by a stainless steel plate or wall of a tube. In direct systems, heating to the specified temperature and cooling from the high temperature is very fast due to transfer of the latent heats of condensation and evaporation, respectively, between the steam and liquid milk. A plate heat exchanger used in UHT processing is able to withstand high temperature and internal pressure as compared to a pasteurizer. A plate heat exchanger provides more surface area for heat transfer, low cost, and simple design. Tubular heat exchangers are more commonly used for thick liquids; do not need to acquire an aseptic homogenizer, as they can withstand 200–300 bar pressure required during homogenization; and by employing homogenizer valve will serve the purpose as a source of contamination in a homogenization pump thus eliminating the requirement of a pump. The rate of fouling of tubular heat exchangers is less as compared to a plate heat exchanger that has narrow channels for milk flow. Cooling to around 20 °C is achieved in a vacuum chamber. Direct heating requires sterilization temperatures 3–4 °C higher than indirect heating to achieve an equal sterilization effect because of the greater heat input during the heat-up phase of indirect heating. As compared to direct heating systems, indirect systems have a low heat transfer rate and a higher rate of deposition over the surface that requires frequent cleaning, but less processing and operational cost (less pumps and accessories, regeneration of energy) and require less controls. To exploit the benefits of direct as well as indirect processes, systems using a combination of direct and indirect heating are available commercially (e.g., the High-Heat Infusion system of APV88 and the Tetra Therm Aseptic Plus Two system of Tetra Pak). These achieve better energy economy than conventional direct systems (due to greater heat regeneration) and cause less chemical damage, especially flavor change, than conventional indirect UHT systems. Some of the adversely affected nutrient components in milk after UHT treatment are ascorbic acid, folacin, vitamin B_{12}, vitamin B_6, thiamine, and riboflavin up to an extent of 15–25%, 10–20%, 0–30%, 0–10%, <10–18%, 0–10%, respectively. Fat-soluble vitamins, proteins, and amino acids are affected to a much lesser extent.

Sterilization

In-can sterilization of milk is usually carried out above 100 °C with a time–temperature combination of 121 °C for 15 min at 15 psi. The sterilization process may be a batch (autoclaves) or continuous process (vertical hydrostatic towers or horizontal sterilizers) and can be carried out in either cans or glass bottles, which are prefilled and hermetically sealed.

Sterilization effect is achieved by using hot water or saturated steam, which transfers the heat to milk and milk products through the walls of the container. The main objective of sterilization is to kill vegetative cells and endospores or reduction of 12 log cycles (12 D reduction) of *Clostridium botulinum* by using a suitable time–temperature combination. The fact that sterilization takes place after bottling eliminates the need for aseptic handling, but on the other hand, heat-resistant packaging materials must be used. Sterilized milk usually has a creamy appearance and an extended shelf life of more than 6 months as compared to a few days for pasteurized milk. Rendering milk to high temperature with a long holding time often results in burnt flavor and brown color, which may be a result of the Maillard reaction. Popularity and consumption of sterilized milk declined after introduction of UHT processed milk. Nutrient loss is a major concern associated with sterilization, as it is reported by various scientists that almost 50% of vitamin C and 30–40% of thiamine and vitamin B_{12} are lost, but

components like vitamin A, riboflavin, carotene, and nicotinic acid remain unaffected.

Homogenization and Microfluidization

Homogenization of milk has become a standard process that is applied as a means of stabilizing the fat emulsion against gravity separation. Gaulin, who invented the process in 1899, described it in French as 'fixer la composition des liquides.' Homogenization is carried out by using a homogenizer that pumps the milk under pressure through an orifice of 0.1 nm to disintegrate the fat globules to less than 2 μm. The disintegration of the milk fat globules is achieved by a combination of contributing factors such as turbulence and cavitation that do not allow visible cream separation in milk and also increase the mouthfeel, color, and digestibility. Homogenizers used in the milk industry are either single-stage or two-stage, depending on the number of homogenizing devices. Single-stage homogenization is used to homogenize products with a high viscosity, whereas two-stage homogenization is applied for products with a high fat content or where high homogenization efficiency is desired. Homogenization temperatures normally applied are 60–70 °C, and homogenization pressure is between 10 and 25 MPa (100–250 bar), depending on the product. In a two-stage homogenization, pressure of 2000 psi and 500 psi is applied at the first stage and second stage, respectively. Pressure at the first stage reduces fat globules size and increases viscosity, whereas a second stage is used to prevent fat cluster reformation. The purpose of homogenization of milk is to stabilize the milk fat emulsion, as during storage and distribution a creamy layer appears at the top surface as a result of separation under gravitational force. Homogenized milk cannot be efficiently separated and also on many occasions it leads to development of sunlight flavor. Moreover, the homogenized milk is also reported to have low heat stability, and also the milk is not suitable for production of semihard and hard variants of cheese, as the coagulum formed will be too soft, which will make it vulnerable during dewatering. Homogenized milk is more sensitive to light and enzymatic activity of lipase, so pre-heat treatment is recommended before homogenization of milk to inactivate lipase.

Microfluidization is a novel technique, using high pressure up to 241 MPa by combining high velocity, shear, turbulence, and collision inside the chamber for a short duration of 5 s to obtain high-quality products by breaking down large particles. It is a continuous process that has a chamber for fluid flow, in which pressure stream is forcibly directed to flow into two different fine orifices. At the point of intersection, both splited microstreams clash into each other at high speed, resulting in the reduction of large-size particles to very small sizes. Breakdown into fine particles inside the interaction chamber occurs due to high speed, high shear, cavitation, air compression, and coerces of the microstreams. The milk obtained after microfluidization is more homogenized and viscous when compared with commercially available homogenized milk using a two-stage homogenizer. Microfluidized milk, when used for cheese preparation, can improve textural and melting characteristics and also lower the microbial population. Yogurt prepared from homogenized milk was comparable to low-fat (1.5%) microfluidized yogurt in terms of texture profile and water retention property. Some of the characteristics associated with microfluidization include chances of contamination, hard to scale up the production rate, loss of product, and encapsulated material structure due to high shear and striking coerces during microfluidization.

Novel Nonthermal Milk Processing Techniques

Consumers prefer products that are minimally processed; have natural aroma, fresh taste, and no additives; are stable; are convenient to use; and are microbiologically safe. Although thermal processing (heating or cooling operation) maintains safety of food, it adversely affects nutritional value. However irradiation, pulse electric field, and HPP are alternatives to traditional thermal processing. Technologies such as ohmic heating, dielectric heating (which includes microwave heating and radio-frequency heating), and inductive heating have been developed that can replace, at least partially, the traditional heating methods that rely essentially on conductive, convective, and radiative heat transfer. They all have a common feature: heat is generated directly inside the food and this has direct implications in terms of both energetic and heating efficiency. Among these nonthermal techniques, HPP of milk is well studied although other techniques has attracted little attention and commercial application but has considerable potent future.

- **High Pressure Processing**

HPP is a technique that involves the application of pressure in the range of 100–900 MPa, which is instantaneously and uniformly transmitted throughout the product irrespective of its size and shape. The principle of HPP is based on Le Chatelier's principle (with increase in pressure, decrease in volume occurs) and isostatic transfer (uniform transmission of pressure in all sides). Pressure of 300–600 MPa breaks ionic and electrostatic bonds but does not disrupt covalent bonds. HPP processing of milk usually has least effect on color, flavor, and nutritional value, but is effective enough to reduce microbial load as well to enhance rennet or acid coagulation of milk. Milk processed at a pressure of 600 MPa was found to enhance the shelf life of milk by reducing the microbial population, and factors that govern the microbial reduction are duration of exposure and target species, as well as composition. Microbial quality of HPP (400–600) treated raw milk was found to be comparable with pasteurized milk (72 °C for 15 s), and treatment at 400 MPa for 15 min and 600 MPa for 3 min is effective enough to increase the shelf life at 10 and 20°C, respectively, for 10 days.

- **Pulse Electric Field (PEF)**

PEF has proven to have a potential for increasing the milk shelf life, as it is highly applicable to liquids. PEF had shown minimal effects on the nutritional, flavor, and functional characteristics of milk and also has an ability to inactivate microorganisms. PEF is based on the application of pulses of high voltage (typically 20–80 kV cm^{-1}) delivered to the product placed between a set of electrodes that confine the treatment gap of the PEF chamber. The process can be conducted at ambient temperature for a fraction of second, and energy loss due to the heating of foods is minimized. Preservation of milk and fluid dairy products seems to be one of the main market

niches for PEF technology because it is mainly intended for preservation of pumpable fluid or semifluid foods. When self-inoculated (*Salmonella*) milk was treated with PEF (36.7 kV cm^{-1} and 40 pulses, 25 min) and stored at 7–9 °C for 8 days, the level of *Salmonella* was below detection limit. PEF-treated cheese milk has not shown any significant changes on physicochemical characteristics and quality of cheese. No adverse effect of PEF on water-soluble vitamins in milk (riboflavin, thiamin, and ascorbic acid) and fat-soluble vitamins (cholecalciferol and tocopherol), after applying treatments of up to 400 μs at field strengths from 18.3 to 27.1 kV cm^{-1}, was found except for ascorbic acid. As compared to LTLT- and HTST-treated milk, PEF-treated milk retained more ascorbic acid after a 400 μs treatment at 22.6 kV cm^{-1} (93.4%) than either a LTLT (49.7%) or HTST (86.7% retained).

- **Other Techniques**

Milk irradiation is a process of exposing milk to ionizing radiation (gamma rays, beta-particles), emitted by a source (cesium and cobalt) to destroy the spoilage-causing microorganisms. Treatment of milk with 2–5 kGy reduced bacterial population by around 99%, but to achieve complete sterilization of milk, a dosage of 10–20 kGy is required. A hurdle in irradiation of milk is development of off-flavor and color change. Irradiation can be effectively used for sterilization of packaging material used for packing of milk and milk products. Ultrasound waves are similar to sound waves but have a frequency that is above 16 kHz. It produces very rapid localized changes in pressure and temperature that cause shear disruption, 'cavitation' (creation of bubbles in liquid foods), thinning of cell membranes, localized heating, and free radical production that have a lethal effect on microorganisms. A combined heat and ultrasound treatment under pressure was termed 'manothermosonication' (MTS) and can be used for enhancing the shelf life of milk. Unfortunately, ultrasound does not inactivate alkaline phosphatase or lactoperoxidase enzymes and hence cannot be used to indicate a successful ultrasonic treatment. If ultrasonication is to be used as an alternative to thermal pasteurization, a need exists to find a quick and efficient method to indicate whether ultrasonication was sufficient in terms of ensuring a microbiologically safe product.

Packaging, Storage, and Distribution

Packaging is a medium between product manufacturers and consumers aiding the maintenance of original quality of the packaged products and providing information and characteristics of the packaged products to the consumers. The functions of packaging are to enable efficient food distribution, maintain product hygiene, protect nutrients and flavor, and reduce spoilage and waste. Immediately after heat treatment, milk products need to be packaged to avoid postprocess contamination that will affect the shelf life. In earlier days returnable glass bottles were used for packaging and distribution of milk, but with technological advancement plastic bottles, tetra packs, laminates, and sachet are now preferred over glass bottles. Before a packaging material is selected for milk and milk products it is important to know the type, composition, compatibility, conditions of storage, and transportation (light, temperature, humidity, mechanical stress during transportation, and storage). The ideal packaging material for milk should be an inert, nontoxic, safe, and hygienic design and should not directly or indirectly impart smell. Packaging material should be well labeled with manufacturing, expiration date, storage conditions, and ingredients. Single-use packages are used for packaging of fluid milk that is predominately plastic pouch (PE, LDPE, HDPE, polyvinylchloride) that has a good moisture barrier properties but poor recyclability and disposal complications. Cartons are generally used as a secondary storage of milk; paper and paperboards materials include laminates consisting of outer kraft paper with PE coatings and aluminum foil. The advantage of single-use packaging material is that they decrease the use of detergents, which is required for washing returnable glass bottles. Apart from sterilizing the milk and milk products and also the packaging material, sterilization of equipment, line, and filling area can enhance the shelf life of milk. Aseptic packaging is being utilized in developing countries for presterilized packages under sterile environment into sterile packaging material.

For storage and distribution of milk, insulated tanks, cans, bottles, tetrahedral package, paperboard cartons, and automatic vending machines are used. The most important factor to be considered during the storage and distribution of milk is the temperature of storage, which should be kept at 5 °C. Hygienic conditions must be maintained throughout the supply chain so that the milk products are not cross contaminated and are also free from defects like off flavor due to exposure to chemicals.

Quality Assurance and Quality Control

Quality assurance is an important element for safe milk and milk products from any of the contaminants that can render the product unsafe for consumers. Addition of water by deceitful middlemen is one of the challenges faced by the dairy industry in developing countries. To provide a quality milk and milk product it is of utmost importance to start the process by procuring good-quality raw milk and maintaining strict quality measures at different checkpoints (collection, transportation, receiving dock, after processing, and during dispatch), including transportation and storage. Quality testing includes a platform test at the receiving dock and physicochemical cum microbiological analysis in the processing (before–after) industry and should follow up the standards as laid out by regulatory agencies/bodies. To ensure the quality, dairy industries should follow good manufacturing policies (GMP), hazard analysis critical control points (HACCP), and ISO:22000 (2005) based programs, which will help in controlling the quality by identifying and reducing the hazards within a safe limit for consumers. Other key factors that control quality are hygiene, safety, adequate thermal treatment during manufacturing, packaging, and postprocess contamination.

Steps Where Preventive Measures Are Required to Maintain Quality

- Good and hygienic milking practices must be carried out at the farm level that can minimize the proliferation of microorganisms from environment, dirt, soil, feces, human beings, and equipment into milk.

- Utensils and equipment used for milking the animals must be well sanitized and preferably manufactured using stainless steel.
- Milk mulched from mulching animals suffering from mastitis and other diseases must not be mixed with a batch of good raw milk.
- Longer storage temperatures of raw milk must be avoided as it allows few psychrotrophic organisms (*L. monocytogenes* and *Pseudomonas* species) to grow that in return can secrete enzymes like proteases and lipases, which produces defects like sweet curdling in UHT-treated milk.
- Monitoring the milk for adulteration with adulterants including urea, sugar, neutralizers, and nondairy proteins.
- Routine monitoring must be done for critical control points (time–temperature) for pasteurization and sterilization that can be evaluated by conducting an alkaline phosphatase test (pasteurization) and turbidity test (sterilized).
- Monitoring the sanitation and CIP programs before processing and after processing to ensure that the residual milk in pipeline/equipment is removed and they are in sanitized condition, which will not support the further growth of spoilage bacteria.
- Hygiene conditions must be maintained during processing and also after packaging of milk to avoid postprocess contamination.
- Usage of unsterilized packaging material for packing of milk and milk products must be avoided.
- Temperature fluctuation during the storage and distribution of milk (collection center, transportation, storage distribution) must be avoided to maintain the product safety.

Good farming practice, animal health management, control of feed, hygienic milking operations, inspection, quality analysis, sanitation, and hygiene during manufacturing as well as packaging and effectively monitoring every parameter during processing will help in reducing microbial load to render products safe for end consumers.

Introduction

Milk has been a part of the human diet for millennia and is valued as a natural and traditional food. Milk and its products are considered to be one of the main food groups (dairy) important in a healthy balanced diet and, as such, features in the majority of national food-based dietary guidelines. The popularity of milk as a staple food over the centuries is owed to its versatility. Bovine (cows') milk is by far the most commonly consumed milk, dominating global milk production. However, in certain parts of the world and locally, milk from other species has a significant share in consumption; after bovine milk (85%), buffalo milk is consumed most (11%) followed by milk from other ruminants (3.9%).

In the context of current dietary advice, it is difficult for most individuals to meet national nutrition goals unless they are consuming milk and dairy products. Early humans discovered that milk could be churned to make butter or fermented to make yogurt preserving some or all of the nutrients in milk for consumption at a later date. Milk is one of the most nutritionally complete foods. Milk and milk products are widely recognized as important sources of nutrients.

Milk provides a wide range of essential nutrients, in particular protein, and a range of vitamins and minerals. It is, however, a poor source of iron and vitamin D and contains no starch or dietary fiber. As milk provides a substantial amount of vitamins and minerals in relation to its energy content, it is a nutrient-dense food. Scientific studies provide evidence that intake of milk, and milk products, is related to improved bone health and lower risk of cardiovascular disease, hypertension, and type 2 diabetes. It is because of these recognized benefits that individuals are encouraged to consume three cups per day of fat-free or low-fat milk (750 ml) or equivalent milk products. On the other hand, milk is also recognized as a source of both calories and saturated fat.

Milk is a rich source of calcium, but it is perhaps less commonly known that milk and milk products are also an important source of good quality protein, B vitamins (B2 and B12), and the minerals iodine, potassium, and phosphorus. Milk consumption has been called a marker for an overall healthy diet because of its association with increased nutrient intake.

Clinical Evidence of Dietary Importance of Milk

The Dietary Guidelines for Americans Advisory Committee report states that, without milk products, 19–50-year-old women achieve only 44% of calcium, 57% of magnesium, and 57% of potassium recommended intakes. Similarly, there are some data to show that nutrient intake is enhanced when dietary patterns include milk and dairy products. For example, in an 18-month randomized controlled trial, British girls in the intervention group were asked to drink extra milk, while the control group maintained their usual diet. Consuming an approximate additional glass (186 ml) of milk every day significantly increased intakes of protein, calcium, phosphorus, magnesium, zinc, and riboflavin, while milk consumption and nutrient intake were unchanged in the control group.

In a US study of milk drinkers, both flavored and plain, intakes of vitamin A, calcium, phosphorus, magnesium, and potassium were significantly higher than among non-milk drinkers.

Milk and dairy products are major contributors to calcium, riboflavin, phosphorus, and iodine intakes for people of all age groups in the United Kingdom. For young children, dairy products contribute significantly to protein, vitamin A, potassium, magnesium, and zinc intake. In countries such as the United States, where milk is fortified, dairy foods make an important contribution to vitamin D, but this is not the case in the UK.

Composition of Milk

Milk of all mammals contain proteins, carbohydrates, fats, vitamins, minerals, and water, but their percentage varies widely between ruminant milk and nonruminant milk. Milk composition differs considerably due to genetic, physiological, and nutritional factors as well as frequency of milking and environmental conditions. The greatest changes in composition occur during lactation. Colostrums have the highest concentration of proteins, especially immunoglobulins and fat, and a low concentration of lactose. Dairy animals on nutritional feed produce milk with a higher level of fat and protein than those on feed of lower quality.

Dietary Importance of Milk

Milk is the first food of newborn mammals, including human beings. It contains all the nutrients required for normal growth. Milk and milk products have had a key role throughout the development of human civilization. It supplies almost all the essential nutrients in significant amounts, more than any other single food. It is essential for the growth and development of infants. It is not just an important food during early childhood but, in one form or the other, continues to provide benefits throughout life. It is one of the most versatile animal-origin foods and is a component of diets globally in many forms, such as cheese, yogurt, ice cream, ghee, and milk powders. The calcium content in cows' milk is lower than

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00462-1

buffalo milk, while buffalo milk is richer in fat. β-Carotene is absent in buffalo milk but is present in cows' milk.

Milk Proteins

The principal proteins found in milk and its products are casein, lactalbumin, and lactoglobulin. Milk has a high biological value as it contains all eight essential amino acids. In addition, milk can improve the overall protein quality of a meal when consumed with foods of lower protein quality, such as cereals and pulses. Milk proteins are complete proteins of high quality. The energy value of milk proteins is 17.2 J g^{-1}. The contribution of milk to nutrient intakes in UK is shown in Table 1. The proportion of bovine casein, which is micellar, depends on the temperature and gravitational force used to sediment casein micelles. The size of casein micelles in cows' milk ranges from 50 to 500 nm (mean 120–150 nm, volume 4.18 ml g^{-1}). Buffalo milk casein micelles contain more calcium and magnesium, but lower levels of sialic acid and hexose. The lactoferrin content of buffalo milk is 3.2 mg ml^{-1} compared to 0.15 mg ml^{-1} in cows' milk. Immunoglobulins, lactoferrin, lactoperoxidase, and lysozymes in milk make it a good dietary and health food.

Bovine milk contains about 3.5% protein of which 80% is casein and 20% whey proteins. Casein, the dominant protein in milk, can be fractionated into four major components: alpha-, beta-, gamma-, and kappa-caseins. Whey protein is composed predominantly of beta-lactoglobulin and alpha-lactalbumin, but other whey proteins include serum albumin, immunoglobulins (IgA, IgG, and IgM), protease peptones, lactoferrin, and transferrin. Colostrum contains minor bioactive components, such as peptides, hormones, and growth factors, which were associated with advantageous intestinal effects in rat studies. Buffalo milk has a slightly higher concentration of β-lactoglobulin than cows' milk, and it is the major whey protein. Human milk contains no β-lactoglobulin, but contains essential and branched-chain amino acids and a retinol-binding protein, which has the potential to modulate lymphatic responses. Milk can yield antibacterial peptides, which are released after proteolytic digestion with trypsin and are active against Gram-positive bacteria. Whey comprises a heterogeneous group of proteins that remain in the supernatant after precipitation of caseins. They are characterized by genetic polymorphisms that usually translate into replacements for one or more amino acid residues in their original peptide sequence.

Milk Fat

The fat content of milk varies depending on whether milk is whole, semiskimmed, or skimmed. Fat in milk is in the form of minute droplets, which rise to the top when milk is left to stand. The principal component of milk fat is triacylglycerol, three fatty acids joined to a glycerol backbone. All triacylglycerols contain mixtures of three families of fatty acids: saturated, monounsaturated, and polyunsaturated. Despite a misconception that milk is 'fattening,' even bovine whole milk contains only around 3.5% fat. Semiskimmed milk contains 1.7% fat and skimmed milk contains only 0.1% fat. Milk fat contributes unique characteristics to the appearance, texture, flavor, and satiability of dairy foods. Dairy fat is a source of energy, essential fatty acids, fat-soluble vitamins, and several other components, such as conjugated linoleic acid (CLA) and sphingolipids.

About a quarter of the fat in milk is monounsaturated. The remainder is mostly saturated, although some polyunsaturated fats and other minor fatty acids are also present. Palmitic, stearic, and myristic acids are the major saturated fats found in milk. It is comparatively rich in the short- and medium-chain saturated fats. There are a variety of saturated fatty acids in milk, many of which have no effect on plasma cholesterol. When milk is skimmed, it is the amount rather than the type of fat that changes, and so the fatty acid profile remains the same. Milk fat contains small amounts of two essential fatty acids, linoleic acid (1.4 g per 100 g fatty acids) and linolenic acid (1.5 g per 100 g fatty acids).

Table 1 Contribution of milk to nutrient intake (% total) in the UK diet

Milk constituents	*Age groups*			
	1.5–4.5 years	*4–18 years*	*19–64 years*	*65+ years*
Protein	24	11	9.7	13.6
Vitamin A	30.5	10.9	7.0	13.0
Riboflavin (B2)	37.5	24.8	23.3	26.7
Vitamin B6	22.5	9.4	8.3	14.0
Vitamin B12	39.7	36.6	29.1	24.7
Calcium	46.9	28.3	26.2	36.1
Iodine	39.6	33.7	28.5	25.5
Magnesium	22.2	10.3	8.1	13.5
Phosphorus	32.7	16.4	15.1	21.2
Potassium	25.6	13.0	10.8	15.7
Zinc	25.0	13.0	9.7	13.6

London: TSO

The nutritional interest in buffalo milk products is higher than cows' milk because its fat-derived products are a good source of CLA, like other food products from ruminants. CLA are a group of polyunsaturated fatty acids that exist as positional and stereoisomers of conjugated dienoic acid (18:2). Synthetic mixtures of CLA can be purchased as nutritional supplements but are composed primarily of the *cis*-9 and *trans*-11 CLA as well as *trans*-10 and *cis*-12 isomers. Numerous potential physiological effects have been attributed to CLA including those related to its potential antiadipogenic, antidiabetogenic, anticarcinogenic, and antiatherosclerotic properties. In dairy products, CLA concentrations typically range from 2.90 to 8.92 mg g^{-1} fat. CLA content of cheeses typically ranges from 3.59 to 7.96 mg g^{-1} fat. CLA content of cows' milk ranges from 3.38 to 6.39 mg g^{-1} fat. Amounts of CLA found in dairy products are a direct reflection of the diet of the milch animals. CLA concentrations increase linearly when animals are pasture-fed and decrease when grass intake declines. Supplementing the diet with polyunsaturated oils, which contain either corn or sunflower oil, increases CLA content of milk fat substantially.

Milk Carbohydrates

The principal carbohydrate found in milk is lactose. Cows' milk contains about 4.5 g lactose per 100 g milk, and there is some evidence that lactose is the least cariogenic of common dietary sugars. It exists in two anomeric forms, α-D-lactose and β-D-lactose, in an equilibrium of about 37.3% α to 62.7% β at 20 °C, and in an inverse relationship with the chloride content, making it isoosmotic with blood. Various other components in milk have also been considered protective against dental caries.

Lactose is a disaccharide comprising a molecule of glucose and a molecule of galactose. This sugar is found naturally only in milk and is much less sweet than sucrose. In the small intestine, lactose is digested by the enzyme lactase (β-galactosidase) to its two component monosaccharides prior to their absorption.

Lactase is present in babies, young children, and most ethnic-European (Caucasian) adults. However, in some adults, enzymatic activity can decrease, making milk in quantity less well tolerated. Such individuals are lactose-intolerant. Most can tolerate small quantities of milk, and fermented milk products are better tolerated as the lactic acid bacteria present produce lactase. Cheese is also usually well tolerated as it contains only trace amounts of lactose. In the UK, lactose intolerance is relatively rare but is more common in those of Asian, Far Eastern, and African descent, particularly first-generation members of these ethnic groups.

Other milk carbohydrates, which are free or bound to lipids, proteins, or phosphate, include a small fraction of oligosaccharides. They are composed of galactose, fructose, *N*-acetylglucosamine, and/or *N*-acetylneuraminic acid (sialic acid) and include mostly a lactose unit at the reducing end. They modulate the growth of intestinal flora, influence gastrointestinal and inflammatory processes, and provide protection against bacterial and viral infections. In general, the oligosaccharide level is much lower in animal milk (0.25–0.30 g l^{-1} goat milk, >0.1 g l^{-1} buffalo milk, 0.03–0.09 g l^{-1} bovine milk, and 0.02–0.04 g l^{-1} sheep milk) compared with human milk (5–10 g l^{-1}).

Minerals in Milk

Milk contributes to virtually all the minerals and trace elements known to be essential for human health. These are often present in a form that is well absorbed and utilized by the body (high bioavailability). Milk is an excellent source of calcium, which is essential for the healthy growth and maintenance of teeth and bones. Calcium is also important for blood coagulation, energy metabolism, muscle and nerve function, digestive function, and regulation of cell division and differentiation. Calcium content of cows' milk is 120 mg/100 ml compared with 160 mg/100 ml buffalo milk. For most people in the Western world, milk and milk products are the primary source of calcium. Almost 60% of the calcium in the typical British diet, for example, is made up of milk and milk products (Table 2).

Milk and milk products are the main sources of calcium in preschool children and adolescents (4–18 years), adults (19–64 years), and the elderly (65 years and over). A 200 ml glass of semiskimmed milk can provide a 6-year-old child with over half (55%) of their calcium requirement and can provide an adult (19–64 years) with over a third (35%) of their daily calcium requirement. Calcium as a bioactive mineral occurs widely in a range of calcium-fortified foods, including fortified milk and other beverages. In the diets of developed countries, milk and dairy products provide approximately 70% of recommended daily intakes of calcium.

The role of calcium as a protective factor in the etiology of colon cancer has been well documented. It is also believed to be associated with binding and removal of carcinogenic agents along the gastrointestinal tract. Calcium is important for the development and maintenance of skeletal integrity and prevention of osteoporosis.

Zinc content in milk is greatest among the trace minerals. Zn in goat and cows' milk is greater than in human milk. Its deficiency results in skin lesions, disturbed immune function, growth retardation, and impaired wound healing. The contribution to zinc requirements made by milk is relatively low compared with meat (major contributor). However, the zinc in milk is highly bioavailable, and there is evidence that the combination of milk (or meat) with vegetables, in which zinc is less bioavailable, can enhance bioavailability of zinc from the whole meal.

In the UK, milk and milk products are the main sources of potassium for preschool children and the elderly (65 years and over) and the second largest contributor, after potatoes, for schoolchildren and adolescents (4–18 years). A 200 ml glass of semiskimmed milk will provide a 6-year-old child with 29% of their daily requirement for potassium and an adult (19–50 years) with 9%.

Milk is also a good source of iodine. Iodine is required for the production of the thyroid hormones and normal thyroid function and for normal energy yielding metabolism and contributes to the maintenance of normal skin.

Milk is naturally low in iron. Despite similar iron contents, bioavailability is greater from goat milk compared with cows'

Table 2 Ranked contribution of milk (and milk products) to vitamin and mineral intakes in the UK diet

	Preschool (1.5-4.5)	*School (4–18)*	*Adult (19–64)*	*Elderly (65+)*
Vitamin B2	37.5 (45.8)	24.8 (31.3)	23.3 (28.7)	26.7 (31.0)
	Largest	Largest	Largest	Largest

London: TSO

milk. Goat milk has a higher share of nucleotides that contribute to enhance iron absorption from the intestine.

Phosphorus plays a vital role in the maintenance of healthy bones and teeth as well as cell membrane structure and regulation of energy metabolism. The main sources of phosphorus, in the UK diet, come from milk and milk products across all age groups. A 200 ml glass of semiskimmed milk will provide a 6-year-old child with 55% of their daily requirement for phosphorus and an adult (19–50 years) with 36%.

Vitamins in Milk

Vitamin content of milk is highly variable depending on feeding regimen of the dam. Levels of water-soluble vitamins are influenced most by feed. All of the known vitamins are found in whole milk (Table 1), although some are present in low quantities.

Milk and milk products make up a significant contribution to intakes of a number of vitamins. Buffalo milk is a rich source of most water- and fat-soluble vitamins. Fat-soluble vitamins – A, D, E, and K – are removed when milk is skimmed. Consequently, they are present only in trace amounts in skimmed milk and in reduced amounts in semiskimmed milk. Whole milk is a good source of vitamin A, a pint (568 ml) providing 47% of the adult male and 55% of the adult female UK reference nutrient intake. All of the three major types of cows' milk (whole, semiskimmed, and skimmed) are good sources of riboflavin (vitamin B2) and vitamin B12. Milk can also make an important contribution to intakes of thiamin (vitamin B1), niacin, and ascorbic acid (vitamin C), particularly where the overall diet is poor.

Vitamin A content is higher in buffalo milk (340 IU kg^{-1}) than cows' milk (230 IU kg^{-1}). However, due to the absence of carotenoids and the high fat content in buffalo milk, the total vitamin A potency/unit weight of fat is less than cows' milk.

Human infants fed solely on goat milk are oversupplied with protein, calcium, phosphorous, vitamin A, thiamin, riboflavin, niacin, and pantothenate per the FAO–WHO requirements.

The tocopherol (vitamin E) content of buffalo milk is 334 μg kg^{-1} and that of cows' milk 312 μg kg^{-1}. However, due to higher fat, buffalo milk is poor in tocopherol (26 μg g^{-1} fat compared with 35 μg g^{-1} fat in cows' milk).

Some vitamins are sensitive to heat and light. Over 90% of milk for liquid consumption is pasteurized, a mild heat treatment that causes vitamin C to be lost. In general, vitamin losses are less than 10% during pasteurization. However, while ultra-heat treatment (UHT) substantially increases the shelf life of milk, the higher temperatures used result in greater losses (10–20%) of some vitamins, particularly B6, B12, and folate as well as vitamin C. Sterilization has a greater effect still with about one-third of thiamin and half of the vitamin C, folate, and B12 destroyed. Some loss of vitamins is inevitable when milk is stored. The extent of these losses is dependent on translucency and permeability to light of the container and the length and conditions of storage.

Milk exposed to bright sunlight on the doorstep will readily lose its vitamin C. Loss of riboflavin is slower but, after 4 h, half will be lost and only a third remains after 6 h. Therefore, measures should be taken to limit such exposure. There will also be gradual losses of some vitamins from UHT and sterilized milks, even under ideal storage conditions, because of the small amounts of oxygen remaining in the pack or bottle. Boiling milk also reduces its vitamin content, ranging from a 5% reduction in vitamin B12 to a half the vitamin C.

Pigments in Milk

Biliverdin IX alpha, a latent blue-green pigment, occurs in fresh buffalo milk but is absent in cows' milk. The average concentration of biliverdin in buffalo skimmed milk is around 60 μg/100 ml. The concentration of this pigment varies significantly at different stages of lactation and lactation number. Biliverdin is primarily associated with α, β, and γ caseins and the proteose-peptone fraction of the milk. It is converted to bilirubin during storage and souring of the milk.

Nutritional Significance of Milk in the Diets of Children

As a child is weaned on to 'solids,' quantities of milk can increase, for example, cows' milk may be used to mix infants' cereals. However, cows' milk should not be introduced as a drink until a child is one-year-old. This is because, unlike infant formulas, cows' milk is relatively low in iron and vitamin D and there is growing concern about the iron status of older infants and preschool children. Whole milk is a good source of protein, calcium, zinc, and vitamins A, B2, and B12. It also makes a valuable contribution to intakes of iodine, niacin (vitamin B), and vitamin B6.

There is adequate evidence that calcium has a major role in the development and maintenance of skeletal strength. Sufficient milk helps to achieve peak bone density in early adulthood, thus protecting against osteoporosis in later life. Approximately 45% of minerals in the adult skeleton are laid down during adolescence. By the age of about 17 years (earlier in girls), more than 90% of bone mineral (e.g., calcium) that will be present in the skeleton is already there. Calcium requirements are, therefore, particularly high during adolescence. Dental experts recommend milk as the most suitable drinks for children to strengthen the dental health.

Nutritional Significance of Milk for Adults

During pregnancy, especially the final months, requirements for a number of nutrients increase. Milk is seen to have a major role in providing a broad range of nutrients. The needs for some nutrients, for example, calcium, rise dramatically after the baby is born in women who choose to breast-feed. Dietary requirements for calcium almost double, and consumption of several servings of dairy products daily is one of the few ways of easily achieving such intakes. Breast-feeding teenagers need even more calcium as their skeleton is still developing as well as that of the baby.

Milk and milk products remain a nutritional safeguard for other adults, especially those who restrict food choices because they are slimming or following a vegetarian diet. For elderly people, whose overall food intake and dietary variety can be limited, milk can be of particular importance in meeting nutrient needs, especially with the convenience of doorstep or other (e.g., online) delivery.

Introduction

Historically, milk from livestock animals has been an important source of nutrients, especially protein for humans. Bovine milk is by far the most commonly consumed type of milk, dominating global milk production because of large cattle population. However, in certain parts of the world and local contexts, milk from other animal species has a significant share in milk consumption. Apart from bovine milk (85%), the buffalo milk is highest (11%), followed by ruminants (3.9%). There is paucity of world statistics on milk of nonruminant animal species, which contributes less than 0.1%. The horse and donkey milk seem to experience a revival in continental Europe with new horse dairies in Belgium, France, the Netherlands, and Norway. A number of therapeutic properties are attributed to these milks. Bovine milk is produced on industrial scale and as such mostly standardized with respect to fat and protein content; equine milk or milk from other species is usually produced on a local scale. The up-to-date information is necessary on how milk and dairy products can contribute to human nutrition and how dairy development can contribute to increasing food security and sustainable development and thereby alleviating poverty.

Composition of Milk

Milk is a complex biological fluid consisting of fats, proteins, minerals, vitamins, enzymes, and sugar. Milk of all mammals contains proteins, fats, carbohydrates, vitamins, minerals, and water, but their content varies widely between ruminant and nonruminant milk. The milk composition differs considerably due to genetic factors, physiological factors, nutritional factors, frequency of milking, and environmental conditions. The greatest changes in composition occur during lactation. Colostrum, the first milk after calving, has a high concentration of fat and protein, especially immunoglobulin, and a low concentration of lactose. The volume of milk produced increases during the early stages, which after peaking slowly declines toward the latter stages of lactation. The mastitis results in changed composition of milk with decreased levels of lactose and potassium and increased levels of sodium, chloride, and serum proteins. In addition, a large number of somatic cells and bacteria are present. Generally, the animals on nutritionally superior feed produce more milk with a higher level of fat and protein than animals on feed of lower nutritional quality. The fat content and protein content of milk are positively correlated within the population of dairy cattle; however, different breeds of cattle vary in average component levels. Gross composition of milk from various mammalian species is depicted in Table 1.

Milk Proteins

Milk proteins are divided into two broad categories: caseins and soluble proteins, which include enzymes. Caseins contribute to about 80% of the total milk proteins in bovine and sheep milk and about 50% of horse milk proteins and less than 50% of human milk proteins. Caseins are organized into macromolecular units called micelles. In general, a distinction is made between 'casein' milk (i.e., ruminant milk, which is relatively rich in casein) and 'albumin' milk (i.e., nonruminant milk, which has proportionally a higher whey protein content as indicated by the lower casein/whey ratio). The main caseins are designated as α_s1-caseins, α_s2-caseins, β-caseins, and κ-caseins with other minor caseins that are derived from these by proteolysis, glycosylation, or phosphorylation. The whey proteins consist of β-lactoglobulins, α-lactalbumins, immunoglobulins, and serum albumin in decreasing amounts.

The nutritional value of milk proteins depends to a great extent on the presence of essential amino acids. As to the thermal stability of milk proteins, differences between species are mainly due to differences in amino acid sequences and in milk environment. Whey proteins of bovine milk are less resistant to heat denaturation compared to those of buffalo milk, which are less heat-resistant than camel whey proteins. Advancement in scientific and commercial interest has been focussed on the biological properties of milk proteins. Intact protein molecules of both major milk protein groups, caseins and whey proteins, exert distinct physiological functions *in vivo*. Many of the bioactive whey proteins like immunoglobulins, lactoferrin, and growth factors occur in colostrum in much greater concentrations than in milk, thus reflecting their importance to the health of the newborn.

The Caseins

α-Casein has four variants, A, B, C, and D, of which B is the most common. Its polypeptide chain has three distinct regions that are strongly hydrophobic. It is highly negatively charged, while the rest of the molecule is essentially neutral. The three hydrophobic regions, 1–44, 90–113, and 132–199, of the B variant contain 21, 8, and 30 hydrophobic residues (Ala, Val, Leu, lie, Pro, Phe, Trp, and Met), respectively. Region 41–80 contains a cluster of phosphoseryl residues and this will be highly charged at pH 6.6. The molecule has little or no α-helical structure, a very small amount of β-structure, mainly around turns, and much random coil.

αs2-Caseins (variants A, B, C, and D) are the most hydrophilic of all the caseins because they contain 10–13 phosphoseryl residues. In the polypeptide chain of the A variant, those

Source: Claeys, W. L., Verraes, C., Cardoen, S., De Block, J., Huyghebaert, A., Raes, K., Dewettinck, K. and Herman, L. (2014). Consumption of raw or heated milk from different species: An evaluation of the nutritional and potential health benefits. *Food Control* **42**, 188–201.

in residues 8–16, 56–61, and 129–133 are clustered. Hydrophobic regions occur at 90–120 and 160–207. The C-terminal is positively charged, containing either basic or neutral residues only and having a net charge of +9.5 at pH 6.6 compared with a net charge of −21 for the first 68 residues of the N-terminal. Thus, electrostatic interactions may be important for its structural stability.

β-Casein occurs in five genetic variants (A1, A2, and A3, B, C, D, and E) and is the most hydrophobic of the caseins. The 21 residues from the N-terminal have a charge of −12 at pH 6.6, while the hydrophobic region (from approximately 69–209) has no net charge. It has at least one cluster of phosphoseryl residues (15–19). As with αs1-casein, the hydrophobic region is a random coil.

κ-Casein is the smallest and occurs in two main variants, A and B. κ-Caseins surround αs-casein and β-caseins in the micelles. κ-Caseins have no phosphoseryl clusters, but have tetrasaccharide chains attached to threonyl residues 31, 33, 35, and 36 (variant A only). Its N-terminal is hydrophobic, while the other terminal is polar and has no Asp or Glu residues. At pH 6.6, the residues of the C-terminal plus the carbohydrate chains confer a net negative charge of −16 or −17. The disulfide form exists *in vivo* as there is sulfhydryl oxidase activity in raw milk. This molecule is thus highly amphoteric and plays a crucial role in the coagulation of milk catalyzed by chymosin.

The Whey Proteins

Whey proteins are well-ordered globular proteins. Bovine milk contains about 3% protein, of which 80% is caseins and 20% is whey proteins. Whey comprises a heterogeneous group of proteins that remain in the supernatant after precipitation of caseins; they are characterized by genetic polymorphisms that usually translate into replacement of one or more amino acid residues in their original peptide sequence. Two major types of proteinaceous material can be found in whey: (1) β-lactoglobulin (β-Lg) and α-lactalbumin (α-La) and (2) proteose peptone (derived from hydrolysis of β-casein (β-CN)), small amounts of proteins derived from blood (including bovine serum albumin (BSA) and immunoglobulins (Igs)), and low-molecular-weight peptides derived from casein hydrolysis. Whey proteins have a compact globular structure that accounts for their solubility. These proteins have amino acid profiles quite different from caseins. They have a smaller fraction of Glu and Pro, but a greater fraction of sulfur-containing amino acid residues (i.e., Cys and Met). These proteins are dephosphorylated, easily denatured by heat, insensitive to Ca^{++}, and susceptible to intramolecular bond formation via disulfide bridges between Cys sulfhydryl groups. A brief account of whey proteins is summarized in the succeeding text:

- β-Lactoglobulin (β-Lg) is found with at least four genetic variants, with A and B being the most common. It is the major whey protein in bovine milk and accounts for about 50% of the proteins in whey, but it is not found in human milk. It poses a variety of functional and nutritional characteristics that have made this protein a multifunctional ingredient for many food and biochemical applications. It has been proved an excellent source of peptides with a wide range of bioactivities, such as antihypertensive, antimicrobial, antioxidative, anticarcinogenic, immunomodulatory, opioid, hypocholesterolemic, and other metabolic effects.
- α-Lactalbumin (α-La) has three genetic variants A, B, and C, of which only B is found in cattle of Western breeds. It is a small molecule having four disulfide bonds but these are much less reactive than those of β-lactoglobulin. It has considerable homology with lysozyme: 47 of its 123 residues are identical and others are conservative replacements. α-Lactalbumin is not an enzyme but it acts as a modifier of galactosyltransferase, which synthesizes lactose in the mammary gland. α-La is the predominant whey protein in human milk and accounts for about 20% of the proteins in bovine whey. It is fully synthesized in the mammary gland where it acts as coenzyme for biosynthesis of lactose. It is a good source of the essential amino acids tryptophan and cysteine, which are precursors of serotonin and glutathione, respectively. It has been speculated that the oral administration of α-La could improve the ability to cope with stress. It also improves cognitive functions in stress-vulnerable subjects by increased brain tryptophan and serotonin activity. Based on its high degree of amino acid homology to human α-La, bovine α-La and its hydrolysates are well suited as an ingredient for infant formulas. A few α-La-enriched formulas have already been launched on the market.
- Immunoglobulins (Ig) and bovine serum albumin (BSA) are identical with the proteins found in blood serum and arise in milk by transferring from the blood in the mammary gland during milk production. It provides the neonates with passive immunity before its own immune system is fully functional. Igs are divided into different classes on the basis of their physicochemical structures and biological activities. The major classes in bovine and human lacteal secretions are IgG, IgM, and IgA. The basic structure of all Igs is similar and is composed of two identical light chains and two identical heavy chains. These four chains are joined with disulfide bonds. IgG content of colostrum varies from one animal to the other and also from one breed to the other. IgG accounts for up to 70–80% of the total protein in colostrum, whereas in milk, it accounts for only 1–2% of the total protein. Colostrum-based products have found a growing worldwide market as dietary supplements for humans. Igs link various parts of the cellular and humoral immune system. They are able to prevent the adhesion of microbes and inhibit bacterial metabolism.
- Lactotransferrin (LF) is similar to serum transferrin. It is active both in iron transport and in helping to protect against gut infections in the neonates. It is an iron-binding glycoprotein found in colostrum, milk, and other body secretions and cells of most mammalian species. It is known to confer many antimicrobial, antioxidative, anti-inflammatory, anticancer, and immunoregulatory properties. During the past three decades, it has become evident in many animal and human studies that oral administration of LF can exert several beneficial effects on the health of human beings.
- Lactoperoxidase (LP) is a glycoprotein that occurs naturally in colostrum, milk, and many other human and animal secretions. LP represents the most abundant enzyme in milk and can be recovered in substantial quantities from

whey using chromatographic techniques. It catalyzes peroxidation of thiocyanate anion and some halides in the presence of hydrogen peroxide source to generate short-lived oxidation products of SCN-, primarily hypothiocyanate (OSCN-), which kill or inhibit the growth of many species of microorganisms. In *in vitro* studies, the LP system has been shown to be active against a wide range of microorganisms, including bacteria, viruses, fungi, molds, and protozoa. It is bactericidal against Gram-negative pathogenic and spoilage bacteria and bacteriostatic against many Gram-positive bacteria. The LP system is considered to provide a natural method for preserving raw milk because milk contains naturally all necessary components to make the system functional.

- Enzymes have been identified in milk to a tune of 60. They are important because they are responsible for certain flavor and stability problems, may help protect the neonate against bacterial infection, and can be used to test the efficiency of pasteurization. In particular, there are several proteolytic and lipolytic enzymes that may cause serious degradation of milk components when milk is stored under less than ideal conditions. The enzyme plasmin, which is found in the milk fat globule membrane (MFGM), degrades caseins even at quite low temperatures. Homogenization of milk releases lipase from the MFGM, which can lead to the degradation of fats into fatty acids, giving rancid flavors to the milk.

Milk Lipids

The lipids in milk are secreted from the mammary gland in the form of globules surrounded by a membrane that derives from the plasma membrane of the gland itself. The fat within the membrane consists mainly of triacylglycerols with small amounts of di- and monoacylglycerols, free cholesterol and cholesterol esters, free fatty and acids, and phospholipids. Bovine milk fat is composed of more than 400 fatty acids with different chemical compositions. Most of these fatty acids are esterified to the glycerol molecule backbone and appear in milk fat mostly as triacylglycerols. There are 15 major fatty acids with chain lengths from C4:0 to C18:3; the rest are present at very low concentrations. They have a strong influence on flavor, especially via C4:0-C10:0 fatty acids. The fatty acids are derived either from the plasma lipids of the animal or by de novo synthesis in the mammary gland. The diet of the animal has considerable influence on the fatty acid profile. There is much variability in the triacylglycerols of bovine milk but certain general trends may be seen. The proportion of each species of fatty acid varies with diet and thus is influenced by the season of the year.

Conjugated linoleic acid (CLA) refers to a collection of positional and geometric isomers of cis-9, cis-12-octadecadienoic acid (C18:2) with a conjugated double bond system. The major CLA isomer in milk fat is 9-cis, 11-trans, also called rumenic acid. CLA is formed partially by bioconversion of PUFA in the rumen by anaerobic bacteria and primarily endogenously by Δ9-desaturation of vaccenic acid in the mammary gland of lactating cows. Milk fat is the richest natural source of CLA and contents range from 2 to 53.7 mg g^{-1} fat. A number of studies have confirmed that pasture feeding can increase significantly CLA concentrations as compared to indoor feeding. Also, the grass composition of pasture seems to affect the CLA levels. Feeding cows with meals containing plant oils and/or marine oils can effectively increase the CLA content. Feeding of concentrates rich in linoleic acid (rapeseed, soybean, and sunflower) has a better impact than other polyunsaturated plant oils (peanut and linseed), whereas the dietary fish oils and their combination with plant oils appear even more effective than plant oils alone.

Milk Sugars

Lactose is quantitatively the main milk sugar. It is a disaccharide. It exists in two anomeric forms (α-D-lactose and β-D-lactose) in an equilibrium of about 37.3% α to 62.7% β at 20 °C. It is in inverse relationship with the chloride in milk, making it isosmotic with blood. It may be that evolution has favored lactose over, say glucose, because a given weight of lactose exerts only half the osmotic pressure of the polysaccharide and therefore twice the energy value for a given osmotic pressure. Its concentration is similar in horse, donkey, and human milk, but lower in bovine or other ruminant milk. Other milk carbohydrates, which are free or bounded to lipids, proteins, or phosphate, include a small fraction of oligosaccharides. They are composed of galactose, fucose, *N*-acetylglucosamine, and/or *N*-acetylneuraminic acid (sialic acid) and contain mostly a lactose unit at their reducing end. They modulate the growth of intestinal flora, influence different gastrointestinal and inflammatory processes, and provide protection against bacterial and viral infections. In general, the oligosaccharide level is much lower in animal milk (0.25–0.30 g l^{-1} in goat milk, >0.1 g l^{-1} in buffalo milk, 0.03–0.09 g l^{-1} in bovine milk, and 0.02–0.04 g l^{-1} in sheep milk) compared to human milk (5–10 g l^{-1}).

Vitamins in Milk

Vitamins are physiological, biochemical, and metabolic bioactive compounds occurring in milk. All known vitamins are contained in milk and they have specific biological functions in the body. The vitamin content of milk is highly variable and depends on feeding regime of the dam. The level of water-soluble vitamins is mostly influenced by the feed than the level of fat-soluble vitamins. Table 2 depicts the vitamin content of milk from some nonruminant and ruminant species. Cow milk is the richest source of human dietary requirements of vitamins, particularly riboflavin (B2) and vitamin B12. Goat milk has higher amounts of vitamin A than cow milk. Goat milk supplies adequate amounts of vitamin A and niacin and excesses of thiamin, riboflavin, and pantothenic acid for a human infant. The human infants fed solely with goat milk are oversupplied with protein, Ca, P, vitamin A, thiamin, riboflavin, niacin, and pantothenic acid in relation to the FAO/WHO requirements. Goat milk, however, has a significant drawback of deficiencies in bioactive vitamins, folic acid, and vitamin B12 as compared to cow milk. Cow milk has five times more folate and vitamin B12 than goat milk. Folate is necessary for the synthesis of hemoglobin.

Vitamin content of horse and donkey milk is on an average lower than that of ruminant milk. An exception is the level of vitamin C, which is relatively higher in horse milk. Camel milk is known to be a rich source of vitamin C. It is reported to be three to five times higher than that in bovine milk. Hence, raw and fermented camel milk could be a good source of vitamin C for the people living in the desert area where vegetables and fruits are not available. Sheep, goat, and buffalo milk have higher vitamin A content than cow milk. Their milk is whiter than other milk due to their ability to convert the yellow β-carotene to vitamin A, which is chalky white.

Due to differences in milk composition, the effect of heating on the vitamin content slightly differs from one milk type to another. Conventional sterilization causes modest losses in vitamins B6 (pyridoxine), B3 (niacin), B5 (pantothenic acid), B7 (biotin), A, D, and E content. As such, the heat lability of vitamin C is higher in camel than in bovine milk, and upon different heat treatments, higher vitamin losses are reported in bovine milk compared to buffalo milk. However, the effect of heating on milk vitamins seems to be insignificant from a nutritive point of view, since many vitamins are naturally found in relatively low levels in milk.

Minerals in Milk

Ash content is lower in nonruminant milk compared to ruminant milk. Although there are major differences in the mineral content of milk from different species, the concentration of most minerals is higher in donkey and horse milk than in human milk, but significantly lower than in ruminant milk. Milk is mainly a good source of calcium (Ca) and phosphorus (P), which are necessary for bone growth, development, metabolism, and maintenance, but is less important with respect to other minerals. The data on mineral content of milk from various species are presented in Table 3.

Ca is an important nutrient involved in the health of bone. The Ca as a bioactive mineral is demonstrated widely in a range of calcium-fortified foods, including modified milk and beverages. In the diets of developed countries, milk and dairy products provide approximately 70% of the recommended daily intake of Ca. Its role as a protective factor in the etiology of colon cancer has been well documented. It is also believed to be associated with binding and removal of carcinogenic agents along the gastrointestinal tract. The Ca is important for the development and maintenance of skeletal integrity and prevention of osteoporosis. Hypertension is another disease that is related to a low Ca intake. Ca supplementation reduces blood pressure in hypertensive patients. It is also showed that people who ingest diets low in sodium and high in potassium, magnesium, and calcium do not have hypertension and cardiovascular disease. Bovine milk contains about 50% more Ca and twice as much P and potassium (K) than horse and donkey milk, but horse and donkey milk contain about 2–3 times more Ca and P than human milk. Sheep, goat, buffalo, and reindeer milk contain on average more Ca and P than bovine milk, although these levels may vary greatly.

Goat milk contains about 121 mg P/100 g but human milk contains only its one-fourth. Phosphorus exerts several important metabolic functions in the body, including bone mineralization, energy metabolism, fat and carbohydrate metabolisms, body buffer system and formation, and transport of nucleic acids and phospholipids across cell membranes for body cell functioning. In underdeveloped countries, where meat consumption is very limited, goat milk is an important daily food source of P and Ca due to lack of availability of cow milk.

There are a large number of elements in milk at concentrations of less than 1 mg l^{-1}. They come from the foods eaten by the animal and some are essential for health. Deficiencies of trace elements in the soil may lead to dietary deficiencies and require the feeding of mineral supplements. Elements in milk that are important in human nutrition include chromium (glucose tolerance), cobalt (in vitamin B12), copper (enzyme cofactor and hemoglobin formation), iodine (in thyroid hormones), manganese (enzyme cofactor), molybdenum (in xanthine oxidase), selenium (vitamin E and enzyme component), and zinc (in insulin and enzyme cofactor).

Iron contents in goat and cow milk are lower than the iron content in human milk. Iron occurs in milk in combination with several proteins, such as lactoferrin, transferrin, and ferrilactin. Iron also occurs in blood as hemoglobin and transferrin in the plasma in the ratio of 1000:1, and a small quantity of ferritin is present in erythrocytes. Iron deficiency causes anemia and impaired growth and affects lipid metabolism. Goat milk has a greater hemoglobin regeneration efficiency and iron bioavailability than cow milk. Goat milk diet has greater iron and copper apparent digestibility coefficient and bioavailability in different animal organs.

Zinc content in milk is greatest among trace minerals. Zn in goat and cow milk is greater than that in human milk. Its deficiency would result in skin lesions, disturbed immune function, growth retardation, and impaired wound healing. In a feeding trial with rats, animals fed with a goat milk diet exhibited a greater bioavailability of zinc and selenium as compared to those fed with a cow milk diet. Goat and human milk contain higher concentrations of selenium than cow milk. Less than 3% of the total selenium is associated with the lipid fraction of milk. The selenium-dependent enzyme, glutathione peroxidase, is higher in goat milk than in human and cow milk. Goat milk total peroxidase activity is 65% as against 29% for human and 27% for cow milk. Goat and cow milk contain significantly greater levels of iodine than human milk, which may be important for human nutrition, since iodine and thyroid hormone are closely related to the metabolic rate of physiological body functions. There are several other trace minerals that exhibit active bioactive functions in the body metabolism, including Mo, Cr, Co, Mn, F, As, Sn, and V.

Comparison of raw bovine milk with UHT-treated and sterilized bovine milk shows essentially no differences in milk salt and trace element levels. Intestinal absorption and utilization, and thus the bioavailability of minerals, depend on their chemical form. Upon heating, the diffusible salt content decreases due to a shift to the colloidal form, the extent of which is proportional to the severity of the treatment. The majority of changes are reversible on cooling, but more severe heat treatments (>90 °C) may give rise to some irreversible modifications. Not only the chemical form or heating but also other milk components also affect the bioavailability of milk minerals. As such, lactose, lactulose, CLA, vitamin D, and casein phosphopeptides have been suggested as potential enhancers of calcium absorption.

Iron (Fe) is naturally low in milk. Despite a similar Fe content, the Fe bioavailability is higher in goat compared to bovine milk. Goat milk has a higher share of nucleotides that contribute to an enhanced Fe absorption in the intestine. On the other hand, calcium and casein that have on average higher levels in goat milk inhibit the absorption of dietary nonheme iron.

Contaminants in Milk

Some trace materials include pesticide residues, fluorine, silicon, and heavy metals. Most of these come from contamination of the feed or from water:

- Pesticide residues may be present in milk as a result of the cow eating contaminated food. Around 160 (out of 209 theoretically possible) polychlorinated biphenyls (PCBs) have been identified in milk. PCBs are highly lipophilic and accumulate in the food chain; hence, it is necessary to monitor their presence. Several chronic maladies are associated with pesticide residues in foods like testicular dysfunction (leading to infertility in human), immune dysfunction, delayed polyneuropathy, and deterioration of memory.
- Dioxins occur in milk by ingestion of contaminated food or by inhalation. They are considered to be some of the most toxic substances known. They are formed during the manufacture of certain pesticides and on burning at relatively low temperatures of a wide range of man-made materials, including PCBs.
- Radionuclides occur in milk by contamination of the food either naturally or from accidents such as at the nuclear reactors. The principal radionuclides found are caesium-137, strontium-89, strontium-90, iodine-131, and barium-140. Strontium is absorbed into the bone along with

calcium leading to highly localized concentrations of radioactivity. Iodine is adsorbed by the thyroid where it can cause significant radiation damage.

Millets

JRN Taylor and J Kruger, University of Pretoria, Hatfield, South Africa

© 2016 Elsevier Ltd. All rights reserved.

Introduction

The millets are small-grained cereals, varying in size between approximately 1/4 and 1/10 that of a wheat grain. Their centers of origin are Africa and Eurasia, and they are still very widely consumed as staple foods and traditional beverages, particularly in Africa, Central and southern Europe, India, and China. Today, millets are cultivated across the world, not only in Africa and Eurasia but also in North and South America and Australia. They are becoming popular in Western diets as components of multigrain foods, primarily because of their generally high content of phenolic phytochemicals and also because they are gluten-free. Millets as nonfood grain are primarily used as poultry and caged bird and game bird feed. Millets are also increasingly being grown as fodder crops.

There are some 13 cultivated millet species. By far, the most important in terms of production are, in descending order, pearl millet, foxtail millet, proso millet, finger millet, teff, and fonio (two species, white fonio and black fonio) (Table 1; Figure 1). Collectively, millets are quantitatively the sixth most important cereal type after maize, rice, wheat, barley, and sorghum. Data on millet production do not seem to be very accurate. According to FAOSTAT, world millet production in 2012 was approximately 30 Mt. However, this figure may well be an underestimate. Information from the International Crops Research Institute for the Semi-Arid Tropics (ICRISAT), the responsible CGIAR organization, states that pearl millet accounts for 50% of the total millet crop and gives figures for the major producing areas that, in total, are in excess of 24 Mt.

Generally, in developing countries, millets are cultivated by traditional agriculture technologies. However, improved varieties and hybrid-type cultivars are being developed and are replacing the traditional varieties and landraces. The hybrids are much higher yielding if provided with optimum agricultural inputs such as fertilizer, as shown in the case of a hybrid foxtail millet from China (Figure 1(e)). Experimental genetically modified (GM) millet lines have been developed with improved disease resistance, for example, downy mildew-resistant pearl millet. However, at present (2014), all cultivated millets are non-GM.

Although millets account for only some 1–2% of the world's cereal production, pearl millet in particular provides a substantial proportion of nutrients in some of the most food insecure African countries, those encompassing the Sahel (Sahara desert margin) region. In 2009, the five countries that obtained the most energy (kJ/capita/day) from millets were Niger (4389), Mali (2184), Gambia (2176), Burkina Faso (1894), and Chad (1235), equivalent to between 14% and 50% of an adult's energy requirement. These five countries in 2009 were home to 1.9, 1.4, 0.2, 3.8, and 4.1 million malnourished individuals, respectively. Individuals in these countries also obtained a substantial proportion of their protein intake (g/capita/day) from millets: Niger (20.5), Mali (11.3), Gambia (14.7), Burkina Faso (11.6), and Chad (8.3), equivalent to between 15% and 40% of an adult's protein requirement.

Despite their importance, the millets are very inadequately researched and much of the available information is incomplete. For example, the USDA National Nutrient Database for Standard Reference lists four millet products. However, the names of the millet species are not given. This article attempts to provide accurate information, where known, about the structure, macronutrient, micronutrient, phytochemical, and antinutrient composition of the major millet species. Additionally, some of the more important traditional millet-based foods and beverages are examined, with a focus on the effects that processing has on their nutritional value. Lastly, this article looks at the future of millets as sources of essential nutrients and phytochemicals in the diets of people in the less developed and more developed world.

Structures of Millet Kernels

Although millet grains are small, the kernels of the various millet species vary greatly not only in size but also in weight and importantly in structure (Table 2). Pearl millet is by far the largest, with a 1000 kernel weight of approximately 8 g (20% of a wheat kernel), and teff and fonio are the smallest, 1000 kernel weight approximately 0.3–0.5 g. In general terms, the structure of millet kernels (Figure 2(a)) is the same as that of the major cereals, comprising three parts: the endosperm that contains the starch and the prolamin and glutelin storage proteins; the germ that is rich in lipids and albumin and globulin proteins, minerals, and tocopherols; and the bran that is rich in insoluble dietary fiber. Strictly speaking, the aleurone layer, which is rich in minerals and B vitamins, is part of the endosperm, but in practice, it is often removed when the grain is debranned.

Pearl millet and teff are naked kernels, which can be eaten in their entirety as 'whole grain.' Finger, foxtail, and proso millets are utricles, whereby the pericarp is loosely attached to the kernel and is removed during harvesting and processing. Fonio has a tightly attached hull (Figure 2(b)), which must be removed by dehulling prior to consumption. Unfortunately, millet compositional data rarely indicate whether the kernels analyzed were complete with pericarp/hull, or as would be consumed. Additionally, a fact often ignored in general articles and even in scientific literature is that the chemical composition of millet grains can differ greatly between species and even within species. Statements such as 'millet (*sic*) is very nutritious' should be treated with caution.

Nutrition and Health-Promoting Aspects of the Different Millet Grains

Macronutrients

In millet grains, starch is the major macronutrient and source of energy for nutrition, as in all cereal grains. However, the energy density of the different millets varies slightly (1396–1522 kJ/100 g), with a 100 g portion of millets providing a possible 52–57% of the daily energy requirements of an average adult (Table 2). Finger millet and fonio have lower energy densities, probably due to their lower lipid and protein contents and high fiber contents.

Like other cereals, whole-grain millets contain high amounts of fiber (8–18 g/100 g), and according to most governmental organizations, foods with a fiber content of 6 g/100 g or higher can claim 'high fiber.' The high fiber contents

Values are the average (range) of reliable published data.

[ ], Percentage contribution a 100 g portion would make to the RDA for each nutrient (WHO recommendations) of an average-sized (65 kg) adult.

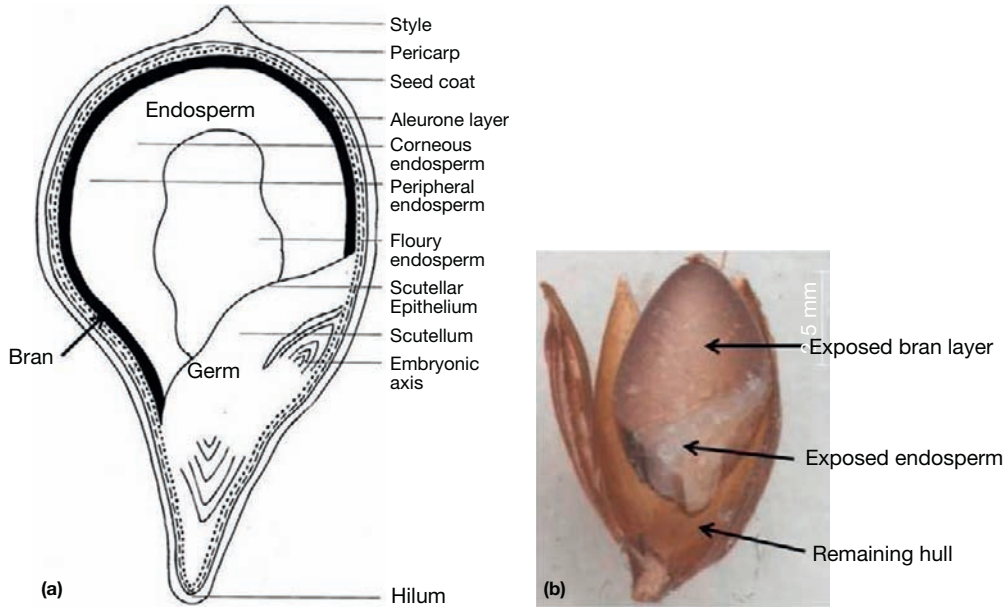

Figure 2 Structure of millet grains. (a) Schematic longitudinal section of pearl millet (courtesy of S. C. Barrion, University of Namibia). (b) Stereomicrograph of partially dehulled and decorticated white fonio (courtesy of Dr M.O. Edema, Federal University of Technology, Nigeria).

of whole-grain millets have also been proposed to contribute to them having a low glycemic index (GI). However, today, there is good evidence that whole-grain cereals in the flour form (as opposed to intact grains) do not have low GI. The millets with the higher fiber contents (pearl, proso, and finger millets and fonio) can, in a 100 g portion, provide between 55% and 66% of the prescribed daily fiber intake, which is associated with health benefits such as reduced risk of cardiovascular disease (CVD), diabetes, and certain cancers.

Millets, like all cereals, have low protein contents compared to legume and animal sources. However, pearl and proso millets have approximately 19–33% higher protein contents than the other millets. A 100 g portion of these two millets can provide approximately 23–26% of the recommended dietary allowance (RDA) for protein, compared to 15–18% of the other millets. This indicates that where millet is consumed as a staple (100 g 2–3 times/day), it could provide a substantial portion (30–80%) of protein RDA. However, millet proteins are not complete, providing only 30–65% of the required lysine, with lysine being the first limiting indispensable (essential) amino acid. The low protein contents of the millet together with the low lysine content of the protein result in millets providing approximately only 9% (foxtail, proso, and fonio millets) to 18% (pearl millet) of the 1.93 g lysine requirement in adults.

There has been an increase in documented cases of celiac disease in both developed and developing countries. This together with the 'fad' trend in Western countries that 'gluten is bad' has resulted in the increased demand for gluten-free food products. Millet grains can be recommended as a safe food for celiac disease patients. The millets are members of the Paniceae and Eragrostideae tribes (Table 1) and hence are only distantly related to the Triticeae cereals like wheat.

According to governmental organizations, most millets qualify to be labeled as 'low fat,' as they contain less than 3 g fat/100 g (1.3–2.0 g/100 g), except for pearl millet and foxtail millet, which can contain up to an average of 5 g/100 g. The lipids in millet are high in both mono- and polyunsaturated fatty acids. The lipids of all the millets (except finger millet) contain high levels of omega-6 fatty acids (linoleic acid), an essential fatty acid. A 100 g portion can provide 20–30% of the recommended intake of this fatty acid, associated with health benefits such as reduced risk of CVD.

Micronutrients

There is considerable variation in the mineral contents of the millets, both within and between species (Table 3). This is caused by inherent (e.g., cultivar and maturity) and environmental (e.g., rainfall, temperature, and soil mineral content) factors. Further, some published data on millet mineral content are suspects. This is related to the fact that as millet grains are so small, the effect of any soil mineral contamination is relatively greater than with the larger-grained cereals. While there are some variations in the average iron and zinc contents of the millets, there is no particular species that has an exceptionally high iron or zinc content. The content of iron and zinc in staple grains is very important as iron deficiency is the most prevalent nutrient deficiency in the world. Also, it is widely agreed that in developing countries, zinc deficiency is as prevalent as and as important as that of iron deficiency. Biofortified high iron and zinc pearl millet has been developed by ICRISAT using conventional breeding. It has a 2.5–3.5-fold increase in iron content and double the zinc content with the highest contents up to 12.4 and 8.4 mg/100 g, respectively. While the increased levels of iron were still within levels previously reported for normal pearl millet and other millets (Table 3), the zinc contents are substantially increased. The biofortified pearl millet has also been found to have improved iron and zinc bioavailability and iron absorption.

Most millets contain very little calcium (19–38 mg/100 g). However, teff has a much higher calcium content (161 mg/100 g), similar to that of the major cereals. Notably, finger

[ ], Percentage contribution a 100 g portion would make to the RDA for each nutrient (WHO recommendations) of an average sized (65 kg) adult.

[a]Retinol equivalence (RE), 1 μg β-carotene = 0.167 μg RE.

[b]α-Tocopherol equivalents.

millet has the highest calcium content (~343 g/100 g) of all cereals. This is important as calcium is thought to play a vital role in reducing the prevalence of rickets, which is still high in developing countries, despite sufficient UV radiation for vitamin D synthesis.

The magnesium contents of all the millets are high, where 100 g can provide more than 50% of the RDA. Importantly, fonio has been reported to have exceptionally high magnesium content (~415 mg/100 g), although this has not been thoroughly investigated. Magnesium is considered as an 'orphan nutrient' as it has been considerably less studied than other minerals such as calcium and iron. However, low magnesium intakes and blood levels (which have been found to be more common than expected) have been associated with type 2 diabetes, obesity, and CVD.

The K:Na ratios of the millets (7:1 and 36:1) are much higher than that of an average Western diet (~1:2). It has been found that increasing the K:Na ratio of foods consumed could decrease the risk of CVD.

The phosphorus in millets, as in all other grains, is largely stored in the form of phytate (*myo*-inositol hexaphosphate), which is an antinutrient. Phytate chelates, especially the divalent minerals (Fe, Zn, Ca, and Mg), which renders them (and the phosphorus in the phytate) insoluble and not bioavailable for absorption. In worst cases, the cause of mineral deficiencies may be actual insufficient dietary intake. However, more frequently, the cause is low bioavailability of nutrients, due to high levels of antinutrients, inhibitors of nutrient absorption. These are mostly found in plant foods and contribute substantially to these deficiencies. While whole-grain millets contain the most minerals, whole grain also contains much higher levels of phytate than refined flour and sometimes also tannins in the case of finger millet (Table 4), which further reduce the already low bioavailability of nonheme iron and zinc. It has also been reported that millets contain some oxalates, which decrease the bioavailability of calcium, iron, and magnesium. However, the documented levels of oxalate in millets are negligible (Table 3) compared with those in dark green leafy vegetables such as spinach and chard.

The millets contain appreciable amounts of some B vitamins, especially vitamin B_1 (thiamine), where a 100 g portion of millets can provide between 20% and 50% of the RDA. A 100 g of millet can also provide 10–15% of vitamin B_2 (riboflavin) and 8–23% of vitamin B_3 (niacin). Some of the millet species have been found to contain β-carotene, but at very low levels, not even contributing to 1% of the RDA. While yellow-endosperm pearl millet has been identified and proposed to have increased levels of β-carotene, very little research has been done. While the information is limited, the millets contain α-tocopherol. As there are no specific recommendations regarding vitamin E intake, it is difficult to comment on the quality of the millets as a source of vitamin E. The data on the α-TE in millets compare well to those of wheat (~1.0 α-TE/100 g).

The challenges in providing adequate macronutrients (protein) and micronutrients (most minerals and vitamins) from a millet-based staple cereal diet are made even worse when the increased nutrient requirements of children and pregnant and lactating women are considered. While the nutrient content of the different millet species differs somewhat, with the

Table 4 Phenolic phytochemicals and health-related aspects of the major millets

Millet species	*Presence of tannins*	*Flavonoids (μg g^{-1})*	*Phenolic acids (μg g^{-1})*	*Some significant phenolics*	*Health-related aspects*
Pearl millet	Probably absent in all varieties	Low levels Soluble – 62 Insoluble – 8	High levels Soluble – 581 Insoluble – 1003	*trans*-Ferulic acid C-Glycosylflavones (vitexin), apigenin, myricetin	Goitrogenic effects
Foxtail millet	Essentially none	Intermediate levels Soluble – 248 Insoluble – 2	High levels Soluble – 628 Insoluble – 1807	*p*-Coumaric acid, *trans*-ferulic acid Catechin, quercetin, apigenin, kaempferol	Antihyperglycemic and hypolipidemic effects
Finger millet	White and red – none Brown – some varieties	High levels Soluble – 2100 Insoluble – 13	Low levels Soluble – 167 Insoluble – 523	*trans*-Ferulic acid, protocatechuic acid Catechin, gallocatechin, epicatechin, epigallocatechin, taxifolin, vitexin, tricin, luteolin, myricetin, quercetin, kaempferol, naringenin, daidzein Procyanidins B_1 and B_2 (some brown varieties)	Antihyperglycemic and anti-inflammatory effects
Proso millet	Essentially none	Low levels Soluble – 54 Insoluble – 34	High levels Soluble – 498 Insoluble – 2082	*p*-Coumaric acid, *trans*-ferulic acid Kaempferol, apigenin, myricetin	Serum cholesterol improvement
Teff	None	No data Higher in brown and red varieties than white varieties	No data Total phenols – 66	*trans*-Ferulic acid, vanillic acid, *p*-hydroxybenzoic acid Quercetin, apigenin, luteolin	
Fonio	None	White fonio – total flavonoids <1 Black fonio – no data but should be higher	White fonio – low levels Soluble – 24 Insoluble – 38	*trans*-Ferulic acid, protocatechuic acid Luteolin, apigenin	

exception of the high calcium content of the finger millet, the millets provide similar levels of macro- and micronutrients compared to other major staple grains.

Bioactives/Phytochemicals

Generally, millet grains are rich sources of phenolic phytochemicals, mainly flavonoids and phenolic acids (Table 4). However, the levels differ considerably between species. Finger millet seems to contain the highest levels of flavonoids. However, the available data are very limited. It is probable that the levels of flavonoids vary considerably between varieties of millet species, particularly pearl millet, finger millet, and teff, with the red and brown pigmented types of these species containing high levels due to the anthocyanin flavonoid-type pigments. With regard to phenolic acids, it appears that pearl millet, foxtail millet, and proso millet contain the highest levels. However, a high proportion of the phenolic acids are insoluble as they are bound in the cell walls and as such may not be bioavailable. Concerning tannins (proanthocyanidins/procyanidins), despite some reports to the contrary, it is probable that finger millet is the only millet that contains tannins and that they are present only in some brown varieties.

Regarding phytochemical-related health-promoting properties of millets, by far, most research has been carried out on finger millet, mainly in India. Although a subject of ongoing research and discussion, there is evidence from human trials that consumption of finger millet foods alleviates type 2 diabetes and its associated conditions. Several reasons have been put forward. Finger millet tannins are powerful inhibitors of digestive amylase enzymes and hence lower glycemic response. The phenolics may also reduce protein glycation, the reactions between glucose and proteins that are associated with, for example, cataracts and kidney damage. Extracts from foxtail millet have also been shown in animal models to exert strong antihyperglycemic effects. Animal feeding experiments have also shown that extracts from finger millet and proso millet can lower serum triglyceride levels and in the case of finger millet also reduce inflammatory responses. The data suggest that consumption of these millets may be protective against CVD.

There is also evidence that phenolics in millets can have negative health implications. It has been found that condensed tannins, as present in some finger millet varieties, have an extremely high inhibitory effect on iron and zinc bioavailability. The inhibitory effect of the tannins can be so high that it completely negates the beneficial effect or reducing/totally removing the phytate from the grain. Consumption of pearl millet as a staple in certain regions of Sudan and India has been implicated as the cause of the high incidence of goiter in these populations. C-Glycosylflavone-type flavonoids, particularly the compound vitexin, a powerful goitrogen, have been proposed as the causal agent. The flavonoids luteolin and apigenin isolated from white fonio have also been shown to exert strong goitrogenic activity.

Millet Foods and Beverages and the Effects of These Processing Methods on the Nutritional and Health-Promoting Aspects

The millets are processed into a very wide range of traditional food and beverage products (Figure 3). These include whole-grain snacks, 'rice,' semolina, couscous, doughs and dumplings,

Figure 3 Traditional millet foods. (a) Pouring injera batter (teff) – Ethiopia. (b) Cooking uji (finger millet) – Kenya. (c) Pearl millet and sorghum couscous agglomeration – Senegal. (d) Foxtail millet and yak milk tea – China. (e) Finger millet porridge – Uganda. (f) Foxtail millet gruel – Taiwan. (g) White fonio rice and peanut sauce – Burkina Faso.

flatbreads, porridges and gruels (nonfermented, fermented, and alkali-cooked), lactic acid-fermented and malted nonalcoholic beverages, malt-based opaque and cloudy beers, and 'wine.' Today, in developing countries, as a consequence of rapid urbanization, an increasing variety of traditional-type millet food products are being manufactured for sale in supermarkets (Figure 4). Also, in Western countries, the market for and production of millets and millet-based products as gluten-free foods (Figure 4(c), 4(f), 4(h)) has expanded greatly over the past decade.

The processing of millets into foods and beverages can greatly change their nutritional value compared to that of the original grain, as is the case with processing any food commodity. Millets, like other cereal grains, are almost invariably debranned (the process being often referred to as dehulling or decortication) in order to improve the palatability of the food. However, debranning substantially reduces the content of insoluble dietary fiber and also reduces the levels of lipids, B vitamins, minerals, and phenolics somewhat. This is because these nutrients and phytochemicals are concentrated in the outer layers of the grain (pericarp, germ, and aleurone). For example, 21%, 12–65%, 72%, and 2% reductions in phenolic content have been reported for finger, foxtail, proso, and pearl millets, respectively, when these grains were 'dehulled.'

Millets are generally cooked by wet cooking (boiling or steaming) but sometimes by a dry cooking technology such as gun-puffing (Figure 4(f)). Both the method of cooking and subsequent cooling can dramatically influence starch digestibility. For example, noodles and biscuits made with finger millet blended with wheat were found to have lower GIs than the products made from wheat alone, whereas finger millet porridge was reported to have a much higher GI than wheat porridge.

In the Sahel region of North Africa, pearl millet flour is used to make a gel-like type of porridge called tô. A common method of preparation involves cooking under alkaline conditions through the addition of wood/millet stalk leachate or lime. Undoubtedly, this leads to a reduction in protein quality, since such conditions result in the formation of amino acid residues such as lysinoalanine and also to intra- and intermolecular covalent cross-links in polypeptides. The high pH could also have a negative effect on mineral bioavailability. Not only does phytate bind more minerals at a higher pH, but also even unbound minerals precipitate out of solution and are unavailable for absorption. Also, with alkaline cooking, there might be large losses of vitamins B_1 and B_2. The effects of cooking millets on phenolics have been observed to be very complex, as both the release of bound phenolics and depolymerization of polyphenols can take place.

The process of making many African traditional millet products such as injera (teff) flatbread, porridges, uji (finger millet-based) gruel, and oshikundu (pearl millet) beverage involves a lactic acid bacteria fermentation. This fermentation can somewhat improve starch and protein digestibility. It may also increase B vitamin content and very substantially reduces phytate content. However, most importantly, the low pH of these lactic acid-fermented products, pH <4, renders them microbiologically safe. This is particularly important as still today, many people in Africa do not have access to safe water. Some of the lactic acid bacteria responsible for these fermentations have been found to be probiotics, viable microorganisms that promote or support a beneficial balance of the microbial population in the gastrointestinal tract. However, currently, there is insufficient evidence as to whether the probiotic organisms confer special health-promoting properties to these traditional lactic acid-fermented products.

Figure 4 Commercial millet foods and beverages. (a) Pearl millet and sorghum couscous – Senegal. (b) Fermented mahangu flour (pearl millet) – Namibia. (c) Pearl millet semolina – Sahel. (d) Instant kunun tsamiya porridge (pearl millet and tamarind) – Nigeria. (e) Uji flour (finger millet) – Kenya. (f) Finger millet and soy flour – Tanzania. (g) Organics Nu-Vit hulled millet – Australia. (h) Puffed foxtail millet – USA. (i) Foxtail millet wine – Taiwan.

In Africa and India, the process of making many traditional millet foods and beverages involves the use of millet malt. Examples are the uji gruel from Kenya and the ragi malt drink in India, both based on finger millet malt. The malting (sprouting) process mobilizes endogenous amylases that liquefy porridges through hydrolysis of the starch to sugars. This improves carbohydrate availability and makes the products sweeter and hence more palatable. Also, importantly, the reduction in viscosity reduces porridge bulk. The high bulk (high water content and sticky paste texture) and consequently low nutrient density of cereal porridges are major factors contributing to infant malnutrition in Africa. Inclusion of malted millet or sorghum flour enables a porridge to be made that has much higher solids content (hence higher nutrient density) but has a sufficiently low viscosity that it can be consumed by infants. The use of malted millet/sorghum flour, referred as power flour or amylase-rich flour in weaning food preparation, has been widely promoted by nutritionists.

Malting also has other nutritional benefits. It improves protein quality, through the synthesis of lysine-rich proteins and making the protein more available for digestion. Additionally, the contents of B vitamins are increased through synthesis, and mineral bioavailability is improved by phytate reduction through the action of endogenous phytases. However, it is important to be aware that malting is a skilled process. Failure to properly control malting conditions such as temperature, moisture, and aeration can easily lead to the proliferation of toxigenic fungi.

Conclusions and Future Directions

The rapid urbanization that is taking place in developing countries, especially in Africa, provides a huge opportunity to develop local food processing industries to meet the needs of people who are now working and living in cities. As explained, with rapid urbanization, many traditional-type millet products are now being produced by small-scale entrepreneurs. The gluten-free market in Western countries also presents a great opportunity for small-holder millet farmers in developing countries. However, the small size of the millet grains remains a challenge, especially with regard to efficient and effective milling to produce high-quality flour for this latter market. In the Sahel region, innovative indigenous technologies have been developed for milling pearl millet and even for fonio, despite it being tiny. Notwithstanding this, there is still a way to go until millet industrial milling technology approaches the level of sophistication as that of the major cereals such as wheat, rice, and maize.

Our knowledge of the phenolic compounds present in millets is increasing rapidly, and it is clear that millets are generally much richer in these phytochemicals than the major cereals. However, the need is now to confirm that these phenolics actually function as nutraceuticals and to establish whether regular consumption of millet foods is preventative against the so-called lifestyle diseases such as type 2 diabetes, CVD, and colorectal cancer. Related to this, the indications that certain flavonoid compounds in millets, especially those in pearl millet, may exacerbate goiter in at-risk communities are serious causes for concern. Research is clearly needed to determine whether regular consumption of such millets actually poses a risk. If so, breeding will be required to substantially reduce the levels of these compounds.

Biofortification of millets, as exemplified by the high iron and zinc pearl millet developed by ICRISAT, is a promising way of improving the nutrition of those who are chronically malnourished and depend on millets as their staple food. However, malnutrition is rarely caused by deficiency of a single nutrient. Thus, there is need to develop millets that are biofortified with other micronutrients, particularly provitamin A, and possibly also to develop types with reduced levels of phytate so as to improve dietary mineral bioavailability.

However, probably the biggest challenge is that millet yields are generally much lower than those of the major cereals. Thus, in developing countries, particularly in India, there is a trend for farmers to switch from cultivating millets as they have done for hundreds years to growing cereals such as maize. An important reason for the lower yields of millets is that they have not been subject to such intensive breeding. The potential of what can be achieved through the development of hybrid lines is shown in the example of foxtail millet. Similar successes have been achieved in many countries with pearl millet. However, for cultivation of millets to expand in developing countries in order to feed their burgeoning populations, the breeding and on-farm implementation of improved open-pollinated varieties and hybrids need to be greatly intensified.

Mineral Water: Sources and Storage

A Astel, Pomeranian University in Słupsk, Słupsk, Poland

© 2016 Elsevier Ltd. All rights reserved.

Drinking water of good quality is essential for human health and sustainable development. One of the most desired kinds of water available for consumers worldwide is mineral water, which comes from springs. They naturally generate water containing minerals or other dissolved substances. These alter the taste or give it a purported therapeutic value. A spring is a place where water issues from the ground and flows or lies in pools that are continually replenished from below. Wholly artificial openings, such as artesian wells, are not regarded as springs. Numerous springs are found around the world and are of diverse characters, from small trickles of water into an old hollowed-out log to large pump lift systems into stainless steel tanks for municipal and industrial use and by the bottled water industry. The location of a given spring is unpredictable. However, the majority are located in mountainous regions and upland areas. The taste and properties of the water are closely connected to the type of soil or geologic structure in which the spring is located. Details of water available in various types of soil are summarized in Table 1.

Springs are classified according to several criteria. One system of classification is based on the magnitude of water flow or discharge. The amount of water that flows from a spring depends on several factors, including rainfall, the size of caverns within the rock, the water pressure in the aquifer, and the size of the spring's recharge basin. Human activities can also influence the volume of water that discharges from a spring. For example, increased groundwater withdrawals can reduce the hydraulic pressure in an aquifer, causing water levels to decline and the spring flow to decrease. Generally speaking, springs have dynamic flows dependent on the climate and hydrogeology, and a spring classified as being a certain magnitude at one time may not continue to flow at that rate at other times. However, it is expected that over an extended period, seasonal fluctuation in flow rate will generate a relatively stable discharge. Moreover, the groundwater table must be deep, with a sufficiently large basin. An example of springs classified by magnitude, used by the Florida Bureau of Geology, is summarized in Table 2. First-magnitude springs discharge the largest amount of water.

Springs may be divided according to temperature into thermal and nonthermal springs. Most nonthermal springs have temperatures that are approximately the same as the mean annual temperature of the air of the region in which they are found. Perennial or permanent springs flow throughout the year. Intermittent or temporary springs flow only during or after rains. Springs due to deep-seated water may be divided into two classes (volcanic and fissure springs), according to their geographic distribution, with respect to localities of volcanic or tectonic disturbance. Volcanic springs are associated with present or past volcanism, while fissure springs in general have a strong and relatively constant flow, not subjected to annual fluctuations. They are usually warm or hot, and many are highly mineralized. They appear to rise along deep fractures, extending far into the Earth's crust. Another classification of springs is those involving shallow water. Springs due to shallow water may be divided into four large groups, according to the character of the rock in which they occur:

- Springs in porous rock
- Springs in porous rock overlying impervious rock
- Springs in porous rock between impervious rock
- Springs in impervious rock

Due to the unique properties of a mineral water taken from a given spring, it is often bottled using a regional name that indicates its location and permits it to be recognizable by consumers, according to the characteristics of the water. Natural mineral waters should not be transported from the source to the bottling plant. In addition, transport from a source to the bottling plant must be in a closed pipeline, made of suitable material (i.e., that will not alter the characteristic properties of the water or cause the water to become contaminated). Equipment used in the filling system must ensure that there is no contamination or alteration of the water prior to closure.

The most common way to transport water-based drinks is in bottles. Bottled water is packaged in either glass or, more commonly, polymer bottles with metallic or plastic caps of a different material, shape, and color. Polymer bottles and containers are made of one or more monomers, involving several additives (e.g., accelerators, catalyzers, stabilizers, antioxidants, coupling agents, and plasticizers). Labels must show an abbreviation indicating the nature of the container. The list of plastics or packaging used for bottling and codes appropriate for recycling factories are summarized in Table 3.

The most common plastic material used for bottling mineral water, soda, and vinegar is polyethylene terephthalate (PET). Other plastics used in the food industry include high-density polyethylene (HDPE) for milk; polyvinyl chloride (PVC) for cooking oil and coffee cups; low-density polyethylene (LDPE) for wrapping films, grocery bags, and sandwich bags; polypropylene (PP) for yogurt cups; and polystyrene (PS) for coffee cups and hot beverage cups.

PET is the material most commonly used to make clear plastic bottles in which water is sold. PET is usually produced by the polymerization of petroleum monomers terephthalic acid and ethylene glycol, using antimony-, titanium-, or germanium-based catalysts. However, PET synthesis without added catalysts is possible. Manufacturers prefer PET because it is relatively safe, transparent, and versatile. Customers choose it for its safety, light weight, resealability, shatter resistance, and recyclability. Up to 100% of a PET package can be made from recycled PET and recycled multiple times.

PE is the most common plastic in commerce. It is a polymer of ethylene, being itself a pair of methylene groups connected together. Catalysts readily combine ethylene into a polymer. The most common catalysts consist of titanium(III) chloride (Ziegler–Natta catalysts) or Phillips catalyst prepared by

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00469-4

Table 1 Details of water available in various types of soils

Type of soil	*Depth at which water may be available*	*Amount*	*Taste*
Clay	Near the surface	Scanty	Not good
Loose gravel	Lower down in the surface	Scanty	Unpleasant
Black earth		–	Excellent
Gravel		Small and uncertain	Unusually sweet
Coarse gravel, common sand, and red sand		More certain	Good
Red rock		Copious	Good
Flinty rock and foot of mountain		Copious	Cold and wholesome

Table 2 Spring classification by magnitude defined by the Florida Bureau of Geology

Magnitude	*Volume of flow (discharge)*
1	100 cfs or more
2	10–100 cfs
3	1–10 cfs
4	0.223 cfs (100 gpm) to 1 cfs
5	0.0233 cfs (10 gpm) to 0.223 cfs
6	0.0022 cfs (1 gpm) to 0.0233 cfs
7	0.00028 cfs (1 pint min^{-1}) to 0.0022 cfs
8	0.00028 cfs or less

Units: cfs, cubic feet per second; gpm, gallons per minute; pint min^{-1}, pints per minute.
Conversions: 100 cfs = 64.6 million gallons per day; 1 cfs = 646316.9 gal per day; 1 gal min^{-1} = 0.0022 cfs; 1 pint min^{-1} = 0.00028 cfs.

Table 3 The type of plastic or packaging used for mineral water bottling and appropriate codes for recycling factories

Abbreviation	*Name*	*Code*
VE	Glass	–
PET	Polyethylene terephthalate polycondensate	1
PE:	According to the IUPAC polyethylene or poly (methylene)	
HDPE	Polyethylene of high density	2
LDPE	Polyethylene of low density	4
PVC	Polyvinyl chloride	3
PP	Polypropylene	5
PS	Polystyrene	6
PC	Polycarbonate	7
CA	Polyethylene-coated board	7
FEP	Fluorinated ethylene propylene	7
PFA	Perfluoroalkoxy polymer	7

depositing chromium(VI) oxide on silica. Polyethylene is classified according to several categories. The most common forms used by manufacturers to produce bottles are polyethylenes of low and high density (LDPE and HDPE, respectively). HDPE is defined by a density of greater or equal to 0.941 g cm^{-3}, while LDPE is defined by a density range of 0.910–0.940 g cm^{-3}.

PVC is a synthetic resin made from the polymerization of vinyl chloride. Its estimated worldwide demand is second only to PE among plastics, relative to production and consumption. PVC is a relatively lightweight polymer and can be manufactured in both rigid and flexible 'plasticized' forms. Because of these features, the list of its uses is endless. It is found in a wide range of consumer products, such as packaging, cling films, bottles, credit cards, raincoats, shower curtains, and construction materials, such as window frames and indoor pipes. Regrettably, PVC products can leak harmful additives during use and disposal, when they are burn or buried.

PP is a thermoplastic of linear structure, based on the monomer C*n*H2*n*. It is synthesized from propylene gas, in the presence of a catalyst such as titanium chloride. A major advantage of PP, in comparison with HDPE, is PP's higher temperature resistance. This makes PP particularly suitable for items such as trays, funnels, pails, bottles, carboys, and instrument jars that have to be sterilized frequently for use in a clinical environment. PP is a translucent material with excellent mechanical properties and has gradually replaced polyethylenes for many purposes.

PS is a thermoplastic polymer made from styrene monomers. Because of its versatility, it can be rigid or foamed and can be made to possess a number of variant attributes. This is why the material is one of the most widely used plastic materials. Applications include housewares, containers, packaging, glazing and light diffusers, casings, cups, take-out containers, and cassette cases. Polystyrene is also widely used as a structural foam and expanded into beads for packaging and cushioning. Polystyrene plastic bottles are often offered by manufacturers since they are excellent moisture barriers for short shelf-life products, and it has extraordinary optical clarity (in its general-purpose form), significant stiffness in both foamed and rigid forms, low density, and thermal conductivity.

PCs are a group of long-chain, linear, thermoplastic polyesters that are easily worked, molded, and thermoformed. PCs receive their names because they contain a carbonate group in a polymer chain. The presence of the phenyl groups on the molecular chain and the two methyl side groups contributes to molecular stiffness in the polycarbonate. This stiffness has a large effect on the properties of polycarbonate. First, the attraction between the phenyl groups of different molecules contributes to a lack of mobility of the individual molecules. This results in good thermal resistance but relatively high viscosity (i.e., low melt flow) during processing. The inflexibility and lack of mobility prevent polycarbonate from developing a significant crystalline structure. The lack of a crystalline structure (the amorphous nature of the polymer) allows for light transparency. It can be injection molded, blow molded, or extruded and is an ideal engineering plastic with good electrical insulating properties. Thus, it finds applications in electric meter housings and covers, casket hardware, portable tool housings, safety helmets, computer parts, vandal-proof windows, light globes, and the food industry.

FEP is a copolymer of hexafluoropropylene and tetrafluoroethylene. It differs from the polytetrafluoroethylene (PTFE) resins in that it is melt-processable, using conventional injection molding and screw extrusion techniques. FEP can be used

in producing articles having a combination of mechanical, chemical, electrical, temperature, and friction-resisting properties, unmatched by any other material. It is essentially inert. Up to the highest use temperature (200 °C), very few chemicals are known to react chemically with these resins. Those that do include molten alkali metals (e.g., Li, Na, K, Rb, Cs, and Fr), fluorine, and a few fluorochemicals such as chlorine trifluoride (ClF_3) or oxygen difluoride (OF_2). Both readily liberate free fluorine at elevated temperatures. Applications include electronic items such as wire covering and FEP spaghetti tubing, FEP linings for pipes in the chemical industry, aircraft wiring, and glazing for solar energy collectors.

PFA is a fully fluorinated, translucent, slightly flexible polymer, with a low coefficient of friction and outstanding antistick properties. From a structural point of view, it is a copolymer of tetrafluoroethylene (C_2F_4) and perfluoroethers (CF_2F_3OR'), where R′ is a perfluorinated group such as trifluoromethyl (CF_3). This tough material resists stress cracking and attack by nearly all chemicals and solvents. PFA is also relatively temperature-resistant, making it ideal for use in both high- and low-temperature environments. PFA is chemically stable and has excellent dielectric strength.

Several additives may be present in plastic containers. Thus, compounds such as lead, zirconium, antimony, bisphenol A (BPA), and dioxins can be among important contaminants and may present serious health risks to humans. Contamination with metals, leaching from glass and plastic bottles, has been evaluated by many researchers under a variety of treatment conditions, for example, heating, cooling, and sunlight exposure. Glass bottles may contaminate bottled water with trace amounts of Pb (see Table 4), whereas many PET bottles contaminate the water with trace amounts of Sb.

Lead poisoning can be hard to detect. Even people who seem healthy can have high blood levels of lead since signs and symptoms usually do not appear until dangerous amounts have accumulated. Unfortunately, according to the Agency for Toxic Substances and Disease Registry and US Environmental Protection Agency (USEPA), there is no such thing as a 'safe' or 'dangerous' threshold level of lead, only levels that we are willing to accept as tolerable. The signs and symptoms of lead poisoning are highly dependent on individual sensitivity, and hence, specification about dangerous limits is difficult. Blood lead levels as low as 2 μg dl^{-1} may not cause distinctive symptoms but are associated with decreased intelligence and slower neurobehavioral development in the form of cognitive and language deficits. Other effects can begin to occur at these low blood levels. Lead present in drinking water consumed on a daily basis can cause a variety of adverse health effects. Consumption 'on a daily basis' is significant to potential toxicity, because lead not stored in the bones is slowly eliminated by the kidneys and gastrointestinal tract. Negligible amounts are lost via perspiration. The 'half-life' of lead in the body varies from about a month in the blood, 1–1.5 months in soft tissue, to about 25–30 years in bones. The USEPA has set drinking water standards with two levels of protection: the maximum contaminant level goal (MCLG) is 0 μg l^{-1}. This is the level determined to be safe by toxicological and biomedical consideration, independent of feasibility. This, therefore, is the goal for lead content in water. The other rule establishes an 'action' level of 15 μg l^{-1}, which is the maximum allowable content in drinking water. Because the concentration of lead caused by leaching from glass and PET is far lower than the 'action' level established by the USEPA (Table 4), consuming bottled water can be considered safe. About 99% of the lead absorbed by an adult is eliminated shortly thereafter, whereas about 32% is lost by a child in the same period. In babies and children, long-term exposure to lead in drinking water from all sources above the action level can result in delays in physical and mental development, along with learning difficulties, irritability, loss of appetite, weight loss, sluggishness and fatigue, abdominal pain, vomiting, constipation, hearing loss, and slowed growth. Recently, the Centers for Disease Control and Prevention (CDC) identified 10 μg lead per deciliter (dl) of blood, the level of concern in children. However, adverse effects can occur at lower levels than previously thought. This is why current experts use a reference level of 5 μg dl^{-1} to identify children with blood levels that are higher than normal. This reference value is based on the 97.5th percentile of the US National Health and Nutrition Examination Survey concerning blood lead distribution in children. Adults who drink water with elevated lead contents for many years could develop kidney problems, abdominal pain, constipation, joint pains, muscle pain, declines in mental functioning, high blood pressure, headache, memory loss, mood disorders, reduced sperm count, abnormal sperm, and miscarriage or premature birth in pregnant women.

The US Environmental Protection Agency and the Council of the European Communities classify Sb as a serious food contaminant. In cases of acute intoxication, the following symptoms can arise: stomachache, diarrhea, desiccation, muscle aches, shocks, anemic uremia, serious myocardial inflammation, shivering, and death-causing liver necrosis. Some research studies report that a single intake of lemonade, accidentally contaminated with antimony to a concentration of 30 μg ml^{-1} Sb, caused nausea, vomiting, and diarrhea in 150 children. Fortunately, most of the affected children recovered within a few hours, and such Sb concentrations do not occur in drinking

Table 4 Median concentration (μg l^{-1}) of some metals in the same water sold in glass and PET bottles and in the same water sold in green and clear glass bottles

Cr	0.209	0.0871	0.138	1.01

water. The concentration of antimony in groundwater and surface water normally ranges from nondetectable to 0.2 $\mu g\,l^{-1}$. Antimony is not likely to occur at significantly higher concentrations in natural waters, except those areas affected by acid mine drainage. Risk to human health, when it occurs, is through ingestion (drinking, cooking, and teeth brushing). Because of the toxic effects of lead and antimony, the maximum allowable limits in mineral water established by the European Union community and selected European countries are 5 $\mu g\,l^{-1}$ and 10 $\mu g\,l^{-1}$ for Pb and Sb, respectively. Slightly higher permissible limits have been established by the USEPA and World Health Organization (WHO) for drinking water (6 and 20 $\mu g\,l^{-1}$ for Sb and 15 and 10 $\mu g\,l^{-1}$ for Pb). Well water with antimony levels higher than 6 $\mu g\,l^{-1}$ may safely be used for bathing, hand washing, and dishwashing. The daily oral uptake of antimony ranges from 10 to 70 μg; however, the total exposure from environmental sources (air and soil) and food/drinking water is low compared with exposure in the workplace. Assuming 20 μg of Sb as an average daily oral uptake of an adult, it is estimated that approximately 38% (about 7.4 μg Sb per day) would come from drinking water, especially when stored in PET bottles. Some scientists consider the leaching of Sb from PET bottles into mineral water could possibly represent a risk to human health. According to data presented in Table 4, the Sb concentration in PET bottles can be about thirty times higher than in glass bottles. However, it is still far below the allowable content established by organizations mentioned earlier. Basing on testing of more than 100 brands of bottled water from Japan, Canada, and several European countries, the observed Sb concentration increased over time and temperature during storage. While Sb leaching is negligibly low (it does not exceed a few % of the total amount of Sb present in the entire plastic bottle) below storage temperatures of 60 °C, above this temperature (i.e., inside automobiles and garages), antimony release can occur rapidly. Moreover, the leaching rate of Sb is generally higher in the case of sparkling mineral waters, compared with the still mineral waters, due to the lower pH. Fortunately, only a very small percentage of the antimony present in PET bottles leaches into the water. For example, when a plastic bottle contains around 250 mg Sb per kg, the leaching rate should not exceed 1 ng Sb per ml after 3 years. Hence, even then, it remains far below the allowable content of Sb in drinking water. Comparing to exposure of the typical urban population to antimony from air, estimated to be between 60 and 460 $ng\,day^{-1}$ per person, the daily intake of 2 l of bottled water, stored in darkness and at room temperature, is fully safe.

In general, water being sold in PET bottles shows a significantly higher concentration of Sb than the same water sold in glass bottles. Nonetheless, glass leaches out a longer list of elements, with trace amounts of Ce, Pb, Al, Zr, Ti, Hf, Th, La, Pr, Fe, Zn, Nd, Sn, and Cr. The majority of these elements have potential toxic effects on humans. However, most toxicity studies have been done on *Drosophila melanogaster*, rats, dogs, or rabbits, since performing the necessary toxicological studies on humans is unethical. Fortunately, the concentrations noted in Table 4 are far from toxic levels (i.e., the toxic dose of lead in pets is 10–15 $mg\,kg^{-1}$, when given as a single dose), and hence, the presence of trace amounts of Ce, Pb, Al, Zr, Ti, Hf, Th, La, Pr, Fe, Zn, Nd, Sn, and Cr in bottled water, according to current knowledge, has no known health significance.

A glass bottle, used as a container for mineral water, comes in five major colors, with clear and green being the prevailing colors. It was found that for several elements, especially for Cr, water stored in the green glass showed a significantly higher concentration than those sold in clear glass. Dark-colored bottles (especially dark green and brown) appear to leach more elements than bottles made of clear glass (see Table 4), due to the elements added to provide the color characteristics to the glass, that is, Fe, Cr, Sn, and REEs (rare earth elements). Iron(II) oxide together with Cr gives bottles a rich green color, while chromium in higher concentrations generates a black color. Chromium together with tin oxide yields emerald-green glass.

As mentioned earlier, inorganic compounds may be present as residues from the catalysts or additives used to produce PET. In addition, some organic compounds can migrate into the water. Formaldehyde and acetaldehyde are the most relevant carbonyl compounds migrating out from PET bottles. These compounds are generated in the thermomechanical and thermooxidative degradation of PET. Despite the fact that phthalates in food are subject to strict regulations, and are not thought to be used in the manufacture of PET, they have been found in PET bottled water.

Diisobutyl phthalate, di-*n*-butyl phthalate, benzyl butyl phthalate, and di(2-ethylhexyl) phthalate have been found in noncarbonated mineral water, with the following concentrations: $<3.0\ ng\,l^{-1}$–$0.2\ \mu g\,l^{-1}$, $6.6\ ng\,l^{-1}$–$0.8\ \mu g\,l^{-1}$, $<6.0\ ng\,l^{-1}$–$0.1\ \mu g\,l^{-1}$, and $16.0\ ng\,l^{-1}$–$1.7\ \mu g\,l^{-1}$, respectively. Up to now, no information is available on any acute and chronic effects in humans from inhalation or oral exposure to di-*n*-butyl phthalate. It has also been detected in some drinking water supplies at levels of 0.1–5 ppb. The MCLG for di(2-ethylhexyl) phthalate, suggested by the US Environmental Protection Agency, is 0 $mg\,l^{-1}$. The current maximum contaminant level (MCL) permitted is 0.006 $mg\,l^{-1}$ or 6 ppb. A person drinking water at or below 5–6 ppb of phthalates, whether briefly, occasionally, or daily for a lifetime, would experience little or no health risk. People who drink water highly contaminated by phthalates for many years may develop liver problems, experience reproductive difficulties, and/or have an increased risk of cancer. Polybrominated diphenyl ethers (PBDEs), in particular decabromodiphenyl oxide (BDE-209), are used as flame retardants in the preparation of both PET and PC plastics, whereas tetrabromobisphenol A (TBBPA) is also used in epoxy and PC resins. Analytic reports on the presence of certain PBDE congeners in plastics, such as BDE-153, BDE-183, BDE-196, BDE-197, BDE-203, BDE-206, BDE-207, and BDE-209, were qualitatively reported in HDPE, polystyrene (PS), PP, and BDE-47 in PET. Although controversial, PET bottles have been designated as a possible source of estrogenic substances.

BPA is released mainly from polycarbonate drinking bottles; however, trace leaching is also observed from PET bottles. It can migrate into water at a similar rate at room temperature from both new and used PC bottles. Exposure to elevated temperatures, above those typically used for washing by consumers, but not outside normal household practice (e.g., boiling to sterilize infant feeding bottles) or outdoor applications (additions of very hot or boiling water or beverages to drinking bottles), greatly elevates the rate of BPA migration. However, the volume of water stored in bottles made

Table 5 The time of storing bottled water in the pantry and in the refrigerator advised by the IBWA

	Pantry	*Refrigerator*
Unopened		
Bottled water lasts for	2+ years	2+ years
Flavored water lasts for	9 months	9 months
Vitamin water lasts for	9 months	9 months
Sparkling water lasts for	1+ years	1+ years
Opened		
Sparkling water lasts for	2–3 h	2–3 days
Bottled water lasts for	2–3 h	3–5 days

from polycarbonate plastic needs to be consumed to reach the tolerable daily intake (TDI) that is estimated at 124 l day^{-1}. In the case of bottles made from PET, the daily consumption required to reach a TDI would have to be even higher, since the migration of BPA from the plastic into water is smaller (does not exceed 24.2 μg l^{-1}).

Bottled drinking water is often stored under unpredictable conditions for prolonged periods before being sold and drunk. The storage time and its conditions will clearly have an influence on how much of an undesirable element or compound leaches into the water. It was found that high-temperature and long-term storage can yield antimony and lead concentrations that approach or exceed the MCLs. In contrast, within a pH range of 6–8, sunlight exposure had small effects on antimony leaching. This is why the International Bottled Water Association (IBWA) advises consumers to store bottled water at room temperature or cooler, away from solvents and chemicals such as gasoline, paint thinners, household cleaners, and dry cleaning chemicals and out of direct sunlight. When water (bottled or tap) is exposed for extended periods to direct sunlight or heat sources, algae or molds may grow in the water. The advised durations for storing bottled water at room temperature or in the refrigerator are noted in Table 5.

Labels on bottled mineral waters are regulated by legislative norms. According to European regulations, there are both mandatory and optional indications:

- *Mandatory indications*: Sales description, volume, the 'best before...' date, storage and use conditions, the name and address of the manufacturer and/or packager, the batch reference, the place where the spring was located, the name of the spring, and the analytic composition for natural mineral waters (mineral content, trace elements, and dry residue) and information on any treatments, among the few permitted (e.g., total or partial elimination of carbon dioxide).
- *Optional indications*: About the properties related to health. All indications attributing properties related to the prevention, treatment, or cure of human illnesses, associated with natural mineral water use, are prohibited, except for indications on a very specific list.

Some indications may be used only when some restrictive criteria are fulfilled. For example, water can only be labeled with the description 'spring water' if it originates from an underground water source, is bottled at the source, and satisfies most of the acquisition conditions, microbiological criteria, and some labeling requirements that apply to natural mineral waters. Similarly, only water recognized as a natural mineral water can be labeled and sold as 'natural mineral water.'

Mineral Water: Types of Mineral Water

A Astel, Pomeranian University in Słupsk, Słupsk, Poland

© 2016 Elsevier Ltd. All rights reserved.

Undoubtedly, water is one of the most important liquids on Earth. As stated by von Goethe (Faust II, 1833): "Everything comes from water! And everything is kept alive by water!" Water has extraordinary taste properties and provides essential elements such as magnesium, iron, and calcium, which have proven to have therapeutic properties. Because of this, both the production and consumption of various types of bottled water have increased in the majority of countries. For example, in the Netherlands, the nationwide consumption has increased from 5.5 to 15.9 l per person within the period 1980–97, while in Poland, consumption increased from 2.4×10^7 l in 1980 to about 20×10^7 l in 2005.

Bottlers should use standard identifiers, prescribed by regulations (e.g., the US Food and Drug Administration (FDA), the European Commission (European Union), and the Ministry of Health (Poland and Italy)), but their specific meaning may be different from country to country. These terms may refer to both the geographic sources of the water and the treatment methods applied. The most common phrase applied is 'mineral water'; however, in many cases, this phrase is colloquially used to mean any bottled water: artesian, sparkling, still, spring, table, etc.

'Mineral water' definitions are based on two general concepts:

- The concept of a protected source and more specifically to bacteriological quality
- The concept of minimal concentration of dissolved salts

According to the Council of the European Communities, natural mineral water is defined as "microbiologically wholesome water, originating in an underground water table or deposit, and emerging from a spring tapped at one or more natural or bored exits" (Directive 80/777/EEC and 96/79/EEC).

Natural mineral water can, in addition, be clearly distinguished from ordinary drinking water by

1. its nature, which is characterized by its mineral content, trace elements, or other constituents and, where appropriate, by certain effects;
2. its original state.

Both conditions have been preserved because of the underground origin of the water, being protected from the risk of pollution. The composition, temperature, and other essential characteristics of natural mineral water must remain stable at the source, within the limits of natural fluctuation. In particular, these properties must not be affected by possible variations in the flow rate. The chemical composition of mineral waters is determined by the composition of the rock from which it is abstracted. Depending on geochemical processes, however, similar types of rocks may lead to different characteristics in the mineral water.

In some countries (e.g., the United States), the definition of what is a 'mineral water' is based on a minimum concentration of dissolved salts. The FDA classifies mineral water as water containing at least 250 parts per million total dissolved solids (TDS), originating from a geologically and physically protected underground water source (21CFR165.110, 2014). According to European regulations (Directive 80/777/EEC), mineral water has to contain a minimum of 150 mg l^{-1} of minerals. However, local standards differ from country to country. In general, mineral water can be classified, according to its mineral salt content, as water of very low mineral content, low mineral content, and rich in mineral salts. According to Directive 2009/54/EC, some indications and their criteria are summarized in Table 1.

Mineral water is characterized by its constant levels and relative proportions of minerals and trace elements at the source. No minerals may be added to mineral water. The dissolved chemical ingredients of mineral waters are made up as presented in Table 2.

Natural mineral water, in its state at source, may not be the subject of any treatment other than (Directive 2009/54/EC):

1. the separation of its unstable elements, such as iron and sulphur compounds, by filtration or decanting, possibly preceded by oxygenation, in so far as this treatment does not alter the composition of the water as regards the essential constituents which give it its properties;
2. the separation of iron, manganese and sulphur compounds and arsenic from certain natural mineral waters by treatment with ozone-enriched air in so far as such treatment does not alter the composition of the water as regards the essential constituents which give it its properties. . .;
3. the separation of undesirable constituents other than those specified in 1 or 2, in so far as this treatment does not alter the composition of the water as regards the essential constituents which give it its properties. . .;
4. the total or partial elimination of free carbon dioxide by exclusively physical methods.

Mineral water can be put on the market and/or exploited for healing purposes only after the recognition by the appropriate official bodies (e.g., the Ministry of Health, Italy). Main authorization procedures valid in the majority of countries comprise:

- permission of research and regional mining claim;
- evaluation of hydrogeologic, chemical, physical, microbiological, chemico-pharmacological characteristics, and recognition by appropriate official bodies;
- operations authorized by the recognition decree;
- authorization for health claims;
- regional authorization for the use of the water in the manufacture of soft drinks;
- regional authorization for marketing.

Due to increased interest and nationwide consumption, the maximum allowable content of mineral elements in mineral water was established by the European Community and selected European Countries and in drinking water by the

Table 1 Mineral water indications and their criteria

Indications	*Criteria*
Very low mineral content	Mineral salt content, calculated as a fixed residue, not greater than 50 mg l^{-1}
Low mineral content	Mineral salt content, calculated as a fixed residue, not greater than 500 mg l^{-1}
Rich in mineral salts	Mineral salt content, calculated as a fixed residue, greater than 1500 mg l^{-1}
Contains bicarbonate	Bicarbonate content greater than 600 mg l^{-1}
Contains sulfate	Sulfate content greater than 200 mg l^{-1}
Contains chloride	Chloride content greater than 200 mg l^{-1}
Contains calcium	Calcium content greater than 150 mg l^{-1}
Contains magnesium	Magnesium content greater than 50 mg l^{-1}
Contains fluoride	Fluoride content greater than 1 mg l^{-1}
Contains iron	Bivalent iron content greater than 1 mg l^{-1}
Acidic	Free carbon dioxide content greater than 250 mg l^{-1}
Contains sodium	Sodium content greater than 200 mg l^{-1}
Suitable for the preparation of infant food	Sodium or chloride content not greater than 20 mg l^{-1}[a] Fluoride content not greater than 0.7 mg l^{-1}[a] Nitrate content not greater than 10 mg l^{-1}[a] Nitrite content not greater than 0.02 mg l^{-1}[a]
Suitable for a low-sodium diet	Sodium content less than 20 mg l^{-1}
May be laxative	–
May be diuretic	–

[a]Obligatory in Poland.

Table 2 Chemical ingredients present in various types of mineral waters

Common ingredients	
Acids	Carbonic, sulfuric, hydrochloric, silicic, etc., usually in combination
Aluminum	Oxide and sulfate
Calcium	Carbonate, chloride, sulfate, phosphate
Iron	Carbonate, bicarbonate, sulfate, oxide
Lithium	Carbonate, bicarbonate, sulfate, chloride
Magnesium	Sulfate, carbonate, bicarbonate, chloride
Potassium	Carbonate, bicarbonate, chloride, sulfate, phosphate
Silicon	Usually as silica or silicon dioxide, occasionally as the bicarbonate
Sodium	Chloride, carbonate, bicarbonate, sulfate
Gases	Carbonic anhydride or carbonic acid gas, carbon dioxide; hydrogen sulfide or sulfured hydrogen gas; oxygen, nitrogen
Rarer ingredients	
Acids	Crenic and apocrenic, usually as crenates
Ammonium	Nitrate, chloride, crenate
Antimony	Oxide and sulfate
Arsenic	Arsenate of sodium and potassium, arsenious acid
Barium	Baryta or barium oxide and the sulfate
Boron	Biborate of soda or borax
Bromine	Bromides of sodium
Cadmium	Sulfate
Cesium	Sulfate
Chlorine	Chlorides, rarely free
Cobalt	Very rare
Copper	Very rare
Fluorine	Fluorides
Iodine	Iodides of sodium and potassium

United States Environmental Protection Agency (US EPA) and World Health Organization (WHO) (Table 3).

Mineral waters may be gaseous (sparkling) or nongaseous (still). Very often, natural mineral water contains dissolved CO_2. Carbon dioxide may be released spontaneously in noticeable ways under conditions of normal temperature and pressure. Because of this feature, gaseous natural mineral waters are divided into three general categories:

- Natural mineral waters, naturally saturated with CO_2 – for identification of water type, in which the concentration of CO_2 in an underground water table or deposit is equal to the concentration of CO_2 after the separation of unstable elements and bottling; in the case of necessity, the water can be again saturated with CO_2 obtained from the same underground water source, to the same concentration as lost during the processes mentioned in the preceding text

Table 3 Maximum allowable content of mineral elements in mineral water established by the European Union (EU) Community and selected European countries and in drinking water by the United States Environmental Protection Agency (US EPA) and World Health Organization (WHO)

Table 4 Classification of therapeutic groundwaters based on their pharmacodynamic factors in Poland

Total dissolved solids (TDS)	*Pharmacodynamic factors – specific components*		*Temperature*
$\geq$1 $g\ l^{-1}$	2 mg F^-	Fluoride water	>20 °C thermal water
	1 mg I^-	Iodide water	
	1 mg S(II)	Sulfide water	
	70 mg H_2SiO_3	Silica water	
<1 $g\ l^{-1}$	10 mg Fe(II)	Ferruginous water	<20 °C cold water
	74 Bq	Radon or radioactive water	
	250 mg free CO_2	Carbonated water	
	1000 mg free CO_2	CO_2-rich water	

- Natural mineral waters enriched with CO_2 from the source – for identification of water type, in which the concentration of CO_2, after the separation of unstable elements and bottling, is higher than determined in an underground water table or deposit
- Natural mineral waters artificially saturated with CO_2 – for identification of water types in which during bottling, water was saturated by CO_2 from an underground water table or deposit or with CO_2 of quality required for food

In the group of sparkling waters, several types are commonly recognized according to the concentration of CO_2:

- Low saturated – below 1500 $mg\ l^{-1}$ CO_2
- Averagely saturated – 1500–4000 $mg\ l^{-1}$ CO_2
- Highly saturated – above 4000 $mg\ l^{-1}$ CO_2

Both concepts used to define 'mineral waters' are applicable for therapeutic mineral waters. They are used in the treatment of disease, either by internal administration or by external application. They owe their virtue to their solid or gaseous constituents or to their elevated temperature. In Poland, several therapeutic groundwaters are defined according to their pharmacodynamic factors (Table 4). Specific criteria may differ per country.

Introduction

In food preservation, an increase in the severity of the process usually decreases the quality of the treated food. Consumers are looking beyond the taste and texture of foods and beverages and are asking for safe, healthy, and high-quality foods. In addition, consumers and fast-food establishments require convenience products, for reasons of either cost or labor. Therefore, minimally processed (MP) foods are preferred. These must have characteristics of freshness or 'just been made' and must be microbiologically safe and stable. The minimal processing of foods has two purposes: to maintain and deliver fresh products conveniently without losing its nutritional quality and to ensure that the product has a sufficient shelf life to allow distribution to intended consumers. Moreover, many of these minimal processes aim at being energy saving and environmentally friendly.

MP products are a major growth segment in the local retail food sales. The increasing demand of these MP products poses a challenge for researchers and processors to make them stable and safe. The main initiatives focussed on by the research community and the industry to harmonize these demands without compromising safety include the optimization of traditional preservation techniques to enhance sensorial, nutritional, and microbiological quality of foods and to increase yield and energy efficiency; the development of mild techniques by novel combinations of traditional physical and chemical preserving factors, applied at a low intensity, to obtain products with quality attributes reminiscent of the fresh or native state of a given food but with longer shelf life; and the development of new techniques to obtain innovative foods with fresh quality attributes by using combinations of emerging preservation factors or combinations of emerging factors with traditional ones, all of them applied at low doses.

These new and improved intervention technologies to enhance food microbiological safety have their own set of limitations and advantages. In most cases, the trend for mildly preserved foods comes with the combined preservation/hurdle technology as the principle in designing the overall treatment, that is, the combination of several mild antimicrobial agents in multifactorial processes capable of delivering safe foods with unaltered quality and nutritional value.

The production and manufacture of MP foods nowadays continues being at a stage of innovative dynamics. The aim of this article is to revise the concept of MP foods and to give an overview of mild technologies and minimal processes, emphasizing preservation of freshly cut fruits and vegetables.

The Concept of Minimal Processing and Types of MP Foods

Currently, the MP concept has evolved to give a wider approach than the terms used earlier by Rolle and Chism, Shewfelt, Huxsoll and Bolin, Wiley, and Ohlsson. According to Rolle and Chism, the manipulation and basic preparation of foods, as well as life permanence in the biological tissue, were the elements that distinguish minimal processing from other processes. Shewfelt added to the definition the possible use of low-level irradiation and individual packaging as preservation factors that allow safety and high quality. Examples of MP products presented by Shewfelt included vegetable stick snacks, packaged tossed salads, chilled peach halves, peeled and cored whole pineapple, shelled fresh legumes, microwaveable fresh vegetable trays, and gourmet chilled dinners, among others. The use of refrigeration appears as a fundamental preservation factor for this type of foods. Huxsoll and Bolin included those foods whose tissues are no longer alive, but freshness should be kept as an important characteristic. Wiley presented the modification and control of atmospheres in food packages as other preservation factors to be employed during the MP food elaboration. Ohlsson and other authors mentioned, as an important element, the necessity that this processing should be enough and adequate to maintain the quality of the product during the storage period that goes from preservation to consumption. Manvell, more recently, defined that MP must be a safe balance between desired and adverse effects of preservation processes, and accordingly, a minimal process is 'the least possible treatment' to achieve a purpose. Thus, he considered as minimal processes the available traditional techniques that have been improved to obtain safe and high-quality products (i.e., aseptic packaging, ohmic heating, radio-frequency heating, and microfiltration) and techniques based on emergent preserving factors (i.e., high pressure, ultrasound, and pulsed electric fields). In the same trend, Ohlsson stated that improved thermal technologies can be considered 'minimal' when they minimized quality losses in foods compared to conventional thermal techniques. Lastly, and in partial agreement with these last two authors, Snyder divided MP foods into three groups according to the type and severity of treatment: foods that need no cooking (i.e., raw foods, nuts, grains, and eggs); foods with a mild disinfection or reduction by 10^{-2}–10^{-5} of pathogenic substances, chemicals, and microorganisms by blanching, washing without or with chemicals, etc. (i.e., freshly cut fruits and vegetables and berries); and

pasteurized foods with a 10^{-5}–10^{-7} reduction of pathogens by applying irradiation, heat, pulsed light, ultraviolet light, high pressure, etc. (i.e., *sous-vide* products, pasteurized and refrigerated products, tomato sauces, and salad dressings with preservatives), as well as foods that are formulated to be safe by fermentation, drying, salting, or acidification.

Presently, MP focuses on preservation while keeping food quality attributes, following the principle of 'as little as possible, but as much as necessary.' 'Minimal processing' includes a number of technologies, mostly nonthermal, that are applied to a food at sublethal levels, aiding in the retention of nutritional and sensory quality while guaranteeing safety. Therefore, the MP concept includes a series of products and processes that may be grouped in diverse food categories such as MP, with invisible processing, carefully processed, and partially processed. These terms are not exactly equivalent but reflect the great diversity of processing alternatives for high-quality foods.

The Hurdle Concept

Preservation procedures overcome, temporarily or permanently, the various homeostatic reactions that microorganisms have evolved in order to resist stress. The degree of change in environmental conditions will determine whether the microorganism will lose their viability, become injured, or express adaptive mechanisms that would allow them to survive or even to grow under stress. When stress is sensed by the microorganism, mechanisms are induced by signals to cope with the stressor. These mechanisms involve modifications in gene expression and protein activities. In foods preserved by combined methods (the so-called 'hurdle' technologies), the active homeostasis of vegetative microorganisms and the passive refractory homeostasis of spores are disturbed by a combination of sublethal antimicrobial factors or stressors at a number of sites ('targets') or in a cooperative manner. That is, low levels of different stresses are employed rather a single intensive stress allowing for a less severe preservation procedure and a higher quality in the product. For vegetative cells (where homeostasis is energy-dependent), the goal is to reduce the availability of energy (removing O_2, limiting nutrients, and reducing the temperature) and/or to increase the demand for energy (reducing water activity, reducing pH, and adding membrane-active compounds). For spores (where homeostasis is nonenergetic and depends on the structures of the organism), the goal is to damage key structures (by chemical, enzyme, or physical attack on coats, cortex, etc.) or to release spores from dormancy (initiating germination with natural germinants or with false triggers or applying high pressures).

The hurdle technology approach could be applicable to a wider spectrum of food preservation processes, not only the interference of homeostasis by additive or synergistic hurdles on the same microorganism but also the selective application of preservation factors that may be effective against a specific organism or group of organisms while not against others.

Nowadays, multiple-hurdle applications have aimed toward improving the quality and safety of food products at the farm level and in the industry. The type, number, and intensity of hurdles could be proposed according to the type of food, spoilage and pathogen microorganisms of concern, impact of hurdles on quality, required shelf life, technical compatibility of the selected factors, and/or available processing/storage infrastructure. Overall, multiple disturbances of microbial homeostasis have been used/suggested in food preservation in different arrangements: (a) using two or more stressors simultaneously to prevent the growth of spoilage and pathogenic microorganisms and (b) using one or more stressors (in simultaneity or in sequence) to inactivate/injure or physically remove some microorganisms and then, in sequential mode, one or more stressors to prevent survival/proliferation of remaining refractory or sublethally damaged cells (these last with greater sensitivity to adverse agents). The order in which sequential inactivation stressors are applied has been reported to affect the effectiveness of inactivation.

One of the most difficult aspects of hurdle technology design is the selection of stressors. The combination of antimicrobial factors should deliver not only the promised improvements in quality but also an equivalent or enhanced level of safety compared to traditional preservation methods. The terms 'additive,' 'synergistic,' and 'antagonistic' were traditionally used to describe possible stressor interactions. The current view of hurdle interactions in the growth domain is that their effects are not synergistic except where one hurdle modifies a target to make it more susceptible to a second hurdle. For inactivation of microorganisms, the bases that underlie synergic or additive effects have so far been hardly determined and a delivery of treatments with the same target would improve the chances of irreversible damage being caused.

Preservation Agents in Minimal Processing

Potential hurdles for use in combination in the minimal processing of foods can be divided into physical, physicochemical, microbial-derived, and miscellaneous hurdles. Some MP techniques utilize many of the classic agents to preserve foods, such as high or low temperature, reduced water activity (a_w), reduced redox potential (E_h), mild heat treatment, increased acidity, preservatives, and competitive flora, while others use what could be considered more novel approaches in food preservation, such as pulsed light, shortwave ultraviolet radiation, high hydrostatic pressures, high-intensity pulsed electric field, sound waves, gas absorbers or emitters, aseptic packaging, controlled/modified-atmosphere packaging, ozone, hydrogen peroxide, edible films, and natural antimicrobials. These stressors have diverse modes of action toward microorganisms: They can restrict the access of microorganisms to products, they can inactivate microorganisms, or they can slow down or prevent the growth of microorganisms. Each agent has pros and cons depending on the initial contamination, the nature and topography of food, the mitigation protocol, the type and dose of the stress factors employed in combination, and the order in which they are applied, among others.

Most of the modern agents cause physical or chemical inactivation of microorganisms at ambient or sublethal temperatures. These nonthermal factors are being encouraged for food preservation because, without the need for severe heating, they cause minimal damage to the flavor, texture, and nutritional quality of some foods. Most of them are effective in inactivating vegetative cells of most microorganisms but spores are far more tolerant. Thus, their applications are analogous to

Table 1 Selected nonthermal inactivation stressors for obtaining fresh-like fruit products

Factors and mechanisms of action	*Advantages*	*Limitations and drawbacks*	*Potential application/ products on the market*	*Hurdles in combination investigated*
High hydrostatic pressure (HHP): application of 100–800 MPa, below 0–100 °C, from seconds to about 20 min, instantaneously and uniformly throughout food, independent of size, shape, and food composition Mechanism: multitarget and dependent on pressure level: membrane damage, protein denaturation, leakage of cell contents, and dissociation of ribosomes	Inactivation of some enzymes according to HHP dose Little change in vitamins, pigments, flavor, and antioxidant activity, although effects depend on fruit matrix, pressure, and temperature	High cost of equipment, increased metal fatigue, long cycle times High resistance of browning enzymes and pectin methyl esterase to HHP Undesirable sensory changes at high doses (color, appearance, skin loss, structural/ texture changes)	Jam, jellies, fruit juices and purees, guacamole, fruit yogurts, dairy-based fruit smoothie, sauces (in use since 1990) Shelf-stable low-acid fruits (combined with moderate temperatures)	Low pH Natural and synthetic antimicrobials Temperatures below or above room temperature Refrigerated storage Vacuum packaging and refrigerated storage Mild heating
Shortwave ultraviolet (UV-C) light: radiation from the shortwave ultraviolet region of the electromagnetic spectrum (200–280 nm) Mechanism: damage to DNA, membranes, and enzyme activity induced by UV-C light absorption; hormetic effects	Moderate to low cost of equipment Little effect on color, vitamin C, and taste of fruit juices Little changes in tissue darkening, color, texture, and visual quality of cut fruits at low doses	Low penetration into solids and opaque juices, long treatment times in solids Enzymatic browning of cut fruit surfaces at high doses, more notorious as storage time increases	Pasteurization of apple cider and clear juices (in use since 2000). Surface decontamination of whole and cut fruit surfaces. Reduction of fruit decay and softening	Refrigerated storage MAP Mild thermal treatment US Sanitizers
Pulsed light (PL): few flashes applied in a fraction of a second of intense pulses of broad spectrum light (ultraviolet to the near-infrared region) Mechanism: damage to DNA and destruction of cellular components by the high peak power and the photothermal effects of visible and near-infrared portions of the flash spectrum	Very short treatment times ($\leq$60 s) Little effect on color, texture, and antioxidant and sensory properties at low doses	Low penetration into solids and opaque juices Engineering solutions needed for juice treatment Thermal damage of product at high doses Browning and dehydration of cut fruit surfaces, more notorious as storage time and PL dose increase	Reduction of microbial load on surfaces of whole and cut fruits and in clear juices	Refrigerated storage UV-C Mild thermal treatment
Pulsed electric fields (PEFs): application of oscillating, bipolar, exponentially decaying, or square-wave electric pulses of high voltage (20–70 KV cm^{-1}, pulse duration 1–30 s) Mechanism: perturbation of cell membrane and loss of membrane permeability	Little effect on food quality attributes Very short treatment times ($\leq$30 s)	Restricted to foods that can sustain high electric fields, have low electrical conductivity, and do not have/ provoke bubbles	Limited to pasteurization of fruit juices (in use since 2005) and fruit smoothies	Biopreservatives, essential oils, other antimicrobials Moderate temperatures UV-C PL
High-power ultrasound (US): energy generated by sound waves of 20 kHz or more and intensities higher than 1 W cm^{-2} Mechanism: disruption of cellular structures (wall, membranes, organelles, DNA) and cell lysis attributed to cavitation, shear, localized heating, and free radical formation	Inactivation of enzymes when US is combined with heat and pressure Little change in the color of juices and cut fruits	High energy consumption, intensity of industrial-scale equipment limited, long treatment times Heating of the product. Undesirable sensory changes and rupture of skin in berries at high doses	No commercial fruit products; suggested for juice pasteurization. Actual applications limited to product modification and process efficiency improvements (enhancement of mass and heat transfer, degassing of liquids, cleaning of surfaces)	Moderate temperature and pressure Sanitizers Natural antimicrobials UV-C PEFs

(*Continued*)

Table 1 (Continued)

Factors and mechanisms of action	*Advantages*	*Limitations and drawbacks*	*Potential application/ products on the market*	*Hurdles in combination investigated*
Hydrogen peroxide: application in aqueous solution or in vapor phase Mechanism: strong oxidant agent; intermediate in oxygen reduction to generate more reactive oxygen species; oxidative damage to bacterial proteins, DNA, lipids and cellular membranes; alterations in proteins of spore coats	Effect on a wide spectrum of bacteria, yeast, molds, viruses, and spore-forming organisms Rapid decomposition into water and oxygen No effect on color and surface fruit structure at low doses Inhibitory or lethal action on microorganisms depending on concentration	Activity very dependent on environmental conditions (pH, T, organic material)	Sanitization of fresh fruits (whole or cut)	pH Temperature Refrigerated storage
Ozone: application in gaseous or aqueous state Mechanism: powerful oxidant action attributed to the subsequent reaction of its decomposition products (hydroxyl radical): effect on intracellular enzymes, nuclear material, components of cell envelope, spore coats, and viral capsids	Effective against bacteria (including bacterial spores), viruses, parasites, and fungi at low concentrations Rapid decomposition to molecular oxygen Inactivation of pectin methylesterase, peroxidase, and polyphenoloxidase No color loss or other negative sensorial effect at low doses	Decreases in ascorbic acid and anthocyanin contents at high doses Difficult monitoring and control of concentration Reduced efficacy in presence of organic materials High capital costs Safety problems	Decontamination of fresh fruits (whole or cut), juices, dried fruits Commercial equipment available	Refrigerated storage Carbon dioxide Low pH $UV/H_2O_2/O_3$ UV/O_3 Hot water Blanching

thermal pasteurization. It is likely that combining nonthermal agents or traditional preservation factors with nonthermal agents in a multihurdle preservation approach will control spoilage and food-borne microorganisms while reducing treatment intensities, detrimental effects on product quality, and energy input.

This contribution does not pretend to cover the impressive number of studies existing in the application of intentional hurdle technology for obtaining MP foods, but focus on some selected examples related to MP fruits and vegetables.

Minimal Processing in Practice: Preservation Techniques for Freshly Cut Fruits and Vegetables

'Freshly cut' can be defined as any fruit or vegetable that has been physically modified from its original form, through several processes such as peeling, slicing, chopping, shredding, coring, trimming, and mashing and washing, to obtain an edible product that is subsequently packaged and stored under refrigeration. These products have been available in supermarkets for sale to consumers since 1930; however, the MP product industry was developed initially to supply hotels, restaurants, and other institutions, since they have a number of advantages, including reduced labor during food preparation, reduced waste and subsequent handling, and reduced preparation time of dishes, with specific shapes of fruits or vegetables.

Generally, MP fruits and vegetables deteriorate faster than their fresh/intact counterparts. In order to choose the right treatments, it is necessary to understand the physiological and microbiological changes that may occur during and after handling, processing, and storage, since these may reduce product quality or even jeopardize its safety. Regarding the deterioration of MP fruits and vegetables, distinctions can be made between physiological deterioration and microbial spoilage, but one definitely influences the other.

From the physiological point of view, minimal processing operations injure the living tissue, which begins a series of metabolic reactions that result in changes in texture, rapid ripening and senescence, development of unpleasant odors, discoloration, and other undesirable events that make products unmarketable. Handling and processing shorten shelf life because they favor a higher production of ethylene, a gaseous hormone involved in plant maturation, which is associated with changes in color and texture of various fruits and vegetables; it also increases the respiration rate, because sugars and acids are used as substrates. From a microbiological spoilage point of view, during peeling and cutting, the product surface is exposed to air and possible contamination from bacteria,

yeasts, and molds. The main sources of contamination are the tools used for processing. In particular, in the case of MP vegetables, most of which fall into the category of low acidity (pH 5.8–6.0), the high moisture and the number of cut surfaces can provide ideal conditions for microbial growth. Microbial growth is characterized by different processes, the production of enzymes and metabolites resulting in visual defects and texture changes, and the development of bad odors. Fruit and vegetable composition will determine the type of spoilage. Finally, peel-removal and sanitizing processes disrupt the normal microbial ecology and allow contamination by pathogenic microorganisms. Pathogens can be present in raw materials or due to cross contamination during processing. Typical sources of microorganisms in primary production are water, soil, or waste waters contaminated with fecal matter. Many pathogens (such as *Listeria monocytogenes*, *Escherichia coli* O157:H7, *Shigella* spp., *Salmonella* spp., *Aeromonas hydrophila*, *Bacillus cereus*, *Yersinia enterocolitica*, and *Campylobacter* spp., parasites, and viruses) have been isolated from MP vegetables and fruits, which serve as carriers of several diseases. Multiple intervention methods that can be sequentially applied aiming to achieve decontamination in produce and the freshly cut produce industry. They include physical cleaning, temperature, chemical-based cleaning treatments, emerging inactivation factors, and modified atmospheres, among others. The efficiency of each intervention practice can be further improved in a combined approach. **Table 1** shows selected chemical and physical inactivation hurdles (already used industrially or still in development or testing) along with the information available about their mode of action on microorganisms, their advantages and disadvantages, and the combined processes in which they have been applied to preserve whole and freshly cut fruits as well as some fruit products.

Future Trends

There is no doubt that MP foods are a growing segment in the food retail industry. Key points for a widespread commercial use include a more in-depth knowledge of microbial behavior at molecular and physiological levels, the availability of systematic kinetic data on the impact on quality attributes (with special emphasis on dose response and the influence of critical process parameters), and the optimization of equipment.

Benjamin Caballero is professor of International Health and of Maternal and Child Health (Bloomberg School of Public Health), and professor of pediatrics (School of Medicine) at Johns Hopkins University.

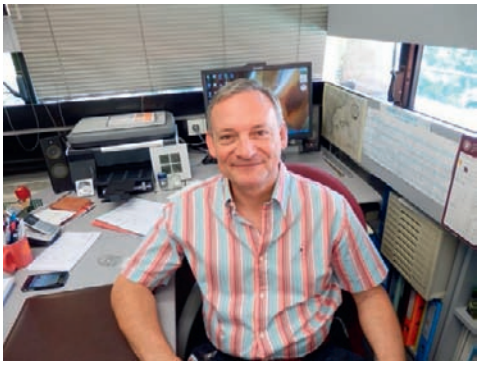
He obtained his MD from the University of Buenos Aires, his MSc in biochemistry from the University of San Carlos, and his PhD in neuroendocrine regulation from MIT, in Cambridge, MA. He started his academic career as assistant professor of pediatrics at Harvard Medical School and director of the Nutrition Unit of Boston Children's Hospital, and subsequently became the founding director of the Center for Human Nutrition at Johns Hopkins University, in Baltimore.

Prof. Caballero has focused his research on child nutrition and health in developing countries. In particular, he has explored the combination of undernutrition and overweight that has become increasingly prevalent in low- and middle-income countries. He was a member of the Food and Nutrition Board of the Institute of Medicine, National Academy of Sciences, USA, and of a number of expert panels created by the Institute, including the Dietary Reference Intakes (DRI) Committee, the Expert Panel on Macronutrient Requirements, and the Childhood Obesity Task Force. He was also a member of the Dietary Guidelines for Americans Advisory Committee, of the Scientific Advisory Board of the Food and Drug Administration (FDA), and of a number of advisory committees of the National Institutes of Health (USA).

He is the editor-in-chief of the *Encyclopedia of Food Sciences and Nutrition*, a 10-volume work on food production, consumption and biological effects. He is also editor-in-chief of the *Encyclopedia of Human Nutrition*, which received the Book of the Year Award from the British Medical Association. His *Guide to Dietary Supplements* summarizes the current scientific basis for the use of mineral and vitamin supplements. His book *The Nutrition Transition: Diet and Disease in the Developing World* explored the impact of demographic and economic development on diet- and lifestyle-related diseases in developing countries. His book *Obesity in China* summarizes research conducted in rural and urban China to track the impact of socioeconomic development on health outcomes. He is also coeditor of a widely used textbook on human nutrition, *Modern Nutrition in Health and Disease*.

He is a member of the Spanish Academy of Nutritional Sciences, and a Fellow of the American Society for Nutrition and of the Royal Society of Medicine (UK). Recent awards include the Donald Medearis Lectureship from the Massachusetts General Hospital/Harvard Medical School, the Mataix Prize for lifetime achievements in nutrition science from the Spanish Academy of Nutritional Sciences, the Ancel Keys Prize for achievements in international public health, and the Thompson–Beaudette Lectureship from Rutgers University.

Paul Finglas joined the Institute of Food Research in 1981 and is currently head of the Food Databanks National Platform and Research Leader in Food and Health at the Institute (http://www.ifr.ac.uk/science/platform/FD/default.html). He has, for most of his science career, been involved in a wide range of research in food composition and analysis, and the nutritional effects of micronutrients in food and health research. Paul has considerable experience of co-coordinating both national and international projects (e.g., EuroFIR, TDS-EXPOSURE, Bacchus and QualiFY (all EU FP7), and is currently of the spin-out EuroFIR AISBL, a non-profit international association based in Belgium, from one of these projects. Paul has a broad range of experience in science publishing and is currently editor of the journals *Food Chemistry* and *Trends in Food Science and Technology*, and was one of the coeditors for the *Encyclopedia of Food Science and Nutrition* (2nd Ed.). Paul has a degree in chemistry from Aston University in Birmingham and has published over 150 publications on a wide range of topics in food science and nutrition.



Fidel Toldrá holds a BSc in chemistry (1980), high degree on food technology (1981) and PhD in chemistry from the University of Valencia (1984). Professor Toldrá was a Fulbright postdoctoral scholar at Purdue University in West Lafayette (US, 1985–86) and visiting scientist at the University of Wisconsin-Madison (1991 and 1995), and the Institute of Food Research-Bristol (UK, 1987). Currently, he is research professor at the Instituto de Agroquímica y Tecnología de Alimentos (CSIC), in Paterna, Valencia (Spain). He is also associate professor of food technology at the Polytechnical University of Valencia.

Prof. Toldrá has focused his research on food biochemistry and its relationship with nutrition, quality and safety. He has filed 12 patents, directed 22 PhD thesis and published over 245 manuscripts in recognized scientific journals and more than 115 chapters of books. His h-index is 41. Prof. Toldrá has authored two books and edited/co-edited more than 30 books for major publishers like CRC Press, Wiley-Blackwell, Elsevier and Springer.

Prof. Toldrá is the European editor of *Trends in Food Science and Technology* (2005–) and associate editor of *Meat Science* (2014–); he was the editor-in-chief of *Current Nutrition & Food Science* (2005–2012), section editor of the *Journal of Muscle Foods* (2009–2010) and guest editor of 12 special journals issues. He is a member of the editorial boards of *Food Chemistry*, *Food Analytical Methods*, *Journal of Food Engineering*, *Journal of Food and Nutrition Research*, *The Open Nutrition Journal*, *The Open Enzyme Inhibition Journal*, *Recent Patents in Agriculture*, *Food and Nutrition*, *Food Science & Nutrition* and *Current Opinion in Food Science*.

He has been a member of the Scientific Panel on food additives, flavorings, processing aids and materials in contact with foods (periods 2003–2008) and the Scientific Panel on flavorings, enzymes, processing aids and materials in contact with foods (2008–2015) of the European Food Safety Authority (EFSA) acting as Chairman of the Working groups on Irradiation (2009–2010), Processing Aids (2011–2014) and Enzymes (2010–2015). He was a member of FAO/WHO group of experts to evaluate chlorine-based disinfectants in the processing of foods (2008–2009). He was a member of the Executive Committee of the European Federation of Food Science and Technology (EFFOST, 2002–2009). He is a Fellow of the International Academy of Food Science and Technology (IAFOST, 2008) and of the Institute of Food Technologists (IFT, 2009–). He received the Iber Award on Food and Cardiovascular Diseases (1992), the Institute Danone award in Food, Nutrition and Health (2001), the International Prize for Meat Science and Technology from the International Meat Secretariat (2002), GEA award on R+D activity from the Valencian Community (2002), and the Distinguished Research Award (2010) and Meat Processing Award (2014), both from the American Meat Science Association.

EDITORIAL ADVISORY BOARD

Siân Astley has worked extensively with individuals and organizations throughout Europe from a variety of disciplines including research, food and biotech industries, and the media. She is the author of more than 300 popular science articles for magazines and trade publications as well as 25 peer-reviewed papers, and she was awarded her Diploma in Science Communication in 2009 (Birkbeck University of London). After 14 years as a bench-scientist, Siân became communications manager for NuGO, one of the first FP6 networks of excellence, and was the European communications manager for the Institute of Food Research in Norwich (UK) until April 2012. Currently, she is the training and communications manager for the European Food Information Resource (EuroFIR AISBL) supporting training within EU-funded research projects and networks, and communication of research activities.

David J. Baer is a supervisory research physiologist with the US Department of Agriculture's Beltsville Human Nutrition Research Center located in Beltsville, Maryland. He serves as the research leader for the Center's Food Components and Health Laboratory and also serves as the director of the Center's Human Studies Facility.

Dr. Baer conducts controlled dietary intervention studies to investigate the relationship between diet and the risk for chronic degenerative diseases, especially cardiovascular disease, cancer, and diabetes in people. His research also includes studies on the health impacts of weight gain and determining the calorie content of foods. Some of the dietary interventions he has investigated include the effects of different types of protein, fats and fatty acids, fiber, margarine, butter, plant sterols, salad dressings, nuts, whole grains, berries, alcohol, and tea on overall nutrition and health. In addition to dietary intervention studies, Dr. Baer is involved in research studies to validate food survey methodologies and in developing new methods for dietary assessment.

Dr. Baer earned his bachelor's degree from the University of Illinois and his master's and doctorate in nutrition from Michigan State University.

Marina Carcea was awarded a master degree in agricultural sciences at the University of Pisa, Italy "cum laude" in 1980, and a PhD in food science also "cum laude."

She is currently a senior researcher in the Research Center on Food and Nutrition of the Council for research in agriculture and analysis of agricultural economy (CRA-NUT formerly INRAN National Research Institute on Food and Nutrition) and she was the director of the Cereals Research Programme in INRAN. CRA-NUT is a primary research institute in Italy under the egis of the Ministry of Agriculture. Dr. Carcea joined INRAN in 1989 after having worked in Italian and English universities (Queen Elizabeth College, King's College, and University of London) and after a two-year contract with the Food and Agriculture Organization (FAO) of the United Nations (UN), Rome.

She has a vast experience in the field of research on foods, cereals in particular. In recent years, her main research interests have been: chemical characterization and study of the functional properties of cereal components; study of the interactions between components and of the interrelationships between the biochemical properties of components and the technological properties of the raw material and derived products; development of new, cereal-based products; development of methods to assess technological parameters of the raw material; nutritional value of cereals; and developments of protocols for quality assurance of cereals, food authenticity.

She has taken part and/or co-ordinated several research projects within national or international programs (European Commission, FAO) involving several institutions. She is the author of more than 160 scientific publications, mostly in international journals, eight book chapters, and two scientific books. She delivered lectures on her research activity at about 150 national and international congresses and she seats in several national and international committees (Italian Ministry of Agriculture, Codex Alimentarius, and European Commission) regarding food and nutrition topics. She is also a member of the editorial board of scientific journals.

From 1994 to 2006, she has also been a lecturer of food science and technology at the University of Tor Vergata, Rome, Italy.

She is a founding member of AISTEC, the Italian Association of Cereal Science and Technology. Since 1996, she is an elected member in the Executive Committee of the same association and since 2009, president of the association.

Since 2000, she is the Italian National Delegate of the International Association for Cereal Science and Technology (ICC) and she was also the president of the same association for 2011–2012.

In 2004, she was the first woman to be awarded the International Harald Perten Prize for her excellent research achievements in the field of cereal science and technology.

She is also a member of the Georgofili Academy in Florence, Italy.

Lawrence J. Cheskin graduated from Dartmouth Medical School and completed a fellowship in gastroenterology at Yale–New Haven Hospital. He is an associate professor of health, behavior, and society at the Johns Hopkins Bloomberg School of Public Health, with a joint appointment in International Health–Human Nutrition, and in medicine (GI) at the Johns Hopkins University School of Medicine. Dr. Cheskin is also a founder and director of the Johns Hopkins Weight Management Center, a comprehensive treatment program for obesity.

In his research, Dr. Cheskin has studied the effects of medications on body weight, the gastrointestinal effects of olestra, how cigarette smoking relates to dieting and body weight, and the effectiveness of lifestyle and dietary changes in weight loss and weight maintenance.

He is also the author of four books: *Losing Weight for Good*, *New Hope for People with Weight Problems*, *Better Homes and Gardens' 3 Steps to Weight Loss*, and *Healing Heartburn*. Dr. Cheskin has appeared on television news programs and lectured to both professional and lay audiences on the topics of obesity and weight control.

Nigel Cook is a graduate of the University of Dundee. After postdoctoral research in the Universities of Aberdeen and Leicester, he moved to the Central Science Laboratory (now the Food and Environment Research Agency (FERA)) at the Food Science Laboratory, Torry, Aberdeen in September 1994, before relocating to new facilities in York. At FERA, he studies the transmission of pathogens, particularly enteric viruses, through foods and the environment. He has a visiting professorship at the Katholieke Universiteit Leuven in Belgium. He is a councilor of the International Association for Food and Environmental Virology. He is a project leader within the standardization working group ISO TC34 SC9 WG6, currently developing a standard for detection of *Cryptosporidium* and *Giardia* on berry fruits and leafy green vegetables. He was a coordinator of the European Framework 7 project "Integrated monitoring and control of foodborne viruses in European food supply chains (VITAL)," and a chair of COST Action 929 "A European Network for Environmental and Food Virology" from 2006 to 2010. Between 2009 and 2014, he was a member of various European Food Safety Authority's Working Groups preparing opinions on the risk of foodborne viruses, and represented the European Communities on the Codex Committee on Food Hygiene Working Group developing *Guidelines on the Application of General Principles of Food Hygiene to the Control of Viruses in Food*. He was a member of the UK Advisory Committee on the Microbiological Safety of Food's Viral Infections Subgroup. He was the founding editor of the journal *Food and Environmental Virology*, published by Springer.

Luca Simone Cocolin graduated in 1994 in food science with a grade of 110/110 and remark followed by food biotechnology PhD studies from 1995 to 1998. In February 1999, he defended his thesis acquiring the title of PhD in food biotechnology. From 1998 to 2001, he received a scholarship from the Friuli Venezia Giulia region (Italy). From November 1, 2001, he was an assistant professor at the University of Udine, Faculty of Agriculture, Food Science Department, Italy, and in October 1, 2006, he became an associate professor at the University of Torino, Italy. In January 2014, he had the habilitation for full professor and from June 2015, he is the full professor in food microbiology at the University of Torino.

From September 2008, he is an executive board member of the International Committee on Food Microbiology and Hygiene (ICFM) part of the International Union of Microbiological Societies (IUMS) (http://www.icfmh.org/). From January 2008, he is the editor-in-chief of the *International Journal of Food Microbiology* and he is a member of the editorial board of *Applied and Environmental Microbiology*, *Food Analytical Methods*, *Frontiers in Food Microbiology*, and *Frontiers in Nutrition and Food Science Technology*. He regularly reviews paper for *Food Microbiology*, *Meat Science*, *Journal of Applied Microbiology*, and *Letters in Applied Microbiology*. He is a co-author of more than 180 papers on national and international journals and he attended national and international congresses with oral and poster presentations. On Scopus (www.scopus.com, consulted on March 2015) he has 172 documents reviewed, which were cited 3520 times, resulting in an h index of 33.

His scientific interests comprise:

development, optimization, and application of molecular methods for the detection, quantification, and characterization of foodborne pathogens;
study of the microbial ecology of fermented foods (mainly sausage, cheese, and wine) by using culture independent and dependent methods;
bioprotection: molecular characterization of bacteriocin production and its study *in vitro* and *in situ*;
selection of new putative probiotics from artisanal fermented foods; and
study of the human microbiome and its influence on human health.

Christopher Duggan, for the past 25 years, has been performing clinical trials in the fields of pediatric nutrition, gastroenterology, and global health. His early work centered on the management of diarrheal diseases in children, including trials that demonstrated the feasibility and efficacy of oral rehydration solutions (ORS) for diarrhea management in the United States and globally. In collaboration with colleagues at Harvard TS Chan School of Public Health and Muhimbili University of Health and Allied Sciences in Dar es Salaam, Tanzania, Dr. Duggan and colleagues are evaluating the efficacy of micronutrient supplementation in infants and young children born to women with or at risk of HIV infection. Recent studies include the development of new biomarkers of environmental enteric dysfunction as well as the evaluation of nutritional status on neurodevelopment. With colleagues at St John's Research Institute in Bangalore, India, he is evaluating the efficacy of maternal vitamin B12 supplementation on biochemical and clinical parameters during pregnancy and infancy. He is a course co-director of the Bangalore, Boston Nutrition Collaborative (http://bbnc.globalhealth.harvard.edu). Past and present research support has come from the National Institutes of Health, the Gates Foundation, and the World Health Organization.

In addition to his global health research interests, he is a pediatric gastroenterologist and a nutrition physician at Boston Children's Hospital where he directs the Center for Nutrition (http://www.childrenshospital.org/nutrition). He is a medical director of the Center for Advanced Intestinal Rehabilitation, one of the largest centers in the United States for the care of children with intestinal failure/chronic diarrhea syndromes (http://www.childrenshospital.org/cair). He is also the course co-director of an inaugural Harvard College course "Nutrition and Global Health" and mentors undergraduate, graduate, and postdoctoral students at HMS and HSPH (http://www.hsph.harvard.edu/nutrition-and-global-health/).

He is a professor of pediatrics at Harvard Medical School and a professor in the Department of Nutrition at the Harvard TS Chan School of Public Health (http://www.hsph.harvard.edu/faculty/christopher-duggan/).

Jed William Fahey's current research concerns elucidating the mechanisms of how plants protect themselves against unfavorable and stressful conditions, and how this understanding can be translated to chemoprotection of eukaryotic mammalian systems. This work draws on elements of natural product chemistry, enzymology, nutritional epidemiology, and clinical research in order with isothiocyanates (e.g., sulforaphane) and glucosinolates. His work led to the discovery that broccoli sprouts are an exceptionally rich and consistent source of phytochemicals that induce the detoxification of carcinogens, and to the development of methods for their detection and for assessing their metabolism in humans. He discovered that one of the inducers, sulforaphane, has potent antibiotic activity against *Helicobacter pylori*, a causative agent of peptic ulcer and stomach cancer, and followed up with trials in animals and in *H. pylori*-infected humans. Ongoing collaborations examine the effects of broccoli, Moringa, and the other plants and their phytochemicals against a range of chronic diseases. Dr. Fahey has for years taught courses in chronic disease prevention and nutrition at both medical and public health schools.

Manuel Franco is an associate professor at University of Alcalá in Madrid (Spain) where he leads the social and cardiovascular epidemiology research group (http://www3.uah.es/cardiosocialepi/). He is also an adjunct professor at Johns Hopkins University (Baltimore).

Prof. Franco's work focuses on the social determinants of cardiovascular diseases and its major risk factors as diet. His methodological interests include the measurement of the urban environment and large social and economic changes in relation to cardiovascular health. He is the lead investigator of the Heart Healthy Hoods, study funded by the European Research Council, that will study the urban environment in relation to cardiovascular health in Madrid (http://hhhproject.eu/). This longitudinal study will be collecting neighborhood level data (via audits, Google Street view, photovoice, and qualitative methods) and linking them to clinical outcomes collected from patients enrolled at the City of Madrid primary healthcare clinics. Prof. Franco trained in Spain and Germany to obtain his MD and obtained his PhD from Johns Hopkins Bloomberg School of Public Health working with Dr. Ana Diez-Roux in the MESA study on food environment and dietary patterns. He has published over 30 international high impact articles and collaborates with universities in the United States, Europe, and Latin America.

Maria Glibetic is a research director of Centre of Research Excellence in nutrition research, Institute for Medical Research in Belgrade, University of Belgrade, Serbia, and member of executive board of directors for food data association EuroFIR AISBL. She is an experienced basic and nutritional scientist with over 250 scientific publications and presentations. Maria has considerable experience in leading national and international projects and since 2006, she participated in nine EU funded projects including EuroFIR, EURRECA, BaseFOOD, CHANCE, BACCHUS, and ODIN. Maria and her team are responsible for the creation of the first online national food database, for designing food data management system, and for the development of different nutritional tools for intake analysis. She was a principal leader of many nutrition intervention studies evaluating the plant bioactive component effects on human cardiovascular health. She leads postgraduate department for integrated nutritional sciences at University of Belgrade, where she teaches two courses.

Linda Harvey obtained her PhD from the University of East Anglia, UK. She is currently the head of the Human Nutrition Unit at the Institute of Food Research, Norwich, UK. Her research interests include micronutrient requirements, bioavailability, and metabolism.

Ronald Jackson received his bachelor's and master's degrees from Queen's University and doctorate from the University of Toronto. His time in Vineland, Ontario, and subsequent sabbatical at Cornell University, redirected his interest in *Botrytis* toward viticulture and enology. As part of his teaching duties at Brandon University, he developed the first wine technology course in Canada. For many years he was a technical advisor to the Manitoba Liquor Control Commission, developing sensory tests to assess candidates of its sensory panel, and was a member of its external tasting panel. He is the author of *Wine Science: Principles and Applications, 4th edition* (2014), *Wine Tasting: A Professional Handbook, 2nd edition* (2009), *Conserve Water, Drink Wine*, and chapters and technical reviews in other multiple books and encyclopedia. He is retired in Bronte, Ontario, but remains active writing, cycling, doing yoga, and traveling, as well as being a fellow in the Cool Climate Viticulture and Oenology Institute, Brock University, St. Catharines, Ontario, Canada.

Joe P. Kerry is a senior college lecturer and the head of the food packaging research group in the School of Food and Nutritional Sciences at University College Cork (UCC). He received his doctorate in microbiology at University College Galway in 1995. Prof. Kerry is also a qualified member of the Institute of Packaging. He is very involved in national and international research projects both at fundamental and applied levels. Primary research interests address various aspects of food packaging, shelf-life stability, food composition, and numerous aspects of food quality, particularly in relation to muscle foods. He also has very strong links with industry and his research team assists companies in relation to many aspects of new food product development. He has over 220 publications in peer-reviewed international journals, over 300 presentations at major international conferences, along with several other significant publications. His expertise includes use and manipulation of modified atmosphere packaging systems for use with foods, use of extrusion technology for the manufacture of food products/packaging materials, and applications and sensor/new technology developments within the area of food packaging, especially in the area of smart packaging.

Frédéric Leroy, after studying bio-engineering at Ghent University, obtained a PhD in applied biological sciences at the Vrije Universiteit Brussel in 2002, where he continued his academic career at the research group of Industrial Microbiology and Food Biotechnology (faculty of sciences and bio-engineering sciences). As associate professor, his lecturing activities include courses in food science and technology (i.e., "Nutrition," "Technology of animal products," "Food microbiology and ecology," and "Quantitative and predictive microbiology"). Dr. Leroy's research primarily deals with the ecology and functional roles of bacterial communities in (fermented) foods, in particular with respect to the generation of quality, safety, and/or nutritional and health advantages. Focus is mostly on meat products, but other food systems are also being studied, including fermented milks and sourdough breads. In addition, his research interests relate to elements of tradition and innovation in foods, both from a technological and societal point of view.

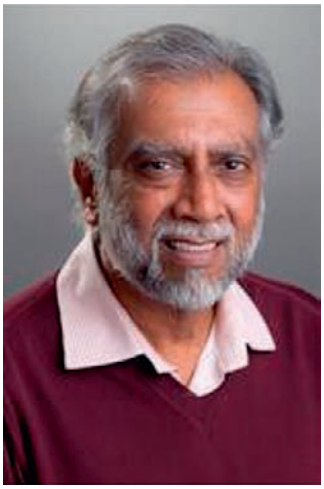
Catherine M. Logue completed her undergraduate and postgraduate degrees in Ireland and earned a PhD in meat microbiology from the University of Ulster, UK in 1996. Dr. Logue was a faculty member at North Dakota State University from 1999 to 2011 rising through the ranks of assistant to associate and full professor. In 2011, she re-located to Iowa State University's College of Veterinary Medicine and is a professor of veterinary microbiology and preventive medicine. Dr. Logue is also the director of faculty and staff advancement and equity for the college. Her research interests focus on foodborne pathogens of food animals and the contamination of meat and meat products destined for human consumption. Her research studies the detection, isolation, and characterization of a range of foodborne pathogens such as *Salmonella*, *Campylobacter*, *Listeria*, *Escherichia coli*, and methicillin-resistant *Staphylococcus aureus* (MRSA) in poultry, bovine, and swine. She also focuses her research on antimicrobial resistance in commensals and pathogens of production animals. She has been an author and a co-author on more than 90 peer-reviewed papers and book chapters as well as more than 150 abstracts and presentations at national and international meetings.

F. Xavier Malcata graduated in chemical engineering in 1986 from the University of Porto (Portugal), received a PhD in chemical engineering/food science from University of Wisconsin, Madison (USA) in 1991, and his habilitation in food science and engineering by Portuguese Catholic University in 2002. He was the dean of College of Biotechnology of Portuguese Catholic University, the chairman of Portuguese Society of Biotechnology, Portuguese representative at VI and VII European Union Framework Programs of research and development, expert for European Food Safety Agency, and a co-ordinator of Portuguese Engineering Accreditation Board in chemical engineering for Northern Region. He is currently a full professor at University of Porto.

His major research interests have focused on technological improvement of traditional Portuguese foods and upgrade of byproducts thereof, development of nutraceutical ingredients and functional foods, design and optimization of enzymatic reactors for edible oil processing, characterization of plant proteases toward cheese and whey cheese manufacture, production of starter and nonstarter cultures from adventitious microflora, and optimized application of unit operations to food processing.

With an academic career of independent research and teaching for more than two decades, Prof. Malcata published more than 450 papers in refereed journals worldwide, wrote 11 books, and prepared more than 45 chapters for edited books. Among many international distinctions, he was

recipient of Ralph H. Potts Memorial Award in 1991 by American Oil Chemists' Society (AOCS, USA), Foundation Scholar Award – Dairy Foods in 1998 by American Dairy Science Association (ADSA, USA), Young Scientist Research Award in 2001 by AOCS, Canadian/International Constituency Investigator Award in physical sciences and engineering in 2002 and 2004 by Sigma Xi (USA), Danisco International Dairy Science Award in 2007 by ADSA, Scientist of the Year Award in 2007 by European Federation of Food Science and Technology (the Netherlands), Samuel C. Prescott Award in 2008 by Institute of Food Technologists (IFT, USA), International Leadership Award in 2008 by International Association for Food Protection (IAFP, USA), Elmer Marth Educator Award in 2011 by IAFP, Distinguished Service Award in 2012 by ADSA, and William V. Cruess Award in 2014 by IFT. He has been elected for the honor societies of food science (Phi Tau Sigma, USA), scientific research (Sigma Xi, USA), and engineering (Tau Beta Pi, USA). He was also elected for fellow of IFT, ADSA, AOCS, and International Academy of Food Science and Technology.



Gopinadhan Paliyath is a professor at the Department of Plant Agriculture, University of Guelph, and the research program director for "Food for Health," under the UG/OMAFRA partnership. Dr. Paliyath is a biochemist and has an interest in various aspects of fruits and vegetables, specifically the nutraceutical components and their mechanism of action. He obtained his BSc Ed degree (botany and chemistry) from the University of Mysore, MSc degree (botany) from the University of Calicut, and PhD degree (biochemistry) from the Indian Institute of Science, Bangalore. Subsequently, he did postdoctoral work at Washington State University, University of Waterloo, and University of Guelph. Dr. Paliyath's research is focused on the biochemistry of plant senescence, specifically pertaining to postharvest biology and technology of fruits and vegetables. Investigations on the role of phospholipase D (PLD) in membrane homeostasis and signal transduction have led to advances in the understanding of the mechanism of membrane deterioration that occur during stress and senescence. Another aspect of his research is focused on understanding the mechanism of action of food components in disease prevention. The efficacy, bio-accessibility, bioavailability, and molecular mechanisms of action of nutraceuticals in fruits and processed products in relation to their cancer-preventive and anti-inflammatory actions are being investigated using mammalian cell lines, and animal model systems.

Dr. Paliyath has developed technologies and products for enhancing the shelf life and quality of fruits and vegetables based on PLD inhibition. R&D activities relevant to the industry sector include: (1) optimization of an enhanced freshness formulation for application to various fruits, vegetables, and flowers; (2) developing methods for nutraceutical carriers that would enhance the functional food quality and delivery (e.g., stabilizing lycopene in tomato juice, sauce, etc., for health beneficial effects); and (3) developing novel technologies to enhance the cancer-preventive ingredients in fruit products, etc. Patents awarded include: (1) # 6,514,914 (US) and 2,298,249 (Canada); (2) #7,198,811 (USA), 4141387-1 (Japan), 260738 (Mexico), 1469736 (Turkey), 028 284763 (China), and 223077 (India). The patents describe the use of nanoformulations based on hexanal and other generally regarded as safe (GRAS) ingredients for enhancing the shelf life and quality of fruits, vegetables, and flowers by pre or postharvest treatments. These technologies are currently being evaluated for extending shelf life and quality of mango in India and Sri Lanka with the assistance of the Canadian International Food Security Research fund. The collaboration involves researchers from Canada, India (Tamil Nadu Agricultural University), and Sri Lanka (Industrial Technology Institute).

Dr. Paliyath is also the research program director for the food and health theme-related activities under the OMAF/MRA/University of Guelph research partnership. He serves on the editorial board of several journals. He is a member of American Chemical Society and Canadian Society of Plant Biologists.

(Total-refereed publications in journals – 92; patents and intellectual properties – 2; disclosures – 4; chapters in books – 27; nonrefereed contributions – 10; research reports – 28; conference proceedings – 88; edited books – 9; book reviews – 6 (Google Scholar: h index – 31, i10 index – 68, citations – 4332; RG score – 35.63)).

Yolanda Picó is a full professor of nutrition and food science at the University of Valencia since 1998. She is currently the head of the research group on food and environmental safety of the University of Valencia. Her research interests are the development of new analytical methods to determine organic contaminants in food and the environment, identification of unknown compounds by liquid chromatography–mass spectrometry, micro-extraction separations, and environmental and food safety. To the date, she is the author of nearly 200 peer-reviewed papers, 170 scientific papers in journals of SCI, 25 book chapters, and editor of four books on food and environmental safety.

Vieno Piironen is a professor of food chemistry at the Department of Food and Environmental Sciences, University of Helsinki, Finland. She received her PhD in food chemistry at the University of Helsinki in 1987 and has approximately 35 years of experience in food research and education on bachelor, master, and PhD levels. She has participated actively in international research and education projects and networks. Her research has focused especially on chemical and nutritional properties, reactions and analysis of lipids, vitamins, and other bioactive compounds. Research on vitamins has been active from the beginning of 1980s. She has studied both lipid- and water-soluble vitamins; their chemical and nutritional properties and importance in foods and diets as well as factors influencing vitamin levels. In addition, development of analytical methods for different vitamers as well as validation and harmonization of the methods through international collaboration have been among the priorities. Recent collaboration projects have focused on enhancing vitamin contents in cereal-based foods by plant breeding, utilization of vitamin-rich grain fractions, and bioprocessing. Currently, the research focus lies on investigating microbial *in situ* synthesis of folate, vitamin B12, and other B vitamins in cereal and legume matrices as a means to improve nutritional quality of foods and to develop new food applications. In lipid research, different lipid classes and their chemical and enzymatic reactions in food matrices are studied. Diverse methods are used to study proceeding of oxidation from primary products to monomeric oxides, volatiles, and polymerization products and to study possibilities to control oxidation. Controlling enzymatic reactions leading to off-flavors in cereal and legume matrices is also among the interests. Phytosterols and their conjugates have been studied as natural food components belonging to the dietary fiber complex. On the other hand, questions related to sterol enrichment such as oxidation susceptibility and mechanisms as well as factors affecting oxidation reactions have been of interest. She has also studied nutrients and anti-nutrients in legumes and more recently started research on utilization of high value components in microalgae. She has approximately 160 papers in international journals and a number of other publications.

David Rodríguez-Lázaro is a doctor in veterinary medicine (DVM), specialized in food science (BSc and MSc) and molecular microbiology (PhD). He is a senior scientist at ITACyL and an assistant professor of microbiology at the University of Burgos. He has performed research stays in the Danish Institute for Food and Veterinary Research (Denmark), the University of Prague (Czech Republic), the Food and Environmental Research Agency (UK), and the University of Bristol (UK). He was a Leverhulme visiting professor in the Institute of Advanced Sciences in the University of Bristol during the years 2004 and 2005 and Marie Curie research fellow in the faculty of medical and veterinary sciences in the University of Bristol (UK) until 2007.

His research interest is focused on the establishment of reliable, quantitative molecular strategies for detection of important food-borne pathogens from environmental sources and various types of foodstuffs, the characterization of the prevalence of the main foodborne pathogens in food and food-related environments, and the development of emergent food preservation processes and their effects in the microbial virulence. He has participated in a number of coordinated EU-funded projects such as PROMISE, BASELINE, VITAL, FOOD-PCR, SACROHN, and MONI-QA, having established active links with the leading European research groups working in food safety.

He has published more than 100 international scientific papers and book or book chapters regarding food safety. He is currently a member of the editorial board of *Applied and Environmental Microbiology*, *International Journal of Food Microbiology*, *Food and Environmental Virology*, and *International Journal of Food Contamination* and the editor-in-chief of the journal *Food Analytical Methods*. He was awarded with the XV Jaime Ferrán Award in 2013 by the Spanish Society for Microbiology for his promising scientific career in microbiology.

Turid Rustad is a professor and the head of the food science group at the Department of Biotechnology, Norwegian University of Science and Technology. The main research focuses on the biochemistry of marine raw materials, the relationship between biochemistry and quality, and changes in raw material properties during processing. Studies of enzymatic activities in different raw materials have been linked to studies of changes in the biochemistry of these raw materials. She has worked with characterization of composition and enzymatic processes in a wide range of different raw materials, such as fish, fish by-products, and zooplankton in relation to different storage and processing methods such as chilling, heating, superchilling, and frozen storage.

Noel W. Solomons has lived and worked in Guatemala for 40 years. He was born and educated in Massachusetts in the United States. As a young child, he became an amateur naturalist and was a nature counselor at various summer camps; this would guide him to a career in science. In his young adulthood, he would participate in the civil rights and anti-war movements, only to become disillusioned by the intractable nature of the injustice elements in the fabric of American society. As a physician by graduate training, he performed his university studies at Harvard College and Harvard Medical School; it was during overseas electives in his medical training that he visited Peru and Colombia and committed to an expatriate life trajectory outside of his homeland. Clinical training included a residency in internal medicine and infectious diseases at the Hospital of the University of Pennsylvania and specialization in gastroenterology and clinical nutrition at the University of Chicago. He became a resident of Guatemala in 1974 as an affiliated investigator at the Institute of Nutrition of Central America and Panama. He would later commute for eight years to a faculty position in the Department of Nutrition and Food Science of the Massachusetts Institute of Technology. Assuming a full-time Guatemala commitment in 1985, he co-founded the Center for Studies of Sensory Impairment, Aging and Metabolism (CeSSIAM) where he remains its scientific director. Over 40 local university theses have been completed by Central American students in that institution as well as an equal number of master's degree research projects from international students from Europe, and North and South America. He has supervised doctoral dissertations for 12 PhD candidates from the United States, Canada, Germany, Spain, and the Netherlands through CeSSIAM.

Dr. Solomons has 332 publications indexed on Medline. In addition, he has edited two books and contributed over 100 articles, reviews, editorials, and commentaries in nonindexed venues and over 50 book chapters. These are dedicated to the scientific and academic interests of his career including: clinical nutrition; human growth and body composition; lactose maldigestion; dietary intake, nutritional status, intestinal absorption, and food fortification related to various micronutrients (vitamins, trace elements, and essential fatty acids); complementary feeding; nutrition in aging and chronic disease; and the interaction of malnutrition and infection.

Among the honors bestowed upon Dr. Solomons are the International Nutrition Prize of the International Union of Nutritional Sciences and the Kellogg Prize of the Society for International Nutrition Research. He is a fellow of the American Society of Nutrition. He is an academic member of the Guatemalan Academy of Medical, Physical and Natural Sciences and the Spanish Academy of Nutrition and Food Science. He was the awardee of the 2010 National Medal for Science and Technology for Guatemala.

He has been a visiting professor in university courses in Mexico, Peru, Brazil, Indonesia, and Spain. He currently holds adjunct professorial appointments at the Boston University School of Public Health, and the Friedman School of Nutrition Science and Policy and the Department of Community Medicine and Public Health, both at Tufts University. He is a founding board of directors, member of the Hildegard Grunow Foundation in Munich and the Essential Nutrient Foundation of Singapore. Finally, Dr. Solomons is a coordinator for Central America of the Nevin Scrimshaw International Nutrition Foundation in Boston, and an associate editor for the Foundation's *Food and Nutrition Bulletin*. He serves on editorial boards for ten scientific journals.

Maria Tsimidou is a professor of food chemistry and the head of the Laboratory of Chemistry and Technology in the School of Chemistry at the Aristotle University of Thessaloniki (AUTh), Greece. Her teaching is food chemistry, analysis, quality control, and food legislation. Research interests are related to virgin olive oil chemistry, quality and authenticity, saffron chemistry, authenticity and quality, antioxidant activity of plant extracts and constituents, new sources of targeted bioactive compounds (squalene, carotenoids, and phenols), and analytical procedures for their determination. She has published many research papers, review articles, and contributions to scientific books and encyclopedias on the above-mentioned topics. Currently, she is an associate editor in the *European Journal of Lipid Science and Technology* and chairs the COST ACTION FA1101 "Saffronomics."

Jorge Welti-Chanes earned his degree in biochemical engineering (1976) and master of science in food engineering (1978) at Tecnológico de Monterrey (ITESM, Mexico), later he moved to Spain to perform his doctoral studies in chemistry, in the area of food technology, obtaining his degree at the University of Valencia. He is currently the national director of graduate studies at School of Engineering and Sciences at Tecnológico de Monterrey also is professor and researcher in the areas of biotechnology and food at the same institution. He started his academic activity in 1976 as a university professor of ITESM, has additionally been a full professor at the National Polytechnic Institute (IPN, Mexico) and the University of the Americas, Puebla, Mexico (UDLA). He has an experience of 37 years as a teacher and university researcher, 20 of which were spent in combination with the development of administration work in education, science and technology. In the UDLA, he was teaching in the Departments of Chemistry and Biology and Chemical Engineering and Food, in the latter was responsible for the leadership for a period of a year and subsequently became dean of the School of Engineering (1986–1988). From January 1989 to June 2002, he was an academic vice chancellor at UDLA. He has published 14 books and has over 200 scientific publications in refereed journals and books, has given more than 250 presentations at international conferences. He is an associate editor of the journals *Food Engineering Reviews* and *Journal of Food Science* and participates as a member of the editorial boards of *Journal of Food Engineering* and *Current Opinion in Food Science*. In May 2011, he received the Life Achievement Award by the International Association for Engineering and Food (IAEF), for his career as a researcher and academic worldwide, and in January 2014, the Romulo Garza Award from the Tecnológico de Monterrey for the impact of their research work and as recognition for being one of the most productive researchers in the life of Tecnológico de Monterrey. He has been the president of ISOPOW and IAEF and is the currently president of the International Society of Food Engineering (ISFE).

Peter J. Wilde graduated in biophysics at the University of East Anglia in 1985 and has been researching the colloidal and interfacial properties of food systems at the Institute of Food Research (IFR) for over 25 years. IFR is the only publicly funded UK research institute that focuses on the underlying science of food and health to address the global challenges of food security, diet, and health, healthy aging, and food waste. IFR is the one of eight institutes that receives strategic funding from the Biotechnology and Biological Sciences Research Council (BBSRC). It also receives funding from government agencies and departments, the EU, charities, and industry, from the UK and overseas.

Pete's research expertise is the interfacial behavior of proteins and other surface active components in food relevant systems. The aim is to determine how the molecular and interfacial processes control the functionality of foams and emulsions. Currently, the functional aspects of his research have focused on improving the dietary impact of emulsified foods. These include fundamental studies on how interfacial layers control emulsion rheology to develop novel fat reduction strategies; the design of interfacial structures to control lipid digestion to promote satiety or the delivery of fat-soluble nutrients and drugs; and to determine the physico-chemical role played by the salivary film in perceiving fat content in emulsions. The impact of this research will be to aid the rational design of foods with enhanced nutritional benefits to address the global challenges of obesity, type 2 diabetes, and other major diet-related conditions.

HOW TO USE THE ENCYCLOPEDIA

All articles in the encyclopedia are arranged alphabetically as a series of entries.

1. Contents

Your first point of reference will likely be the contents. The complete contents list appears at the front of each volume providing volume and page numbers of the entry. We also display the article title in the running headers on each page so you are able to identify your location and browse the work in this manner.

2. Cross-references

The majority of articles within the encyclopedia have an extensive list of cross-references that appear at the end of each article, for example:

See also: Anemia: Causes and Prevalence; Anemia: Prevention and Dietary Strategies; Iron: Biosynthesis and Significance of Heme; Iron: Physiology of Iron.

3. Index

The index provides the volume and page number for where the material is located, and the index entries differentiate between material that is a whole article; is part of an article, part of a table, or in a figure.

4. Contributors

A full list of contributors appears at the end of volume 5.

INTRODUCTION

Until a few decades ago, virtually all known health effects of foods were related to their content of essential nutrients. The clinical description of most diet-related illnesses mirrored the signs of essential nutrient deficiencies, such as pellagra, beriberi, and others. Consequently, the key public health concern regarding diet was ensuring that everyone consumed enough food. It was only in the past 50 years that large-scale epidemiological observations began to associate chronic diseases like diabetes and cardiovascular disease with nonessential diet constituents such as saturated fat, fiber, and cholesterol. Taking advantage of the emergence of digital informatics, these studies were able to manipulate increasingly large sets of data and provide, for the first time, a picture of the secular changes in the health of large populations and its association with what they ate regularly. These findings progressively shifted the concern from eating enough to avoiding excessive consumption of certain foods. Eating enough was replaced by eating well.

But it turned out that defining how to eat well is far more complex than defining minimum needs of essential nutrients. First, there is no single paradigm to study those relationships, given the wide variety of biological mechanisms and the long exposures involved. Second, many of the experimental models used to define essential nutrient needs are not applicable to the study of long-term effects of diets in free-living populations. And it is now clear that experiments with isolated dietary compounds do not reflect the actual effects of the complex food matrix we consume daily. Finally, while the discovery of essential nutrients and their role in health was the domain of a few specialties speaking a common language (primarily biochemists and physiologists), the study of the long-term effects of whole diets in humans must of necessity involve epidemiologists, social and behavioral scientists, food scientists, clinicians, policy experts, etc., making far more difficult the development of consensus and foundational concepts.

It is thus not surprising that today we have still not achieved a stable consensus on how to eat 'well.' Furthermore, while few nonscientists would care about the minimum requirement of a vitamin to sustain life, there are plenty of opinions among nonscientists on how to eat 'well.'

Our goal in preparing this encyclopedia has been to contribute to the understanding of that complex diet–health relationship by providing a multidisciplinary, integrative and accurate source of information. We aim to serve the needs not only of established and in-training scientists, but also of the increasingly important group of professionals who are key to disseminate and sustain the practice of science: journalists, science writers, science administrators, fund raisers, donors, and policymakers. In preparing this work, we had the enormous advantage of working with one of the publishers with the most extensive expertise in major reference works, Elsevier. This first edition builds on the impressive breadth of knowledge of over 922 authors and on the tireless work of our editorial advisory board. We are very grateful to all of them.

Introduction

Mushrooms are important constituents of minor forest produce; they grow on cellulose, the most abundant biomolecule. Macrofungi, in the form of mushrooms and truffles, have been used as food and medicine from ancient times. Geologically, mushrooms existed on the earth before man as evidenced by the fossil records from the lower cretaceous period. Originally, these organisms were reported to be associated with the Mediterranean region and are described in Egyptian temples in some poems. During the Greek and Roman eras, they were imported from Libya and sold in the southern part of Europe and, in Africa, the nomadic people of the Kalahari Desert have consumed truffles for millennia.

Mushrooms are visible to the naked eye as they grow above the ground; whereas truffles grow underground at depths between 5 and 10 cm (Figure 1).

Truffles are usually collected by specialists who have the skills and experience to locate this type of flora (Table 1). Sometimes, truffle collectors use trained animals, such as pigs and dogs, to discover this underground fungus. The animals do this using their high sensitivity to the characteristic truffle volatile compounds. Traditionally, mushrooms and truffles are treated as prized foods and may be consumed either raw or cooked. In addition, they have been used widely as components of folk medicine, because of their rich content of proteins and amino acids, fatty acids, fiber, minerals, vitamins, terpenoids, sterols, flavor compounds, and carbohydrates.

Mushrooms

Mushrooms are epigeous macrofungi and have been highly valued in many cultures because of their nutritional value and characteristic aroma and taste. Out of ~3000 edible species of mushrooms only 100 are cultivated commercially, and only ten are produced on an industrial scale. Their global economic value is, nevertheless, considerable. The prime reason for the upswing in consumption is increased health awareness. This has led to selection of foods with superior nutritional or (perceived) nutraceutical benefits.

The nutritional value of mushrooms is established; they are rich sources of complete proteins, containing all the essential amino acids and fiber and very little fat. Mushrooms also provide significant quantities of vitamins (B_1, B_2, B_{12}, C, D, and E) and bioactive compounds such as unsaturated fatty acids, phenolic compounds, tocopherols, and carotenoids.

Mushroom production has increased over the last two decades. As depicted in Figure 2, China has emerged as the biggest producer of mushrooms (~2.0 million tonnes). The species mostly cultivated worldwide is *Agaricus bisporus* followed by *Lentinula edodes*, *Pleurotus* spp., and *Flammulina*

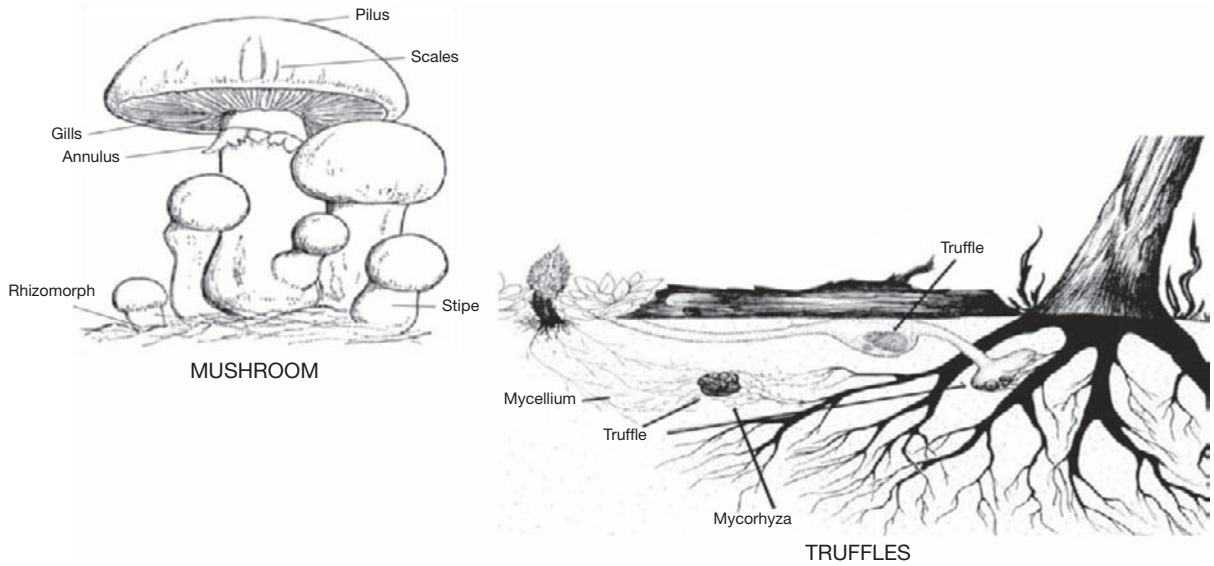

Figure 1 Morphology of mushrooms and truffles.

Table 1 Some illustrative truffle species and their properties

Truffle species	*Common name*	*Characteristics*	*Image*
Tuber aestivum	Summer truffle	The black summer truffle is found across Europe and is prized for its culinary value. Native to France, Italy, and Spain, the summer truffles are usually at their best in July, but can be found from May to October. They have a black exterior and off-white interior, and a relatively light scent	
Tuber uncinatum	Burgundy truffle	Burgundy truffles are harvested in autumn until December and have aromatic flesh of a darker color.	
Tuber gibbosum & *T. oregonense*	Oregon white truffle	These are firm and brittle, will have a beige to smokey-colored marbled interior, and a pleasant earthy odor. Mushroom eggs (and many truffle species that are only appetizing to squirrels) are generally squishier, spongy, or cartilaginous	
Kalapuya brunnea	Oregon brown truffle	It has a reddish-brown exterior and a grayish mottled interior. When mature, the odor can be quite garlicky	
Leucangiumcarthusianum	Oregon black truffle	Less common than Oregon white truffles, Oregon blacks are larger (golf-ball to baseball size), and are often much deeper in the soil than Oregon whites (commonly 4–10″ deep). They are very dark inside and out, and have a very pungent, earthy odor when ripe. Some equate the aroma to a strange mix of pineapple, port, mushrooms, rich soil, and chocolate	
Tuber melanosporum			

Table 1 (Continued)

Truffle species	*Common name*	*Characteristics*	*Image*
	French black (Perigord) truffle	Native to the oak forests of the Perigord region of central and southwest France, it is now widely cultivated in Spain, Australia, and the United States. It has a blue-black exterior when fresh, fading to brown-black with age, and a pungent, earthy odor	
Tuber magnatum	Italian white (Piedmont) truffle	Considered to be second best to the French black truffles, its cost can exceed that of the Perigord. The flesh is solid, light-colored, and very brittle; it is not unheard of for a fresh truffle to shatter if dropped on the floor. Large specimens can weigh as much as a pound, but most are the size of large walnuts. The white truffle is slightly more perishable than its darker cousins, and the flavor and aroma diminishes within a week or two after harvest. The white truffle has a distinctive pepper edge and is often eaten raw. The skin is a dirty beige when fresh, turning a darker brown with age	
Tuber borchii	Tuscan truffle	Similar to the Italian white truffle in appearance, having a chestnut to muddy tan exterior and a softish interior equally divided between chocolate brown and white. The flavor can be distinctly garlicky	
Tuber sinensis, *Tuber indicum*, and *Tuber himalayensis*	Chinese truffles	These are three distinct species found in southwest China, but pickers tend to lump them together as Chinese truffles. This is unfortunate because the flavor and quality vary from one species to another. *T. indicum* is recognizable by its brown interior and very fine white veins. *T. sinensis* has a dark brown interior with large ivory veins, and is said to be chewy and oily with a bitter aftertaste	
Terfezia boudieri, *Terfeziapfeilii*, *Terfezia claveryi*, and others	Desert truffles	Native to northern Africa and the Middle East, these truffles have been a staple for many nomadic tribes for millenia. Sometimes called the Lightning Truffle, they often fruit shortly after thunderstorms wet the desert	

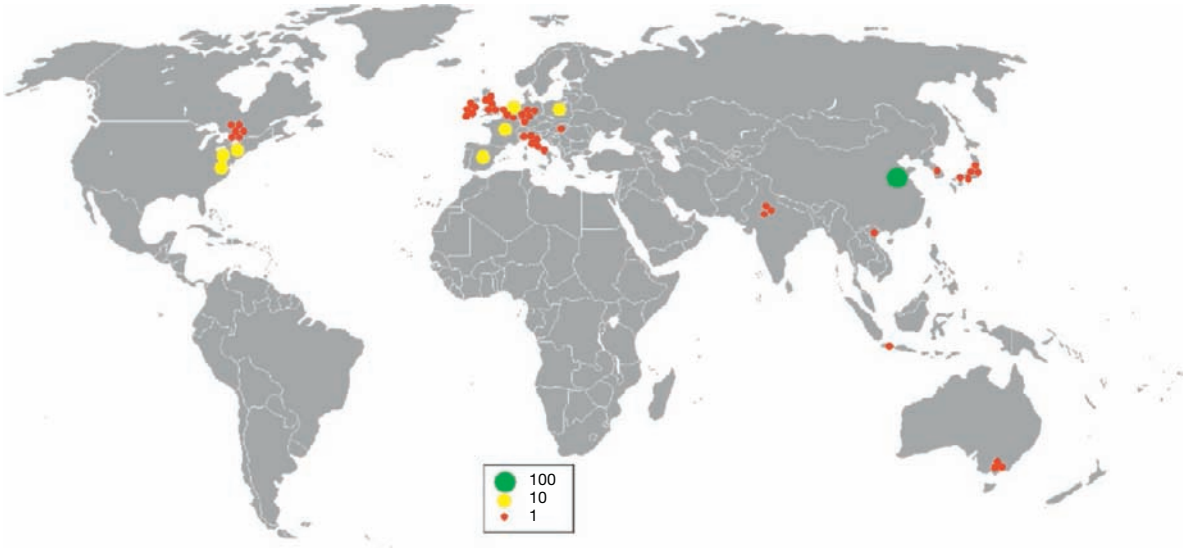

Figure 2 Mushroom and truffle growing – a global scenario on by percent.

velutipes. These species grow to market size in a short period compared with other edible mushrooms. As a result, by controlling some of the environmental parameters, these species can be cultivated in a simple and affordable way.

Truffles

The truffles are hypogenous mushrooms that grow exclusively underground and are recognized as ectomycorrhizal fungi. They usually occur at the interface between the organic litter and the mineral soil, about 2.5–15 cm deep, but can emerge at the surface or be found at more than 30 cm deep. A truffle is the fruiting body of a subterranean *Ascomycete fungus*, one of the many species of the genus *Tuber*. They rely on animals eating them (*mycophagy* from the Greek words 'mykes' meaning fungus and 'phagein' meaning to eat, fungivores) to distribute spores, instead of air dispersion like mushrooms. Truffle spore-bearing surfaces are enclosed, and they do not form a prominent stem, rather resembling small potatoes.

Truffles are made up of two parts: the fruiting body, which is edible, and the roots. The fruiting body appears during different seasons depending on the type of truffle. It is made of an exterior layer (peel) of variable thickness, which can be smooth or sculptured in appearance (with bumps or wrinkles) and light or dark in color, and an internal mass (pulp or gleba), which may range from white to brown, gray, pink, or black and is marked by criss-crossing 'veins.' This internal mass varies in thickness and the alveoli contain cells bearing spores (ascospore).

No specific environment is required for truffles and they can potentially be found almost anywhere trees grow. Truffles prefer woods that have mixed trees with a little undergrowth to maintain humidity and are often found along the banks of streams, but also by footpaths, and under pine trees or poplars. Each species of truffle needs different soil and climate conditions (Table 1). Only a few families of trees (e.g., maples and cedars) are not associated with truffle-forming fungi.

There are hundreds of different kinds of truffles, and while none are known to be poisonous, only a few of them are considered to be delicacies by humans. Truffles and mushrooms are the only fruits of the fungus; the main perennial fungal body exists as a web of filamentous hyphae in the soil.

All of the truffle fungi form a symbiotic (Mycorrhizae) (i.e., mutually benefiting) association with the roots of trees, and are essential for the tree to acquire some nutrients. The fungal hyphae not only permeate the soil, but also penetrate root cells of plants and facilitate nutrient exchange where the host plant acquires nutrients from the soil via the fungi, and the fungi (which cannot perform photosynthesis) obtains sugars from the host plant.

As most truffles never break the surface of the soil, they rely on animals to eat them and distribute spores. To ensure they are found, truffles have evolved to exude pungent, fruity, and sometimes unpleasant aromas when mature.

Role of Mushrooms in the Diet

Since antiquity, man has hunted for the wild mushrooms and higher fungi have been treated as a food due to their unique palatability and flavors. They are low in calories, but contain high amounts of vegetable protein, specifically chitin. Mushrooms consist of two main parts, the mycelium and the fruity body (sporocarp). The mycelium consists of a tree-like structure (hyphae), which remains buried under the soil or substrate. The mycelium absorbs nutrients while the hyphae form mycelia, which in turn forms the fruit (sporocarp) structure on the surface when atmospheric conditions, particularly humidity, are favorable. The spore-producing tissue is called the hymenium. Mushrooms vary in size, color, texture, and structure, which favors spore formation. The cap is called the cuticle and varies among mushroom species; it may be sticky or slimy. The stalk is the stem-like structure on which the cap is mounted and varies in length depending on the species.

Many species of mushrooms are edible. *Ganoderma* spp., *Omphalotus olearius* and *Hebeloma mesophaeum* are species commonly found in Africa and reported to be among the most edible. Some are medicinal such as *Auricularia* spp. and *Tremella fuciformis*, which are used for treating hemorrhoids and maintaining healthy lung tissue, respectively; others are poisonous including *Pholiota semarrasa* and *Amanita vaginata*. Mushrooms have assumed greater importance in the diets of both rural and urban dwellers. The success in utilizing plant proteins as ingredients depends largely on the beneficial qualities they impart to foods, which, by extension, depend on their functional properties. The functionality of plant protein has been reported to be dependent on the chemical characteristics inherent in the seed. Some mushroom extracts are used as a component for soups and teas to boost the immune system. Consumption is also associated with reduced risk of cancer and heart disease.

Mushrooms have begun to be treated as nutriceuticals and there is a body of research exploring their chemical composition, which suggests consumption may not only reduce risk of disease but also treat others. Traditional medicine has used mushrooms such as *Hydnum coralloides*, *Agaricus campestris*, *Helvella crispa*, *Hypoxylon vernicosum*, *Morchella esculenta*, and *Polyporus mylittae* as a health food for generations and 100–200 g daily (dry weight) are thought to maintain optimal nutritional balance in a man (60 kg). It has even been suggested the food value of mushrooms lies with vegetables and is comparable with meat, egg, and milk food sources.

In general, mushrooms contain 83–90% water and 10–16.5% dry matter (Table 2). Importantly, the protein content varies between 27% and 48%. Carbohydrates are $<60\%$ and lipids are between 2% and 8%. On average, a mushroom is about 16.5% dry matter of which 7.4% is crude fiber, 14.6% is crude protein, and 4.48% is fat and oil (Table 2). There is also a significant difference in the nutrient contents of the pileus versus the stalks.

Several thousand mushroom species are known worldwide, and around 3000 are considered edible.

Table 2 Nutritional facts about mushrooms

Nutrients	*Range*
Energy (kcal/100 g)	24–31
Moisture (g/100 g)	83–90
Protein (g/100 g)	1.94–3.00
Fat (g/100 g)	0.20–0.34
Ash (g/100 g)	0.79–0.91
Carbohydrate (g/100 g)	3.69–8.42
Dietary fiber (g/100 g)	1.45–2.70
β-Glucan (g/100 g)	0.21–0.79
Ergosterol (mg/100)	37–69
Calcium (mg/100 g)	1–4
Copper (mg/100 g)	0.11–0.30
Iron (mg/100 g)	0.22–1.15
Magnesium (mg/100 g)	10–16
Manganese (mg/100 g)	0.05–0.10
Phosphorus (mg/100 g)	74–105
Potassium (mg/100 g)	204–359
Sodium (mg/100 g)	1–15
Riboflavin (mg/100 g)	0.20–0.33
Niacin (mg/100 g)	2.80–7.03
Pantothenic acid (mg/100 g)	0.27–1.36
Vitamin B_6 (mg/100 g)	0.05–0.10
Folic acid (mg/100 g)	6–52

Proteins

Protein is an important constituent of mushroom dry matter with digestibility values as high as 72–83% and it contains all essential amino acids. The protein content of mushrooms depends on the composition of the substratum, size of the pileus, harvest time, and species, but ranges from 14% to 27% crude protein (dry weight). In terms of the amount of crude protein, mushrooms rank below meat, but above most other foods, including milk. In general, mushrooms are very useful for vegetarians because they contain essential amino acids that are usually obtained from animal proteins. The total nitrogen content of dry mushrooms is 79% compared with 100% for an ideal protein (Table 2).

Carbohydrates

The carbohydrate content of mushrooms represents the bulk of the fruiting bodies, accounting for 50–65% (dry weight), with free sugars amounting to about 11%. Mannitol, also called mushroom sugar, constitutes about 80% of the total free sugars, and a fresh mushroom contains 0.9% mannitol, 0.28% reducing sugar, 0.59% glycogen, and 0.91% hemicellulose. Water-soluble polysaccharides of mushrooms have been shown to have some antitumor activity, and mannitol is associated with improved brain function.

Fats

Mushrooms contain very little fat compared with carbohydrates and proteins, ranging from 1% to 5%. The fats present in mushroom fruiting bodies are dominated by unsaturated fatty acids rich in linolenic acid, which is an essential fatty acid (Table 2).

Vitamins

Mushrooms are an excellent source of some vitamins, particularly the B vitamins, and wild mushrooms contain much more vitamin D_2 than dark cultivated mushrooms. Mushrooms also contain a small amount of vitamin C.

Minerals in Mushrooms

The fruiting bodies of mushrooms contain high levels of minerals including potassium, phosphorus, sodium, calcium, and magnesium as well as copper, zinc, iron, molybdenum, and cadmium. K, P, Na, and Mg constitute $\sim$56–70% of the total ash content of mushrooms while potassium alone forms 45% of the total ash (Table 2). Mushrooms have been found to accumulate heavy metals including cadmium, lead, arsenic, copper, nickel, silver, chromium, and mercury. The mineral proportions vary according to the species, age, and the diameter of the fruiting body as well as the type of the substratum.

The mineral content of wild edible mushrooms has been found to be higher than cultivated mushrooms.

Therapeutic Value

First century Greek physician Dioscorides included the lurch polypore (*Fomitopsis officinalis*, *Laricifomes officinalis*) in his *De Materia medica* known then as *Agaricum* and later as the Quinine conk. It was used for the treatment of a disease now known as tuberculosis. Moreover, mushrooms as a medicine have been used in China since 100 AD, but these properties have only been investigated since ca. 1960. Mushrooms have been used in healthcare for treating age-old common diseases to present-day more complex conditions.

Mushrooms possess antiallergic, anticholesterol, antitumor, and anticancer properties. The antitumor effects of hot water extracts from several mushrooms has been observed where the main active components are polysaccharides, especially β-D-glucans such as *lentinan*. It is also reported that mushrooms 'cure' epilepsy, and help with wounds, skin diseases, heart ailments, rheumatoid arthritis, and cholera besides intermittent fevers, diaphoresis, diarrhea, dysentery, colds, anesthesia, liver disease, gall bladder diseases, and they are used as vermicides. Most of the treatments including mushrooms are now available in tablet form. Mannentake (*Ganoderma lucidum*) are known to lower blood pressure and serum cholesterol concentration whereas *Lentinus tigrinus* and *G. lucidum* have been shown to reduce cholesterol levels. *L. edodes* have been used to enhance vigor, libido, and energy as well as being an antiaging agent. Lentinan sulfate obtained from the *Lentinus* species inhibits human immunodeficiency virus (HIV).

Mushrooms are thought to act as biological response modifiers by promoting positive factors and eliminating negative factors from the human body. They are regarded as part of conventional cancer treatment in some countries; polysaccharide-K (PSK), an anticancer treatment based on the mushroom, *Coriolus versicolor*, accounted for a quarter of chemotherapeutic drug sales in Japan in 1987. Mushroom health supplements, marketed in the form of powders, capsules, or tablets, are made from dried fruiting bodies, extracts of mycelium, biomass, or extracts from liquid fermentation; *P. sajor-caju* has been reported to induce growth of probiotic bacteria. Waxy cap mushroom extracts (*Hygrocybe coccinea*) inhibit sarcoma and immunoceticals, isolated from more than 30 mushroom species, have been shown to have anticancer action in animals. Schizophyllan from *Schizophyllum commune* may also be effective in head and neck cancer.

Antioxidant Activity

Antioxidants protect cells and cell components from damage caused by unstable molecules including free radicals and reactive oxygen (ROS) and nitrogen species (RNS). Oxidants react with enzymes such as superoxide dismutase, catalase, and glutathione peroxidase, but over production leads to oxidative stress meaning food antioxidants and bioactive compounds are an important defense against ROS/RNS. Mushrooms are rich sources of these compounds. Many species of mushrooms have also been found to be potent immune enhancers, enhancing the immune response to neoplastic changes.

Role of Truffles in Diet

Truffles are highly sought after because of their strong scent, which comes from the aromatic hydrocarbon compound bis(methylthio) methane. The nutritional value of truffles is very high and almost identical for the different species. It varies depending on the environmental conditions in which truffles are grown. Unlike mushrooms, no truffles are known to be poisonous.

Truffles are appreciated in French, Georgian, Greek, Italian, Middle Eastern, and Spanish cooking as well as in international *haute cuisine*. Truffles are rare and luxurious tubers, and one of the most sought after ingredients by top chefs internationally. They have been called the 'diamond of the kitchen,' and widely acknowledged as one of the most desirable gourmet foods. Truffles are used to season dishes or as an accompaniment in greater or lesser quantities. Thus, their contribution to human nutrition remains relatively low.

Truffles are different from other vegetables because of their flavors; small amounts can bring out the taste, flavor, and aroma of a dish. Because they are found rarely, truffles are expensive, but truffles are also noted for their medicinal value. Like mushrooms, truffles are also low in fat, cholesterol-free, and regular consumption may lower serum cholesterol.

Nutritional Facts and Health Benefits of Truffles

Truffles contain 72% water, very little fat (0.6%) and some protein (8.6%) (Table 3). Truffles are some of the most nutritious fungi available. Their proteins are intact and rich in methionine, cysteine, and lysine. Truffles are also rich in minerals, such as phosphorus, calcium, magnesium, potassium, sodium, iron, zinc, fiber, sulfur, chlorine, and silicone. They also contain fiber (7.6%), an important component to facilitate digestion and intestinal motion. Details of truffle nutritional composition are given in Tables 3 and 4. The calorific value of truffle per serving is about 62.1 kJ.

Truffles are a good source of oil, but cooking over 90 °C causes the oil to lose its flavor; it is only designed for salads and

similar dishes. Black truffles have the strongest flavor and a pungent smell, and black truffle oil has an earthy smell. White truffles, on the other hand, have a tendency to take on the characteristics of the soil they are found in, meaning they have a more delicate taste and, often, a garlic-like aroma.

Handling and Storage of Fresh Truffles

After buying fresh truffles, they should be cleaned by rubbing gently with a small brush under running water. Truffles are highly perishable and need to be consumed immediately after harvesting: they tend to dehydrate (at room temperature they lose 1–2% of their weight every day) and lose their scent. Often, truffles are sold in containers filled with rice, which absorbs the flavor and aroma of the fungi and can be used for cooking. Truffles can be stored between uses in dry paper towel, which is changed daily, in an airtight glass jar at 2–5 °C for about 1–2 weeks.

Health Benefits: Mode of Action of Mushrooms and Truffles

Mechanisms through which mushrooms and truffles influence health remain an emerging area of research. Moreover, the chemical composition and total intake determine any potential health attributes.

Gut Microbiota

The relationship between host and gastrointestinal microbiota are increasingly recognized to be crucial for health. A healthy microbiota controls pathogens, promotes development and appropriate response of the immune system, and supports tolerance of food antigens and harmless microbes. Consuming 1% of the total dietary intake of white button mushrooms (equivalent to 75 g fresh weight) in a restricted diet increased gut bacterial diversity. In two different models of gastrointestinal injury (dextran sulfate sodium treatment and *Citrobacter rodentium* infection), resolution and recovery were improved by mushroom consumption, including weight gain and colonic length, and reduced hyperplasia and immune infiltrates in the colon histopathology. These findings highlight the potential of white button mushrooms to reduce risk of diseases where the microbiota has been shown to have an impact. White button mushrooms also influence gastrointestinal tract healing through the action of prebiotics, nondigestible food ingredients that stimulate the growth and/or activity of commensal bacteria. It has been hypothesized that the microbiota and host both use nutrients present in white button mushrooms, and the microflora make bioactive compounds from the polysaccharides in mushrooms.

Immunomodulatory Effect

Dietary mushrooms have been reported to improve the activity of natural killer cells, which are an important component of the innate immune system responsible for antiviral and antitumor defense. Increased natural killer cells activity may be mediated through increased production of interferon gamma and tumor necrosis factor alpha. Mushroom consumption appears to elicit a shift toward T-helper 1 response, and there is a trend for higher interleukin-2 production and lymphocyte proliferation. Mushroom supplementation *in vitro* has been shown to promote maturation and function of dendritic cells, which are the most important antigen-presenting cells bridging innate and adaptive immunity, suggesting an enhanced development of adaptive immunity. Dendritic cells maturation was enhanced by changes in dendritic cell function, including increased interleukin-2 production, reduced phagocytosis, and enhanced antigen presenting function, resulting in an elevated T-cell response to the specific antigen. These results suggest that mushrooms may have the potential to improve the development of adaptive immunity after initial exposure to an antigen or pathogen.

Poisonous Wild Mushrooms

Some mushrooms are poisonous and symptoms range from mild gastrointestinal discomfort to death. For example, a wild species of mushroom, *Amanita phalloides*, famously known as the 'death cap,' contains amatoxins that cause severe gastroenteritis and hepatic necrosis. The toxin of *Psilocybe semilanceata* (liberty cap) is a potent hallucinogen; anxiety and peripheral sympathomimetic symptoms may follow ingestion. Another species, *Amanita pantherina* (panther cap) may cause severe anxiety and agitation, hallucinations, and peripheral anticholinergic symptoms. The toxin in *Cortinarius speciosissimus* has an almost exclusively nephrotoxic action.

The most common reason for poisoning is misidentification or the close resemblance of edible mushroom species to toxic mushrooms. Thus, an expert should inspect mushrooms before consumption. Most importantly, there are no antidotes for mushroom poisoning and symptoms can only be treated in the hospital, and may still be fatal. It is worth noting that:

- Symptoms can appear after 12 h or longer following consumption.

- Toxins will remain in the system and continue to cause harm, meaning raw samples should be retained for (correct) identification.
- While casual handling of poisonous mushrooms is not problematic, these should not be mixed with edible mushrooms if harmful contamination of foods is to be avoided.
- Some people are allergic to edible mushrooms.

Introduction

Mustard (*Brassica* spp.), a native to temperate regions of Europe, was one of the first domesticated crops. This crop's economic value resulted in its wide dispersal, and it has been grown as a herb in Asia, North Africa, and Europe for thousands of years. Ancient Greeks and Romans enjoyed mustard (*Sinapis*) seed as a paste and powder. In about 1300, the name 'mustard' was given to the condiment made by mixing mustum, which is the Latin word for unfermented grape juice, with ground mustard seeds.

Mustard has been a major specialty crop in North America since supplies from Western Europe were interrupted by World War II. California and Montana were the major production areas until the early 1950s. The production of mustard in the Upper Midwest began in the early 1960s. Mustard is currently grown on approximately 250 000 acres annually in the United States. Canada is the world's largest producer of pure mustard seed, accounting for an average 28% of the world crop (Table 1). Canadian mustard production increased for 20 years until it peaked in the mid-1980s. Alberta, Manitoba, and Saskatchewan currently grow a large share of the world's mustard crop. The French people are the largest consumers of mustard (1.5 lbs/person/year) and buy approximately 70% of the annual Canadian production. Three types of mustard, yellow, brown, and oriental, are grown in North America. Yellow mustard (*Brassica hirta*) comprises about 90% of the crop in the Upper Midwest. In Europe, yellow mustard is also known as white mustard (*Sinapis alba*) – an older botanical name.

Ignoring mustard/rapeseed blends that are grown on the Indian subcontinent, world mustard seed production averages just under 529 000 Mt year^{-1}. Most of this production is destined for the condiment and spice trade.

Mustard has been used as a spice for over 5000 years, with references appearing in ancient Sumerian and Sanskrit texts around 3000 BC, Egyptian texts around 2000 BC, and Chinese texts around 1000 BC. Its use as a condiment is thought to have started with the Romans. The production of Dijon mustard in France started around the tenth century. In recognition of the long tradition of making mustard, Dijon was granted an appellation d'origine contrôlée in 1937. The first use of mustard as a hot dog condiment was reported at the St. Louis World's Fair in 1904 when R. T. French Company introduced its mild prepared mustard, which is bright yellow due to turmeric.

General Description and Cultivation

Brassica juncea (L.) Czern. belongs to the Cruciferae (Brassicaceae) plant family, commonly known as the mustard family. The name crucifer is derived from the shape of the flowers that have four diagonally opposed petals in the form of a cross. *B. juncea* has pale green foliage, with a few hairs on the first leaves and leaf blades that terminate well up the petiole. Mature *B. juncea* plants grow to a height of 1–2 m. The lower leaves are deeply lobed, while the upper leaves are narrow and entire. *B. juncea* is distinct from its close relatives *B. napus* and *B. rapa* in that the upper leaves of *B. juncea* are not clasping. The inflorescence is an elongated raceme, and the flowers are pale yellow and open progressively upward from the base of the raceme. The seed pods are slightly appressed and 2.5–5 cm in length exclusive of the beak. The beak is 0.5–1 cm long. Seeds are round and can be yellow or brown.

There are both vegetable and oilseed varieties of *B. juncea* that possibly have different origins. Both types are considered to be natural amphidiploids (AABB genome, $2n=36$) of *B. rapa* (AA genome, $2n=20$) by *B. nigra* (BB genome, $2n=16$) crosses. It has been shown by molecular analysis that *B. juncea* contains conserved genomes of the progenitor species. *B. juncea* can be divided into four subspecies, with different morphologies, quality characteristics, and uses.

1. *B. juncea* ssp. *integrifolia*, used as a leaf vegetable in Asia
2. *B. juncea* ssp. *juncea*, cultivated mainly for its seed, occasionally as fodder
3. *B. juncea* ssp. *napiformis*, used as a root-tuber vegetable
4. *B. juncea* ssp. *taisai*, stalks and leaves being used as vegetables in China

For spice purposes, the appearance of the seed is particularly important, and therefore, the crop is grown in more southerly, drier regions where the risk of green seed in the harvested crop is reduced. Compared with the more widely grown canola species *B. napus* and *B. rapa*, *B. juncea* is more tolerant to heat and drought stress. The species does not shatter as readily as *B. napus* and so it can be straight cut or swathed and combined. Features of few cultivated species (Table 2) of mustard (Cruciferous) group of crops have been reported.

Crop Production and Nutrient Management

Cultivation of oilseeds that require high *S* is concentrated in rainfed regions. Maintenance of optimum organic matter level is imperative to avoid multiple nutrient deficiencies. Among micronutrient disorders, Zn deficiency in soils is the most common. In general, mustard is grown on coarse textured soils, very low in organic matter. Under such situations, organic manures can be exploited to boost the production of rapeseed–mustard and to improve fertilizer use efficiency. Balanced fertilization is all the more essential even at low levels of fertilizer usage for maintaining long-term fertility.

Mustard is reported to respond to zinc application at 10–20 kg ha^{-1} as basal spray or 0.5% as foliar spray. Next to

zinc, boron nutrition is important to mustard. Deficiency of boron could be corrected either through soil application or foliar application of borax. *Azotobacter* and *Azospirillum* are the two major microorganisms that are found to help rapeseed–mustard group of crops to fix atmospheric N. The associative and antagonistic actions of soil microflora and organic matter content of the soil greatly influence the growth of *Azotobacter* and its N-fixing ability. The lack of organic matter in mustard-growing areas is a limiting factor, and the beneficial effects of small amounts of humus on the growth of *Azotobacter* and its N fixation are well documented.

Technologies like resource conservation technology, crop contingency planning, precision farming, crop ecological zoning, and crop modeling and simulation are some of the key areas of innovative agrotechniques. Resource-conserving technologies improve the efficiency of the use of natural resources, including water, air, fossil fuels, soils, inputs, and people. Resource-conserving technologies have been successfully developed, tested, and deployed for rice–wheat cropping system. The development of suitable machinery, studies on residue management in oilseed crops, development and agronomic testing of varieties suitable for zero tillage conditions, impact of land leveling on rapeseed–mustard production, productivity and input use efficiency, etc., are some of the indicative areas of research gaps that need to be addressed.

Chemical plant growth regulators are being increasingly used as an aid to yield enhancement. Brassinolide is the most bioactive form of the growth-promoting plant steroid termed as brassinosteroids. Biologically active brassinosteroids show high growth-promoting as well as antistress activity besides other multiple effects on growth and development. NPK accumulation and yield were maximal when spraying of GA3 was done at 40 DAS.

The Mustard Species

Black mustard plants are tall (up to 3 m) and sparsely branched, and they produce many short pods (sliques). As the pod matures, the highly pungent, small (1.5 g per 1000 seeds), round, dark brown seeds are shed, necessitating frequent hand harvesting or cutting and stacking immature plants on the threshing floor.

The characteristic seed shedding and seed dormancy of black mustard made it unsuited to monoculture and mechanized agriculture, and the spice trade turned to the production of a closely related species, *B. juncea* (L.) Czern and Coss. Plants of *B. juncea*, when compared to black mustard, are shorter (1–2 m) and have many upright, heavily podded branches with longer pods that retain their seeds when ripe. The seed is larger (3 g per 1000 seeds) but produces the same pungency. The seed color is either brown (brown mustard) or yellow (oriental mustard).

The species originated from a natural cross between *B. nigra* and *B. rapa* L. (turnip rape) followed by chromosome doubling to produce a vigorous and productive interspecific hybrid. This interspecific cross is believed to have occurred more than once where the two species occupied the same region. Possible centers of origin are believed to be North Africa, northern India and Pakistan, and western China.

The third condiment mustard species, *Sinapis alba* L., is called yellow or white mustard and produces a different pungency from both *B. nigra* and *B. juncea* seeds. From its Mediterranean center of origin, it has been widely disseminated throughout the temperate regions where day lengths (hours of sunshine) were sufficient to stimulate flowering. When moistened, the ripe seed will exude a mucilage from its yellow seed coat to form a whitish coating when dry. This may explain why white mustard is the common name in Europe, while in North America, it is called yellow mustard.

Plants of yellow mustard are shorter (0.6 m) than either *B. nigra* or *B. juncea* and have deeply lobed leaves. The short,

Table 2 Salient features of cultivated species of mustard (Cruciferous) group of crops

No.	*Common name*	*Botanical name*	*Days to maturity (days)*	*Yield potential (kg ha^{-1})*	*Oil (%)*

Source: Shekhawat, K., Rathore, S. S., Premi, O. P., Kandpal, B. K., and Chauhan, J. S. (2012). Advances in agronomic management of Indian mustard (*Brassica juncea* (L.) Czernj. Cosson): an overview. *International Journal of Agronomy*, Article ID 408284, 14 pp, http://dx.doi.org/10.1155/2012/408284

hairy pods, with flat beaks, contain and retain 5–6 seeds when ripe. The seed is significantly larger than the other mustard species (6 g per 1000 seeds), which aids in rapid seedling establishment. In Europe, the crop is frequently sown and plowed under as a green manure crop.

Centers of Origin

The origins of *B. juncea* are unclear. *B. juncea* is an amphidiploid with a chromosome number of 18. It is believed to have derived from natural interspecific hybridization between *B. nigra* ($n=8$) and *B. rapa* ($n=10$). *B. juncea* likely originated where distributions of *B. nigra* and *B. rapa* overlap, such as in the Middle East and neighboring regions. The foliage types (Chinese) and oleiferous types (Indian) have suggested separate origins, a concept supported by the glucosinolate studies. The view that *B. juncea* probably evolved somewhere between Eastern Europe and China is also supported.

Reproductive Biology

B. juncea varieties are annuals, usually self-pollinated, pollinated by bees, at times outcrossing has been reported among closely located plants. The pollen is heavy and sticky. Outcrossing using a herbicide resistance marker in resistant *B. juncea* surrounded by nonresistant plants has been studies. Gene flow data for *B. napus* involving gene flow between commercial fields of cultivars with different herbicide resistance traits have been studied. Many variables affect outcrossing between fields, including size of fields, fertility of recipient plants, environmental conditions, and the presence of insect pollinators.

Crop Breeding and Improvement Programs

B. juncea breeders aim to make simultaneous improvement of agronomic performance, disease resistance, and quality traits. Agronomic traits include yield, lodging, maturity, herbicide tolerance, drought tolerance, shattering resistance, and seed size. Disease resistance breeding efforts may include blackleg, white rust, *Alternaria* black spot, and *Fusarium* wilt resistance. For mustard varieties, low oil content, high glucosinolate content, and a fatty acid profile with a moderate level of erucic acid are desired.

Most varieties of mustard are pure lines, developed through repeated cycles of inbreeding or through the use of doubled haploid technology. As with most inbred crops, developing a new variety begins with the creation of F1 hybrid seed by crossing two or more parents. The aim is to combine the desirable traits from the parents into a new variety. In pedigree breeding programs, F2 populations are created by selfing the F1. Selection of highly heritable traits may begin in the F2 generation. Selection will continue on either a single plant or family basis for several generations. Selection for complex traits such as yield will wait until the breeding line is reasonably uniform. Doubled haploid technology is also used, where immature pollen grains from F1 plants are grown through tissue culture techniques to produce haploid plants. A mitotic inhibitor such as colchicine is used to develop homozygous breeding lines. Molecular markers are sometimes employed to help select for traits that are difficult to measure and to help select parents or pollen donor plants.

The major crop breeding programs focus on

- improving oil and seed yield,
- hybrid development,
- stabilizing yield through insulation of cultivars against major biotic (white rust, *Alternaria* blight, sclerotium rot diseases, and aphid insect) and abiotic stresses (drought and salinity),
- improving oil (low erucic acid) and seed meal (low glucosinolate) quality,
- developing suitable varieties for nontraditional areas.

Improved Varieties

There are several varieties of yellow mustard with desirable qualities like earlier maturing, lower yielding, and shorter in height than brown or oriental varieties. Yield differences among the types of mustard are reflected usually in the prices offered by contracting firms. Some mustard varieties include the following:

Gisilba: yellow mustard; similar to ochre in field performance; originated in Germany; distributed by Northern Sales Co. Ltd., Winnipeg; licensed in 1974

Kirby: yellow mustard; released by Colman Foods, Norwich, England, in 1970; distributed by Minn-Dak Growers Association, Grand Forks, ND

Ochre: yellow mustard; released by Agriculture Canada, Saskatoon; licensed in 1981

Tilney: yellow mustard; similar to *Kirby* in field performance but has a high mucilage content desired by processors; released by Colman Foods, Norwich, England, in 1978; distributed by Minn-Dak Growers Association, Grand Forks, ND

Carrow 85: oriental mustard; undesirable small seed; released by Colman Foods, Norwich, England, in 1980

Domo: oriental mustard; released by Agriculture Canada, Saskatoon; licensed in 1977

Lethbridge 22A: oriental mustard; released by Agriculture Canada, Saskatoon, in 1967; licensed in 1974

Blaze: brown mustard; released by Agriculture Canada, Saskatoon; licensed in 1976

Improved Indian varieties with desirable traits like salinity, high temperature tolerance, high oil content, earliness, intercropping, frost tolerance, drought (rainfed) tolerance, low erucic acid/glucosinolate, and white rust resistance and varieties for nontraditional areas and late sowing have been developed and are listed in Table 3.

The Chemistry of Mustard

All three mustard species contain a significant amount of edible oil and high quality protein. On the Indian subcontinent, *B. juncea* seeds are the second most important source of edible

Table 3 Improved varieties of Indian mustard for specific environmental conditions

Stress/situation/ condition	*Varieties recommended*
Salinity	Indian mustard: CS-52, CS-54, CS 234-4, Narendra Rai-1
High-temperature-tolerant	Indian mustard: Kanti, Pusa Agrani, RGN-13, Urvashi
High oil content	Indian mustard: Narendra Swarna Rai 8
Earliness	Indian mustard: Kanti, Narendra Ageti Rai 4, Pusa Agrani, Pusa Mahak
Intercropping	Indian mustard: RH-30, RH781, Vardan
Nontraditional areas	Indian mustard: Pusa Agrani, Pusa Jaikisan, Gujarat Mustard 2
Late-sown	Indian mustard: Ashirwad, RLM 619, Swaran Jyoti, Vardan, Navgold
Frost-tolerant	RGN13, RH-781, Swaran Jyoti

Source: www.circ.org/fileadmin/documents/Bulletins/B25/B25_06.

vegetable oil, and the residual high protein meal, after it is soaked in water, is fed to cattle. However, for the spice trade, the important ingredient is the presence and concentration in the seeds of sulfur compounds called glucosinolates. Over 40 such compounds are known, and their presence and quantity determine the flavor and odor of the cole vegetables as well as the taste and heat of the mustards. The glucosinolate that imparts the pungency and flavor to black and *B. juncea* mustards is called 'sinigrin,' while in *Sinapis alba*, it is 'sinalbin.' When the seeds are stored whole and dry, they retain their quality for several years. However, when the cells of a mustard seed are broken and moisture is present, the enzyme myrosinase, also present in the seed, breaks down the glucosinolates to release sugar, sulfur, and the hot principles called isothiocyanates. Black and *B. juncea* mustard seeds release the pungent, volatile, biting allyl isothiocyanate found in powdered and Dijon mustards. Yellow mustard, on the other hand, releases the milder, nonvolatile *para*-hydroxybenzyl isothiocyanate.

Comparing protein and oil contents of yellow and brown varieties, it was observed that yellow mustard has higher protein content (36.73%) than brown mustard (32.48%), whereas the oil content was higher in brown mustard (36.32%) when compared with yellow mustard (31.78%).

The flavor of mustard seeds is derived from glucosinolates, which are isothiocyanate glycosides. Sinalbin is responsible for the flavor of white mustard seed, and sinigrin is responsible for the sharper taste associated with black and brown mustards. The pungency is due to glucosinolates, which are hydrolyzed by myrosinase enzyme to flavor active isothiocyanates. Allyl isothiocyanate (AITC) has the potential to be used as flavoring, antibacterial, antifungal, antifermentative, and antibrowning agent in food industry.

The aroma and pungent flavor of mustards come from the essential oil *sinalbin*. This compound releases isothiocyanate chemicals upon enzymatic reaction mediated by myrosinase: a glycoside (sinigrin) and an enzyme (myrosin); in contact with water, myrosin acts on sinigrin, setting free AITC (mustard oil) responsible for mustard's pungent smell.

Phytonutrients

Mustard seeds contain high amounts of phytonutrients, particularly glucosinolates, according to a 1990 study published in *Plant Science*. Glucosinolates are sugar-derived compounds that are found naturally in many flowering plants. A study published by the *International Journal for Vitamin and Nutrition Research* in 2002 found that glucosinolates found in plants may have a protective effect against certain types of cancer, especially lung cancer.

Healthy Minerals

Mustard seeds contain a variety of minerals, including iron, magnesium, zinc, calcium, and phosphorus. Getting adequate amounts of these minerals is essential for the normal function of many biological and biochemical processes within your body and can help prevent a mineral deficiency, which can have potentially debilitating side effects. According to USDA National Nutrient Database for Standard Reference, ground mustard seed contains 26.6% of your daily calcium, 51.2% of your daily iron, 92.5% of your daily magnesium, 40.5% of your daily zinc, and 82.8% of your daily phosphorus.

Omega-3 Fatty Acids

Mustard seed is acidic and a source of omega-3 fatty acids, according to the book, *Today's Herbal Health: The Essential Reference Guide*. The University of Maryland Medical Center states that omega-3 fatty acids found in some foods can benefit individuals with high cholesterol, high blood pressure, heart disease, diabetes, rheumatoid arthritis, systemic lupus erythematosus, osteoporosis, depression, bipolar disorder, schizophrenia, attention-deficit disorder, skin disorders, inflammatory bowel disease, asthma, macular degeneration, menstrual pain, and some cancers. However, omega-3 fatty acids are not intended to treat or prevent any disease. Consult with your physician before taking food items or supplements containing omega-3 fatty acids.

Crop Protection and Disease Management

This crop is vulnerable to several diseases, among which the most serious are sclerotium stalk rot (white mold), downy mildew, white rust, leaf spots, and mosaic virus. Good cultural practices are the most effective control measures for diseases. These practices should include keeping records of disease occurrence, compliance with the proper crop rotation, control of host plants for diseases in fallow fields and non-crop areas, and the use of seed treatments.

Sunflower, rapeseed, canola, safflower, soybeans, crambe, and dry beans should not be grown in rotation with mustard since they have similar disease problems. If these crops are produced in rotation with mustard, damage from these diseases can increase to economic levels. Numerous broadleaf weeds can also serve as hosts or sources of infection for these diseases. Wild mustard, pigweed, field pennycress, and shepherd's purse are examples of predominant hosts. One of the best methods to avoid serious disease problems in mustard (and leaf diseases of small grains) is to produce this crop in a small grain rotation. Mustard should be spaced four or more years apart in the crop rotation to avoid problems with soilborne diseases. After potato or flax crops, 1 year should pass before mustard is raised on the same field due to the presence of root rot or damping-off pathogens.

The following strategies are helpful for disease management:

- Choosing the sowing time is very important as it affects the disease incidence significantly.
- Deep summer plowing.
- The use of disease-resistant or disease-tolerant or early maturing disease-escaping cultivars.
- The use of good quality seeds.
- Seed treatment with biocontrol agents, namely, *Trichoderma viride* and *Gliocladium virens*, or botanicals like *Allium sativum* bulb extract (1% w/v) or carbendazim at 0.1% a.i. or mixture of carbendazim and Apron 35 SD (6 g kg^{-1}). There is a need for mixture of fungicides for avoiding resistance development in pathogens to fungicides. The use of biocontrol agents is advantageous as they are often effective against a wide range of soilborne pathogens. Moreover, they are eco-friendly and cost-effective and their use avoids the risk of development of resistance in the pathogen towards the control agent.
- Application of recommended doses of N, P, and K fertilizers with split application of N.
- Maintenance of optimum plant population with recommended spacing.
- Proper drainage to avoid water stagnation.

Insects

These crops are highly vulnerable to a large number of insect pests. About 50 insects are known to damage *Brassica* crops. Among these insects, mustard aphid (*Lipaphis erysimi*) is the key pest of the Brassica crops, while sawfly (*Athalia proxima*) and painted bug (*Bagrada cruciferarum*) cause yield losses. Yield losses due to aphid may be up to 97% and sawfly and painted bug up to 15% and 30%, respectively. The period of peak activity for aphids is January–February in most part of the country. The economic threshold level values for aphid in rapeseed–mustard for different states have also been worked out. The integrated insect management strategies are as follows:

- Crops should be sown at optimum time recommended for particular area.
- Overuse of fertilizers particularly nitrogen attracts more aphids; hence, the use of balanced dose of fertilizers is recommended.
- Plucking and destruction of infested twigs/plants at initial stage of attack are very useful.
- Plucking the infested leaves and burying them in soil help in the reduction of the pest.
- Plant extracts of *Azadirachta indica*, *Lantana camara*, and *Ipomoea carnea* proved toxic to mustard aphids.
- Microbial pesticides have been widely used in the management of insect pest and avoiding the development of resistance. The use of *Verticillium lecanii* against the mustard aphid and other aphids has been found encouraging.

With no available sources of durable resistance in the presently cultivated varieties of rapeseed–mustard, efforts are being made throughout the world to develop stable disease resistance in oilseed brassicas by utilizing the contemporary tools of biotechnology. The *Alternaria* blight pathogen and various technologies, namely, embryo rescue, somatic hybridization, somaclonal variations, genetic transformation, molecular markers, and signal transduction, being used for the incorporation of resistance against the pathogen in oil-yielding brassicas have been described as the studies on the diversity of sclerotium isolates.

Utilization of Biotechnological Tools

Biotechnological techniques like tissue culture and genetic transformation have revolutionized the search for economically promising disease-resistant crops, helping to combine the traits from distantly related *Brassica* sp. for the development of superior *Alternaria* blight-tolerant varieties of *Brassica*.

In vitro embryo rescue technique was proved to be very efficient for transferring *Alternaria* blight tolerance in oilseed brassicas. *In vitro* ovary culture was used to transfer the resistance against *Alternaria* blight from *B. tournefortii* to *B. juncea* 'RH 30'. Intergeneric hybrids of *B. campestris* and *B. spinenscens* have been developed and multiplied using somatic embryogenesis. The resistance trait from *Sinapis alba* 'Carine' was transferred to *B. napus* 'Brutor' using *in vitro* fertilized ovary culture. Intergeneric hybrids with *Alternaria* blight resistance were developed between *Erucastrum cardaminoides* and *B. oleracea* var. *alboglabra* using sequential ovary and ovule culture. Interspecific hybridization in combination with *in vitro* ovule culture was used to incorporate high tolerance to *Alternaria* blight and white rust.

Somatic hybridization has been utilized effectively in brassicas, but the studies are limited to *B. napus* and *B. oleracea*. Attempts to transfer *Alternaria* resistance trait from *B. carinata* to *B. juncea* have been made. Leaf mesophyll protoplasts from *Moricandia arvensis* and *B. napus* were hybridized to produce disease-resistant hybrid plants. *B. carinata* has been resynthesized by protoplast fusion between *B. nigra* and *B. oleracea*. The hybrids thus obtained were fertile and grew into robust plants.

Studies have shown the use of somaclonal variations for the incorporation of disease resistance/tolerance against *Alternaria* blight. Resistance to susceptible varieties of *B. juncea* was achieved by inducing variations through mutagenesis, by exposing the seeds to gamma radiations, and by treating the

microspores/microspore-derived embryos with chemical mutagens.

Transformation systems have been developed in almost all the economically important species of *Brassica* and *B. nigra*.

Uses

In general, three main varieties of mustard are grown worldwide for use:

- White mustard seeds (*Brassica alba*): The seeds are light straw yellow-colored and are slightly larger than the other two varieties. White seeds exhibit mild pungency.
- Black mustard seeds (*Brassica nigra*): The seeds are commonly seen in South Asia. The seeds are sharp and more pungent than other two varieties.
- Brown mustard seeds (*Brassica juncea*): The seeds are native to sub-Himalayan plains of northern India.

Nutritional Benefits of Mustard Seeds

Mustard seeds are indeed very rich in phytonutrients, minerals, vitamins, and antioxidants (Table 4) and are rubefacient, irritant, stimulant, diuretic, emetic, pungent, and laxative and aid in digestion. This well-known spice has its use in medicine as a stimulant when applied externally. The rubefacient action causes a mild irritation to the skin, stimulating the circulation in that area and relieving muscular and skeletal pain. Its stimulating, diaphoretic action can be utilized in the way that cayenne and ginger are. An infusion or poultice of mustard will aid in cases of bronchitis:

- Mustards are very high in calories; 100 g of seeds provides 508 cal, and the seeds are made of quality proteins, essential oils, vitamins, minerals, and dietary fiber.
- The seeds are high in essential oils as well as plant sterols. Some of important sterols include *brassicasterol*, *campesterol*, *sitosterol*, *avenasterol*, and *stigmasterol*. Some of glucosinolate and fatty acids in the seeds include *sinigrin*, *myrosin*, *erucic*, *eicosenoic*, *oleic*, and *palmitic acids*.
- Mustard seeds are an excellent source of essential vitamin B complex such as folate, niacin, thiamin, riboflavin, pyridoxine (vitamin B_6), and pantothenic acid. These vitamins are essential in the sense that the body requires them from external sources to replenish. These B complex groups of vitamins help in enzyme synthesis, nervous system function, and regulating body metabolism.
- 100 g of mustards provides 4.733 mg of niacin (vitamin B_3). Niacin is a part of nicotinamide coenzymes and helps lower blood cholesterol and triglyceride levels.
- Mustard seeds contain flavonoid and carotenoid antioxidants such as carotenes, zeaxanthin, and lutein. In addition, the seeds comprise a small amount of vitamin antioxidants such as vitamins A, C, and vitamin K.
- The seeds are a source of vitamin E and gamma-tocopherol and contain about 19.82 mg per 100 g. Vitamin E is a powerful lipid-soluble antioxidant, required for maintaining the integrity of cell membrane of mucus membranes and skin by protecting it from harmful oxygen-free radicals.
- Mustards are a rich source of health-benefiting minerals. Calcium, manganese, copper, iron, selenium, and zinc are some of the minerals especially concentrated in these seeds. Calcium helps build bone and teeth. Manganese is used by the body as a cofactor for the antioxidant enzyme *superoxide dismutase*. Copper is required in the production of red blood cells. Iron is required for the red blood cell formation and cellular metabolism.

Phytonutrient Compound

Like other *Brassicas*, mustard seeds contain plentiful amounts of phytonutrients called *glucosinolates*. The seeds also contain *myrosinase enzymes* that can break apart the glucosinolates into other phytonutrients called *isothiocyanates*. The isothiocyanates in mustard seed (and other *Brassicas*) have been repeatedly studied for their anticancer effects. In animal studies – and particularly in studies involving the gastrointestinal tract and colorectal cancer – intake of isothiocyanates has been shown to inhibit growth of existing cancer cells and to be protective against the formation of such cells.

Anti-inflammatory Effects from Selenium and Magnesium

Mustard seeds emerged from our food ranking system as an excellent source of selenium, a nutrient that has been shown to help reduce the severity of asthma, decrease some of the symptoms of rheumatoid arthritis, and help prevent cancer. They also qualified as a good source of magnesium. Like selenium, magnesium has been shown to help reduce the severity of asthma, to lower high blood pressure, to restore normal sleep patterns in women having difficulty with the symptoms of menopause, to reduce the frequency of migraine attacks, and to prevent heart attack in patients suffering from atherosclerosis or diabetic heart disease.

Mustard seeds also qualified as a very good source of omega-3 fatty acids and manganese as well as a good source of phosphorus, copper, and vitamin B_1.

Medicinal Uses

- Mustard seeds and its oil have traditionally been used to relieve muscle pain, rheumatism, and arthritic pain. In India, mustard oil is applied over the scalp and is believed to stimulate hair growth. Its ground seeds act as a laxative and stimulant to gastric mucosa and increase intestinal secretion. Mustards have been used in traditional folk medicine in Turkey, to treat a variety of ailments including peritonitis and neuralgia. They are used in mustard plasters to treat rheumatism, arthritis, chest congestion, aching back, and sore muscles by making a mustard plaster with equal parts of flour and powdered mustard and spreading it on a doubled piece of soft cloth and applying it to the affected area for about 15 min.
- *Anticarcinogenic properties*: Mustard seeds are suggested to prevent and slow the progress of cancers especially in the gastrointestinal tract. Evidences also suggest that mustard seeds may restrict the growth of already present cancer cells and prevent the formation of new cancers. AITC, which occurs in many common cruciferous vegetables, was

recently shown to be selectively delivered to bladder cancer tissues through urinary excretion and to inhibit bladder cancer development in rats.

- Sinigrin, a major glucosinolate present in Indian mustard (*Brassica juncea* L.) seeds and leaf tissue, is also reported to be a precursor of the anticancer compound AITC.
- *Antioxidant properties and antiaging action*: Mustard seeds and powder contain the amino acid, cysteine, which acts as an antioxidant in your body. Cysteine protects our body from free radicals, which are harmful compounds in your body that damage DNA and cell membranes, according to the University of Maryland Medical Center. Cysteine may also be useful in individuals suffering from angina, bronchitis, influenza, and other conditions. Mustard is a great source of carotenes, zeaxanthins, and lutein (also called flavonoid and carotenoid antioxidants) and vitamins A, C, and K. All these components put together make it rich in antioxidants, which in turn slows the aging process.

Apart from these, mustard usage has been suggested to

- *Relieve symptoms of asthma*: Mustard seeds are high in selenium and magnesium. Both the components give it unique anti-inflammatory property. Consumed regularly, it is known to control and keep the symptoms of asthma, cold, and chest congestion at bay.
- *Prevent obesity*: The wonder seeds are packed with vitamins B complex like folate, niacin, thiamine, and riboflavin. Apart from all the individual merits of these components, they are great in speeding up one's metabolism leading to weight loss.
- *Lower cholesterol levels*: Mustard contains high levels of niacin or vitamin B_3. Niacin has properties that help lower cholesterol levels and protect the arteries from atherosclerosis (plaque buildup). It also helps to regulate blood flow and protects the body from hypertension.
- *Relieve constipation and symptoms of piles and fissures*: The seeds contain mucilage, which is a thick slimy substance that is the key to relieving constipation. Apart from that, it is also high in fiber
- *Fight skin infections*: Packed with sulfur, mustard seeds are a great way to curb skin infections. Sulfur gives the seed antifungal and antibacterial properties that help fight common skin ailments.
- *Improve immunity*: Because mustard has a large number of elemental minerals like iron, manganese, and copper, it helps improve the body's ability to fight disease.
- *Act as preservative*: Mustard oil is rich in tocopherols and acts against rancidity. This contributes to longer shelf life of finished food products.

Culinary Uses

- Mustards are used extensively in Indian, Pakistani, Bangladesh, Mediterranean, and German cooking. Whole seeds, ground or powdered form; prepared pastes; sauces; and oil are all used in cooking.
- Mustard seeds are used in condiments from time immemorial by Romans, Greeks, and Indians. Pilani a physician of Rome writes: "It is so pungent in flavour that it burns like fire, though at the same time it is remarkably wholesome

for the body." Used internationally as an appetizer, flavoring agent, and food preservative, its presence in the food and pickles prevents the growth of *Aspergillus niger* (black mold).

- Raw mustard seeds have a face-warping bitter quality, which seems to render the medicinal properties accrued to their use.
- But when treated with heat, mustard's fragrance transforms to an acceptable pungency that renders all preparations an appetizing flavor, making it an indispensable topping in all Indian curries. Powdered or crushed mustard is used in pickles, and the whole seeds are used to flavor vegetables and pulses, where they are fried in hot oil to give the flavor.

Mixing ground mustard seeds with water causes a chemical reaction between the enzyme myrosinase and glucosinolates such as sinigrin, myrosin, and sinalbin. The myrosinase enzyme turns the glucosinolates into various isothiocyanate compounds known generally as mustard oil. The concentrations of different glucosinolates in mustard plant varieties and the different isothiocyanates that are produced make different flavors and intensities. AITC and 4-hydroxybenzyl isothiocyanate render the sharp hot pungent sensation in mustards by stimulating the heat and acidity-sensing pain receptors of both oral and nasal passages. The gradual chemical breakup of 4-hydroxybenzyl isothiocyanate leads to the dissipation of heat from prepared mustard, over a period of time. Thioglucoside is hydrolyzed during the processing of mustard seeds, releasing glucose, which supplements the natural reducing sugars.

Skin Care

- *As a natural sunscreen*: Due to its thick consistency and high levels of vitamin E, topical application of this oil protects your skin against the harsh ultraviolet rays and other pollutants, thus preventing skin cancer. Vitamin E prevents aging and wrinkles besides acting as a sunshield.
- *Stimulates sweat glands*: Whether consumed or applied topically, mustard oil stimulates the sweat glands and opens the pores of the skin. Thus, it helps in reducing the body temperature and removes unwanted toxins, water, and salts from the body.
- *Treats rashes and infections*: Due to its antibacterial and antifungal properties, mustard oil is effective in treating rashes and other skin infections, thus preventing your skin from dryness, dullness, and itching. A body massage with mustard oil rejuvenates and cleans skin by increasing blood circulation. Besides, due to its anti-inflammatory properties, it is effective in reducing skin inflammation and facilitates quick healing of cuts and wounds.

The functional properties of Brown mustard seed and its flavor have been reviewed. The whole mustard seed has no flavor but can provide a pungent taste after chewing. The heat experienced in yellow mustard is on the tongue, whereas in brown and black mustards, the heat is also felt in the nose and eyes. The severity of pungent aroma varies with different mustards. The white or yellow mustard seed has a less pungent aroma than brown mustard seeds, which have a very pungent aroma. Black mustard seeds have the highest pungency. In ground mustard, aroma does not persist. However, flavor and pungency are experienced when enzymatic action is triggered in the presence of water, which releases mustard's flavor or pungency. It is due to a variety of isothiocyanate compounds that exist in mustard tissue as glycosides.

Conclusion

Mustard crop offers immense scope for further yield enhancement. Yield enhancement possibilities exist with improvement in crop production and crop programs. The development of crop production and protection techniques that are eco-regional in scope and simultaneously incorporate the constraints imposed by the natural resource availability of the region is the need of the hour. With the growing demand for edible oil crops like brassicas and the immense losses caused by the fungal pathogens like *Alternaria*, there is an urgent need to curb this pressure and focus on the production of disease-free superior brassica. Biotechnology has revolutionized the classical breeding process and has enabled the combining of traits from distant species for developing promising hybrids. Studies on host-pathogen interactions would help identify the genes activated during pathogenesis and the defense-related proteins released in response to the *Alternaria*. Integrating conventional breeding methods with the modern tools will help in evolving a disease management strategy in brassicas with superior agronomic traits.
