Source: United Nations FAO statistics.

tart cherry production ranged, for example, from 38000 to 133000 metric tons in the last several years, but there has been a gradual downward trend in average production since the mid-1960s to about 120000 tons (in 2014), with a farm value of about $50 million, but the processed value is at least thrice that. Sweet cherry production, however, has been increasing, especially recently as markets develop in Japan and the Far East of the Pacific Rim for fresh cherries grown in the Western United States and elsewhere.

Between 2010 and 2012, the world's cherry acreage increased by 4.2%, reaching over 400000 ha, according to the United Nations Food and Agriculture Organization (FAO). Turkey has the largest cherry acreage worldwide (increasing its share from 11% to 12% in 2012), with the United States being the second with 8.7%. Italy is third with Syria (at 7.4%) and then Iran and Spain, with shares of 7.2% and 6%, respectively. Chile's share increased (from 3.4% to 3.8%). Turkey also increased its share in the world's production, with 21.3%. The United States was second with 17%, while Iran, Syria, and Italy reduced their shares to 8.9%, 4.6%, and 3.6%, respectively. Chile ranked sixth in world production, with a 4% share of the total in 2012, a sharp increase compared with the 2.8% in 2010.

Growth and Management

Flowering and fruit set – Sweet cherry flowers are in clusters of two to four usually borne laterally on short spurs on 2-year-old twigs or near the base of longer 1-year-old shoots. Floral initiation takes place in July, after the crop is harvested, and only on buds where the subtending leaves opened relatively early in summer. Flower buds are of the unmixed type and do not give rise to a lateral or bourse shoot. As a result, flowering spurs, unlike those on apples and pears, do not remain productive. Flowers generally have a single pistil but in very hot summers may form two pistils that result in undesirable double fruits. With few exceptions, for example, 'Stella' (and its progeny) and the new 'Lapins' and 'Sweetheart' cultivars, commercial sweet cherries are self-sterile (self-incompatible) and therefore require another cultivar for pollination. There are, however, intrasterile groups, where none of the group will cross-pollinate any other member of the group. Bing, Lambert, and Napoleon are one such group.

Tart cherry flowers develop much like sweet cherry, with buds of two to four flowers on either spurs or lateral buds. Tart cherry cultivars range from compatible to self-incompatible. Montmorency, for example, is only partially compatible but is always grown without a pollinator. Fruit set, however, clearly limits yield on the fully incompatible cultivars, but overcropping may occur in other cultivars with excessive flowering or fruit set resulting in too few leaves or leaf buds to develop fruit of adequate size and quality.

In both sweet and tart cherries, flower development and fruit set may frequently be harmed by late frosts, although tart cherry is hardier and generally blooms later than sweet cherry. Wide annual supply fluctuations are consequently common in major growing areas for both species due to spring frosts or to low midwinter temperatures where lack of wood hardiness is a contributing factor. Sweet cherries are less hardy than apples, but some tart cherry cultivars may be as hardy as the apple cultivars McIntosh or Northern Spy. In addition, the best-quality sweet cherry cultivars tend to be more susceptible to rain cracking and do best in regions with dry summer growing conditions. Fruit also develops good quality in regions often too cool for peaches or apricots. Climate also dictates that

cherries be grown where winter chilling temperatures (about 1000 h for most sweet cherries, longer for tart cherry) are adequate to break rest; thus, cherry culture is generally limited to cooler temperate regions.

Tree size and rootstocks – Tree size plays a central role in production of quality fruit. Dwarf trees have many advantages: Light penetrates better, favoring photosynthesis; the tree produces more and better fruit; spraying can be done more efficiently, usually with reduced use of chemicals; and dwarf trees are easier to harvest. Cherries are no exception, but dwarfing rootstocks have not until recently been available for either sweet or tart cherry. The common rootstocks, 'Mazzard' and 'Mahaleb,' only slightly affect tree size, if at all. 'Colt' is similar and may be somewhat drought- and cold-susceptible. Recently, however, dwarfing rootstocks have been developed in several breeding programs, and is being tested. For example, of 17 cherry rootstocks developed in Giessen, Germany, most produce relatively large trees, but two of these rootstocks give trees about 25% of the standard, and several rootstocks developed in Belgium may also be promising.

Harvesting and handling – Sweet cherries are almost all hand-harvested, particularly those intended for the fresh market. Avoiding pitting and bruising throughout harvest, sorting, and packing is a major problem in delivering high-quality fruit to the fresh market. Bruise susceptibility of some white- or yellow-fleshed cultivars may even require field packing to minimize loss. Mechanical harvesting of tart cherries for processing, however, has been a major technological development, which substantially reduces grower costs. A grower and his family plus some high school students (a crew of 6–8) can mechanically harvest as much as 200–300 hand pickers formerly did. The results include huge savings in direct labor costs, large reductions in housing costs, and substantial savings in labor fringe costs. The US tart cherry industry used essentially completely mechanical harvesting during the 1970s, although there have since been additional improvements in equipment and techniques.

Some aspects of cherry processing have also substantially changed, which has led to greater efficiencies and product quality in the cherry industry. Almost all tart cherry processors have adopted electric-eye sorting equipment, which substantially reduces in-plant sorting labor, and destemming equipment efficiently removes the stems from mechanically harvested cherries. Although picking of sweet cherries for the fresh market is still by hand, subsequent handling has been improved dramatically very recently with the substitution of hydraulic flumes for conveyor belts to reduce bruising and pitting throughout sorting and packing.

Quality Factors

Soluble solids (primarily hexose sugars and sorbitol) and fruit color (depending on the type) are the best indicators of quality for both sweet and tart cherries, although fruit acid level may be important in tart cherry. Except for soluble carbohydrates, vitamins A and C, and certain flavonoids that may be important as antioxidants in some cultivars, cherries are relatively low in nutrients, but calcium, iron, magnesium, phosphorus, and copper contents are high compared to apple, peach, grape, and strawberry. High-quality tart cherry fruit typically has at least 15% soluble solids, while sweet cherries should have nearly 20% (or higher). Standards for harvesting and marketing may, however, often be lower. Optimum conditions also often vary with use. To facilitate brining (bleaching in sulfur dioxide solutions for maraschino cherries), fruit may be picked prematurely before color and soluble solids are adequate for the fresh market. Stem fruit removal force is carefully monitored for tart cherries that will be mechanically harvested, and abscission may be brought on by treatment with ethephon, which releases ethylene, expediting abscission and fruit drop in response to mechanical shaking.

Disorders, Diseases, and Pests

Disorders – In processing brined sweet and tart cherries, the solution pocket problem involves subepidermal splits in the flesh, which fill with brine solution and with ruptured cell contents. Time of harvest, degree of turgidity at brining, temperature, or any procedures that reduce either the sugar or water content of the fruit will tend to decrease the problem.

Rain cracking (swelling followed by rupture of the epidermis) of sweet cherries occurs mostly during the harvest period when the fruit is mature or nearly so and has been wet with rain for some time. Primary cause is absorption of water directly through the skin of the fruit and not through the root system. Cultivar cracking susceptibility has been tested extensively. In testing, Bing, one of the best-quality cultivars, was worst, followed by Napoleon, Lambert, Emperor Francis, Giant, Schmidt, Yellow Spanish, and Montmorency, which did not crack. In another ranking, Bing invariably cracked very badly and was followed by Lambert, Giant, Gil Peck, and Hedelfingen. In still another test, Van, Merton Glory, Vega, and Vista were very susceptible, while Emperor Francis, Schmidt, and Sam were less, and Sue, Kristin, Ulster, and Early Rivers were the least susceptible. From the long-range viewpoint, breeding programs under way ultimately may produce desirable crack-resistant cherries. Cracking may be reduced by some chemical treatments, for example, rain-activated calcium sprayers, but results with hormone (auxin (NAA) and gibberellin (GA_3)) applications are equivocal. In some parts of the world, for example, Europe, covering trees with plastic film has been widely used to avoid cracking. Elsewhere, this approach or a high tunnel method has also been used to promote earlier flowering and fruiting, thus capturing high early market returns that justify the extra costs.

Pitting of sweet cherry is a condition in which areas near the surface of the fruit become sunken, forming dimples or pits, and may occur before or after harvest, and there are at least three different sources: usually from bruising during handling, from feeding by sucking insects such as the soldier bug, and perhaps from physiological injuries, for example, adverse low-temperature stress during postharvest cooling or growing conditions.

Diseases – Bacterial canker, one of the most important sweet and tart cherry pathogens, is caused by two different pathogens, *Pseudomonas syringae* and *Pseudomonas morsprunorum*, and is characterized by oozing of gum (gummosis) at infection sites. Disease development is most prevalent during the

cool, wet periods of early spring. Crown gall, caused by *Agrobacterium tumefaciens*, can affect sweet and tart cherry rootstocks and is characterized by galls forming usually near infection sites caused by wounds, sometimes man-made, for example, cultivation injuries, or due to damage from subterranean chewing insects or rodents. Some rootstocks, however, are only moderately susceptible, and some hybrids may be tolerant. Brown rot, caused by the fungi *Monilinia fructicola* or *M. laxa*, affects both sweet and tart cherries and reduces yield in infected and decaying blossoms, twigs, and fruit. Fruit decay after harvest is also a problem. The fungi persist in mummified fruit on the tree and the ground and infection continues from these inocula the following spring. Growing regions with cooler and drier summers provide some relief. Cherry leaf spot, *Blumeriella jaapii* (*Coccomyces hiemalis*), is the most serious disease affecting tart cherry and most ground cherries. Infection occurs in the spring on expanding leaves and continues throughout the season under favorable conditions, for example, high humidity. Severely infected leaves become chlorotic and abscise, and if defoliation is severe, fruit may not ripen properly and tree vigor and hardiness are reduced. Powdery mildew (*Podosphaera oxyacanthae*) is similar. Other fungal pathogens may sometimes be important, causing blights, crown or root rots, and replant (orchard reestablishment) problems. Cherry dieback is thought to be a complex of several disorders, one of which may be mycoplasma disease. X-disease, leafhopper-transmitted and often devastating, is also due to mycoplasma.

Several viruses cause poor vegetative growth, reduce yields, and may even result in tree death, but others are symptomless. Among the most severe is prunus necrotic ringspot virus, which is pollen-transmitted and present in all cherry-growing areas of the world. Little cherry (prune dwarf) disease is another pollen-transmitted virus and very destructive. *Prunus* stem pitting disease is caused by the tomato ringspot virus and is spread by nematodes.

Pests – Bird damage can be very serious, and some areas may require protective netting to reduce predation. The cherry fruit fly passes the winter in the soil as a pupa, adult flies emerge in late spring, and females feed on surfaces of leaves and fruit and lay eggs in the nearly ripe fruit. On hatching, the larvae (maggots) feed on the fruit flesh. The larvae are easily killed by holding fruit near 0 °C, but fumigation, until recently most often with methyl bromide, may be required to meet quarantine restrictions for shipping overseas. Other pests include black cherry aphid, plum curculio, European red mite, peach tree borer, and two-spotted mite.

Economic Problems and Future Developments

Although the tart cherry industry is facing a serious problem of excessive productive capacity in some years and persistent oversupplies, this industry has adopted new technologies and practices in the last 10 years, which substantially improve its cost efficiency and productivity. Much of the newly planted acreage uses efficient trickle irrigation and closely planted orchard systems that also involve hedging techniques. These recent new techniques, especially in combination, provide large increases in yields per hectare and hence substantial reductions in costs.

Considerable genetic diversity still exists in Eastern Europe and Russia, the center of origin for both tart and sweet cherries. Although breeding programs have been limited, exploiting that diversity should do much to overcome the growing, handling, and processing problems that face growers using the industry standards, the sweet 'Bing' and the tart 'Montmorency' in the United States. Sweet cherry growers especially need dwarfing rootstocks and spur types for growth control, and all growers need cultivars with disease and pest resistance, less self-sterility, and a range of maturities so that there are longer seasons for fresh markets. Sweet cherry growers also need cultivars with rain-cracking resistance and, for postharvest fresh market quality, resistance to bruising. Tart cherry growers need new cultivars for diversifying and strengthening marketing options, for example, fresh and frozen juice products, dyes for cosmetics and the food processing industry, and dry stem scars and small freestone pits to facilitate handling and processing. A combination of new marketing strategies and products for tart cherries and advances in breeding of both sweet and tart cherries would clearly benefit the economic potential of the entire cherry industry.

Chilled Foods: Effects on Shelf-life and Sensory Quality

D Bermúdez-Aguirre and J Welti-Chanes, Tecnológico de Monterrey, Monterrey, Nuevo Leon, Mexico

Introduction

The commercial cold chain has been evolved together with the progress on *Food Science and Technology*. In the past, chilled food was a term used for those items that need to be kept under refrigeration because of quick microbial spoilage. Sometimes, these products were seafood and fish caught in remote areas of the world and needed to be transported to specific markets. However, nowadays, the chilled food chain also includes some novel products that must be kept under refrigerated conditions; temperature abuse is not an option because of the microbial risk inherent in the product. These novel products are called cooked-chilled foods or ready-to-eat meals.

During the storage of chilled foods, temperature must be kept at specific values and recorded to ensure the microbial safety of the product. Consumers must be aware of the importance of controlling the temperature of these products and make sure their responsibility to handle the product from the store to the final consumption. Even if the product is kept with ice on a boat or kept on a supermarket on the fridge, temperature must be carefully monitored to ensure that spoilage microorganisms are growing slowly or the microbial growth is delayed.

Several microbial species have been identified in specific products and these are the ones that should be monitored during the storage; microorganisms such as *Bacillus* spp. are frequently found in chilled goods and it is recognized as one of the foodborne organisms, and high counts of this sporeformer microorganism can promote gastrointestinal diseases. Pathogens such as *Listeria monocytogenes*, or even spores of *Clostridium botulinum*, can be identified in some chilled foods, because of a poor pasteurization process, lack of hygienic measures, cross contamination, or underprocessing of the product.

Furthermore, sensory quality of chilled foods can be drastically compromised because of some chemical reactions taking place during storage, such as rancidity, changes in color and flavor, or changes in texture. Refrigerated temperatures delay some of these chemical reactions but do not eliminate them completely. Even if the reaction rate is slow, the chemical processes are taking place, and if the product is stored for several weeks, noticeable changes on sensory properties could be observed.

This article presents a brief discussion about some microbial and sensory changes in chilled foods. The specific microbial groups of representative food products are included as well as some of the novel approaches to minimize microbial risks and to improve the current technologies used to preserve chilled foods. Sensory changes in some refrigerated products and some novel strategies used by food technologists are also included.

Chilled Foods

The term chilled foods includes a number of products: some of them are ready-to-eat, others require some quick preparation by the consumer, and another category includes chilled products that will be used as ingredients for other products. In general, chilled foods must be kept at a temperature $\leq 5\ ^{\circ}C$ to ensure the microbial quality of the product through the chilled chain until they reach the consumer. Chilled foods include entrées, pasta, vegetables, fresh soups, salad dressing, desserts, deli products, dips, ready-to-eat meals, different kinds of meat, fish and seafood, and poultry products. All of them, regardless of the product, must follow the food safety regulations in each country for processing, handling, transportation, storage, and final consumption. Often, a hazard analysis and critical control point (HACCP) program is followed to process, preserve, handle, prepare, transport, and package chilled foods.

Some of the main concerns of chilled foods are related with chemical, sensory, and microbial changes of the product by the end of the shelf life when the consumer is eating the product. Chemical changes on the product can seriously compromise the nutritional quality of the product leading to a food item without the original nutrient content. Sensory changes are related more with the acceptability of the product by the consumer; even though these changes do not put at risk the health of the user, they might affect the perception and consumption of the product, making it unsuitable for eating. Finally, one of the most important characteristics of the chilled foods is the microbial quality; even though the growth of the microorganisms is delayed during storage of these products because of low temperature, there are some species such as psychrophilic microorganisms that can grow and represent a risk for the consumption. Besides, some of the emerging pathogens might stay alive on the product and grow if the temperature is not controlled, producing a high risk of foodborne illnesses.

Shelf Life

The shelf life of the product depends on several factors such as initial microbial counts, the quality of the raw ingredients, the processing technology, the addition of antimicrobials, and the use of preservation factors such as decrease of pH or a_w and storage temperature. The chemical composition of the product will also be an important factor to consider during the shelf life studies, as the richer in nutrients the product is, the faster its microbial growth. Furthermore, a_w is an important fact to consider during the shelf life, especially for chilled foods that have high moisture content. Water is important not only for microbial growth but also for the promotion of chemical reactions on the product.

Regardless of the chemical composition of the product and the initial microbial population, an additional aspect to consider during the shelf life is the packaging material and the packaging conditions of the product. Some packaging materials represent a strong barrier against moisture, oxygen, and temperature, which together will extend considerably the shelf

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00144-6

life of the product. However, on the chilled food chain, some products are not packaged because they are sold 'fresh and raw' such as fish or produce or some products have a very weak barrier with very basic packaging materials. Some products might be packaged using some specific conditions such as vacuum and modified or controlled atmospheres, which also contribute to the extension of the shelf life. Also, several preservation factors have been tested together with low temperatures during food processing to extend the shelf life of different products; physical and chemical hurdles have been used as shown in Table 1.

Microbial Shelf Life

Fish and seafood

Several marine products such as seafood and fish have a short shelf life because of the chemical reactions taking place together with the postmortem changes. All of these chemical changes can promote faster microbial growth of the product. Spoilage microorganisms on fish include aerobic and proteolytic bacteria, coliforms, and lactic acid species. Pathogens on fish include *Vibrio cholera*, *L. monocytogenes*, *Escherichia coli*, and *Salmonella* spp., among others (Table 2). Numerous studies have been conducted to incorporate some compounds on the ice that keeps the temperature of chilled foods low. Some of the compounds have antimicrobial properties to delay the microbial growth and extend the shelf life of the product. Studies have been done with plants and herbal extracts, for example, thyme, oregano, clove, basil, and rosemary, among others. Other compounds that have been tested together with ice include some organic acids, alone and in combination. Some examples are citric, ascorbic, and lactic acids. The food products tested include marine species such as seafood (anchovies) and different kinds of fish (sardines and mackerel, among others). In most of the cases, the shelf life of the product has been considerably extended when comparing with control samples kept only on ice; microbial loads reported for muscles are considerably lower for those treated products compared with control samples. Counts of aerobes, anaerobes, psychrotrophs, Enterobacteriaceae, and lipolytic and proteolytic microorganisms are affected because of the presence of acids and free radicals.

This traditional method to preserve fish, using ice, is commonly used for transportation from the origin to the final market of the fish. Boxes with ~30% of ice are used to keep the fish with low microbial growth and minimize the chemical reactions during transportation.

In the last few years, a new approach has been studied to reduce the amount of ice required for transportation of fish. Superchilled fish has 10–15% of ice since the temperature of the product is reduced to about 1–2 °C below its freezing point. The ice is surrounding the product, protecting it from microbial spoilage and enzymatic reactions, creating an ice shell within the product. Other studies on keeping chilling temperatures on fish include the use of ice with different shapes such as the traditional flake ice or the use of small spherical ice crystals known as slurry, flow, or fluid ice. The latest provides an extended shelf life of the fish rather than the flake ice (up to two times longer) because of the direct contact of the crystals within a bigger superficial area of the fish delaying microbial growth and preserving the texture of the product.

Other approaches that have been researched to extend the shelf life of fish include the use of chilling slurry, edible films,

Table 1 Examples of preservation factors used together with refrigerated conditions to extend the shelf life of chilled foods

Food item	*Physical factors*	*Chemical factors*
Fish and seafood		Herbal extracts
Ready-to-eat meals (meats and vegetables)	Irradiation	
Ready-to-eat meals (beef)	High hydrostatic pressure

	Bacillus cereus		
	Clostridium perfringens		

[a]No common microorganisms but they might be present if the food has not been properly handled.

and modified and/or controlled atmosphere. The use of chilling slurry has been tested in cod, basically using seawater slurry (−2 °C) that can reduce the temperature of the product faster than regular ice. During the shelf life, chilling slurry has shown better results on the fish because of the low microbial growth and the freshness of the product. However, some of the problems associated with the use of chilling slurry are associated with the weight gain and salt intake of the fish, both considered drawbacks for the product.

Meat products

One of the meat that are highly valued is lamb; some of the most important markets are away from the highest consumers, for example, the lamb from New Zealand needs to travel to foreign markets that sometimes takes several weeks to reach its final destination. The vacuum-packed lamb needs to keep a temperature below −1.5 °C to ensure a shelf life between 60 and 70 days. Some of the bacteria that can be found in lamb meat include *E. coli*, *Pseudomonas* spp., lactic acid bacteria, and even *Yersinia enterocolitica* (Table 2). It is essential to keep the product under strict temperature conditions to delay the microbial growth; besides, such as in other meat products, cross contamination can occur during the handling of the animal.

Miscellaneous foods

As part of this category, there is a group of very complex foods that include all the cooked-chilled foods that have meat, poultry, fish, and vegetables as part of the list of ingredients. Sales on these products have been drastically increased in the last few years because of the variety of products, innovative concepts, and developed products that fit several lifestyles. The average shelf life of these products is about 5 days when the temperature has been ≤3 °C. However, if the temperature is not well controlled, the products might represent a risk for consumption because of the kind of bacteria that can grow on them. These products are generally pasteurized and packaged such as mashed potatoes, pork chops, ratatouille, minced fish, spaghetti, and mac and cheese. A comprehensive list of these products is presented in Table 3. However, one of the main risks of these products is associated with the presence of some pathogenic microorganisms such as *L. monocytogenes* and spores of *C. botulinum* that can survive the pasteurization and be latent on the product. These cooked-chilled foods are also known as refrigerated processed foods of extended durability (REPFED) ready-to-eat meals.

Depending on the thermal treatment applied to this kind of products, there are three categories of REPFEDs:

(a) Mild thermal treatment at 70 °C for 2 min. Basically, this treatment is applied to inactivate *L. monocytogenes* in at least 6 log reduction. These products are pasteurized in the package used to sell them. However, this mild thermal treatment cannot inactivate spores in the product and represents a risk for the consumer if the food is not adequately handled by the consumer until the final consumption.
(b) Medium thermal treatment at 90 °C for 10 min. This treatment has the goal to inactivate the strains of nonproteolytic vegetative cells of *C. botulinum*, *Bacillus cereus*, and *L. monocytogenes*. The product is pasteurized in the package used to sell it, and because the thermal treatment is not really strong, some spores can resist the process and survive. However, the temperature used for this process can produce some thermal damage on the spores reducing the possibility of producing a foodborne problem.
(c) Repackaged chilled foods. This kind of products is pasteurized in some packaging material and after is repackaged in the intended final package. Sometimes, these products are pasteurized in opened containers and after packaged to be sold. The big risks in these products are related with cross contamination after the pasteurization with pathogenic strains.

Cold storage is one of the hurdles used on these products to extend the shelf life and delay the microbial growth; however, most of the time, a previous thermal treatment and some other preservation factors (such as reduction of pH, a_w, and antimicrobials) are used together.

One of the microorganisms that have been also associated with chilled foods is *B. cereus*. The spores of this microorganism can survive high temperature during conventional pasteurization but it can also survive refrigeration temperatures and grow during the storage of food, representing a microbiological concern. *B. cereus* is frequently associated with foodborne gastroenteritis. Several foodborne outbreaks have been reported in the food industry in the last decades because of the presence of spore-forming bacteria, mainly from the genera *Bacillus*. The vehicle of these microorganisms has been mainly associated with the vegetables that are part of most of these cooked-chilled foods.

Chemical Shelf Life

One of the main chemical reactions taking place on fish is oxidation of the lipids; these reactions known as rancidity are responsible of the generation of off-flavors and odors on the product. Marine products have a characteristic odor that can be easily noticeable. However, when there is lipid oxidation

Table 3 Examples of cooked-chilled foods (REPFEDs) available on the market; classification is made based on the main ingredient

Meat	*Poultry*	*Fish*	*Vegetable*	*Pasta*
Pork chops	Chicken and rice	Salmon and rice	Mashed potatoes	Spaghetti
Meatballs with tomato paste	Curry chicken	Fish in sauce	Spinach mash	Cannelloni
Veal stew	Chicken with vegetables	Minced fish	Ratatouille	Penne with vegetables
Beef burgers	Grilled chicken	Crab cakes	Carrots	Mac and cheese
Sliced ham	Turkey meat	Lobster cakes	Leak and potato mash	Lasagna
Roast beef	Poultry sausages	Surimi	Rice with vegetables	Fresh pasta salad

because of the changes in pH during the shelf life, this odor changes to a very unpleasant and putrid smell because of the several biochemical reactions taking place, in addition to microbial growth. Also, there are chemical changes associated with proteins and microbial growth together with enzymatic activity, releasing some nitrogen that is associated with fish deterioration. Some metabolites coming from the microbial activity such as amino acids are related with the protein hydrolysis taking place on fish and are also responsible for changes on the texture of the product.

On the other side, in some meat products, the chemical reactions taking place during the chilled storage are part of the natural process of tenderization of the product. Changes in pH, water-soluble compounds, and lipids on meat muscle during the storage will promote some desirable chemical reactions that provide the product with the characteristic flavor during the cooking process. For example, on beef, the biochemical changes during the postmortem period involving the adenosine triphosphate (ATP) degradation will produce specific flavor precursors on the product once it is cooked. These changes involve the reaction between sugars and amino acids producing specific volatile compounds. Nevertheless, the degree of production of these compounds is also influenced by other factors such as the diet and race of the animal, the season, the animal age, and the conditions of slaughtering, among others.

Because the quality of the product depends on the control on the chemical reactions taking place during the storage, several efforts focus on how to optimize these chemical changes. Some examples are the reduction of temperature keeping the product in special chambers, the use of special packaging materials and conditions, the incorporation of some chemicals on the ice, and the use of antioxidants and radical scavengers, among others. The use of antioxidants has been extensively documented; several compounds have been tested in different food products to delay microbial growth, to inhibit enzymes or reduce the chemical reactions catalyzed by them, and to scavenge the free radicals in those products having rancidity problems during storage.

Sensory Quality

The basic sensory evaluation of food products includes the assessment of odor, flavor, taste, texture, and appearance. During chilling of foods, some physicochemical changes take place; in some cases, these changes are part of the conditioning process of the product, for example, the postmortem changes mentioned earlier (such as ATP degradation) on fish, beef, pork, and poultry products. The flavor and aroma compounds in different kinds of meat are present on the water-soluble and lipid fractions of the product. Furthermore, these biochemical changes will impact the texture, general acceptability, and overall sensory quality of the product. The chemical reactions associated with the sensory characteristics of the food involve sugars, lipids, and amino acids.

Several studies have shown that the conditioning process of beef and pork meat provides better products in terms of sensory characteristics when the product is kept at chilled conditions as long as 21 days. Important and significant changes are observed in aroma, flavor, taste, and texture characteristics such as tenderness, juiciness, and chewiness when the meat is allowed for a long conditioning process. Another example is the use of CO_2 snow and brine chilled ($-2\ ^\circ C$) in ground beef; both techniques are able to delay the microbial growth on the meat up to 21 days. The use of CO_2 snow produced also a better texture on the product having a more tender meat; meanwhile, the chilled option showed cooking losses on the product.

Some specific products from beef, such as the heart and liver, which are used as by-products for other industries, are preserved as chilled foods. However, when the product is removed from the animal and immediately packaged under vacuum conditions, the meat is better preserved in terms of weight loss, off-flavor generation, and minimum microbial growth. Then, it is highly recommended for this kind of products to package the product under vacuum just as the postmortem period starts.

The use of herbs has also been used in the meat industry to improve the sensory quality of some products such as chilled lamb. Some extracts from rosemary have antioxidant effects, and once applied to chilled lamb, the product can have a longer shelf life not only with minimum lipid oxidation but also with excellent sensory properties in terms of flavor, texture, color, and aroma.

The main sensory issues observed on fish during the shelf life are related to the loss of freshness observed on the flesh, the changes on pigmentation, the presence of off-flavors, and the appearance of the skin. Regarding some of the novel applications in chilled foods, some of the previously mentioned studies using herbal extracts to extend the shelf life of fish have shown positive results regarding sensory characteristics. When the ice contains some herbs such as oregano, thyme, and rosemary, the product acquires a similar taste and flavor, making it more appealing to the consumer.

Furthermore, when fish is stored under specific preservation factors, the shelf life can be extended and the quality improved. For example, studying the use of superchilled ($-2\ ^\circ C$) and chilled ($4\ ^\circ C$) salmon and having the same fish under modified atmosphere, it is possible to extend the shelf life considerably. Products under superchilled conditions are able to show good quality and lower microbial counts (<1000 cfu g^{-1}) after 24 days of storage (total aerobic plate, H_2S-producing bacteria, and psychrotrophic counts). The superchilled salmon shows also acceptable sensory properties after 21 days of storage. The salmon kept under modified atmosphere and chilled was spoiled after 10 and 7 days, respectively.

Fruits and Vegetables

In this group, there are not only some products highly consumed such as the ready-to-eat salad blends because of the practical approach for the consumer but also some other products with lower demand such as some fruit cuts sold as chilled food or just regular fresh produce. Chilled salads represent a very good example of vegetables that have a reduced shelf life because of the natural characteristics of the ingredients. Some brands are sold using modified atmospheres to provide additional hurdles for the microorganisms. In most of the cases, the

microbial growth is delayed long enough to provide a safe product for the consumer but all the biochemical reactions affect considerably the sensory characteristics of the product, mainly the texture. Although chilled fruits and vegetables can be considered a safe product, it is well known that some foodborne outbreaks come from these products such as the salad blends involving pathogens such as *Salmonella*. Also, some consumers prefer to purchase fresh produce and disinfect and prepare them at home rather than use commercial chilled vegetables.

Some common products kept under chilling conditions and sold by piece include leafy greens, mushrooms, cucumbers, green and red peppers, carrots, herbs, squash, green beans, turnips, and celery, among others. These products are kept under chilling conditions to preserve their freshness and delay the microbial growth. However, when these products remain on cold storage for longer periods of time, the known chilling injury is observed. Some of these products kept at 4–5 °C and 95% of relative humidity can start to show some signs of injury such as tissue electrolyte leakage, stress because of ethylene production, and changes observed on appearance.

Conclusions

The chilled food chain represents a high percentage of the food production around the world. Hundreds of food items are currently sold as final products or ingredients and hundreds are new in the market each year. However, one of the main concerns related with these goods is still the microbial quality because of the constant foodborne outbreaks and the possibility of microbial growth during storage. It is really important to monitor the storage temperature of chilled foods throughout the production chain until the product reaches the consumer. Research has been done and is ongoing in the food technology field trying to identify new preservation factors to be used together with low temperatures not only to extend the shelf life of the product but also to ensure that pathogenic microorganisms are completely eliminated from the product after processing. The main challenge is to find these preservation factors strong against microorganisms but gentle with the nutritional and sensory quality of the product.

Chilled Foods: Modified Atmosphere Packaging

LM Cunha and SC Fonseca, Universidade do Porto, Vairão, Portugal

Rationale

Preservation of food products, by quality optimization and shelf life extension, is an important challenge of the food industry that allows the valorization of the final food product. Because food products are very sensitive to temperature, the reduction and maintenance of low temperatures are a crucial technology for food preservation. The technological development of chilling equipment in the last century allowed a wider range of food items in the market and enlarged the number of consumers. With the benefits of preservation by chilling, foods do not need to be so severely processed, such as in the traditional operations of canning, drying, smoking, and salting, and could be presented in the fresh state, minimally processed, or mildly processed as in pasteurization. Therefore, chilled foods, submitted to low-impact processing, result in higher quality and nutritional retention, however, typically with a relative short shelf life that reduces product marketability. Thus, this type of products may take advantage of the hurdle concept, associating chilling with the modified atmosphere packaging (MAP) technology in order to enlarge product shelf life from 50% to 400%. One success example of this hurdle technology concept is the application of MAP in chilling-sensitive produce, allowing to overcome the impact of low-temperature injury.

Modified Atmosphere Packaging

MAP technology relies on modification of the atmosphere inside the package and surrounding the food product that leads to an increased product shelf life, by acting at the microbiological, metabolic, and physicochemical levels in the product.

The modified atmosphere inside the package is maintained over storage time due to the control of gas transport through the packaging material that should have different barrier properties depending on whether it is nonrespiring or respiring products. Packaging of nonrespiring products needs a high-barrier material for gases in order to maintain the atmosphere injected, since no relevant metabolic activity exists in the product. Packaging of respiring products, such as fresh fruits and vegetables, is more complex than nonrespiring products because it involves the interplay between the natural respiration process of the fresh products and the gas exchange through the package containing the product, to generate and maintain the adequate atmospheric composition to product preservation. Thus, the packaging material needs a selective permeability to the gases involved.

MAP consists in the generation of an atmosphere that is different than normal atmospheric air. The typical composition of atmospheric dry air is 78.08% (v/v) N_2 (nitrogen), 20.96% O_2 (oxygen), 0.93% Ar (argon), and 0.04% CO_2 (carbon dioxide) and other trace gases. Normally, nitrogen, oxygen, and carbon dioxide are the three most common gases used in MAP. In very limited cases, it is also used carbon monoxide, ozone, ethylene oxide, nitrous oxide, helium, neon, argon, propylene oxide, ethanol vapor, hydrogen, sulfur dioxide, and chlorine. The presence of O_2 inhibits the growth of anaerobic microorganisms but promotes the growth of aerobic ones and some undesired reactions of oxidation and vitamin loss. The increased level of CO_2, compared with air, leads to a bacteriostatic and fungistatic effect, in part due to the acidic effect of dissolved CO_2 in the product, and also contributes to respiration rate reduction of many respiring products. The lower level of O_2, compared with air, has a positive effect on respiration rate reduction. Superatmospheric O_2 (30–80%) may have an identical effect on reducing the metabolic processes. The inert and tasteless N_2 gas, due to its low solubility in food products and inhibition of aerobic spoilage microorganisms growth, is normally used as filling gas to maintain the atmospheric pressure and avoid package collapse.

Even though vacuum packaging (VP) may be interpreted as a modification of the original package atmosphere and in that sense could be considered a type of MAP, normally, it is not regarded in literature as a MAP system due to the large differences between both packaging systems; in fact, VP has no atmosphere inside the package.

The term scientifically used as modified atmosphere is commercially substituted by protective atmosphere in food labeling, in order to be easily understood and not raise suspicions from consumers. Another term close, which sometimes is wrongly applied as synonymous, is controlled atmosphere that should not be confused with modified atmosphere. In controlled atmosphere, the gas composition surrounding the product is continually monitored and regulated to maintain the desired gas concentrations, normally applied not in a package but in a container or a storage room. Thus, the control of the atmosphere in modified atmosphere is less precise than in controlled atmosphere.

MAP is a technology that despite its wide commercial application in Europe dates back to the 1970–80s of last century meets the demands of today's consumer and market trends for safer and healthier products and convenience products, products already sliced and ready to eat or to prepare. This preservation technology, combined with temperature control, does not need to use chemical preservatives and based on the concept of barriers ('hurdles') allows the reduction of salt and additives in the product, maintaining its nutritional value. Moreover, the increase in the shelf life of the product has the effect of reducing product losses, thus reducing distribution costs and widening the market for such products. Thus, with the use of chilling and MAP technologies for preservation, many food products may be available out of season and/or shipped to distant consumer markets with a high standard

quality. However, the following limitations should also be pointed out: (i) increased product cost, (ii) loss of benefits once the pack is opened or leaked, (iii) restricted temperature control, (iv) specific recommended atmosphere for each type of product, and (v) consequently development of a MAP solution for each type of product.

The two most common types of retail MA packages are ellipsoid–cylindrical polymeric bags with sealed ends and parallelepipedic trays heat-sealed across the top with polymeric films. Polymeric films are the most popular among available barriers to create modified atmospheres. These materials present different properties depending on the chemical structure, production process, and additives. The plastic material may be composed of only a film (monolayer) or a set of layers of different polymers (multilayer). Since there is no monolayer plastic material having properties that make it suitable for all applications in the food industry, it is necessary to combine the properties of various plastics in a multilayer system suitable for each case.

The main desired factors to consider in the selection of the polymeric material for MAP are

- type of packaging (e.g., flexible or rigid package or tray with a semirigid cover);
- permeability properties of CO_2 and O_2;
- permeability to water vapor;
- physical properties (e.g., strength, transparency, and durability);
- effectiveness and strength of heat sealing;
- resistance to degradation by chemicals;
- nontoxic and chemically inert;
- easy printing on the outer surface.

The most common plastic polymers used for packaging foods are EVOH (ethylene vinyl alcohol), PVC (polyvinyl chloride), PVDC (polyvinylidene chloride), PET (polyethylene terephthalate), PP (polypropylene), PE (polyethylene), amorphous polyester, and nylon. Typically, these polymers are coated on the inside face with a chemical agent for dispersing droplets of condensed water during storage, ensuring good visibility of the product. LDPE (low-density polyethylene) and PVC have permeability characteristics that make them most suitable for the packaging of respiring products and PVDC and polyester in the case of products with low respiration rates.

MAP for Nonrespiring Chilled Foods

Definition

MAP of nonrespiring products consists of complete removal of the original atmosphere inside the package, replacing it with the desired atmosphere by injection at the time of closing or sealing of the package, without additional manipulation of the atmosphere inside the package. Therefore, the package has a crucial role in maintaining the initial atmosphere throughout storage time of the product.

The main reason of food preservation in nonrespiring products is the control of microbial growth, and the most common atmospheres used are the ones rich in CO_2 and poor or absent in O_2. There are many studies in literature studying different atmospheres in specific products to conclude the most appropriate atmosphere for the preservation of that specific product.

Design

The successful application of MAP technology is dependent on a correct design of the packaging system, taking in attention of the gas transfer phenomena between outside and inside packaging material and between inside atmosphere and product itself. If the desired atmosphere composition is initially injected, the purpose of the packaging material will be to maintain over time, as close as possible, that initial atmosphere. The packaging material should therefore be

- CO_2 barrier (after the initial injection of CO_2 into the atmosphere within the packaging, the packaging is intended to prevent the outflow of this gas over time since CO_2 has a beneficial antimicrobial activity),
- O_2 barrier (after the initial removal of O_2 from the atmosphere within the packaging, the packaging is intended to prevent the entrance of O_2 over time that would lead to color changes and reduce product acceptability by the consumer, with the exception of red color fresh meat that is favorable in the presence of O_2),
- barrier to aromatic compounds (in order to prevent loss of natural flavor of the product and prevent entry of off-flavors to the product),
- barrier to water vapor (normally, food products have a higher water content that facilitates its loss; thus, the packaging should prevent the exit of water that decreases product sensorial quality and commercial value).

However, temperature fluctuations in the distribution chain occur frequently, and the presence of condensed water inside the package is depreciated; water condensed could be a good medium for microbial growth and consequently limits the shelf life of the product. Therefore, it would be desirable that the packaging would be capable of absorbing the water released from the product.

The volume of gas should usually be between two and three times the volume of the food product due to the high solubility of CO_2 in the product.

Examples of MAP Applications

The main MAP applications in nonrespiring products are in cheeses, fresh meat, cured and smoked meat-based products, snacks (potato chips), fresh fish, fresh pasta, coffee, bakery products, and ready-to-eat foods.

For food products where the main spoilage parameter is oxidative rancidity, the gas mixture should be O_2-free. In opposition, the presence of O_2 in the MA composition is used in fresh red meat in order to avoid the red color loss. Usually, a mixture of around 20–60% CO_2 and 40–80% N_2 is adequate if the main objective is the microbial control. The use of concentrations of 20–30% (v/v) CO_2 and nonuse of O_2 for cooked and smoked meat-based products are common nowadays.

MAP for Respiring Chilled Foods

Definition

MAP of fresh produce is an atmospheric modification that relies on the interplay between the natural process of product respiration and gas exchange through the package. The main goal is the control of the metabolic activity, using low-O_2 and high-CO_2 atmospheric compositions that interfere in many metabolic processes. The potential effects of low levels of O_2 and high levels of CO_2 are related with reduction of (i) respiration rate, (ii) ethylene production and sensitivity to ethylene action, (iii) developmental alterations, (iv) incidence and severity of certain physiological disorders, and (v) susceptibility to decay, with the resultant benefit of retarding senescence and extending the shelf life of the fresh produce. Each different product and in some cases different cultivars have different responses to low O_2 and high CO_2. Exposure of fresh fruits and vegetables to O_2 levels below their tolerance limits or to CO_2 levels above their tolerance limits may hazard the product and decrease their storage life. The beneficial and injurious effects of low O_2 and high CO_2 specifically for fresh fruits, fresh vegetables, and fresh-cut fruits and vegetables were thoroughly studied and presented in scientific literature. The normal gas mixtures are 1–5% O_2 and 0–20% CO_2.

Types of MAP

The modified atmosphere inside a package can be achieved by either passive or active procedures. In passive procedure, the package is closed with the atmospheric air, and due to product respiration process, there are increase in carbon dioxide (CO_2) and a depletion of oxygen (O_2) concentration, changes that are regulated by the gas exchange through the package so that, at equilibrium, adequate low O_2 and high CO_2 concentrations are reached. The O_2 concentration decreases and the CO_2 concentration increases until the product respiration rate equals the gas exchange rate through the package and steady state values are attained. At steady state, the O_2 flow entering the package is equal to the O_2 consumed by respiration, and the CO_2 flow leaving the package is equal to the CO_2 produced by respiration. Throughout the transient period, the O_2 and CO_2 concentrations are not the most adequate to product preservation. In order to achieve the desired atmosphere more rapidly, the modification of the atmosphere in the package can be accelerated by the active procedure, although an increasing cost is inconvenient. In the active one, the procedure is similar with the nonrespiring products: removal and replacement of the atmosphere before closing the package. In this procedure, there is no lag time to achieve the optimal gas concentrations, and the interplay between the product respiration and the gas exchange through the package will allow to maintain the desired gas concentrations over product shelf life.

Design

An MAP system not properly designed may be ineffective or even shorten the storage life of a product. If respiration is much slower than the gas exchange through the package, the initial concentrations will almost not be altered. In opposition, if respiration is much faster than the gas exchange, O_2 concentrations will rapidly deplete and anaerobic respiration will be induced, thus the importance of a correct design of the packaging system. MAP design can be improved by the development of mathematical models used to predict the gas concentrations inside a package instead of the 'trial and error' approach. Modeling a MAP for a particular food product requires the analysis of different components of the system package–environment–commodity: (i) the gas exchange through package, (ii) the recommended gas concentrations, and (iii) the respiration rate for a specific product and storage conditions. Several models have been developed to predict the gas concentrations inside an MAP system with different levels of mathematical complexity.

Examples

MAP has a special interest in high added value and highly perishable products, achieving an increase in shelf life of up to 800%. For example, the export of highly perishable products such as strawberries and other red fruits needs an increased product shelf life. The recommended storage conditions under MAP for strawberry are 4–10% (v/v) O_2 and 15–20% (v/v) CO_2, at 0–5 °C combined with high relative humidity (90–95%). The use of MAP to extend the shelf life of mushrooms has been extensively reported, and the recommended MAP conditions for mushrooms at optimum storage temperature (0–2 °C) combined with high relative humidity (95%) are 3–5% (v/v) O_2 and $<12\%$ (v/v) CO_2, depending on each mushroom species.

Another example of high added value and highly perishable products are the fresh-cut ones. Fresh-cut products have shorter shelf life than intact products, owing to cell damage. Thus, chilling and MAP technologies for extending fresh-cut product shelf life may have a major impact on the fresh-cut market. The higher respiration rates of fresh-cut products, as well as their higher tolerance to CO_2 in general, require the use of packaging materials with a high O_2 transfer rate. Recent advances in MAP have been driven by the requirements of minimally processed vegetables. An important commercial application of MAP is cut lettuce. The success is attributed to retardation of browning, coupled with maintaining a fresh appearance. The recommended MAP conditions for cut lettuce at optimum storage temperature (0–5 °C) combined with high relative humidity (90–95%) are 0.5–3% (v/v) O_2 and 5–10% (v/v) CO_2. Other common fresh-cut products taking advantage of MAP are shredded carrots (2–5% (v/v) O_2 and 15–20% (v/v) CO_2 at 0–5 °C).

Chilled Foods: Packaging Under Vacuum

M Rossi, Sealed Air s.r.l., Milan, Italy

© 2016 Elsevier Ltd. All rights reserved.

This article is reproduced from the Encyclopedia of Food Sciences and Nutrition, volume 2, pp. 1191–1196, © 2003, Elsevier Science Ltd.

The Role of Oxygen in Food Spoilage

The presence of oxygen is one of the major factors of spoilage of foods and causes the following:

(1) Oxidation reactions, damaging vitamins, fatty substances, pigments, and flavoring substances that are often catalyzed by enzymes
(2) Growth and activity of aerobic microorganisms (aerobic bacteria, yeasts, and molds)

It is therefore essential, in order to prolong the freshness of foodstuffs, to eliminate the presence of oxygen in contact with the foodstuff itself, and to prevent further access of oxygen during storage. Vacuum packaging is one of the simplest and most widely used systems to achieve this objective. This type of packaging has enjoyed increasing success since the late 1950s, in parallel with the development of the technology of plastics owing also to the changes in the distribution chain of perishable foods requiring increased hygiene and storage life.

This article outlines the principles of vacuum-packaging technology and the features of the packages utilized and describes the main fields of application of vacuum packaging to chilled foods.

Vacuum Packaging: A Definition

'Vacuum packaging' is a term improperly but commonly used to define a packaging system that implies the reduction of the partial pressure of atmospheric gases (oxygen being 20% of them) inside a package. A vacuum inside a package can be obtained mainly through two systems:

- Steam flushing of the headspace
- Sucking of air from the package headspace by means of equipment (vacuum chamber and nozzle) based on a vacuum pump

The former system is mainly utilized in hot packaging of shelf-stable products, which are generally packaged in rigid containers. The elimination of air is achieved by means of a steam flush that replaces atmospheric gases inside the package; steam condensation in the package headspace after chilling reduces the inner gaseous pressure. The latter system is commonly utilized for packaging of perishable foodstuffs that have to be stored in chilled conditions. In this case, packaging equipment based on a vacuum pump is generally utilized in combination with flexible packages, which, after evacuation, are closed hermetically (by means of a seal or sometimes a tight clip) and collapse on the packaged product once the package is exposed to atmospheric pressure. Depending on the type of equipment employed, a residual pressure of atmospheric gases as low as 500 Pa can be obtained in the package.

Figure 1 illustrates the main systems utilized for evacuating flexible packages:

(1) Nozzle (Figure 1)
(2) Single vacuum chamber (Figure 1)
(3) Divided vacuum chamber (Figure 1)

Packaging Materials Utilized for Vacuum Packaging

Plastics are the main raw material utilized for manufacturing the flexible materials employed in vacuum packaging of chilled foods. These materials must have the following properties:

- Flexibility
- Mechanical resistance to various forms of abuse (abrasion, puncture, and flex cracking)
- Gas-barrier properties adequate to the application requirements (generally expressed as gas permeation rates)
- Thermosealability or clippability
- Good optics (haze and gloss)
- Printability
- Suitable dimensional behavior (dimensional stability to heat, formability after heating, and shrinkability after heating)

To combine and balance to the required level of the earlier mentioned properties, it is often necessary to mix different types of individual materials. Different resins can be mixed together (resin blends), resin additives (such as plasticizers, pigments, stabilizers, and slip agents) can be used, and, more commonly, a multilayer material is produced, each layer being composed of a distinct individual material that imparts its properties to the overall structure.

Individual components most commonly used in manufacturing flexible materials utilized for vacuum packaging are listed in the succeeding text, together with their abbreviations and main properties:

- Polyethylene (PE): sealability, formability, moisture barrier, and low cost
- Polypropylene (PP): moisture barrier, thermal resistance, and dimensional stability
- Ethylene–vinyl acetate (EVA) copolymer: easy sealability and thermal shrink properties
- Ionomers: mechanical strength, easy sealability, grease resistance, and formability
- Polyamides (PA): mechanical strength, gas barrier, and formability
- Polyesters (PET): mechanical resistance, heat resistance, and gas barrier
- Ethylene–vinyl alcohol (EVOH) copolymer: gas barrier and easy processability in coextrusion
- Polyvinylidene chloride (PVDC): gas barrier and grease barrier

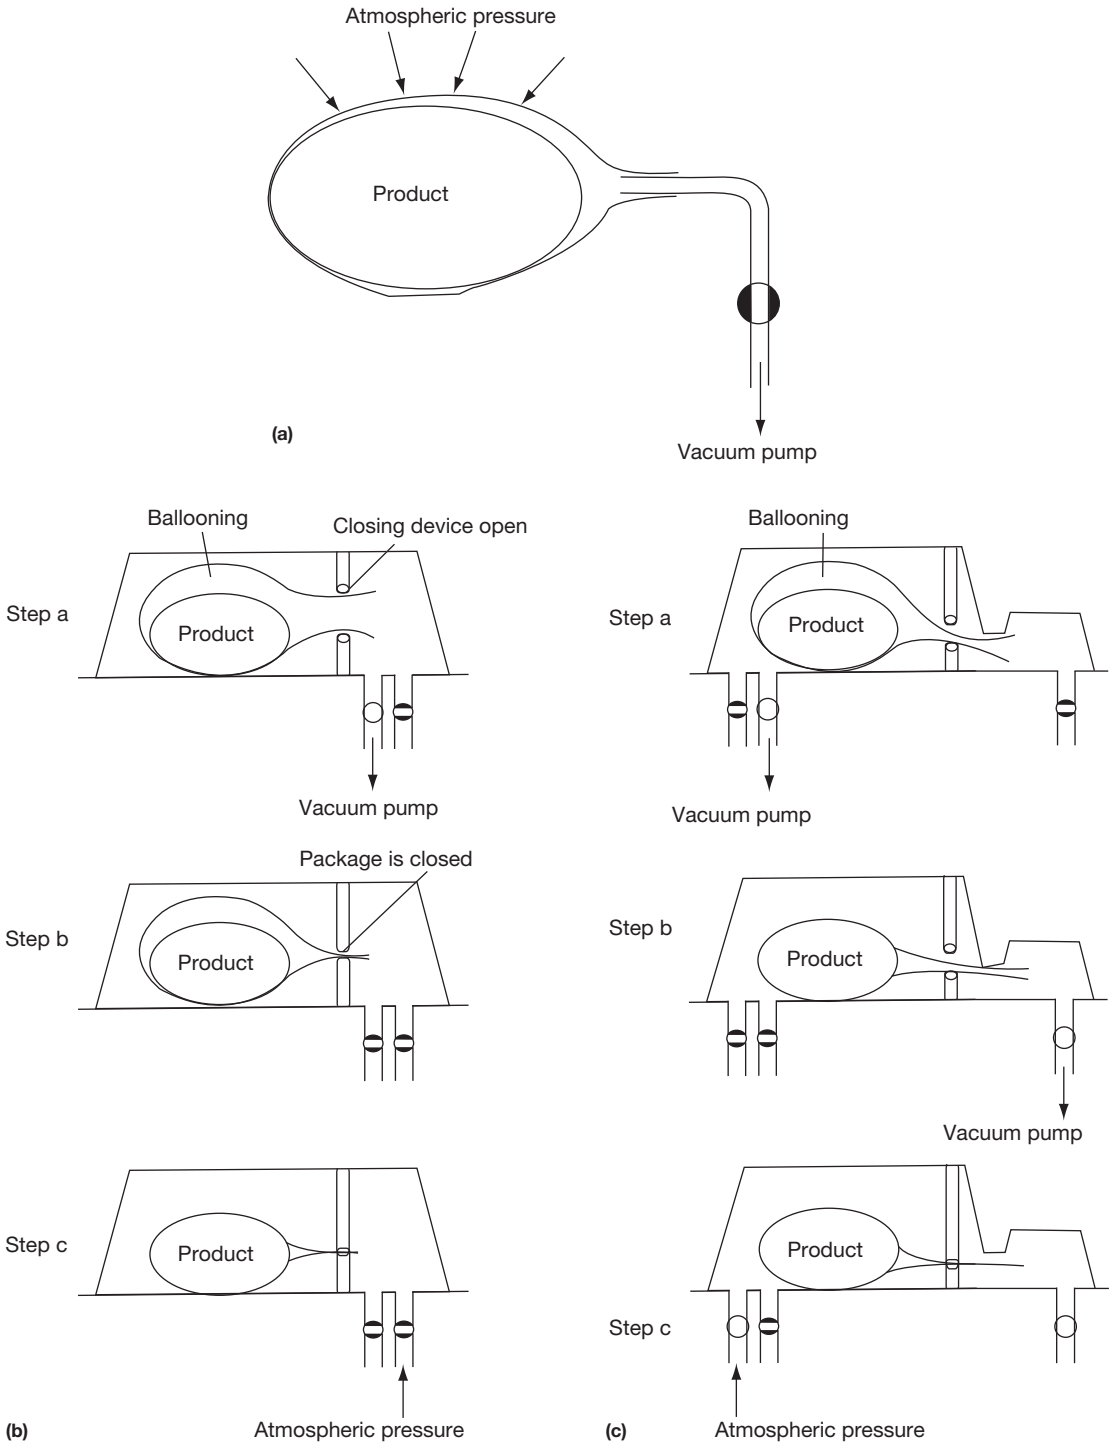

Figure 1 Main systems utilized for obtaining vacuum packages. (a) Nozzle system. Air is extracted from the package (a bag or a pouch) through a nozzle, and then, the package is closed. This is the simplest way of extracting the air, but it does not allow high levels of vacuum in the package. (b) Most common system utilized for evacuating bags, pouches, and thermoformed packages. (c) Divided vacuum chamber. This allows a better evacuation of the package headspace by using two separate chambers where a vacuum is applied sequentially. Reproduced from Chilled storage: packaging under vacuum. Macrae, R., Robinson, R. K. and Sadler, M. J. (eds.) (1993). *Encyclopedia of food science, food technology and nutrition*. Academic Press.

PE, PP, EVA, and ionomers are classified in the wide family of resins called polyolefins. Aluminum foils and vacuum-metallized plastic films are also utilized because of the excellent gas-barrier properties of aluminum.

Multilayer materials are manufactured using various techniques:

(1) Coextrusion: the molten resins are combined in the final structure by extruding them through a round or flat extrusion die, which keeps them separate in discrete layers.
(2) Lamination: previously extruded plastic films and, sometimes, aluminum foil are joined together by means of glues (glue lamination) or with resins that have adhesive properties (extrusion lamination).
(3) Coating: preextruded films are coated with a layer of molten or dissolved resin (a latex).

Package Configurations Used for Vacuum Packaging of Chilled Foods

These can be classified into four main categories: shrink bags such as Cryovac, pouches, thermoformed packages, and skin packages such as Darfresh (Cryovac and Darfresh are registered trademarks of Cryovac Inc., a subsidiary of Sealed Air Corporation).

Shrink Bags

Shrink bags are available in the form of premade bags that can be prepared in different packages (e.g., taped bags) to allow their utilization on automatic equipment. The main feature of these bags is their ability to shrink when exposed for a short time to heat (for instance, a few seconds at 90 °C). This behavior is the consequence of treatment imparted to the packaging material during its production (oriented polymeric chains that retain a built-in tension, making them able to shrink when relaxed by heating).

Shrinking increases the packaging material thickness (which varies between 40 and 120 μm), improving mechanical resistance and gas-barrier properties; determines a tighter package around the product, limiting dripping out of juices in moist products such as meat; and improves the appearance by eliminating excess of packaging material around the product. Shrink bags, at the onset of their introduction on the market in the 1950s, were monolayer PVDC materials, but subsequent technological evolution gave rise to complex coextruded multilayer structures having polyolefins as the main components and gas-barrier layers made of PVDC or EVOH.

Some materials are electronically cross-linked to improve mechanical properties.

Shrink bags are used for vacuum packaging of industrial units of fresh meat, processed meat, and cheese and for consumer units of processed meat and cheese.

Pouches

Pouches can be utilized in two forms:

- Premade plastic envelopes of different sizes that are loaded with the product, then evacuated, and sealed in vacuum chambers
- In-line prepared pouches from machines using rollstock material (horizontal form fill seal and vertical form fill seal machines)

The earlier mentioned machines, starting from a flat web, produce a film tubing that can be either horizontal or vertical (hence the different definitions), which is filled with the product, sealed transversely, and cut into final packages.

The machines can be equipped with a vacuum chamber to evacuate the pouch before final sealing. Form fill seal machines are widely employed in food packaging; however, their utilization for vacuum packaging of perishable foods is rather limited as thermoforming is preferred whenever a high packaging output and automation of packaging operation are required.

Premade pouches are commonly utilized for vacuum packaging of industrial units of fresh red meat such as whole primal cuts, processed meat (ham, bacon, salami, and bologna), and cheese. Typical structures of materials for pouches, obtained by means of glue or extrusion lamination, are based on bioriented PA6 or PET (biorientation plus heat setting enhances dimensional stability and mechanical resistance), which can be coated with PVDC to increase the gas-barrier properties and are laminated to suitable sealing layers (PE, EVA, or PP and ionomers when heat resistance for pasteurization or cooking in the package is requested). For long storage-life applications (pasteurized cooked ham or sausages) where maximum gas-barrier properties are needed, aluminum foil is also used.

The total thickness of the materials mentioned earlier varies between 70 and 250 μm, the higher thickness being employed for heavy and hard products.

Thermoformed Packages

These are obtained on continuous thermoforming machines, which use rollstock materials. Two rolls are used, one for the bottom web, which is unwound, heated by a warm plate, and formed into cavities where the product to be packaged is subsequently loaded, and one for the top web, which is sealed onto the bottom web inside a vacuum chamber from which the air has been removed. Thermoforming is widely applied to the packaging of perishable foodstuffs because of the flexibility of the process, the packaging speed, and the ease of automation.

A wide variety of packaging materials are utilized. Bottom webs are generally based on PA laminated or coextruded with all types of polyolefins. PVDC and EVOH are used when high gas-barrier properties are needed. Some bottom webs are also heat-shrinkable after thermoforming.

Top webs are generally laminated structures similar to those used for pouches, the thickness of which seldom exceeds 100 μm. Metallized materials are often used in the top web formulation.

Thermoforming is utilized for packaging many kinds of perishable products, both consumer and industrial units, including whole ham and fresh meat primal cuts, with the exception of the biggest units of cheese and processed meat.

Skin Packages

Skin packaging represents an evolution of thermoforming where the top web is softened by means of heat and subsequently formed onto the packaged product.

The bottom web can be either flexible or rigid and can be preformed into a tray or a product-sized cavity into which the product to be packaged is loaded.

In skin packaging, the top film conforms tightly to the product shape with advantages in terms of appearance, limited product crushing due to vacuum, and the possibility of contour sealing around the product, limiting the exudation of liquids from the product. Because of its appealing appearance and the high cost of the packaging materials, skin-packaging utilization is limited to consumer or family units of meat (both fresh and processed), fish, prepared meals, and cheese.

Top webs are usually based on ionomeric resins or on coextruded structures of polyolefins. PVDC or EVOH provides the necessary gas barrier.

Bottom webs are generally either laminated or coextruded structures similar to those used for thermoforming.

When a rigid tray is required, polyvinyl chloride (PVC), polystyrene (PS), or PET is employed.

Influence of Vacuum Packaging on the Storage Behavior of Chilled Foods

Fresh Meats and Poultry

Meats contain an abundance of nutrients necessary for the growth of microorganisms; they are particularly rich in soluble organic substances such as carbohydrates, amino acids, and nucleotides. Therefore, spoilage of fresh meat and poultry during chilled storage is mainly due to the growth of aerobic psychrophilic bacteria belonging to the Pseudomonadaceae family and to the *Moraxella–Acinetobacter* group. The growth of these bacteria results in development of off-odors (due to hydrogen sulfide, ammonia, amines, and indole) and bacterial slimes, which contribute to meat discoloration.

Vacuum packaging in oxygen-impermeable materials limits oxygen supply to the typical aerobic spoilage microflora, providing conditions suitable only for the slower-growing lactic acid bacteria, which, in chilled conditions, require several weeks to produce off-odors.

In addition, vacuum packaging has an impact on meat color, which is mainly due to the presence in the muscle tissue of myoglobin, a conjugated protein where the protein moiety (globin) is bonded to a heme group.

The iron atom of the hematin nucleus can form complexes with different ligands and can be in either the ferrous (Fe^{2+}) or ferric (Fe^{3+}) oxidation state. The globin can be in either the native or the denatured state. Among the different complexes of heme, globin, and ligands, three are important in fresh meat:

- Oxymyoglobin, with oxygen as the ligand and iron in the ferrous state, characterized by a bright red color
- Myoglobin, with water as the ligand and iron in the ferrous state, characterized by a purplish-red color
- Metmyoglobin, with water as the ligand and iron in the ferric state, characterized by a brown color

Oxymyoglobin is the pigment normally present on the surface of meat exposed to air and gives the meat its bright and attractive color.

During storage, as a consequence of the growth of aerobic bacteria that reduce the availability of oxygen on the meat surface and of the reduction in the capability of the meat to reduce its own metmyoglobin level, metmyoglobin tends to predominate, imparting its brown color to the meat surface, which contributes to consumer rejection of the product.

In vacuum-packaged meat, as a consequence of preventing oxygen access to the meat surface, the pigment is of the myoglobin color, and the meat appears darker than a sample exposed to air or packaged in modified atmospheres. Displaying of vacuum-packaged consumer units of fresh meat can create problems of consumer acceptance because of the purplish color of the meat surface. In this case, proper consumer warning has to be given to explain the origin of the color and the advantages of vacuum packaging in terms of prolonged storage life.

The storage life at 0–2 °C of fresh primal meat vacuum-packaged in bags or pouches is 4–8 weeks, allowing full aging of meat types such as beef that require maturation. Consumer units in the form of meat slices have a storage life of 2–3 weeks.

Processed Meats

It is useful to classify the many existing types of processed meats into two main categories of products:

- Products having high water activity, the production processes of which often imply cooking (frankfurters, patties, bologna, fresh sausages, cooked ham, and luncheon meats)
- Cured products with low water activity (raw ham, salami, and bacon)

All the products mentioned earlier can benefit from vacuum packaging, which avoids surface drying and mold growth and greatly slows down the oxidation of fat and pigments. Pasteurizable packages are also commonly used for microbial stabilization of some products (cooked ham, patties, and frankfurters). Furthermore, cook-in-the-package technology has been developed for the production of cooked ham, allowing optimization of the production process, hygienic quality, and yield.

The chilled storage life of vacuum-packaged processed meats is very variable, depending primarily upon product composition and packaging material characteristics, and can vary from a couple of weeks (certain types of fresh sausages) to several months (cured products and pasteurized or cook-in-the-package products).

Cheese

Vacuum packaging is mainly applied to hard and semihard types of cheese, for both industrial and consumer units, and its effect in storage-life extension is due mainly to

- elimination of surface drying,
- slowing down of fungal growth,
- limitation of oxidation of fatty substances.

An interesting application of vacuum packaging is the curing in the package technology that is utilized for certain types of cheeses (Emmentaler, Gouda, and Edam). The cheese is vacuum-packaged at an early curing stage and cured inside

the package. This technique improves yield (limiting rind formation and water loss) and allows a certain product standardization. Curing in the package is particularly demanding in terms of gas transmission properties of the packaging material; a good compromise is necessary between a sufficiently high carbon dioxide permeability to allow the escape of gas formed inside the cheese during curing and a sufficiently low oxygen transmission rate to avoid mold growth. The gas transmission rate requirements can vary from cheese type to cheese type and also depend upon production conditions, which are often variable among different dairies.

Fish

Wet fish is probably the most perishable type of foodstuff because of the high content of soluble substances in the flesh, many of which contain nitrogen and triglycerides characterized by polyunsaturated fatty acids (in fatty types of fish such as clupeids, salmonids, and scombroids). In addition, fish flesh is characterized by a high level of enzymatic activity, which plays a major role in the early stages of spoilage.

Vacuum packaging retards the growth of aerobic spoilage bacteria and limits the oxidation of fat. However, vacuum-packaged fish is very perishable and has to be carefully stored at temperatures below 2 °C, the normal storage life being 5–7 days. Prepackaged consumer units of wet fish, utilizing skin packages, have recently been introduced at a commercial level due to the need for a distribution system capable of handling in a relatively easy way a product characterized by bad smells, dripping out, and hygienic and preparation problems at the consumer level. For processed fish (smoked, salted, and pickled), vacuum packaging is commonly utilized because it limits the spoilage factors of this kind of product (mainly fat oxidation and mold growth). The storage life of vacuum-packaged processed fish depends upon the water activity level, ranging between 2 and 3 weeks for slightly salted fish and a few months for highly salted fish.

Prepared Foods

Vacuum packaging is also utilized for a wide range of prepared foods (delicatessen products, cooked meats and poultry, prepared meals, and salads).

The spoilage mechanism and perishability of these products are related to their chemical composition (pH and additives) and heat treatment (pasteurization), and therefore, their storage life is very variable, ranging from 2 weeks to several months.

An interesting application of vacuum packaging to prepared foods is the cook-in-the-package technique, which implies packaging under vacuum of raw or partially cooked foods that are cooked inside the package, pasteurized (when required), chilled and stored, and reheated and unpackaged at the time of consumption. This technology allows the rationalization of meal preparation in central units (e.g., in institutional kitchens and restaurant chains) because of the storage life of the prepared meal (1 week or more) and it has also been introduced to food-processing plants to prepare meals to be distributed chilled at the retail level.

Chilled Foods: Principles

GG Amador-Espejo and ME Bárcenas Pozos, Universidad de las Américas Puebla, Cholula, Mexico

Introduction

Nowadays, the population exodus to urban areas has required some improvements in food preservation techniques and greater distribution services of perishable products. Due to modern consumer preferences of quality, the most important method of preservation and distribution to the main world market is by chilling and freezing. Today's lifestyles have also changed consumer behavior, product preferences, and eating trends resulting in new requirements for food producers.

Chilling is one of the preservation techniques that is most applied with food products, having been established in the nineteen century. Because of the complexity of the refrigeration process, it needed more time to be developed than the heating process. People learned to produce heat about 500 000 years ago, but the chilling process started about 150 years ago—although some reports from the second century (BC) established the use of 4° of coldness for medical purposes. By definition, the refrigeration process can be described as a simple reduction of the ambient temperature (i.e., if the ambient temperature is around 40 °C the product transport can operate with a refrigeration system to reduce the temperature to 30 °C), even though some authors have considered the refrigeration temperatures to only be in the range of 0–10 °C, based on the preservation principle involved.

The refrigeration principle consists of a reduction in the product temperature which reduces the kinetic energy, ultimately minimizing the rate of motion of the molecules inside the product. This rate determines the speed at which many important reactions take place. In the case of food products, many spoiling reactions can be controlled by temperature, such as: microbial growth, physiological processes (ripening of fruits and vegetables), and chemical and enzymatic reactions (enzymatic and non-enzymatic browning, vitamin degradation, lipid oxidation, and biocompound degradation).

Basically, all food products can be preserved by refrigeration for some time, depending on the final temperature reached and the chilling rate. However, the final storage temperature and the amount of time that the product is subjected to refrigeration have different effects that can compromise the product quality. In this sense, in rapidly cooled peaches, a serious defect can be observed, known as 'wooly texture,' in which a lack of juiciness without variation of the tissue water content is shown. Another typical case of the effect of the refrigeration process on food products is the phenomenon called 'cold shortening,' which is an irreversible reduction of the muscle tissue – that can be detected in beef, lamb, and pork meat – when the temperature is reduce rapidly.

This contribution establishes the principles related to the chilled process, equations related, new techniques, and also, improvements in the refrigerant compounds employed in food processing.

Chilling

The chilling process can be described as the method to remove heat from a product. It is the most benign process applied to food, presenting only a few changes in flavor, texture, and nutritious value. In general, refrigeration temperatures for food product preservation are below 15 °C and above the freezing point. Although human beings have been using cold storage since ancient times – by placing products in ice or at low temperatures outside – the refrigeration process, or mechanical refrigeration, has no more 150 years of application.

Due to their nature, food products are vulnerable to spoiling, reducing their commercial life by three mechanisms:

- The growth of live organisms can contaminate and deteriorate food products. Microorganisms, such as bacteria, parasites, and molds can be in the air and soil. Insects and rodent can contaminate food products with their own microbial fauna.
- Chemical reactions, such as browning or oxidation, can produce different compounds causing changes in flavor or texture of the product.
- Biochemical reactions, like respiration, ripening, and browning (in vegetables and animal meat after slaughter) are basically carried out by enzymes within the product. Also, these reactions may reduce the product quality and other physical phenomena such as gain or loss of moisture that reflects on moisturize or dehydration.

On the other hand, the term 'shelf life' refers to the timeframe that the product (stored under the recommended conditions) will:

- remain safe for consumption;
- be certain to retain desired sensory, chemical, physical, and microbiological characteristics; and
- fulfill any label declaration of nutritional information.

This definition of shelf life implies the storing conditions, which, when referring to refrigerated conditions, may vary enormously due to temperature changes during the transportation and in-home handling before their consumption.

The main effect of chilling is the decrease of storage temperatures, which also implies a reduction in the rate of the reactions mentioned above, presenting an increase in the shelf life of the product. The deterioration rate can lessen as the temperature decreases to the minimum in the range of the refrigeration temperatures. Although, even below freezing temperatures, some reactions still take place in some products.

The most important effect of the chilling process on food products is the reduction of the microbial growth, which increases the shelf life of the product. The most common temperature for microorganism growth is around 36 °C; but microbial growth has been detected in extremely low (−34 °C), and extremely high (100 °C) temperatures as well.

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00143-4

The microbial grow division in this large range of temperature refers to three main groups. The first group of microorganisms that grow well at or below 7 °C, and have their optimum between 20 and 30 °C, are referred to as *psychrotrophs*. Further, the group that can grow well between 20 and 45 °C, with their optimum range between 30 and 40 °C, are referred to as *mesophiles*. While the group that grows well at and above 45 °C, with their optimum range between 55 and 65 °C, are referred to as *thermophiles*.

Psychrotroph microorganisms that can grow under refrigerated conditions are: a. bacteria *Shewanella*, *Alcaligenes*, *Flavobacterium*, *Corynebacterium*, *Lactobacillus*, *Micrococcus*, *Pseudomonas*, *Psychrobacter*, *Brochothrix Enterococcus*, and others, being *Pseudomonas* and *Enterococcus* the most commonly detected and c. molds c strains of *Aspergillus*, *Cladosporium*, and *Thamnidium*. Under refrigerated conditions, the growth of some yeast has been detected, but in less numbers than bacteria and molds.

Although shelf life is enhanced by chilling, it only increases by a small amount of time compared to other preserving techniques, such as heat treatment, freezing, or drying.

Further, it is important to point out that chilling can be applied not only to enhance the product shelf life, but to control the growth reaction rate of specific microorganisms desirable in food products. This is the case of the chilled ripened process in some cheeses, meats, and wines.

It can be assumed that the lower the storage temperature, the higher the shelf life; but this is not always true. Some products, mainly fruits and vegetables, may suffer when they are stored at temperatures close to 0 °C. For instance, peaches can suffer undesirable internal and core browning (in a process called woolliness) if they are stored at temperatures close to 0 °C. In the case of potatoes, when they are stored below 3 °C quality deterioration occurs as a consequence of changes in the starch–sugar system that produces the accumulation of sugars. Table 1 presents the most common deterioration problems related to cold storage. Further, much research has been carried out to find the best temperature storage conditions for different food products, with the intention to reduce undesirable reactions and optimize their shelf life. Table 2 presents the optimum storage conditions for some food products.

Moreover, another parameter that must be considered during food refrigeration storage is the relative humidity. If the water activity in the product is higher than the relative humidity inside the refrigeration room, there will be loss of moisture in the product. On the contrary, if the relative humidity in the refrigeration room is higher than the water activity, water condensation may occur, which, in many cases, produces microbial growth and spoilage of the product. In this sense, high relative humidity conditions (between 90% and 95%) are preferred for fruit and vegetable products—based on their high moisture content. On the contrary, products with low moisture content, such as cheese or nuts, should be stored under reduced relative humidity conditions ($<85\%$). To prevent microbial growth in the refrigeration chamber with high relative humidity, it is necessary to avoid water condensation on the chamber walls.

The Refrigeration Process

Refrigerants

Refrigerants are chemical substances that can take the heat out from the product and release it outside the refrigeration system. The substances employed in vapor compression systems, such as NH_3, CO_2, and R134 are named primary refrigerants

Table 1 Deterioration of fruits and vegetables under refrigeration storage conditions

Product	*Critical storage temperature (°C)*	*Type of deterioration between the critical and freezing temperature*
Mango	10–13	Gray discoloration of peel Unequal ripeness
Melon	7–10	Spot, peel putrefaction No ripeness
Apple	2–3	Internal and core browning, scald, moist breaking
Orange	3	Spot, brown marks
Sweet potatoes	13	Internal discoloration, spot Rotting
Eggplant	7	Scald on surface Rotting
Olive	7	Internal browning
Avocado	4–13	Brown discoloration in pulp
Squash	10	Rotting
Green beans	7	Spot and redness
Lime	7–9	Spot
Lemmon	14	Spot, red mark
Papaya	7	Spot, rotting No ripeness
Cucumber	7	Spot, rotting
Pineapple	7–10	Green color upon ripening
Banana	12–13	Opaque color upon ripening
Watermelon	4	Spot, unpleasant odor
Tomato (green)	13	Light color upon ripening, rotting
Tomato (ripe)	7–10	Rotting, softening, soaked water

Table 2 Optimum storage conditions different foods

Food product	*Storage temperature (°C)*	*Relative humidity (%)*	*Storage life (days)*
Banana	11–15.5	85–95	7–10
Apricot	−0.5 to 0	90	7–14
Bean (snap)	7	90–95	7–10
Broccoli	0	95	10–14
Carrot	0	98–100	28–42
Celery	0	95	30–60
Cherry	−1	90–95	14–20
Chicken	Just above the freezing point	85–90	20–30
Cucumber	10–15	90–95	10–14
Eggplant	7–10	90–95	7–10
Fish	Just above the freezing point	90–95	7–10
Lemon	10–14	85–90	30–180
Lime	9–10	85–90	40–140
Lettuce	0–1	95–100	14–20
Meat	Just above the freezing point	85–90	10–15
Milk (pasteurized)	Just above the freezing point	<85	10–15
Mushroom	0	90	3–4
Peach	−0.5 to 0	90	14–30
Plum	−1 to 0	90–95	14–30
Potato	3–10	90–95	150–240
Spinach	0	95	10–14
Strawberry	−0.5 to 0	90–95	5–7
Tomato	4–10	85–90	4–7
Watermelon	4–10	80–90	14–20

Table 3 Application of different refrigerant compounds used in the industry

Refrigerant						
Formula	*Number*	*Latent heat (kJ kg^{-1})*	*Boiling point 100 kPa (°C)*	*Environmental classification*	*Toxicity*	*Flammability*
CCl_3F	R-11	194.20	23.8	CFC	Low	Low
CCl_2F_2	R-12	163.54	−29.8	CFC	Low	Low
$CHCl_2F$	R-21	254.20	−44.5	HCFC	Low	Low
$CHClF_2$	R-22	220.94	−40.8	HCFC	Low	Low
	R-123	170.47	27.83	HCFC	Low	Low

NH_3	R-717	1328.48	−33.3		High	High
CO_2	R-744	352.00	−78.5		Low	Low

and are used to chill the product. Substances employed for the transportation of the chilled product from one cooled place to another are named secondary refrigerants. In this sense, solutions with a freezing point below 0 °C are used as secondary refrigerants; the most commonly employed of these solutions being ethylene glycol, propylene glycol, and calcium chloride. Their properties are similar; however, propylene glycol has the advantage of being safe if it comes into contact with food.

The first refrigerant applied in the industrial vapor compression systems was ethyl ether, around 1850. After, other refrigerant products were employed, such as carbon dioxide, methyl chloride, butane, ammonia, ethane, and gasoline—among others. During the decade of the 1920s, after many factory workers were injured and or killed due to leaks of these first refrigerants, their use was limited and finally prohibited for use in the industry.

Later, during the first part of the twentieth century, the company DuPont developed the refrigerant R-21; the first member of the chlorofluorocarbon family. Sometime later, the company developed R-12 (Freon), naming it as the most adequate refrigerant for commercial use. However, during the 1970s, it was discovered that Freon had a negative impact on two worldwide problems: the thinning of the protective ozone layer at the stratosphere (protecting the ground from ultraviolet radiation from the sun); and the increase in global warming by the greenhouse effect on the atmosphere. For these reasons, the refrigerants R-12 and R-22 have been replaced by other kinds of refrigerants, such as R-134a and R-123. Table 3 presents the main characteristics of the primary refrigerants used in the industry and in domestic equipment. From this, the most important characteristics are the vaporization heat and low boiling point, followed by the toxicity and

flammability. Even though the ammonia (R-717) has good thermodynamic properties, the high toxicity and flammability make it extremely difficult to use in chilling industry.

Refrigerants can be classified by the halocarbon numbering system. This system was first adopted by the DuPont Company. But also, it has been adopted by some professional associations, such as the American Association American Society of Heating, Refrigerating and Air-Conditioning Engineers (ASHRAE). The general model to name a refrigerant is R-*xyz*C, where R stands for refrigerant, x stands for the number of carbon atoms, y stands for the number of hydrogen atoms and z stands for the number of fluorine, chlorine atoms. Table 4 presents the classification convention for this system.

Further, there is a classification systems presented by the International Union of Pure and Applied Chemistry (IUPAC). In this case, the refrigerants are classified by chemical composition, being:

- CFC. Chlorine-Fluor-Carbon compounds. They are presently banned because of their ozone depletion potential (ODP). Production stopped world-wide in 1995 and usage in 2000 (e.g., R12, R13, R500).
- HCFC. Hydro-Chlorine-Fluor-Carbon. The use of these refrigerants is not allowed because of their zero ODP, their production is going to stop in 2015, and usage in 2030, worldwide, but in the European Union, in 2001 for new equipment, in 2010 for old equipment, and in 2015 for any use (e.g., R22, R409).
- HFC. Hydro-Fluor-Carbons. Their use is allowed because of their zero ODP, but they contribute to the global warming potential (GWP). Fluorocarbons, where all hydrogen atoms are replaced by fluorine atoms, are often called perfluorocarbons (PFC) (e.g., R134a, R410A, R404A, and R407C).
- HFO. Hydro-Fluor-Olefin. It almost has equal thermal behavior to that of R132a, but with a much smaller GWP. The most common R1234yf (2,3,3,3-Tetrafluoropropene, $C_3H_2F_4$) is being used as a replacement for R134a in automobile air conditioners.
- Natural refrigerants (no ODP or GWP): such as air, water, ammonia (R717, NH_3), carbon dioxide (R744), and propane (R290, C_3H_8), are flammable, or toxic, or have very large vapor pressures.
- Halons. Containing bromine which replaces some chlorine compounds. This refrigerants were developed in the 1960s, and were employed more as a fire-fighting agents. However, because of the ODP, their production stopped in the 1990s.

There are signs used to detect a leakage of the refrigerants, such as odor in natural (ammonia) and artificial (hydrocarbons) refrigerants, some physical effects (bubbling), chemical effects (catalytic reaction in platinum wires) and fluorescence excitation with ultra-violet lighting to detect CFC, HCFC, and HFC refrigerants.

Cryogenic chilling is the term applied to refrigerants that change their phase by absorbing latent heat to cool the food. There are only three kinds of cryogen refrigerants: solid carbon dioxide, liquid carbon dioxide, and liquid nitrogen.

The phase change mechanism in solid carbon dioxide is by sublimation (solid to gas), removing latent heat of around 352 kJ kg^{-1} at −78 °C. Liquid cryogens remove latent heat by vaporization, obtaining around 358 kJ kg^{-1} at −196 °C for liquid nitrogen. In the case of liquid carbon dioxide, the latent heat is similar to the solid. Further, the gas obtained also absorbs sensible heat as it warms from −196 °C (liquid nitrogen) or from −78 °C (CO_2) to give a total refrigerant effect (the total amount of heat that can be removed by the refrigerant) of

Table 4 Refrigerants nomenclature by halocarbon numbering system

Code	*Significance*	*Examples*
R*xyz*	Halocarbons x = number of carbon atoms −1 y = number of hydrogen atoms +1 z = number of fluor atoms	R12: (R012) 1C → x = 0, 0H → y = 1, 2F → z = 2, plus 2Cl, that is, dichloro-difluoro-methane, CCl_2F_2 The number of Cl is calculated by diminishing the number of flourine R22: (R022) 1C → x = 0, 1H → y = 2, 2F → z = 2, R134a: 2C → x = 1, 2H → y = 3, 4F → z = 4, $C_2H_2F_4$ Plain hydrocarbons were also included: R50 = CH_4, R170 = C_2H_6, R290 = C_3H_8

690 and 565 kJ kg^{-1}, respectively. This effect can be used to chill diced meat or vegetables at up to 3 ton h^{-1}, making the plant operation and storage processes faster.

The main disadvantages of these substances are their cost (because most of the time the refrigerant is not reusable), and their ability to cause asphyxia, which is higher for carbon dioxide, and to a lesser extent with nitrogen. Regulations are set for a maximum safe limit for operators of 0.5% CO_2 by volume, and that excess carbon dioxide must be removed from the processing area by an exhaust system to ensure operator safety, which also incurs additional setup costs. Other hazards associated with liquefied gasses include cold burns, frostbite, and hypothermia after exposure to intense cold.

A refrigerant's safety classification is based on the combination of toxicity and flammability. According to the ANSI/ASHRAE Standard 34-1997, safety groups are classified as follows:

- A1 lower toxicity and no flame propagation
- A2 lower toxicity and lower flammability
- A3 lower toxicity and higher flammability
- B1 higher toxicity and no flame propagation
- B2 higher toxicity and lower flammability
- B3 higher toxicity and higher flammability

The Refrigeration Cycle by Vapor Compression

The refrigeration process taking place in household and warehouse fridges includes a mechanism that removes energy from a place with low temperature and transfers it to a place with high temperature. In the first place, the second law of the thermodynamics indicates that heat flows from a place with higher temperature to a place with lower temperature to equilibrate the temperature in the system. However, according to the Clausius statement, heat can flow from a place with low temperature to a place with higher temperature by applying some effort. In the refrigeration process, the objective is to transfer heat from a place with low temperature to a place with higher temperature. To achieve this, the refrigerant uses the transformation enthalpies presented when it changes from the liquid to vapor. A scheme of this process is presented in Figure 1. The refrigeration process starts in point 1, called the compression point, in which the fluid in a vapor state receives energy from the compressor and circulates to the point 2. At point 2, the fluid increases its pressure, temperature, and enthalpy. Then, the refrigerant enters into the condenser, where the fluid liberates heat to the system surroundings—due to the temperature differences between them. As a consequence of this heat transfer, the refrigerant decreases its temperature and condenses, presenting a phase change from the vapor to the liquid phase at constant pressure (point 3). Afterward, the refrigerant flows through an expansion valve, with a decrease in pressure in an isoentropic process, to obtain a vapor–liquid mixture (point 4). Finally, the mixture enters into the evaporator (which corresponds to the inside part of domestic fridges) where the refrigerant receives heat from the food products, until it reaches the conditions presented in point 1 to restart the cycle.

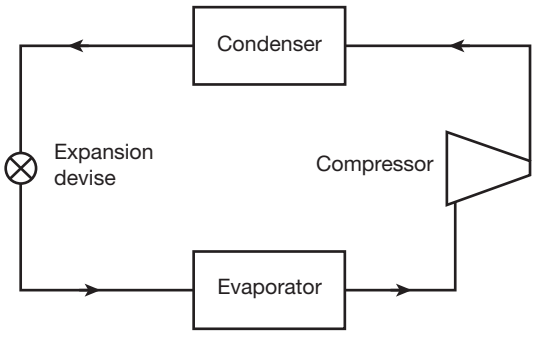

Figure 1 Chilling cycle system (Qi is the heat remove from the food product; Qo is the heat released to the environment).

Further, the refrigeration cycle can be described in a pressure-enthalpy diagram (Figure 2). First, the refrigerant increases the pressure during the compression process (points 1–2). Later, there is a decrease in the enthalpy during the condensation that takes place at constant pressures (point 2–3). After, the fluid reduces its pressure in the expansion valve at isoenthalpic conditions (points 3–4). Finally, the refrigerant increases its enthalpy (by the increase in the temperature) at isobaric conditions (points 4–1) to restart the process.

In this diagram, the amount of energy released by the refrigerant in the condenser can be determined by the enthalpies in points 2 and 3. In this sense, the heat flow released by the refrigerant is:

$$\dot{Q}_s = w(\hat{H}_3 - \hat{H}_2) \quad [1]$$

In the eqn [1], w represents the flow mass of the refrigerant and H represents the enthalpy per unit mass of refrigerant. In this case, the heat value obtained is negative because the amount of energy in point 2 that represents the enthalpy of the refrigerant when the fluid leaves the compressor is higher than in point 3, when the refrigerant leaves the condenser.

To know the amount of energy removed by the refrigeration system, it is necessary to apply the eqn [2]. In this equation, w represents the flow mass of the refrigerant, H_1 represents the enthalpy in point 1 after the evaporation process in the chilling chamber, and H_4 (point 4) represents the energy of the refrigerant before flowing to the evaporator.

$$\dot{Q}_E = w(\hat{H}_1 - \hat{H}_4) \quad [2]$$

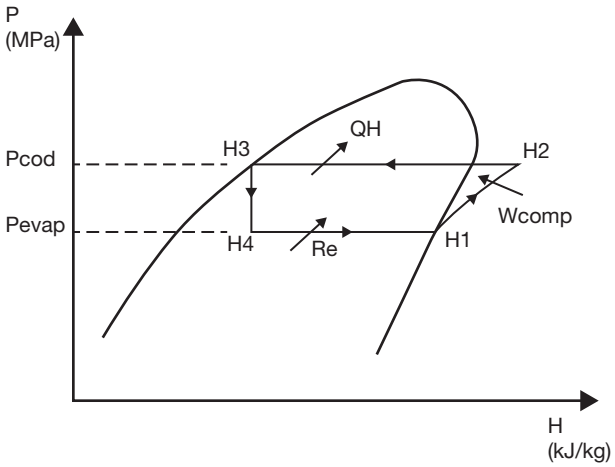

Figure 2 Chilling cycle system in an enthalpy–pressure diagram.

The value of Q_E represents the most important part of the refrigeration system, a parameter known as refrigerant capacity. Another important parameter in the refrigeration process is the coefficient of performance (COP), which is defined as the quotient of the refrigerant capacity and the work externally provided to the system (in the compression operation) (eqn [3]).

$$\mathrm{COP} = \frac{(\hat{H}_1 - \hat{H}_4)}{\hat{H}_2 - \hat{H}_1} \quad [3]$$

Further, the refrigeration facilities used for these applications must be designed to overcome heat gain through the walls of the system, and also to perform the descent of the temperature. To calculate the energy required for chilling food products, the following equations must be applied (eqn [4]).

$$Q = mCp(T_i - T_f) \quad [4]$$

- Q is the total energy removed from the food product
- m: mass of the product being chilled (kg)
- Cp: Specific Heat value (kJ kg^{-1} K) of the food product
- $T_i - T_f$: Difference between the initial and final chilling temperature (K)

There is abundant information regarding the Cp of different food products above the freezing point and below the freezing point. However, the Siebel equation for above freezing products ($T_k < 274$ K) can be applied to predict the Cp in kJ kg^{-1} K; in which, 'a' is the mass fraction of water in the food product (eqn [5]).

$$Cp = 3.3494a + 0.8374 \quad [5]$$

Moreover, the size of the refrigeration plant and the processing time required to chill different products are calculated using unsteady-state heat transfer methods. Many assumptions are made to simplify the estimation, that is, the initial temperature of a food is constant and uniform throughout the product and the temperature of the cooling medium, respiratory activity, and all thermal properties of the food are constant during cooling.

Total heat load = Heat from respiration
+ Sensible heat of containers
+ Heat evolved from operators and lights
+ Heat loss through roofs and walls
+ Heat loss through floor

A *British thermal unit* is defined as the amount of heat energy required to raise the temperature of one pound of water 1 °F from 59 to 60 °F; and 1 Btu h^{-1} = 0.293 watt (W).

Another unit of refrigeration widely used in the industry of ventilation and air conditioned is ton of refrigeration, or simply ton, being 1 ton = 12 000 BTU h^{-1} of heat removed. This equals the heat absorbed by 1 ton (2000 lb) of ice melting at a temperature of 32 °F over 24 h, and because the heat of fusion of ice at 32 °F is 144 Btu lb^{-1} (eqn [6]).

$$1\,\mathrm{ton} = \frac{1 \times 2000 \times 144}{24} = 12000\,\mathrm{BTU\,h^{-1}} \quad [6]$$

The conversion factor of 1 ton in the SI system is 1 ton = 3.516 kW

Refrigeration System Derivations

With the intention of reducing the power needed in the compression stage or achieving higher evaporation values than in the regular vapor compression cycle, many derivations of this arrangement have been developed, and they are presented in the following sections.

Chilling system with gas separation (flash economizer)

In systems with a gas separation arrangement, the fraction of vapor is separated from the saturated liquid in a manner that, conditions of a saturated liquid that, when expanded produces a mixture (point 3), which can be separated into a liquid (point 4) and a vapor (point 6). This vapor is send into the compressor, while the liquid is fed into an expansion valve to the evaporator; for this reason, the system needs two compressors. The power savings in the compressors by employing this system can be up to 16% (Figure 3).

Systems with two compressors and one evaporator

A useful option to achieve an important reduction in the power needed to compress the refrigerant is the application of a two-stage compression systems. In this system, a two-stage compression and intermediate refrigeration section are employed. This system requires higher initial investments, but the savings in power in the long term, and the low temperature achieved in the evaporator section justify its use.

Systems with two compressors and two evaporators

Sometimes different refrigeration temperatures are required in diverse processes in a food industry in the operation plants. Then it is required to develop a chilling system with more than one evaporator. Evaporators operating at two different temperatures can work in an efficient way in a two-stage system, employing an intermediate refrigerator and vapor separator. In this system, the point 3 corresponds to the saturation temperature $T3$ of the second evaporator, and is set by this temperature (Figure 4).

To evaluate this system, it is necessary to carry out a mass and energy balance in the different sections of the arrangement.

The next assumption is taken within the system, where w is the flow mass in the system (eqn [7]):

$$w_1 = w_2 = w_7 = w_8 \quad [7]$$

Balances in the evaporators:

$$Q_{E1} = w_1(\hat{H}_1 - \hat{H}_7) \quad [8]$$

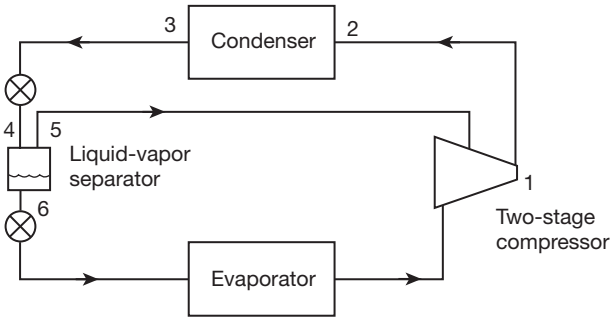

Figure 3 Expansion process with gas separation.

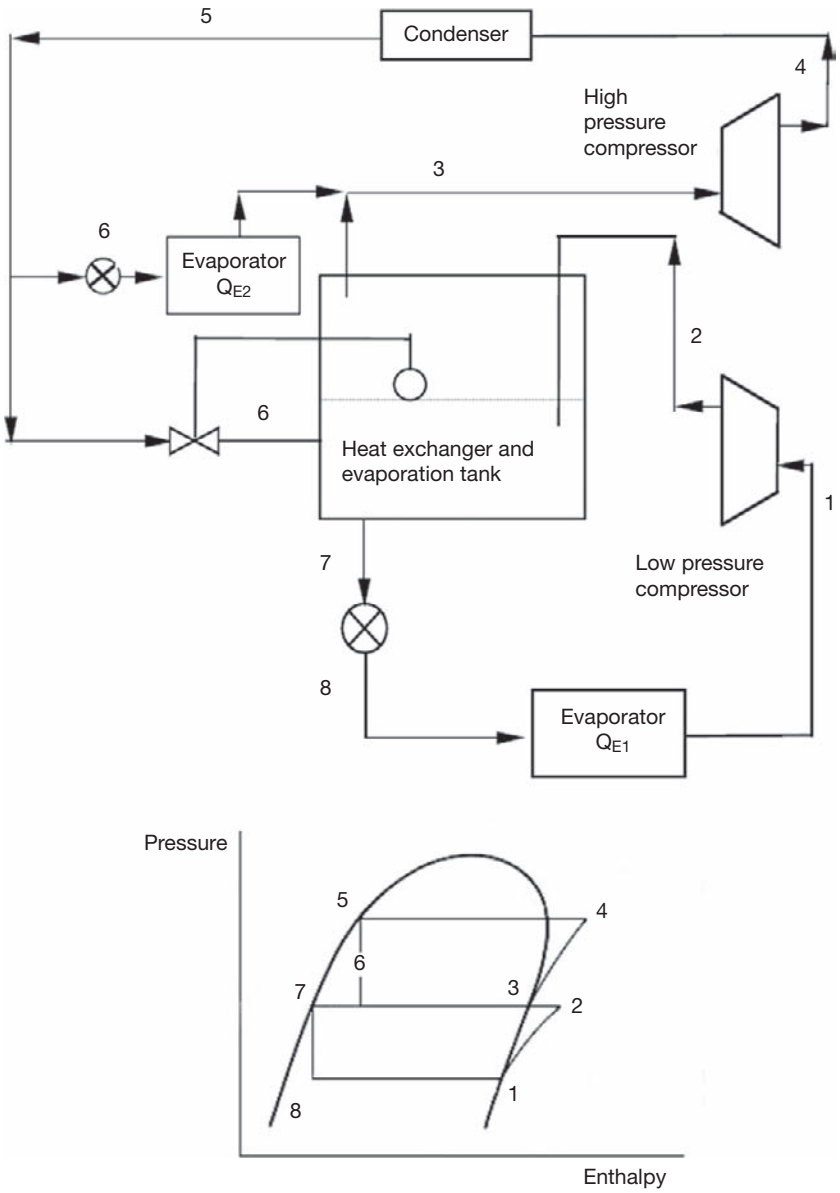

Figure 4 Operation with two compressors and two evaporators.

$$Q_{E2} = w_6\left(\hat{H}_3 - \hat{H}_6\right) \quad [9]$$

Balances in the second evaporator and intermediate refrigerator:

$$w_2\hat{H}_2 + w_5\hat{H}_5 + Q_{E2} = w_3\hat{H}_3 + w_7\hat{H}_7 \quad [10]$$

Also, in this subsystem, the flow mass can be determine by the eqn [11].

$$w_2 + w_5 = w_3 + w_7 \quad [11]$$

Since $w_2 = w_7$, it is also true that $w_3 = w_5$; therefore:

$$w_3\left(\hat{H}_3 - \hat{H}_5\right) = w_2\left(\hat{H}_2 - \hat{H}_7\right) + Q_{E2} \quad [12]$$

Power of the compressors:

$$\text{First compressor}: (Pow)_1 = w_1\hat{W}_1 = w_1\left(\hat{H}_2 - \hat{H}_1\right) \quad [13]$$

$$\text{Second compressor}: (Pow)_2 = w_3\hat{W}_2 = w_3\left(\hat{H}_4 - \hat{H}_3\right) \quad [14]$$

Chilling system with heat exchanger

In this arrangement, the liquid refrigerant, before passing through the expansion valve, is sent to a heat exchanger with the intention of increasing the heat in the system (and it facilitates the state change to vapor). The vapor flowing after the evaporator, before entering the compressor, is providing the heat in the heat exchanger (Figure 5).

Magnetic refrigeration

As an emerging technology, magnetic refrigeration has the potential to achieve high energy efficiency using environmentally friendly refrigerants. These devices use the magnetocaloric effect (MCE), defined as the temperature change that most of the magnetic materials present when

they are subjected to a changing magnetic field. Since the MCE in the best magnetocaloric materials available presents a maximum temperature change of 4 K in a magnetic field of 1 T, the magnetic refrigeration device must use a regenerative process to obtain a temperature span high enough to be applied for refrigeration purposes. The only disadvantage of this technology is the high price of the magnets.

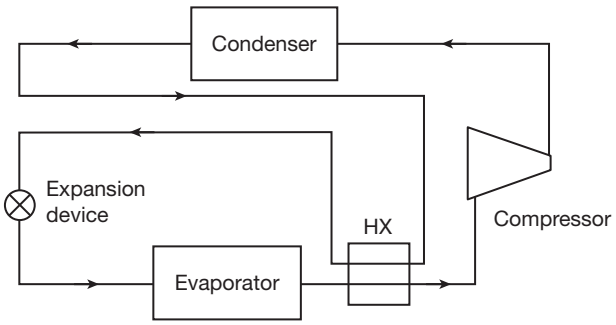

Figure 5 Chilling system with heat exchanger.

One of the most recent devices with interesting results is the one developed with a rotating mechanism in which the magnet rotates with magnetocaloric material. The magnet's (which has a high price, one of the disadvantages of this technology) design consists of a complex arrangement of permanent magnets and soft magnetic materials, which are assembled in the shape of an inner rotor. This device seems to be the prototype with better characteristics for being successfully applied in refrigeration systems. It also can help to obtain the higher temperature span in the system.

Refrigerated transport

The refrigerated transport of chilled foods must be seen as a global operation, taking into account the movement of chilled products from one cold storage area to another without variations in the temperature. For this, the actual movement of food products is carried out by way of refrigerated vehicles, ships, and aircrafts, the latter being the shipment mode least used. In the movement of products, temperature preservation is crucial to delivering products of the highest quality. Use of the finest

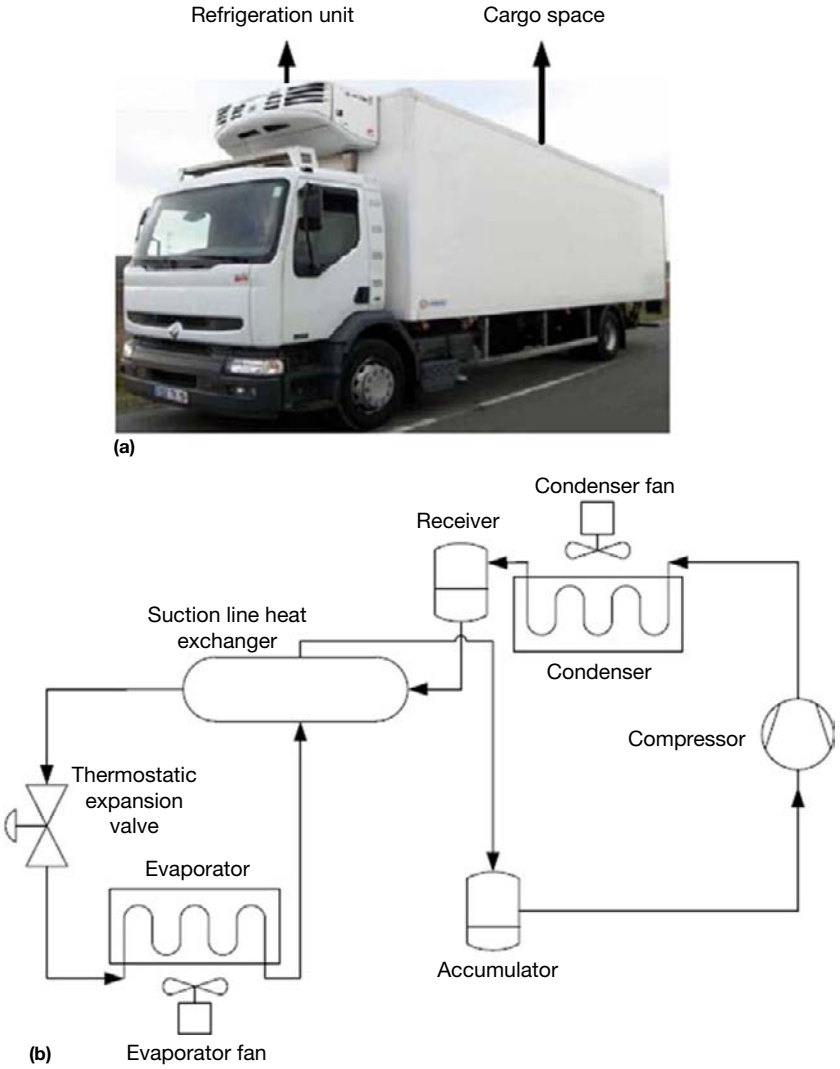

Figure 6 (a) A refrigerated truck system and (b) schematic of the refrigeration unit.

facilities cannot compensate bad manufacturing or handling practices, such as mistakes in the loading, packaging, or fluctuations in the storage temperatures. Furthermore, it is important that the temperature of the refrigeration equipment be adequate; but it is even more important to make sure that the food product is stored at the correct temperature.

The amount of refrigerated containers around the world is getting bigger every day. In 2002, at least a million refrigerated road vehicles, and about 400 000 refrigerated containers were reported in use all over the world. The temperature range of the refrigeration equipment is wide, from an insulated box containing ice, to a complex container equipped with computer systems to maintain the temperature, depending on the product being transported, within a range of −25 to 30 °C.

A typical refrigeration transport system is presented in Figure 6. In this, the refrigeration unit interacts with the truck cargo space to regulate the space to a certain temperature. Figure 6 shows the scheme of the refrigeration unit, in which all the components are interconnected, forming a complete vapor compression system. As in the common chilling system, the system employed in the vehicle uses energy to extract heat from the refrigeration chamber and transfer it to the external environment to maintain the product temperature.

Chlorophyll

C Yilmaz and V Gökmen, Hacettepe University, Ankara, Turkey

© 2016 Elsevier Ltd. All rights reserved.

Sources and Production

Chlorophyll is a natural green pigment found in photosynthetic organisms such as plants and algaes. In higher plants and algaes, except the blue-greens, chlorophyll is located in chloroplasts. Chlorophyll takes an important role in human diet as it is consumed as a part of vegetables and fruits. To date, there have been no standardized and certain information about the chlorophyll content of plants in literature. The change in chlorophyll contents depends on cultivar, harvest time, ripening stage, and parts of the plant. Storage conditions and processing of plants may also play an important role. Besides, various extraction and quantification methods cause incompatible chlorophyll contents. Chlorophyll contents of some raw vegetables, obtained from different studies, are given in Table 1.

Due to having green color and widespread occurrence in many plants, chlorophyll might be thought of as a natural coloring agent in foods. However, it is not a suitable coloring agent due to its unstable nature against processing conditions. Therefore, to have stable green coloring agents, metal-substituted chlorophylls are commercially produced by chemical modification of natural chlorophylls. The most popular and industrially used metal-substituted chlorophyll is water-soluble copper chlorophyllin. It is produced from crude chlorophyll extract as a result of hydrolysis of phytyl and methyl esters, removal of cyclopentanone ring, and replacement of magnesium by copper. It is generally present as its sodium or potassium salt.

Chemical and Physical Characterization of Chlorophyll

The basic chemical structure of chlorophyll is a cyclic tetrapyrrole. Tetrapyrrole is not only found in the structure of chlorophyll but also in some other biologically important molecules such as heme and vitamin B_{12}. It has four pyrrole rings linked together at their carbon atoms via a one-carbon bridge. It is generally present bound with a metal ion, which provides different biological functions to the molecule. In chlorophyll, four pyrrole rings are linked with methine (—C═) bridges, and the four nitrogen atoms are coordinated with a central magnesium atom (Figure 1). Beside four pyrrole rings (A, B, C, and D), chlorophyll contains an additional fifth isocyclic ring (ring E). A monounsaturated isoprenoid alcohol (phytol) esterified to propionic acid located at C-17 gives chlorophyll a hydrophobic character.

There are five types of well-known chlorophylls named as chlorophyll a, b, c, d, and e. Apart from them, chlorophyll f has been identified in recent years. Chlorophyll a and chlorophyll b are the most abundant types in higher plants. They are generally present in an average ratio of 3–1. However, it has been stated that this ratio varies depending on genetic and environmental factors. Chlorophyll a and chlorophyll b differ from each other due to a chemical compound on the second pyrrole ring (ring B) at the C-7 position. Chlorophyll a has a methyl group ($-CH_3$) at the C-7 position, whereas chlorophyll b has a formyl group ($-CHO$). Chlorophyll d has a very similar structure with chlorophyll a, except that it contains formyl group instead of vinyl group ($—HC═CH_2$) at the C-3 position. Although chlorophyll a, b, and d are formed from the dihydroporphrin macrocycle named as chlorin, chlorophyll c has a fully unsaturated porphyrin macrocycle. It also has a propenoic acid (a *trans* acrylic acid) at the C-17 position instead of propionic acid. This propenoic acid is not esterified with a long-chain alcohol like phytol as in the other chlorophylls. Molecular structures of major chlorophylls are shown in Figure 1.

Chlorophylls have many conjugated double bonds with the ability to absorb visible light. However, all chlorophylls have specific wavelength absorptions due to their differences in structures causing different green hues among plants. The absorbance spectrums of chlorophylls show two dominant bands as Q-band and Soret band. Chlorophyll a has characteristic bands in the 432 and 669 nm regions that correspond to the Soret band and Q-band, respectively. The corresponding bands for chlorophyll b are located at 455 and 644 nm, respectively. Chlorophyll c has characteristic bands between 578 and 630 nm and between 443 and 450 nm. Due to being structural similarity, absorbance spectrum of chlorophyll d is very close to that of chlorophyll a.

In chloroplasts, chlorophylls are found bound to carotenoids, lipids, and lipoproteins via noncovalent bonds. For that reason, chlorophylls are easily extracted with organic solvents, especially polar solvents such as acetone, methanol, and ethanol.

Effect of Processing and Storage Conditions on Chlorophyll

Stability of chlorophyll depends on storage and processing conditions such as pH, temperature, oxygen, metals, and enzymes. Depending on the conditions, there could be changes in molecular structure of chlorophyll causing discoloration that is an indicator of low quality. Thus, several studies have been carried out to prevent chlorophyll degradation.

pH

Chlorophyll is susceptible to low pH conditions. Chlorophyll degradation with the effect of acidic conditions is the result of degradation of chlorophyll to pheophytin (Figure 2). This reaction is called pheophytinization, and two hydrogen ions replace the magnesium ion found in the center of the porphyrin ring. As a result, the bright green color of chlorophyll turns to olive-brown, which causes negative consumer perception. In

the presence of chlorophyllase enzyme, pheophytin losses its phytyl group, resulting in pheophorbide formation. Pheophorbide also has an olive-brown color like pheophytin.

Although acidity is not enough for the formation of pheophytin at the beginning of the process, pH may decrease during the process. For instance, fermentation of vegetables lowers the pH in brine causing chlorophyll degradation. Besides, higher process temperatures trigger the formation of pheophytin in processed vegetables. Natural organic acids found in food matrix and fatty acids arising from lipid hydrolysis might be released as a result of heat treatment.

To prevent pheophytin formation and accordingly discoloration, alkalizing agents such as magnesium carbonate might be used. However, alkalizing agents cannot maintain alkaline conditions permanently. It is especially important during long period of storage that results in color losses.

Heating

Heat treatment is widely applied in food processing, especially for pasteurization, sterilization, blanching, and drying purposes. Chlorophyll is susceptible to heat treatments, which causes some structural changes. Mild heat treatments result with the formation of chlorophyll isomers (Chlorophyll a′ and Chlorophyll b′). They differ from chlorophyll

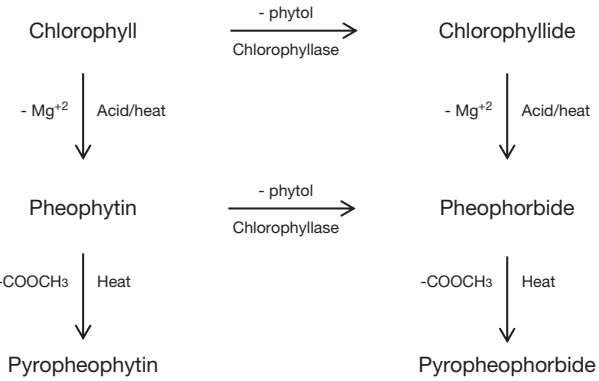

Figure 2 Formation of chlorophyll derivatives and factors affecting.

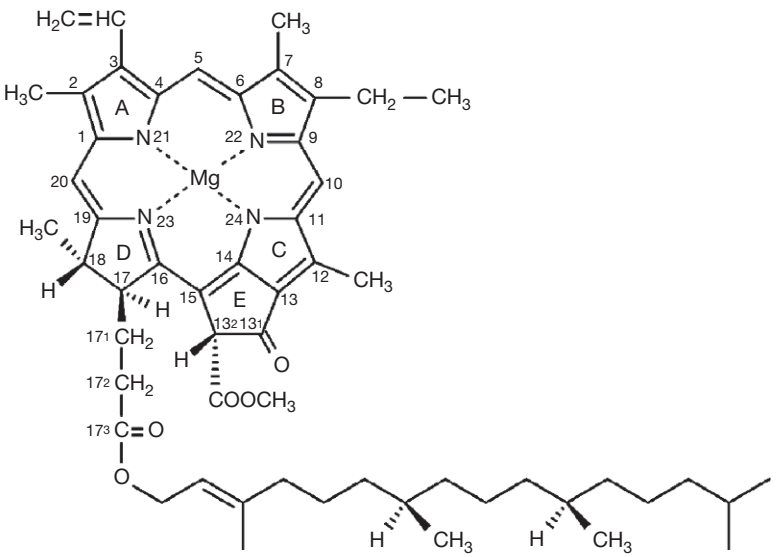

Figure 1 Molecular structure of chlorophylls.

with carbomethoxy group ($-COOCH_3$) at the C-13^2 position. Heat treatments may also cause loss of Mg^{2+} ion and formation of pheophytin. Chlorophyll a leads to formation of pheophytin more rapidly than chlorophyll b, as its heat stability is lower. Increased temperatures or long periods of heat treatments result in the formation of pyroderivatives of chlorophylls (pyropheophytin and pyropheoporbide); those have no carbometoxy group at the C-13^2 position (Figure 2).

Blanching is a heat treatment implemented prior to freezing or canning of vegetables to inactivate enzymes. This treatment provides protection of nutritional and sensorial quality. However, conditions that require inactivating enzymes are different from each other. It has been reported that blanching conditions required to inactivate lipoxygenase (LOX) causes more chlorophyll loss than peroxidase (POD). Thus, it could be said that blanching conditions required to inactivate LOX are not proper for protection of chlorophyll.

To preserve the green color of fruits and vegetables, control of the thermal treatment is important. It has been shown that high temperature in a short time might be an effective approach to preserve chlorophyll.

Enzymes

Enzymes such as chlorophyllase, LOX, POD, and polyphenol oxidase induce loss of quality in fruits and vegetables. Chlorophyllase, a thylakoid membrane glycoprotein, is found in green plants and causes the destruction of chlorophyll. Its activity continues during the processing and storage period of fruits and vegetables. Chlorophyllase cause the conversion of chlorophyll to chlorophyllide by catalyzing cleavage of the phytol group. Chlorophyllide is known as a green chlorophyll derivative. Formation of chlorophyllide is desirable to preserve the green color in canned vegetables. However, when acid is present in the medium, chlorophyllide losses its magnesium ion and causes pheophorbide formation. Olive fermentation could be a good example for formation of chlorophyllide and then pheophorbide. Besides, chlorophyllase hydrolyzes pheophytins, which gives rise to the formation of pheophorbide (Figure 2).

The formation of chlorophyllide depends on temperature conditions as chlorophyllase is activated in a temperature range (60–82.2 °C) and degraded at higher temperatures (>100 °C). Studies have shown that degradation of chlorophylls to pheophytins and degradation of chlorophyllides to pheophorbides follow first-order kinetics.

Besides chlorophyllase, POD and LOX enzymes in fruits and vegetables play a crucial role in chlorophyll degradation. LOX oxidizes fatty acids containing *cis*,*cis*-1,4-pentadiene structure. LOX is responsible for formation of hydroperoxides and free radicals that cause khaki/yellow or colorless products. Oxidative degradation of chlorophyll is named 'chlorophyll bleaching.' LOX could be inactivated by heat treatment. Therefore, blanching is generally performed for canned or frozen vegetables to inactivate LOX and protect color.

POD is one of the oxidoreductase enzymes and is found in many cell organelles including chloroplast. Although POD plays a significant role in ripening of fruits and vegetables, it is also responsible for chlorophyll degradation. In the degradation mechanism of chlorophyll via POD, phenolic compounds are oxidized with hydrogen peroxide. As a result, formed phenoxy radicals oxidize chlorophyll to colorless compounds.

Metals

Chlorophyll forms complex with some metal ions, which causes some changes in color. In canned vegetable foods, the magnesium ion at the center of chlorophyll might be replaced with iron. This replacement results in an undesirable brown-gray color. If zinc and copper salts are present in the medium during processing, some greener areas on the surface of vegetables could appear. This color change is called as 'regreening.' From this point of view, green vegetables are blanched in water containing certain amounts of Zn^{2+} and Cu^{2+} salts, and they become greener than their natural forms. Formation of complexes between chlorophyll and Zn^{2+} and Cu^{2+} are named the 'Veri-Green process.' These metal complexes are more stable than natural chlorophyll. The complex formation rate could change depending on types of chlorophylls, metals, and environmental conditions such as pH. Although complexes provide stable green color, their usage might cause detrimental health problems. Zn-chlorophyll complexes are preferably used in the industry, as Cu-chlorophyll complexes are not innocent.

In canned foods, after pheophytin is formed with the effect of heat, it is complexed with zinc and resulted with formation of zinc-pheophytin. Decarboxymethylation of zinc pheophytin causes the formation of zinc pyropheophytin. Another suggested pathway for zinc pyropheophytin formation is direct complexation of zinc with pyropheophytin.

Surface-active anionic compounds affect the formation of metal complexes. These compounds adsorb onto the chloroplast membranes, which results in increasing the negative surface charge and thereby increasing complex formation.

Oxidation

Chlorophyll is found in many vegetable oils such as virgin olive oil and rapeseed oil. During bleaching of edible oils, chlorophyll and its derivatives are generally removed or their concentration is reduced as much as possible. Due to being sensitizers, chlorophyll and its derivatives might cause photosensitized oxidation in edible oils. Photosensitized oxidation should be taken into account, as it is as important as autoxidation by means of oxidation products. Low-molecular-weight off-flavor compounds, degradation products of fatty acids, and oxidized polymers are some of the products that cause unacceptable consumer perceptions.

Photosensitizers such as chlorophyll, riboflavin, and myoglobin absorb light energy and turn into an excited single-state sensitizer. Following that, an excited triplet-state sensitizer is generated from the excited single-state sensitizer via intersystem crossing. An excited triplet-state sensitizer might follow two pathways. In the type I pathway, sensitizers play a role as free-radical initiators. An excited triplet sensitizer reacts with a substrate such as linoleic acid by donating an

electron or accepting hydrogen. Accordingly, free radicals are generated, and they react with triplet oxygen via a free radical oxidation mechanism. In type II pathways, an excited triplet sensitizer reacts with triplet oxygen, which results in formation of a singlet sensitizer and singlet oxygen. After that, the singlet oxygen interacts with unsaturated fatty acids, and hydroperoxides are produced. The amount of hydroperoxides depends on the number of double bonds of unsaturated fatty acids.

When chlorophyll is dissolved in alcoholic solutions or exposed to air, oxidation at the C-13^2 position might occur. Oxygen or oxygen-containing compound are located in the C-13^2 position of the chlorophyll.

Free radical scavengers such as carotenoids and tocopherols prevent chlorophyll-sensitized oxidation of fatty acids. β-carotene, a singlet oxygen quencher, prevents oxidation in edible oils. Moreover, storage in a controlled atmosphere might be used for the same purpose.

Refining

Chlorophyll and pheophytins are critical compounds and impart a greenish color to edible oils. Chlorophyll is especially responsible for color of olive oil that depends on the types and ripeness degrees of olives. However, excess chlorophyll causes an unacceptable consumer perception. Chlorophyll and its derivatives could be partly removed by decolorization step of refining process. However, removing chlorophyll completely is a difficult and not economical process.

Bioavailability and Health Effects

Knowledge about potential health-related benefits of chlorophyll has drawn attention in recent years. Therefore, many studies about the bioavailability of chlorophyll have been carried out to expose the effectiveness of chlorophyll on human health. However, investigations about the bioavailability of chlorophyll generally focus on *in vitro* studies.

Absorption of natural chlorophylls might change depending on such factors as type, solubility, digestive stability, and food matrix. During digestion, natural chlorophylls are converted to pheophytins because of acidity in the stomach. As a result, Mg-free derivatives might be predominantly found in human feces. According to studies, the absorption of Mg-free chlorophyll derivatives by intestinal cells is easier than that of natural chlorophyll. It has been also found that specific metallo-chlorophyll derivatives like Zn-pheophytin are stable in the gastric conditions and available for absorption.

Commercial copper chlorophyllin is a complex mixture containing different chlorin-based components such as copper chlorin e^6 and copper chlorin e^4. These chlorin-based components are absorbed at different rates. The absorption rate of copper chlorophyllin components might be changeable depending on the food matrix that may protect them from ingestion conditions.

Although chlorophyll causes photosensitized oxidation, it might show an antioxidative effect based on some conditions. If chlorophyll is exposed to light, the prooxidant effect of chlorophyll increases. However, it plays an important role as an antioxidant in dark medium. Change of chlorophyll structure also affects antioxidant activity. It has been reported that the antiradical capacity of metallo-derivatives such as Mg-chlorophylls and Zn-pheophytins is much more than that of metal-free derivatives such as pheophytins and pyropheophytins. In addition to natural chlorophyll derivatives, it has been remarked that copper chlorophyllin displays antioxidant activity against oxygen species.

Chlorophyll and its derivatives have antimutagenic and anticarcinogenic effects. These effects are against many mutagens and carcinogens such as polycyclic aromatic hydrocarbons, heterocyclic amines, and aflatoxin B_1. According to a common opinion, the protective mechanism of chlorophyll is formation of complex between porphyrin ring of chlorophyll and carcinogens–mutagens. However, the chemical structure of mutagens–carcinogens is an effective factor for formation of a complex. As a result, DNA-adduct formation is prevented and bioavailability of dietary carcinogens or mutagens is reduced. It has been shown that green vegetables might decrease the risk of colon cancer in humans. Moreover, it has been stated that chlorophyll and its derivatives prevent skin cancer when experimental animals are used. Studies have also shown that chlorophyllin has a significant antimutagenic effect against antitumor drugs that might have detrimental effects on healthy cells.

The amount of chlorophyll in the diet is significant to determine contribution of chlorophyll consumption to human health. Because of its high concentration in vegetable-rich diets, health benefits of chlorophyll might increase. As can be seen from **Table 1**, the average chlorophyll content of green beans (90 mg chlorophyll per kg vegetable) is less than that of parsley (800 mg chlorophyll per kg vegetable). Therefore, the health effect of chlorophyll in green bean could be provided by a lower amount of parsley.

Cholecalciferol: Properties and Determination

AK Hewavitharana and FP Gomes, University of Queensland, Brisbane, QLD, Australia

© 2016 Elsevier Ltd. All rights reserved.

Background

Cholecalciferol (vitamin D_3) is the common form of vitamin D synthesized in animals. Ergocalciferol (vitamin D_2) is the form that is synthesized mainly in plant sources such as mushrooms. The term vitamin D usually covers both forms, and it plays a crucial role in the regulation of intestinal absorption and metabolism of calcium and phosphate, both of which are vital for the healthy homeostasis of bones. Despite being known as a vitamin, vitamin D is a prohormone that is converted to its hormonal active form (1,25-dihydroxyvitamin D ($1,25(OH)_2D_3$ or $1,25(OH)_2D_2$)). Vitamin D was discovered in the early twentieth century from research on the treatment of rickets, a bone disorder caused by vitamin D deficiency in children. The original vitamin D, which was named D_1, was a mixture of compounds that was prepared by ultraviolet (UV) radiation of ergosterol that was found in plants and fungi. In 1931, vitamin D_1 was purified by Askew and the compound ergocalciferol or vitamin D_2 was isolated. At that time, synthesis of vitamin D in human was not understood, as ergosterol could not be found in human tissues. Few years later, Windaus synthesized 7-dehydrocholesterol (ergosterol equivalent in human skin) from cholesterol, and its UV-radiated product was named cholecalciferol or vitamin D_3.

Physical and Chemical Properties

Cholecalciferol is a white crystalline powder with the chemical name 9,10-seco(5Z,7E)-5,7,10(19)-cholestatriene-3β-ol. As shown in Figure 1, its chemical structure differs from that of steroids by the bond cleavage at 9–10 followed by ring opening, which is responsible for antirachitic activity. This ring opening reaction occurs in human skin on exposure to UV-B radiation (290–315 nm) of 7-dehydrocholesterol (provitamin D_3). As shown in Figure 1, the ring opening is followed by the formation of a double bond to produce previtamin D_3. Subsequent temperature-dependent rearrangement of this double bond produces cholecalciferol with a characteristic conjugated triene structure. Once formed, it is carried into circulation by vitamin D-binding protein. Cholecalciferol itself is biologically inactive, and its conversion to function biologically comprises two enzymatic hydroxylation reactions, producing 25-hydroxyvitamin D_3($25(OH)D_3$) followed by $1,25(OH)_2D_3$. Ergocalciferol, which is ingested through plant food sources, also undergoes similar process to produce the biologically active form $1,25(OH)_2D_2$. The structures of the vitamin D analogues commonly found in human plasma are shown in Figure 2, and these and many other analogues found in plasma and other biological fluids are collectively called vitamin D.

Although vitamin D is traditionally implicated in bone health, its deficiency was found to have effects on many other diseases such as hypertension, diabetes mellitus, cancer, and autoimmune and cardiovascular diseases. As a result, there has been a proliferation of research on vitamin D in recent times. Some research indicates that different forms of the vitamin D may be responsible for this variety of physiological effects. In general, the activities of vitamins are expressed in international units (IU). Expression in IU is useful in expressing the total activity when several forms of the vitamin with different biopotencies are present in one food source. With vitamin D, both cholecalciferol and ergocalciferol are considered to have a similar potency: 1 IU = 0.025 μg. However, the potencies of other forms of vitamin D are not available in IU; therefore, this concept is not as widely used as with other vitamins such as vitamin A. Evaluation of potencies of different forms of vitamin D is made more challenging due to the fact that each form may have different physiological effects. As shown in Figure 2, in terms of chemical structure, cholecalciferol differs from ergocalciferol at the C17 side chain where ergocalciferol has an additional methyl group at C24 and an extra double bond between C22 and C23. It is worth mentioning that cholecalciferol and ergocalciferol possess similar physical and chemical properties. Table 1 lists the physical and chemical properties of cholecalciferol and ergocalciferol. While their potencies in humans are considered equivalent by pharmacopoeias, some studies have demonstrated that cholecalciferol is more potent than ergocalciferol and better absorbed by the intestine. It has also been found that its major circulating metabolite $25(OH)D_3$ has higher affinity than that of ergocalciferol (25-hydroxyvitamin D_2 ($25(OH)D_2$)) to vitamin D-binding protein, resulting in a longer half-life.

Cholecalciferol is the common form that is consumed as vitamin D. It has been extracted from fish liver oil, but nowadays, it is mostly synthesized for use in nutritional supplements and in fortified foods. Despite its insolubility in water due to high lipophilicity, cholecalciferol is readily soluble in a wide range of organic solvents including alcohols and both chlorinated and nonchlorinated hydrocarbons such as chloroform and hexane. Cholecalciferol undergoes a reversible thermal isomerization to previtamin D_3 and/or degradation when stored in alcoholic solutions and exposed to oxygen and light. However, it is stable for long periods when stored in absolute ethanol without the presence of oxygen and light at low temperature (−20 °C). It is also stable in oils, fats, and fortified food, when stored in dark at low temperatures. It has been found that cholecalciferol is protected against degradation in food matrices and once released from them can be vulnerable to degradation by light and oxygen. Cholecalciferol is stable in alkaline solutions but not in acidic conditions. In acidic conditions, it undergoes isomerization to inactive forms such as isotachysterol and 5,6 trans isomers.

Occurrence and Forms in Food

It is well known that cholecalciferol is primarily obtained via exposure of the skin to sunlight. Some critical factors including skin pigmentation, time of day, sunscreen use, altitude, skin

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00148-3

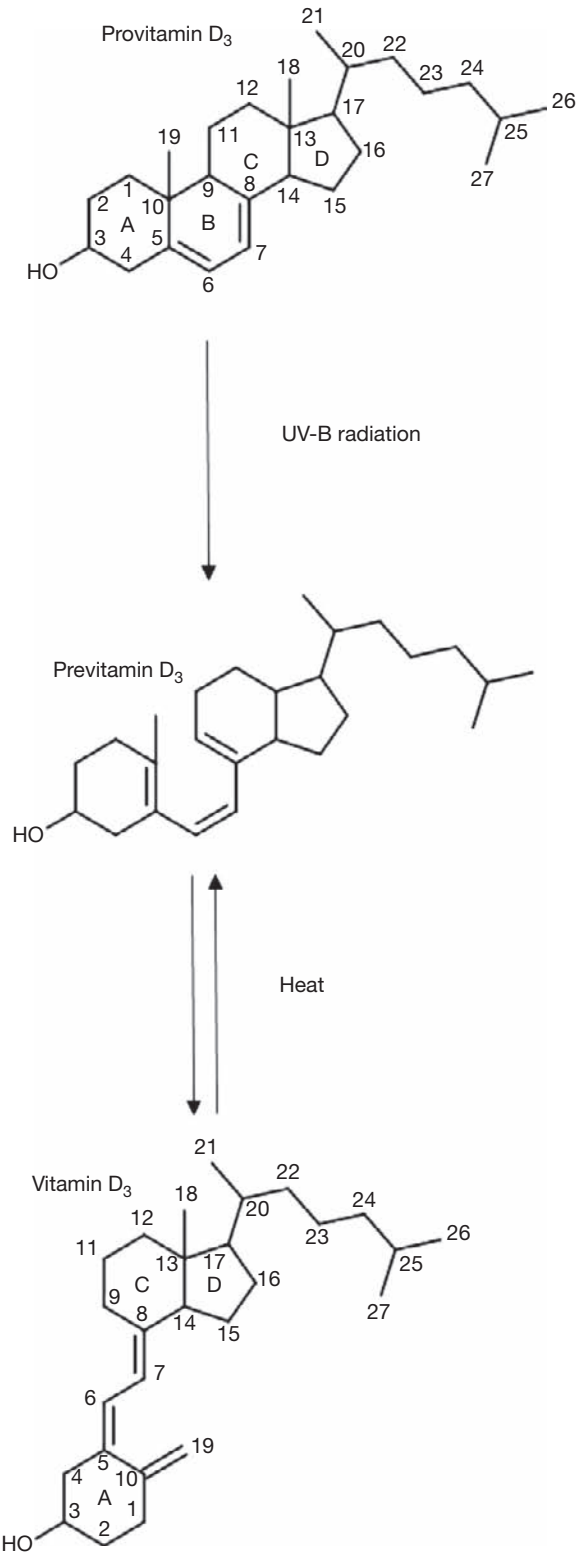

Figure 1 Photochemical conversion of provitamin D_3 to vitamin D_3.

type, age, obesity, latitude, clothing, and season directly influence the vitamin D intake from the sun. Due to concerns of the depleted ozone layer and skin cancer, the significance of sunlight in vitamin D production has decreased in recent years; hence, dietary intake has become the main source as vitamin D deficiency has become common.

Vitamin D can be naturally found in a limited number of foods. Cholecalciferol is usually present in animal foods, while ergocalciferol can be found in fungi (mushrooms) and plants. Provitamins (7-dehydrocholesterol and ergosterol) are present in animals and plants (including the ones used as food sources by humans); therefore, exposure to sunlight produces vitamin D in them. Mushrooms dried in sunlight are considered a good plant source of vitamin D_2. Fish liver oils are regarded as the best source of cholecalciferol. Fish, such as tuna and salmon, are generally accepted as relatively good sources. Both cholecalciferol and ergocalciferol can be found in milk, cholecalciferol being the predominant form. Seasonal variations can affect the concentration of cholecalciferol in cow's milk due to changes in sunlight exposure of its skin. Although alimentary forms are mainly composed of ergocalciferol and cholecalciferol, small portions of calcidiol and calcitriol can also be found in some dietary products. Table 2 provides a list of nonfortified foods containing vitamin D with their respective concentrations. It should be noted that the analytical methods available for measuring vitamin D in food were usually developed to measure only the two calciferols; therefore, the reported values may not reflect the total amounts that include the contributions by other forms.

Fortification of Foods

The serious concern of the adverse outcomes (wrinkling and skin cancer) that can occur with high exposure to sunlight has decreased obtaining vitamin D through sunlight exposure. In addition, the general trend of low-fat diets causes vitamin D deficiency because this fat-soluble vitamin is removed along with fat during the production of low-fat food. Although an optimal cholecalciferol daily intake level has not yet been established, current recommended daily intake is in the range 400–600 IU. This is difficult to obtain through dietary sources alone without exposure to sunlight. As a result, vitamin D supplementation is commonly prescribed. In order to address the vitamin D deficiency in a large fraction of the population, a common practice used in many countries is to fortify certain foods with vitamin D. However, fortification of food with vitamin D must be monitored because of toxicological concerns such as hypercalcemia with fatal consequences at very high levels. Either cholecalciferol or ergocalciferol is used in the fortification of food, although cholecalciferol is the preferred form. There is no consensus about the extent to which food fortification should be performed and the prevalent action varies according to the legislation of each country.

Common vehicles of vitamin D fortification are milk, milk-based beverages, milk powder, margarine, and cereal products. Cholecalciferol is usually added to the milk in oily form due to its easier solubilization in oil-based foods. Milk powder is fortified by mixing cholecalciferol powder with milk powder into the bulk. In this process, it is important to make sure particle sizes of milk powder and vitamin powder are compatible in order to avoid separation of the components, leading to a heterogeneous mix. It must be stored in a cool and dry space to ensure minimal cholecalciferol loss. In the case of

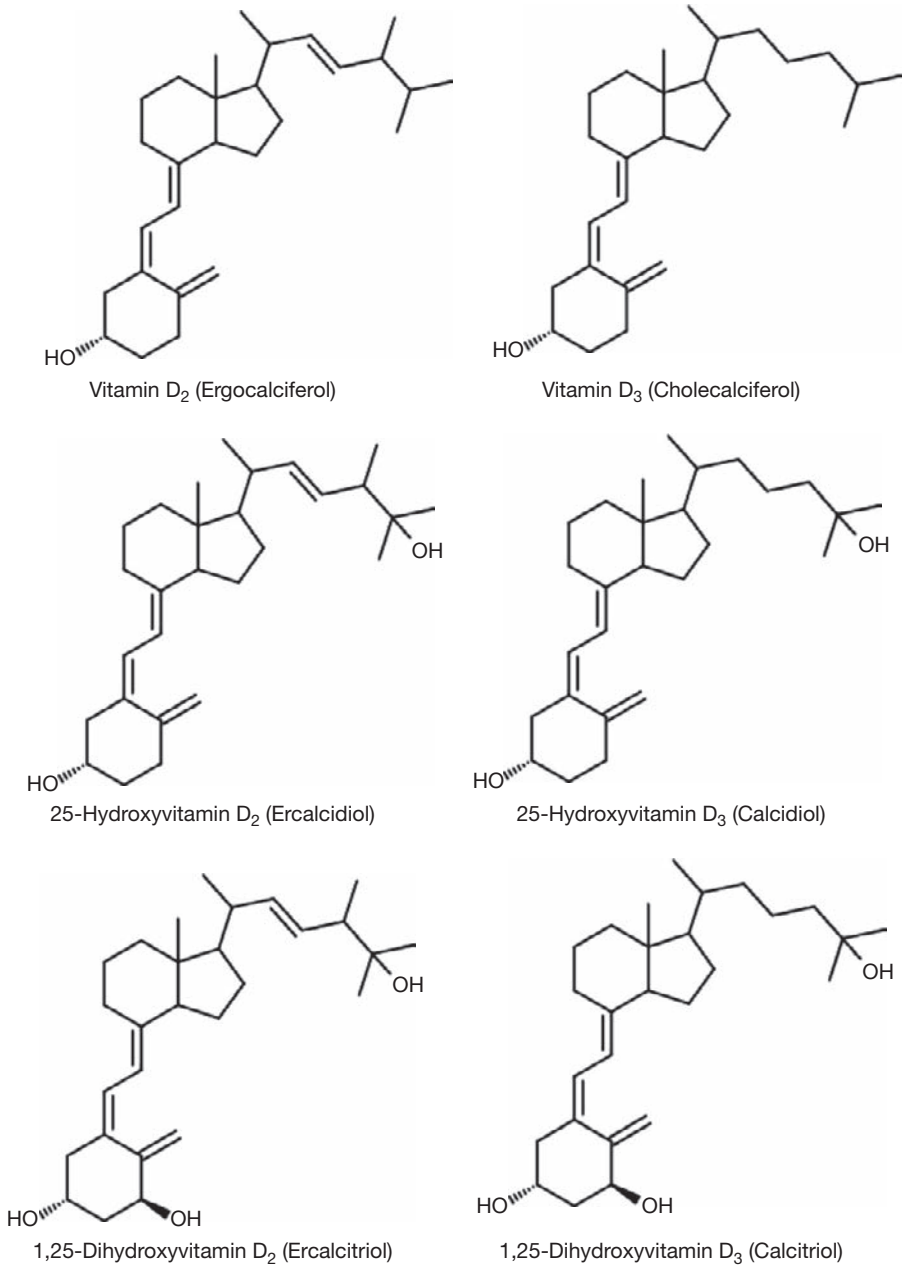

Figure 2 Chemical structures of ergocalciferol, ercalcidiol, ercalcitriol, cholecalciferol, calcidiol, and calcitriol.

margarine, the fortification is performed by mixing oily cholecalciferol with a fraction of warmed oil, followed by homogenization with the fat blend prior to the emulsification procedure. In addition to fortified foods, cholecalciferol can be obtained from vitamin D supplements that generally contain 1000 IU in each tablet.

Analytical Methods

Unlike with photosynthesized vitamin from skin, with dietary intake, vitamin D levels can rise to over 400 ng ml^{-1} (about 2 mg or 80 000 IU in total), leading to vitamin D toxicity. The natural levels of vitamin D in common foods are very low and the fortified levels are also relatively low unlike with most other vitamins. The determination of cholecalciferol content in foods is a challenging analytical task as, in natural foods and even in fortified foods, only small amounts are present and a wide range of compounds are extracted along with cholecalciferol that cause difficulties in sample preparation and instrumental analysis.

Vitamin D molecules in foodstuffs and biological fluids are bound to lipids and/or proteins; therefore, chemical bonds need to be broken to release the vitamin before analysis. In general, saponification is used to release vitamin D and to remove other lipids from foodstuff, and solvent-based protein

Table 1 Properties of ergocalciferol and cholecalciferol

Properties	*Ergocalciferol (vitamin D_2)*	*Cholecalciferol (vitamin D_3)*
Molecular formula	$C_{28}H_{44}O$	$C_{27}H_{44}O$
Molar mass (g mol^{-1})	396.63	384.62

Shrimp	150
Salmon	220–440
Sardines	1500
Mackerel	120
Herring liver oil	140 000
Herring	330

precipitation is used to release it from biological fluids. In saponification, vitamin D compounds are released from lipoprotein complexes. In protein precipitation, vitamin is released from the proteins by denaturing the protein. Commonly used saponification procedure consists of mixing the sample with ethanolic potassium hydroxide and heating to approximately 80 °C for about 1 h. The unsaponifiable portion containing the vitamin is then extracted using a nonpolar solvent such as hexane. Subsequently, the organic phase is removed by evaporation and the residue reconstituted in a suitable solvent depending on the analytical method used. Commonly used protein precipitation method consists of mixing the sample with acetonitrile to precipitate out the proteins by denaturation. The precipitated proteins are removed after centrifugation, the supernatant is dried under nitrogen or by evaporation, and the residue is reconstituted in a suitable solvent depending on the analytical method used. The extracted vitamin is subsequently detected and quantified using techniques such as ELISA, radio immunoassay, or high-performance liquid chromatography (HPLC) with UV spectrophotometric or mass spectrometric detection (HPLC-UV or HPLC–mass spectrometry (MS)). HPLC–MS is the most common chromatographic technique used nowadays due to its superior selectivity and sensitivity relative to HPLC-UV. However, vitamin D compounds produce weak signals in MS detector because of their poor ionizability. Recently reported methods have overcome this problem by derivatization with 4-phenyl-1,2,4-triazoline-3,5-dione (PTAD) to produce Diels–Alder adducts that have better ionization efficiency in MS detection.

Chromatographic separation is usually carried out on a reversed-phase analytical column, and the detection wavelength commonly used with UV detection is 265 or 280 nm. Electrospray ionization and atmospheric pressure chemical ionization are the most frequently used mass spectrometric ionization modes, and most methods used tandem mass spectrometric detection (HPLC–MS/MS) rather than HPLC–MS to achieve better specificity and sensitivity.

There are many different immunoassay kits commercially available for vitamin D assay. With immunoassays, the vitamin extract is subjected to an antibody-specific vitamin D assay. The detection step of immunoassays is based on different spectroscopic techniques such as UV–visible, chemiluminescence, Raman scattering, and radioactivity measurements. Two major limitations of immunoassays for vitamin D analysis are matrix effects and the inability to distinguish between 25(OH)D_3 and 25(OH)D_2. Raman spectroscopy for immunoassay has shown high sensitivity, enabling the detection of vitamin D metabolites at very low concentrations; however, this method still cannot distinguish between the different vitamin D metabolites.

Despite being the best method for vitamin D analysis, one of the major drawbacks of HPLC–MS or HPLC–MS/MS is that the MS detection is susceptible to matrix effects. Matrix effects in MS occur when the compounds that coelute with the analyte interfere with the ionization process causing ionization suppression or enhancement. As there is no way to ensure complete elimination of the interfering compounds that coelute with the analyte, the only way to obtain accurate data is to remove the contribution from the interferences at the quantification step. The inclusion of stable isotope-labeled (SIL) internal standards

(IS) in both the samples and standards followed by quantification using internal standard calibration has become the most common method used to correct for matrix effects in MS detection. As the chemical properties and ionization process of SIL-IS are almost identical to those of the vitamin, and as it elutes at the same retention time as the vitamin and experiences the same extent of matrix effects, it provides the best option to correct for matrix effects when IS calibration method is used. As a separate SIL-IS is needed for each form of the vitamin quantified, and some of them are not commercially available, many published methods for vitamin D had no corrections applied for matrix effects of MS detection. Some methods used a single SIL-IS for all vitamin forms although this does not remove matrix effects from all vitamin D analogues. Quantification with HPLC-UV methods has used either IS calibration using noncoeluting compounds such as laurophenone or retinyl acetate or external standard calibration.

Eleven analytical methods for the analysis of vitamin D in foodstuffs have been validated by the Association of Official Analytical Chemists International (AOACI); however, only four of them have been used in laboratories. In summary, these methods are similar, in which saponification is used to extract the vitamin D content and HPLC-UV is used for quantification. The scope of these methodologies is only vitamin D_3, limiting their applications to food matrices containing other forms of vitamin D. In addition, these approaches were validated for a limited number of food matrices, containing high levels of fat, which make them inappropriate to the application in matrices with low-fat content such as cereals and juices.

Cholesterol: Absorption, Function and Metabolism

V Vučić, University of Belgrade, Belgrade, Serbia
Z Cvetković, Clinical Hospital Center Zemun, Belgrade, Serbia

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Cholesterol plays an essential role in maintaining membrane integrity and proper fluidity. It is an abundant component of the plasma membranes of eukaryotic cells, which makes up around 25–30% of the total lipids present in cell membranes. The cholesterol contents of cell membranes are tightly regulated and have an impact on cell permeability. The large hydrophobic domain of cholesterol fits into spaces between phospholipids, thereby preventing diffusion of water-soluble molecules through the membrane. Furthermore, cholesterol reduces the fluidity of cell membranes with its rigid structure and stabilizes membranes under different conditions. Alterations in membrane fluidity further influence membrane transport processes, including Na^+/K^+-ATPase. Although around 70% of plasma cholesterol is esterified, cholesterol in cellular membranes is in free form.

In addition to the role in the stability and architecture of the plasma membrane, cholesterol is a precursor for the biosynthesis of bile acids, vitamin D, and steroid hormones in mammals. Fluctuations of circulating levels of cholesterol under physiological conditions are controlled by a series of mechanisms that balance between *de novo* synthesis, absorption of dietary cholesterol, and removal from peripheral tissues. Therefore, cholesterol levels in circulation depend not only on the amount of cholesterol supplied from the diet (exogenous) and synthesized in the body (endogenous) but also on the removal, uptake from cells, and the conversion of cholesterol into other molecules (bile acids and steroid hormones). Concentration of intracellular cholesterol is coordinated by the same mechanisms, in line with the phases in the cell cycle. All these processes are tightly regulated and maintain concentration of cholesterol within a normal range. However, many chronic noncommunicable diseases are associated with alterations in these mechanisms, including cardiovascular diseases and cancer.

Cholesterol Biosynthesis

Most animal cells are able to produce cholesterol, but the production rates vary depending on the cell types and organ function. Cholesterol *de novo* synthesis is a highly regulated, multistep process known as the mevalonate pathway. Primary place of cholesterol production is the liver, which contributes 20–25% of total cholesterol synthesis, while cholesterol is also synthesized in the intestines, adrenal glands, and reproductive organs. The only precursors for the biosynthesis of cholesterol are two-carbon metabolite of acetate, acetyl coenzyme A (acetyl CoA). Two acetyl-CoA molecules form acetoacetyl CoA, which is combined with another acetyl CoA and then hydrated to 3-hydroxy-3-methylglutaryl CoA (HMG-CoA) in the cytoplasm. This reaction is catalyzed by the enzyme HMG-CoA synthase. The next step is the reduction of HMG-CoA to mevalonate (the key intermediate in cholesterol biosynthesis) by the enzyme HMG-CoA reductase in microsomes, which requires NADPH. This is an irreversible and rate-limiting step in the cholesterol biosynthesis, which is commonly used as therapeutic target in hyperlipidemic disorders using statin drugs (HMG-CoA reductase-competitive inhibitors).

HMG-CoA reductase is placed in the membrane of the endoplasmic reticulum (ER). This enzyme contains multiple transmembrane domains and a catalytic domain that converts HMG-CoA into mevalonate. The catalytic domain (C-terminal domain) faces the cytosol, while the membrane domains play an important regulatory role. Namely, these domains are sterol-sensitive, and they change the conformation of the enzyme when interact with sterols. Hence, when cholesterol level in the cell is high, conformation changes downregulate the activity of HMG-CoA reductase, and less mevalonate is produced. Lower synthesis is compensated by increased rate of uptake of cholesterol from blood to cells, thereby lowering the level of cholesterol in the circulation. On the contrary, when levels of cholesterol in cells decline, they respond by increasing the gene expression of not only proteins included in cholesterol biosynthesis, in particular HMG-CoA reductase, but also proteins responsible for the uptake of cholesterol from the external environment, such as low-density lipoprotein (LDL) receptor. In this way, cholesterol concentration in cells increases.

Further, conversion of mevalonate to 3-isopentenyl pyrophosphate includes three reactions, which all require ATP. These reactions, as well as those that follow, are carried out in the ER. The next steps involve the synthesis of farnesyl pyrophosphate, which is used for the synthesis of squalene. Squalene is converted to lanosterol through series of cyclization and migrations of hydrogen and methyl groups. Finally, cholesterol is synthesized from lanosterol in several reactions including oxidation, reduction, and demethylation. The whole process consists of 37 reactions.

Cholesterol Transport

Although cholesterol in synthesized in the ER, its concentration in the ER is very low. This is because the largest part of synthesized cholesterol is transported to other sites. Most of the cholesterol is carried to the plasma membrane, where it modulates membrane fluidity and maintains barrier between cell and environment. However, cholesterol is also sent to other organelles. Some of them are a part of the secretory pathway (e.g., the Golgi complex and lysosomes), and they receive cholesterol by vesicular transport. For the other intracellular destinations, such as the mitochondria, lipid transport proteins deliver cholesterol. These proteins interact with the ER membrane, bind cholesterol, then diffuse through the cytoplasm to target organelles, and release cholesterol into their membranes.

Furthermore, cholesterol is delivered to circulation. Given that cholesterol is a highly insoluble molecule, it is transported

through circulation by endogenous transporters called lipoproteins. The five major classes of lipoproteins are chylomicrons, very low-density lipoprotein (VLDL), intermediate-density lipoprotein (IDL), LDL, and high-density lipoprotein (HDL), and their characteristics are presented in Table 1. Lipoproteins have a common structural configuration, although the relative lipid and protein composition of each lipoprotein varies. All of them contain phospholipid monolayer with anchored proteins, which protect inner hydrophobic core of neutral lipids, for example, cholesterol esters and triglycerides. On the surface of lipoproteins, there is some free cholesterol as well. Based on this architecture, lipoproteins are ideal carriers for lipophilic compounds. In addition to other lipids, lipoproteins not only transport and deliver dietary cholesterol to peripheral tissues but also remove the excess cholesterol from peripheral tissues to the liver, thereby maintaining the homeostatic balance. However, each class of lipoproteins has different structures, specific functions, and thus different effects on health. From the clinical point of view, LDL cholesterol and HDL cholesterol are particularly attractive, even though other lipoproteins have clinical significance as well.

Cholesterol Absorption

Absorption of dietary cholesterol is closely related to plasma concentrations of cholesterol. In human diet, the major sources of cholesterol are egg yolk, meat, and dairy products. A variable proportion of dietary cholesterol is esterified to fatty acids, while the rest remains free. However, only free cholesterol appears to be absorbed, so cholesterol esters have to be hydrolyzed prior to absorption, mostly by the action of pancreatic enzymes. Additional and often overlooked source of cholesterol originates from the bile, and all biliary cholesterol is nonesterified and therefore suitable for absorption. Moreover, among 60–80% of cholesterol that is absorbed from the diet and the bile, greater part originates from the bile since it is already prepared to be absorbed.

The main sites of cholesterol absorption are the duodenum and proximal jejunum. The process occurs through the intestinal mucosal cells on the surface of the intestinal villi. Digestion of lipids starts in the stomach when the food is mixed with gastric and lingual enzymes, forming a crude emulsion. This emulsion is mixed in the duodenum with pancreatic enzymes and bile salts. Pancreatic enzymes, lipase, cholesterol esterase, and phospholipase A all have hydrolytic functions and liberate cholesterol from the esters. Since many products of pancreatic enzymes are poorly soluble, the role of bile salts is to emulsify lipids, acting as a surfactant. The obtained mixture of lipids, triglycerides, and cholesterol is readily soluble and is able to pass through the thin water layer around luminal cells. In this way, the mixture comes up to absorptive enterocytes. Although it has been thought for years that lipids passively diffuse through the plasma membrane of enterocytes, recent studies have shown that several proteins are involved in intestinal transport of cholesterol. The cholesterol carriers that are identified so far are NPC1L1, SR-B1, CD13, CD36, P-glycoprotein, and annexin 2–caveolin 1 complex. Some of them affect intracellular concentration of cholesterol and are controlled by transcription factors. However, the list of protein mediators of intestinal cholesterol transport is likely still incomplete.

Inside the intestinal cell, cholesterol is shuttled to the ER, where it is packaged into chylomicrons. Chylomicrons are large particles (around 1 um), with lipid-containing core (similar to the other lipoproteins) and the surface with anchored apoproteins, mostly apoB-48, apoE, A-1, A-2, and A-4. Amphipathic nature of apoproteins makes chylomicrons soluble in blood and lymph fluid. Because of the size of chylomicrons, they cannot pass through the blood vessels, but instead enter the lymph. This secretion into the lymph fluid requires apoB-48 on the surface of chylomicrons. From the lymph, chylomicrons enter the bloodstream via the thoracic duct and the right subclavian vein. Thence, they are sent to the adipose and muscle tissue that utilize a part of the triglycerides in chylomicrons, before arriving at the liver. The triglycerides from chylomicrons are extracted by the enzyme lipoprotein lipase (LPL) while passing through the capillaries of the muscle and adipose tissue and used by muscles or stored in adipocytes. The remaining particle is called chylomicron remnant. The remnant is denser than chylomicron; it contains less triglycerides and thus is relatively rich in esterified cholesterol. It is rapidly removed from the circulation by the liver, via LDL receptors or the LDL receptor-like protein (LRP). Chylomicron receptor LRP is placed on the surface of hepatocytes, interacts with apoE in the remnants, and thus facilitates the uptake to the liver.

In the liver, lipids are repackaged into VLDL particles, which necessarily contain apoB-100, synthesized mainly in hepatocytes. The amounts of apoB-100 are controlled by the amount of lipids: When more lipids are available, the

Table 1 Composition and physical properties of lipoprotein classes

Lipoprotein	Chylomicrons	VLDL	IDL	LDL	HDL
Source	Intestine	Liver, intestine	VLDL	VLDL	Liver, intestine, VLDL, chylomicrons
Diameter (nm)	90–1000	30–90	25–35	20–25	5–25
Density (g ml^{-1})	<0.95	0.95–1.006	1.006–1.019	1.019–1.063	1.063–1.210
Total lipids (%)	98–99	90–93	88–90	78–80	43–67
Triglyceride	85–88	50–55	25–30	10–15	3–15
Free cholesterol	1	8–10	8–10	8–10	2–10
Cholesteryl esters	3	12–15	32–35	37–48	15–30
Phospholipids	8	18–20	25–27	20–28	26–46
Protein (%)	1–2	7–10	10–12	20–22	33–57
Apoprotein	A-I, A-II, B-48, C-I, C-II, C-III	B-100, C-I, C-II, C-III, E	B-100, C-I, C-II, C-III, E	B-100	A-I, A-II, C-I, C-II, C-III, D, E

proteolysis of apoB-100 is reduced and the production of VLDL increases. In contrast, when the concentration of lipids falls down, more apoB-100 is proteolyzed and the generation of VLDL decreases as well. Therefore, the concentration of VLDL is regulated by the proteolysis of apoB-100. VLDL are secreted from the liver, and they are the main carriers of endogenously produced triglycerides. As with chylomicrons, VLDL is also subjected to LPL-mediated hydrolysis of triglycerides in capillary walls, and then, surface proteins (with the exception of apoB-100) are transferred to HDL. One important protein involved in the transfer of cholesteryl esters and triglycerides between VLDL, LDL, and HDL is facilitated by cholesterol ester transfer protein (CETP), which is also an important target for cholesterol-lowering drugs. Therefore, both chylomicrons and VLDL deliver triglycerides to tissues for storage or as a source of energy. Although a part of the remnants of VLDL is removed by the liver, most are converted to LDL via IDL. In addition, there is another pathway for lipid transfer by chylomicrons and VLDL, heparan sulfate proteoglycan-mediated pathway.

After hydrolysis of triglycerides from VLDL, IDL particles are produced. Some of IDL are taken up by the liver, through the binding of apoE to the LDL receptors. Nevertheless, the majority of IDL is modified by hepatic lipase forming LDL.

LDL Cholesterol

In LDL particles, cholesterol makes ~50% of the weight, while around 25% are proteins. The crucial protein component is apolipoprotein B-100 (apoB-100), along with 80–100 additional ancillary proteins that increase LDL solubility. Core of the LDL particles is highly hydrophobic and contains mostly triglycerides and cholesterol esterified by various fatty acids. The basic function of LDL is delivering cholesterol to cells for storage or further biogenesis, by receptor-mediated endocytosis involving the uptake of the whole lipoprotein particle. Especially during periods of rapid growth and development, LDL particles provide cholesterol to most peripheral tissues via the LDL receptor. In spite of this important function, high levels of LDL cholesterol in serum strongly correlate with increased risk of cardiovascular events. Thus, LDL cholesterol is widely called 'bad cholesterol.' Furthermore, recent evidence showed possible relationship between oxidized form of LDL and atherosclerosis. The oxidation of LDL is a complex process, which affects both the protein and the lipids: they undergo oxidative changes and form complex products. Primarily, nonenzymatic oxidative changes in amino acids result in extensive alteration in the apoB-100 composition and structure. In addition, lipid peroxidation causes generation of aldehydes and ketones that covalently modify amino acid side-chain residues of apoB-100 and the other proteins. Modified LDL is then scavenged and degraded by macrophages. They bind oxidized LDL by the scavenger receptor, which is expressed primarily on macrophages. The receptor–LDL complex is taken up and then targeted to the lysosome for degradation. If macrophages phagocyte a high amount of LDL, cholesterol accumulates in their cytoplasm, which becomes filled with lipid droplets. The lipid droplets in the cytoplasm give the macrophages a foamy appearance, because these cells are named foam cells. They are not harmful as such, but they can accumulate in the wall of large blood vessels, leading to the formation of an atheroma, which are known as precursors for atherosclerosis. The unrestricted generation of foam cells and its ability to promote inflammatory responses and differentiation of monocytes in the arterial wall imply that oxidized LDL is a key factor in the development of atherosclerosis.

In order to be packaged into lipoproteins, a large amount of cholesterol is esterified with long-chain fatty acids. In this way, the problem of transport of insoluble cholesterol through circulation is solved. However, cholesterol esters cannot pass through membrane and delivery is enabled by lipoprotein receptors. A prototype of these receptors is LDL receptor, which mediates the uptake and lysosomal degradation of plasma LDL, thereby providing cholesterol to cells. This is a cell surface transmembrane protein that binds LDL on apoprotein sites and carries it into the cell by receptor-mediated endocytosis. After binding LDL, the receptor–LDL complex is taken up, clustered, and then endocytosed by clathrin. Then, the vesicle is fused with an acidic endosome. The decrease in pH induces a conformational change in the LDL receptor, which releases the LDL cholesterol, and the receptors either are then destroyed or can be sorted into vesicles and returned to the surface of the cell. The remaining endosome is delivered to the lysosome, which is more acidic than endosome. Lysosomal enzymes degrade the protein component and hydrolyze the cholesterol esters. The liberated cholesterol can be used by the cell for the synthesis of plasma membranes, vitamin D, and steroid hormones or stored in the cytoplasm in the form of cholesterol ester droplets.

This mechanism is crucial for efficiently removing the excess LDL and maintaining desirable levels of LDL in blood. Therefore, it is important that cells express an adequate amount of LDL receptors on their surfaces and that their function is appropriate. Several genetic mutations in the LDL receptor diminish its function or reduce the number of receptors on the cell surface, leading to increased levels of serum LDL and hypercholesterolemia.

LDL Receptor Mutations

Mutations in the LDL receptor gene cause inherited disorder characterized by high serum cholesterol level, called familial hypercholesterolemia (FH). FH is principally an autosomal dominant disorder. LDL receptor is located on chromosome 19 at 19p13.1–p13.3, and more than 1000 mutations have been identified in this gene so far. In addition, mutations in two other genes also produce the FH phenotype: the apolipoprotein B-100 gene that codes the most important protein component of LDL and proprotein convertase subtilisin/kexin type 9 (PCSK9). Nevertheless, mutations in LDL receptor gene are more common and affect about 1 in 500 individuals. These genetic changes are classified in five broad classes according to the effect on LDL receptor function. Class 1 mutations affect the synthesis of the receptor in the ER, and these mutations are alternatively referred to as 'receptor-negative' mutations. In class 2 mutations, the LDL receptor is not transported from the ER to the Golgi that leads to the degradation of the receptor. In class 3 mutations, the binding of LDL to the receptor is improper. In class 4 mutations, the internalization of the receptor–ligand complex is inhibited, and in class 5 mutations, the internalized receptors cannot recycle properly. The classes

2–3 are often termed 'receptor-defective.' Class 5 mutations cause relatively mild phenotype of FH, since LDL receptors are still present on the cell surface, although they have to be newly synthesized. Classes 2 and 3 are identified as the most common.

Most people with FH are heterozygotes, having one normal copy of the LDL receptor gene and one mutated copy of the gene. These people have an increased risk of cardiovascular disease that typically begins in their forties or fifties. However, homozygotes have two mutated genes for the LDL receptor, inherited from both affected parents. In these people, clinical picture is more severe and their FH clinical onset of symptoms usually appears in childhood or adolescence.

HDL Cholesterol and Reverse Cholesterol Transport

Unlike LDL, HDL cholesterol is widely known as 'good cholesterol' because of its strong inverse association with the risk of cardiovascular disease. HDL particles play the largest role in removing cholesterol from the peripheral tissues to the liver, suppressing cholesterol accumulation in the peripheral tissues. The essential function of HDL cholesterol is the initiation of a multistep process, reverse cholesterol transport, via plasma to the liver, which processes the excretion of excess cholesterol from the body. Furthermore, many other atheroprotective activities have also been attributed to HDL, such as antioxidant, anti-inflammatory, hemostasis, and endothelial cell maintenance functions. It prevents oxidative modification of LDL, thereby reducing the generation of macrophage foam cells and atheroma plaque formation within the arteries. HDL also decreases the activity of macrophage chemotactic factor 1 that participates in low-grade systemic inflammation and signals the infiltration of monocytes to arterial walls. In addition, HDL acts opposite to LDL inhibiting platelet aggregation and enabling activity of nitric oxide synthase, which is also inhibited by oxidized LDL. Nevertheless, the most important function of HDL is the promotion of reverse cholesterol transport, especially removing cholesterol from atherosclerotic plaques. A number of epidemiological studies have suggested that low level of this lipoprotein induces the development of coronary artery diseases. On the contrary, high HDL cholesterol level is associated with the reduction of incidence of atherosclerosis and cardiovascular disease.

HDL constitutes a heterogeneous group of lipoproteins that differ in density, size, lipid composition, and apolipoprotein content, as well as electrophoretic mobility. Based on the electromobility determined by electrophoresis, HDL particles could be separated into two major subfractions, HDL2 and HDL3. Although the proteomics of HDL is very complex, the majority of HDL particles contain apolipoprotein A-I (apoA-I), which is the most abundant apolipoprotein in human plasma in healthy population. The second most abundant protein in HDL is apoA-II, which is also included in many HDL particles. In addition, over 85 other proteins have been identified so far, showing proteomic complexity and diversity of HDL that is related to numerous functions of HDL.

ApoA-I synthesis in the liver and intestine is the first step in HDL metabolism. The next step is the interaction of ApoA-I with cells expressing ABCA1, a member of the ABC transporter superfamily (ATP-binding cassette transporters) that transports the specific substrates across cell membranes utilizing the energy of ATP binding and hydrolysis. ABCA1 is situated at the plasma membrane and intracellular organelles, where it can facilitate transport of various molecules across extra- and intracellular membranes. Although studies in animal models of tissue-specific ABCA1 deficiency confirmed that hepatic ABCA1 was crucial for HDL biogenesis, nonhepatic tissues are also very important. The ABCA1 pathway not only is involved in lipid efflux from both peripheral and hepatic tissues but also is important for the formation of nascent HDL and maintenance of plasma HDL levels. At first, lipid-poor apoA-I removes free cholesterol from peripheral cells through ABCA1 transporter to generate nascent pre-βHDL. This particle, consisting of a phospholipid bilayer surrounded by a protein coat, has a great affinity for free cholesterol and collects cholesterol, which is then stored in the lipid bilayer. This process is enhanced by the activation of the lecithin–cholesterol acyltransferase enzyme, which esterifies free cholesterol stored in the bilayer with fatty acyl groups from lecithin (phosphatidylcholine), forming hydrophobic cholesterol esters. The obtained esters are moved to the hydrophobic core, which is growing up. During circulation, nascent HDL increases binding more cholesterol and phospholipids. The shape of HDL is then changing from the disk to a sphere in a complex process mediated by ABCG1, hepatic lipase, endothelial lipase, CETP, and phospholipid transfer protein. At this step, further cholesterol collection is ceased; mature spherical HDL particle is formed and recognized by the liver. Mature HDL interacts with other apoB-containing lipoproteins, such as IDL and VLDL. Thus, ABCA1 and its transporter are important for HDL metabolism, and the defective ABCA1 transporter due to mutations leads to severe reduction of HDL, a rare inherited disorder called the Tangier disease.

In humans, HDL cholesteryl esters are cleared from plasma via two major pathways. In the first one, CETP facilitates an exchange for triglyceride in HDL cholesteryl ester and transfer to LDL, which is returned to the liver through the LDL receptor-mediated pathway. The other way is nonendocytic hepatic uptake of HDL by scavenger receptor B1, multiligand receptor that binds not only HDL but also VLDL and LDL. The final step for the elimination of cholesterol from the liver is secretion into bile, either directly or after conversion to bile salts. Several transporters are involved in biliary cholesterol secretion, such as ABC transporters (ABCB11, ABCB4, and ABCG5/G8), the Niemann–Pick C1-like protein 1, the phosphatidylserine flippase, ATPase class I type 8B member 1, and the HDL cholesterol uptake receptor – SR.

Cholesterol-Lowering Drugs

Regarding the established role of the total and LDL cholesterol in atherosclerosis and CVD, the American College of Cardiology (ACC) and the American Heart Association (AHA) proposed in 2013 the guideline on the treatment of blood cholesterol to reduce atherosclerotic cardiovascular risk in adults. Atherosclerotic cardiovascular disease (ASCVD) includes coronary heart disease, stroke, and peripheral arterial disease. Healthy diet, maintenance of healthy weight, and lifestyle modification (regular exercise and avoidance of tobacco) are proposed as crucial

components in ASCVD risk reduction, both prior and with the use of cholesterol-lowering drugs.

The most used cholesterol-lowering drugs are *statins*, a large group of inhibitors of HMG-CoA reductase. A comprehensive meta-analysis from the Cholesterol Treatment Trialists' Collaboration of 27 randomized trials revealed that they reduced the risk of major coronary events by 24% for each 1 mmol l^{-1} reduction of LDL concentration, stroke by 15%, and coronary revascularization by 24%. It has been assumed that fully implemented public policies would result that more than a third of all middle-aged and older adults in the United States and United Kingdom will be recommended for statin therapy.

Statins act on crucial step of cholesterol biosynthesis, the mevalonate synthesis, which is regulated to ensure sufficient production of isoprenoids. The inhibition of cholesterol biosynthesis leads to raised expression of LDL receptors in liver cell membranes, enhancing clearance of the circulating LDL particles from blood, and to raised expression of PCSK9, an enzyme responsible for LDL receptor catabolism. Additional 'pleiotropic' effects of statins (such as reduced vascular and systemic inflammation, including sepsis, and reduced cancer risk) may result from the inhibition of the biosynthesis of isoprenoid intermediates and of small GTP-binding protein, thus influencing the signal transduction in membrane receptors involved in processes of cell proliferation, differentiation, and apoptosis. Statins downregulate antigen presentation and decrease T-cell activation and reduce antigen expression on endothelial cell and the levels of inflammatory cytokines TNF-α, IL-1β, IL-6, IL-8, NF-κB, and C-reactive protein. Furthermore, they reduce the production of reactive oxygen species, inhibit the production of thrombin and thrombomodulin, decrease plasminogen activator inhibitor-1 expression, and increase tissue plasminogen activator levels and tissue factor, thus leading to increased degradation of fibrin. The increased anticoagulation and fibrinolysis prevent endothelial cell disruption.

Statins are strongly recommended as secondary prevention in individuals with clinical ASCVD and as primary prevention in individuals with primary elevation of LDL above 4.9 mmol l^{-1}, in individuals with diabetes, and in those with estimated 10-year ASCVD risk $\geq$7.5% with LDL concentration 1.8–4.9 mmol l^{-1}. High-intensity statin therapy on average lowers LDL by $\geq$50%, moderate-intensity statin therapy lowers LDL by 30–50%, and lower-intensity statin therapy lowers LDL by approximately <30%. In people over 75 years of age, high-intensity statin therapy in secondary prevention is not recommended. These drugs are not routinely recommended for individuals with NYHA class II–IV heart failure or who are receiving maintenance hemodialysis.

Statins are metabolized by cytochrome P450 pathway and thereby occasionally may cause hepatotoxicity (<3% of patients) and myopathy (<0.2% of patients), and in <0.05% of statin-treated patients, muscle injury leads to rhabdomyolysis, myoglobinuria, and renal failure. After over 25 years of wide use of statins, it is proved that benefits of statin therapy are of far greater significance than the risk of adverse effects of statins such as muscle weakness, impairment of hepatic function, the increased incidence of type 2 diabetes, and cataract.

Approved nonstatin agents for LDL reduction include *bile acid-binding resins* (colestipol, cholestyramine, and colesevelam), which have the advantage of not being absorbed systemically and can be used in pregnancy; *fibrates* (fenofibrate, bezafibrate, and gemfibrozil), which mainly decrease triglycerides and increase HDL; *niacin*, which slightly decreases LDL and triglycerides while increasing HDL; *cholesterol absorption inhibitor* ezetimibe, which acts on epithelial Niemann–Pick C1-like protein; and *omega-3 fatty acid* supplements. Although these agents can clearly improve lipid profiles in many patients, contemporary event reduction trials have shown little evidence to support their use either as monotherapy or as an adjunct to statins in general population.

The new agents – mipomersen and lomitapide – were approved in 2013 by the US Food and Drug Administration to treat patients with homozygous FH. *Mipomersen* is an antisense oligonucleotide that binds to a specific 20-base sequence on messenger RNA coding for apolipoprotein B-100. *Lomitapide* is an inhibitor of microsomal triglyceride transport protein assisting in the transfer of triglyceride to apolipoprotein B and also reduces circulating LDL cholesterol by targeting VLDL production.

CETP inhibitors such as anacetrapib and evacetrapib are very effective in raising HDL (>100% in phase 3 trials), but their effects on HDL function are not fully understood, although some data suggest that they have the potential to promote cholesterol efflux capacity. They are also effective in reducing LDL levels (>30%) and concentrations of Lp(a).

The most promising novel agents effective in LDL reduction are *monoclonal antibodies targeting PCKK9*, a protein secreted by hepatocytes that binds to the LDL receptors leading to its cellular internalization and lysosomal degradation. The inhibition of PCSK9 also reduces Lp(a). Three large randomized control human trials on safety and efficacy of alirocumab, bococizumab, and evolocumab are currently ongoing.

Introduction

Whole-body cholesterol balance is regulated by the net effects of dietary cholesterol absorption, *de novo* cholesterol biosynthesis, and whole-body cholesterol clearance, mostly by biliary excretion from the liver.

In the intestinal tract, cholesterol originates from two sources: food intake and biliary secretion into the duodenum. Several proteins in the brush border membrane of enterocytes are involved in mediating intestinal cholesterol absorption. Whereas various transporters, including fatty acid translocase/cluster determinant 36, scavenger receptor class B type I (SR-BI), and Niemann-Pick C1-like 1 (NPC1L1), may influence cholesterol uptake, the ATP binding cassette (ABC) transporter family, including several cholesterol carriers (ABCA1, ABCB1, and ABCG5/G8), act as efflux pumps favoring cholesterol export out of absorptive cells into the lumen or basolateral compartment. Among all the cholesterol transporters, the enriched NPC1L1 protein in the apical membrane of enterocytes is considered essential for intestinal cholesterol absorption, and genetic modifications of NPC1L1 in cultured intestinal cells alter cholesterol uptake.

Although all tissues in the body are capable of synthesizing cholesterol from acetyl coenzyme A (CoA), the liver is the main site for *de novo* cholesterol synthesis and stores it as cholesterol ester after esterification by acetyl-CoA acetyltransferase. The major rate-controlling enzyme in hepatic cholesterol synthesis is 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA) reductase, which is used as a pharmacological target of statin treatment.

Cholesterol, as a water-insoluble molecule, needs to be transported in the plasma associated with various lipoprotein particles, such as chylomicrons, very low-density lipoproteins (VLDLs), intermediate-density lipoproteins (IDLs), low-density lipoproteins (LDLs), and high-density lipoproteins (HDLs). Approximately 60–80% of cholesterol is transported through the bloodstream in the core of LDL particle. On the other hand, crucial molecules in cholesterol transport are apolipoproteins located on the surface of LDL particles. Each LDL particle contains one molecule of apoB, a lipoprotein responsible for carrying cholesterol to peripheral tissues and binding to LDL receptors. Since more than 90% of the removal of LDL takes place in the liver, the liver determines the rates of LDL clearance from plasma. Hence, the liver is the only organ capable of eliminating excess cholesterol from the body, by either secretion into bile or conversion into bile acids. The movement of excess cholesterol from peripheral tissues to the liver is a result of reverse cholesterol transport (RCT), which is promoted by HDL particles.

The body maintains a stable cholesterol pool by regulating mechanisms of absorption, synthesis, and elimination. The dominant factor that determines cholesterol absorption in the small intestine is intake. Hence, when dietary cholesterol intake is very low, its absorption is upregulated. Conversely, if dietary intake is too high, absorption is decreased and biliary excretion is intensified. The percent of cholesterol absorbed in healthy subjects vary significantly from person to person from 29% to 80%. However, about 25% of the population has exaggerated response to an overload of dietary cholesterol. Additionally, among dietary and genetic factors, many physiological and pathological conditions can influence plasma cholesterol levels.

Aging

Numerous studies have demonstrated that regardless of physical activity levels and nutritional status, levels of plasma total cholesterol rise progressively with age. Plasma LDL cholesterol (LDL-C) levels increase progressively from young adulthood to approximately age 60 in men and to age 70 in women. Prolonged intestinal transit time may be a factor for increasing cholesterol absorption with aging. Slow intestinal transit is associated with an increased rate of bacterial biotransformation of bile acids, with enhanced enterohepatic recirculation of deoxycholic acid. At the same time, diet rich in cholesterol and saturated fatty acids (SFA), usually presented in elderly subjects, can be the reason for increased cholesterol absorption. Another possible explanation could be a gradual reduction in the rate of LDL clearance from the circulation, presumably as the result of a reduced activity of LDL receptors, diminished number of functioning hepatic LDL receptors, and prolonged turnover time ('downregulation') of the recirculating LDL receptors. In response to cholestyramine, a bile acid-binding agent, the elderly can reach the same values of LDL clearance as younger individuals, which explains that they still have the capacity for 'upregulation' of hepatic LDL receptors. Another explanation for reduced LDL receptor expression may be a consequence of a reduced hepatic demand for cholesterol, due to a reduced bile acid synthesis occurring with age. In mice, aging increases biliary cholesterol secretion and reduces level of hepatic bile acid synthesis, which hence increases the susceptibility of developing cholesterol gallstones in elderly animals. This finding may be explained with the decreased activity of hepatic 7-α hydroxylase, an enzyme that metabolizes cholesterol to biliary salts. Some of the rise in LDL-C levels with age could be related to the sedentary lifestyle and increase of body weight, which is typical in older population. In addition, various concomitant diseases (diabetes mellitus, hypothyroidism, and nephropathy) and commonly used drugs more frequently present in the elderly population are associated with hypercholesterolemia. Also, it has been shown that growth hormone (GH) has key roles in cholesterol metabolism

and that its secretion is reduced with aging. Experiments performed in rodents have demonstrated that the administration of GH is able to completely reverse age-dependent increase in plasma cholesterol and the reduced levels of bile acid synthesis to the same level as seen in young animals.

Gender

Compared with men, women have lower levels of LDL-C and VLDL cholesterol and higher HDL cholesterol (HDL-C) levels. There is no difference in cholesterol absorption fraction between men and women. Lower concentrations of LDL-C are associated with accelerated LDL production and enhanced LDL clearance, which may be explained with higher levels of estrogens in women. Studies in rats have shown that estrogen treatment is followed by an increase of hepatic LDL receptors and a faster clearance of LDL particles. The sex difference in HDL concentrations is associated with greater synthesis rate of apolipoproteins A-I and A-II, major proteins of HDL particle responsible for fat efflux from peripheral tissues to the liver. It has been shown that postmenopausal women have higher plasma cholesterol levels than premenopausal women of the same age. In postmenopausal women, the decrease in plasma estrogen levels after menopause may play a significant role in the reduction of the clearance of LDL particles and subsequent increase of LDL-C. Estrogen replacement treatment has been shown to markedly decrease LDL-C in dyslipidemic postmenopausal women. Sexual dimorphism in cholesterol metabolism cannot be explained only by the different levels of sex hormones. There are studies that showed that surgically induced menopause without hormone replacement therapy has no effect on plasma cholesterol concentrations when compared with surgical control group (hysterectomy with conservation of the ovaries). There are seemingly many factors that need to be explored in the future, and one of them is certainly the difference in insulin action between men and women, with higher rate of circulating insulin and therefore greater suppression of lipolysis in women. It is unlikely that differences in body composition are responsible for this phenomenon, because sex differences in cholesterol metabolism exist even they are matched for percentage of body fat. Androgen action is most likely not responsible for the sex differences in plasma LDL-C concentration. Testosterone administration is associated with only modest reduction of LDL-C concentration when given to hypogonadal men in replacement doses and has no effect on LDL-C concentration in eugonadal men.

Genetic Factors

Serum lipid levels are associated with genetic factors. It has been estimated that genotype participates with around 40–60% in the serum total cholesterol variability. There is growing evidence about association between 95 genetic loci and LDL-C, HDL-C, and triglycerides, discovered in genome-wide association studies. In the Framingham Heart Study (FHS), offspring and third-generation cohorts (3110 participants) of middle-aged to elderly adults with available genomic DNA were genotyped for lipid single-nucleotide polymorphisms (SNPs), and genetic risk scores (GRS) were calculated for each individual and lipid fraction. The results showed modest association between lipid GRS and corresponding lipid, which was the strongest with the long-term average lipid measure, and between HDL-C GRS and TG GRS. Lu et al. investigated whether common genetic variants in genes involved in cholesterol metabolism could predict the plasma cholesterol levels. They found that out of 361 SNPs in 243 genes, 23 SNPs were associated with plasma total cholesterol levels. The results of the study with the multiple gene approach reported that 10 out of 17 candidate genes were associated with lipid levels in Caribbean Hispanic subjects, where the genetic variants on three genes, APOA5, APOB, and CYP7A1, accounted for the largest proportion of lipids variation. The longitudinal cohort of black and white siblings, enrolled in the Bogalusa Heart Study, showed association of long-term levels and trends of LDL-C with chromosomes 1 and 19. There are several evidences of strong connections between ten common variants in the genes for LPL, CEPT, and APO and plasma lipid concentrations in children according to the Gene–Diet Attica Investigation on childhood obesity (GENDAI). Significantly higher total cholesterol and LDL-C were observed in APOE $\epsilon 4$ carriers compared to $\epsilon 3/\epsilon 3$ homozygotes and $\epsilon 2$ carriers. The association of APOE genotype with total cholesterol/HDL-C ratio was further modulated by body mass index (BMI). Carriers of the cholesteryl ester transfer protein (CETP) TaqIB B2 allele had significantly higher HDL-C and lower total cholesterol/HDL-C ratio compared to B1/B1 individuals. Suggested potential prediction of lifelong exposure to an adverse lipid profile in children is very important for applying precautionary principle and preventive measures.

Dietary Factors

Modern diet is characterized by the high intake of SFA, refined starches and sugars, both known to have adverse effect on serum lipids levels. In addition, the human diet contains a large portion of oxidized fatty acids and oxidized cholesterol because of the food processing (e.g., frying and heating).

Lipid Intake

It is clear that plasma cholesterol levels correlate to the quality and quantity of dietary lipid intake. Tarahumara and Guatemalan Indians who are consuming a diet low in fat exhibit low serum total cholesterol and LDL-C. However, when these people are placed on typical Western diet, their total cholesterol and LDL-C increase and synthesis of VLDL increased, mainly due to increased flow of free fatty acids (FFA) to the liver. In subjects with increased BMI, it has been demonstrated that excess body weight correlates with increased synthesis and turnover of cholesterol in the adipose tissue.

SFA and Cholesterol

Effects of dietary fats and cholesterol on circulating cholesterol levels, among others, depend on the type of fats and individual characteristics. A high intake of dietary cholesterol increased fasting LDL levels by $\sim$10% in a dose-dependent manner, while 12% reduction of fasting LDL levels reduced coronary

risk by 19%. It was estimated that each 100 mg increase in dietary cholesterol intake resulted in an increase of 0.05 mmol l^{-1} in serum LDL-C concentration. On the other hand, very-low-fat diets caused dyslipidemia (high triglycerides and low HDL-C concentrations). In the 'Great Fat Debate,' scientists emphasized that the adequate replacement of SFA in diet is crucial in terms of reduction of LDL-C and cardiovascular risk. The general recommendation is to minimize dietary saturated fat by displacing it with unsaturated fat, primarily polyunsaturated. However, in practice, people usually replace it with refined carbohydrates, which also increase cardiovascular risk.

Polyunsaturated and Monounsaturated Fatty Acids

The beneficial effect of unsaturated fatty acids on lipid metabolism in man is well documented. Supplementation of diet by linoleic acid ($n-6$) leads to a decrease in total cholesterol, LDL-C, and HDL-C levels and in LDL/HDL ratio. Lowering effect on serum total cholesterol and LDL-C could come from polyunsaturated and monounsaturated fatty acids from the corn oil. Favorable fat content from the corn oil positively influence HDL-C, rising its level and also increasing ratio of HDL-C to total cholesterol and decreasing ratio LDL-C to HDL-C. The ($n-3$) fatty acids have an effect different from that of the ($n-6$) fatty acids, in that they enhance HDL-C levels. The effects of $n-3$ PUFA on circulating levels of plasma lipoproteins have been shown to be variable. No consistent changes have been observed in LDL-C or HDL-C concentrations with $n-3$ PUFA consumption. Greater part of this variability is attributed to a lack of control of confounding factors such as dietary cholesterol, fat level, and fatty acid composition. The most comprehensive study evaluating benefits of fish oil (i.e., EPA + DHA) supplementation represents meta-analysis comprising 47 placebo-controlled randomized trials, which found clinically significant reduction of triglycerides (by 0.34 mmol l^{-1}), no change in total cholesterol, and slight increases in HDL-C and LDL-C (by 0.01 and 0.06 mmol l^{-1}, respectively) in hyperlipidemic subjects. Another meta-analysis of 21 trials evaluating lipid outcomes after fish oil consumption found net change in triglycerides (0.30 mmol l^{-1}), HDL-C (0.04 mmol l^{-1}), and LDL-C (0.15 mmol l^{-1}) and no effect on total cholesterol. According to previous reports, the mechanisms by which dietary $n-3$ PUFA may induce changes in plasma LDL-C levels by decreasing absolute rates of LDL synthesis and catabolism without any effect on the fractional catabolic rate. Studies using rats have shown that consumption of fish oils alters hepatic LDL receptor expression. Now, it is known that the effect of EPA/DHA on blood lipids (including cholesterol) is based on the action of these $n-3$ PUFAs as ligands of the various PPAR isoforms and on the modulation of the signaling pathway of the transcription factor SREBP. Principal transcription factor that binds the promoter region of the genes coding for proteins controlling cholesterol homeostasis is SREBP-2. However, the fact that since SREBP-2 is not directly ligated by DHA (EPA), a relationship between PPARa ligation and SREBP-2 activation is presumed and is still not unequivocally explained. The last relationship is possibly species-dependent. Furthermore, the more efficient absorption of dietary cholesterol by rodents compared to humans may account for the differences in the extent of observed increases in LDL-C. The limited but rather consistent increases reported in LDL-C in humans consuming fish oils may be due to the relatively small proportion of dietary cholesterol being delivered to the liver compared to the amount delivered to the livers of hamsters. Improvement of HDL-C together with insulin resistance index HOMA (homeostasis model assessment) was noted in hemodialyzed patients, after EPA + DHA supplementation. That was explained by probably activation of PPAR isoforms and consequently improving insulin signaling on postreceptor level. It was shown that consumption of fatty seafood can modulate fasting insulin, ghrelin, and leptin during an 8-week intervention in obese young adults. Effects were partly gender-specific, and the most consistent effect on circulating hormones was mediated by weight loss. PPARα agonists are the center of a regulatory hub impacting fatty acid uptake, fatty acid activation, intracellular fatty acid binding, mitochondrial and peroxisomal fatty acid oxidation, ketogenesis, triglyceride turnover, lipid droplet biology, gluconeogenesis, and bile synthesis/secretion.

Therefore, it is important to understand the effects of dietary $n-3$ PUFA on cholesterol metabolism and circulating lipid levels and their interrelation with other dietary components, so that the beneficial effects of $n-3$ PUFA are not compromised.

As to the influence of oleic acid ($n-9$), controversial results have been published. Some authors did not see modification of HDL-C levels, but others showed an increase of HDL-C especially after an olive oil regime. Significant increase of HDL-C and apo A1 levels among walnut consumers without modified regular diet was established. The increase of HDL-C may be due to the fatty acid composition of walnuts, as it provides mostly linoleic acid ($n-6$), alpha-linolenic acid ($n-3$), and oleic acid ($n-9$), or might be related to the nature of the protein amino acids.

Dietary Fiber, Soy Protein, and Plant Sterols

The serum levels of total cholesterol, LDL-C, Apo A1, and Apo B were significantly lower in one Chinese ethnic group, who consume diet primarily based on corn and then on rice, soy, buckwheat, sweet potato, and pumpkin products, compared with another Chinese ethnic group, who primary consume rice and then corn, broomcorn, potato, and taro products, which are more harmful for lipid profile. Corn-based diet of the first group is rich with dietary fiber that reduces serum total cholesterol level in healthy and hyperlipidemic subjects and with plant high-quality protein that might raise serum HDL-C levels and promote the transportation and excretion of free cholesterol.

Consumption of soy protein significantly decreases concentrations of total cholesterol, LDL-C, and triglycerides in circulation. It was shown that after 24 weeks of treatment based on soybean, patients with combined hyperlipidemia, isolated hypercholesterolemia, and isolated hypertriglyceridemia have decreased LDL-C level by 38%, 32%, and 8%, respectively. Results of the meta-analysis showed association of soy protein with significant decreases in serum total cholesterol by 77%, LDL-C by 5.25%, and triglycerides by 7.27% after short initial period and significant increases in serum HDL-C by 3.03% after more than 12 weeks of consumption. A better effect on the lipid profile was found after intake >80 mg. Dietary fiber from fruits, vegetables, and whole-grain products lowers levels of total

cholesterol and LDL-C possibly through the bile acid metabolism and alteration in serum sex hormone concentrations.

Plant sterols (around 2 g day^{-1}) have been shown to block intestinal absorption of cholesterol and lower total plasma LDL-C.

In nutritional epidemiology, examining the relation between diet and its effect should not be focussed on the intake of single nutrients, food items, or food groups, but should be focussed on the overall diet and food preparation methods and eating patterns. If we want to achieve healthy serum lipid levels and prevent chronic diseases, we should follow general diet recommendations to consume great amount of fruits, vegetables, nuts, and fish; moderate amount of dairy and vegetable oils; and whole-grain foods in place of refined starches and sugars and to avoid sugar-sweetened beverages, processed meats, and foods that contain partially hydrogenated vegetable oils.

Alcohol Consumption

Serum lipid level is associated with alcohol consumption. Effects depend in part on the amount of consumed alcohol, so that moderate intake protects individuals against cardiovascular diseases. Alcohol consumption was the independent negative risk factor for insulin resistance and improved lipid profiles that are known to be worsened by insulin resistance. The increase in HDL-C and decrease in LDL-C in drinkers result from the inhibition of CETP that promotes transfer of cholesteryl ester from HDL to VLDL (a precursor of LDL) and LDL. Inconsistent results among earlier studies may partly result from variability in the prevalence of obesity among subgroups and according to the amount or frequency of alcohol consumption. Harmful effect of heavy alcohol consumption may be attributable to increased triglyceride synthesis.

Coffee Consumption

Coffee is consumed as a beverage worldwide; however, its effect as a cardiovascular risk factor is still controversial. Roasted coffee contains naturally present antioxidants and others that are formed during the roasting process. Chlorogenic acids and caffeine may play a role in the inhibition of lipid peroxidation, free radical scavenging, and anti-inflammatory activity. However, coffee also contains diterpenes, cafestol, and kahweol. High consumption of these compounds can raise serum levels of total cholesterol and LDL-C. Most of them are retained by the paper filter, which substantially reduces the cholesterol-raising effects. It should be mentioned that instant coffee was associated with lower serum concentrations of total cholesterol and higher serum LDL-C level. Average change in total cholesterol for each cup ranged from 0.007 to 0.026 mmol l^{-1}. When examining the effects of coffee beverage on serum lipoprotein levels, we should take into account coffee preparation such as the use of milk, sugar, ice cream, and alcohol.

Physical Activity

The sedentary lifestyle is one of the principal risk factors of highly prevalent illnesses such as type 2 diabetes, cardiovascular disease, osteoporosis, and some cancers. Association between sedentary lifestyle and the current pandemic of obesity and metabolic syndrome is clear. Attempt to exactly measure the effect of sedentary lifestyle on metabolic syndrome and other cardiovascular risk factors, based on duration of leisure-time physical activity, have shown that even 25 min day^{-1} produces benefits, better HDL-C function or higher level of paraoxonase 1 activity. The difference for glycemia, total cholesterol, and HDL-C level disappears after adjustment for age, gender, and cigarette smoking. However, low physical fitness among young adults has been shown to longitudinally predict hypercholesterolemia and, among middle-aged adults, hypertension. This association was attenuated when adjusted for obesity.

Seasonal variation in physical activity has been reported to coincide with seasonal changes in blood lipid levels, particularly total cholesterol. Environmental changes in ambient temperature, daylight, and monthly precipitation are thought to induce seasonal changes in physical activity, particularly by extreme environmental factors (e.g., hot or cold temperatures). Significant increase in nonoccupational activity due to yard work and exercise or recreational activities was noted during the warmer months. Estimates of the amplitude of seasonal variation in activity energy expenditure in this report were consistent with those in the Framingham Offspring Study. The FHS is a population-based prospective family study that began in Framingham, MA, in 1948 with the recruitment of the Original Cohort. In 1971, children of the Original Cohort, called the Offspring Cohort, were enrolled, and finally, in 2002, the grandchildren of the Original Cohort were enrolled making the FHS the longest-running family-based study in history. For the past 62 years, investigators at the FHS have collected data related to CVD and its risk factors. Recent public health recommendations have noted the importance of environmental factors as potential barriers to regular participation in healthful levels of such activity.

Environmental Contaminants

There are increasing evidences of the role of environmental contaminants (e.g., heavy metals and persistent pollutants) in serum lipid level variation. Nonoccupational exposure to various chemicals can occur through contaminated drinking water, foods, air, and cigarette smoking, and even low-level exposure may be harmful to health. Hereafter, examples of the influences of the most common contaminants on lipid metabolism will be described.

Arsenic is widely distributed in the environment and usually contaminates drinking water sources. Experimental studies on rats have shown an increase in total cholesterol level after 10–20 weeks of exposure to arsenic, added as arsenite or arsenate in drinking water. This effect becomes more significant under high-cholesterol diet and when the exposure occurs earlier in life. Mechanism by which arsenic modifies cholesterol metabolism has not been yet elucidated. Possible way is modulation of RCT that transfers cholesterol from the periphery back to the liver by modifying the densities of cholesterols.

Altered lipid metabolism (low HDL-C, hypertriglyceridemia, and high total cholesterol and LDL-C level) may be a

consequence of chronic *cadmium* exposure, possibly due to decreased plasma lipoprotein lipase activity and increased activity of HMG-CoA reductase.

The results of relationship between blood *lead* level and serum cholesterol and lipoprotein levels are conflicting. Occupational exposure to lead was positively associated with levels of total cholesterol and HDL-C. Lead-exposed patients had decreased total cholesterol and LDL-C and increased HDL-C levels. Recently, an association between blood lead and total cholesterol based on an age-adjusted model has been confirmed.

Fat-soluble chlorinated *organics*, such as dioxins, furans, polychlorinated biphenyls (PCBs), and chlorinated pesticides, were related with unfavorable serum lipid levels. Correlation between serum PCBs levels and plasma lipid levels was firstly showed in occupational studies. The strong relationship between PCBs levels and cholesterol and triglycerides was reported with average value for the sum of PCB congeners of 4.2 μg. The proposed mechanisms by which PCBs affect serum lipids are the activation of certain cytochrome P450 enzymes and increased synthesis of lipids.

Perfluorooctanesulfonate (PFOS) used as surfactant in a wide variety of commercial products has been recently recognized to disrupt serum lipid level. Positive association between plasma concentration of PFOS and serum concentration of HDL-C and negative association with total cholesterol/HDL-C ratio and triglycerides level were reported. The possible pathway is peroxisome proliferation, leading in hepatotoxicity and alteration of lipids homeostasis.

It was postulated in the systematic association study about broad environmental correlation to lipid levels. There was favorable association of HDL-C (3–4% higher HDL-C) with iron and mercury exposure and unfavorable association with PCBs, dibenzofurans, organochlorine pesticides, and all persistent organic pollutants. Multiple environmental factor analysis enabled better understanding of their relationship with characteristics in the general population.

Cigarette Smoking

Cigarette smoking is a well-known risk factor for atherosclerosis and may influence serum lipid levels. Significant increase in serum total cholesterol, triglycerides, VLDL, and LDL-C and decrease in protective HDL were reported among chronic smokers, hypertensives, and chronic smokers with high blood pressure. However, confounding factors such as diet, BMI, stress, alcohol consumption, and physical activity have not been controlled in some studies. The effect of smoking on the serum lipid profiles may be influenced by age, gender, and different smoking statuses. It was found that smoking was associated with lower total cholesterol and LDL-C levels in elderly men and in middle-aged women and also with decreased HDL-C levels in 65–74-year-old men and 55–64-year-old women when compared with nonsmokers. The data from meta-analysis were in contrast due to differences in study populations and their dietary habits, physical activities, lifestyle, or public health awareness. Positive association between current smoking and dyslipidemia was reported in women but not in men. Further, current female smokers in the age groups between 20 and 34 years and of 50 years or older have had the highest risk of dyslipidemia. The possible reason for gender difference in the association between cigarette smoking and unfavorable serum lipid levels could be an interaction of some hormonal factors with components of the inhaled smoke. The nicotine provokes the secretion of catecholamines and other hormones (e.g., cortisol and GH) leading to an increased serum concentration of FFA, which stimulates hepatic secretion of VLDL and triglycerides. Cigarette smoke has great oxidative potential and can promote oxidative modifications in LDL and other biomolecules and may contribute to additional endogenous oxidant formation, through its effects on the inflammatory-immune response. Some natural antioxidants such as dietary polyunsaturated fats and vitamin E are connecting with lower risk for atherosclerosis, although they may contribute to lipid oxidation in smokers. Further studies are needed to explain the mechanism by which cigarette smoke changes serum lipid levels and what are the most responsible substances for these changes, since cigarette smoke besides nicotine contains multiple toxic compounds.

Stress

Serum cholesterol levels are changing under emotionally stressful situations. Numerous studies have demonstrated that acute and chronic stressors are related in alterations in cholesterol concentrations. Investigators have established a negative link between cholesterol and psychological and physical aggressions. However, there is a positive correlation between cholesterol and psychological stress. This correlation can be explained with increased peripheral fat tissue lipolysis caused by heightened sympathetic nervous system activity and increased levels of catecholamines, glucocorticoids, and glucagon. The final result of these processes is increased release of fatty acids into the circulation. In contrary, deficit of serotonin and lower cholesterol levels have been implicated with physical aggression and increased incidence of accident, suicide, and homicide. The possible explanation can be that in primitive man, cholesterol served as a sentinel compound for survival. Hence, when primitive man was experiencing lack of food, low blood cholesterol was leading and preparing him for food seeking and increased risk in hunting. Chronic stress induces both functional and structural adaptations within the hypothalamo–pituitary–adrenal axis that are suggestive of long-term alterations in neuroendocrine reactivity to subsequent stressors. Experimental evidence of chronic stress-induced hyperlipidemia in animal models has been documented by significant increases of blood total cholesterol, LDLs, and triglycerides and decrease in HDLs concomitant with increased oxidative stress.

Diseases

Obesity

It is hard to interpret the influence of obesity itself on cholesterol metabolism, due to the confounding of metabolic disorders accompanied with this condition. Abnormalities, such as hypertriglyceridemia, hyperglycemia, and insulin resistance,

commonly seen in obese population, may affect the distribution and size of lipoprotein particles independently of adiposity. The typical dyslipidemia observed in obesity does not include total cholesterol level disturbances. Obesity is characterized by the higher development of small dense, more atherogenic LDL particles. Viscerally, obese men were found to have significantly reduced LDL receptor binding of lipoproteins compared with lean healthy controls. Although hypercholesterolemia is not a concomitant feature of insulin resistance and obesity, both of them are characterized by decreased expression of hepatic LDL receptors due to higher rates of hepatic cholesterol synthesis and diminished cholesterol absorption.

Many studies show that total cholesterol and LDL-C concentrations respond more weakly to diets low in saturated fat and cholesterol in obese than in lean subjects, due to large amount of cholesterol in the enterohepatic pool in obese people. Additional amount taken in with the diet would not be recognized as small to activate hepatic LDL receptors, and hepatic LDL receptors are most probably suppressed by this large stream of endogenous cholesterol from enterohepatic circulation. Therefore, the most effective way for the obese to normalize their blood cholesterol is to lose weight. This shows us that cholesterol metabolism is tightly regulated so that if cholesterol synthesis is upregulated, cholesterol absorption is diminished and vice versa.

Diabetes Mellitus and Metabolic Syndrome

Considerable attention has been focussed on dyslipidemia accompanying diabetes and metabolic syndrome. Metabolic syndrome is generally characterized by abdominal obesity, insulin resistance, hypertension, and blood lipid disorders including high TG and low HDL-C, high apoB, and small dense LDL-C. Metabolic syndrome is associated with increased endogenous cholesterol synthesis and reduced intestinal cholesterol absorption predominantly as a consequence of visceral obesity, independently of overall obesity. It has been proposed that hyperinsulinemia in insulin resistance may upregulate the expression of SREBP-1c, a transcription factor that stimulates the synthesis of fatty acids and the production of VLDL particles. However, SREBP-2, another transcription factor that upregulates *de novo* cholesterol synthesis, does not appear to be affected by hyperinsulinemia or hyperglycemia. Besides elevated liver VLDL production, decreased postprandial triglyceride metabolism represents a major pathway of the hypertriglyceridemia that characterizes diabetic condition. Increased cholesterol absorption has also been reported in type 2 diabetes with slightly increased concentrations of total cholesterol and LDL-C. It has been shown that changing carbohydrate content of a mixed meal altered the postprandial accumulation of chylomicrons. Furthermore, a high glucose level alters the genetic expression of various genes involved in HDL metabolism in HepG2 cells, including human ABCA1, SR-BI, and hepatic lipase.

Cushing Syndrome

It is well known that chronic overt hypercortisolism, as in Cushing syndrome, is characterized by systemic alterations leading to increased risk of metabolic and cardiovascular diseases. Cortisol excess could inhibit insulin secretion, glucose uptake, and glycogen synthesis; worsen insulin sensitivity; and increase gluconeogenesis. However, it was hypothesized that adrenal incidentaloma (the presence of adrenal mass and patient has no signs of hormonal excess or obvious underlying malignancy) may be itself an unrecognized manifestation of the metabolic syndrome. The pattern of dyslipidemia in Cushing syndrome is the same as in metabolic syndrome or in type 2 diabetes.

Hypothyroidism

Hypothyroidism is associated with increased TC and LDL-C due to limited synthesis of the LDL hepatic receptors. Also, the activity of HMG-CoA reductase is significantly lowered, which may explain the poor response to hypolipemic treatment.

Acromegaly

Patients with acromegaly have a relative risk to present glucose alterations, with a 2.6 times and 2.1 times higher risk of impaired glucose tolerance and diabetes, respectively, than the general population, and show a higher prevalence of hypertriglyceridemia and low HDL-C. Active acromegaly in women is strongly associated with higher visceral adiposity dysfunction, insulin resistance, and the features of MetS; therefore, more careful metabolic management is suggested in acromegalic women.

Chronic Renal Failure

The typical dyslipidemia in *chronic renal failure* is characterized by hypertriglyceridemia and low levels of HDL-C, as the result from decreased lipoprotein lipase activity. The decreased level of hepatic lipase observed in renal failure may account for the presence of IDLs and the high HDL2 subfraction. The pattern of dyslipidemia depends on the degree of proteinuria and the kind of terminal renal failure treatment. Total and LDL-C can also be increased, with a predominance of the small dense LDL in the event of proteinuria or peritoneal dialysis.

Drugs

Many drugs, besides lipid-lowering drugs, can affect serum cholesterol levels. It has been reported that thiazide diuretics increase total and LDL-C levels by 5–10% in a dose-dependent way. These side effects are short term and not contraindication for their use. Loop diuretics have a similar effect. In contrary, the use of potassium-sparing diuretics and indapamide shows no changes in cholesterol levels. The effects of beta-blockers on total cholesterol and LDL-C are negligible. Furthermore, they could decrease HDL-C by ~5–20%. However, Celiprolol, a selective beta1 blocker with weak beta2 sympathomimetic activity even improves the lipid pattern. The only antihypertensive agents that lower total and LDL-C levels are alpha1-blocking agents.

Oral estrogen preparations given to postmenopausal women, premenopausal women, women with polycystic ovary syndrome, men with prostatic carcinoma, and male-to-female transsexuals reduce total and LDL-C and increase HDL-C levels.

Combined (estrogen/progestogen) hormone replacement therapy has similar effect. Tamoxifen, a selective receptor estrogen modulator, beneficially affects both total cholesterol and LDL-C, by decreasing them, due to its partial estrogenic activity. Danazol, a drug that is used in treatment of endometriosis, induces an increase of LDL and decrease of HDL-C level. Isotretinoin treatment increases LDL and total cholesterol levels by ~15% compared to pretreatment levels. Patients treated with immunosuppressive therapy (cyclosporine, azathioprine, and corticosteroids) show increased level of total cholesterol, LDL-C, and HDL-C in spite of the combination of drugs and gender of the patient. The largest effect on cholesterol metabolism has cyclosporine in female population, and it is associated with small dense, more atherogenic LDL particles. Tacrolimus does not affect total cholesterol and LDL-C levels.

Protease inhibitors, especially ritonavir, increases total cholesterol level by 30–40%.

Considering anticonvulsive therapy, carbamazepine seems to have most effect on TC levels, which are more pronounced in women and independent of the dosage. Contrary, valproic acid is the only anticonvulsant with a more favorable effect on the lipid profile.

Conclusions

In this article, we try to summarize all factors that determine cholesterol balance in the body, from absorption, to synthesis, to clearance. Some of them, as age, gender, and unbalanced food with more saturated fats and refined carbohydrates, are well known. However, there is growing amount of evidence about the benefit effect of diet, which contains more fatty seafood, corn, soy protein, olive oil, and dietary fiber from fruits, vegetables, and whole grain. Maybe, it is possible to improve, by epigenetic impact with regular diet, known specific genetic variants of genes involved in cholesterol metabolism in childhood. We also emphasize that improvement of low physical fitness could reduce hypercholesterolemia. In the future, we have to pay attention to environmental contaminants (e.g., heavy metals and persistent pollutants) that are able to influence lipid metabolism.

Properties

Introduction

Cholesterol is the most highly regarded small molecule in biology because of the great research effort by multidisciplinary scientists and the number of highly decorated research awards, especially the 13 Nobel Prizes, bestowed upon those scientists dedicating their work to study the structure, biosynthesis, biological functions, absorption and metabolism, and quantification of this fascinating molecule. Cholesterol, a complex four-ring molecule with essential biological functions, is surprisingly synthesized from the most basic two-carbon substrate, acetate (Figure 1). Although being an essential cellular component of animal tissues and the sole precursor of many steroid hormones, cholesterol creates various health complications by being oxidized or accumulating elsewhere excessively, such as in the artery wall, which are preconditions to the formation of atherosclerosis. Cholesterol was first discovered in 1815 as a component of human gallstones by the French chemist M.E. Chevreul. The structure of cholesterol was correctly identified in 1932; however, the process amazingly had begun decades before without modern technologies such as nuclear magnetic resonance. From then on, using isotopic tracers, the discovery of various biosynthetic and metabolic pathways of cholesterol began.

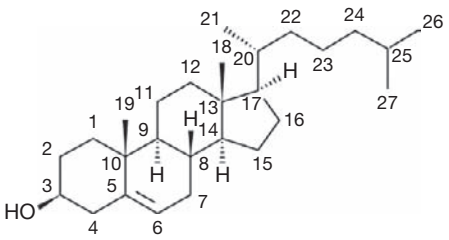

Figure 1 Cholesterol: the most regarded small molecule in biology. ACD/ChemSketch Freeware 2012, Advanced Chemistry Development, Inc., Ontario, Canada.

Chemical Properties

Naturally occurring sterols, including cholesterol, have 1,2-cyclopentano-phenan-threne skeleton with 27–30 carbons, a hydroxyl group at C-3, and a minimal 7-carbon side chain at C-17 of the ring structure (Figure 2). The variation in the structures of the ring skeleton and the side chain differentiates mammalian and plant sterols. Cholesterol is the most abundant sterol in animals and the vital structural component of animal plasma membranes and is essentially absent in plants.

Cholesterol can be found free or esterified to long-chained fatty acids in animal tissues. Hepatocytes need cholesterol to synthesize lipoproteins and bile acids, whereas other cell types incorporate cholesterol into their cell membranes. Cholesterol required for cellular functionality can be taken exogenously through low-density lipoprotein (LDL) from the bloodstream or synthesized endogenously from acyl-coenzyme A (CoA). Cholesterol is hydrophobic, which is enhanced by the loss of the hydroxyl group through esterification. Cholesterol is transported in the bloodstream by lipoproteins, primarily in the form of cholesterol esters. Because of their hydrophobicity, cholesterol esters are more suitable for cellular storage, whereas free cholesterol acquired by cells through hydrolysis of cholesterol esters accumulates in the cell membranes as a structural component.

Uptake and Use

Isotopic labeling techniques confirmed that a two-carbon metabolite of acetate in acetyl-CoA was the sole building block for the biosynthesis of cholesterol in the endoplasmic reticulum. In addition to endogenous biosynthesis, cholesterol is also available to enterocytes from dietary sources, bile, and turnover of intestinal mucosal epithelium. Cholesterol enters the intestine in the free-form by the action of pancreatic cholesterol esterase. It is packed into more hydrophilic micelles containing conjugated bile acids, monoglycerides, and lysolecithin to approach the absorptive cells. Approximately 60–80% of dietary and biliary cholesterol is absorbed; however, biliary cholesterol is to a greater extent absorbed because it is already in the form of micelles. Cholesterol is transported in the circulatory system and to the body tissues by plasma lipoproteins, which share a common structure of a neutral lipid core consisting of triglycerides and cholesterol esters, surrounded by a monolayer of phospholipids, free cholesterol, and alipoproteins. Chylomicrons (synthesized in the intestine) and very low-density lipoproteins (VLDL, largely synthesized in the liver) deliver triglycerides to tissues for storage or energy purposes, and they are converted to LDL in the process. The LDL can also be synthesized in the liver. The LDL primarily transports cholesterol to tissues and glands for storage or further synthesis. Both endogenously synthesized and exogenously absorbed cholesterol must be returned to the liver for excretion or degradation. The removal of cholesterol at the extrahepatic tissues and in the circulatory system is facilitated by the high-density lipoprotein (HDL). The HDL is removed by the liver or steroidogenic tissues through a selective uptake process of cholesterol and other lipid components.

Cholesterol, if not stored as cholesterol esters in the cytoplasm, is used for structural purposes in the cell membrane or the synthesis of bile acids, steroid hormones, and vitamin D. Cholesterol contributes up to 30% of lipid mass in the cell membrane and is vital to the less fluid and more structured lipid phase. The oxidation of cholesterol in tissues, governed by enzymatic pathways, yields important steroid precursors; however, the oxidation caused by food processing through

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00150-1

nonenzymatic pathways usually results in biologically toxic oxysterols.

Cholesterol Content in Foods

Cholesterol in the human diet primarily comes from meat, poultry, eggs, dairy products, and seafood (Tables 1–4). Therefore, it is expected that, of all the food groups presented in the USDA National Nutrient Database for Standard Reference (SR), only those without the previously mentioned protein sources such as vegetables, spices and herbs, cereals, and vegetable cooking oils have an undetectable amount of cholesterol. The database provides the cholesterol content of various types of protein sources in various forms of raw, cooked, and further processed products, which makes it possible to extrapolate the approximate cholesterol content of similar foods. Cholesterol is an integral component of the animal cell membrane, and it is also deposited in fat droplets; therefore, cholesterol content of fresh ingredients does not change much unless there is a remarkable change in the structure and metabolism of muscle or fat cells. Factors influencing cholesterol content across protein sources are species, diet, muscle oxidative pattern, muscle fiber type and structure, and fat content.

In general, raw and cooked meat and poultry have approximately 40–100 mg of cholesterol per 100 g of meat (Table 1). Few exceptions, such as nonenhanced, cooked chicken dark meat, can contain up to 150 mg/100 g. Chicken skin, both raw and cooked, also has more than 100 mg/100 g. Mechanically deboned meat and poultry have an approximately 10–20% greater amount of cholesterol because of bone marrow contamination. Variety meats have much greater cholesterol content, from 300 mg/100 g of raw liver to 3000 mg/100 g of braised brain. Egg and dairy products are other sources of cholesterol in the human diet (Table 2). With an exception of more than 200 mg/100 g in few salted butter products, cholesterol content

of dairy products is less than 100 mg/100 g. Cholesterol in dairy products is accumulated for storage purposes in the form of cholesterol esters within the fat globules; therefore, more concentrated and more fatty dairy products have more cholesterol, for example, most milk products with approximately 4 mg/100 g, regular cream cheese with 110 mg/100 g, and fat-free cream cheese with 12 mg/100 g. Most cottage cheeses are low in cholesterol, around 4–10 mg/100 g. Similarly, egg products containing more yolk have much more cholesterol than those containing more egg white because majority of the lipid components of eggs are located in egg yolk. Whole chicken eggs have approximately 372 mg cholesterol/100 g, whereas cholesterol in most egg white powders is undetectable. Moreover, whole eggs from turkey or goose can have as much as 900 mg/100 g. Most cholesterol in eggs occurs in free-form, whereas much of cholesterol in dairy products is esterified.

Fish generally has similar or lower cholesterol content compared with meat and poultry, for example, raw and cooked tuna with 38–49 mg/100 g. Some fish such as salmon or trout can have up to 60 mg/100 g of raw meat and up to 100 mg/100 g of cooked meat. Shellfish and crustaceans have much greater cholesterol content than meat, poultry, and fish. Crustaceans such as shrimps, crabs, and lobsters have lower cholesterol content than mollusks, in the range of 50–70 mg/100 g of raw and 90–120 mg/100 g of cooked meat. Some canned and breaded shrimp products of mixed species can have up to 138–252 mg/100 g of meat. Squid has been reported to have the greatest cholesterol content among seafood, in the range of 200–300 mg/100 g for both raw and cooked products. Mollusks with shell such as oysters have similar cholesterol content to that of crustaceans (**Table 3**).

Processed meat products and other processed foods formulated with cholesterol-containing protein sources vary greatly in cholesterol content, from a few milligrams in 100 g of soups

to more than 100 mg in 100 g of ready-to-eat sausages (Table 4). The variation is a direct result of diverse formulations, ingredients, cooking processes, storage conditions, and the oxidation of cholesterol during processing. Cholesterol content of meat, poultry, eggs, dairy products, and seafood provided by the SR and their labeled proportions can be used to calculate the cholesterol content of processed foods. Many restaurant foods are also available in the database. It is expected that restaurant foods containing large amounts of animal fat and ingredients such as chicken dark meat, bacon, and shrimp are abundant in cholesterol.

Dietary Recommendations

Despite the fact that cholesterol is a necessary physiological and structural component, the body synthesizes adequate levels of cholesterol to meet physiological needs. Evidence exists that in certain individuals, excessive consumption of dietary cholesterol may raise serum LDL cholesterol, thereby increasing the risk of cardiovascular disease. As such, in the *Guidelines for Americans 2010*, the US Department of Agriculture and the US Department of Health and Human Services recommend that Americans consume less than 300 mg of cholesterol per day to help maintain normal levels of serum cholesterol as well as a healthy ratio of HDL/LDL cholesterol.

Processing Effects

Effects on Cholesterol Content

Most value-adding processes cause little chemical effect on cholesterol content of foods. Cholesterol is primarily diluted or concentrated through food processing because of changes in protein, lipid, and moisture contents. Therefore, cholesterol-reducing strategies for foods normally involve protein and fat replacement by those from plant sources and the development of further processes that compensate for the loss of texture and flavor, such as extrusion or restructuring of protein, lipid hydrogenation, and flavor addition (natural or synthetic). It is also important to note that the replacement by plant sources will dramatically increase the content of phytosterols, many of which are estrogen analogs and have potentials to cause physiological effects on human. An important aspect of food processing that changes cholesterol concentration is the loss of moisture. Cooking or any heat application usually increases cholesterol content because moisture is lost, whereas cholesterol is retained. However, some cholesterol can be lost during

cooking because of oxidation or fat drip. Oxidation occurs more easily to free cholesterol, for example, cholesterol in eggs or lean tissues, whereas cholesterol esters in fat droplet are more likely to be lost through cooking, for example, chicken skin or fat tissues. Many studies have documented an increase in cholesterol content in cooked meat and poultry compared with raw and have explained the phenomenon, at least in part, through the migration of cholesterol from adipose tissues or poultry skin to cooked lean tissues. The USDA Nutrient Data Laboratory, responsible for quality control of data published in the SR, routinely uses dry matter basis (based on solid content) to evaluate data. Occasionally, depending on cooking methods, some chicken products cooked with skin on showed an increase in solid percentage, more than what was expected through moisture loss, and an increase in dry matter-based concentration of cholesterol, which could only be explained by the migration of lipid from the skin, which has more cholesterol than cooked lean tissue. Interestingly, such a phenomenon was not observed in chicken cooked with skin side down or with added water because of either fat drip or water dilution, respectively.

Oxidation of Cholesterol

Cholesterol can be oxidized during cooking, heat applications such as extrusion or pasteurization, irradiation, and prolonged processes such as fermentation or storage. The oxidation of cholesterol has a similar mechanism to that of unsaturated fatty acids. With a double bond between C5 and C6, the single bonds C4–C5 and C6–C7 are most prone to the attack by free radicals from lipid oxidation and reactive oxygen species. Cholesterol esters, however, are more susceptible at C7. Cholesterol oxidation products (COPs), cholesterol oxides or oxysterols, have similar carbon backbone to that of cholesterol but possess more oxygen-containing functional groups such as hydroxyl, ketone, or hydroperoxide (**Figure 2**). Most of the added functional groups are located at C7 and sometimes at C5 and C6. Rarely does the oxidation happen on the side chain, such as at C25 (25-hydroxycholesterol). To initiate the oxidation, a free radical can subtract a hydrogen at the C7 next to the C5=C6 double bond, creating a free radical in the cholesterol structural rings. The migration of this free radical and subsequent formation of hydroperoxide, hydroxyl, or ketone derivative preferably occur at C7 rather than C4 because of the existing hydroxyl group at C3. Reactive oxygen species such as triplet oxygen may attack C5=C6 double bond in an addition mode to form 5,6-epoxycholesterol. This epoxy can be hydrated to form a very toxic triol (cholestane-3β,5α,6β-triol). The degradation of hydroperoxide at C7, however, forms hydroxyl radical and 7-alkoxyl radical, which becomes 7-hydroxycholesterol through hydrogen abstraction or 7-ketocholesterol through reaction with 7-peroxyl. In addition, further dehydration of cholesterol and intermediate products by prolonged heating can promote the formation of conjugated cholesta-3,5-dien, 7-ketocholesterol, cholesta-3, 5-dien-7-one, and cholesta-3, 5, 7-trien. Cholesterol 7-hydroperoxide and intermediate free radicals such as 7-alkoxyl, 7-peroxyl, or hydroxyl propagate new free radicals from other cholesterol or unsaturated fatty acid molecules to start the chain reaction (**Figure 3**). Factors influencing cholesterol oxidation are similar to those affecting fatty acid oxidation, such as pH and the availability of free radicals, reactive oxygen species, light, antioxidants, and metal catalysts. The physical state of cholesterol, which influences the exposure and the arrangement of the ring structure, the side chain, the double bond, and the hydroxyl group, is also very

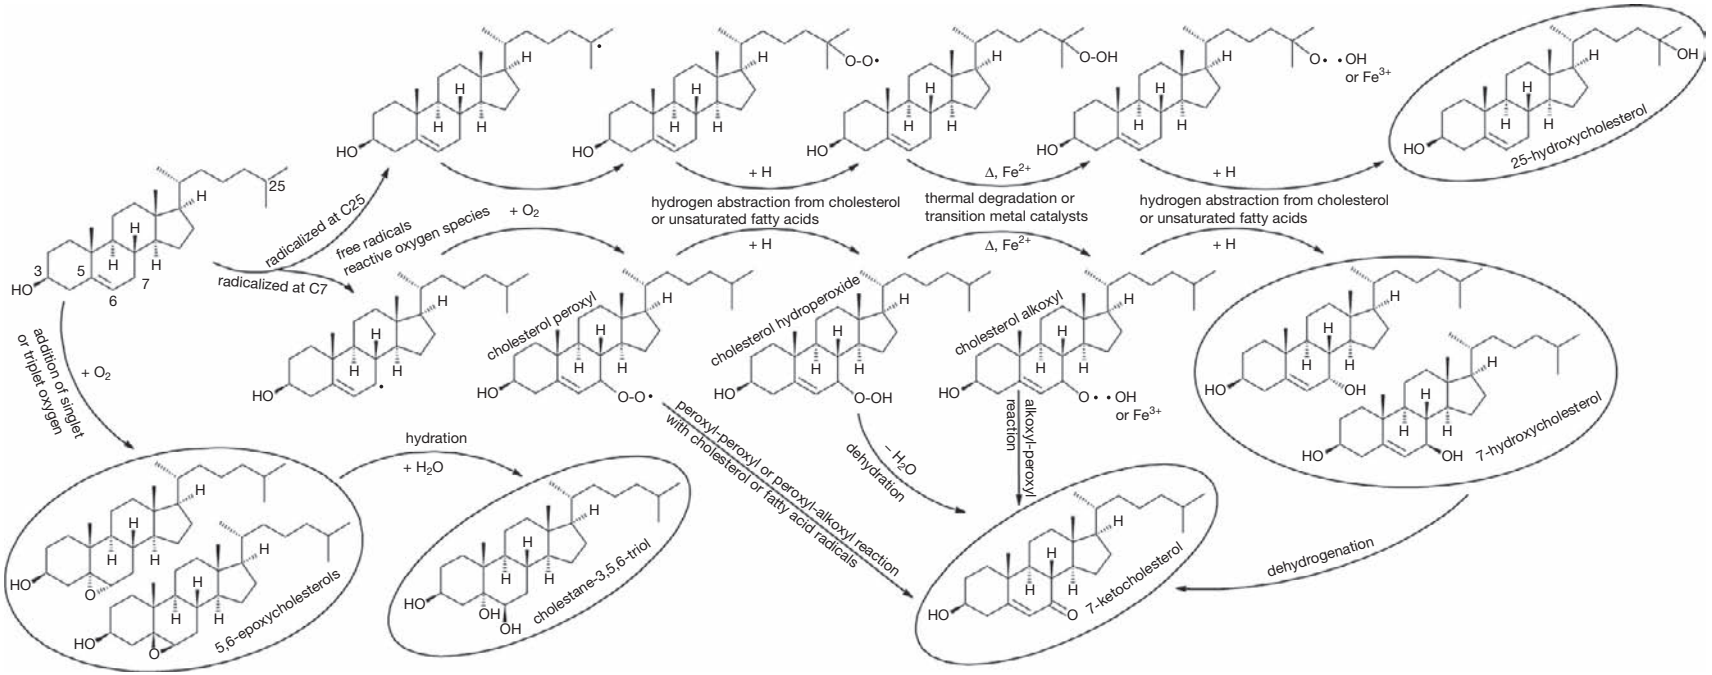

Figure 3 Primary pathways of cholesterol oxidation by free radicals. ACD/ChemSketch Freeware 2012, Advanced Chemistry Development, Inc., Ontario, Canada.

important to the oxidative degree and the production of oxysterols. Cholesterol esters are less susceptible to oxidation than free cholesterol, as evidenced by a much greater percentage of cholesterol lost in dried egg powder (primarily containing free cholesterol) than that in cooked separable fats (primarily containing cholesterol esters) found in the SR and various studies. In addition to heat applications, irradiation has been reported to accelerate the autoxidation of lipids including cholesterol. However, refrigeration, freezing, and vacuum packaging provide a protective effect, as expected. Moreover, it is important to recognize the photosensitized oxidation of cholesterol during retail display under fluorescent light. Muscle foods are especially susceptible because myoglobin, muscle pigment, is a photosensitizer and significantly increases the generation of the excited singlet oxygen. Singlet oxygen can be added directly to the double bond of cholesterol molecule. Initial products of photosensitized oxidation are primarily 5-hydroperoxycholesterol and 6-hydroperoxycholesterol, which differ from those generated through free radical-mediated pathways. As previously discussed, stable oxidation products are epoxycholesterols and cholestanetriol. Most commonly found oxysterols in foods are 7-OH, 7-keto, 5,6-epoxy, 3,5,6-triol, and the side-chain derivative 25-OH (Figures 2 and 3).

Cholesterol Oxides in Foods and Health Implications

Similar to cholesterol, cholesterol oxides are limited to foods of animal origin and seafood. Irradiation, direct heating, and processing methods with high heat or high degree of dehydration for a prolonged period have been reported to produce more oxysterols than the milder processing methods. The 7-hydroxycholesterol derivative was most commonly found in egg products at an average concentration of 0.2 to less than 50 ppm. Spray-dried egg yolk, however, was reported to have more than 100 ppm of cholesterol oxides, most were epoxycholesterol. More cholesterol oxide derivatives, as previously mentioned, have been found in meat and poultry products. Using beef tallow for prolonged deep-frying was reported to oxidize 25% cholesterol, most of which was converted to 7-hydroxycholesterol and conjugated dien and trien derivatives. Moreover, prolonged storage of dried pork for 3 years could oxidize more than 30% cholesterol, the products of which also included 5,6-epoxycholesterol. Cholesterol oxides have not been found in milk regardless of fat content even after prolonged heating. However, dehydration, fermentation, and prolonged storage seem to be the primary causes of cholesterol oxidation in dairy products. Examples of cholesterol oxides found skim milk powder are especially troubling, including up to 2.5 ppm of toxic triol and 25 ppm of 7-ketocholesterol. A level of up to 17 ppm of 5,6-epoxycholesterol, 7-hydroxycholesterol, and other side-chain oxidation derivatives has also been reported in butter and cheeses. Grated cheeses have much more cholesterol oxides, possibly because of greater surface area that promotes oxidation. Seafood has a low concentration of cholesterol oxides, approximately 5–9 ppm, which is primarily in products subject to smoking and prolonged storage. Dry-heat cooking methods seem to increase cholesterol oxides in fish more than moist-heat cookery.

The structures of cholesterol oxides resemble that of cholesterol; therefore, they can be delivered to various tissues in similar pathways and interfere with the biological functions of cholesterol. Cholesterol oxides have an increased polarity compared with cholesterol, which allows them to be absorbed more efficiently into the bloodstream. Macrophages also absorb LDL with oxidized cholesterol at a much greater rate. COPs have been reported to have greater atherogenic and cytotoxic effects than cholesterol. The atherogenic effects of cholesterol oxides were found in animal models at prolonged ingestion rates of 1–40 mg kg^{-1} body weight. Although most oxidation derivatives cause cytotoxicity in culture of various cell types, only 25-hydroxycholesterol and cholestanetriol have been reported to cause severe necrosis *in vivo*, for example, aortic muscles and endothelium of rabbits. Radioactive labeling indicates that VLDL and LDL, the preferred cholesterol transporter to human vascular cells, are also the preferred mode of transportation for cholesterol oxides. Therefore, oxidized VLDL and LDL are suspected to cause damage to the endothelial integrity and death of the vascular muscle cells. In addition, cholestanetriol, 7-ketocholesterol, and 25-hydroxycholesterol interfere with cholesterol synthesis, membrane formation and integrity, and cell growth of various tissues *in vitro* and *in vivo*. Recently, evidence indicates that cholesterol oxides, primarily epoxycholesterols, can also be mutagenic and even carcinogenic. They were reported to cause mutation in the lungs of hamsters and tumors in skin of mice. Some cholesterol oxides, for example, 7α-hydroxycholesterol, are physiological metabolites and have not been found to exhibit adverse effects on human health.

Quantification

Cholesterol and cholesterol esters are usually determined together as total cholesterol, although cholesterol esters are usually hydrolyzed to the free-form. Cholesterol must be extracted and separated from other interfering lipid compounds, especially fatty acids before it can be quantified. Although various means can be used to measure cholesterol, gas chromatography (GC) with flame ionization detection (FID) and high-pressure liquid chromatography (HPLC) with ultraviolet (UV) detection or mass spectrometry (MS) have become the predominant techniques. The majority of the recent cholesterol data in foods, however, have been generated by GC-FID, including those in the SR.

Extraction

Cholesterol is traditionally analyzed together with fatty acid composition; therefore, lipid extraction has been the first step of most cholesterol determination procedures found in the literature. The lipid extraction employs mixtures of midpolar and nonpolar solvents, among which the 2:1 (v/v) chloroform/methanol is most popular. The two most commonly used methods of this mixture were proposed by Folch and coworkers in 1957 and Bligh and Dyer in 1959, which have been modified by many others. Other solvent mixtures of hexane, diethyl ether, isopropanol, and butanol have also been examined; however, none comes close to the recovery of the chloroform/methanol mixture. The polarity of the extraction mixture is very important, especially in a two-step procedure (a polar solvent followed by a

nonpolar one), because cholesterol exists in a slightly polar free-form (with hydroxyl group) and a much less polar esterified form. Cholesterol, as a structural component of the cell membrane, is also bound by other polar compounds such as proteins and phospholipids. After chloroform/methanol extraction, the organic layer is separated from the aqueous layer. It is important to maintain a chloroform/methanol/water ratio of 8:4:3 to prevent the selective loss of lipid compounds into the aqueous phase, including cholesterol.

Following lipid extraction, lipids are saponified primarily using concentrated ethanolic or aqueous potassium hydroxide (KOH) solutions to liberate cholesterol from the esterified form with fatty acids. With cholesterol becoming more and more important because of its health implications, analysts have explored shortcuts to simplify the analytic procedures, the most important of which has been the use of direct saponification when cholesterol is the only lipid compound of interest. Direct saponification yields either similar or better recovery compared with the traditional two-step extraction/saponification procedure. In some cases of complex matrices, especially those with high emulsifying capability such as eggs or emulsion-type meat products, direct saponification is much more accurate and precise. Samples of various natures are directly hydrolyzed in either ethanolic or aqueous KOH solution, which is followed by an extraction of the unsaponifiable compounds by a nonpolar solvent, similar to that of lipid extraction. Toluene or a mixture of hexane and a miscible alcohol is most commonly used. Hexane is sometimes used alone; however, at least three extractions are needed to obtain the exhausted recovery and maintain the ratio of cholesterol and an internal standard. Toluene so far has been the best solvent for cholesterol extraction, accommodating a wide range of polarity with a single extraction. However, the use of toluene is prone to the formation of an emulsion, especially with the direct saponification because soap, an emulsification agent, is formed during saponification. Extraction using toluene, therefore, is followed by a careful cleanup process. A few cautions are needed for direct saponification technique such as the strength of the KOH solution, saponification time, and type of KOH solution (i.e., alcoholic or aqueous).

Derivatization

Cholesterol is usually converted to the suitable derivatives for various means of measurement. GC requires volatility and thermal stability, whereas liquid chromatography requires sensitivity and specificity, that is, enhanced UV absorption or more informative ion fragments if cholesterol is quantified by UV absorption or MS, respectively. Recently, cholesterol has been determined without derivatization because of dramatic improvements in columns and detectors.

Trimethylsilyl (TMS) ether is the most common cholesterol derivative. The ether provides great volatility and improves peak shape because the hydroxyl group is converted to a much less polar ether group, preventing the interaction with the polar sites of the GC columns. Among various derivatizing reagents and conditions, N,O-bis(TMS)trifluoroacetamide (BSTFA) in 1% trimethylchlorosilane is recommended because of the maximum ether conversion and the ability to produce hydrofluoric acid, which volatizes silicon dioxide and helps maintain the sensitivity of the FID detector. In addition, the use of butyrate and acetate cholesterol esters has been explored; however, the resultant conversion rates and peak shapes were compared less favorably than those of the TMS ether. The ether, on the other hand, is susceptible to moisture; therefore, moisture-free environment and moisture trap for the GC system are required.

Free cholesterol has been analyzed by HPLC-UV, HPLC-photodiode array (PDA), and HPLC-MS. Liquid chromatography provides great resolution between cholesterol and other interferences; however, the UV detection is much less sensitive than the FID. MS is typically used for definitive purposes rather than for routine analysis. Cholesterol, if not derivatized, does not yield informative mass fragments because it has only one functional group. Recently, the development of high-temperature, low-bleed GC columns with fused silica and bonded or cross-linked stationary phase has allowed for the determination of free cholesterol by GC-FID. The temperature program can be isothermal or gradient, depending on the interferences that need to be separated from cholesterol. Free cholesterol often interacts with silanol groups on the surface of the fused silica, which causes the tailing of the cholesterol peak. This phenomenon can affect the linearity of the calibration curve if a wide range of standard concentrations and a less polar internal standard such as cholestane are used. A column with a nonpolar stationary phase, for example, (5%-phenyl)-methylpolysiloxane, and a thick stationary film, that is, more than 0.25 μm and preferably 1 μm, can be used to improve peak shape and linearity. However, a nonpolar column may not provide the best resolution for a mixture of unsaponifiable compounds, the majority of which are slightly more polar than the saponified fatty acids. A thick stationary phase can increase column bleeding and hinder the sensitivity; therefore, high-temperature limits of the columns are important. The column technology nowadays seems to provide adequate thermal stability through cross-linked and bonded phases. Longer conditioning time during column installation can be helpful.

Separation

Chromatographic separation of cholesterol depends primarily on columns; and in the case of HPLC, it also depends on the separation mode, that is, normal-phase or reversed-phase. Cholesterol has been most commonly determined by GC; therefore, many GC columns are available. Packed columns have been mostly replaced by capillary columns because of much better resolution and reproducibility. Most capillary columns used in cholesterol analysis have typically 10 000–30 000 theoretical plates, providing a much better resolution than the 3000–5000 theoretical plates of the packed columns. Cholesterol is classified as a nonpolar compound with a slight polarity provided by one hydroxyl group; therefore, both nonpolar and polar stationary phases have been used. A nonpolar phase (100% dimethylpolysiloxane) such as HP-1, DB-1, SE-30, CP-Sil 5CB, or SPB-1; a slightly polar phase (5%-phenyl-methylpolysiloxane) such as HP-5, DB-5, SPB-5, RTX-5, or ZB-5; and a midpolar phase (50%-phenyl-methylpolysiloxane) such as DB-17, DB-1701, NB-17, or CP-Sil24CB are the most commonly used GC stationary phases for cholesterol determination. The low-polarity phase with 5% phenyl group has been used much more than other two

phases in analyzing both free cholesterol and derivatized cholesterol. Cholesterol derivatives have been separated on a thin-film column, that is, less than 0.25-μm film thickness, whereas a thicker film has been used for free cholesterol. A thickness of more than 0.5 μm will improve peak shape of free cholesterol as previously discussed but will significantly prolong the retention of cholesterol in the GC column, sometimes unnecessarily.

Most HPLC methods for cholesterol determination were not developed for routine analysis. The advantage of HPLC is that it can be used to separate cholesterol, cholesterol esters, triglycerides, diglycerides, tocopherols, and other sterols without derivatization, and sometimes in a single run. It has been reported that the GC does not provide an adequate separation of free cholesterol from phytosterols and tocopherols, whereas such a separation can be accomplished by manipulating the HPLC mobile phase polarity in both normal-phase and reversed-phase modes. Normal-phase HPLC mostly employs highly pure silica microparticles (5 μm) such as μPorasil, Inert-Sil, or Spherisorb and a 1–3% isopropanol/hexane mobile phase. Other polar columns of alcohol-bonded silica and cyanopropylsilica have also been used. Reversed-phase mode employing a nonpolar column offers better selectivity because it allows for more manipulation of mobile phase polarity. Most compounds coexisting with cholesterol in a post-preparation mixture are also retained better on a reversed-phase column. Reversed stationary phase commonly used for cholesterol determination consists of an octyl (C8) or octadecyl (C18) being bonded to a highly pure silica microparticle (5 μm). The C18 columns provide excellent retention and require mobile phases with lower polarity. Common organic modifiers for reversed-phase HPLC are acetonitrile, ethanol, methanol, and isopropanol. Recently, ultrahigh-pressure liquid chromatography (UPLC) has been used more for cholesterol determination because it uses much less solvent and decreases the retention time significantly to approximately 5 min. UPLC can also increase the resolution substantially through using submicron particle sizes.

Detection

Cholesterol derivatives have been quantified by FID or MS although the latter is primarily used for research or definitive purposes. A flame ionization detector provides great sensitivity and linearity over a wide range of concentrations. MS, however, is the method of choice when cholesterol is analyzed in a more complex mixture and expected to coelute with other unsaponifiable compounds, such as phytosterols or tocopherols. MS is better used for cholesterol derivatives than free cholesterol because cholesterol derivatives respond better to the ionization and produce more informative ion fragments for identification and quantification. Free cholesterol, like many sterols with very few functional groups, does not respond well to atmospheric pressure ionization such as electrospray; therefore, electron impact ionization in a vacuum chamber is usually employed. The detection limit for FID and MS is in the range 1 ng on-column. The MS can be more sensitive, depending on the ion-monitoring mode.

In addition, cholesterol and cholesterol derivatives have been successfully determined by UV, fluorescence (FD), evaporative light-scattering, and electrochemical (ECD) detections, which are usually coupled with an HPLC system. UV detection is the most commonly used technique, which is probably a matter of convenience more than technical considerations because of the issues with specificity or sensitivity. Cholesterol has been detected in the range of 202–210 nm with the maximum absorption at 205 nm. A simple scan of spiked cholesterol standard may be needed to confirm λ_{max} in a specific solution. A PDA detector improves specificity of UV detection because of multiwavelength monitoring. Fluorescence-generating or fluorescence-tagging reagents such as 3,4-dihydro-6,7-dimethoxy-4-methyl-3-oxoquinoxaline-2-carbonyl azide and naproxen acyl chloride can be used to convert cholesterol and other sterols to fluorescing derivatives, which will substantially increase specificity and sensitivity. The limit of detection (LOD) for the FD is within few picograms on-column. UV absorption can be enhanced to a LOD of 0.1 ng at a much more favorable λ_{max} of 250 nm by converting cholesterol to cholest-4-en-3,6-dione in the Jones oxidation reactions. Such a LOD is very unusual for UV detection. Electrochemically active derivatives of cholesterol such as carbamate ester can be quantified by ECD at very sensitive levels of picograms on-column. Cholesterol can also be determined on the ECD without precolumn derivatization in an oxidation mode, however, with much less sensitivity at nanogram levels. An evaporative light-scattering detector is mostly suitable for cholesterol determination in simple biological fluids and is a generic technique, having a similar LOD but lower precision compared with those of UV detection. Electrochemical and fluorescence detectors are most specific and sensitive for the HPLC technique but may require cumbersome precolumn preparation.

Determination of COPs

Similar to the determination of cholesterol, that of COPs follows a series of extraction (direct or postextraction saponification), derivatization, separation, and detection processes. The separation and detection can be achieved by both GC and HPLC with various detection techniques, also similar to those used for cholesterol. Cholesterol oxides, however, normally occur at very low concentrations, approximately 1% of cholesterol content, and in various forms, which makes the extraction process extremely important. Direct saponification has been recommended to separate COPs from the interferences because it eliminates selective losses of COPs during lipid extraction. Hot alkali conditions, however, can generate more cholesterol oxides or alter the ketone derivatives. Some researchers have suggested that the selection of saponification temperature depends on the COPs of interest and the nature of food matrices and that the cold saponification may be more suitable for the ketone derivatives. Antioxidants such as butylated hydroxytoluene can be added to prevent further oxidation of COPs. Preparative chromatography has been used to isolate COPs directly from lipid extract or to remove cholesterol from the unsaponifiable materials and, in some cases, is the most important step to improve selectivity and sensitivity. Cholesterol oxides, similar to cholesterol, can be determined in the free-form or derivatized form. However, COPs are much more susceptible to further degradation. Therefore, the GC determination usually requires derivatization, primarily to TMS ethers, to improve the thermal

stability. Although GC, coupled with FID or MS, offers relatively quick and sufficient separation of major COPs, the use of temperature programs hinders the ability of this technique to analyze thermally sensitive COPs. As a result, HPLC is preferred for COP determination. Most COPs are more polar than cholesterol; therefore, normal-phase HPLC has been used more than reversed-phase HPLC. However, reversed-phase HPLC methods, especially those using C18 columns, are becoming more and more popular for the same reason previously discussed. Although the use of a UV detector has been the detection method of choice, some COPs do not possess UV chromophores. In addition, a large number of COPs occur in foods, similar to the case of flavor volatiles, which makes an absolute separation and identification almost impossible. Hence, HPLC-MS will probably be the primary technique to study COPs in foods in the future because MS is a much more specific technique and some COPs have been suggested to contribute to Alzheimer's disease, Parkinson's disease, multiple sclerosis, and inflammation. Recently, the isotope dilution MS has also been employed to study the roles of COPs in various pathological pathways of these diseases.

Metabolism of Choline

There have been several comprehensive reviews of the metabolism and functions of choline that describe its role in the synthesis of the phospholipids in cell membranes, methyl metabolism, cholinergic neurotransmission, transmembrane signaling, and lipid–cholesterol transport and metabolism. Choline can be acetylated, phosphorylated, or oxidized.

Choline, methionine, and folate metabolisms interact at the point that homocysteine is converted to methionine (Figure 1). Betaine–homocysteine methyltransferase catalyzes the methylation of homocysteine using the choline metabolite betaine as the methyl donor. Elevated plasma homocysteine is an independent risk factor for cardiovascular disease and stroke in humans. Treatment with betaine or choline also lowers elevated plasma homocysteine in humans. In an alternative pathway, 5-methyltetrahydrofolate–homocysteine methyltransferase regenerates methionine. In addition, tetrahydrofolate is needed to scavenge one-carbon groups when betaine is metabolized. Perturbing metabolism of one of the methyl donors results in compensatory changes in the other methyl donors, owing to the intermingling of these metabolic pathways. Rats ingesting a choline-deficient diet have diminished tissue concentrations of methionine and *S*-adenosylmethionine, doubled plasma homocysteine concentrations, and diminished hepatic methylfolate content. These effects are reversible by refeeding choline. Rats fed with diets deficient in both methionine and choline for 5 weeks have hepatic folate concentrations that are half of those present in controls. Rats treated with the antifolate, methotrexate, have diminished pools of choline metabolites in the liver. Severe folate deficiency induced in rats, by feeding an amino acid-defined diet containing no folate and succinylsulfathiazole for 4 weeks, has resulted in hepatic choline and phosphocholine concentrations that were 65% and 80% lower, respectively, than in controls.

Dietary Requirements

Though there is a pathway (in all tissues, but most active in the liver) for the *de novo* biosynthesis of the choline moiety via the sequential methylation of phosphatidylethanolamine using *S*-adenosylmethionine as the methyl donor (Figure 1), only some of the demand for choline can be met by using methyl groups derived from one-carbon metabolism. Animals and humans fed with a choline-deficient diet deplete choline stores and develop liver dysfunction. Healthy male humans with normal folate and vitamin B_{12} statuses fed with a choline-deficient diet have diminished plasma choline and phosphatidylcholine concentrations and develop liver damage (elevated plasma alanine aminotransferase). Liver cell death occurs in choline deficiency, because hepatocytes initiate programmed cell death (apoptosis) when deprived of choline. Because methyl supplementation with betaine, methionine, folate, or vitamin B_{12} does not prevent apoptotic death induced by choline deficiency in hepatocytes, it must be that depletion of intracellular choline moieties, rather than depletion of methyl groups, is the critical parameter involved in the induction of apoptosis. Some humans (male and female) fed with total parenteral nutrition solutions devoid of choline, but adequate in methionine and folate, develop fatty liver and liver damage that resolve when a source of dietary choline is provided. Fatty liver occurs because choline is required to make the phosphatidylcholine portion of the very-low-density lipoprotein particle. Animals fed with a choline-deficient diet may also develop growth retardation, renal dysfunction and hemorrhage, or bone abnormalities. A metabolite of choline, betaine, is used in the kidney glomerulus as an osmolyte, and for this reason, choline-deficient animals have trouble excreting concentrated urine.

Human studies of choline requirements in women, children, or infants have not been conducted. Thus, we do not know whether choline is needed in the diet of these groups. Female rats are less sensitive to choline deficiency than are male rats perhaps because estrogen enhances females' capacity to form the choline moiety *de novo* from *S*-adenosylmethionine. Pregnancy may be a time when dietary supplies of choline are especially limiting. Though female rats are resistant to choline deficiency, pregnant rats are as vulnerable to deficiency as males are. During pregnancy, large amounts of choline are delivered to the fetus across the placenta, and this depletes maternal stores of the various forms of this nutrient. At birth, humans and other mammals have plasma choline concentrations that are much higher than those in adults. Also, the need for choline is increased during lactation, because so much must be secreted into milk; lactating rats are more sensitive to choline deficiency than are nonlactating rats.

The Institute of Medicine (IOM) recently made recommendations for choline intake in the diet. There were insufficient data with which to derive an estimated average requirement for choline, and so, only an adequate intake can be estimated. The IOM report cautioned, "this amount will be influenced by the availability of methionine and methyl-folate in the diet. It may be influenced by gender, and it may be influenced by pregnancy, lactation, and stage of development. Although AIs are set for choline, it may be that the choline requirement can be met by endogenous synthesis at some of these stages." The IOM recommendations are shown in Table 1.

The recent report by Jacob that folate deficiency in humans exacerbates choline deficiency highlights why studies of choline–folate–homocysteine interrelationships in humans are important for the future refinement of these recommendations.

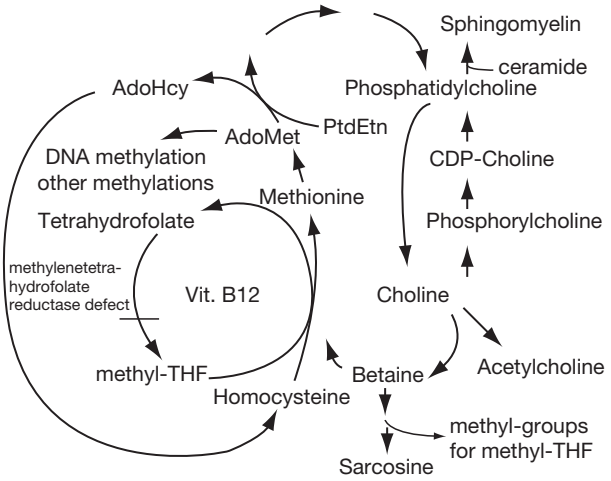

Figure 1 Choline, folate, and homocysteine metabolisms are closely interrelated. The pathways for the metabolism of these three nutrients intersect at the formation of methionine from homocysteine. PtdEtn, phosphatidylethanolamine; AdoHcy, *S*-adenosylhomocysteine; and AdoMet, *S*-adenosylmethionine.

Table 1 Institute of Medicine recommendations for choline intake in the diet

AI for infants	0–6 months	125 mg per day, 18 mg kg^{-1}
	6–12 months	150 mg per day
AI for children	1–3 years	200 mg per day
	4–8 years	250 mg per day
	9–13 years	375 mg per day
AI for males	14–18 years	550 mg per day
	19 years and older	550 mg per day
AI for females	14–18 years	400 mg per day
	19 years and older	425 mg per day
AI for pregnant women	All ages	450 mg per day
AI for lactating women	All ages	550 mg per day

AI, adequate intake level.

The plasma choline concentration varies in response to diet and can rise as much as twofold after a two-egg meal. Fasting plasma choline concentrations vary from 7 to 20 μM, with most subjects having concentrations of 10 μM. Individuals that have starved for up to 7 days have diminished plasma choline, but levels never drop below 50% of the normal. The plasma phosphatidylcholine concentration also decreases in choline deficiency, but these values are also influenced by factors that change plasma lipoprotein levels. The fasting plasma phosphatidylcholine concentrations are ~1–1.5 mM.

Choline and Brain Development

Choline availability during embryogenesis and perinatal development may be especially important. There is a sensitive period in rodent brain development during which treatment with choline (about three times the dietary intake) produces long-lasting enhancement of spatial memory that is lifelong. This period occurs during embryonic days 12–17 in the rat (rats give birth on day 21; mice give birth one day earlier and probably have a slightly different period of susceptibility). Choline supplementation during these critical days elicits a major improvement in memory performance at all stages of training on a 12-arm radial maze. Choline deficiency during the critical time frame reduces memory performance. The choline-induced spatial memory facilitation correlates with changes in the birth, death, and migration of cells in the hippocampus during fetal brain development, with altered distribution and morphology of neurons, biochemical changes, and electrophysiological changes in the hippocampus. Human and rat brains mature at different rates; the rat brain is comparatively more mature at birth than the human brain, but in humans, hippocampal development may continue for months or years after birth.

Choline and Cancer

Dietary deficiency of choline in rodents causes the development of hepatocarcinomas in the absence of any known carcinogen. Choline is the only single nutrient for which this is true. It is interesting that choline-deficient rats not only have a higher incidence of spontaneous hepatocarcinoma but also are markedly sensitized to the effects of administered carcinogens. Several mechanisms are suggested for the cancer-promoting effect of a choline-devoid diet. A progressive increase in cell proliferation that is related to regeneration after parenchymal cell death occurs in the choline-deficient liver. Cell proliferation and its associated increased rate of DNA synthesis could be the cause of the heightened sensitivity to chemical carcinogens. Methylation of DNA is essential to the regulation of expression of genetic information, and the undermethylation of DNA observed during choline deficiency (despite adequate dietary methionine) may be responsible for carcinogenesis. Choline-deficient rats experience increased lipid peroxidation in the liver. Lipid peroxides in the nucleus are a possible source of free radicals that could modify DNA and cause carcinogenesis. Choline deficiency activates protein kinase C signaling, usually involved in growth factor signaling in hepatocytes. Finally, a defect in cell suicide (apoptosis) mechanisms may contribute to the carcinogenesis of choline deficiency.

Summary

Choline in the diet is important for many reasons. As our understanding of the importance of folate and homocysteine nutrition increases, there should be increased interest in how choline interacts with folate and homocysteine metabolisms. Recent findings about choline in brain development should stimulate comparable studies in humans. During the next few years, it is likely that food composition data will be available for choline, and this will make it possible to examine interactions between choline, folate, and methionine when considering epidemiological data. In addition, we should learn more about choline requirements in women. For these reasons, interest in choline as a nutrient for humans should be sustained.

Choline: Properties and Determination

MM Phillips, National Institute of Standards and Technology, Gaithersburg, MD, USA

Published by Elsevier Ltd.

Introduction

Choline is an essential nutrient that is required for normal cell function, with involvement in lipid synthesis and transport, cellular methylation reactions, neural tube development, stem cell proliferation and apoptosis, and cholinergic neurotransmission. Choline is a precursor for phosphatidylcholine, which comprises over half of the phospholipid content in mammalian cell membranes, and is critical in the transport of excess triglycerides from the liver. As a result, choline deficiency has been associated with the development of hepatosteatosis, or fatty liver, and is the only nutritional deficiency found to cause cancer in the absence of known carcinogens. One important cellular methylation reaction involving choline is in the biosynthesis of methionine, one pathway for which in mammals involves the choline metabolite betaine. The alternative pathway involves folate metabolism, linking the intakes of these nutrients through a sensitive metabolic equilibrium. This shared pathway, through methyl group donation, is believed to be responsible for neural tube closure *in utero*, explaining a fourfold increase in risk for neural tube defects in the children of pregnant women with choline deficiency. Rodent studies have similarly indicated that choline supplementation during pregnancy altered the brain structure and long-term potentiation of offspring through increased stem cell proliferation and decreased stem cell apoptosis; the reverse was observed for mothers with choline deficiency. Choline is also the precursor for acetylcholine, one of the most common neurotransmitters responsible for influencing the function of the brain, heart, and numerous other organs and organ systems (Figure 1).

Estimation of Choline Intake

Choline is produced in the body as a by-product of the biosynthesis of phosphatidylcholine. In this process, *S*-adenosylmethionine is converted to phosphatidylcholine by the enzyme phosphatidylethanolamine-*N*-methyltransferase, and a new choline molecule is formed. The production of choline via this pathway, however, is not sufficient to support proper function, and thus, dietary supplementation of choline is necessary. The one exception may be in women of childbearing age; high levels of circulating estrogen may be linked to upregulated biosynthesis of choline. Adequate intakes (AIs) for choline have been established by the US Institute of Medicine at 425 mg day^{-1} for women and 550 mg day^{-1} for men. The AI increases to 450 or 550 mg day^{-1} for women who are pregnant or lactating, respectively. In a monitored dietary intake study, the average daily choline consumption was determined to be 630 mg day^{-1} for men and 440 mg day^{-1} for women, levels comparable with the AIs. Tolerable upper limits were determined as the lowest level causing adverse effects (hypotension) in humans to be 1000 mg day^{-1} in children 1–8 years of age, 2000 mg day^{-1} from 9 to 13 years of age, 3000 mg day^{-1} from 14 to 18 years of age, and 3500 mg day^{-1} over age 19. In addition to hypotension, other adverse effects from high choline intake include fishy body odor (from triethylamine production) and cholinergic side effects such as sweating, vomiting, and diarrhea.

Choline intakes can be attributed to a number of choline-related compounds, including free choline and betaine, and a number of esterified forms such as phosphocholine (PCho), phosphatidylcholine (PtdCho), glycerophosphocholine (GPCho), and sphingomyelin (SM) (Figure 2). Choline is a small quaternary amine containing two carbons and a hydroxyl group. Betaine, also known as glycine betaine or trimethylglycine, is formed from choline by oxidation of the alcohol group to a carboxylic acid. Because the oxidation of choline to betaine is irreversible, however, the intake of betaine is not typically included in the considerations for choline intake. In the phosphorylated forms of choline, the hydroxyl group is replaced with a phosphate (PCho and SM) or glycerophosphate group (GPCho and PtdCho). In the polar PCho and GPCho molecules, the phosphate and glycerophosphate groups are the respective molecular termini. In PtdCho, the phosphate group joins the choline molecule to a glycerol moiety esterified with two fatty acids, forming a phospholipid. A large number of structures make up the group of phospholipids classified as PtdCho, with fatty acids that vary from 16 to 22 carbons with varying degrees of saturation. In SM, the phosphate group connects the choline molecule with a ceramide, which contains a sphingosine (an unsaturated 18-carbon amino alcohol) and a fatty acid with 16–24 carbons and up to one degree of saturation. These structural differences result in a group of compounds with significantly different chemical characteristics.

In 2004, the US Department of Agriculture (USDA) released a database outlining the choline content of 630 common food items, and a selection of the entries from this database have been summarized in Table 1 to represent foods high in choline from a variety of categories. The USDA database includes individual values for betaine, free choline, PCho, PtdCho, GPCho, and SM and a summed total choline content determined in each food product. Foods highest in total choline content include egg yolks, liver (from beef, veal, chicken, and turkey), and wheat germ. The total choline content, however, is a mathematical sum of free choline, PCho, PtdCho, GPCho, and SM and may not represent the bioavailable choline content upon consumption. Betaine content is not included in the calculation of total choline because, as mentioned previously, the conversion from choline to betaine is irreversible, and therefore, the consumption of betaine does not directly translate to choline intake. Studies indicate that in a rat model, the bioavailabilities of choline, PCho, and GPCho are similar, but studies have not been conducted to translate these findings to human subjects; no data are available to elucidate the

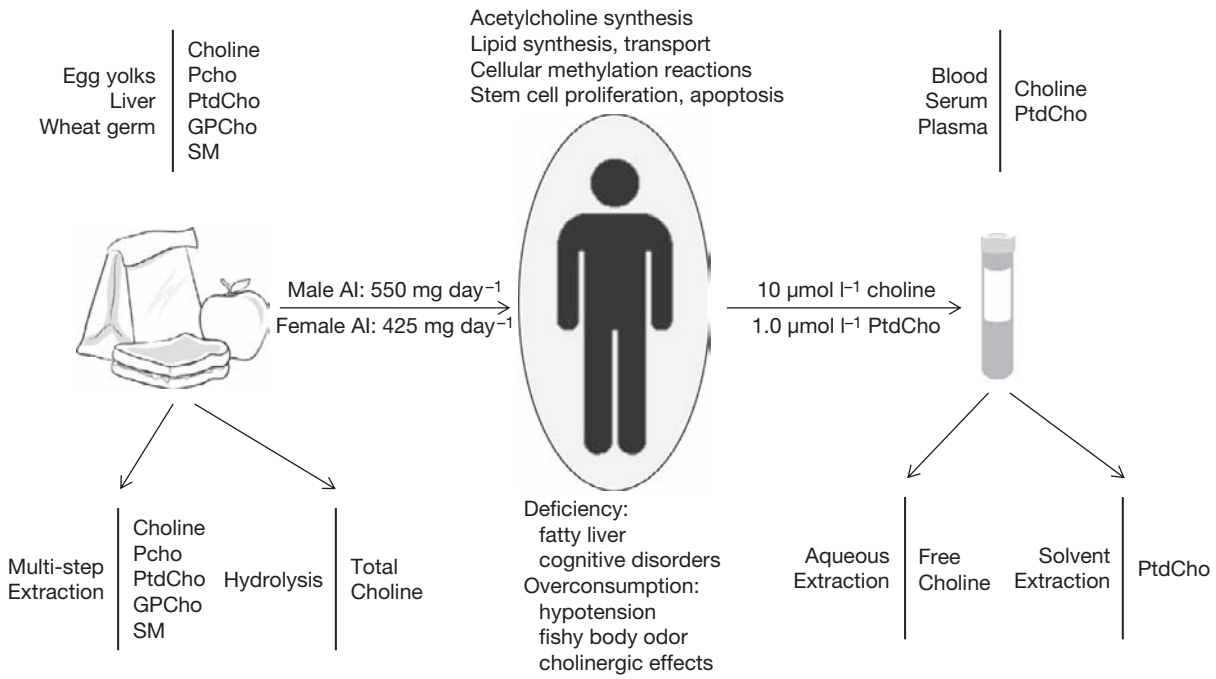

Figure 1 The interrelationship and analytical determination of choline-containing compounds in dietary intake, metabolism, and health status.

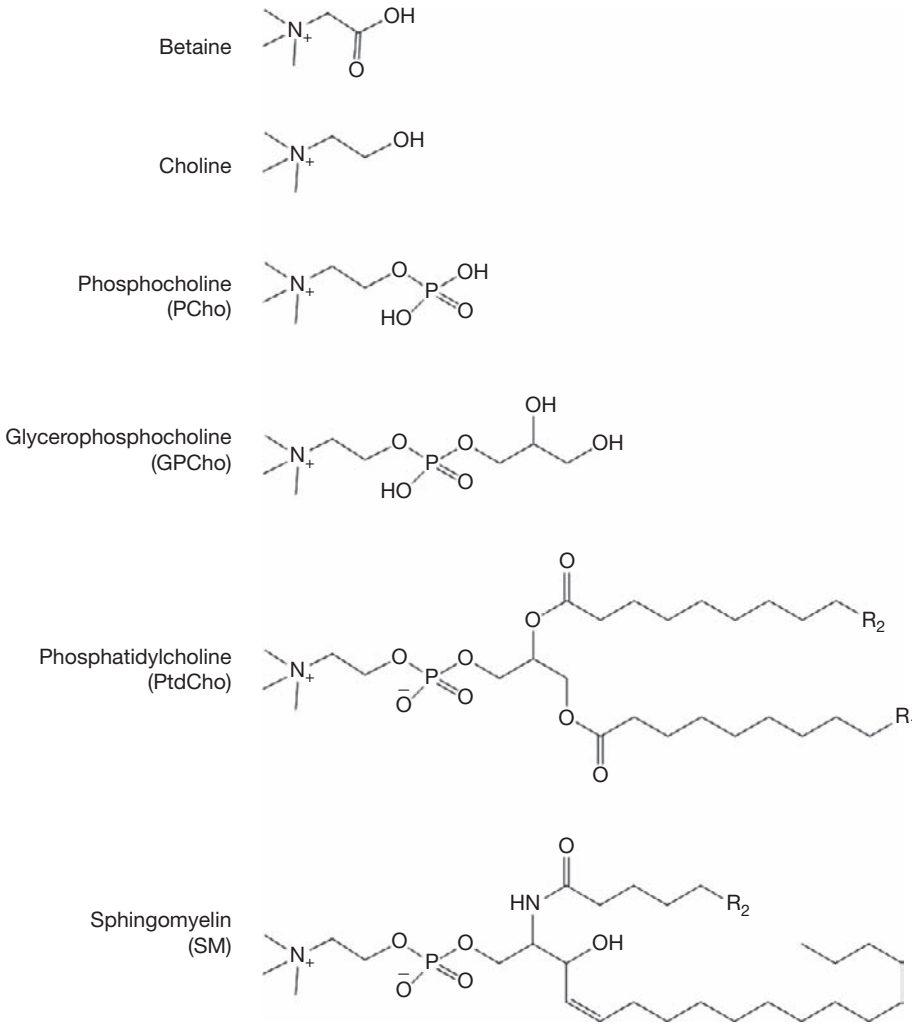

Figure 2 Chemical structures of choline-related compounds.

Table 1 Foods high in choline content

Food description	*Category*	*Free choline (mg/100 g food)*	*Total choline*[a] *(mg/100 g food)*	*Major form*
Egg, yolk, raw, fresh	Dairy, eggs	1.3	682.4	PtdCho
Beef, variety meats and by-products, liver, cooked, braised	Beef	61.8	426.1	PtdCho
Beef, variety meats and by-products, liver, cooked, pan-fried	Beef	56.7	418.3	PtdCho
Veal, variety meats and by-products, liver, cooked, pan-fried	Lamb, veal, game	92.9	411.0	PtdCho
Veal, variety meats and by-products, liver, cooked, braised	Lamb, veal, game	88.6	398.8	PtdCho
Beef, variety meats and by-products, liver, raw	Beef	56.2	333.2	PtdCho
Veal, variety meats and by-products, liver, raw	Lamb, veal, game	85.3	309.9	PtdCho
Chicken, liver, all classes, cooked, pan-fried	Chicken, turkey	69.1	308.5	PtdCho
Chicken, liver, all classes, cooked, simmered	Chicken, turkey	47.9	290.1	PtdCho
Egg, whole, cooked, fried	Dairy, eggs	0.7	272.6	PtdCho
Egg, whole, raw, fresh	Dairy, eggs	0.6	251.0	PtdCho
Egg, whole, cooked, hard-boiled	Dairy, eggs	0.6	225.2	PtdCho
Turkey, liver, all classes, raw	Chicken, turkey	63.8	221.9	PtdCho
Turkey, liver, all classes, cooked, simmered	Chicken, turkey	9.7	220.2	PtdCho
Chicken, liver, all classes, raw	Chicken, turkey	49.2	194.5	PtdCho
Turkey, heart, all classes, cooked, simmered	Chicken, turkey	3.9	172.5	PtdCho
Cereals ready-to-eat, wheat germ, toasted, plain	Breakfast cereals	69.2	152.1	Free choline
Pork, cured, bacon, cooked, pan-fried	Pork	12.3	130.8	PtdCho
Cake, chocolate, dry mix, regular, prepared without frosting	Baked products	5.4	128.4	PtdCho
Turkey, heart, all classes, raw	Chicken, turkey	24.6	126.8	PtdCho
Pork, cured, bacon, cooked, microwaved	Pork	11.6	124.7	PtdCho
Spices, mustard seed, yellow	Spices, herbs	46.2	122.6	PtdCho
Pork, cured, bacon, cooked, baked	Pork	12.3	119.3	PtdCho
Pork, fresh, loin, center loin (chops), bone-in, separable lean only, cooked, broiled	Pork	2.2	102.8	PtdCho
Coffee, instant, decaffeinated, powder	Beverages	93.7	101.9	Free choline
Mutton, roasted from mutton sandwich	Lamb, veal, game	1.7	100.6	PtdCho
Beans, navy, mature seeds, raw	Legumes	49.9	87.4	Free choline
Fish, cod, Atlantic, cooked, dry heat	Finfish, shellfish	17.7	83.7	PtdCho
Noodles, egg, dry, enriched	Cereal grains, pastas	50.4	78.7	Free choline
Nuts, pistachio nuts, dry roasted, with salt added	Nuts, seeds	10.7	71.5	PtdCho
Candies, milk chocolate	Sugars, sweets	9.1	46.1	GPCho
Salad dressing, mayonnaise, soybean oil, with salt	Fats, oils	0.2	46.0	PtdCho
Brussels sprouts, cooked, boiled, drained, without salt	Vegetables	23.4	40.1	Free choline
Orange juice, frozen concentrate, unsweetened, undiluted	Fruits	8.1	19.9	Free choline

[a]Total choline includes the sum of free choline, glycerophosphocholine (GPCho), phosphocholine (PCho), phosphatidylcholine (PtdCho), and sphingomyelin (SM).

differences in the human absorption of the various forms of choline. The water- and lipid-soluble forms of choline are known to have different absorption mechanisms in the human body, which translates to differences in both the method and rate of distribution to tissues. It is also interesting to note that in animal products (meats, dairy, and eggs), the major choline-containing compound identified is PtdCho, while in plant products (fruits, vegetables, and grains), PtdCho is not the major choline compound. In addition to endogenous choline and choline-containing compounds, choline can be added to foods and supplements as choline chloride, choline bitartrate, or lecithin. The PtdCho content of lecithin, a natural emulsifier of plant or animal origin, is roughly 25% by mass, corresponding to approximately 3–4% choline by mass.

In order to establish whether AIs are met, accurate and precise analytical methods must be utilized for determination

of choline and choline-related compounds in foods and food products. In general, two approaches have been taken in the characterization of foods for total choline content: extraction-based methods in which free choline and each choline ester are determined independently and hydrolysis-based methods in which all choline esters are hydrolyzed to free choline and the total free choline content is subsequently determined. The extraction approach, while complicated and time-consuming, is valuable because the concentration of each choline-related compound can be determined independently, and therefore, the bioavailability can be considered with respect to evaluation of total choline intake. This approach requires multiple steps to isolate the hydrophilic (free choline, betaine, PCho, and GPCho) and hydrophobic (PtdCho and SM) components and separate quantitative analyses of the two groups. Conversely, hydrolysis approaches utilize acid, base, and/or enzymes to cleave the esters from the choline moiety, allowing a single analysis to be performed to determine the total concentration of hydrolyzed free choline. The hydrolysis approach is appealing because the overall methodology is often more simple and rapid, but unfortunately, the efficacy of the chemical hydrolysis of the choline esters does not reflect the bioavailability of the various chemical forms.

Once choline intakes are established, appropriate methods are needed to assess the choline status in the population through measurement of choline or choline biomarkers in plasma and/or serum. Experts believe that choline health status is most accurately reflected in the concentration of choline and/or PtdCho in plasma. Fasting choline concentrations in human plasma have been reported in the range of 7–20 $\mu mol\,l^{-1}$, with a median concentration of 10 $\mu mol\,l^{-1}$. Concentrations of PtdCho in human plasma have been reported in the range of 1.0–1.5 $\mu mol\,l^{-1}$, representing mostly the PtdCho that constitutes plasma lipoproteins. The methods for determination of choline and PtdCho in plasma and serum face the same challenges as those for determination in foods, as the extraction and sample cleanup steps are different for the hydrophilic choline and hydrophobic PtdCho. In determination of biomarkers, however, the concentrations of choline and PtdCho are both measured; hydrolysis-based approaches for determination of total choline content are not routinely utilized.

Extraction-Based Approaches for Total Choline Determination in Foods

Extraction-based approaches that separately quantify individual choline-containing compounds in foods and food products are desirable from a nutritional standpoint, as the bioavailabilities of the various choline esters may not be equivalent, leading to misrepresentation of total choline from a simple summation. These approaches typically include both aqueous and organic extraction steps (either simultaneously or in parallel) followed by direct analysis to determine the concentration of each choline-containing compound in the sample. Most approaches rely on a classic liquid–liquid extraction approach in which the sample is diluted to a level of approximately 80% water and combined 1:3 with a mixture of chloroform and methanol (2:1). After homogenizing, an additional one part chloroform is added and one part water in distinct steps separated by additional mixing. The mixture is then allowed to settle; the upper water/methanol layer contains the hydrophilic components, including free choline, betaine, PCho, and GPCho, while the lower chloroform layer contains the hydrophobic PtdCho and SM. This method has been demonstrated to remove 94% of the lipid content into the chloroform layer, with no significant cross extraction between the two layers. Reprocessing of any remaining solid material with an additional aliquot of chloroform has been found to remove the remaining lipid-soluble components, and by combination of the separate chloroform layers, quantitative extraction can be achieved. Other approaches for extraction of choline-containing compounds from food and food products have been described using a parallel approach in which the sample is split, hydrophilic compounds are isolated using dilute acid, and hydrophobic compounds are isolated using a combination of chloroform and methanol.

Once choline-containing compounds have been isolated from a food or food product, they must be isolated from one another for accurate quantitation. Some approaches separate the various compounds using preparative techniques such as liquid chromatography (LC) and thin-layer chromatography (TLC); isolated compounds are then hydrolyzed individually to release choline, and the free choline is measured by a technique such as gas chromatography-mass spectrometry (GC-MS). Performing separate analyses for each compound is time- and resource-intensive, however, which has led to improvements in the analytical approach. Newer methods have converted the preparatory approach described in the preceding text into the overall analytical approach, removing the need for compound collection and separate analysis. In these approaches, both the aqueous and organic extracts can be analyzed using the same LC approach with different mobile phase compositions, leading to a fivefold reduction in the analysis time. This approach has been coupled with mass spectrometry (MS) using stable isotope-labeled internal standards to assign the values reported in the USDA database (Table 1). In addition, the use of an isotope dilution approach to quantitation greatly improves the accuracy and precision of an LC-MS method by reducing errors from sample handling and variability in sample injection and ionization within the mass spectrometer.

Improvements in column technology and better understanding of fundamental chromatographic processes have also led to improvements in the simultaneous determination of choline-containing compounds. Utilization of hydrophilic interaction liquid chromatography (HILIC) may be the future of total choline analysis, as both hydrophilic and hydrophobic components can be analyzed simultaneously, again reducing the analysis time by a factor of 2. Coupled with isotope dilution-tandem mass spectrometry (ID-MS/MS), this type of analysis can even provide information about the distribution of various fatty acid moieties of the choline esters PtdCho and SM. Although still in its infancy, this approach may offer the full suite of information needed to truly understand choline intake from foods in a more straightforward and high-throughput technique.

Hydrolysis-Based Approaches for Total Choline Determination in Foods

Despite concerns about equivalence in bioavailability of different choline-containing compounds in foodstuffs, a majority of

historical approaches for determination of total choline rely on hydrolysis by acid, base, and/or enzymes, which removes all information about the distribution of choline esters. The benefit of hydrolysis, although the sample preparation can be labor- and time-intensive, is that the subsequent determination of the total liberated choline becomes significantly more straightforward than the analysis of individual choline esters.

Classically, colorimetric approaches have been widely used for choline determination. Following the release of choline-containing compounds from foods using three cycles of hot methanol extraction, liberated choline can be reacted to form a Reinecke salt, which is easily detected by absorbance at 520 nm. While this method is simple and straightforward, losses have been observed during the preparation of the precipitate, and the method lacks specificity as the reagent forms the colored product with any amine. The AOAC Official Method of Analysis for choline in infant formula and milk (999.14) is also a colorimetric reaction with choline liberation by acid and enzyme hydrolyses. The reaction mixture includes choline oxidase to release hydrogen peroxide, which will react with peroxidase, 4-aminoantipyrine, and phenol to form a quinone imine dye with absorbance at 505 nm. Modifications to this approach have replaced the phenol and 4-aminoantipyrine with dichlorofluorescein, added a basic hydrolysis step to release PtdCho from lecithin, and added acid-washed decolorizing carbon (Norit) to the sample to remove interference from vitamin C, making the approach more broadly applicable to foods and dietary supplements other than infant formula and milk. Methods based on choline oxidase are more specific for choline, but as demonstrated by the number of necessary modifications, interferences are still possible in the formation of the detectable colored compound.

To increase specificity for choline and remove interferences from other sample components that might be simultaneously extracted, separation-based approaches have been developed. Some methods utilized base hydrolysis to generate triethylamine, which can be determined by GC with flame ionization detector (FID) or MS. Like the colorimetric methods described previously, however, these methods are specific only for quaternary amines and may result in a positive bias from other compounds in the food matrix. Other methods utilized acid hydrolysis or a combined acid and enzyme hydrolysis followed by LC-IDMS or ion chromatography with conductivity or ion-exchange membrane detection. Approaches that did not utilize an enzymatic step with the acid hydrolysis yielded results up to 15% lower than those using a combined approach, because PCho is not completely hydrolyzed under acidic conditions. However, in one modification that conducted the acid hydrolysis in a microwave digestion chamber, an additional enzyme hydrolysis step was not necessary to completely extract total choline from food products. Another approach has also been reported utilizing base hydrolysis, followed by capillary electrophoresis with indirect absorbance detection in the presence of 1-methylimidazole as a carrier electrolyte.

Other less common methods for quantitation of choline in foods and food products have utilized the reaction of choline oxidase with choline from sample extracts by monitoring the consumption of molecular oxygen or the generation of hydrogen peroxide. More specifically, molybdenum-catalyzed oxidation of iodide by hydrogen peroxide has been detected potentiometrically for quantitation of total choline in foods. Biosensors have also been utilized for the detection of O_2 decrease or H_2O_2 increase upon introduction of a choline-containing sample to a reactor containing choline oxidase, in either a standalone or flow-through design. One potential benefit of the biosensor approach lies in the ability to determine choline and choline esters using the same biosensor, by analyzing the same sample pre- and post-hydrolysis. These methods have not been widely adopted, however, as LC and LC-MS equipment are more common in food laboratories, and the use of biosensors for routine analysis has not yet been demonstrated as robust.

Determination of Choline for Health Marker Status

For evaluation of choline health status, the most commonly measured biomarkers are free choline and PtdCho in the serum and/or plasma. Free choline and PtdCho are often separated from the serum and/or plasma matrix by liquid–liquid extraction as described previously for foods; free choline can also be isolated from serum or plasma using ion-exchange resins. Early methods for determination of free choline and PtdCho in plasma and serum involved a radioenzymatic assay in which free choline is extracted into the aqueous layer by liquid–liquid extraction (as described previously) and converted to ^{32}PCho using ATP-γ-^{32}P in the presence of a choline kinase catalyst or ^{32}P-labeled acetyl-CoA in the presence of choline acetyltransferase. Following the separation from the labeled precursor via electrophoresis or ion-exchange chromatography, the radioactive decay of ^{32}PCho is measured by scintillation counting. The organic phase can be analyzed separately for PtdCho by isolation with preparative LC or TLC, hydrolysis to release choline, and repetition of the free choline determination procedure by radioenzymatic assay. PtdCho can also be measured via total phosphorus content by colorimetric assay. These assays are simple, fast, reproducible, and specific for choline and PtdCho and have been demonstrated to have little interference from other choline esters; the only significant drawback is the sensitivity of the assay to the source of the enzymes used in the various hydrolysis and reaction steps.

Several other traditional chemical methods have been utilized as well for determination of choline and PtdCho in biological fluids. Chemiluminescence approaches have been explored, utilizing the reaction of choline with choline oxidase to form peroxide and the subsequent oxidation of acridinium-9-carboxamide or luminol catalyzed by peroxidase. These methods also described the option for hydrolysis of PtdCho by phospholipase D to form free choline, allowing both biomarkers to be determined by the same approach. Another approach utilized the decay of the fluorescence of choline oxidase (native or derivatized) as the reaction with free choline progresses. While these traditional methods have the benefit of simplicity and low instrumentation demand, developing technologies demand demonstration of specificity and increased accuracy and precision for true understanding of clinical health.

Instrumental approaches have been explored more recently to give a more accurate profile of choline and choline esters in plasma and serum. Some of the methods used for food analysis (described previously) have also been applied to clinical analyses, separating the various choline-containing compounds

using preparative chromatography such as LC or TLC. Isolated compounds are then hydrolyzed individually to release choline, and the free choline is measured by a technique such as GC-FID or GC-MS. GC can also be coupled to radiometric assays described previously, by using GC to separate the radiolabeled compounds of interest and monitoring the radioactivity at the column exit. To utilize any GC-based technique, the choline must first be volatilized. Although one pyrolysis–GC-MS technique has been described, the most common approach to volatilization is via chemical derivatization, which can add lengthy sample preparation time and potential for the introduction of error or bias. To reduce error or bias that may result from sample preparation, techniques using stable isotope-labeled compounds as internal standards have been described. By spiking ^{2}H-, ^{13}C-, or ^{15}N-labeled variants of each compound of interest into samples at the start of processing, inefficiencies in extraction, sample losses, and variability in molecular ionization can also be mitigated.

Other approaches have utilized LC with electrochemical detection following postcolumn enzymatic reaction with choline oxidase to generate and electrochemically detect hydrogen peroxide. Free choline has also been derivatized with 1-naphthyl isocyanate prior to LC to utilize fluorescence detection or with 3,5-dinitrobenzoyl chloride prior to LC to utilize absorbance detection. Because choline is a relatively small, hydrophilic molecule, early approaches to LC often included the addition of an ion-pairing agent, which led to challenges in maintaining a robust, reproducible separation. As described for GC-based techniques, the utilization of an internal standard is critical in LC determination of choline as well. The numerous sample preparation and analysis steps allow the possibility for various sources of bias and error in the final analytical determination of choline, and the proper use of an internal standard can reduce the impact.

Taking advantage of the benefits of an internal standard approach, most recent methods for choline determination in serum and plasma have utilized LC with MS or MS/MS detection and isotope dilution for quantitation. As described previously for food analysis, emerging technologies such as HILIC allow simultaneous analysis of choline and PtdCho. Many current approaches utilizing isotope dilution describe the addition of an acetonitrile or methanol solution containing the internal standards to force protein precipitation from serum or plasma. Following centrifugation, these samples can then be directly analyzed by HILIC LC-MS/MS. Because similar methods have been demonstrated in foods for the profiling of numerous choline-containing compounds, it stands to reason that an HILIC LC-MS/MS method could be used to screen serum or plasma samples if a new choline biomarker is discovered.

Conclusions

Choline is a small quaternary ammonium compound that plays an important role in numerous metabolic processes and can be present in numerous forms, each having distinct chemical and nutritive properties. To understand the role of choline in health and function, foods (intake) and biological fluids (output) must be accurately monitored for choline content. As a result, understanding and interpretation of the role of choline in human health rely heavily on the availability of appropriate analytical methodologies.

Introduction

The advanced analytic technologies are revealing a complex profile regarding the food and health research. Most foodstuffs are produced from living organisms and tissues, thus reflecting the complexity of the biological systems they are coming from. Generally, two types of opposite food components, namely, beneficial and hazardous ones, gain the emerging attention. These components play a key role in food nutritional, functional, or hazardous properties. Among the toolkits of techniques developed to investigate food at wide scale including small molecules, peptide, and proteome, chromatography combined with MS has gained popularity especially because of its ability to handle complex food matrices. The chromatography–MS methods demonstrate high resolution ratio, specificity, speed, and reliability of the analytic response in a high-throughput mode. For these reasons, chromatography–MS methods have been extensively employed in food analysis.

In this article, applications of chromatography–MS to food safety and quality is discussed in detail, including detection, identification, and quantification. In this way, the identification and determination of food could be addressed, especially for the certification and traceability of foodstuffs. Moreover, the relationship between structure and function in food systems could be clarified.

Combined Chromatography to MS Strategies

MS method is based on the production of ions, which are subsequently separated or filtered according to their mass-to-charge (m/z) ratio and then detected. The resulting mass spectrum is a plot of the (relative) abundance of the generated ions as a function of the m/z. It provides excellent selectivity, which is of utmost importance in quantitative trace analysis. The mass spectrometer is a highly sophisticated and computerized instrument, which basically consists of ion source, a mass analyzer, and a detector. In principle, liquid chromatography (LC), gas chromatography (GC), and capillary electrophoresis (CE) are used as the separation technique, while the mass spectrometers are employed as a detector. The different physical and chemical properties between analytes and their relative affinity for the stationary/mobile phases promote their separation. The molecules are retained in the column and then elute (come off) from the column at different times (retention time) that depend on the analyte affinity for the mobile phase. This allows the mass spectrometer downstream to capture, ionize, accelerate, deflect, and detect the ionized molecules separately, by breaking each molecule into ionized fragments and detecting these fragments using their m/z. However, online chromatography–MS systems offer additional value, especially in terms of selectivity that allows sensitive and specific analysis in food for various purposes.

Mass Spectrometer

A mass spectrometer contains three major components, namely, an ion source, a mass analyzer, and a detector. The analyte previously separated from other analytes and the matrix bulk eluted to the ion interface, where a portion of the sample is converted into ions. The ions that meet certain characteristics are trajected through the mass analyzer and onto the detector. The mass analyzer is used to sort the ions (according to their m/z values) and to calculate their abundances.

With the ion source, the target of interest is ionized and then transported by magnetic or electric fields to the mass analyzer. For gases and vapors, electron ionization (EI) and chemical ionization (CI) can be applied. For liquid and solid biological samples, electrospray ionization (ESI) and matrix-assisted laser desorption/ionization (MALDI) are the most commonly used ionization sources. Inductively coupled plasma (ICP) sources can carry out cation analysis, although it appears seldom in food analysis. In the combination of HPLC/GC to MS, the ionization sources are classified according to hard and soft ionization of the molecule. Hard ionization types, such as EI, provide a high degree of fragmentation and important information for structure of unknown compounds. However, the EI source is not the most appropriate for HPLC–MS, because of the short EI shelf life at atmospheric pressure. On the country, EI source can be used in GC–MS due to its high vacuum. Soft ionization indicates that ions are formed using lower residual energy, such as fast atom bombardment (FAB), chemical ionization (CI), atmospheric pressure chemical ionization (APCI), electrospray ionization (ESI), and MALDI. These sources provide mostly the molecular ions (or protonated or deprotonated molecules and few fragments).

Mass analyzers separate the ions according to their m/z ratio by using an electric and/or magnetic field. There are different types of mass analyzers. Time-of-flight (TOF) analyzer records the pass-through time by using an electric field to accelerate the ions with the same potential, thus allowing the most rapid reach of lighter ions. Nowadays, TOFs provide accurate m/z. Quadrupole mass filter can chose ions in a certain range of m/z by using oscillating electrical fields and can filter m/z as the quadrupole ion trap. Three-dimensional quadrupole ion trap can trap and eject ions sequentially. A linear quadrupole ion trap can trap ions in a two-dimensional quadrupole field, instead of a three-dimensional quadrupole field as in a 3-D quadrupole ion trap. In the Orbitrap method, ions are electrostatically trapped in an orbit around a central, spindle-shaped electrode.

The final element of the mass spectrometer is the detector. The detector records the charge induced or the current produced when an ion passes by or hits a surface. The electron multiplier, Faraday cups, or ion-to-photon detectors are commonly used.

GC–MS

GC–MS method combines the features of GC and MS to identify different substances within single food sample. The use of a mass spectrometer as detector in GC was developed during the 1950s after being initially assembled by James and Martin in 1952. GC involves an oven and inside of it capillary column with proper dimensions (length, diameter, and film thickness) and optimized phase properties that helps to separate the targets of interested by volatilization using a temperature gradient of the oven. The mobile phase is an inert carrier gas (as helium or nitrogen), while the stationary phase is a microscopic layer of liquid or polymer on an inert solid support (silica). In principle, the targets of interest are volatilized and then interact with the GC stationary phase coated in the column walls. Each compound elutes at a different time (retention time) depending on their boiling point and affinity by the stationary phase.

The typical components of GC instruments are carrier gas, flow controller, sample injector, column oven, column, and detector (any type of mass analyzer). In the GC separation process, a certain volume of gaseous or liquid sample is injected into the column head by using, usually, a microsyringe (solid-phase microextraction fibers can also be used). The carrier gas sweeps the targets through the GC column and, then, the analyte elute of the column when the oven temperature raises its boiling point. Different adsorption strengths between the targets and stationary-phase materials allow also variations in retention time, in favor of the identification and determination by MS.

Recently, comprehensive two-dimensional (2-D) GC, or GC × GC – originally developed in 1991 by Professor Phillips – was employed to separate targets that are difficult to separate by conventional GC. The two GC columns are connected sequentially, the 1-D column is a conventional one and the 2-D column is a short fast one. Between the 2-D columns, a modulator is employed to collect small fractions of the effluent from 1-D, focus them as a narrow pulse, and transfer them to the 2-D. This so-called modulation cycle is repeated throughout the 2-D GC run. For example, a typical modulation is the thermal modulation. The liquid nitrogen is used to immobilize all the components eluting from 1-D. A hot stream pulse mobilizes a part of the compounds through the second column, where the 2-D elution starts again.

GC–MS method offers high sensitivity and resolution power, excellent reproducibility, and extensive and highly reproducible fragmentation, providing excellent identification potential through well-established databases, such as the NIST library. Other advantages are the easy use of the technique and its low cost. The major disadvantage is that GC–MS is by its nature limited to the analysis of small volatile molecules and molecules that can be made volatile. The problem of by-product formation and degradation needs consideration.

The GC-MS methods allow much finer degree of substance identification than either of the unit used separately. It is difficult to make an accurate identification by single GC or MS methods. The MS process normally requires a pure sample, while GC using a traditional detector (e.g., flame ionization detector) cannot differentiate between molecules that coeluted in the same peak. GC–MS method reduces the possibility of error, because two different molecules that behave in the same manner in GC and MS are very rare. Therefore, when an identifying mass spectrum appears at a characteristic retention time in a GC–MS analysis, it typically increases certainty that the analyte of interest is in the sample. Two different molecules can also have a similar pattern of ionization in a mass spectrometer (isobaric interferences). However, accurate mass instruments reduce or eliminate the possibility of these interferences.

LC–MS

LC–MS is a powerful technique that has very high sensitivity and selectivity and so is useful in many applications such as food safety. This separation principle is similar to GC (different affinities of the analytes for the stationary/mobile phases). However, in GC, the analyte separation is between the liquid stationary phase and the gas mobile phase, while, in HPLC, the analyte separation is between the solid stationary phase and the liquid mobile phase. Then, analytes are separated according to their polarity independently of whether they are volatile or not. In HPLC, the separation is forced by a liquid at high pressure (as the mobile phase) through a column. This HPLC column is previously packed with a stationary phase generally composed of irregularly or spherically shaped particles. Usually, octadecylsilyl (C_{18}) is used as stationary phase with pure or pH-adjusted water–organic mixtures (as water–acetonitrile or water–methanol), which is termed reversed-phase liquid chromatography (RP-LC). Silica gel is also can be applied as stationary phase with neat or mixed organic mixtures, which is called normal-phase liquid chromatography (NP-LC). RP-LC is most often used because of its superior separation capabilities.

LC–MS is currently (probably) the most widely used mass spectrometry technology, due to its ability to separate and detect a wide range of molecules. The method allows for the collection of both qualitative and quantitative data and can achieve pgL^{-1}level of detection.

The combination of the separating potential of liquid chromatography and the analyzing power of mass spectrometry makes LC–MS a highly useful tool for analytical chemists. Due to its high selectivity and sensitivity, it is finding increasing use in the analysis of a wide range of substances in complex mixtures. The major challenge in coupling of LC with MS is posed by the fact that gas-phase ions must be produced in order to obtain a mass spectrum.

There are many types of LC–MS interface, such as ESI, APCI, atmospheric pressure photoionization (APPI), and MALDI. Currently, there are mainly two types of API interfaces. One is ESI, which is best suited to ionic compounds with high polarity and the other APCIs. As already mentioned, ESI is a soft ionization technique, producing little fragmentation. For better structural information, ESI interface can be coupled with tandem MS (ESI-MS/MS).

CE–MS Method

CE includes a group of electrokinetic separation methods carried out in submillimeter capillaries and in micro- and nanofluidic channels. In these methods, analytes migrate through electrolyte solutions under the influence of an electric field.

Analytes can be separated according to ionic mobility; additionally, they may be concentrated by means of gradients in conductivity and pH. The identity of sample components can be established by direct coupling of the capillary electrophoresis with mass spectrometers. Commonly, to connect both instruments, the capillary outlet is introduced into an ESI source modified to introduce a sheath liquid that closes the electrical circuit. CE-MS offers a powerful tool for the targeted analysis of polar metabolites, such as amino acids, organics acids, and nucleotides with superior resolution and sensitivity.

Application in Food Analysis

Food products can be regarded as complex mixtures and consist of beneficial and hazardous compounds that naturally occur in food or are introduced during food processing. Beneficial food components include lipid, carbohydrate, polyphenols, carotenoid, amino acids, peptides, and proteins, while the hazardous ones consist of mycotoxin, marine toxin, plant toxins, pesticide, and veterinary drugs. As example of natural beneficial food compounds, lipids such as fats and sterols are able to store energy and act as structural components of cell membranes. The positive health benefits associated with the consumption of omega-3 fatty acids on infant development, cancer, cardiovascular diseases, and various mental illnesses, such as depression, attention-deficit hyperactivity disorder, and dementia, should also be kept in mind. On the contrary, toxic substances generally originating from crop protection treatments against pest, agrochemical treatments, or packaging materials have been frequently found in foodstuffs. Pesticide residues can cause acute and chronic health effects in human and livestock, ranging from simple irritation of the skin and eyes to the destruction of the nervous system, reproductive problems, and even cancer. All these compounds, toxic or beneficial, can be determined using chromatography combined with mass spectrometry. In the next section, the determination of both, beneficial and hazardous compounds, in food is discussed.

Analyzing Beneficial Food Components via Chromatography–MS

Lipid

Lipids are macronutrients that contribute significantly to the nutritional and sensory value of food. Lipids can be found in various forms, such as free fatty acids, acylglycerols, phospholipids, sphingomyelins, glycosphingolipids, steroids, and bile acids. Some lipids have simple structure (as fatty acids), but many others have complex and variable structures. The structures can be ascertained and completely resolved by HPLC–MS or GC–MS methods, helping to establish the structure/function relationship. HPLC–MS method is one of the most powerful tools for the analysis of lipid components in food. Lipid content from various foodstuffs has been extensive investigated. To simplify sample preparation, HPLC–MS method has been an attractive alternative. The main trend of diverse lipids' analysis is the employment of HPLC–MS methods. Triacylglycerols, fatty acids, carotenoids, and phospholipids found in various foodstuffs have been studied in detail via HPLC–MS method. In addition, the use of tandem mass spectrometry (MS/MS) enhances dramatically their structural elucidation, for example, individual triacylglycerols. Besides, GC–MS is also used to analyze free fatty acids and triacylglycerols, although it required derivatization procedures (e.g., transformation of free fatty acids in the methyl esters).

Carbohydrate

Carbohydrates, the most abundant natural products, can be classified according to their degree of polymerization (DP). They can be divided initially into three principal groups, namely, simple sugars (DP 1–2), oligosaccharides (DP 3–9), and polysaccharides (DP > 9). They are one of the most important components for nutrition and health, because they have important physiological role. They can serve as structural elements in plants (as cellulose), important sources of dietary fiber, and major sources of energy (as starch or glucose) in food. For the reasons mentioned earlier, carbohydrates are specially targeted via HPLC–MS or GC–MS methods in food. Monosaccharides and small oligosaccharides have been traditionally analyzed via GC–MS. However, the use of derivative reaction in GC–MS method hampered its application to larger oligosaccharides and molecular conjugates. Due to the high polarity and low volatility of carbohydrates, ESI ionization is usually preferred over APCI ionization. Carbohydrates can be hardly observed in negative ionization, due to its lower sensitivity, while they can be sensitive in the positive ionization mode. For example, the addition of Li salts with low concentration to the HPLC eluents produces $[M+Li]^+$ ions and can increase the sensitivity of carbohydrate compounds in food.

Carotenoids

Carotenoids are lipid-soluble pigments responsible for the color of a wide variety of fruits and vegetables. Some of them are provitamin A carotenoids, subsequently transformed into vitamin A, which can prevent serious eye diseases, such as night blindness; susceptibility to infection; rough, scaly skin; and retarded tooth and bone development. There are about 700 carotenoids in nature, but only about 50 have provitamin activities. Of those 50 compounds, the three most important precursors of vitamin A in humans are α-carotene, β-cryptoxanthin, and β-carotene.

A range of LC-based techniques have been used to analyze carotenoids, most of them coupled to a PDA or UV–vis detector. Although LC separation coupled to UV–vis instruments has been the most common analytic method for determining carotenoids qualitatively and quantitatively, the spectra of many carotenoids are very similar, so many researchers have complemented the identification of carotenoids using other detectors, such as MS. With UV and PDA systems, it is impossible to provide molecular structure information for identification, especially for unknown carotenoids in complex sample matrices. The MS instruments are used to overcome spectral interferences in UV–vis and, therefore, to achieve high sensitivity in complex mixtures and to obtain molecular structure information on the basis of the molecular mass and fragmentation pattern under tandem MS (MS/MS and MS/MS/MS).

For HPLC–MS, usually ESI, sometimes APCI ionization, is used. There are many examples of analysis and quantitation of vitamins in food via HPLC–MS. Most carotenoids are apolar compounds, so APCI (possibly also APPI) ionization may be more advantageous than the more commonly used ESI.

HPLC–MS/MS has also been used to distinguish between structurally related molecules and their epoxidized forms, products of carotenoid oxidation, that are potential oxidative stress markers and difficult to profile due to their small amounts and the difficulty in separating them from hydroxyl carotenoids.

Amino Acids, Peptides, and Proteins

There is currently a general trend in food science towards the consideration of food as an affordable way to prevent diseases. In this sense, one of the main challenges is to improve our limited understanding on the interaction of food compounds with genes and their subsequent effect on proteins and metabolites; this knowledge should allow a rational design of strategies to manipulate cell functions through diet, which is expected to have an extraordinary impact on our health in the nondistant future.

Proteomics is the large-scale analysis of a proteome that includes all the expressed proteins in a particular biological system at a given time, whereas peptidomics is the analysis of all peptide content within an organism, tissue, or cell (peptidome) including not only the peptide present in the system but also the transient products of protein degradation. In general, the major difficulty in the analysis of protein and peptides comes from the different physicochemical properties of proteins, the high number of peptidic sequences that can become available, and the huge dynamic concentration range of both families of compounds in real samples. Proteomics and peptidomics offer multiple applications in food science including food processing, food quality, food safety, and characterization of healthy food ingredients.

LC–MS has been extensively used in the identification and determination of amino acids, peptides, and proteins. In earliest studies, for example, conventional RP-HPLC with chiral derivatization agents was used for the determination of amino acids. However, these methods were not applicable in real food samples because of the insufficient sensitivity and the interference from the numerous coexisting amino acids. For the determination of peptides and proteins, HPLC–MS plays a critical role. By using RP-HPLC, ion exchange, hydrophobic interaction chromatography, etc., peptides and proteins can be separated via the differences in surface hydrophobicity or surface charge. These methods provide the practical technologies to separate complex food matrices, and the affinity chromatography allows the purification of targeted peptides and proteins. After HPLC separation, most peptides and proteins in the low concentration range can be identified by MS techniques.

CE-MS has been mainly applied for proteomics, peptidomics, and metabolomics studies. Capillary electrophoresis techniques coupled to MS are ideal analytic techniques for different 'omics' approaches such as metabolomics, proteomics, and peptidomics mainly due to the particular characteristics of this separation technique. CE provides fast and highly efficient separations, low reagent and sample consumptions (CE is particularly well suited for samples that are volume-limited), and high versatility considering the different CE modes available. The main drawback of CE is its poor sensitivity, but it can be improved by combining CE with MS detection, while the use of preconcentration strategies can give further sensitivity gain. Besides, the use of MS as detector provides additional selectivity and structural information of the detected compounds.

Polyphenols

Flavonoids are polyphenolic compounds, usually found in food and beverage. The motivation of flavonoids analysis using HPLC–MS or GC–MS methods arises from their potential beneficial effects on human health. Flavonoids are usually present in low amounts in a complex matrix of plant extracts and thus generally are difficult to isolate in higher quantities. This, combined with their good sensitivity in electrospray, makes HPLC–MS the method of choice for flavonoid analysis. To increase selectivity (often a critical aspect) and high mass resolution and to increase structural information, tandem mass spectrometry is often used in HPLC–MS analysis of flavonoids.

In the other side, several CE-ESI-MS methods have been developed for the analysis of flavonoids, using high-pH running buffers containing ammonium acetate and MS detection in the negative-ion mode. Other natural compounds bearing phenol structures have been analyzed by CE-MS. Thus, a comparison between HPLC-ESI-MS and CE-ESI-MS for the analysis of phenolic compounds from red wines showed that in spite of CE providing much higher separation efficiency than HPLC, 24 compounds could be identified by HPLC–MS vs. 13 compounds identified by CE-MS in the mentioned red wine extracts.

Food additives

Food additives are strictly limited; only additives explicitly authorized may be used in food. Monitoring foodstuffs for additives is an area of increasing concern and importance. Due to its excellent figures of merit, HPLC–MS is often a method of choice. Food additives are groups of substances commonly classified according to their application and not to their chemical structure. Some of these are small molecules (like benzoic acid used for conservation), some are macromolecules (like the 'infamous' guar gum, causing concern a few years ago), some are synthetic products, while others are natural extracts. For these reasons, it is difficult to generalize the 'proper' analytic method to be used for their characterization. Some methods are compound-specific (and do not estimate total amount of a given class of compounds); some characterize groups of substances. Often, both identification and quantification are required. Generic procedures for the simultaneous extraction of various classes of food additives and residues in various matrices are in use.

Analyzing Hazardous Food Components via Chromatography–MS

Mycotoxin

Mycotoxins are toxic secondary metabolites of fungi (usually molds) that readily colonize crops or foodstuffs during storage. Most often, these are present in cereals and oil seeds. A

database reported 474 mycotoxins and fungal metabolites, while previously unknown metabolites have recently been created. These toxins are dangerous even in very small amounts. Therefore, for some mycotoxins, maximum residue level of aflatoxins B_1, for example, as low as $0.1\mu gkg^{-1}$ has been established by the EU for baby foods and processed cereal-based foods for infants and young children (please see EC No 1881/2006). For mycotoxin analysis, two different strategies can be followed to develop and validate analytic methods. One is to set up a screening method to detect and roughly quantify as many metabolites as possible, reducing the selectivity in extraction and cleanup steps. The other approach is to develop a high-performance method to accurately quantitate a few selected mycotoxins in selected cases. For both approaches, a number of methods have been developed and validated by diverse research groups. The combination of HPLC with MS/MS has proved to be a powerful tool for the simultaneous determination of different classes of mycotoxins.

Besides mycotoxins, also their metabolites often formed in plants and animals might be hazardous for man. Such conjugated or masked mycotoxins can also be analyzed with LC–MS/MS methods, very well suited for high sample throughput, and should be included into multimycotoxin analysis for the direct detection and characterization of metabolites in complex biological and food matrices.

Mycotoxin analysis uses a variety of mass spectrometric methods. Electrospray (in both positive-ion mode and negative-ion mode), APCI, and APPI ionizations are all frequently used. Triple-quadrupole instruments are often used for targeted analysis, while high-resolution analysis is used to look for unexpected derivatives. When quantitation is needed, using isotope-labeled standards, whenever available, is highly advantageous for accurate and precise analysis.

Pesticide residues

Pesticide residues in food are a growing concern, both for the consumers and for legislation. Widespread use of pesticides necessitates their trace analysis in vegetables and various food products. There are several hundred active ingredients and thousands of formulations currently in use. Like in the case of mycotoxins, a large number of compounds need to be screened and, if found, accurately quantified. Simultaneous analysis of pesticides requires development of efficient high-throughput methods.

A significant fraction of pesticide trace analysis is based on HPLC–MS. In most cases, tandem mass spectrometry is utilized, as it allows simplification of sample treatment prior to the analysis and achieves multiresidue analysis in a single chromatographic run. When quantitation is needed, using isotope-labeled standards, whenever available, is highly advantageous for accurate and precise analysis.

For chromatography, often, UHPLC (ultrahigh-performance liquid chromatography) is used. UHPLC allows fast and efficient separation and analysis is usually performed in less than 15 min chromatograms. For analysis, most often, a C18 column with small particle size (1.7 m) is used. The most often used mass spectrometer is the triple quadrupole (QqQ) that achieves tandem mass spectrometry. The QqQ literally has three quadrupole mass analyzers in the same instrument. The first analyzer is set to transmit the precursor (usually the molecular) ion; in the central quadrupole, collision-induced dissociation (CID) takes place, while the second analyzer transmits the expected product ion, which is detected. In this instrument, several precursor ion → product ion transitions are selected (selected reaction monitoring (SRM)) to increase sensitivity.

Increasing selectivity is of prime importance for analyzing trace components in complex materials. For this reason, conventional selected ion monitoring (SIM) in a single quadrupole is usually not considered sufficiently selective to identify pesticide traces in food. Besides tandem mass spectrometry, analysis using high mass resolution (HRMS) is another direction to increase selectivity. This can be carried out using time-of-flight (TOF), Orbitrap, or Fourier transform (FT) mass spectrometers.

A further option to increase accuracy and reliability of pesticide analysis is the use of isotope dilution (that means to use the isotopically labeled analyte as internal standard). This enhances accuracy of analysis and at the same time may allow a simplified sample preparation process. However, it increases the costs of analysis significantly, so for this reason, it is rarely used for routine pesticide analysis in the agrifood sector. Pesticide analysis is one of the most important applications in the agrifood sector. A large variety of different foodstuffs are routinely analyzed, including baby food, vegetables, vegetable oil, honey, fruit juice, wine, and milk.

Conclusion

In the past years, there has been an emerging investigation for the food safety and food quality analysis using chromatography–MS methods, including HPLC, GC, and CE. These combined methods allow the rapid, reliable, and accurate analysis, identification, and quantification in food matrices. State-of-the-art MS instruments enhanced analytic sensitivities for the identification of trace components of food and provide a powerful tool for analyzing various foods to meet the requirements of food legislation or the concerns about toxicity. Combined MS (LC–MS, GC–MS, etc.) and MS/MS methods can reduce the time and labor-consuming sample preparation processes and improve the selectivity for both qualitative and quantitative analyses of food samples present in complex matrices. The advances of simple, robust, and reliable portable chromatography–MS method can promise an on-site, rapid, accurate identification and quantification of unknown compounds in food.

Chromatography: Focus on Multidimensional GC

C Cordero, C Cagliero, E Liberto, B Sgorbini, P Rubiolo, and C Bicchi, Università degli Studi di Torino, Torino, Italy

Introduction

Over the last decades, consumers' preferences have been addressed to healthier and flavorsome food with higher nutritional value: the driving force has been food quality. Primary condition for quality is safety that is closely related to the compliance with legal standards on human health risks, the environment, animal welfare, protection of natural resources, and ethical requirements. On the other hand, the sensory impact due to flavor, smell, and appearance has assumed an equally important role. In this perspective, food end products, semifinished products, and raw food matrices require control analyses to establish quality requisites and to verify compliance with legal standards.

Since its introduction in the early 1950s, gas chromatography (GC) demonstrated to be an effective, flexible, and sensitive technique for food analysis and has been successfully adopted as the 'core' of the analytic process for

- flavor and aroma characterization (*sensomics*);
- studies of composition and of origin authentication;
- characterization of the volatile compounds from vegetable matrices, essential oils, and differently produced extracts;
- fat analysis and characterization (short-chain fatty acids, fatty acids methyl esters (FAMEs), triglycerides, sterols, etc.);
- residue and contaminant determination (pesticides, veterinary drugs, endocrine-disrupting chemicals (ECDs), food packaging migration products, and environmental contaminants such as polychlorinated biphenyls (PCBs) and polyaromatic hydrocarbons (PAHs).

However, one-dimensional GC not always provides adequate efficiency and selectivity to obtain the required results in terms of analyte separation (and as a consequence identification and quantitation), in particular when complex samples have to be analyzed. On the other hand, although the new generation of mass spectrometric detectors thanks to improved performances (new ionization sources/interfaces and analyzers) enables reliable identity confirmation and quantitation even without a separative step, chromatographic separation provides additional information on analyte physicochemical properties that in some cases are necessary for unknown identification (i.e., isomers).

Multidimensional chromatography (MDC) has therefore emerged as a valuable alternative thanks to the peak capacity enhancement as well as the possibility to combine orthogonal discrimination principles (including those provided at the detection level) to investigate sample composition and to process results to obtain higher and further levels of information.

MDC combines two, or more, independent (or nearly independent) separation steps, increasing significantly the separation power of the resulting system. In the early 1980s, the comprehensive definitions of MDC already distinguished those system configurations providing a simultaneous zone displacement from those adopting coupled columns that provide sequential displacement of analytes.

More recently, because of modern instrumental innovations and MDC developed applications, a more general definition of MDC as '*n*-dimensional analysis that generates n-dimensional displacement information' was proposed.

When gas-phase separations are considered, the most intuitive and descriptive definition was given by Marriott, who has defined multidimensional gas chromatography (MDGC) as "the process of selecting a (limited) region or zone of eluted compounds issuing from the end of one GC column, and subsequently subjecting the zone to a further GC displacement."

A typical MDGC separation focuses on a fixed number of fractions eluting from the first dimension (^{1}D), the so-called heart-cuts (H/C) (the approach is referred to as heart-cut multidimensional gas chromatography (H/C MDGC)) that are subsequently analyzed in the second dimension (^{2}D), with the aim to improve separation by combining different discrimination principles exploiting 2-D-system selectivity. Alternatively, when a fast and continuous heart-cutting (named modulation) is implemented by applying sampling periods compatible with the ^{1}D peak width, the resulting MDGC approach is named comprehensive 2-D GC or GC × GC.

Figure 1 shows a schematic description of monodimensional and different multidimensional GC instrumental configurations; Figure 1(a) reports a conventional monodimensional GC system, and Figure 1(b) a typical H/C MDGC including a switching system (or valve V) located at the junction between the two columns. The system also includes an auxiliary gas line from an electronic pressure controller (aux EPC) that provides flow for the switching valve and/or a makeup flow for the ^{2}D column that is located in a separate oven. The system is also equipped with a primary detector (Det 1) and with a monitor detector (Det 2), optional. Figure 1(c) shows a comprehensive two-dimensional system configuration that includes a modulator (M) that interfaces the two columns (^{1}D and ^{2}D) coupled in series. The detection is placed at the end of the ^{2}D column.

The next sections present basic operative principles, instrumental configurations, and applications of H/C MDGC and comprehensive two-dimensional gas chromatography (GC × GC).

Heart-Cut Multidimensional Gas Chromatography

Basic Operative Principles and Instrumental Configurations

A classical H/C MDGC configuration basically consists of two conventional capillary columns (e.g., 30 m × 0.25 mm ID × 0.25 μm film thickness – d_f) coated with stationary phases differing in selectivity, connected in series. Columns can be located in a single or in two separate ovens, and a suitable interface is located between the two dimensions enabling to

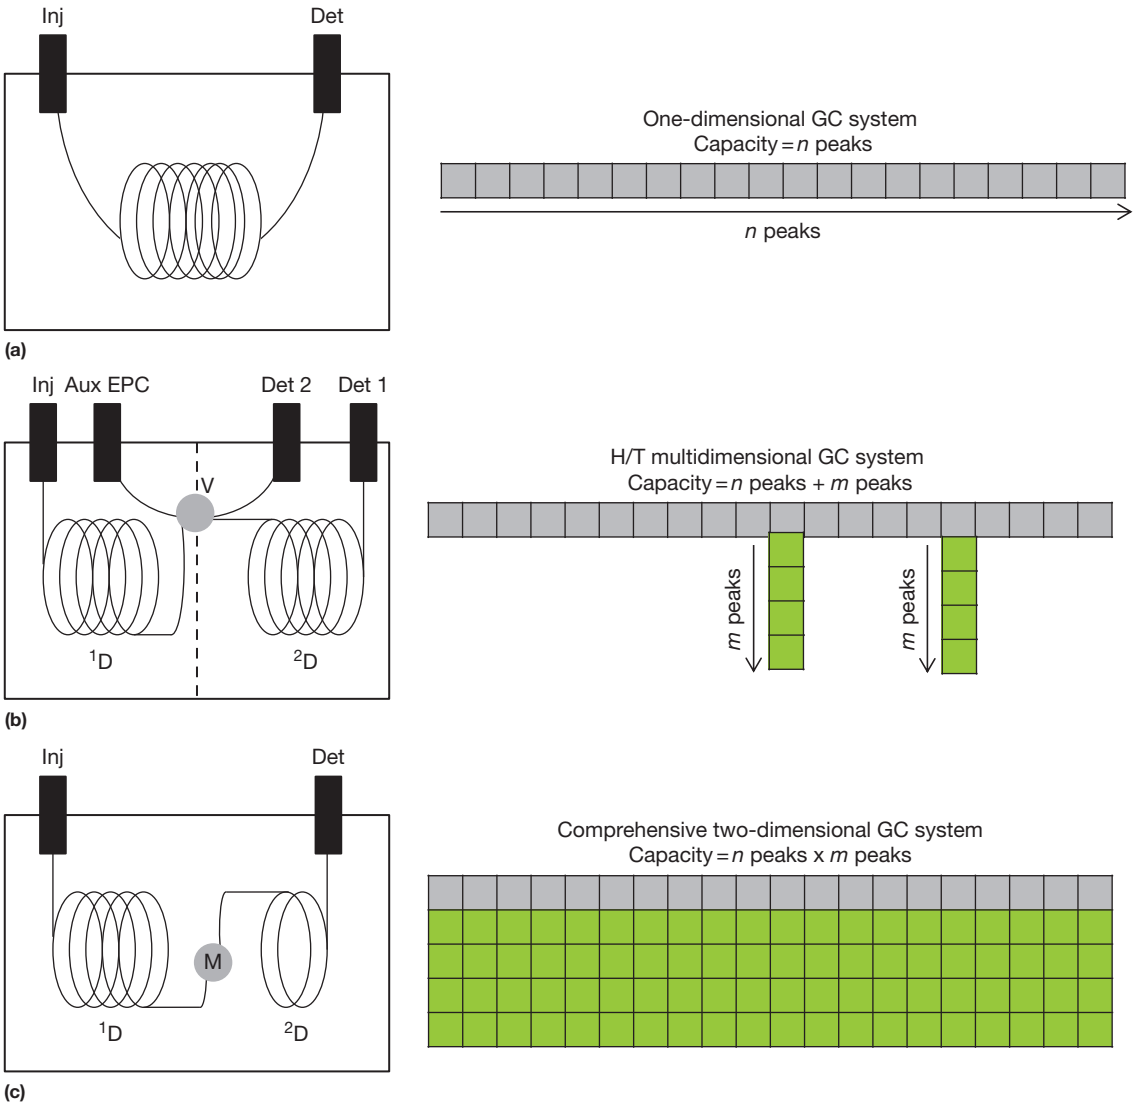

Figure 1 Schematic visualization of mono- and multidimensional GC instrumental configurations and their actual peak capacity: (a) shows a typical one-dimensional system, (b) shows an H/C MDGC, while (c) shows a comprehensive two-dimensional system. Inj, injector; aux EPC, auxiliary gas electron pressure controller; Det 1, primary detector; Det 2, monitor detector; V, switching interface; M, modulator; ^{1}D, first dimension column; ^{2}D, second dimension column; n^{1}D, peak capacity; m^{2}D, peak capacity.

transfer chromatographic bands from the ^{1}D to the ^{2}D column (see Figure 1(a)). The use of a cryotrapping device, between the two capillaries, position V in Figure 1(a), makes the system more efficient, affording a better band focussing and reconcentration that results in an improved ^{2}D peak capacity and higher system sensitivity for trace analytes.

The transfer devices developed since the beginnings of the technique can be classified in three groups: in-line and out-line valves, the most popular systems, and valveless systems.

Valve-based systems, although straightforward in principle, are affected by several limitations due to efficiency and inertness. Band dispersion caused by dead volumes and retention time fluctuations may occur. The modern SilTite™ technology enabled to overcome valves surface activity and improved mechanical robustness when installed in a hot oven.

Six-port–two-position W-type valves from Valco, live-coupling/switching pieces, and Deans-switch interfaces utilizing Valco microvolume T-piece are nowadays the most popular devices for valve-based systems in MDGC.

However, thanks to the evolution electronic pressure control systems and their integration into the GC, most of the MDGC systems adopt nonintrusive, valveless flow-modulated devices (based on pneumatic flow switching). Some examples of H/C MDGC systems available on the market are the multi-Deans-switching technology from Shimadzu, the moving capillary stream switching (MCSS) from Brechbühler, the capillary flow technology (CFT) from Agilent, the Swafer™ microchannel system from PerkinElmer, and the SilFlow™ microchannel device (MCD) from SGE. Effluent-switching devices by Agilent, PerkinElmer, and SGE are based on microchips that connect individual switch components into a single, small deactivated microchip plate.

The Swafer™ system has laser-fabricated microchannels on circular metal disks present in the device body and is available

with different configurations allowing flow switching and splitting between two or four inputs and two or up to four outputs. With the SilFlow™ technology, the MCD has options for three-port or four-port GC splitters. Advantages of microfabricated devices rely on the possibility to overcome and eliminate chromatographic distortions (peak tailing, peak broadening, and/or analyte loss) thanks to surface inertness, low thermal mass, and low dead volumes.

From an operative point of view, they are based on a microfluidic Deans-switch technology; a description of the principle of operation is reported in section '**Thermal and Pneumatic Modulators**.'

H/C MDGC Applications in Food Analysis

One of the most remarkable fields of the application of multidimensional gas chromatographic techniques is the analysis of medium-to-high complex mixtures of volatiles and semivolatiles that include aroma-active compounds, botanical tracers, and origin authentication markers. Thanks to MDGC technology, food flavor analysis undoubtedly experienced advances and improvements, in terms of results' accuracy and reliability. Key features in flavor analysis include the possibility to obtain better separations, after ^{1}D prefractionation of complex samples and improved sensitivity for target analyte detection due to higher system loadability that is not affected by column or detector overloading; in addition, when separation is followed by olphactometric detection to screen for sensory-active compounds, GC effluent can be diverted to a suitable sniffing port and contemporarily subjected to further separation and/or detection.

Another field where MDGC is very popular is chiral recognition of chiral food flavors; the adoption of chiral selectors as stationary phases for capillary columns in the ^{2}D provided a further approach for flavor authentication.

Figure 2 shows an interesting application of ES-MDGC-MS for the characterization of wine aroma and in particular in the identification of the chiral flavor analytes responsible of the rose note of a Riesling wine.

A further advancement in flavor authentication is represented by MDGC coupled with isotopic ratio mass spectrometry (IRMS). MDGC–IRMS affords to define the origin of diagnostic flavor compounds in consideration of the natural variation in isotope distribution. Constant-flow MDGC–combustion/pyrolysis–IRMS was successfully applied to the authenticity assessment of (*E*)-α(β)-ionone from raspberry cultivars.

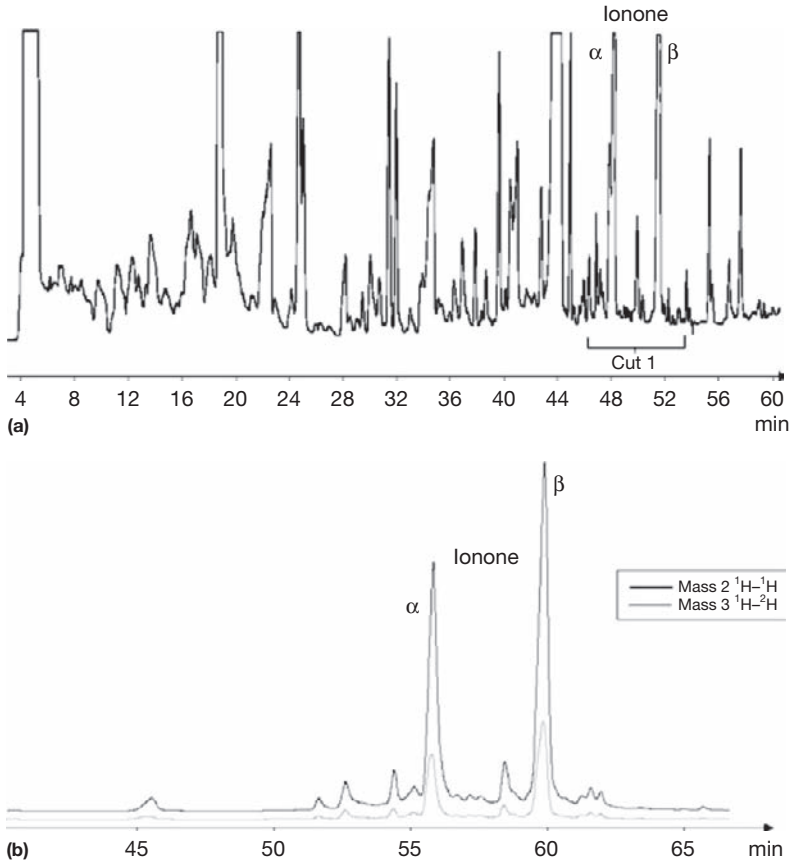

Figure 2 Isolation and characterization of aroma-active compounds in Riesling wine. (a) One-dimensional GC-FID/O on polar stationary phase (Carbowax 20M) enables to identify an aroma-active zone with rose notes. The heart-cut window (inset) shows the same region separated on an apolar (5% phenyl–95% polydimethylsiloxane) ^{2}D column. (b) Combining MS and olphactometric detection, analytes responsible for the rose aroma are univocally identified. (c) Separation of rose oxide enantiomers from a standard racemic mixture by ES-MDGC-MS on a 6TBDMS-DiAc-β-CD together with their odor threshold (OT) values. Lower trace reports the enantiomeric distribution of rose oxides found in a Riesling wine. Reproduced from Marriott, P. J., Chin, S. T., Maikhunthod, B., Schmarr, H. G. and Bieri, S. (2012). Multidimensional gas chromatography. *Trends in Analytical Chemistry* **34**, 1–21.

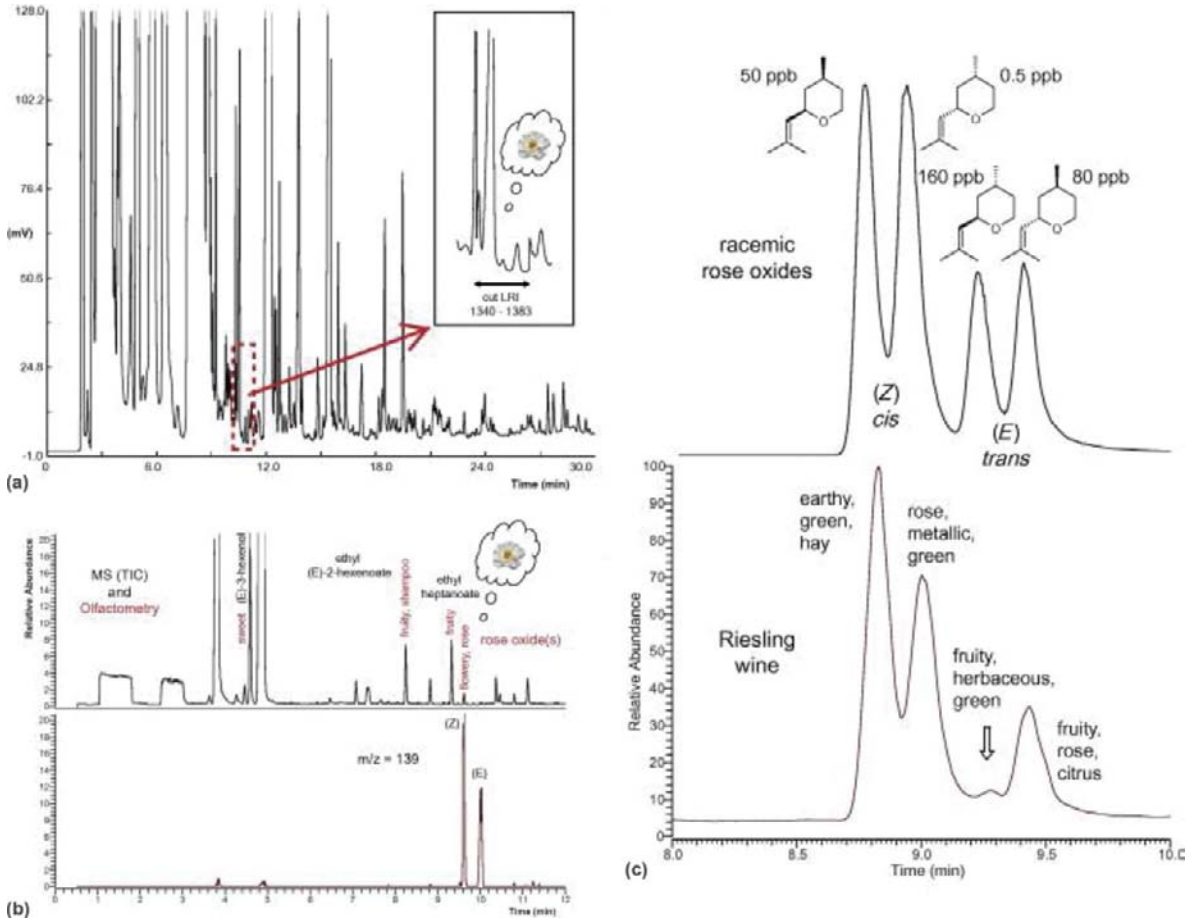

Figure 3 One-dimensional chromatogram (a) with FID detection and H/C MDGC – pyrolysis – isotope ratio mass spectrometry (H/C MDGC–P–IRMS) separation of the ionones eluting region (b) with MS selected ion monitoring (SIM) detection of a raspberry extract. $^{2}H/^{1}H$ isotope ratios were measured by H/C MDGC–P–IRMS run on a twin-oven system from HP model 6890 GC with autosampler A200S (CTC Analytics, Zwingen, Switzerland); multicolumn switching system MCS2 (Gerstel, Mülheim, Germany) coupled to an isotope ratio mass spectrometer (DeltaplusXL) via a pyrolysis reactor (ceramic tube (Al2O3), length = 320 mm, 0.5 mm i.d., and reactor temperature = 1450 °C); and an open split (Thermo Electron, Bremen, Germany). The ^{1}D was equipped with an Rtx-1701 column (30 m × 0.25 mm ID, 1 μm d_f) (Restek, Bad Homburg, Germany) and ^{2}D column with a ZB 5 (30 m × 0.25 mm ID, 0.50 μm d_f) (Zebron, Phenomenex, Aschaffenburg, Germany). The following conditions were employed: splitless injection (injector temperature, 220 °C); ^{1}D temperature program, starting from 100 °C, isothermal for 2 min, and increasing by 2–220 °C min^{-1}, isothermal for 40 min; transfer line temperature, 220 °C; and cut, 46–54 min. The ^{1}D retention times of the ionones were determined by a monitor detector, FID, temperature = 250 °C. The ^{2}D column temperature program started from 60 °C, isothermal for 2 min; increased by 6–180 °C min^{-1}, isothermal for 10 min; and increased by 1.5–220 °C min^{-1}, isothermal for 10 min; carrier gas flow (helium) was 0.8 ml min^{-1}, constant flow. Reproduced from Sewenig, S., Bullinger, D., Hener, U. and Mosandl, A. (2005). Comprehensive authentication of (*E*)-α(β)-ionone from raspberries, using constant flow MDGC-C/P-IRMS and enantio-MDGC-MS. *Journal of Agricultural and Food Chemistry* **53**, 838–844.

Figure 3 reports the total chromatogram (a) and the resulting H/C MDGC chromatogram (b) of a raspberry extract measured by MDGC–IRMS. For accurate and precise isotopic measurement of (*E*)-α-ionone and (*E*)-β-ionone, it is necessary to cut exclusively the ^{1}D band eluting in correspondence to (*E*)-α(β)-ionone. The chromatographic system of this example includes a ^{1}D Rtx-1701 column (30 m × 0.25 mm ID × 1 μm d_f) and a ^{2}D equipped with a ZB 5 column (30 m × 0.25 mm ID × 0.5 μm d_f).

H/C MDGC has demonstrated to be a valuable tool to solve targeted analytic problems: quantitation of informative analytes and identification and abundance assessment of authenticity markers. However, when comprehensive investigation has to be run, through untargeted approaches, multidimensionality has to be extended to the whole analytic run.

Two-Dimensional Comprehensive Gas Chromatography (GC × GC)

Basic Operative Principles

In H/C MDGC, dedicated time-programmable interfaces transfer automatically, and online, fractions consisting of a few components (peaks) eluting from the ^{1}D column for a limited time fraction of the whole chromatographic run to the ^{2}D column; conversely, in GC × GC, each component eluting from the first column is online and automatically trapped, refocussed, and reinjected into the second column. This operation is run by a modulator, thermal or valve-based focussing interface, within a fixed time (4–8 s), which is also the time allowed for the analysis in the ^{2}D.

Comprehensive MDGC (i.e., GC × GC) was firstly introduced by Phillips in 1996, and today, it is widely accepted. This technique has superior separation performance than H/C MDGC due to the comprehensive application of multidimensional separation to the entire sample in every single analytic run. Figure 1 shows how H/C MDGC (Figure 1(b)) and GC × GC (Figure 1(c)) effectively exploit system separation power and the resulting theoretical peak capacity compared to one-dimensional separations (Figure 1(a)).

The core of a GC × GC system is the modulator that accumulates (or traps), refocuses, and rapidly releases fractions eluting from the ^{1}D to the ^{2}D column. These operations are run within a fixed time frame, named modulation period (PM), and repeated across the entire chromatographic run. Modulation has to be sufficiently rapid to preserve the original ^{1}D separation, while ^{2}D separation has to be fast enough to be finished before the injection of the subsequent fraction from ^{1}D effluent.

Appropriate selection of columns' dimensions, combination of stationary phases, PM, and timing enables the full exploitation of system potentials, optimized peak capacity, and high reproducibility in terms of 2-D peaks' distribution over the chromatographic plane and accurate mass transfer (accuracy in quantitative determinations).

Thermal and Pneumatic Modulators

Modulators can be essentially divided into two main categories on the basis of the operative principle: thermal and pneumatic modulators. Thermal modulators use positive and/or negative temperature difference, with respect to the GC oven, to transfer fractions from the ^{1}D to the ^{2}D. Common feature of these systems is the sensitivity enhancement, obtained by the band refocussing promoted by temperature difference, being their duty cycle equal to 1, meaning that the mass transfer is complete without leaks.

Conversely, pneumatic interfaces adopt valves connected either in-line or out-line with the column set, for band transfers.

Until 1998, when a hybrid cryogenic/pneumatic interface was firstly implemented, all modulators were thermal and basically inspired to or developed on Phillips models.

Above all, and excluding prototypes and/or innovative thermal interfaces still close in research and development laboratories, commercial instrumentation is nowadays equipped with different design two-stage thermal modulators.

Briefly, fundamental steps include the following:

I step: The narrow band eluting from the ^{1}D (generally a 25 m × 0.25 mm ID × 0.25 μm d_f) is focussed under a cold jet stream (CO_2, liquid N_2, or compressed air for high-molecular-weight analytes). Focussing can be done on a portion of the ^{1}D column, in a deactivated tubing of suitable inner diameter (generally a narrow bore capillary 0.10 mm ID), or at the head of the ^{2}D column (generally a 1 m × 0.10 mm ID × 0.10 μm d_f).

II and III steps: Reinjection is achieved by heating and volatilizing the condensed fraction; this operation is typically done by switching off the cold jet and letting modulation capillary to be heated by oven temperature (longitudinally modulated cryogenic system – LMCS and dual-jet CO_2 developed by Beens) or by activating an hot jet upstream (loop-type dual jet from Zoex and quad-jet modulators) as depicted in Figure 5. Typically, remobilization has a pulse duration from 10 to a few hundred milliseconds depending on the analyte volatility and on the differential temperature achieved in the cold–hot jet duty cycle.

Analytes are then subjected to a further cycle of focussing and reinjection (*IV step*) to achieve an optimized band width at the entrance of the ^{2}D column. When orthogonal displacement is applied between the two dimensions (by adopting different stationary phases), analytes, not separated in the ^{1}D, can be separated in the ^{2}D.

Despite the superior effectiveness of cryogenic modulation, it is also rather expensive due to the cryogenic fluid consumption and instrumental management. The development of cryogenic-free, low-cost interfaces has therefore been a field of active research in the last few years. Pneumatic modulation has experienced an increasing interest, grown in parallel with the spreading of the technique both in the scientific community and in the industry.

In-line connected pneumatic interfaces adopt multiport diaphragm valves or solenoid valves, some of them also applied in H/C MDGC. The first example of a diaphragm valve-based system was able to sample only very narrow timed fractions from the effluent of the first dimension. With early pneumatic modulators, the band focussing was done by rapid sampling of narrow fractions (50 ms wide, twice a second) from the ^{1}D; being so sharp, they do not need further focussing to enter the ^{2}D column. This interface is not mass-conservative and about 90% of the first column effluent is lost. A step forward was done by the introduction of valve-based systems with flow diversion, which implement the band focussing 'in time' thanks to the adoption of a sampling loop, connected for the 80% of the time in series with the ^{1}D column, and an extra flow of carrier gas toward the ^{2}D column. This system maintains a ^{2}D linear velocity at least 20 times higher than that of the ^{1}D column; the injected band therefore becomes compressed and about 80% of the original mass passes to the second dimension. Alternative configurations may include two parallel ^{2}Ds and consequently two detection systems.

Out-line pneumatic interfaces, located outside the GC oven and not along the sample path, are based on the principles of flow switching implemented in the Deans-switch technology. The device, in its first construction, consisted of a planar metal plate housing a collection chamber connected (via two metal branches) to a three-way solenoid valve. More recently, to attain flexibility and differential flow velocity required by GC × GC, the fixed volume chamber has been replaced by a flow restrictor (a capillary) with selectable inner diameter and length (also define as flexible loop). An electronic pressure-control module supplies the auxiliary gas through a solenoid valve that can be switched. The collection chamber (or the restrictor) is filled periodically with ^{1}D column effluent when the solenoid valve is in the bypass mode. At the end of the collection period, the internal 'loop' is flushed for 100–200 ms by a very high gas flow (typically 20 ml min^{-1}), generated by switching the valve to the inject mode. By setting the first- and second-column flow at a ratio of F_1:F_2 = 1:20, the ^{1}D column band can be compressed (in time) to form a 20-fold narrower

^{2}D column pulse (1.0 s pulse can be injected as a 50 ms pulse). This modulation interface has theoretically no temperature restriction and can be considered truly comprehensive being able to transfer the 100% of the column effluent of the first column into the second column.

Other pneumatic modulators adopting flexible loops and/or multichannel chip-based capillaries, connected via multiport valves to auxiliary gas controllers, have been introduced but to date are not available as commercial products.

Detectors for GC × GC

Narrow peaks of about 50–300 ms base peak width necessitate fast acquisition rates (i.e., at least 50–100 Hz). Flame-ionization detection (FID) with its high maximum frequency of acquisition (50–300 Hz) has been used for years, while element-selective detectors, such as electron capture detector (μECD), nitrogen- and sulfur-chemiluminescence detectors (NCD and SCD), and nitrogen–phosphorous detector (NPD), need careful optimization although in specific field of application they provide useful complementary information for analyte identification. For example, GC × GC with dual detection by NPD and ECD, obtained thanks to microfluidic splitting interfaces, has been successful for multiclass pesticide-residue analysis in vegetable samples.

Mass spectrometry, on the other hand, can be considered the elective detector for GC × GC platforms enabling univocal analyte identification, in combination with retention data, and accurate quantitation. Time-of-flight mass spectrometry (TOF-MS) operating in low-resolution mass detection and fast acquisition is the preferred detector because of its high data-acquisition rate, selectivity, reliable deconvolution of overlapping peaks, and ability to scan for broad mass range. On the other hand, high-resolution TOF-MS, although in principle very straightforward in terms of information potentials related to accurate mass detection, is characterized by slower acquisition speed. The recent introduction of (HR)TOF-MS benchtop instrumentation has opened new perspectives for metabolomics and foodomics applications.

Quadrupole MS (qMS) has experienced in the last years a renewed interest for a number of applications, including qualitative and quantitative. Modern fast quadrupoles (operating with acquisition rate up to 50 Hz for scan and selected ion monitoring (SIM) mode) have in fact demonstrated to be really competitive in terms of quality and reliability of the results provided; in addition, commercial MS databases, prevailing in qMS spectra, can successfully be adopted for unknown identification.

Data Visualization and Elaboration

Although GC × GC is a true two-dimensional separation, the process produces data values that are sequential: chromatographic bands eluting from the ^{1}D are collected, focussed, and reinjected in the ^{2}D where they undergo further separation before detection. In the detector, an analog-to-digital (A/D) converter collects the chromatographic signal at a certain frequency. The digitalized data and related metadata (information about the data) are stored in a file with a specific format for subsequent access. GC × GC systems use an A/D converter to map the intensity of the chromatographic signal to a digital number as a function of time. Single-channel detectors (i.e., FID, ECD, and SCD) produce a single value at each time sample of the chromatogram, while multichannel detectors (such as MSs) produce multiple values (typically over a spectral range) for each time sample.

Data collected are generally stored under proprietary data file format but can be converted to text, as ASCII format comma-separated values (CSV), or to the ASTM format named analytical data interchange (ANDI) that is a standard for chromatography and MS data. Although these standards lack some information specific for GC × GC metadata, as, for example, the modulation cycle, they are commonly used to communicate raw data and to enable elaboration within different software platforms.

Visualization is the next step and enables, at first, a qualitative inspection of chromatographic separation. It can be implemented through *rasterization* by arranging data values acquired during a single modulation cycle as a column of pixels (picture elements), so that the ordinate (*Y*-axis, bottom to top) is the elapsed time for the ^{2}D separation, and then, by arranging these pixel columns so that the abscissa (*X*-axis, left to right) is the elapsed time for the ^{1}D separation. This ordering presents the data in the commonly used right-handed Cartesian coordinate system, with the ^{1}D retention times as the first index into the array.

Data processing extracts higher level of information from raw data enabling peak detection, peak identification, quantitative analysis, and sample comparison, classification, and recognition based on ^{2}D patterns. A detailed description of data processing approaches is beyond the scope of this contribution, but information can be retrieved in suggested further readings. However, an example of advanced fingerprinting is presented in section '**GC × GC Applications in Food Analysis**' for food origin authentication.

GC × GC Applications in Food Analysis

GC plays an important role as an analysis tool for aroma extracts and essential oils, due to the complexity of the matrix and the variable abundance of components from trace (ng/g) to several per cent (g/100 g). Groups of chemically related components (e.g., monoterpenoids and sesquiterpenoids, saturated and unsaturated hydrocarbons, alcohols, carbonyl derivatives, and esters) are common. These compound classes possess similar chromatographic behavior and may have common isobaric molecular ions and/or MS spectra, which makes MS interpretation and analyte identification difficult. The capability to adopt different GC × GC separation mechanisms, as well as producing rationalized ^{2}D patterns, can overcome these problems.

GC × GC in food analysis covers a wide range of applications from the identification and profiling of fats, oils, essential oils, and extracts to food contaminant determinations. Very recently, several authors have demonstrated its potentials in *sensomics* applications by combining advanced sample preparation with multiple detection, including olfactometry in GC (O) × GC-MS platforms.

A typical application of GC × GC in fat and oil characterization is the detailed analysis of FAMEs. FAMEs differ among each other primarily in their chain length, their number of unsaturations, and the *cis*/*trans* configuration of their double

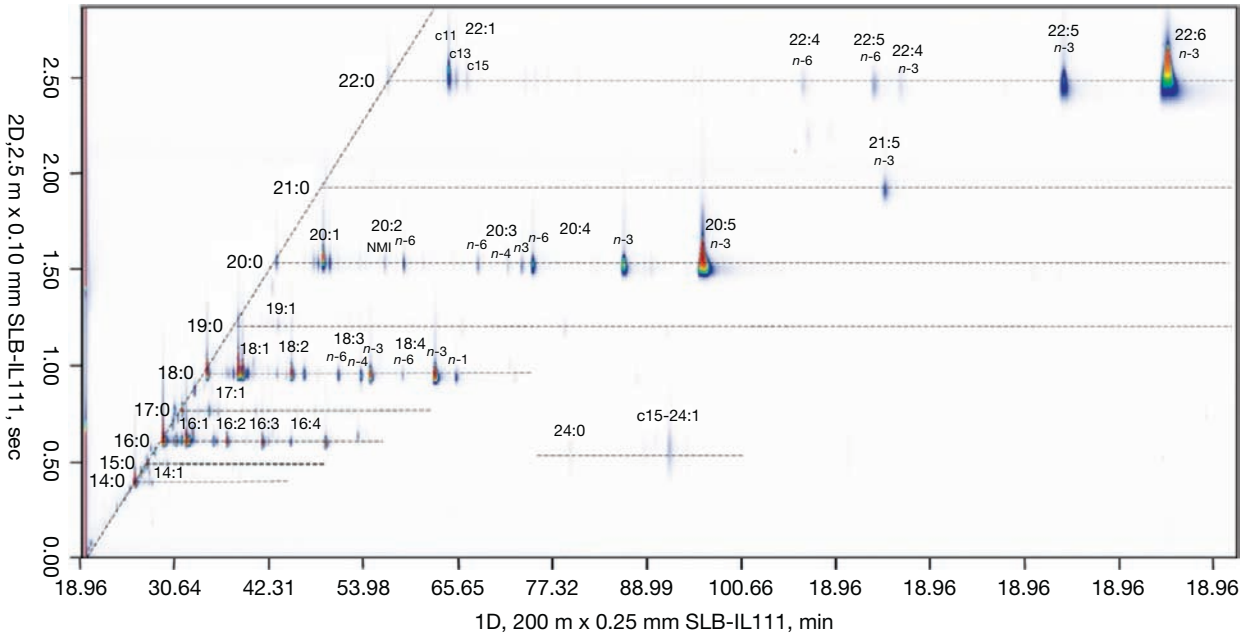

Figure 4 GC × GC separation of FAMEs from a menhaden fish oil. System consisted of an Agilent 7890A GC (Agilent Tech., Wilmington, DE) combined with a Zoex ZX2 dual-stage cryogenic modulator (Houston, TX). The injection port of the gas chromatograph was connected to a 1034 kPa electronic pressure control module, and hydrogen was used as the carrier gas. Supelco SLB-IL111 capillary column (200 m × 0.25 mm ID × 0.2 μm d_f, Bellefonte, PA) was used for ^{1}D separation, and the same capillary column but with different dimensions (2.75 m × 0.10 mm ID × 0.08 μm d_f) was used for the ^{2}D separation. The cryogenic modulator first loop consisted of a 2 m × 0.10 mm deactivated capillary. The 50 cm × 0.15 mm Pd capillary reactor was placed between the ^{1}D column and the modulator. The timing of the modulation was set to 3.5 s; the temperature of the hot jet was set at 350 °C with a pulse of 350 ms. The column oven temperature was set to 170 °C, and the injector port at 300 °C. Analysis was acquired in constant pressure at 690 kPa and the split flow was set to 125.69 ml min^{-1}. Reproduced from Delmonte, P., Fardin-Kia, A. R. and Rader, J. I. (2013) Separation of fatty acid methyl esters by GC-online hydrogenation × GC. *Analytical Chemistry* **85**, 1517–1524.

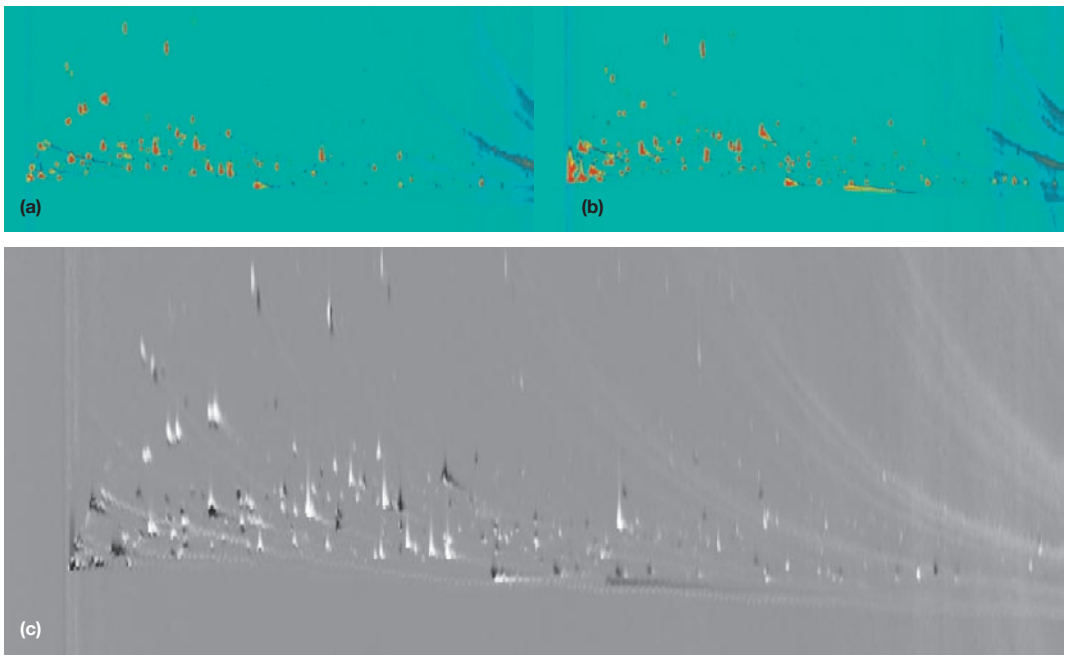

Figure 5 2-D plots of the volatile fraction from an Italian extra virgin olive oil sample and from a defected sample where *muddy* notes where perceived by the official panel (b). Image comparison (c) results, visualized in a grayscale ratio mode (GC-Image™ software), reveal compositional differences by lighter and darker areas. Analysis conditions: HS-SPME sampling, 2 cm StableFlex 50/30 μm DVB–Carboxen–PDMS fiber (Supelco, Bellefonte, the United States); sample amount, 1.000 g; vial volume, 20 ml; sampling time, 40 min; and temperature, 40 °C. GC × GC analyses: GC × GC-MS system: Agilent 6890 GC–Agilent 5975 MSD ionization mode: EI 70 eV (Agilent, Little Falls, DE, USA); transfer line temp., 280 °C; scan range, *m/z* 35–250 in fast scanning mode (10 000 amu s^{-1}). GC × GC interface: KT 2004 loop modulator (Zoex Corporation, Houston, TX, USA); modulation time, 4 s. Column set: ^{1}D, CW20M column (30 m × 0.25 mm ID, 0.25 μm d_f); ^{2}D OV1701 column (1 m × 0.10 mm ID, 0.10 μm d_f) (MEGA – Legnano (Milan), Italy). Analysis conditions: injection mode, split; ratio, 1/20; temp., 250 °C; carrier gas, helium; T. program, 40 °C (1 min)/ 2.5 °C/min/260 °C (5 min).

bonds. Recently, a straightforward investigation approach was proposed. This approach uses identical highly polar separation columns based on ionic liquids (i.e., SLB IL-111 from Supelco) with an online chemical derivatization made on a Pd tubing in the presence of hydrogen carrier gas. The hydrogenated derivatives, which are the saturated forms of eluting FAMEs, are successively separated in the ^{2}D on the basis of their chain lengths. Operating under isothermal conditions, saturated FAMEs lie on a straight diagonal line bisecting the separation plane, while FAMEs with the same carbon skeleton but different number, geometric configuration, or position of double bonds lie on lines parallel to the ^{1}D time axis. **Figure 4** reports the pattern of menhaden oil analyzed under isothermal conditions.

^{2}D separation patterns, obtained by comprehensive methods, have an intrinsic potential as unique and highly informative sample fingerprints, being potentially useful for sample characterization, differentiation, discrimination, and classification. However, this improvement in the informative content produces large and complex datasets (consisting of bidimensional retention data, detector responses, and MS spectra) that require suitable data mining: (1) to interpret the higher level of information and (2) to extract useful and consistent data on sample compositional characteristics.

^{2}D fingerprint analysis can be adopted in food authentication as well as in flavor and aroma characterization, to define the so-called product signature in terms of sensory properties (*sensomics*) and botanical/geographic origins and/or to study modifications induced by thermal treatment, through the volatile fraction of the matrix investigated. **Figure 5** reports the results of a pairwise comparison of the volatile fraction of two olive oil samples from Italian productions: an edible extra virgin olive oil and a defected one classified by the official panel as *muddy*. Differences, visualized in the comparative image analysis, correspond to green and red areas of the chromatographic plane where analytes differing for their abundance between samples are present. Black and white regions correspond to analytes present in just one of the two samples.

Brighter areas correspond to ^{2}D peaks with a larger difference between the reference (*muddy* sample) and the analyzed (extra virgin olive oil) patterns and more abundant in the analyzed image; darker areas conversely correspond to ^{2}D peaks whose abundance is higher in the reference (*muddy* sample) image.

HPLC: The Separation Workhorse

HPLC is a widely applied analytic technique as evidenced by the number of instruments installed, practitioners, analyses performed, and research papers published annually. HPLC is applied in quality control and is the workhorse of the analytic departments within the pharmaceutical and food industries and environmental control. Furthermore, HPLC holds a central place in most research laboratories: HPLC methods are developed to study drug delivery, adsorption and metabolism, genetic expression of proteins, emerging pollutants in the environment, and nutrients in foodstuffs or in the gastrointestinal tract of animal models or humans, to name only a few characteristic examples. Figure 1 depicts the continuous increase in the number of published articles per year based on a literature search on Scopus, using the terms 'liquid chromatography' in combination with one of the terms 'clinical,' 'pharmaceutical,' 'food,' and 'review.' The fact that more than 1000 reviews are published annually on HPLC and its applications is impressive and indicative of the width and significance of the technique. Indeed, the corresponding numbers for atomic spectroscopy or electrochemistry for the year 2013 are approximately five times less.

With the advent of systems biology and the development of the 'omics' fields, for example genomics, proteomics, and metabolomics, HPLC maintains its major position as an indispensable research tool: new high-resolution mass spectrometry (HRMS) instruments such as the time of flight (TOF) and the Orbitrap MS are ideally combined with different modes of HPLC to map the protein or small metabolite content of samples, cells, or organs. As explained later in this article, difficult analytic tasks require extensive method development in both LC and MS and cannot be served by a single technique.

In HPLC, sample constituents are separated as they migrate through a column in different velocities and elute from the system in different times. The analytes take part in a three-mode interaction between the stationary phase, the sample, and the mobile phase. Analytes that are strongly retained on stationary phase elute late, while analytes that do not interact strongly migrate faster and elute sooner through the system. HPLC utilizes a variety of column formats, dimensions, and chemistries, while mobile phases include a wide range of organic solvent and buffer mixtures. Detection of eluted analytes can be achieved by a single detector or multiple detectors connected in series. Figure 2 depicts a schematic of an HPLC system with its components.

Modes of HPLC

HPLC is practiced in discrete modes that employ different separation mechanisms and find application in different areas. The separation mechanism is governed by the selection of the stationary phase. The two major separation mechanisms are the following:

(a) Normal phase (NP), where analytes partition between a polar stationary phase (e.g., silica) and a low-polarity mobile phase (e.g., hexane, chloroform, or dichloromethane). Dipole–dipole and hydrogen bonding interactions are the major contributors; nonpolar analytes elute quickly, while polar analytes interact strongly with the stationary phase eluting later.
(b) Reverse phase (RP), where polarities are reversed, with the stationary phase being less polar than the mobile phase. Polar analytes remain mostly in the mobile phase showing little attraction towards the stationary phase and elute early. Nonpolar analytes are retained by the stationary phase by a combination of interactions, including nonspecific hydrophobic interactions.

Reversed-phase liquid chromatography (RPLC) is by far the widest applied mode largely due to its more robust nature and its compatibility with aqueous samples such as biological, environmental, and food samples and extracts. However, RPLC is restricted to the analysis of medium-polarity and medium-molecular-weight compounds. Polar or high molar mass compounds are usually problematic. The former include some of the most important metabolites in the biochemical pathways: amino acids, nucleotides, organic acids, and amines. These are not retained in RPLC and elute rapidly with the solvent front.

One solution towards the analysis of polar molecules is derivatization, which is used to modify analyte molecules and improve retention and detectability; for example, amino acids are analyzed as derivatives that absorb in UV or exhibit fluorescence. However, derivatization as a reaction of organic molecules imposes a number of drawbacks:

1. Analytes react at different rates.
2. Molecules can behave differently in different environments (different pH or salinity values may yield inconsistent results).
3. An excess of reagents is introduced to the system.
4. Derivatives have a limited lifetime, thus introducing a potential error source.

Rapid advances in MS enabled the development of multianalyte methods that can determine hundreds of analytes in a single run, thus partially overcoming the need for improved analyte detector response. Nevertheless, nonderivatized polar molecules will show poor retention and thus, significant efforts are invested in the development of separation modes appropriate for the analysis of polar analytes and ionic or ionizable species. These include aqueous normal-phase

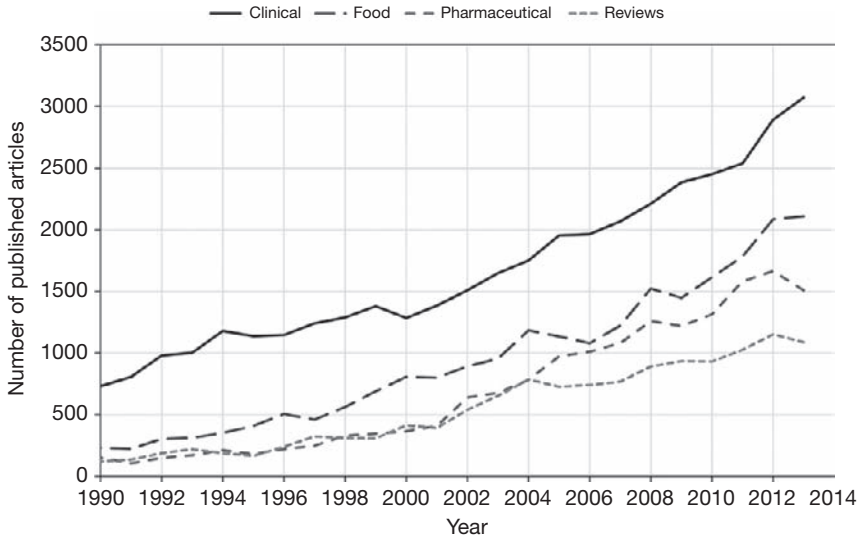

Figure 1 Number of published articles per year, returned when using the terms 'liquid chromatography' and 'clinical,' 'food,' 'pharmaceutical,' or 'review.' Search performed on Scopus on April 27, 2014.

(ANP) chromatography, ion pair chromatography (IPC), ion exchange chromatography (IEC), and hydrophilic interaction liquid chromatography (HILIC). HILIC can be considered as a reversed reversed-phase chromatography: analytes are separated using principally organic mobile phases and a hydrophilic stationary phase, eluting in order of increasing hydrophilicity. HILIC phases are categorized as neutral (where electrostatic interactions are not evident), charged (where electrostatic forces dominate the separation), and zwitterionic. HILIC is increasingly used in the analysis of polar compounds, providing the elution order reversed to the order provided by RPLC. However, certain polar groups, such as phosphorylated molecules, may remain problematic, so other LC modes are employed: IEC and IPC make use of mobile phases that contain ionic species typically dissolved in the mobile phase (in IEC, ionic species may be immobilized in the stationary phase).

Ionic interactions are stronger and thus harder and slower to disrupt, and as a result, IEC generally provides wider peaks compared with RPLC. IEC is extensively used in the analysis of proteins, taking advantage of ionic interactions between charged proteins and the stationary phase. IEC can be further divided into cation or anion exchange chromatography, while certain stationary phases encompass ampholytes or species that may appear at a neutral or charged state: tertiary amines will acquire a positive charge at low pH but will be neutral at high pH. The strength of the ionic interactions between ligands and analytes is determined by the number and location of the corresponding charges. To facilitate analyte binding, mobile phases of low to medium salinity are initially employed (loading phase). To achieve analyte elution, the salt concentration in the mobile phase is increased, thus eluting analytes in the order of strength of ionic interactions.

On the other hand, IPC uses ion pair reagents to modify the stationary phase: these are dissolved in the mobile phase and interact with the hydrophobic ligand of RP stationary phases. The polar part of the ion pair reagent is exposed to the mobile phase, ready to interact with polar metabolites increasing their retention. IPC when coupled to MS faces severe limitations due to the high background signal generated by many widely used ion pair reagents. The latter contaminate MS systems almost permanently, rendering the MS system practically nonusable for different analyses. IPC has recently found an important application area in the analysis of metabolites involved in central metabolism: intracellular metabolites such as nucleotides, coenzyme A esters, nucleosides, phosphorylated sugars, and metabolites involved in energy metabolism such as AMP, ATP, and NADP.

Additional liquid chromatographic techniques relevant to food and clinical analyses include affinity chromatography

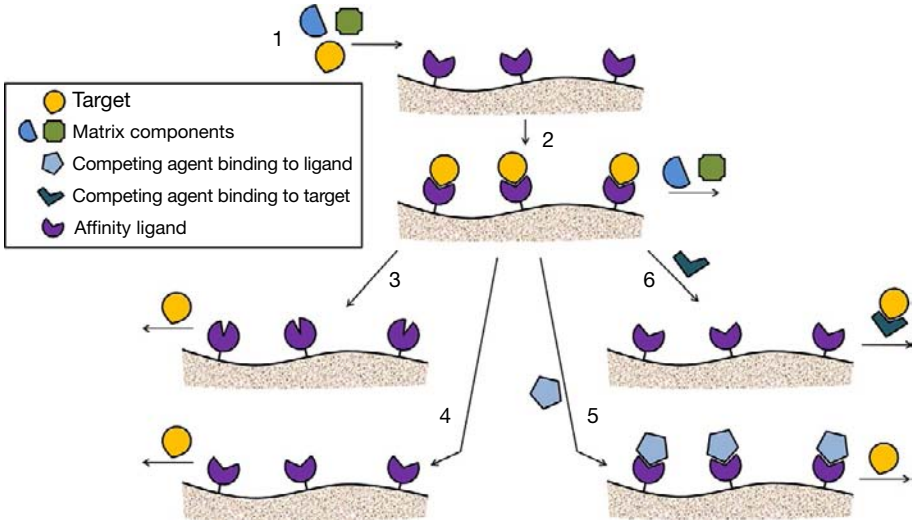

Figure 3 Schematic representation of the binding mechanism and elution protocols applied in affinity chromatography. 1: Sample loading; 2: targeted analytes bound, other matrix components eluted; 3: elution of targeted analyte by change of conditions (pH and ionic strength); 4: isocratic elution; 5: addition of competing agent binding on the affinity ligands; 6: addition of competing agent binding on the targeted compound.

(AC) and size exclusion chromatography (SEC). In AC, separation is based on analyte affinity to ligands or receptors bound on the stationary phase. AC shows potential in the isolation of valuable compounds of biological interest from complex matrices taking advantage of the natural affinity between two counterparts, such as an enzyme for its substrate/inhibitor or an antibody for its antigen. One of the counterparts is immobilized on a chromatographic column, acting as a receiver, binding its specific partner over other compounds. The captured analyte is eluted by changing the conditions in the mobile phase (pH, ionic strength, and competitive analyte) isolated in pure form (Figure 3).

SEC utilizes stationary phases of a controlled porosity that physically block the flow path of the analytes as they migrate through the column. Analytes of molecular volume smaller than the particle pores penetrate deeper and elute slower, compared with relatively large molecules that will be excluded from the pores and elute faster. Using appropriate standards, SEC can be used to determine the molecular weight of synthetic and natural macromolecules, while both AC and SEC are widely used in the separation and isolation of proteins and polysaccharides from complex mixtures.

A recent development is two-dimensional LC (2-D-LC), which is employed to address the need for additional separation power. 2-D-LC is increasingly used in biomarker discovery and identification, in the oil industry, in the analysis of polymers and biopolymers, and wherever additional separation power is necessary. 2-D-LC implements two orthogonal separation mechanisms that run sequentially. The two modes should be based on different complementary separation mechanisms. For example, in protein/peptide analysis, the ion exchange or size exclusion column is coupled online with RP: analytes are separated in the first column and subsequently in the second column (RPLC). The second column is typically smaller in dimension so that analysis is rapid to cope with the continuous flow of analytes eluting from the first column. 2-D-LC requires sophisticated instrument control and data handling in order to synchronize the pumping of different solvents through two columns, movement of the valves to alter the flow path, switch from column to column for loading, and elution and washing. Results are depicted as heat maps or contour plots.

Stationary Phases

The vast majority of HPLC columns utilize porous, spherical octadecyl (C_{18})-functionalized silica particles of 3–5 μm diameter, while other chemistries include octyl (C_8), phenyl-hexyl, and amine-modified phases. Fluorinated phases provide alternative selectivity and separation characteristics, exhibiting higher retention for polar compounds.

These phases have typical surface areas up to 400 $m^2\,g^{-1}$ and pore diameters of ~100 Å. Such materials owe their popularity to their relative ease of manufacturing in large quantities, simplicity of surface modification, chemical and mechanical stability, excellent batch-to-batch reproducibility, and extensive documentation on their utilization as separation media. However, the growing demand for analysis of increasingly complex samples and higher sample throughput has driven the development of new stationary phases, with numerous new materials introduced every year. Perhaps, the most important recent development was the introduction of ultra-high-pressure LC (UHPLC) systems in the early 2000s. UHPLC employs sub-2 μm particles and accommodates operating pressures higher than 1000 bar. This development necessitated major advances in column technology and instrumentation. Apart from the obvious advantages of higher separation power that lead to higher specificity (analytes are less likely to coelute with interferences) and sensitivity (lower background noise), UHPLC can increase the analytic throughput: an HPLC method of 10 min per sample may be reduced to 3–4 min in UHPLC. The major advantages and operating parameters of UHPLC are presented in Table 1.

Table 1 Characteristics and typical operating parameters of UHPLC

Characteristics of UHPLC	*Comments*
Operating parameters	Pressure: $\leq$20 000 psi ($\sim$1400 bar) Flow rate: $\leq$5 ml min^{-1} Particle size: sub-2 μm particles Column dimensions: $\geq$to 2 mm i.d. Detection rate: $\geq$40 points s^{-1}
High throughput	$\sim$3–10-fold increase in throughput vs. HPLC, without loss of resolution
Rapid method development	Ideal for rapid column and mobile phase screening and method optimization
High resolution	Up to $\sim$3-fold increase compared with HPLC
Reduced solvent consumption	Typical 5–15-fold reduction vs. HPLC due to shorter analysis times and smaller i.d. columns
High sensitivity	$\sim$3–10-fold increase of mass sensitivity
Higher precision	$\sim$2–3-fold increase in retention time and peak area precision
Compatibility	Compatible with high temperatures, 2-D-LC and core–shell columns

Despite its clear advantages, UHPLC is associated with significant equipment costs that hinder global transition from HPLC. To this end, core–shell or superficially porous particles have recently attracted significant interest. These have a solid, impenetrable core that supports a thin, porous layer, typically from 0.2 to 0.6 μm (Figure 4). In totally porous particles, diffusion paths within the pores are longer, increasing peak broadening and decreasing column efficiency; superficially porous particles exhibit superior mass transfer properties, reducing peak broadening and enhancing column performance. In fact, the efficiency for columns of 2.7 μm core–shell particles rivals that for sub-2 μm totally porous particles, while the operating back pressure is halved, eliminating the need for UHPLC instruments. An example of the performance of 5 μm core–shell vs. fully porous particles is shown in Figure 5.

Monolithic columns were introduced mainly aiming to overcome limitations of mass transfer described as the C term in the Van Deemter equation. Compared with particulate materials, monoliths exhibit very low C values that do not vary significantly within the flow rate. Monoliths comprise a polymer or silica network where pores are interconnected generating an unobstructed flow path that in contrast to particulate columns does not have closed pores. Mass transfer is enhanced enabling higher flow rates. Monoliths have found application mostly in the analysis of larger molecules (e.g., proteins and polynucleotides) and in large-scale biotechnology applications, for example, in the form of convective media conveniently used for the purification of target proteins produced in bioreactors.

Furthermore, nano-LC and chip-based LC are increasingly used especially in the analysis of biomolecules such as proteins. Nanoflow enhances analyte sensitivity and at the same time is well suited to handle reduced sample volumes. Recent developments bring HPLC in the core of the MS tip (e.g., in the form of ionKey/MS^{TM}). While developments such as the latter appear attractive, especially for use by less-trained personnel, their adaptation requires significant capital investment costs.

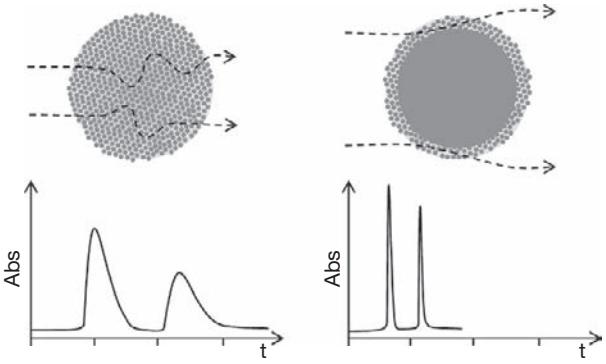

Figure 4 Schematic depicting the cross sections of fully porous (left) and core—shell (right) silica particles with the corresponding chromatographic traces showing sharper peaks on the core—shell material.

Column chromatography will most likely continue to dominate as it provides unparalleled versatility and peak and loading capacity. Chip-based LC and other such formats that have been presented in recent years are still in the development stages and, although some promise has been shown, are still a long way from claiming the HPLC market.

Instrumentation

Analytical instrumentation of (U)HPLC shows continuous development since the introduction of the method in mid-1970s. Instrument manufacturers have invested in the development of higher quality materials, instruments, and software, and by the end of the twentieth century, HPLC technology had overcome most reproducibility and stability issues faced in its first decades. In the early days, HPLC suffered from issues such as the use of additives, the blockage of tubes and columns, the introduction of unnecessary peak broadening, and poor quality of frits, ferules, connectors, etc. Such issues have now been addressed with the development of advanced quality or fit-for-purpose media: Metal-free systems can be used for the analysis of proteins; sample preparation removes particulate matter before clogging the system; developments in the production phase allow high column batch-to-batch reproducibility: change to a new column of the same material will not result in difference in method performance. As a result, analysis throughput has increased dramatically, while method transfer and interlaboratory repeatability are greatly enhanced.

Detection and Hyphenation

Detection in HPLC typically utilizes optical, electrochemical, and spectroscopic detectors. These should provide fast data acquisition to cope with the flow dynamics of LC. Given that ten or more data points are required for optimum peak quantitation, fast data acquisition becomes of primary importance for accurate quantitative analysis in HPLC and UHPLC in particular, where peaks may have widths of less than 5 s.

In practical terms, a spectrophotometric detector is an integral part of the modern (U)HPLC instrument and thus hyphenation means coupling LC to a mass spectrometer. UHPLC–MS dominates the field of biopharmaceutical, food,

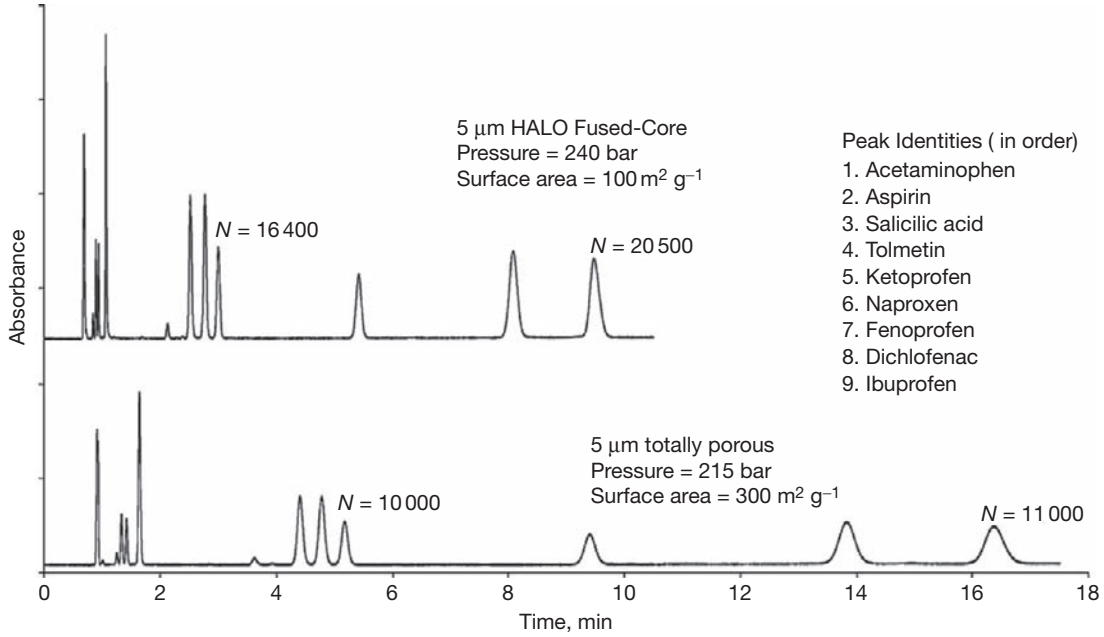

Figure 5 Comparative separations with 5 μm particles: fused-core vs. totally porous. Column dimensions: 4.6 mm × 150 mm; temperature: 35 °C; flow rate: 2.0 ml min^{-1}. Performance characteristics of new superficially porous particles. *Journal of Chromatography A* **1258**, 76–83.

and environmental analyses. MS spectroscopists may consider HPLC as merely an introduction step to the MS system, while chromatographers argue that MS is another type of LC detector; however, the truth is that separation is necessary prior to MS for a number of reasons, such as the need to separate isomeric/isobaric substances and the drive to avoid ion suppression effects. No matter the sophistication and the cost of the MS analyzer, such incidents would lead to poor or no analyte detection even for analytes of high concentrations. Implementation of HPLC, and UHPLC in particular, reduces this threat, albeit it cannot eliminate it, by adding an orthogonal element of separation: molecules are first separated according to physicochemical properties and are next introduced to MS.

Applications

This section aims to illustrate selected examples of HPLC applications in the analysis of biological and food samples. LC–MS has become the gold standard in a number of application fields and this has been recognized by regulatory authorities, which require its application for the majority of analyses of primary importance such as contaminants in foods, prohibited substances (e.g., steroids in foods or biological samples), narcotics, pharmaceuticals, and endogenous metabolites. Adaptation of the technology is enforced in order to ensure that ion suppression effects are minimized in the analysis of unknown samples and that analyte identification by a combination of retention time and MS signal is unambiguous: identification is verified by retention time, precursor and product ion mass, and product ion ratios and is corroborated against reference standards analysis using explicitly set tolerance levels.

Application of HPLC in Food Analysis

Our food supply includes a variety of increasingly processed materials from various sources. Substances such as fertilizers, pesticides, veterinary drugs, growth promoters, colorants, antioxidants, natural and artificial sweeteners and flavors, natural and synthetic vitamins, and carbohydrates are used to improve productivity and thus increase competitiveness and profit margins of the food industry. To ensure food safety and nutritional quality, regulations have been established for the assessment of food quality, the assessment of nutritional intake, and traceability especially for foods and products with designation of origin and so forth. Regulation agencies often deal with the detection of prohibited substances and substances with maximum permitted levels such as chemical additives, residues, and contaminants in food products explicitly specifying methodological considerations to harmonize methods and ensure interchangeability of results across different laboratories and states.

Increasingly, food analysis methods are built around HPLC, which has proved to be an optimal technology for detecting and/or quantifying the vast majority of food analytes. In recent years, the demands for high sample throughput, high efficiency, and high resolving power have significantly boosted (U)HPLC technology in areas of analytic research. Several multianalyte methods have been developed offering simplicity and reduction in cost. The key requirement for developing such multimethods is the application of generic extraction procedures with a careful examination of matrix effects. Recently, methods covering more than 250 veterinary drugs, pesticides, mycotoxins, and other potential chemical contaminants have been developed and are applied in routine analysis.

Fused-core columns have been applied in the analysis of bisphenols in canned food and soft drinks, phenolic

compounds in beverages, and banned substances in egg, honey, and milk. HILIC has proved to be complementary to RPLC in the analysis of foods: meat, milk and its products, eggs, packaged food, natural products, honey, and cereals. Fluorinated phases found use in the separation of tocopherols, alkaloids in natural products, and photoinitiators in packaged food. Higher temperatures (i.e., >60 °C) may expedite analysis due to the reduction of solvent viscosity and back pressure. Using elevated temperatures, 12 triazine herbicides were separated in 2.5 min. Other applications showed separation improvements (increase in resolution) at very low temperatures (5 °C) for the analysis of photoinitiators in packaged food.

Sample preparation is still one of the most important steps of an analytical method. Effective sample preparation is important to reduce matrix interferences and achieve reliable analytic results. A sample preparation method should be fast, simple, accurate and facilitate the analysis of a large number of samples. Modern sample preparation techniques such as on-line solid-phase extraction (SPE), supercritical fluid extraction (SFE), turbulent flow chromatography, and molecularly imprinted polymers (MIPs) can permit high-sensitivity HPLC analysis in the parts per trillion (ppt) range. Utilization of advanced techniques in the determination of target analyte groups such as antibiotics and growth promoters in a variety of food products has improved sensitivity and selectivity, cleaning up target analytes and removing matrix-interfering compounds.

Current rapid development of UHPLC has led to its increasing adoption as the approach of first choice for confirmatory analysis for multiple-target analysis in a variety of food products. Despite technological challenges, such as narrower peaks, and the impact of sample matrix effects, the overall injection cycle times have shortened, detection limits have improved, and chromatographic resolution and the number of compounds in multianalyte methods continue to increase. We expect the speed of analysis to increase further by using even higher temperatures and pressures, allowing the separation of a much larger number of analytes in the field of food analysis.

Application of HPLC in Health-Related Analyses

Contemporary bioanalytical laboratories are equipped with HPLC or UHPLC systems used in the analysis of small molecules or macromolecules in trace or semipreparative quantities. A major advantage is that basic instrumentation may be conveniently modified for a variety of purposes. Hence, a single LC pump can deliver the mobile phase or can be combined with additional pumps in 2-D-LC systems for, for example, proteomics or for purification and isolation of analytes of interest for characterization purposes.

Two decades ago, pharmaceutical industry laboratories relied on HPLC and immunoassays for drug discovery and development: HPLC assays accounted for more than 80% of pharmacokinetics/pharmacodynamics (PK/PD) needs and toxicity studies. The landscape is now totally dominated by LC–MS/MS where RPLC is a key element of method development and validation. Regulatory bodies such as the FDA and EMEA publish explicit guidelines for the validation of LC-based methods.

The development of UHPLC facilitates high-throughput screening (HTS), a powerful tool that enables the performance of routine analysis in, for example, food quality control or the environmental monitoring sector. The pharmaceutical industry utilizes HTS to promote products to the next development step at a faster rate: from combinatorial synthesis to drug target finding and lead finding, structure–activity evaluation, *in vitro* and *in vivo* application, and PK/PD assessment. As a drug candidate moves through the different sections of a pharmaceutical industry, assays are developed, and for all these purposes, the advantages offered by (U)HPLC remain unparalleled.

HPLC and LC–MS have achieved significant penetration in clinical laboratories, substituting other types of assays, such as ELISA or photometric assays. The major drivers behind this development are the benefits offered by HPLC and LC–MS with regard to detection specificity compared with cross-reactivity often observed in enzymatic assays or immunoassays. HPLC and LC–MS in particular can offer unambiguous detection and wide dynamic ranges for quantitation even when multianalyte methods are applied. HPLC is now used in parallel to GC–MS, and both methods cover the majority of potential target analytes in the clinical environment. GC–MS remains indispensable in the analysis of small volatile molecules, organic acids, and other key analytes in clinical and forensic toxicology; however, HPLC–MS/MS offers higher sensitivity while reducing the time and labor required for sample preparation (e.g., for derivatization necessary prior to introduction in GC). A major limitation however, is the lack of commercial mass spectral libraries, which necessitates the generation of local databases (lab-built libraries). At present, HPLC is practiced in virtually all hospitals in the developed world, while most of the major hospital laboratories are equipped with a variety of LC–MS and LC–MS/MS systems. Analytic tasks are distributed to specialized laboratories that are national reference centers for the analysis of groups of key analytes (e.g., amino acids, endocrine disruptors, and antibiotics). HPLC–MS/MS systems are widely used in clinical chemistry laboratories and pharmacology, toxicology, and forensic facilities. These laboratories are tasked with the analysis of toxins and drugs of abuse, therapeutic drug monitoring (TDM; such as the quantification of pharmaceuticals with a narrow window of therapeutic level concentration, e.g., certain groups of antibiotics and the majority of immunosuppressants and antipsychotic drugs), clinical trials of new pharmaceuticals, and the emerging field of bioequivalence of generic drugs. Emerging fields such as the assessment of occupational exposure and workplace drug testing represent new application areas.

Conclusions

HPLC offers an indispensable analytic tool in modern science, with thousands of new methods and protocols published every year. Instrument and column manufacturers continue to improve the specifications, performance, and quality characteristics of their products making the technology more robust, reliable, and capable to address emerging analytic problems resulting from modern human activities. As HPLC represents a

key element in the majority of bioanalytical and biotechnology fields, the central position of the technology seems secure for many years to come. A general advice for the practitioners, especially those coming from other scientific fields and using HPLC only as a tool for a certain purpose, is to remember that LC represents a dynamic process; hence, results can be influenced by different physicochemical factors. The sophistication of current state of the art is based on sound scientific principles and decades of dedicated work from thousands of scientists from the manufacturer and the research sectors. This striking science can be recognized every day in the separations achieved in thousands of LC systems globally. Separations undreamed of some years ago can now be achieved conveniently and offered as kits or standard operating protocols (SOPs). The continuing investments from the academia and the manufacturers will maintain the drive toward lower detection limits, higher resolution power, and higher quality separations.

Chromatography: Supercritical Fluid Chromatography

C Galea, D Mangelings, and YV Heyden, Vrije Universiteit Brussel (VUB), Brussels, Belgium

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Supercritical fluid chromatography (SFC) is a variant of high-performance liquid chromatography (HPLC) in which a supercritical fluid is used to replace the liquid mobile phase. HPLC, in particular reversed-phase liquid chromatography, has long established itself as a pertinent analytical technique in the food and health areas. Decades of application and research have led to this established technique being the mainstay of analysis in all steps of food analysis and health analysis.

SFC is considered as a valuable alternative over HPLC because the mobile phase properties differ significantly. A supercritical fluid has properties intermediate between those of a liquid and a gas. The temperature and pressure of a component in its supercritical state should be higher than the critical values, T_c and P_c, respectively, as seen in Figure 1. When a component is in its supercritical state, it cannot be liquefied by increasing the pressure. Supercritical carbon dioxide (CO_2) is most commonly used in SFC, mostly because it is cheap, readily available, and environmentally friendly. Moreover, it is very safe to be used in the food industry since it is easily removed from samples by simple expansion and evaporation.

SFC was from its early years recognized as a hybrid of HPLC and gas chromatography (GC). SFC was acknowledged as a technique that enables rapid separations, comparable to HPLC, and allows separation of substances with high boiling points, which is also possible in GC. The properties of supercritical CO_2 differ from those of liquids used in HPLC, in the sense that CO_2 is less viscous and has a higher diffusivity than liquids. This leads to rapid mass transfer, therefore resulting in a higher sample throughput, faster equilibration, and shorter cycle times. Since solvent consumption is low, waste generation is also negligible.

Supercritical fluids are used for extraction and for chromatography. Food products analyzed or produced by the utilization of supercritical fluids are seen in everyday life. Some of these products are highlighted in Figure 2.

The main difference between an HPLC and SFC system is that in SFC, the pumping system needs to be adapted to allow the pumping of a compressible fluid (Figure 3). The second difference is that there is a pressure regulation system, which restricts the column outlet flow and creates a system back pressure, keeping CO_2 in its super-/subcritical state. It is known that the solvent strength of the supercritical mobile phase is strongly related to its density (being controlled by temperature and pressure). It is also well known that the polarity of the nonpolar carbon dioxide can be increased by the addition of polar organic solvents, such as methanol. Hence, the partition between the mobile phase and stationary phase, of analytes with varying polarities, can be changed and their retention altered.

SFC can be coupled with a number of other techniques, for example, mass spectrometry (MS), ultraviolet (UV)–Vis spectroscopy, flame ionization detection (FID), LC, and supercritical fluid extraction (SFE). These numerous advantages are quite appealing and are possibly the reasons why there has been an increase in the utilization of this technique in both the food and health sectors. This is reflected by the number of publications in the area, which has shown a steady increase in the last years.

SFC is a versatile technique and can be used to analyze a large number of compounds. However, it has the unique ability of analyzing thermally labile and nonvolatile substances. Substances with such properties are also found in the food and health industries, for example, thermolabile pesticides, fatty acids, and numerous medicinal drugs. Moreover, SFC is a powerful technique in the separation and analysis of chiral substances. A chiral compound is one that consists of stereoisomer pairs referred to as enantiomers that have nonsuperimposable mirror images. Chirality may lead to one enantiomer being responsible for the biological activity, while the other might be much less potent as in the case of adrenaline. Antagonistic, toxic, and no effects are also possible with the other enantiomer. Twenty-five percent of pesticides used in the food industry are also chiral. The importance of chirality was highly recognized after the thalidomide (Softenon®) disaster in the early 1960s. Thalidomide was being used by pregnant women to treat morning sickness. However, it was later shown that one enantiomer was responsible for the teratogenic effect, affecting fetuses during their development, resulting in babies with missing extremities. This article will focus on the applications of SFC in food, health, and drug analysis. The studies presented are not exhaustive, but they will give the reader a good understanding of the applicability of SFC in different domains.

SFC in Food Analysis

Food analysis is a sector of vital importance in analytical chemistry, which may sometimes prove to be a challenge due to the number and wide variety of compounds that must be analyzed. These compounds range from nutrients and compounds with bioactivities to pesticides, contaminants, or illicit substances that are considered harmful. Food analysis with SFC focussed mostly on lipids and fat-soluble vitamins, probably due to the high solubility of these analytes in CO_2. However, the trend is moving to use SFC also for the analysis of more polar compounds, for example, amino acids and carbohydrates, and the analysis of compounds with low volatility or UV absorbance such as triterpenoid compounds. This section presents an overview of different applications of SFC in food analysis. Table 1 shows a summary of SFC applications in food analysis, which will be discussed shortly.

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00160-4

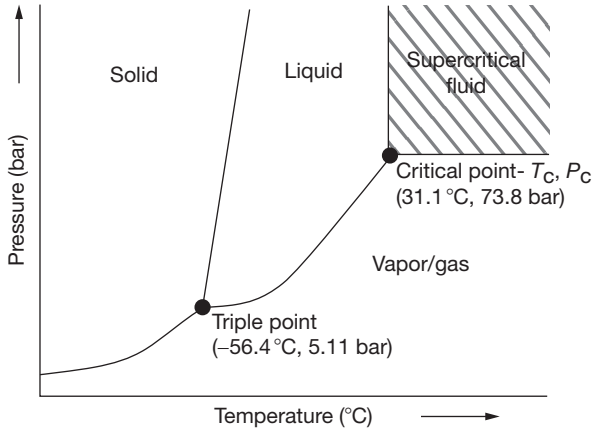

Figure 1 Phase diagram for carbon dioxide.

Analysis of Lipids

Lipids play a vital role in cellular signaling and energy storage, while phospholipids are the main cell membrane constituent. Lipids are hydrophobic compounds, but they vary greatly in their polarity due to the diverse moieties that can form part of lipids. Some include hydrophobic acyl chains; others, hydrophilic phosphoric acid or sugar moieties. Therefore, analyzing lipids in a mixture is not easy. The study of lipid classes in their natural environment is referred to as lipidomics.

An SFC–MS method that allows the simultaneous analysis of lipids with diverse structures and polarities has been established by Bamba et al. SFC–MS was used to analyze a complex mixture of 14 lipids, including phospholipids, glycolipids, neutral lipids, and sphingolipids, extracted from the leaf of *Catharanthus roseus*. All lipids were successfully separated within 15 min. This system is suitable for studies on lipidomics because it is useful as a fingerprinting method for the screening of diverse lipids and also for the profiling of the specific constituents.

The following three studies concerning lipids were developed at analytical scale, optimized, and then upscaled to the preparative level. The first study ([1] – refer to Table 1) focuses on the isolation of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) ethyl ester concentrates from transesterified tuna oil using SFC. The interest in these compounds is coming from the fact that EPA and DHA polyunsaturated fatty acids (PUFAs) are found in fish oils in ranges between 6% and 26% weight of the total fatty acids. These fatty acids have shown clinical benefits in cardiology, neurology, and mental health, among others. They continue to be studied due to their market in food additives and supplements and also in pharmaceutical products.

Pettinello et al. ([2] – refer to Table 1) investigated the attainment of enriched fractions of eicosapentaenoic acid ethyl ester (EPA-EE). Different operating conditions were investigated at bench scale. The final conditions (Table 1), which gave a purity of EPA-EE of 90% and a recovery of 49%, were used as a starting point for pilot plant experiments. This study continues confirming the versatility of SFC, in that it can be used for a number of purposes, starting from separation and analysis to large-scale production.

A subgroup of lipids is the phospholipids. These are components of living cell membranes and play an important part in enzyme activation – thus, phospholipids are important in nutrition. SFC was used to fractionate phospholipids in a multiunit process after being extracted from soybean flakes ([3] – refer to Table 1). This process produced purities above 75% for the individual phospholipids, phosphatidylcholine, and phosphatidylethanolamine.

Analysis of Fat-Soluble Vitamins, Including Carotenoids

Fat-soluble vitamins (A, D, E, and K) play a major role in anabolism and catabolism. Deficiency of these vitamins can lead to serious diseases, such as night blindness (vitamin A), rickets (vitamin D), rupturing of blood cells and cancer (vitamin E), and blood coagulation disorders (vitamin K). Methods for the extraction and enrichment of these vitamins from natural sources like plants and seeds are constantly sought after, to be able to produce food supplements. SFC has been widely used for this group of compounds as can be seen from the following examples.

Tocopherols (α, β, and γ) are components of vitamin E and are particularly interesting for the food industry because of their antioxidant and nutraceutical activities. SFE and SFC were used to isolate tocopherols from olive by-products ([5] – refer to Table 1). The residue obtained from olive pomace was subjected to SFE with subsequent fractionation by two successive depressurizations. Tocopherols were separated and quantified using SFC subsequently. This study thus resulted in the isolation of tocopherols in an environmentally friendly way.

In a study by Jiang et al. ([6] – refer to Table 1), the effects of temperature, pressure, and modifier concentration in the mobile phase on the retention factor and resolution of tocopherols were studied. It was concluded that the separation of

α-tocopherol from γ- and δ-tocopherols was best at 18 MPa and 80 °C and with 5% ethanol in the mobile phase. This study also showed that the resolution of tocopherols increases when the temperature increases and the pressure decreases.

Another study ([7] – refer to Table 1) investigated the application of SFC to quantitatively analyze minor components found in palm oil. Carotenes, five isomers of vitamin E, sterols, and squalene were separated in <20 min. Results obtained from this study were comparable with those from an established analytical technique, such as GC. However, the SFC method showed several advantages. The conventional analysis of palm oil components requires the use of several techniques, such as GC, HPLC, and UV–Vis spectroscopy since no technique is able to identify all components. Moreover, the different techniques require different sample preparations. Using SFC, labor and time were saved for the sample preparation and separation of all components ($\approx$25 min) from the palm oil. This study also showed that there was a significant difference in the concentrations of vitamin E isomers analyzed by SFC and HPLC. Prolonged exposure of vitamin E isomers to organic solvents in HPLC resulted in destruction of the compounds, leading to lower levels found than in the SFC analysis.

Carotenoids are naturally occurring fat-soluble pigments, of which some act as provitamin A. Their potent antioxidant properties have led to increased investigations as potential anticancer, antiaging, and cardiovascular drugs. Carotenoids are known to be sensitive to temperature; therefore, low temperatures have to be employed in their analysis. This means that analysis takes place in subcritical conditions. Lesellier's research group ([4] – refer to Table 1) worked on the method development and improvement of the separation of β-carotene *cis*/*trans* isomers. The factors that affected retention differences were the dielectric constant of the modifier, solubility parameters, type of mobile phase, and stationary phase conformation.

Oxidation of carotenoids leads to the formation of epoxycarotenoids, which may be better markers for low-density lipoprotein (LDL) oxidation, an important process in atherosclerosis. A decrease in the carotenoid levels is seen before the increase in lipid peroxide levels during the oxidation of LDL. However, the low levels of carotenoids in the blood cannot be directly correlated to oxidative stress levels, because of individual differences in dietary intake. A method employing SFC–MS was used to identify epoxycarotenoids proving the sensitivity of the technique and therefore its applicability to biomarker screening ([8] – refer to Table 1).

Nutraceuticals

A number of natural products, including plants, contain constituents that show biological activities. A nutraceutical is defined as a food that possesses medicinal or nutritional properties, including the prevention and/or cure of an illness. Rosemary, davana, and grape seed extract are examples of such harvests, from which beneficial products can be separated and isolated by SFC as discussed in the succeeding text. Processes can then be scaled up to ease their productivity.

Rosemary is well known for its antioxidant properties. The most active compounds are the phenol diterpenes, primarily carnosic acid and also carnosol, rosmanol, and epi- and isorosmanol. Ramirez et al. ([10], [11] – refer to Table 1) worked on the separation and isolation of compounds with antioxidant and antimicrobial properties. Initially, the group focussed on the optimization of the separation of carnosic acid from other antioxidants in rosemary extracts obtained by SFE. Then, semipreparative SFC was used to obtain fractions with enhanced functional activities. The biologically active fractions were then shown to have improved antioxidant and antimicrobial properties. The optimized method resulted in two very active fractions. The CO_2-based mobile phase with a low percentage of modifiers has advantages for upscaling, since the lower the percentage, the lower the costs and residues incurred and the easier the evaporation of the mobile phase.

Davana is an aromatic herb from India. The oil of davana was initially only recognized for its importance in the perfume industry. However, davanone, a sesquiterpene, is a principal component of this oil. Davanone exhibits antifungal and antispasmodic properties. This compound was separated from the bulk matrix or natural davana oil by SFC ([11] – refer to Table 1). The final sample was nearly 100% optically pure.

Grape seed extract is a popular nutritional supplement with polyphenols that have antioxidant properties. Phenolics vary in their distribution and content depending on the raw material. Kamangerpour et al. ([12] – refer to Table 1) worked on the development of a fast SFC method for the isolation and identification of these polyphenols. The method was then used to separate phenolics in a grape seed extract.

Two other examples of nutraceuticals extracted from plants are glucobrassicin and sinalbin, both glucosinolates, with anticancer properties, coming from the plants of the *Brassicaceae* and the seeds of the *Sinapis alba* L. families, respectively ([13], [14] – refer to Table 1). White cabbage was used as a source of glucosinolates, while mustard was used as a source of sinalbin. The developed SFC methods can be used to separate and isolate the individual compounds of interest.

Monitoring of Pesticides

Pesticide or chemical residues in food, added during planting or processing phases, put the health of consumers at risk of adverse effects. It is therefore vital to monitor, identify, and quantify pesticide levels in food samples. A number of studies have used SFC to separate and analyze pesticides, for instance, contaminants in actual food samples. Toribio et al. ([15] – refer to Table 1) worked on the enantiomeric separation of six triazole fungicides, namely, cyproconazole, propiconazole, diniconazole, hexaconazole, tebuconazole, and tetraconazole. A polysaccharide-based chiral stationary phase was used and the effect of different modifiers studied. It was found that the organic modifier that provided the highest resolutions depended on the analyzed pesticide.

El-Saeid ([16] – refer to Table 1) monitored pesticide residues in canned foods, fruits, and vegetables, obtained from a local market in Houston, Texas. SFE was used to extract the pesticides from the samples, which were then analyzed by SFC. A total of 39% of foods tested were found to contain four pyrethroids, four herbicides, four fungicides, and six carbamates in different food samples. All the tested foods had different levels of pesticide residues ranging from 0.03 ± 0.005 to 0.8 ± 0.12 ppm. This study helped to promote consumer safety by assaying pesticide residues in food items.

Analysis of Other Compounds

Due to the nonpolarity of CO_2, SFC is mainly used in the analysis of hydrophobic or weakly polar compounds. However, by modifying the mobile phase polarity, a wider range of compounds can be analyzed. Figure 4 shows a chromatogram of a separation of amino acids, which are very polar compounds: proline (Pro), threonine (Thr), hydroxyproline (Hyp), serine (Ser), glutamic acid (Glu), and aspartic acid (Asp). Methanol, with water and triethylamine as additives, was used as a modifier to separate mixtures of underivatized amino acids. When a modifier gradient was used, even a higher number of amino acids were resolved in <10 min ([17] – refer to Table 1).

Carbohydrates were also separated with SFC ([18] – refer to Table 1). Mixtures of caffeine, fructose, glucose, sucrose, and neohesperidin dihydrochalcone (NHDC), which is an artificial sweetener, are commonly found in soft drinks. The mixture was separated in <5 min when SFC was used. Another sweetener, sucralose, was also identified and quantified in two sports drinks using SFC. Sucralose is roughly 600 times sweeter than sucrose with only 12% of the calorie count. The beverage marketed as 'low calorie' was indeed found to have a small amount of the sweetener.

Triterpenoids are recognized to possess a variety of biological activities, such as antibacterial, antioxidant, antitumor, antihyperglycemic, anti-HIV, antisclerotic, and cardiovascular activities ([19] – refer to Table 1). These compounds can be found in natural plants and in resinous natural materials. However, these compounds have a low UV absorbance; thus, a UV detector could not be used in this case. An alternative detector, evaporative light scattering detector (ELSD), was used, which gave acceptable peak intensities.

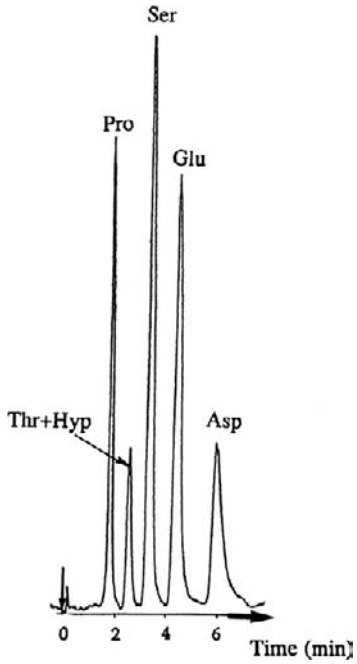

Figure 4 SFC chromatogram of a standard mixture of polar amino acids. Diol stationary phase; flow rate, 5 ml min^{-1}; inlet pressure, 230 bar; temperature, 0 °C; CO_2 modifier (80:20, v/v); modifier, methanol/additives (87.95:12.05, v/v) with water–triethylamine–pyridine (7:0.05:5, v/v) ([17] – refer to Table 1). SFC in Health Analysis

The determination and quantification of drug levels in plasma play an important role in the monitoring and development of modern pharmaceutical products. Data generated from these measurements help in the understanding of toxicological effects and offer insight to a drug's mode of action (pharmacodynamics) and are used to establish pharmacokinetic parameters related to the absorption, distribution, metabolism, and elimination of the drug. Such studies are needed for all drugs in order to obtain regulatory approval. The following are just three examples of the use of SFC for health analysis, which help contribute to the safety and efficacy of medicinal products in patients.

Malaria is still prevalent in many areas of the world, and it continues to be studied to find treatments. Artemisinin, also known as qinghaosu (QHS), mefloquine, and sulfadoxine are all compounds recognized as having antimalarial activity. Developing GC and HPLC methods is challenging because on the one hand, these compounds are thermally labile, while on the other hand, they do not contain a UV, visible of fluorescent chromophore to facilitate their detection. Acidic hydrolysis or basic hydrolysis of QHS was done to produce a UV chromophore, but acidic hydrolysis lacked specificity, while the basic hydrolysis method required a lot of experimental work. An SFC–ECD (electron capture detection) method proved to be sensitive enough to measure QHS levels for therapeutic drug monitoring by Mount et al. This method had a limit of detection of 20 ng ml^{-1}. However, this limit can be lowered further by decreasing the baseline noise of the detector, possibly by using carbon dioxide of a better quality. This SFC–ECD method was also used to quantify mefloquine in blood samples. More work was required for sample preparation when compared with HPLC–UV and GC–ECD methods, but the method proved to be more sensitive and selective than HPLC–UV and more robust than GC–ECD. In another study by Bhoir et al. concerning the method development for the measurement of sulfadoxine levels in human plasma, SFC was found to be sensitive, rapid, and reproducible. The SFC method was found to be superior to an HPLC–UV method in terms of speed and cost.

Ketotifen, an analgesic, is another medicine where pharmacokinetic studies were done by SFC. A method for the determination of (*R*)- and (*S*)-ketotifen in human plasma was developed. Oral ketotifen shows a bioavailability above 92%; however, the maximum plasma concentrations reach low microgram per milliliter levels after a 25 mg dose. SFC was used to plot a plasma drug concentration versus time curve for both enantiomers by Hoke et al. A chiral stationary phase consisting of (*R*)-1-naphthylglycine and 3,5-dinitrobenzoic acid was used. The method was shown to be valuable to

measure ketotifen levels in human plasma, between 0.05 and 2500 ng ml^{-1}, after both topical and oral administration.

A final example concerns the use of the antineoplastic antimetabolite cytarabine, which is used in the treatment of leukemia. To understand better the pharmacodynamics of cytarabine, its plasma concentrations were monitored using an SFC–MS/MS method and an HPLC–MS/MS method by Hsieh et al. The results obtained from both methods displayed equivalent accuracy, and they can thus be used in an alternative manner.

SFC for Preparative Use

Preparative chromatography has had a significant impact on both food and pharmaceutical industries. The advantage of this technique arises from the ease of scalability, robustness of the equipment, and the possibility to separate diverse mixtures. Moreover, this technique can be used routinely for purification, from a few grams to tons per day. When SFC is used for preparative purposes, once again, the technique exhibits advantages over HPLC. In preparative SFC, the mobile phase is recycled online, which is not the case for preparative HPLC. Other advantages of prep-SFC stem from the inherent properties of CO_2 like the higher diffusivity, low viscosity, and retention control by the variation of pressure and temperature. Productivity in preparative chromatography is increased by the use of overlapping or stacked injections. This is a technique where a second injection is made before all the substances from the first injection have eluted from the stationary phase. Restrictions of prep-SFC include samples that are not soluble in methanol or CO_2, high-polarity compounds, and, just like in HPLC, cases where impurities coelute with a particular product.

Prep-SFC is used for the separation of diverse compounds in given mixtures, for example, the production of functional food ingredients. It is commonly utilized for the fractionation and purification of extracts acquired with SFE. Triglycerides, diglycerides, free fatty acids, carotenes, tocopherols, and tocotrienols were successfully separated from crude palm oil. Purified PUFA ethyl esters were obtained from tuna oil, while free sterols and ferulate phytosterol esters were attained from corn bran. The oil that is obtained as a by-product of corn bran dry milling contains cholesterol-lowering phytosterols – which are thus interesting for the nutraceutical market. Prep-SFC was also applied by Li et al. to the separation of polymethoxyflavones (PMFs), mainly nobiletin, tangeretin, 3,5,6,7,3′,4′3-heptamethoxyflavone, and 5,6,7,4′-tetramethoxyflavone, from orange peel extracts. PMFs show anti-inflammatory, anticarcinogenic, and antiatherogenic properties. The botanical species, *Thymus vulgaris* L. is well known for its food flavoring properties. However, thymol, which is a monocyclic terpenoid found in thyme, possesses antiseptic, analgesic, and anti-inflammatory properties. This terpenoid was extracted and isolated by prep-SFC, with a recovery of up to 97% of the total thymol content by Garcia-Risco et al.

Moving to drug analysis, prep-SFC has already been implemented as a routine tool in a number of pharmaceutical laboratories. White has described the integration of prep-SFC for large-scale chiral purification. The technique proved to reduce the overall sample throughput time and running costs while delivering high-purity fractions and acceptable recoveries. In another study by Toribio et al., the semipreparative chiral separation of lansoprazole, pantoprazole, and rabeprazole was presented. The recoveries and production rates obtained for the first eluted enantiomer were lower than those obtained for the second, especially if high-purity levels were aimed at. Several fractions of the first enantiomer were contaminated with the second, decreasing the recovery and production rates. This is possibly due to overloading conditions, where the peaks were distorted in the front.

Other Use of Supercritical Fluids in Food and Health: Extraction

SFE is the most common application for supercritical fluids. The process takes advantage of the properties of supercritical fluids, just like SFC. The major parameters on which the extraction depends are temperature, pressure, and flow rate. Supercritical CO_2 has been used to extract a wide range of analytes, ranging from essential oils to phytochemicals. These extracts can then be used for analytical purposes, for supplementation, and for flavor and fragrance purposes.

In addition to the benefits of using CO_2 in SFC, namely, the higher speed and lack of chemical residue, still, a few more advantages can be seen in SFE. Supercritical CO_2 shows no surface tension. Therefore, it penetrates the pores of heterogeneous matrices rapidly, helping to enhance the extraction efficiency. Moreover, the CO_2 used in an extraction can be recycled and reused. Products obtained from the extraction can then be further separated into different components by SFC. From the analytical point of view, SFE is compatible with SFC since the two techniques can share the mobile phase and some devices, like the CO_2 pump and condenser.

Some constituents extracted by SFE include lycopene from tomato seeds and skins, ginger oleoresin from ginger, oil from coriander seeds, and caffeine, theobromine, and cocoa butter from Brazilian cocoa beans. In the pharmaceutical sector, hyperforin and adhyperforin have been extracted from *Hypericum perforatum* L., commonly known as St. John's wort. Products from St. John's wort are known to have anti-inflammatory, antidepressive, antiviral, and antimicrobial effects.

SFE can also be used to determine the presence of drug abuse in human hair. Amphetamines, such as methylenedioxyethylamphetamine, methylenedioxymethamphetamine, and methylenedioxyethylamphetamine, can be investigated with a fast and reproducible method. The SFC method gives results that are similar to those obtained from established techniques used to extract amphetamines from hair, such as solid phase extraction and liquid–liquid extraction.

Conclusions

This article briefly explained the benefits of using supercritical CO_2 in the food and health sectors, with special reference to the SFC technique. SFC is considered as an environmentally friendly technique since the use of supercritical CO_2 reduces the consumption of organic solvents, CO_2 is obtained as a by-product of fermentation processes, and minimal waste is generated. The high diffusivity and low viscosity of CO_2 enable experiments to be conducted at higher flow rates, therefore achieving a higher analysis throughput without compromising on efficiency. These properties are leading to an expansion of

SFC applications in the food and health industries. The use of SFC continues to expand, and we anticipate it will continue growing in the future.

SFC is maturing and is establishing its position in analytical and preparative analyses. The technique provides highly accurate, precise, and sensitive measurements, especially when coupled with an MS detector. SFC has been conducted on a broad range of food, plant, and biological samples for the analysis of minor components, additives, contaminants, and medicinal products. Moreover, the technique can also be used to characterize compounds, for example, in lipidomics.

The separation mechanism of SFC can be compared with that of normal-phase liquid chromatography (NPLC). Just like in NPLC, in SFC, the polarity of the mobile phase here, supercritical CO_2, can be modified by the addition of polar modifiers. In this way and also by adjusting the density of the CO_2, one can vary the retention of the analytes on the stationary phase. SFC can be seen as a complementary technique to HPLC since many separations that are impractical or impossible to accomplish by HPLC can more easily be achieved by SFC.

Online coupling of SFE with SFC facilitates high throughput analysis as long as the compounds under study are soluble in CO_2. This system is suitable for the analysis of compounds that are easily destroyed during organic solvent extraction, for example, by the high temperature, in a Soxhlet extractor.

The versatility and wide applicability of SFC in the food and health sectors are very promising. More research is needed to discover the full application potential of this technique. In the coming years, more applications of SFC are expected, not only for research purposes but also more in routine agricultural, food, and clinical applications.

Chromium: Physiology

JB Vincent, The University of Alabama, Tuscaloosa, AL, USA

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Recently, a paradigm shift has occurred in the understanding of the physiological effects of trivalent chromium, Cr^{3+}. While initially proposed to be an essential trace element for mammals in the late 1950s, the initial studies have been found in hindsight to be methodologically flawed. As a consequence of this and recent data, no unambiguous data for chromium being an essential element exist. The data demonstrating beneficial effects are best interpreted in terms of a pharmacological role for chromium at supranutritional doses. While guidelines from governmental agencies and textbooks have not yet caught up with the recent literature, chromium should be removed from the list of essential trace elements.

Absorption, Transportation, Storage, and Excretion

Chromium Absorption

While aspects of the mechanisms of absorption and transport of Cr^{3+} ions are known, overall, the process is poorly elucidated. Most notably, little is known of the fate of Cr^{3+} taken orally before the Cr reaches the bloodstream. Essentially, no data exist on the forms of Cr^{3+} in food as a result of its very low concentration. The fate of dietary chromium at a molecular level in the digestive tract is also essentially unknown, although >98% of Cr^{3+} passes through without being absorbed. This lack of knowledge is in stark contrast to what has been established for ferric iron (Fe^{3+}), with a similar charge to size ratio as Cr^{3+}. Dietary iron is probably primarily in the ferric form. Absorption of iron takes place in the proximal portion of the duodenum. Unlike Cr^{3+}, whose reduction potential is such that it should not readily be reduced under the conditions in the gastrointestinal tract, ferric ions can be reduced chemically or enzymatically by a brush border ferrireductase of the enterocytes. Subsequently, iron enters the enterocytes as ferrous iron via the transmembrane protein DMT1 (divalent metal transporter 1), which is probably responsible for the entry of a variety of divalent metal ions. The transported iron is then stored or is released from the enterocyte by the basolateral transmembrane protein ferroportin. Iron probably passes through the enterocyte in the ferrous state (Fe^{2+}) and is returned to the ferric state (Fe^{3+}) by ferroxidases for transport in the bloodstream by the protein transferrin (vide infra). The failure of Cr^{3+} ions to be reduced requires a unique absorption system to be present for chromium, compared with other proposed essential metals ions, if chromium is actively absorbed and essential.

However, the preponderance of evidence suggests that chromic ions are passively absorbed, that is, absorbed via simple diffusion. In rats, chromium has been established to be absorbed via passive diffusion. Only a small percentage (<1%) of dietary Cr is absorbed, while the remainder is excreted in the feces. Inorganic chromium salts are generally used to mimic dietary chromium and are absorbed to a similar extent, that is, <1%, over a wide range of doses. (The most commonly used salt is chromium(III) chloride hexahydrate, which is actually the chloride salt of the *trans* isomer of the $[CrCl_2(H_2O)^4]^+$ cation.) Chromium supplementation of the diet results in an increase in urinary chromium loss, and most of the absorbed chromium is rapidly excreted. Recently, rats that were gavage-dosed with $CrCl_3$ were found to exhibit ~0.2% absorption of Cr over a 2000-fold range of doses, consistent with the absorption of simple inorganic chromium(III) salts occurring via diffusion and not active transport. The concentration of Cr in the urine, blood, and tissues is proportional to intake. In fact, Cr content of the liver and kidney for multiple complexes of Cr(III) has been shown to increase linearly with intake. Urinary Cr loss appears to be controlled by intake. When followed by isotopically labeled chromium (^{50}Cr or radioactive ^{51}Cr) in rats or humans with increased urinary Cr loss from diabetes or strenuous exercise, the increased urinary Cr loss has been found to be offset by an increase in Cr absorption. In fact, the increased uptake of water in these conditions may simply result in the increased diffusion of Cr and the subsequent increase in urinary chromium loss.

Additional data come from studies of the absorption of Cr^{3+} from a rat intestinal perfusate with added Cr as $CrCl_3$. A double-perfusion technique has been utilized in which the intestinal vasculature, from the superior mesenteric artery to the portal vein, and the intestinal lumen, from the duodenum to the ileum, were perfused simultaneously. Over a greater than 100-fold range of Cr^{3+} concentrations, Cr absorption was found to be a nonsaturable process, consistent with animal studies. These results led to the conclusion that the Cr^{3+} was absorbed by the nonmediated process of passive diffusion in the small intestine of rats fed with a Cr-adequate diet.

However, the fate of dietary chromium(III) organic complexes could be different to that of the inorganic chromium salts if the complex (or some product thereof) absorbed is different from the form absorbed using inorganic chromium (III) salts. For example, the presence of added amino acids, phyate (high levels), and oxalate in the diet reportedly alters Cr uptake, as does ascorbic acid. Yet, none of these studies disproves that absorption is passive, only that the extent of chromium available for diffusion may be altered by the addition of these potential chelators to the diet and that the potential chelators may alter steps subsequent to absorption. The possibility that complexes of chromium with organic ligands may have altered the absorption properties is part of the impetus behind the various Cr(III) complexes used or proposed as nutritional supplements, although generally, this has not proven to be the case. In fact, studies comparing the blood, urine, and tissue concentration in rats of ^{51}Cr from labeled $CrCl_3$ and the most popular chromium supplements, chromium picolinate and chromium nicotinate, indicate that all are absorbed to a similar extent within experimental error.

Another interesting conclusion that can be drawn from the intestinal perfusate studies is that chromium appears to be

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00162-8

actively transported out of the intestinal cells, as nearly all of the chromium entering the cells is cleared from the cells (leaving <10% behind to be stored). Yet, no transporter is known for chromium. Cr^{3+} bound to some chelating ligand has been proposed to be transported by monocarboxylate transporters (MCT) as occurs for chelated Al^{3+} (a nonessential metal ion). Chromium complexes with free carboxylates are known; for example, the complex formed between Cr^{3+} and EDTA (ethylenediaminetetraacetate) is the violet [Cr(Hedta)(H_2O)], where one of the carboxylate groups is protonated. More importantly, the common complex of Cr^{3+} and citrate possesses a free carboxylate in the solid state and in solution. This idea is also supported by the perfusate studies. When amino acids were left out of the solutions perfused through the intestinal lumen, less chromium was transported into the vascular perfusate, while additional chromium was retained by the intestinal mucosa. Thus, potential ligands for the chromium may need to be transported into the intestinal cells for chromium to be efficiently transported out of the cells. However, the recent studies showed that monocarboxylate transporters are not involved in Cr^{3+} transport, at least from endosomes in hepatocytes.

Chromium Transport from the Blood to the Tissues

The fate of chromium in the bloodstream is better understood. *In vivo* administration of Cr^{3+} to mammals by injection results in the chromic ions being bound by the iron-transport protein transferrin, while administration of $^{51}CrCl_3$ by stomach tube to rats results in 80% of the chromium immunoprecipitating with transferrin. *In vitro* studies of the addition of chromium sources to the blood or blood plasma also result in the loading of transferrin with Cr(III), although under these conditions, albumin and some degradation products also bind chromium. When chromium is added to the blood *in vitro*, chromium binds to both transferrin and albumin; *in vivo*, only transferrin binds appreciable quantities of chromium. Thus, studies in which Cr sources are added to the whole blood, blood plasma, or serum should be avoided.

Transferrin is an 80 kDa blood serum protein that tightly binds two equivalents of ferric iron at neutral and slightly basic pH values. The protein exhibits amazing selectively for Fe^{3+} in a biological environment because the metal sites are adapted to bind ions with large charge to size ratios and is primarily responsible for the transport of iron through the bloodstream. In humans, transferrin is maintained only on average ~30% loaded with iron; consequently, the protein has been proposed to potentially carry other metal ions, although data to support this under physiological conditions are limited. The similar charge and ionic radii of chromic ions to ferric ions suggest that chromic ions should bind relatively tightly to the protein. *In vitro* studies of the addition of chromic ions to isolated transferrin reveal that Cr^{3+} readily binds to the two-metal-binding sites, resulting in intense changes in the protein's ultraviolet spectrum. Two equivalents of (bi)carbonate are concomitantly bound. Ultraviolet and Raman spectra suggest that each chromic ion binds to two tyrosine residues from the protein, strongly indicating that the chromic ions bind in the two ferric ion binding sites. Visible spectra suggest the d^3 chromic centers are in pseudooctahedral environments. Variable temperature magnetic susceptibility studies confirm that the chromium centers are trivalent (i.e., $S=3/2$). Estimates of the binding constant for chromium and the maintenance of transferrin on average only 30% loaded with ferric ions suggest that the protein appears to be primed to be able to transport chromium through the bloodstream.

Chromium-loaded transferrin has been demonstrated to transport chromium *in vivo*. Injection of ^{51}Cr–transferrin into rats results in incorporation of ^{51}Cr into tissues. Injection of labeled transferrin and insulin results in a severalfold increase in urinary chromium; iron transfer by transferrin had previously been shown to be insulin-sensitive. Thus, transferrin, in an insulin-dependent fashion, can transfer Cr to tissues after which Cr is ultimately excreted in the urine. Cr_2–tranferrin serves as an inhibitor for the binding of Fe_2–transferrin to the surface of reticulocytes, presumably at the site of binding transferrin to transferrin receptor. Cr-loaded human transferrin is a better inhibitor than apotransferrin but not as good as mono- or diferric transferrin.

Chromium Transport from the Tissues to the Bloodstream and Urine

Cr^{3+} appears to be moved from the tissues to the bloodstream and subsequently urine via a peptide named low-molecular-weight chromium-binding substance (LMWCr or chromodulin). The peptide is 10 or 11 amino acids long; is composed of glycine, aspartate, glutamate, and cysteine; and tightly binds four chromic ions. The peptide has been isolated from mammals, chickens, and alligators where all appear to contain the contiguous peptide of sequence Glu-Glu-Glu-Glu-Gly-Asp-Asp. The peptide is rapidly cleared from the body after binding Cr^{3+}. Spectroscopic studies indicate that the chromic ions are bound to the peptide primary via the carboxylate side chain of the aspartate and glutamate residues. The chromic ions appear to be arranged in a multinuclear assembly.

The movement of Cr(III)–LMWCr is stimulated by increases in blood insulin concentration; thus, increased movement of Cr from the bloodstream to the tissues by transferrin results in a subsequent elimination of chromium from the body bound to LMWCr. The peptide appears to be maintained in the tissue in the apo form; levels of the apo form potentially are under homeostatic control. At a minimum, LMWCr functions to rapidly clear Cr from tissues.

The Cr(III)-containing form of LMWCr has been proposed to be the biologically active form of chromium. *In vitro*, it has been found to activate the kinase activity of insulin receptor; this activation was proportional to the Cr content of LMWCr. In a proposed mechanistic scheme, at high intakes of Cr, LMWCr would accumulate to pharmacological levels, bind to the insulin receptor (helping to maintain the receptor in its active confirmation), and result in increased insulin sensitivity. The validity of this proposal requires testing *in vivo*.

Metabolic Functions and Deficiency Symptoms

'Low-Chromium' Diets

Traditionally, evidence for chromium being an essential element for mammals has come primarily from four sources: (i) studies attempting to provide rats with chromium-deficient diets, (ii) studies examining the absorption of chromium as a

function of intake, (iii) studies of patients on total parenteral nutrition (TPN), and (iv) studies looking for an association between insulin action and chromium movement in the body.

The field of Cr nutrition had its beginnings in 1955 when rats fed with a *Torula* yeast-based diet apparently developed impaired glucose tolerance in response to an intravenous glucose load from which a new dietary requirement, coined glucose tolerance factor (GTF), absent from the *Torula* yeast-based diet and responsible for the glucose intolerance was proposed. The active ingredient of GTF was Cr^{3+}. Inorganic compounds containing over 40 different elements (200–500 mg kg^{-1} body mass) could not restore glucose tolerance, while several inorganic Cr(III) complexes (200 mg Cr per kilogram body mass) restored glucose tolerance. Unfortunately, these Cr studies were methodologically flawed. For example, the Cr content of the diet was not reported. The rats were maintained in wire mesh cages, possibly with stainless-steel components, allowing the rats to obtain Cr by chewing on these components. Consequently, the actual Cr intake of the rats in these studies is impossible to gauge, putting into question the suggestion that the rats were Cr-deficient. The use of the large amounts of the metal ions is also of concern; as will be discussed (vide infra), supranutritional doses of Cr pharmacological effects in rats with insulin resistance. These doses are probably about 103 times the typical daily content of a rat's diet.

Details of the 'isolation' of Brewer's yeast GTF were reported in 1977. However, the isolation procedure included harsh procedures such as an 18 h reflux in 5 M HCl, which would hydrolyze any proteins, complex carbohydrates, or nucleic acids. Nicotinic acid was apparently sublimed from the material (although no data or experimental details were presented for the mass spectral, sublimation, or extraction studies). Amino acid analyses indicated the presence of glycine, glutamic acid, cysteine, and other amino acids, although the relative amounts were not reported. The results were interpreted to indicate that GTF was a complex of Cr, nicotinate, glycine, cysteine, and glutamate. In paper chromatography experiments, the material on which the studies in the preceding text were performed gave several bands, only one of which was active in bioassays. Based on this work, GTF has been proposed to be a Cr (III)–glutathione–nicotinate complex as glutathione is a tripeptide of glutamate, glycine, and cysteine. A three-dimensional structure has also been proposed for Brewer's yeast GTF that has two *trans* N-bound nicotinic acid ligands and amino acids occupying the remaining four sites of an octahedral around the chromic center. However, Cr^{3+} has been demonstrated repeatedly to be separable from agents in yeast responsible for *in vitro* stimulation of glucose metabolism in adipocytes. Thus, the component of yeast that is active in the bioassays apparently does not contain Cr. The characterization of a Cr fraction from yeast was performed on a mixture that contained multiple Cr-containing species and other components, and the Cr-containing components of the mixture probably do not reflect what bound Cr initially in the intact yeast. Yet, despite the numerous publications refuting the GTF studies, these studies unfortunately continue to be cited as evidence of the essential role of Cr.

Since the initial GTF studies and prior to 2011, the most notable efforts of work with rats to generate a chromium-deficient diet were studies utilizing high-sugar or high-fat diets. For the high-sugar diet studies, rats in plastic cages (with no access to metal components) were given a purified diet consisting of 55% sucrose and providing 33 ± 14 μg Cr per kilogram diet. A supplemented pool of rats was given with water containing 5 ppm $CrCl_3$. At 12 weeks, Cr-deficient rats had lower fasting plasma insulin concentrations and similar fasting plasma glucose levels compared with supplemented rats; yet, both concentrations were similar after 24 weeks. In intravenous glucose tolerance tests after 24 weeks on the diet, plasma insulin levels tended to be higher in Cr-deficient rats; rates of excess glucose clearance were statistically equivalent. Thus, a high-sucrose diet can lead to hyperinsulinemia that appears to be partially corrected by chromium. This research group also obtained similar results using a high-fat diet that contained 33 mg Cr per kilogram diet. After 16 weeks on the diet alone, rats had higher fasting plasma insulin levels, compared with rats also receiving drinking water containing 5 ppm Cr. Thus, the high-fat diet also appears to induce increased fasting insulin levels, which can be corrected with chromium administration. Some calculations are in order to put this work into perspective. Humans lack signs of Cr deficiency with a daily intake of 30 μg Cr; assuming an average body mass of 60 kg, 30 μg day^{-1} corresponds to 0.5 μg Cr per kilogram body mass per day. Thus, for a rat, this is equivalent to 5 μg Cr per kilogram body mass per day, ten times what a human intakes. Thus, the 'low-Cr' high-sugar and high-fat diets cannot be said to be deficient at all unless rats require more than ten times the chromium that humans do on a per kilogram body mass basis. Consequently, the effects of the diet cannot be attributed to Cr deficiency; the high doses of Cr in the Cr-supplemented rats can only be considered as having a pharmacological role on those rats whose physical condition were impaired by the high-sucrose or high-fat diets and/or the other mineral stresses. In 2011, the effects of a purified diet (AIN-93G without Cr in the mineral supplement, 16 μg Cr per kilogram diet) on male Zucker rats in metal-free cages for 16 weeks were examined. Zucker rats also received the normal AIN-93G diet (i.e., with 1000 μg Cr added per kilogram diet) and the normal diet supplemented with an additional 200 or 1000 μg Cr per kilogram diet. No ill health effects were noted for the rats on the low-chromium diet. Plasma insulin concentrations in glucose tolerance tests decreased as a function of chromium dose indicating a pharmacological effect for the dietary chromium.

Thus, with no added stresses, a purified diet with as little chromium content as possible does not result in symptoms that can be attributed to chromium deficiency, although effects on insulin sensitivity can be observed at supranutritional, that is, pharmacological, doses of chromium. Hence, establishing whether chromium is an essential nutrient is apparently not feasible from traditional nutrition studies, because developing a chromium-deficient but otherwise sufficient diet appears not to be possible. This could be simply because chromium is not an essential element or uniquely because such low amounts of chromium are required that generating a deficiency is not possible. Similarly, no genetic disorder that alters chromium transport or distribution or other function has been identified; the study of such disorders for other metals has pointed to the essential nature of those elements and the biomolecules that utilize the metal. How then can the potential essential nature of chromium (or other elements such as silicon, vanadium, arsenic, and boron that have been proposed to be essential but

in such miniscule amounts that generating a dietary deficiency is impossible) be established? The most obvious method is establishing that a biomolecule containing the element *in vivo* performs an essential biological function at physiological levels of the element. For chromium, this has proved less than straightforward, as several mechanisms for chromium action at a molecular level have been proposed, while none have been adequately established *in vivo*. In fact, major questions shroud each proposal, and open scientific discussions of these issues and the other issues described in the preceding text have proved to be quite difficult given the financial implications of the outcomes.

Total Parenteral Nutrition

Evidence for an essential role of chromium in humans has also been inferred from studies of patients on TPN. Patients on TPN have developed impaired glucose utilization or glucose intolerance and neuropathy or encephalopathy. These symptoms were reversed by chromium infusion while unaltered by other treatments. While limited to about ten individual cases, these studies have been interpreted as providing evidence of clinical symptoms associated with chromium deficiency that can be reversed by supplementation. Curiously, the development of the symptoms that were reversible by chromium supplementation does not correlate with serum chromium levels, indicating either that serum chromium levels are not an indicator of chromium deficiency or that another factor is in operation. Additionally, these incidences of diagnosed potential chromium deficiency have been questioned as they lack consistent relationships between the chromium in the TPN, time on TPN before symptoms appear, serum chromium levels, and symptoms. Yet, subjects, albeit a limited number, with certain conditions not responsive to other treatments appear to have improved glucose control and reduction in insulin needs in response to intravenous chromium.

The level of Cr administered must be examined carefully. In the cases where reversal of symptoms was reported, the TPN solutions provided 2–10 μg Cr per day. All the Cr in the TPN is introduced into the bloodstream, while only ~0.5% of Cr in the regular diet is absorbed into the bloodstream. Thus, 30 μg of Cr in a typical daily diet results in only ~0.15 μg of Cr entering the bloodstream. The TPN solutions utilized in these studies are consequently presenting ~13–67 times the required amount of chromium; thus, based on these data, the TPN solutions cannot be considered Cr-deficient. For the treatments, the subjects received 40–250 μg Cr per day added to the TPN solution to alleviate their conditions, clearly pharmacological doses as the largest dose provided 1.7×10^3 times more chromium than a standard diet when one considers that this administration corresponds to the equivalent of 100% absorption so that the values should be multiplied by 100 for comparison against oral studies. Consequently, the results with the insulin-resistant TPN patients can only be considered as providing evidence for a pharmacological role of chromium. The data are not relevant for examining whether chromium is an essential element.

Not surprisingly, as TPN provides ten or more micrograms of chromium per day, TPN patients accumulate chromium in their tissues. Calls are appearing for the reexamination of the chromium levels in TPN solutions in terms of a need to reduce recommended levels.

Absorption

The absorption of Cr as a function of intake by humans is still widely cited as evidence for the essentiality of chromium, although this is based on a single study. An inverse relationship between dietary chromium intake and degree of absorption was observed, in contrast to rodent studies described in the preceding text. Cr intake was determined from the amount of various food consumed where the Cr content of each food had been previously determined; Cr absorption was estimated from the Cr content of the urine as use of radiolabeled Cr to track the fate of all the administered Cr is not possible in humans. The data suggested that absorption of Cr varies approximately from 0.5% to 2.0% for Cr intakes of ~15–50 μg day^{-1}. This difficult to perform study is far from definitive and desperately requires repeating. For example, a distinct difference is found when the data are separated into male and female subjects. For males, no statistical variation occurs for apparent chromium absorption as a function of intake, while an inverse trend was observed for the female subjects. A thorough statistical treatment including a propagation of error analysis is needed. Additionally, these data are in striking contrast to a similar human study. Chromium absorption was determined to be ~0.4% for free-living individuals; when Cr intake was increased by over fourfold, urinary chromium excretion increased over fourfold while maintaining ~0.4% absorption of chromium for both males and females. The difference between the two studies lies in the range of Cr intakes of ~15–50 μg day^{-1} for the former and ~60–260 μg day^{-1} for the latter, suggesting that an inverse relationship between Cr intake and absorption, if it exists, exists only at the lowest portion of the range of intakes. These results have led to the proposal that Cr homoeostasis is maintained at the level of excretion, not absorption, and that the mechanism of Cr uptake by rats may be different from that in humans. However, the assumption that chromium is in a state of homoeostasis is unproven. In fact, the extent of absorption appears to determine the amount of urinary excretion. As noted in the preceding text, absorption appears to be directly determined by intake – the amount of chromium intake determines the amount of chromium excretion. No evidence for chromium homoeostasis can be derived from these studies (with the exception of the data for female humans).

Thus, in summary, Cr appears to be absorbed by diffusion, not actively transported. The process of chromium absorption could possibly be different in humans (i.e., at least females) from that in rats, but this would seem unlikely and would require more research for this to be firmly established. If chromium intake by humans is active, this transport system would only play a significant role at low chromium intake and would be overwhelmed by diffusion at higher intakes. Clearly, chromium absorption in rodents is not inversely proportional to intake, distinct from that of other reported essential elements. Based on absorption studies, at least in rodents, chromium does not appear to be an essential element; and this probably extends to other classes of mammals.

Chromium Movement

The rates of absorption and transport of Cr are altered in humans with type 2 diabetes and in rodent diabetes models. Increases in blood insulin concentration (such as those following a glucose challenge or similar dietary stress) result in decreases in plasma glucose concentration followed by increases in urinary Cr loss with the amount of increased urinary Cr loss roughly equivalent to the decrease in the amount of blood chromium. Serum chromium levels of diabetic patients are lower than those of healthy subjects, while urinary Cr loss is increased in diabetic subjects. As noted in the preceding text, the increases in chromium loss are accompanied by (if not the result of) increases in chromium absorption. While the association between insulin insensitivity/diabetes and rates of chromium transport is suggestive, it is not proof of an essential role for chromium and is explained in part by the transport of chromium by the iron-transport protein transferrin. A role for transferrin in the detoxification of chromium resulting from increases in chromium absorption associated with insulin insensitivity/diabetes could also explain its phenomenon.

Pharmacological Effects

Supplementation with Cr has been proposed to result in beneficial responses in mammals with demonstrated glucose intolerance or insulin insensitivity, including type 2 diabetes, cardiovascular disease, and related conditions. However, studies in humans tend to be negative or at best ambiguous. The clinical studies, while focused primarily on type 2 diabetic subjects, tend to have small subject pools and not be well designed. One study has dominated attention; 185 adult-onset diabetic Chinese patients participated in the study, in which decreases in the concentration of fasting serum glucose, insulin, hemoglobin A1C, and total cholesterol and decreased glucose and insulin levels in response to glucose challenges were observed as a result of Cr supplementation in a dose-responsive manner. Unfortunately, attempts to reproduce these results with other populations, including Western populations, have been unsuccessful. Two meta-analyses commissioned by agencies of the US government have generated inconclusive results on whether Cr affects symptoms of type 2 diabetes. One in 2002 with funding from the Office of Dietary Supplements of the National Institutes of Health (NIH) identified only four quality studies for analysis and found that the results were inconclusive as the combined results except for those of the Chinese study found no effects. Another in 2007 with funding from the Department of Health and Human Services identified 18 studies. The authors concluded that Cr supplementation might have a modest effect on glucose metabolism in type 2 diabetics but that large heterogeneity combined with the overall poor quality of the studies limited the strength of any conclusions. Unfortunately, the positive effects of the greatest magnitude used in the analysis came from the 12 studies ranked lowest in quality, including the Chinese study. A trend was observed that commercial industry-sponsored studies were more likely to observe beneficial effects. Consequently, the position of the American Diabetes Association (ADA) is that insufficient evidence exists to support the use of chromium to improve glycemic control in people with diabetes.

In contrast, studies with rodent models of diabetes and peripheral tissue insulin resistance generally observe beneficial effects on insulin sensitivity and often also observe beneficial effects of serum cholesterol and triglyceride levels. These rat studies generally provided rats between 80 and 1000 μg (or even more) Cr per kilogram body mass daily for periods of weeks or months. Based only on mass, this would correspond to 5.2–65 mg Cr daily for an average 65 kg human. Even when corrected for the increased metabolic rate of rats compared to humans, this range corresponds to ~1–13 mg Cr daily. Thus, human clinical trials may have only started to approach the dose necessary to see a beneficial effect in humans. The amount of Cr used in clinical trials needs to be increased before determining whether or not chromium supplementation has an effect on individuals with type 2 diabetes, insulin resistance, or related conditions. However, one also cannot rule out that beneficial effects might be unique to rodents and perhaps certain other animals.

Requirements

The basis for the use of chromium as a nutritional supplement stems from chromium being on the list of essential vitamins and minerals under examination by the NRC (National Research Council of the National Academies of Science, the United States) since 1980 when an estimated safe and adequate daily dietary intake (ESADDI) for 50–200 μg was suggested. In 2001, the National Academies of Science established an adequate intake (AI) of chromium of 35 μg day^{-1} for men and 25 μg day^{-1} for women. AI is defined as the recommended average daily intake level based on observed or experimentally determined approximations or estimates of nutrient intake by a group (or groups) of apparently healthy people that are assumed to be adequate. The AI is more conservative than a recommended daily allowance and is expected to cover the needs of more than 97–98% of individuals. Thus, essentially, all Americans are believed to be chromium-sufficient, and little if any need exists for chromium supplementation. The bases for this determination are rather limited. The AI is primarily based on the Cr content of nutritionist-designed diets (on average roughly 35 μg Cr for men and 25 μg Cr per day for women), which turns out to be almost identical to the chromium content of self-selected American diets. Diets in other developed nations appear to be similar in Cr content, if not slightly higher. The National Research Council is currently reviewing dietary requirements of trace elements and vitamins. What decision is made in terms of the status of chromium as an essential element will be interesting.

Dietary Sources and Content in Food

Chromium is ubiquitous in foods but at very low concentrations. However, during processing, particularly in stainless-steel (~10–40% chromium) equipment, the concentration of chromium appears to increase; in fact, most of the Cr in some foods may come from processing. Foods particularly rich in Cr (i.e., >100 ppb) include broccoli and black pepper and certain beers; however, values for vegetables must be considered

carefully because of the variable amount of chromium that comes from soil contamination. The low concentrations of chromium in food, the ease of contamination, and the low suggested dietary requirement for chromium (vide supra) make preparation of a low-chromium (or chromium-deficient) diet difficult if even possible (as this assumes that chromium is actually an essential trace element). Given the amount of Cr in the diet that comes from modern processing, the Cr intake of early humans must have been extremely limited.

Reference Doses

No tolerable upper limit (UL) has been set for Cr^{3+}. No significant health concerns have been found for chromium supplements other than chromium picolinate at current doses. However, a study commissioned by the National Toxicology Program (National Institutes of Health) has found that providing chromium picolinate up to 5% of the diet of male and female rats and mice for 2 years had no conclusive deleterious health effects. This is probably the result of chromium picolinate dissociating in the gastrointestinal tract when provided orally. In contrast, cell culture study and *in vivo* studies suggest that if intact chromium picolinate reaches cells intact that it is toxic and clastogenic, mutagenic, and possibly carcinogenic, hence, the supplement should not be used intravenously, for example, in TPN.

Physical and Chemical Properties

Chromium(6+)

Only two oxidation states of chromium, Cr^{3+} and Cr^{6+}, are generally considered biologically and environmentally relevant and stable; in other words, they are stable in the presence of air and water. Chromium(III) complexes are both kinetically and thermodynamically stable; however, chromium(VI) complexes are kinetically stable but thermodynamically unstable. In the presence of appropriate reducing agents, Cr^{6+} can readily be reduced via Cr^{4+} and/or Cr^{5+} intermediates ultimately to Cr^{3+}. The biochemistries of both Cr^{3+} and Cr^{6+} have controversial histories. The public is generally more familiar with the chemistry of Cr^{6+} (or chromate) because of its toxicity.

Chromium(6+), d^0, is most commonly encountered as the intensely colored chromate, $[CrO_4]^{2-}$, or dichromate, $[Cr_2O_7]^{2-}$, anions. These two species are interconvertible in water. Chromate has a distinctive yellow color and exists at basic pH values. Insoluble $PbCrO_4$ was previously used as the pigment in paint for yellow highway lines. Below pH 6, chromate is in equilibrium with the yellow-orange dichromate anion. Acidic dichromate solutions are potent oxidants. The coordination environment of the chromium centered in both the chromate and dichromate anions is tetrahedral. The intense color of both anions stems from ligand to metal charge transfer bands. Mixed ligand complexes of Cr^{6+} with oxides and halides or oxides and amines are well known, as are Cr(VI) peroxo complexes. The diamagnetic Cr^{6+} center does not give rise to ESR (electron spin resonance) spectra, while NMR (nuclear magnetic resonance) studies of Cr(VI) complexes with oxo, peroxo, and halo ligands are of limited utility.

While Cr(VI) complexes are known to be potentially potent carcinogens and mutagens when inhaled, a serious debate has arisen with regard to the effects of the oral intake of these complexes, as illustrated in recent years by the popular movie *Erin Brockovich*. Chromium(VI) complexes could give rise to these effects through a number of mechanisms, including oxidation of biomolecules by the complexes or by the subsequently generated Cr^{4+} and Cr^{5+} intermediates, reactions of reactive oxygen species generated as by-products of these oxidations, reactions of organic radicals generated in these processes, and the binding of the ultimately generated Cr^{3+} to biomolecules. The relative importance of these mechanisms is far from being deciphered. The nature and significance of the coordination of Cr^{3+} ions to DNA as a result of Cr^{6+} reduction is a current topic of much debate. Chromate can readily enter cell via sulfate (SO_4^{2-}) and phosphate (HPO_4^{2-}) transporters given its similar shape and charge.

Chromium(3+)

Coordination complexes of Cr^{3+} are nearly always octahedral. Consequently, the chromic center has a d^3 electron configuration with three unpaired electrons ($S = 3/2$), one in each of the three t_{2g} orbitals. This configuration is responsible for the kinetic inertness of Cr(III) complexes, where ligand exchange half-times are generally in the range of hours. The hexa-aquo ion of chromium, $[Cr(H_2O)_6]^{3+}$, is purple in aqueous solution. Solutions of the ion are acidic; at neutral and basic pH, the ion readily oligomerizes to give hydroxo-bridged species starting with the $[(H_2O)_5Cr(\mu\text{-}OH)_2Cr(H_2O)_5]^{4+}$ ion. The Cr^{3+} ion has a large charge to size ratio and is considered as a hard Lewis acid, preferring oxygen and nitrogen coordination. With common biomolecules, coordination to anionic oxygen-based ligands such as phosphates and carboxylates would be expected; however, the structure of Cr(III) biomolecules generally is poorly characterized to date.

Common commercially available forms of Cr^{3+} include chromium chloride ($CrCl_3 \cdot 6H_2O$), chromium nitrate ($Cr(NO_3)_3 \cdot 9H_2O$), and chrome alum ($K[Cr(SO_4)_2] \cdot 12H_2O$), which are utilized because of their solubility. The commonly used commercial form of $CrCl_3 \cdot 6H_2O$ is actually *trans*-$[Cr(H_2O)_4Cl_2]Cl_2\ H_2O$. Dissolution of this green solid initially yields green solutions of the $[Cr(H_2O)_4Cl_2]^+$ cation. Chromium chloride, chromium picolinate, and chromium nicotinate are the most popular forms of chromium used in nutritional supplements. Chromium picolinate is the meridional isomer of the tris-chelate complex of Cr^{3+} and the picolinate anion, [Cr(picolinate)$_3$]. Chromium nicotinate is a poorly characterized insoluble polymer of Cr^{3+}, nicotinate, and hydroxide; its composition varies depending on the method of synthesis. The hydrochloride of a complex of Cr^{3+} and methionine ([Cr(L-methionine)$_3$].HCl) and 'chromium propionate' have been used in nutritional supplements for cattle ('chromium propionate' only) and swine in the United States. Trivalent chromium is not approved as a feed additive in the European Union. Although originally characterized as anhydrous chromium propionate, Cr(propionate)$_3$, chromium propionate is actually the trinuclear cation $[Cr(III)_3O(propionate)_6(H_2O)_3]^+$. The structural, spectroscopic, and magnetic properties of this cation and its analogs with other carboxylate ligands have been extensively studied. Limited characterization has been reported on chromium methionine.

The magnetic and spectroscopic properties of chromium (III) complexes do not readily lend themselves to providing much information on the coordination environment of chromic centers in biomolecules. For mononuclear complexes, a magnetic moment close to the spin-only value for an $S = 3/2$ center (3.88 BM) is generally observed. While ^1H and ^{13}C NMR spectra can be obtained on Cr(III) complexes, the spin 3/2 center results in greatly broadened and shifted resonances in NMR spectra. The structure of the complex generally needs to be known in order to interpret the NMR spectra, rather than the reverse. In contrast, Cr(III) complexes can give rise to sharp features in ESR spectra; however, the ESR spectra of biomolecules have often proved to be quite broad, providing limited information. ESR spectroscopy is probably a

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00161-6

significantly underutilized technique in characterizing chromium in biological systems. Cr^{3+} as an impurity in the Al_2O_3 matrix of emeralds and rubies gives rise to the green and red color of these gems; yet, the electronic spectra of chromium-containing biomolecules are usually very simple. Three spin-allowed $d \rightarrow d$ transitions are expected; two normally occur in the visible region, while the third is expected in the ultraviolet region (where it can be hidden by ligand-based features). No charge transfer transitions generally occur while the visible absorption bands have extinction coefficients of typically less than 100 M^{-1} cm^{-1}. Thus, only relatively concentrated solutions of Cr^{3+} have observable color. Cr(III) complexes are generally stable against oxidation or reduction, although the redox potential can be significantly altered by certain ligands.

Although chromium as the Cr^{3+} ion was proposed to be an essential element about 50 years ago, its status is currently in question, as recent experiments appear to demonstrate that the element can no longer be considered essential. Supplemental nutritional doses of Cr^{3+} have been proposed to result in body mass loss and lean muscle mass development, leading to an appreciable nutraceutical industry being built around chromium. However, these claims have been thoroughly refuted. Chromium has also been suggested to be a conditionally essential element whose supplementation could lead to improvements in carbohydrate and lipid metabolism under certain stress situations, including type 2 diabetes and the effects of shipment of farm animals; this is currently an area of intense and hotly debated research with recent findings suggesting that beneficial effects from Cr^{3+} supplementation are pharmacologically, not nutritionally, relevant. However, while beneficial effects from chromium supplementation have reproducibly been demonstrated in rodent models of diabetes and insulin resistance, well-performed meta-analysis indicates that no clinical effects in humans result from dietary supplementation up to 1 mg chromium per day. Rodent studies use proportionally greater doses based on body mass than the human studies suggesting that clinical trials using larger doses of Cr^{3+} are required to establish if the metal ion has beneficial effects in humans. At the same time, supplementation of the diet with at least certain Cr(III) complexes has been proposed to have potentially deleterious effects, although recent data suggest that oral chromium supplementation is safe.

Determination in Food and Drink

Chromium levels in tissues, body fluids, food components, and other biological samples reported prior to c.1978 are problematic and should be ignored. At this time, improvements in analytic techniques revealed several problems, including appreciable contamination of biological samples (as these samples were often homogenized in a stainless steel blender); in fact, measured Cr levels reflected the levels of contamination not the actual tissue or fluid Cr concentrations, which were extremely small. Another major problem in atomic absorption experiments prior to 1978 was that workers were attempting to measure a tiny signal against a large background; a linear correspondence was actually found to exist between background absorbance and the reported apparent Cr content of samples. Currently, analyses of human blood and urine samples with Cr concentrations above 1 ppb should be considered suspect, unless the subjects are taking chromium supplements; even values above 0.5 ppb may be considered suspect. Consequently, studies prior to 1978 utilizing patients who were believed to be Cr-deficient based on Cr tissue or fluid concentrations and that reported Cr levels in tissues, foods, or fluids of one order to several orders of magnitude too high must be ignored. Thus, with the exception of some ^{51}Cr-labeled tracer studies, the fields of chromium nutrition and biochemistry really began in the late 1970s when chromium uptake and loss could be followed to a reasonable degree of accuracy. At present, chromium levels in tissues and biological fluids are usually determined by graphite furnace atomic absorption spectrometry (GFAAS), although neutron activation analysis (NAA) and inductively coupled plasma-mass spectrometry (ICP-MS) can also be used, with the latter growing in popularity. Inductively coupled plasma-atomic emission spectrometry (ICP-AES) has also seen some use although the detection limit is not suitable for urine and plasma samples so that the technique will not be discussed further. Neutron activation and ICP-MS have also been utilized with stable isotopes of Cr for determining Cr levels in tracer studies, in addition to the continuing use of radioactive ^{51}Cr for such studies. As most researchers have limited access to NAA, the technique will not be discussed further. These techniques are compared in Table 1.

Chromium is ubiquitous in foods but at very low concentrations. However, during processing, particularly in stainless steel (~10–40% chromium) equipment, the concentration of chromium appears to increase; in fact, most of the Cr in some foods may come from processing. Foods particularly rich in Cr (i.e., >100 ppb) include broccoli and black pepper and certain beers; however, values for vegetables must be considered carefully because of the variable amount of chromium that comes from soil contamination. The low concentrations of chromium in food, the ease of contamination, and the low suggested dietary requirement for chromium (30 μg day^{-1}) make

Table 1 Comparison of chromium analysis techniques

	GFAAS	*ICP-AES*	*ICP-MS*	*NAA*
Analysis time	2–3 min for only Cr	2–5 min all elements	2–5 min all elements	days multiple elements
Detection limit	0.1–0.01 ppb	10–1 ppb	1–0.01 ppb	~0.1 ppb
Isotope specific	No	No	Yes	Cr-50
Sample volume	Small	Moderate	Small	Varying
Instrument cost	Moderate	High	Very high	Extremely high
Operating cost	Moderate	High	High	High

preparation of a low-chromium (or chromium-deficient) diet difficult if even possible (as this assumes chromium is actually an essential trace element). Given the amount of Cr in the diet that comes from modern processing, the Cr intake of early humans must have been extremely limited.

Tables of chromium content for various foods are probably of limited utility because of the variability of chromium content of samples based on history (processing, growth conditions, etc.). For example, a 50-fold difference in chromium content has been found for different types of oatmeal. Foods used in nutrition studies need to be analyzed for each study, rather than depending on tabulated values in the literature. The chromium content of commercial rodent chows is surprisingly high and extremely variable, even between lots of the same brand. The amount of chromium in commercial rodent chows is normally about 500 $\mu g\,kg^{-1}$. The purified AIN-93G diet has 1 $mg\,kg^{-1}$ of added Cr^{3+} as potassium chromium sulfate dodecahydrate.

Precautions to Be Taken in Chromium Determination

Chromium concentrations in urine and blood are in the sub part per billion range unless subjects receive chromium supplementation. Hence, the concentration of Cr in these fluids is within about an order of magnitude of the detection limit of current techniques. Thus, contamination is a major concern. Similarly, the chromium concentration of tissues and foods generally range from 1 to 1000 ppb, meaning that contamination can be a major problem as well. For foods, knowing the history of the sample is important as processing can provide more chromium than the food initially contained. Differences in commercial processing can result in large differences in chromium content. Similarly, differences in chromium content of vegetables and other plants in terms of growth conditions are poorly known.

Because of the chromium content of stainless steel, contact with stainless steel should be avoided during sample collection and handling. For example, the use of a stainless steel blender to homogenize samples transfers appreciable amounts of chromium. Needles for venipuncture, thus, can be a challenge. Most of the chromium removed from a stainless steel needle during blood collection appears to be removed by the first 20 ml of blood; consequently, collecting samples after allowing several milliliters of blood to pass through the needle has been proposed. However, contamination, while reduced, still appears to be substantial. Siliconized stainless steel needles seem to be suitable. Plastic cannula or catheters are suitable. For plasma, anticoagulants, for example, ethylenediaminetetraacetic acid, used should also be low in chromium.

Plasticware (such as those made of polyethylene or polypropylene) should be used wherever possible in transferring and storing samples, and all glassware or quartz tubes should be acid-washed. Rubber stoppers are a source of chromium and should be avoided. All water and chemical reagents need to be of ultra high purity. Investigators should wear nonpowdered nitrile or polyvinylchloride gloves. All methods should be verified with the use of a certified chromium standard.

Sample Digestion

Discussion will be limited to samples for GFAAS, for which more data exist. Similar procedures are required for ICP-MS.

Urine

Sample digestion can be avoided for urine samples, although the use of the method of standard addition may be required to remove matrix effects and is recommended. Wet ashing can also be utilized; for example, digestion with HNO_3 and 30% H_2O_2 at subboiling temperatures for 15 h has been utilized. The solid can be dissolved in water for analysis.

Blood

For dry ashing, magnesium nitrate has been added as a matrix modifier to samples in quartz tubes followed by lyophilization using a stainless steel-free lyophilization apparatus. The solid is then ashed in a muffle furnace at 480 °C and then dissolved in HCl for analysis. Following this technique because of the uniformity of samples, the use of the method of standard addition has been reported to not be necessary.

Alternatively, blood plasma has also been enzymatically digested and used directly with the addition of magnesium nitrate as a matrix modifier; the method of standard addition was also utilized.

Tissues and Foods

For such samples, digestion of samples is essential. (Numerous variations of the procedures described have been used.) For dry ashing, magnesium nitrate is added before placing in a muffle furnace; the ash is dissolved in HCl for analysis. For wet ashing, samples can be treated with a mixture of nitric and sulfuric acids and heated to dryness at subboiling temperatures followed by dissolution in water for analysis. A combination of wet and dry ashing has also been used. Samples in borosilicate glass tubes are heated in a muffle furnace at 375 °C for 48 h; subsequently, nitric acid is added to the cooled samples that are then heated in a heating block at 90 °C. Additionally, hydrogen peroxide (50%) is added at time intervals until carbon particles are dissolved. Alternatively, the use of microwave digestion systems has become popular. Nitric acid is added to samples before heating in the microwave digestion system.

Determination Methods

Graphite Furnace Atomic Absorption Spectrometry

In GFAAS, a furnace dissociates a sample into its component atoms. Light from a hollow cathode tube (which is element-specific) is passed through the generated cloud of atoms where the atoms of the element of interest absorb the light. The absorption of light is proportional to the concentration of the element in the sample. The furnace, an electrically heated graphite tube with an opening for sample introduction, replaces the flame in traditional atomic absorption spectrometry. The furnace, in contrast to the flame, generates a higher

Table 2 Furnace program for chromium determination by GFAAS

Mode	Step	Temperature (°C)	Ramp time (s)	Hold time (s)
Dry	1	100	5	20
Dry	2	140	15	15
Char	3	1600	10	20
Atomization	4	2500	0	4
Clean	5	2600	1	3

density of atoms with a longer residence time in the cloud, increasing the sensitivity of the method. The use of modern instruments with their background corrections removes some of the pre-1978 difficulties; however, contamination given the low concentration of chromium in biological samples will always be a potential problem.

Generally, the protocol of Veillon and coworkers or variations thereof are utilized. After being injected into the furnace, samples are subjected to a program of drying (two steps at 100 and 120–140 °C), charring (1150–1350 °C), atomization (2500–2700 °C), and cleaning (2600–2700 °C). A typical program is shown in Table 2.

Inductively Coupled Plasma-Mass Spectrometry

ICP-MS generates the constituent atoms and ions using an ICP. In contrast to GFAAS where the absorption of light is detected, the generated ions are detected directly. The ions are separated based on their charge to mass ratio in the mass spectrometer, generally using a quadrupole analyzer or magnetic sector analyzer. The detection limit of ICP-MS is normally about an order lower than GFAAS based on the number of ions generated in the former compared to the number of atoms excited in the latter. Contamination becomes a greater concern as the level of detection is pushed to lower limits. ICP-MS has the advantage of being isotope-specific, whereas GFAAS is only element-specific. ICP-MS instruments are considerably more expensive than GFAAS, which is why GFAAS is currently more commonly used for Cr analysis. ICP-MS instrument currently also requires more care in operation, although analysis time is shorter than for GFAAS.

Chromium(III) and Chromium(VI) Speciation

Given the different chemistries and toxicities of chromium(III) and chromium(VI) complexes, determining of the concentration of one or the other rather than the total chromium concentration is often desired. However, none of the techniques described earlier can separate complexes of the two oxidation states but rather only measure total chromium content. Techniques, such as colorimetric assays that can specifically test for chromium(IV) species, lack the sensitivity to measure biological concentrations. Consequently, some type of separation technique is required before detection of chromium using one of the determination methods described earlier. This separation must be accomplished without the oxidation states of the chromium changing. The separation also can lead to dilution requiring preconcentration before chromium analysis. The concentration of each ion can be measured, or the concentration of one ion in combination with the total chromium concentration can be measured allowing for the calculation of the concentration of the other ion.

Developing methods to separate these ions at low concentrations without altering the oxidation states is an area of active research. Most research has been focused on water samples that generally lack the complexity of biological samples. Yet, studies have shown that Cr^{3+} and Cr^{6+} concentrations can be determined in urine and plasma samples, although nothing has been adapted for routine use to date. For example, cloud point extraction has been combined with GFAAS to determine the concentrations of Cr^{3+} and Cr^{6+} in human blood serum samples, while ion-pair reversed-phase high-performance liquid chromatography (HPLC) has been coupled with ICP-MS to measure the concentrations of Cr^{3+} and Cr^{6+} in human urine (from chromate workers).

Conclusion

Cr^{3+} and Cr^{6+} ions have distinctly different chemistry. Most notable, Cr(VI) complexes are kinetically stable and thermodynamically unstable, while Cr(III) complexes are both kinetically and thermodynamically stable. In a biological environment, only Cr^{3+} is stable as Cr^{6+} is reduced via Cr^{5+} and/or Cr^{4+} intermediates to Cr^{3+}. This chemistry results in Cr^{6+} being toxic, mutagenic, and carcinogenic, while Cr(III) complexes are generally nontoxic. Chromium concentrations in tissues, body fluids, foods and beverages, and other biological samples are very low. Chromium concentrations in these samples reported prior to c.1978 are problematic (except when radioactive Cr-51 was used as a tracer), and these values must be disregarded as they are often too low by as much as three orders of magnitude. Currently, chromium concentrations in biological samples are generally measured using graphite furnace atomic absorption spectroscopy or ICP-MS, with the former being more popular because of instrument expense and ease of maintenance. Sample preparation must be performed carefully to prevent contamination, particularly from stainless steel. Currently, research in the separation and determination of Cr^{3+} and Cr^{6+} simultaneously is an active area.

Cider (Cyder; Hard Cider): The Product and Its Manufacture

E Coton and M Coton, Université de Brest, Plouzané, France
H Guichard, Institut Francais des Productions Cidricoles, Le Rheu, France

© 2016 Elsevier Ltd. All rights reserved.

Definition and Origin

Cider is generally defined as an alcoholic beverage obtained by apple juice (apple must) fermentation. Noteworthy, in North America, the term 'cider' is rather associated with a cloudy unfermented and unpasteurized apple juice, whereas the fermented product is called 'hard cider.' In Europe, the fermented product is mainly named 'cider' in the UK, 'cidre' in France, 'sidra' in Spain, and 'apfelwein' in Germany. Another common fruit fermentation is obtained from pears and leads to a product named 'perry' in English or 'poiré' in French. It is worth mentioning that cider can either be a final product ready for consumption or an intermediate product used for apple brandy (e.g., 'Calvados' in Normandy and 'Lambig' in Brittany) production by distillation or cider vinegar via an acetic fermentation. Moreover, Calvados blended with apple must leads to an aperitif-type beverage (i.e., predinner drink) named 'Pommeau' in France.

Like the other major fermented beverages (i.e., wine and beer), cider is one of the oldest alcoholic beverages in the world; Hebrews called it 'sichar,' whereas Romans and Greeks called it 'sicera' and 'sikera,' respectively. From an etymological point of view, the name *cider* would come from 'sicera' (meaning any fermented beverage that is not wine; Cambridge Psalter); this can especially be observed in Normandy, as 'cidre' was originally spelled 'sidre.' Although the name *cider* was not used at the time, during antiquity, a certain number of writings by Pliny the Elder or Palladius refer to alcoholic beverages obtained from apples or pears. During the ninth century, the term 'sicetores,' referring to brewers producing ale but also 'pomacium' from apples, was used by Charlemagne. In France, the first use of the word 'cidre' was found in the Conception de Nostre-Dame (Wace, twelfth century). From this time, and thanks to the invention of the press (thirteenth century), cider production extended to various apple-producing European regions. From the fourteenth to twentieth centuries, technological practices and processes were optimized and led to higher volumes and better-quality products. Nowadays, cider production, although far more limited than wine and beer, can be found on every continent in apple-growing regions worldwide. In Europe, the UK (mainly West Country, West Midlands but also Wales), France (mainly Normandy and Brittany), Spain (mainly Asturias and Basque country), and Germany are the main cider-producing countries, although many others have local productions (e.g., Ireland, Austria, Poland, Sweden, Norway). In North America, hard cider production is done in the United States, Canada, and even Mexico. Interestingly, in Quebec, a new cider type named 'ice cider' (equivalent to icewine in enology and thus using apples with high sugar contents due to natural frost) has recently appeared. In South America, cider is produced in Argentina and Chile. Cider production is also found in Asia (China and Japan), Africa (South Africa), Australia (Tasmania), and New-Zealand.

Although the generic term 'cider' is commonly used, the term 'ciders' is more appropriate to reflect the large variety of fermented apple products. According to production region, cider can be produced from only apples, with the addition of pear or from apple concentrate. Additives such as sugar, acid, or coloring agents can also be used. Sugar content may vary leading to dry, semidry, or sweet ciders. Carbon dioxide (CO_2) may be absent or present and obtained in the final product by carbonation or a secondary fermentation. In this context, beyond the classical definition of the term *cider*, it is important to note that several country regulations exist to define cider and cidermaking. Examples of regulations include the French "Décret n°87–600 du 29 juillet 1987 modifiant le décret n° 53–978 du 30 septembre 1953 relatif à l'orientation de la production cidricole et à la commercialisation des cidres et des poirés," the UK "Customs & Excise Notice 162: cider production" and the Spanish "Orden de 1 de agosto de 1979 por la que se reglamentan las sidras y otras bebidas derivadas de la manzana." In these regulations, authorized products entering the cidermaking process as well as specific analytical parameters (e.g., ethanol, volatile acidity, or SO_2 levels) are defined.

Moreover, to ensure cider product quality, several certifications exist at the national or international (European) level. They are delivered based on certain product specifications and requirements to ensure product authenticity and quality for consumers. Examples of these certifications, which are generally easily recognizable by specific logos on the label, include

- Protected Designation of Origin (PDO) and covers, as defined by the European Commission, "agricultural products and foodstuffs which are produced, processed and prepared in a given geographical area using recognized know-how" (e.g., Cidre Pays d'Auge, Cidre de Cornouaille and Sidra de Asturias).
- Protected Geographical Indication (PGI) and covers, as defined by the European Commission, "agricultural products and foodstuffs closely linked to the geographical area. At least one of the stages of production, processing or preparation takes place in the area" (e.g., Cidre de Bretagne, Cidre de Normandie, Gloucestershire cider, Herefordshire cider, and Worcestershire cider).
- Organic farming corresponds to products that must comply with strict EU requirements covering not only production and processing, but also the control and labeling of organic foods. This certification has gained interest due to strong societal demand but also higher commercial value for the product.
- 'Label Rouge' (red label) is specific to France and attests that the product, examined by a national commission, presents superior overall quality compared to a similar product (e.g., Cidre de Normandie, Cidre Royal Guillevic).

Production

Cider production practices in France (Figure 1) and the UK, although both leading to products called ciders, exhibit major differences that in some instances can even be considered opposite. In the following section, these practices will be used as examples.

Raw Material

Although cider can be produced from any apple cultivar, in Europe, a distinction is traditionally made between dessert, cooking, and cider apples. Cider apples have distinct organoleptic qualities that make them uninteresting for direct consumption linked to their acidity or natural polyphenol content. On the contrary, these traits provide high product qualities in terms of body equilibrium (sweetness, acidity, astringency, and bitterness) that are not obtained using dessert apples. Different cider apple cultivars exist, and more than 1000 have been described, although only a few are used for production. They are classified into six categories based on juice-specific savors:

- *Sweet*: These apple varieties are the blandest of the six categories. They have low acid (<60 mequiv.l^{-1}) and polyphenol (<2 gl^{-1}) contents and up to 15% sugar (cultivars: *Douce Coëtligné, Doux Normandie, Muscadet Petit de l'Orne, Rouge Duret, Sweet Copin, Sweet Alfortd, Nortwood* . . .).
- *Sour*: These apples are mildly sour (60–90 mequiv.l^{-1}) with low polyphenols (<2 gl^{-1}) (cultivars: *Guillevic, Judeline, Rouget de Dol, Locard blanc* . . .).
- *Sharp*: These apples provide sourness and freshness to cider due to their high acidity (>90 and up to 240 mequiv.l^{-1}) and low polyphenol (<2 gl^{-1}) contents (cultivars: *Petit Jaune, Judor, Avrolles, Locard vert, Crimson King, Brown's Apple* . . .).
- *Bittersweet*: This apple type corresponds to intermediate cultivars with low acidity (<60 mequiv.l^{-1}) and high polyphenol (>2 gl^{-1} and <3 gl^{-1}) contents providing bitterness and astringency to cider (cultivars: *Douce Moën, Bedan, Binet Rouge, Bisquet, Ashton Bitter, Dabinett, Yarlington Mill, Tremlett's Bitter* . . .).
- *Bittersharp*: These apples have high acid (>60 mequiv.l^{-1} and up to 240 mequiv.l^{-1}) and total polyphenols (>2 gl^{-1} and up to 6 gl^{-1}) (cultivars: *Cazo jaune, Kingston Black, Foxwhelp* . . .).
- *Bitter*: These apples have low acid (<60 mequiv.l^{-1}) and high total polyphenols (3–9 gl^{-1}) (cultivars: *Marie Ménard, Kermerrien, Petit Amer, Fréquin rouge, Bramtot, Ellis Bitter* . . .).

Traditionally, ciders are not obtained from a single cultivar. Indeed, blending ('pommage') of different apple types allows for the production of balanced ciders with various organoleptic qualities. Also, three maturity stages can be distinguished: early season (beginning to end of September), midseason (beginning of October to mid-November), and late season (mid-November to end of December). After harvest, which is rather mechanically performed nowadays, apples are stored for a maximum of 5 days before processing to reach full maturity and to ensure that all starch has been converted into sugar. This short time period allows good fruit preservation and texture compatible with optimal pressing.

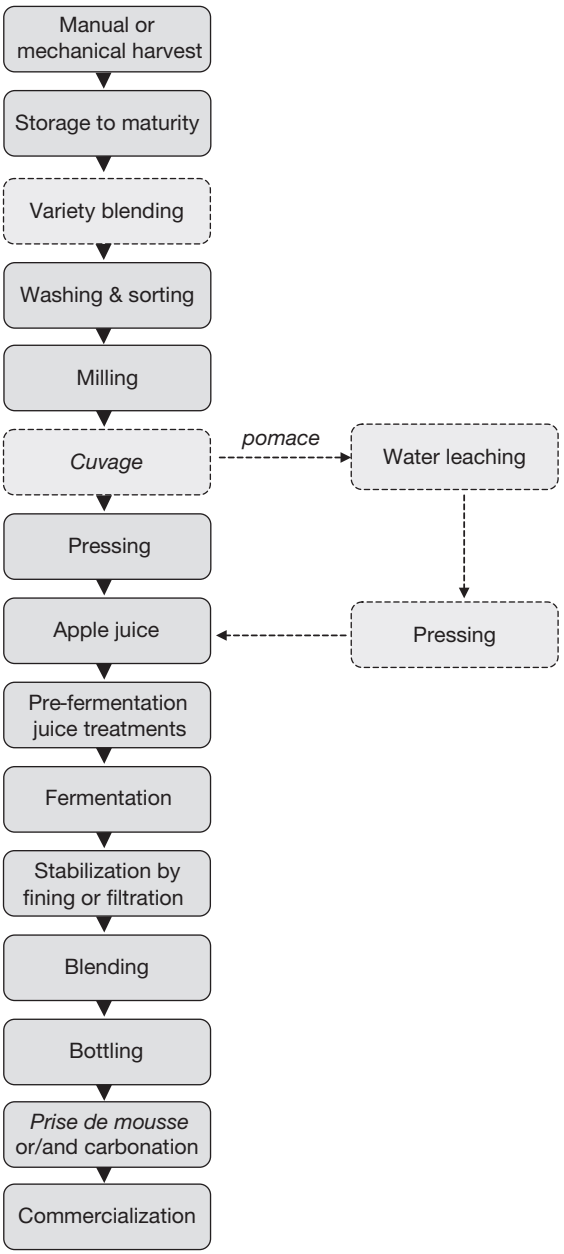

Figure 1 French cidermaking diagram. Steps in lighter gray and discontinued lines are optional.

Milling and Pressing

Before any processing operation, fruit sorting and washing are required to eliminate rotten fruits and potential foreign materials (e.g., wood pieces, grass, soil, and stones) that could impact overall product quality. Rotten fruits are associated with mold contamination and originate either directly from the apple tree itself (*Monilia* spp.) or indirectly after impacts due to falling and being in contact with the ground

(*Fusarium* spp.). All damaged fruit, especially in the case of mechanical harvesting, can also be spoiled by secondary molds belonging to *Botrytis* and *Penicillium* genera. Beyond the rotten aspect of these fruits and potential associated off-flavors, it is worth noting that some molds are also able to produce toxins (mycotoxins) that may have an impact on human health. Milling (*rapâge* in French) is then performed to obtain fruit pulp for more efficient juice (or must) extraction. In general, a high-speed mill corresponds to a wheel bearing graters or coarse knives rotating against a fixed surface; they are calibrated to tear the fruit tissues without smashing the seeds. Fine milling is used for firm apples, whereas rougher milling is used for very ripe apples. In France, an extra step called 'cuvage' (pectin leaching for 2–5 h for better pressing yields) can be performed.

In both the UK and France, the next step involves pressing the pulp by exerting high pressure. Nowadays, technological evolutions have led to the use of semicontinuous, continuous, or even automated presses, although discontinued and more traditional presses can still be encountered in farm and artisanal cider productions. The main types encountered are

- *Horizontal presses*: They correspond to compressible chambers, equipped with several juice ducts, in which the pulp is introduced. Then pressure is applied through the action of a piston or a membrane. Thanks to several cycles of pressure and homogenization, high extraction yields (up to $800\,l\,T^{-1}$) can be reached.
- *Continuous belt presses*: In this case, the pulp is placed between two bands that will go through a series of rollers that apply pressure onto the belt, resulting in a pressing action. This type of press gives yields ranging from 600 to $750\,l\,T^{-1}$.

Pressing leads to two products, on the one hand, a liquid phase corresponding to the juice, also called 'apple must' (*moût pur jus* in French), and on the other hand, a solid phase called pomace (*marc* in French). After coarse screening, the juice is transported through piping systems to stainless steel, HDPE (high-density polyethylene) or fiberglass tanks. Less commonly, wood tanks can still be encountered in more traditional cider productions, even though this material is more difficult to clean and sterilize, thus leading to potential product spoilage.

The obtained pomace (200–400 kg per ton) still contains compounds of interest. A second extraction can therefore be performed by water leaching (countercurrent water percolation of the pomace) or by pressing the watered pomace. These actions lead to diluted juice (*moût de diffusion* or *petit jus* in French) that will be added to the first juice obtained. The extraction step may be facilitated by using enzymatic cocktails (pectinases and hemicellulases, or pectin methylesterase [PME] in the presence of calcium) – by themselves or in combination with the mechanical material.

Prefermentation Juice Treatments

In France, juices are subjected to additional specific steps called *défécation* and *décantation* (keeving and settling in English) to obtain slow and long fermentations. Keeving corresponds to the traditional juice treatment, and about half of French cider juices are still treated by this method.

- Keeving relies on the ability of pectins to form a gel via PME enzyme and calcium action. All compounds necessary for keeving (pectin, PME, and calcium) are naturally present in juice. During PME demethylation, an increase of acidic groups on pectin chains is observed. In the presence of calcium, bonds will form between pectic chains, thus leading to gel formation. After 2–6 days, CO_2 is generated by the onset of the fermentation process, and the bubbling action will force the gel to rise to the top of the tank, carrying along suspension deposits (rich in nitrogen) that form a complex structure called *chapeau brun*. At the same time, complexed materials will also sediment to the bottom of the tank. The clarified juice is situated between the gel and sediment layers. The natural process is slow and not always reliable. Nowadays, in order to increase the reliability of this static system, fungal PME preparations and $CaCl_2$ are added. Recently, a continuous dynamic system, termed *flottation*, has also been used by some cider producers. In this case, the juice is treated for up to 48 h, before being introduced in a specific device with nitrogen bubbling in the presence of $CaCl_2$.
- Settling is obtained by pectin hydrolysis, using a combination of enzymes (PME, endopolygalacturonase and pectinlyase). The clarified juice is obtained by decanting; sometimes this is followed by fining by gelatin addition. This method is widely used by industrial cider producers.

The clarified juice obtained by either method is then transferred to another tank to begin the next production step. Prefermentation clarification generates juices without any suspension deposits and low bacterial counts, thus reducing potential microbial spoilage. Moreover, amino nitrogen content and yeast counts are also reduced, thus leading to a slow fermentation. Polyphenols have also been shown to be affected by these treatments, mainly through a reduction in both flavanol content and average degree of polymerization.

In the UK, keeving is not performed but juice additions are. The goal is to obtain a blend of fermentable sugar sources, including juice but also apple juice concentrates and/or syrups that give a final product of 10–12% alcohol after fermentation. Whereas in the case of French cider production, everything is done to allow for slow fermentation by reducing nutrients, reducing yeast counts, and using cold temperatures. In the UK, the goal is to ferment juices to dryness in as a short time as wine. To achieve this, several nutrients are added to the blend. Although there is obviously no sugar shortage in apple juice, ammonium nitrogen and vitamins (enzymatic cofactors), which are essential for yeast development and thus for fermentation, can be limiting, thereby leading to sluggish or stuck fermentations. This is especially the case for apple juice concentrates and syrups. In this context, ammonium phosphate (250 ppm) will be used to standardize the blend in amino nitrogen content (about 100 mM). Thiamin, biotin, panthoneate, or pyridoxine vitamins can also be added. As performed in France, British cider makers also depectinize the juice using pectinolytic enzyme preparations. This indeed facilitates filtration operations and prevents haze formation.

Finally, sulfur dioxide (SO_2) is an important technological additive that is added during both French and British fermentation processes. It presents two main properties of interest for cider making and is widely used in oenology. First, it exhibits antiseptic activity against bacteria and non-*Saccharomyces* yeast. The multiple SO_2 targets leading to microbial cell death explains why no sulfite resistance has been observed to date. Second, sulfite has antioxidant (leading to sulfate formation in the presence of oxygen) and antioxidative (oxidase inhibition) activities. SO_2 performance is directly linked to pH as only the undissociated form (termed 'molecular SO_2') is active. Therefore, it is recommended to adjust the pH of the juice to pH 3.75 by adding malic acid, the main organic acid found in apples. Moreover, SO_2 interacts with various chemical compounds (especially aldehydes), microorganisms, and solids; therefore only the so-called free SO_2 will be active and participate to the overall juice or blend quality. However, SO_2 can negatively affect cider aroma, in particular due to its action on oxidative flora, and more important is considered to be an allergen (legal limits for SO_2 contents in ciders have been set in Europe). Although no efficient alternative has been found to date, ascorbic acid (antioxidant properties) addition can help reduce SO_2 concentrations.

Fermentation

Fermentation refers to microbial activities that will transform the juice into cider. Like any other technological process, the key factor to obtain the desired end product is control. This is especially true and critical when living organisms are involved. In the context of cidermaking, several technological levers can be used. These levers correspond to biotic factors (microbial inoculation or indigenous flora) and abiotic factors, either intrinsic (pH, amino nitrogen content, sugar content) or extrinsic (temperature, oxygen content). As discussed earlier for amino nitrogen content, the contrast between the French and British processes is also obvious for the fermentation step.

French production relies exclusively on indigenous flora. The typical fermentation temperature is between 5 and 15 °C, due to the fact that cider tanks were traditionally situated outside the buildings and thus directly influenced by seasonal temperatures. This also prevents or inhibits lactic acid bacteria (LAB) and spoilage microorganism growth. The combination of low temperature, low amino nitrogen content, and lower yeast counts (by centrifugation or filtration at strategical time points) yields slow fermentation times, in accordance with the desired organoleptic qualities. In the case of PDO and *Label Rouge* ciders, a 6-week minimum fermentation time before bottling is required. In the cider industry, temperature is regulated between 8 and 10 °C by refrigeration systems to control the fermentation, whereas in traditional ciderhouses, racking, centrifugation or filtration can still be used for control.

French cider production consists of several phases:

- *Oxidative phase*: This phase is named oxidative due to the presence of oxygen in juice and lasts from 5 to 15 days. From a microbiological point of view, high species biodiversity can be observed (Tables 1 and 2) with oxidative or slow fermentative yeasts especially belonging to the *Metschnikowia*, *Hanseniaspora*, and *Candida* genera (Figures 2(a) and 2(c)). During this stage, little alcohol is produced (<1%), but numerous volatile compounds are produced, especially esters that largely contribute to the aromatic qualities of the final product.
- *Alcoholgenic phase (alcoholic fermentation)*: During the transition between the oxidative phase and this phase, microbial diversity largely decreases and the *Saccharomyces uvarum* species becomes dominant (Figures 2(a) and 2(c) and Table 1). Under anaerobic conditions, this species, more adapted to cold temperature than *Saccharomyces cerevisiae* (the main species carrying out the alcoholic fermentation in many fermented beverages), mainly metabolizes sugars into ethanol and CO_2 as well as contribute to the organoleptic qualities of the cider by producing fusel alcohols, acids, and more important, ethyl esters.
- *Maturation phase*: This stage actually corresponds to a slower fermentation period, usually associated with a decrease in *S. uvarum* counts and sometimes with the appearance of other yeast species such as *Lachanceae cidri*, *S. cerevisiae*, *Brettanomyces anomala*, or *B. bruxellensis*. In general, LAB counts can also rise at this time (Figure 2(b)), due to increased fermentation temperatures (climate changes) and their metabolism (especially for the *Oenococcus oeni* species). They induce malolactic fermentation (this transformation sometimes happens concurrent with the alcoholic fermentation). LAB species encountered mainly belong to *Oenococcus*, *Lactobacillus*, *Leuconostoc*, and *Pediococcus* genera (Table 2). Malolactic fermentation results in the decarboxylation of the main apple juice acid (malic acid) to lactate. The loss of a carboxylic (–COOH) function leads not only to the production of CO_2 but also to a reduction in acidity. Although this metabolic step can positively contribute to the overall organoleptic quality of the product, it is not always desired as it may lead to ciders with high pH values (>3.75), compatible with microbial spoilage. Malolactic transformation can be controlled by racking, centrifugation, and filtration operations. The maturation stage can last until bottling.

Except for traditional ciders, British fermentation can be considered as the complete opposite. Indeed, in the UK cider industry, rapid and complete fermentations are performed. To do so, not only are juice compositions adjusted as described earlier, but they are also inoculated with commercial active dried yeasts (*S. uvarum*, *S. bayanus*, or a mix of both). The commercial yeasts usually originate from the wine industry. Notable technological traits of these yeast strains include aroma production, killer activity (favors strain development in the presence of other yeasts), and flocculation (for easy clarification). Inoculation trials, concerning both alcoholic fermentation (even using mixed cultures for ester production), but also malolactic transformation, have been performed in various countries; however, to this date, this method has not yet been widespread.

Usually in the UK cider industry, an aerobic phase is performed to favor yeast sterol production, essential to cope with the final ethanol content. After this step, the inoculated juice is fermented to dryness under anaerobic conditions for one week at temperatures ranging between 15 and 20 °C.

In all cases, alcoholic fermentation is monitored by following density or specific gravity, until the desired residual

Table 1 Yeast biodiversity in cider during the various production steps

Species	*Cider type*	*Dominance*	*Fermentation stages when species can be found*
Arthroascus schoenii[a] *(formerly Endomyces schoenii)*	French cider	+	Cider must, oxidative phase

[a]Filamentous fungi.

sugar concentrations are reached (in the UK: dry, in France: $< 28\,g\,l^{-1}$ for 'Brut,' between 28 and $42\,g\,l^{-1}$ for 'Demi-Sec,' and $> 35\,g\,l^{-1}$ for 'Doux' ciders). Malolactic fermentation is monitored by the follow-up of malate and lactate using classical biochemical methods (ex. paper thin layer chromatography).

Postfermentation Treatments

After fermentation, different operations are performed before bottling. In most cases, cider is racked from the lees to clarify and stabilize the product. If not, a limpid and stabilized product is obtained by fining, centrifugation or filtration operations that can be combined or applied individually. Fining consists of adding proteins that interact with polyphenols and form complexes to entrap matter in suspension while settling out. Typical fining agents correspond to gelatin (animal protein) or chitosan (prepared from crab-shell chitin); however, bentonite, a negatively charged absorbent clay, can also be added to accentuate sedimentation. Filtration is performed using either kieselguhr, an unconsolidated form of diatomite, or plate filtration or microfiltration. For traditional ciders, fining and filtration are not performed, thus leading to yeast haze and deposit in the bottle.

Table 2 LAB biodiversity in cider during the various production steps

Species	*Dominance*	*Fermentation stages when species can be found*
Lactobacillus brevis	+	MLF fermentation phase, maturation phase
Lactobacillus buchneri	++	All stages
Lactobacillus casei/paracasei	+	Early and late phases
Lactobacillus collinoides	+++	All stages
Lactobacillus diolivorans	+	Occasionally identified
Lactobacillus mali	+	All stages
Lactobacillus pentosus	+	All stages
Lactobacillus sp.	+	Maturation phase
Lactobacillus fermentum	+	All stages
Lactobacillus plantarum	+	All stages
Leuconostoc mesenteroides	+++	Early, oxidative phase, less frequent in late phases
Oenococcus oeni	+++	Dominant during alcoholic, MLF, and maturation phase, can be present in all stages
Pediococcus ethanodurans	+	Occasionally identified
Pediococcus parvulus	+	All stages
Pediococcus pentosaceus	+	All stages

Dominance based on studies available in the literature and unpublished data (French ciders). +, punctually identified; ++, regularly present; +++, dominant species.

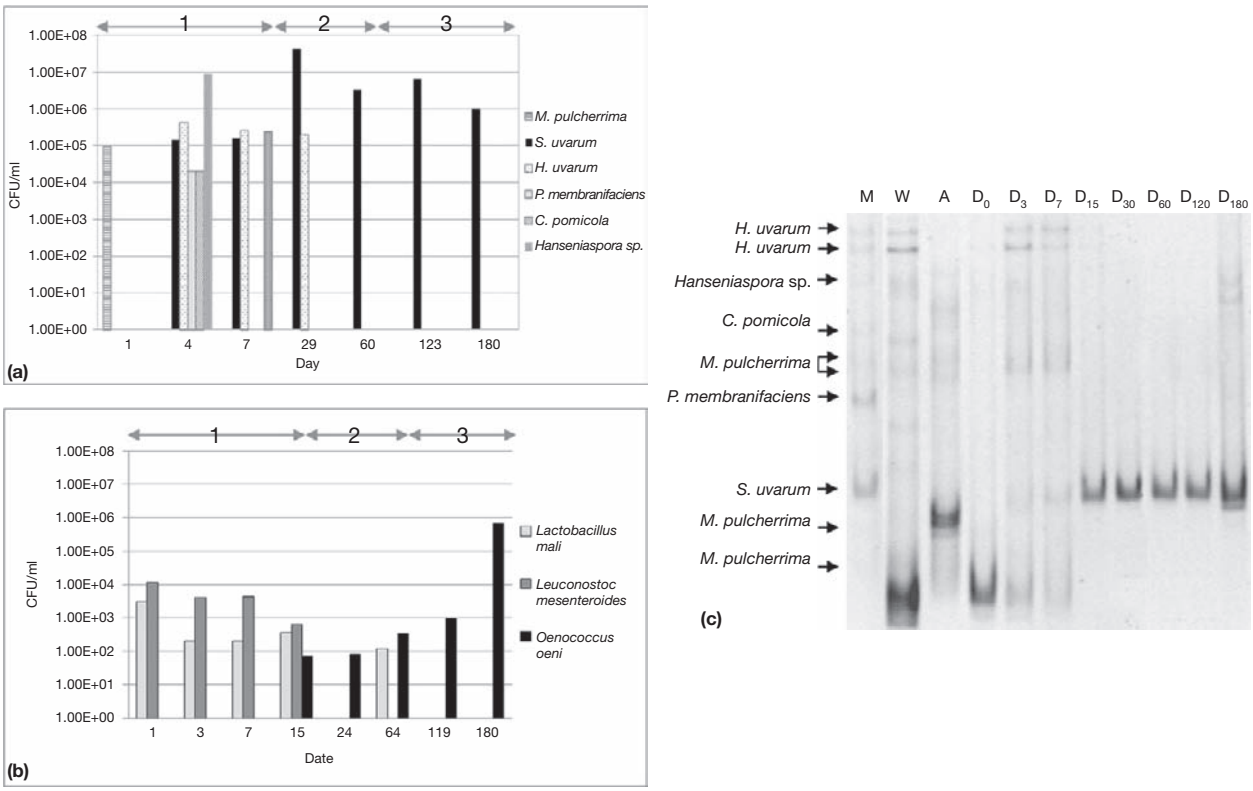

Figure 2 Examples of microbial dynamics during cidermaking observed using culture-dependent (PCR-RFLP for yeast (a) and ARDRA for LAB (b)) and culture–independent (using TGGE for yeast (c)) methods. All methods showed a decrease in biodiversity leading to the dominance of *S. uvarum* for yeast (responsible for alcoholic fermentation) and *O. oeni* for LAB (responsible for malolactic fermentation). 1, 2, 3 correspond to fermentation stages; W, water used to transport apples; and A, apples in silos.

Ciders are then blended based on the experience of the cidermaker. Noteworthy, although limited additions are allowed in most countries (see detailed legislations), in the UK, water is added to reach the desired alcoholic level. Other additives permitted include sweetening agents such as sugar, but also acids, coloring agents, and preservatives to obtain expected organoleptic qualities. Unlike in Germany and Spain, British and French ciders are expected to be effervescent. In industrial or artisanal ciders, carbonation is performed to saturate the liquid with *ca.* 5–6 g l^{-1} CO_2. Natural effervescence is obtained through a supplementary step, called *prise de mousse* in French, and is usually performed during the maturation phase. To do so, indigenous yeast fermentation, or inoculation of active dry yeasts in bottles or in tanks is

performed. The yeasts naturally ferment residual sugars to form CO_2. Temperature, yeast counts, and residual amino nitrogen will be the main factors affecting effervescence in the final product.

Finally, the product is bottled in glass or PET bottles or kegs using an isobarometric filling machine to preserve product effervescence. Pasteurization is possible according to product type and nature of the container (tunnel pasteurization after filling for glass bottles, flash pasteurization and chilling before bottling for PET bottles). Although the temperature and duration applied for microbiological stabilization are not necessarily high, due to pH and alcohol content, this step may still impact the organoleptic characteristics of the final products (typical cooked apples or caramel flavors). The product is then commercialized.

Cider Spoilage

Different types of spoilage can occur during cidermaking and can arise from either the presence of undesirable microorganisms or specific physicochemical parameters. A survey performed in 2004 among French cidermakers showed that microbial spoilage was of greater importance. In terms of frequency and economic impact, the main microbial spoilages are

- *Phenolic off-flavor*: This organoleptic defect is due to volatile phenols usually associated with 'animal,' 'leather,' 'phenolic,' or 'spicy' aromatic notes. This spoilage has been extensively studied in wine and to a lesser extent in cider. It has been shown that *Brettanomyces* spp. yeasts are responsible for the transformation of hydroxycinnamic acids into volatile phenols via vinyl phenol intermediates (these reactions are mediated by hydroxycinnamate decarboxylase, and vinylphenol reductase activities). However, in wine as in cider, hydroxycinnamic acid mainly exists in an esterified form (with tartaric acid in wine and quinic acid in cider) that *Brettanomyces* cannot metabolize. In wine, it was shown that commercial enzymatic preparations, containing a cinnamoyl esterase, were mainly responsible for hydroxycinnamic acid production. In cider, it was recently shown that *Lactobacillus collinoides* could metabolize the main hydroxycinnamic ester, chlorogenic acid (= caffeoylquinic acid), and produce the caffeic acid precursor. This precursur can be further metabolized into ethyl catechol by either *L. collinoides* or *B. anomala* species.
- *Cider-sickness*: This spoilage, known as 'framboisé' in France, is less frequent but can have a severe economic impact. It mainly concerns sweet ciders. It occurs in tanks or in bottles and is characterized by an excessive production of acetaldehyde (often above regulatory limits, see following). This leads to unpleasant flavors (rotten banana, vegetal aromas), haze formation, high pressure in bottles, and excessive foaming. This spoilage is associated with the development of the Gram-negative bacterium, *Zymomonas mobilis* (the subspecies *pomaceae* is associated with British cider-sickness, whereas the subspecies *francensis* is associated with French 'framboisé' ciders). It vigorously ferments sugars into multiple end products including excessive amounts of acetaldehyde and CO_2. Favorable factors are residual sugars, absence of SO_2 addition, pH >3.75, and high amino nitrogen. Acetaldehyde levels are regulated in France (<100–120 mg l^{-1}).
- *Acrolein spoilage*: This spoilage is mainly associated with ciders fermented to dryness and used for apple brandy production. Spoilage is associated with LAB able to degrade glycerol (including *L. collinoides*, although this trait may be strain-dependent). Glycerol is produced (*ca.* 5 g l^{-1}) by yeast during fermentation and provides roundness to the product. Glycerol is degraded via a glycerol dehydratase into 3-hydroxypropionaldehyde (3-HPA). This molecule is a precursor for acrolein and can be nonenzymatically formed via spontaneous dehydration in acidic conditions. It leads to pepper flavors and a strong bitter taste.
- *Lactic acid spoilage*: This is due to the natural metabolism of LAB, associated with their early development before alcoholic fermentation is complete (in the presence of fermentable sugars). It can be easily detected as malolactic transformation only leads to L-lactate while lactic acid spoilage is associated with both D- and L-lactate isomers. Acetic acid is also formed by heterofementative LAB. The economic impact of lactic acid spoilage is rather low.

The following microbial spoilages are less frequent:

- *Ropiness*: This spoilage is characterized by abnormal viscosity associated with the presence of exopolysaccharides (sugar polymers). The type of exopolysaccharides depends on the producing microorganism. Responsible microorganisms in cider have been associated to LAB (e.g., *Pediococcus damnosus*, *Lactobacillus sicerae*), or sporulating bacteria (*Bacillus licheniformis*).
- *Acetic acid spoilage*: This alteration is easily recognizable due to its characteristic acidic taste and vinegar flavor. It is associated with the development of acetic acid bacteria (e.g., *Acetobacter*, *Gluconobacter* spp.) that metabolize ethanol in the presence of oxygen. Acetic acid can then react with ethanol to form ethyl acetate, another off-flavor molecule. Therefore, maintaining the product in anaerobic conditions will prevent this spoilage.

Concerning, physicochemical spoilage ('casse' in French), they are observed when cider is in contact with air and thus, as stated earlier, can be controlled by using anaerobic conditions. In the presence of oxygen, polyphenol oxidation occurs conferring product instability and color change. This reaction is observed in the presence of metals (iron or copper) that contribute to polyphenol complexation. Oxidative spoilage is associated with the polyphenol oxidase enzyme, linked to overripened or moldy fruits. Finally, protein haze, characterized by deposits in bottles, is associated with protein–polyphenol combinations. Noteworthy, protein concentration being low in cider, it is rarely observed.

Cider Composition, Organoleptic Qualities and Health Impact

Composition

Cider composition (Table 3) first depends on apple juice composition and thus not only on the apple varieties but also culture conditions, fruit maturity, and physical (cracks and bruises) or

Table 3 Physicochemical parameters determined for 150 ciders representative of French cider production

(Source: IFPC)

biological (molds, worm holes) damage. Then, the process and microbial activity during fermentation impact the product. Apple juice is mainly constituted of water (80–90% w/v) but also contains various soluble compounds:

- *Sugars*: They are the principal component of the soluble matter, representing from 75% to 90% (80–170 g l^{-1}). They are encountered in various forms: mono-, oligo-, and polysaccharides (amylose, amylopectin, pectins). However, the main sugar is fructose. It is the only one present in the final fermentation phase, as other fermentable sugars (glucose and the disaccharide: sucrose) are rapidly metabolized into fructose during the first two-thirds of the fermentation. Noteworthy, glucose can still be found in semisweet or sweet ciders. At the end of fermentation, all or part of these sugars are transformed into ethanol (generally 2–8% but up to 12% ABV – alcohol by volume). In ciders, residual sugar concentrations are generally situated between 8 and 67 g l^{-1}. Moreover, sorbitol, a nonfermentable sugar alcohol, ranges from 3 to 14 g l in cider.
- *Acids*: The main acid, as noted earlier, is malic acid. It can occur at concentrations between 1 and 10 g l^{-1}, according to apple variety (*ca.* 85% of total acidity). Citric, acetic, quinic, and citromalic acids can also be detected. Galacturonic acid can be detected when enzymatic preparations have been used due to pectin degradation. In ciders, lactic acid is detected if malolactic transformation has occurred.
- *Polyphenols*: Cider phenolic compounds are (1) flavan-3-ols (composed of the monomers (+)-catechin et (−)-epicatechin and their corresponding polymer: procyanidin; 2–5 g kg^{-1}), (2) hydroxycinnamic acids (caffeic, *p*-coumaric and ferulic acids), and their esters (chlorogenic acid or 5- caffeoylquinic acid being the most represented; 0.3–2.5 g kg^{-1}), (3) dihydrochalcones (phloridzin, phloretin et phloretin-2′-O-xyloglucoside; 0.02–0.10 g kg^{-1}) as well as (4) flavonols (e.g., quercitrin, hyperin, or avicularin) and anthocyanins in smaller quantities.
- *Nitrogenous compounds*: They are only present in small quantities, although their content may vary considerably according to the considered cultivar (40–150 mg l^{-1}). Yeast-assimilable nitrogen substances are of interest as they will condition fermentation speed and achievement (as noted earlier, keeving can be used to control amino nitrogen content in apple juice). They mainly correspond to amino acids, in particular asparagine but also aspartic acid (*ca.* 50% and 5% of total nitrogen, respectively).
- *Vitamins*: Vitamin C is the main vitamin found in apple juice, but is generally lost during the process. Vitamin C may be added in some productions.
- *Minerals*: Iron, potassium, as well as calcium and sodium, are present in both apple juice and cider.
- *Volatile compounds*: These molecules are either varietal (originating from the fruit) or fermentative (originating from microbial metabolism). They belong to various chemical families: alcohols, esters, ketones, aldehydes, phenols, sulfur compounds, and organic acids.

Organoleptic Qualities

Concerning cider taste, the three main components that interact to give the overall perception in the mouth are sugars, acids, and polyphenols. Sugars contribute to sweetness and roundness perception. In this context, fructose, and to a lesser extent sorbitol, largely contributes to the sugary flavor of the final product. Acids contribute to cider flavor and directly influence sweetness perception. A positive acidity perception is associated with product freshness. Finally, polyphenols contribute to several product traits: bitterness, astringency, and color. Concerning aroma, many volatile molecules contribute, according to their sensory perception threshold, to cider aroma. Although some cider aromas are already present in apple juice (apple cultivar aromas such as hexanol, ethyl 2-hydroxycaproate, ethyl lactate, or diacetyl), a large majority are produced during fermentation. The molecules correspond to alcohols like propanol, isobutanol, isopentanol, benzylic alcohols, and 2-phenylethanol (known for its rose aroma). Yeasts also produce esters during the alcoholic fermentation (e.g., ethyl 3-methylbutyrate, 2-phenylethyl

acetate, ethyl hexanoate, ethyl octanoate, ethyl decanoate among many others). Terpene derivatives, sulfur-containing compounds, and lactones can also be detected.

All these compounds contribute to the aromatic complexity of the final product and rely on a subtle balance between them (Table 4). As stated earlier, this balance can be affected by several metabolites (e.g., volatile phenol, acetaldehyde, lactic acid, acetic acid) originating from spoilage microorganisms. Moreover, this can also be affected by aroma compounds present at much higher levels than their sensory perception threshold. Noteworthy, the amount of effervescence, bubble size, and persistence will also affect overall product perception.

Health Impact

Like any other food product, a 'benefits and risks' approach should be considered. The first aspect to consider is the nutritional value of the product. As stated earlier, there is not one cider but many ciders; thus a range of nutritional values can be observed according to the considered cider. Examples of values for French dry and sweet ciders are as follows: water 92.70 and 94.1, carbohydrates 2.35 and 3.21, fibers 0.5 in both types, alcohol 3.2 and 1.9 g/100 g, respectively. No fat, starch, or proteins are found.

Potential Benefits

- *Microbial safety*: Due to its intrinsic characteristics (low pH, presence of alcohol and polyphenols – exhibiting bacteriostatic effects – and anaerobic conditions) and, in some cases, the cidermaking process (pasteurization), cider does not contain pathogenic bacteria or permit their growth. Reported cases of *Shiga toxin-producing E. coli* (serotype O157:H7) have been reported in the literature, but are actually associated with the nonfermented and unpasteurized North American nonalcoholic product called cider (by opposition to hard cider).
- *Antioxidant effect*: Cider (like apples and apple juice) is rich in polyphenols that exhibit antioxidant properties. These dietary molecules have been recognized as having health benefits by inactivating free radicals (O_2^- and other reactive oxygen species) naturally produced in the body. In this context, like other polyphenol-rich food and beverages, cider and related apple products may contribute to

lowering risks of some chronic medical problems (particularly cardiovascular diseases and cancers).

- *Minerals*: Apple cider is a good source of potassium and iron. It is also low in sodium, making it compatible with a sodium-restricted diet.
- *Low calorie content*: Ciders possess low calorie contents, compared to other alcoholic beverages (especially wine). For example, in France, whereas 79 kcal/100 g were determined for average wine, the following calorie contents have been determined for average cider, dry cider, and sweet cider: 30.2, 32.8, and 27.1 kcal/100 g, respectively. Dry ciders have more calories than sweet ciders due to the fact that, for a same quantity, ethanol represents more calories than sugar (7 vs. 4 kcal g^{-1} for ethanol and sugar, respectively).
- *Gluten-free*: Cider is a gluten-free fermented beverage and thus can be an alternative to beer for gluten-intolerant people. This is especially used as a marketing argument in North America, where a higher percentage of the population is concerned with celiac disease.

Potential Negative Aspects

- *Alcohol*: Although ciders possesses low alcohol contents (generally ranging from 2% to 8%) and observational studies suggest that moderate alcohol consumption is linked with lower risks of coronary heart disease, cider should be consumed in moderation like any other alcoholic beverage. This is especially true for white ciders (7.5 ABV), an almost colorless product made either by processing dessert apples and pomace or by using apple concentrates with glucose or corn syrup addition for alcohol production. This product, although often containing little apple juice, falls under the UK regulation cider definition (Customs Notice 162).
- *Sugar*: According to the amount of residual sugars or sugar added, cider may contain little to high amounts of simple sugars (up to more than 8 g per 100 ml). Therefore, this should be taken into consideration in a balanced diet.
- *SO_2*: As stated earlier, sulfites are added during the production process to control microbial growth. However, SO_2 can also be considered as an allergen to some individuals. In Europe, labeling is compulsory if concentrations of more than 10 mg kg^{-1} or 10 mg l^{-1} (expressed as SO_2) of sulfur dioxide and sulfites are present (Directive 2003/89/EC).
- *Patulin*: This mycotoxin is a secondary metabolite produced by a number of fungal species (*Aspergillus*, *Byssochlamys*, and *Penicillium*) with *Penicillium expansum* being the most frequent. Although patulin can be found in apples and apple juice, studies suggest that it is metabolized by *Saccharomyces* spp. during alcoholic fermentation to form (*E*)- and (*Z*)-ascladiol, apparently less toxic compounds. Although ciders are less at risk, similar to fruit juices, concentrated fruit juices and other fermented drinks from apples or containing apple juice, patulin content is regulated to maximum levels of 50 μg kg^{-1} at the EU level (Commission regulation (EC) N°1881/2006).
- *Biogenic amines*: These molecules result from the metabolism of living organisms (LAB in cider), mainly through the decarboxylation of the corresponding precursor amino acid. Histamine, tyramine, as well as putrescine and cadaverine, can be encountered. They are undesirable due to their physiological activity, especially in sensitive consumers (with natural or drug-related mono-amine oxidase deficiencies). No legislation exists limiting the presence of these metabolites in cider.

Cirrhosis

S Honigbaum, J Lucas, and KB Schwarz, Johns Hopkins University School of Medicine, Baltimore, MD, USA

© 2016 Elsevier Ltd. All rights reserved.

Malnutrition is a prevalent clinical complication of end-stage liver disease (ESLD) among pediatric and adult populations. The spectrum of malnutrition seems to worsen in relation to the progression of liver dysfunction, further increasing the risk of mortality especially in the case of the patient awaiting transplantation. Optimizing the nutritional status of patients with ESLD is therefore a key component of care.

Underlying Pathways Resulting in Malnutrition

Malnutrition is generally recognized in the setting of nutritional losses, increased nutritional requirements, inadequate ingestion, and/or metabolic disturbances. In patients with ESLD, it is possible that each of these aspects may contribute to malnutrition.

Nutritional Losses and Metabolic Disturbances

Lipids

With regard to malabsorption, hepatic dysfunction with cholestasis results in decreased circulation of bile salts causing nutritional losses of dietary lipids via steatorrhea. Deficiency of the essential fatty acids (EFAs) can result. Since lipids provide a substantial amount of kilocalories (9 Cal g^{-1} of fat), steatorrhea also leads to losses in overall energy intake and poor growth. In an effort to promote increased total fat intake and calorie absorption, medium-chain triglyceride (MCT)-based products are often utilized because of their ability to be absorbed without micelle formation. However, this practice should be weighed carefully for risk–benefit, as this can contribute to a greater degree of displacement of long-chain triglycerides and EFAs (a very high ratio of MCT to total lipid >80% is particularly risky). It is also of note that elongation and desaturation of EFAs are decreased in cirrhosis. The liver of a cirrhotic patient is more likely to depend on fuel from fat stores versus carbohydrates.

Fat-Soluble Vitamins

Steatorrhea often results in deficiencies of fat-soluble vitamins (vitamins A, D, E, and K) in ESLD.

Vitamin A

Vitamin A (retinol) deficiency can lead to poor immune function, growth failure, anorexia, epithelial keratinization, and night blindness. Nearly all of retinol absorption is facilitated by emulsification by bile acids and micelle formation. Vitamin A is available to the tissues primarily via transport by the retinol-binding protein (RBP). When the synthetic function of the liver is affected, the production of RBPs is decreased. However, assessment of true vitamin A status is difficult, since serum retinol levels are not in accordance with actual hepatic stores. Therefore, the use of the retinol/RBP molar ratio can be used to help detect vitamin A deficiency (deficiency defined as a molar ratio <0.8).

Vitamin D

Vitamin D deficiency can lead to rickets and osteomalacia. Micelle emulsification is necessary for vitamin D absorption. It has been estimated that 25–33% of children and adult patients with chronic liver disease will have vitamin D deficiency.

Vitamin E

Vitamin E deficiency can result in peripheral neuropathy, myopathy, and hemolytic anemia. Lipoproteins are required for vitamin E transport. Therefore, in disease states such as cholestasis where lipoprotein production may be altered, it is recommended that vitamin E status is assessed by the ratio of serum vitamin E to total serum lipids (deficiency defined as the ratio <0.6). It has been noted that vitamin E may be more malabsorbed than vitamin D.

Vitamin K

Deficiency of vitamin K can cause bleeding, bruising, and hemorrhage by way of impairing the synthesis of clotting factors, which can be compounded by hepatic failure also. Prothrombin time (PT) is generally used as an indicator of vitamin K status; however, more sensitive measures of vitamin K status (protein induced by vitamin K absence-II (PIVKA-II)) are increasingly available.

Carbohydrates

Cirrhotic patients are also more vulnerable to hypoglycemia, in the setting of decreased hepatic glycogen stores and gluconeogenesis. In this case, ESLD patients, especially infants and young children, are at high risk for catabolism in the fasting state. Insulin resistance also complicates glucose utilization in patients with ESLD.

Protein

The production of several key proteins (including albumins, retinol-binding proteins, protease inhibitors, coagulation factors, iron-binding proteins, and insulin-like growth factors) is decreased when the synthetic function of the liver is impacted by disease. Protein degradation and amino acid oxidation and proteolysis are all increased. Patients with chronic liver disease have altered concentrations of amino acids (AAs), namely, increased concentrations of aromatic AAs and decreased concentrations of branched-chain AAs. Moreover, hyperammonemia may result from decreased function of the enzymes involved in the urea cycle. There is also protein malabsorption due to enteropathy in portal hypertension.

Water-Soluble Vitamins

Pediatric patients may be susceptible to water-soluble vitamin deficiency due to malabsorption and inadequate ingestion. Adult patients, particularly those with alcoholic liver disease, have been found to be deficient in thiamine, folate, vitamin B12, and niacin. Folate and vitamin B12 deficiencies can result in macrocytic anemia, while deficiency of vitamins B6 and B12 and thiamine can cause neuropathy. Thiamine deficiency has been highly associated with alcoholic liver disease, which can ultimately lead to Wernicke's encephalopathy.

Minerals

Iron losses may result from gastrointestinal bleeding, and iron stores may be affected in repeated episodes of bleeding. Zinc and magnesium losses may affect those patients who are prescribed diuretics. Zinc deficiency may also result due to poor intake and decreased absorption. Zinc deficiency may result in altered taste perception and anorexia, which may further contribute to poor intake. Insufficient calcium levels can be found due to steatorrhea and 'hungry bone' phenomenon in vitamin D deficiency. On the other end of the spectrum, copper and manganese may accumulate in the liver to the point of hepatotoxicity, and those patients who may be susceptible should be monitored.

Inadequate Ingestion

Inadequate intake can be a significant causative factor of malnutrition in ESLD. Taste changes, lack of appetite, early satiety, and nausea and vomiting are all possible variables leading to poor intake. Poor appetite and early satiety may be related to increased leptin, tumor necrosis factor, and tryptophan. Poor oral intake may be found in patients who are receiving a salt-restricted diet due to the perceived unpleasant taste or unpalatable nature of the diet. Delayed gastric emptying in the setting of hepatomegaly and ascites can contribute to nausea and discomfort with eating.

Increased Nutritional Requirements

Energy

Hypermetabolism and increased energy requirements are characteristic of adult patients with cirrhosis. Historically, predictive equations have been used to estimate caloric requirements, despite their inaccuracies. A few studies have validated the use of indirect calorimetry to determine the resting energy expenditure (REE) in cirrhotic adult patients. Indirect calorimetry is the gold standard but is not available in all centers. Among the few studies in pediatric patients who underwent measurement of REE, the results generally showed hypermetabolism (upward of 125–140% of estimated needs). When indirect calorimetry is not available, periodic serial assessment of anthropometrics (especially arm circumference and triceps skinfold) can serve as a guide for nutritional provision.

Protein

Patients with ESLD have increased protein needs. For pediatric patients, a minimum of protein intakes of 2 g kg^{-1} day^{-1} has been suggested. However, some studies have shown that intakes of 2 g kg^{-1} day^{-1} do not support appropriate growth. Ranges of 2–4 g kg^{-1} day^{-1} are therefore suggested. Age-based guidelines for children with severe liver disease have not been established. However, it might be reasonable to say that such children might require at least twice the US Dietary Reference Intakes for age. Expressed as g protein/kg/day, these values for healthy children are as follows: 0.5–1 years 1.0 g, 1–3 years 0.87 g, and 4–8 years 0.76 g; males 9–13 years 0.76 g and 14–18 years 0.73 g; and females 9–13 years 0.76 g and 14–18 years 0.71 g. Protein restriction is not recommended in adult or pediatric patients unless they evidence hepatic encephalopathy. Pediatric patients with cholestasis may require more branched-chain amino acids (BCAAs). However, children receiving ready-made commercial formulas, particularly those that contain hydrolyzed protein, generally meet their BCAA requirements. In adults, the ASPEN guidelines recommend the use of standard formulas in critically ill adults with liver disease, with provision of BCAA formulas only in refractory encephalopathy. A 2003 Cochrane review evaluated 11 randomized trials and did not find a benefit to the use of BCAAs in patients with encephalopathy.

Nutritional Assessment in End-Stage Liver Disease

Nutritional assessment in liver disease is challenging yet is the integral basis of nutritional intervention and management. Nutrition assessment should be performed at the initial meeting and routinely for monitoring. Nutrition assessment can be composed of four constituents – anthropometric, biochemical, clinical, and dietary components.

Anthropometry

Anthropometry is a very challenging component of the nutrition assessment in liver disease. Many of the traditional measures of nutritional status, primarily weight, can be affected by fluid status, hepatomegaly, and ascites and therefore may not be a valid indicator of nutritional status. Monitoring of abdominal circumference may be helpful. Length or height may be a better indicator of nutritional status, especially when measured in serial occurrences over a period of time. Growth should be plotted and tracked on the appropriate growth charts (World Health Organization for ages 0–24 months and Centers For Disease Control and Prevention for ages 2–20 years). It can also be helpful to assess weight gain velocity and linear growth velocity (i.e., gains in grams per day or centimeters per month), and these data can be compared with standard reference ranges. Weight-for-length and body mass index (BMI) are also important markers. Monitoring the weight-for-length or BMI is crucial for identifying the underweight and trends in weight changes. Since weight and linear growth can be affected in liver disease, the use of arm anthropometry should ideally be a component of every nutrition assessment. Mid-arm circumference (MAC) and triceps skinfold (TSF) thickness are quick, noninvasive measures of lean body mass and fat reserves, respectively.

Biochemical (See Section on Monitoring)

Clinical

Clinical findings play a large role in the dynamic process of nutrition assessment and monitoring and, in fact, may represent the most important component. Clinical findings such as edema, ascites, hepatomegaly, jaundice, vital signs, and gastrointestinal symptoms can shed light on the nutritional status of patients with ESLD. The skin, hair, and nails of patients should be reviewed or examined. Assessment of muscle wasting, fat reserves, bone fractures, bowed legs, and acanthosis should be considered as well.

Dietary

Lastly, an estimation of dietary and intake history should be performed including administration, route, frequency, use of alternative medicine and/or supplements, behavior, knowledge and beliefs, food security and availability, and physical activity. Information regarding food allergies and tolerance should also be obtained. Careful attention should be paid to assessing formula and enteral and parenteral nutrition intake. Nutritional needs may vary according to the type and severity of liver disease.

Hepatocellular Disorders

Alcoholic Cirrhosis

Excessive alcohol consumption causes a spectrum of liver disease ranging from fatty hepatic infiltration to cirrhosis. Though there is a clear association between alcohol intake and liver disease, only a small proportion of people progress to cirrhosis. It is generally accepted that the risk of the development of cirrhosis increases proportionally with the amount of alcohol ingested. Typically, cirrhosis occurs in patients who ingest more than 30 g of alcohol per day for more than 10 years (standard drinks estimated at 14 g per drink). The highest risk for the development of cirrhosis is associated with ingesting more than 120 g day^{-1} (8.5 standard drinks per day).

Alcoholic cirrhosis poses several nutritional challenges because of its multifactorial nature. Factors that contribute to malnutrition in this group of patients include anorexia, decreased energy intake because of substitution of calories from food for those in alcohol, poor nutrient digestion and absorption, hypermetabolism, and decreased protein synthesis and secretion. In addition, ascites can be present and lead to premature satiety. Also, pancreatic insufficiency may coexist and further lead to malabsorption.

In addition to the typical deficiencies seen in patients with cirrhosis (i.e., fat-soluble vitamin deficiencies and protein–energy malnutrition), individuals with alcoholic cirrhosis are also predisposed to water-soluble vitamin deficiencies. The vitamins and minerals most typically found to be suboptimal in this population include vitamin A, vitamin D, thiamine, folate, pyridoxine, and zinc. Thiamine deficiency (i.e., beriberi and Wernicke–Korsakoff syndrome) may occur in alcoholic cirrhosis due to decreased intake, decreased absorption, and reduced thiamine storage. Thiamine deficiency is so common in adults with chronic alcohol intake that it is generally recommended that these patients receive daily supplementation with thiamine as a preventive measure. In addition, it is important to administer thiamine prior to glucose infusions to prevent Wernicke's encephalopathy (confusion, ataxia, and coma) in these patients. Alcohol consumption can also commonly cause pyridoxine (vitamin B6) deficiency with clinical manifestations of stomatitis, peripheral neuropathy, and confusion. These patients also commonly have folate deficiency, resulting in macrocytic anemia (although liver disease itself can cause macrocytosis). In general, nutritional therapy involves cessation of drinking and providing adequate nutrition of proteins, carbohydrates, and lipids.

Viral Hepatitis

Hepatitis B and hepatitis C can progress to chronic liver disease and ultimately to cirrhosis, though the prevalence of cirrhosis in these two populations is highly variable. Neonates who have acquired hepatitis B infection perinatally have a much higher chance of developing chronic hepatitis than those who acquire it later in life. Hepatitis C, however, has a higher rate of developing into chronic liver disease in adults with approximately 80% of infected individuals developing chronic infection and up to 50% of those individuals developing cirrhosis within 10–20 years. The nutritional recommendations for this patient population are similar to the recommendations for other etiologies of cirrhosis.

Autoimmune liver disease

The two main categories of autoimmune liver disease are autoimmune hepatitis (AIH) and primary biliary cirrhosis (PBC). PBC will be further discussed in the hepatobiliary section. Though not all patients with AIH will progress to cirrhosis, the progression may occur. The management of AIH typically involves immunosuppressive medications including azathioprine and prednisone. Since prednisone is often needed for a prolonged period of time, nutritional needs may be required to combat the multiple negative side effects of steroids including glucose intolerance, body composition changes, growth velocity disturbances, and osteoporosis, among others.

Metabolic Disorders

Wilson's Disease

Wilson's disease is an autosomal recessive inherited disease involving improper copper excretion resulting in the accumulation of copper in many organs including the brain, kidneys, liver, and eyes (Kayser–Fleischer rings). In general, nutritional recommendations for this disease involve avoidance of excessive copper in the diet such as found in liver, mushrooms, shellfish, nuts, beans, and chocolate. In addition, providers often use zinc supplementation to help prevent copper absorption from the gastrointestinal tract and chelating agents such as penicillamine and triethylenetetramine (trientine). For cases of severe liver disease, transplantation is sometimes needed despite dietary restrictions and pharmacological interventions.

Hemochromatosis

This is an autosomal recessive disorder that results in increased iron absorption from the gut. Excess iron is deposited in many

organs including the liver and patients typically present in adulthood with lethargy, abnormal liver function tests, hyperpigmented skin, and diabetes. Chronic alcohol use or concomitant viral hepatitis can again exacerbate the progression of liver disease. The treatment for this disease is primarily periodic phlebotomy. In general, patients should avoid supplements containing iron, but diets are generally not restricted from food high in iron, such as red meat, especially in the patients undergoing therapeutic phlebotomy.

Nonalcoholic Fatty Liver Disease (NAFLD)

NAFLD is defined as hepatic fat accumulation without any other known causes for secondary fat accumulation (i.e., excessive alcohol consumption). It describes a range of liver diseases from isolated hepatic steatosis (fatty deposits in the liver without inflammation), to nonalcoholic steatohepatitis (NASH) (which includes steatosis and inflammation), to hepatic fibrosis or cirrhosis and ESLD. The most common risk factors for the development of NAFLD are central obesity, type 2 diabetes mellitus, dyslipidemia, and metabolic syndrome. There is an increasing prevalence of NAFLD over the last few years with it now being considered the most common form of chronic liver disease in the Western world. Nutritional therapy is geared toward weight loss through dietary and lifestyle changes with a reasonable goal of losing 1–2 lbs per week.

Hepatobiliary Disorders (Including Neonatal Cholestasis Disorders)

Neonatal Cholestasis

There are many causes of neonatal cholestasis with the most common being extrahepatic biliary atresia, idiopathic neonatal hepatitis, alpha-1-antitrypsin deficiency, total parenteral nutrition (TPN)-associated liver disease, cystic fibrosis, intrahepatic cholestasis syndromes (i.e., Alagille syndrome), infection, metabolic/genetic disorders (i.e., bile acid synthetic defects and galactosemia), and endocrine disorders (i.e., hypothyroidism). For all of these disorders involving varying degrees of cholestasis, there is an underlying theme involving malabsorption of fat-soluble vitamins and steatorrhea. Typically, nutritional management involves supplementation of vitamins A, D, E, and K. Elemental formulas are preferred because they are rich in MCT and more easily digested. MCTs should account for 50% of the fat intake, and providers should be aware that diets with excessive proportion of total fats from MCTs (>80%) may result in fatty acid deficiency. Overall, these patients often require energy needs estimated at 130–150% of predicted needs for age. Risk factors for poor growth in this population include patients with ESLD, patients awaiting liver transplant, and patients with complications such as bleeding varices and ascites.

Biliary Atresia

Biliary atresia is a pediatric disease of unknown etiology that results in the obliteration of the extrahepatic biliary system. It causes neonatal cholestasis and ultimately progresses to hepatic fibrosis and to liver failure if untreated. It remains the number one cause of pediatric liver transplantation at this time despite surgical intervention attempts with the Kasai hepatoportoenterostomy to restore the drainage of bile. As with many other causes of cholestasis and cirrhosis, severe steatorrhea and malnutrition are common. Extra attention to nutritional status should be paid to children with biliary atresia. Studies have shown that poor nutritional status pretransplant is linked to prolonged hospital stay, increased risk of mortality, and increased cost of medical care. Efforts should be made immediately after the Kasai procedure to improve the nutritional status of this patient population, and clinicians should provide supplemental nutrition via a nasogastric tube if needed and even consider parenteral nutrition if enteral nutrition is inadequate or poorly tolerated.

Primary Biliary Cirrhosis

Primary biliary cirrhosis (PBC) is an autoimmune process that destroys the intralobular bile ducts, eventually progressing to hepatic cirrhosis and ultimately to liver failure. As with other patients with cholestasis, patients with PBC have decreased synthesis of bile acids leading to steatorrhea and decreased absorption of fatty acids. The treatment of PBC is ursodiol, and nutritional efforts should be made to monitor for fat-soluble vitamin deficiencies, osteopenia/osteoporosis, and overall malnutrition. Because PBC often occurs in postmenopausal women, the incidence of osteoporosis is very high in this population.

TPN-Associated Liver Disease

TPN-associated liver disease results from chronic intravenous nutrition, typically in the setting of prolonged enteral fasting. This condition is most frequently observed in pediatric patients with short bowel syndrome who are dependent on intravenous nutrition for extensive periods of time. The cause is multifactorial with a large contributor being enteral starvation. When patients with TPN-associated liver disease have cholestasis, they are at risk for the fat-soluble vitamin deficiencies as mentioned previously. When dependent on intravenous nutrition, providers must be careful to monitor for deficiencies in vitamin E and selenium. Conversely, copper, manganese, and aluminum can accumulate to toxic levels. The treatment of this disease is aimed largely on prevention. Many providers limit the amino acid and lipid components when clinically possible. In addition, though dextrose itself does not promote liver injury, excess dextrose can lead to excess fatty acid synthesis that causes hepatic steatosis.

Nutritional Therapies

In this section, the various types of nutritional support that can be given to a patient with cirrhosis will be reviewed in relationship to outcome. The recent Cochrane review of nutritional support listed in the reference section contains a very detailed summary of randomized clinical trials addressing these questions. The types of support include oral supplements, enteral nutrition, and parenteral nutrition. Outcome has been assessed as nutritional (weight gain, anthropometric measures, serum chemistries such as albumin and bilirubin, and nitrogen

balance), clinical (effects on ascites, gastrointestinal bleeding, and hepatic encephalopathy and rates of infection and postoperative complications), economic (length of stay in the intensive care unit and hospital and readmission rates), and global (mortality). Various means of monitoring will be discussed as will drug–nutrient interactions.

Types of Support

Oral Nutrition

Frequent feeding can ameliorate the preferential early utilization of fat and protein that occurs in patients with cirrhosis. Late evening meals can positively affect nitrogen balance compared with an equicaloric diet without a late evening meal.

Oral Supplements

A multitude of trials have been performed in adults with compensated cirrhosis, malnourished cirrhosis, cirrhosis, and encephalopathy. None of these trials showed an effect on mortality except for one that actually showed increased fatal outcome in the supplemented group. Likewise, there was no difference in the development of encephalopathy, although one randomized controlled trial did show resolution of hepatic encephalopathy in patients receiving supplements with branched-chain amino acids. None showed resolution of ascites although several showed decreased development of ascites. No effect on serum albumin was seen. Several trials examined the effects of oral supplements on gastrointestinal bleeding, and no beneficial effects were observed. Effects of oral supplements on health-related quality of life have been investigated. In general, no benefits were noted with the exception of the effects of branched-chain amino acid-rich supplements on some measures related to hepatic encephalopathy. Likewise, in malnourished patients with cirrhosis undergoing liver transplantation, the use of oral nutritional supplements was not associated with effects on serum bilirubin, ascites, hepatic encephalopathy, postoperative complications, length of stay in the hospital or intensive care unit, mortality rates, or even anthropometrics such as triceps skinfold or mid-arm muscle circumference.

In summary, the administration of oral nutritional supplements to patients with cirrhosis has been associated with few benefits except for decreased development of ascites and improvement of chronic hepatic encephalopathy.

Enteral Nutrition

Most trials failed to show a benefit although one was associated with improved nitrogen balance in medical patients and another showed reduced postoperative complications in surgical patients.

Parenteral Nutrition (PN)

Although most studies of PN have failed to show any specific effect in cirrhotic patients, one showed a reduction in serum bilirubin and improved nitrogen balance. Another showed a reduced incidence of postoperative ascites and yet another showed that PN was associated with a reduction of postoperative infections. However, in general, recipients of PN have better survival versus comparable controls not receiving PN.

Special Nutritional Recommendations

Poor growth secondary to fat malabsorption in cholestasis can be reversed by oral medium-chain triglycerides (but long-chain triglycerides must be administered to avoid essential fatty acid deficiency). Dietary sodium restriction and potassium supplementation should be used to help manage ascites. To prevent muscle wasting and negative nitrogen balance, 1 g kg^{-1} day^{-1} of protein is indicated for adults; 2 g kg^{-1} day^{-1} of protein is recommended for infants and young children. Normalization of zinc status should be done for patients with hepatic encephalopathy (HE). Protein restriction is rarely necessary short term and should never be done in the medium term or long term. Branched-chain amino acid supplements are controversial for acute HE; they do help with chronic HE.

Cholestatic patients require supplementation of fat-soluble vitamins. Supplementation of water-miscible versions of vitamin A is often utilized in clinical practice, but careful monitoring is of paramount importance as toxicity can lead to further hepatic damage. The recommended oral supplements of vitamin A range from 5000 to 25 000 IU day^{-1}. However, shortages of water-miscible vitamin A supplements may limit administration. Vitamin D should be supplemented as vitamin D3 (cholecalciferol). If the serum 25-OH vitamin D is low, amounts of cholecalciferol three to ten times the DRI might be necessary. Vitamin E should be supplemented with the water-miscible form containing D-α-tocopheryl polyethylene glycol succinate, also known as TPGS. Usually, 25 IU kg^{-1} day^{-1} will suffice. Oral supplements of vitamin K 2.5–5 mg two to seven times per week should be given. It has been suggested that all fat-soluble vitamin supplementation be given with TPGS to enhance absorption.

Monitoring

Monitoring the administration of nutrition to a cirrhotic patient includes the assessment of weight, length in a growing child, and anthropometrics, which may be the most reliable noninvasive way to assess nutritional status. Serum metabolites include electrolytes, blood urea nitrogen, creatinine, acid–base status, calcium, magnesium and phosphorus, triglycerides, liver enzymes, complete blood count/differential, platelets, prothrombin time and partial thromboplastin time, iron indexes, trace elements especially zinc and selenium, carnitine, and folate/vitamin B12. Cholestatic cirrhotic patients should be monitored for deficiencies of vitamins A, D, and E. The use of triene/tetraene ratio can be used to assess EFA deficiency, while a lipid panel can be used to assess metabolic syndrome or lipogenic changes. Although albumin and prealbumin should be assessed as indexes of protein malnutrition, the interpretation of values below normal may be difficult as both of these are affected by protein nutrition and hepatic synthesis. Similarly, prolonged prothrombin time may reflect malabsorption of vitamin K, poor hepatic synthesis, or both. Although ammonia is classically measured to monitor the risk of hepatic encephalopathy and as an indication for pharmacological management,

this analyte is notoriously subject to artifact. The ratio of plasma BCAA/aromatic amino acids may be more useful to assess HE.

If nutrients are administered enterally, then gastrointestinal tube placement and nose care should be monitored as needed to assess the correct position of tube placement. If nutrients are administered via an ostomy, then careful site care of the gastrostomy/jejunostomy should be done. If parenteral nutrition is administered via a peripheral or indwelling central venous catheter, then the line site should be assessed frequently for signs of infection.

Given all the limitations of monitoring the nutritional status of cirrhotic patients, it is useful to understand that the subjective global assessment of nutritional status, which has been modified for the cirrhotic patient, is perhaps the most useful means of assessing the nutritional status of patients with this condition. It is simple, reproducible, and validated and includes the history of nutrient intake, physical examination, and anthropometrics that can be easily performed.

Drug–Nutrient Interactions

Some of these interactions of particular importance in a cirrhotic patient are the effects on reduced elimination of potassium by cyclosporine and spironolactone. Cirrhotic patients are generally total body salt-overloaded, so it is particularly important to be aware of how much sodium is being delivered in intravenous lines to support the patient such as saline in arterial lines and/or peripheral intravenous lines for antibiotic delivery. Many parenteral medications are available as sodium salts, further adding to the salt burden of the cirrhotic patient. Antacids and sucralfate can bind phosphorus in the gut and lead to hypophosphatemia. Thiazide diuretics may also lead to phosphaturia and increased excretion of potassium. Hyperglycemia may result from cyclosporin A, tacrolimus, and/or corticosteroids; however, given that marked insulin resistance is characteristic of cirrhosis, the precise cause of hyperglycemia in a cirrhotic patient receiving one or more of these drugs may be difficult to determine. The hepatic metabolism of 25-hydroxyvitamin D is lowered by the anticonvulsants diphenylhydantoin and phenobarbital.

A number of drugs commonly used in cirrhotic patients are incompatible with parenteral nutrition solutions, including amphotericin B, acyclovir, sodium bicarbonate, and ciprofloxacin. Drugs used to treat HE such as lactulose and neomycin may result in nutrient malabsorption.

Overall Recommendations

1. Nutritional assessment by anthropometrics should be done to assess the basis for nutrient recommendations.
2. Given that there is little solid support for specific nutritional interventions in cirrhotic patients, it is reasonable to provide nutrients to meet basic requirements in the most cost-effective manner possible that is easiest for the patient and provides the best quality of life. Thus, the logical order of provision of nutrients is oral nutrition with frequent small meals including a bedtime meal and oral nutritional supplements as necessary to maintain normal vitamin status and manage chronic HE. If this approach does not work, then provision of all or at least partial nutritional requirements via enteral feeding is recommended with PN reserved for those who are unable to meet their nutritional needs via the oral or enteral route. PN should ideally be administered cyclically as opposed to constant infusion and for as short a period of time possible, to avoid metabolic and infectious complications.
3. Monitoring should be done for all cirrhotic patients to assess the safety of nutritional interventions (weekly or more frequently for those receiving parenteral nutrition) and the effect of nutrients on nutritional status (monthly or every other month) for anthropometrics. For selected cirrhotic patients, additional studies could be undertaken to investigate hepatic osteodystrophy (DEXA scan), retinopathy (evoked response electroretinography to assess the functional consequences of vitamin A and E deficiencies), and HE (ammonia and branched chain/aromatic amino acids in plasma and proton magnetic resonance spectroscopy for brain glutamine).

Citrus Fruits

Citrus fruit is one of the major horticultural crops grown worldwide, and they are the most traded horticultural commodity in the world. The exact place of origin of citrus fruits is still under debate, but it is believed that it originated from Southeast Asia and spread to the other parts of the world. Citrus crop is grown in developed and developing countries as well. Citrus fruits constitute a crucial source of vitamin C. Brazil, the Mediterranean countries, China, and the United States account for about two-thirds of the total citrus production. In the last 30 years, there has been a steady increase in the per capita consumption of citrus fruits worldwide. North America has the highest per capita consumption of citrus fruits in the world followed by South America and Europe. According to FAO, fresh citrus fruit consumption is decreasing in the developed countries while some of the developing countries are showing an increase in consumption. Great variation exists in the types of citrus fruits produced and consumed throughout the various parts of the world. Oranges occupy the major portion of world citrus production followed by mandarins. Oranges form the majority of the citrus crop produced in the United States. About one-third of the citrus fruits produced globally are used for processing.

Members of Citrus Genus

Citrus is the largest genus of the Rutaceae family. The *Citrus* genus is composed of several species and each species has many varieties. Taxonomic identification is very complicated and the precise number of species is still unclear because there are many spontaneous and commercial hybrids. According to the Swingle system, 16 species were recognized and the Tanaka system identifies 156 species in the genus. Citrus fruits can be generally classified into the following categories: sweet oranges (*Citrus sinensis*; blood and acidless oranges), mandarins (such as satsuma (*C. unshi*), tangerines (*C. tangerina*), *C. reticulata*, and clementines (*C. clementina*)), sour/bitter oranges (such as Seville (*C. aurantium*)), lemons (*C. limon*), limes (*C. aurantifolia* and *C. latifolia*), grapefruit (*C. paradisi*) and pomelo (*C. grandis*), hybrids (e.g., tangelos, tangors, and limequats), and citrons (*C. medica*).

Types of Citrus Fruits

Sweet Oranges

Blood, navel, mandarin, and common oranges are the four groups of sweet oranges. Sweet oranges belong to the species *C. sinensis*.

Common Oranges

They are mostly globose but oval or ellipsoid is also common. Common Valencia is oblong to spherical. The base of the fruit is flattened in most varieties. The surface is not only smooth but also finely pitted. Generally, most sweet oranges have yellow to yellow-orange rind and flesh. The fruits in this group are spherical, globose, or ovate. Valencia, Shamouti, and Sathgudi are some sweet orange types.

Blood or Pigmented Oranges

The blood oranges are characterized by pink to red coloration of the flesh, juice, and rind. Coloration is due to the presence of anthocyanin pigments in the rind and flesh of the fruit. Red color develops with warm days and cool nights, which is the main feature of the Mediterranean climate. The common blood oranges are 'Maltese,' 'Moro,' 'Sanguinello Moschato,' etc.

Navel Oranges

This is an important group of fresh fruit orange varieties due to its excellent quality. Navel oranges have a navel-like structure at the stylar end or apex, which is a rudimentary secondary fruit embedded in the primary fruit. Navel orange fruits are ovate to oblong in shape. Most navel oranges, particularly the 'Washington navel' orange variety, the most widely grown navel cultivar in the world, are ellipsoid or obovate in shape. Its fruit's surface is generally smooth and is moderately pitted and pebbled. The fruits are mostly large and seedless. Other common navel oranges are Navelate, Palmer, etc. Orange-colored fruits are juicy and seedless with aromatic flesh. They are excellent for fresh fruit market, but do not keep well on the tree, not adapted to hot arid climate.

Mandarin (*C. reticulata* Blanco)

Most mandarins are deep orange to reddish orange in color when fully mature and are easily peelable. Their fruits are small or large (4–8 cm in diameter) with a low to high collar base and a deeply depressed apex. Their fruits are globose to oblate, 5–9 cm in diameter, with a thin or thick rind with sunken oil glands and a relatively smooth or, sometimes rough, surface. Their fruits are seedless or seeded with nearly 3–7 or more seeds and have 7–17 segments. Most mandarins lose quality and the rind 'puffs' if not picked when internally ripe.

It is an evergreen tree with many spiny branches tolerant to drought and cold. Although mandarins prefer subtropical climate, they can also grow in tropical areas. Mandarin oranges are classified into five groups: Satsuma, King, Willowleaf (Mediterranean), common, and small-fruited. Mandarins are usually eaten fresh or as desserts as they are easily peelable and have a distinctive pleasant flavor.

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00165-3

Grapefruits (*C. paradisi*)

Grapefruits (*C. paradisi*) are considered to have originated in the West Indies as a hybrid of pomelo or as a mutant. They have many attributes similar to pomelos. They are one of the large citrus fruits (although smaller than pomelos) with diameters of up to 10–15 cm and have commercial possibilities as fresh fruits. They are oblate to spherical in shape, slightly depressed at the stylar end, and flat at the stem end. The rind is medium in thickness, yellow or pink-blushed, and smooth-surfaced. Grapefruits are borne in clusters like grapes and are seeded to seedless. There are red-fleshed and white fleshed cultivars of grapefruits. Red fleshness is due to the accumulation of carotenoid and lycopene pigments. In tropical regions, fruits develop with high juice content, thinner peel, and lower acidity. Grapefruits can stay on the tree from September to July in the northern hemisphere. However, it is not suitable to leave the fruits on the trees for a prolonged time because granulation may develop and seeds may germinate within the fruit. People in North America, Europe, and Japan prefer fresh grapefruit.

Pomelo (*C. grandis* or *C. maxima*)

Pomelo (*C. grandis* or *C. maxima*) originated in southern China and is found growing wildly in China and in many northeastern states of India. Its fruits are the largest among the commercially grown citrus in the world. The fruit diameter commonly ranges from 20 to 30 cm. The fruits are globose to pyriform in shape and are borne singly. Pomelos have a much bigger fruit with thick peels and are less juicy than grapefruits. They also have a firm flesh with crisp carpellary membranes and juice sacs. They are white- or pink-fleshed and are seeded.

Lemon (*C. limon* (L.) Burm.)

Lemons are believed to have originated in India. The lemon tree is a small thorny tree that grows well in subtropics and tropics. The fruit size and shape of the lemon are highly variable from spherical in Baramasi lemon or Eureka to oblong. The fruit color is green to bright yellow at maturity and is with or without a collar at the neck. Thickness and smoothness of rind vary among varieties and lemons are either seedless or seedy. Some varieties have large and prominent nipple, while others have very small, inconspicuous nipple. The flesh of lemon is pale yellow and very acidic. Some varieties of lemon are quite juicy, while others have less juice. The quality of the lemon fruit is excellent in semiarid irrigated areas and coastal areas. In humid tropics, lemon trees produce fruits with coarser peels. The lemon juice is valued for its tart, tangy, and fresh flavor and is used as a common food ingredient in many cuisines. The fruit rind is a source of commercial essential oil and aroma compounds. Lemon trees are cold-sensitive than oranges and grapefruits and the fruit can freeze at low temperatures owing to its low sugar content. Argentina, Spain, California, and Italy are the leading producers of lemon. The lemon fruit structure is similar to other citrus fruits and is composed of the outer peel and the interior edible pulp. The outer peel is composed of the exterior flavedo or the epicarp and the interior white spongy part known as the albedo (mesocarp). The flavedo contains carotenoid pigments, vitamins, and essential oils. The albedo is composed of cellulose and soluble carbohydrates (pectin and protopectin), flavonoids, amino acids, and vitamins.

Acid Lime (*C. aurantifolia*)

Acid lime fruits are high in acid. *C. aurantifolia* grow throughout tropical and warm subtropical regions of the world and the world's leading producers are Mexico, Florida, the West Indies, and Egypt. The most common acid lime is the small-fruited acid lime or *C. aurantifolia* Swingle. It is also known as the 'Mexican' or 'Key' lime in the Florida Keys. The fruits are round or elliptical in shape with a thin or thick rind depending on the variety. The fruits have very small neck, a flat base, and a small nipple at the apex. The highly acidic flesh is juicy with a distinct aroma and flavor. The fruits are mostly seeded but seedless varieties are also commercially available. The fruits of *C. latifolia* Tan. are large (80–100 g) and are oblong in shape. These limes are also known as Tahitian or Persian lime. Lime trees are small shrubby and spiny, and they are cold-sensitive. The rind surface is greenish yellow to yellow at maturity and the tender flesh is juicy.

Sweet Lime (*C. limettioides* Tan.)

Sweet lime is also known as Indian sweet lime or Palestine lime. It is mainly utilized for its medicinal properties. The medium-sized fruit is pale yellow to orange yellow at maturity. The fruit shape is round to oblong and the juice is nonacidic. These limes are not commonly processed.

Citron (*C. medica* L.)

Citrons are grown in India. Citron fruits are long-oval or ellipsoidal to obovate in shape like some of the lemons. Their fruits are quite large with a yellow color and a very thick, rough, and bumpy peel at maturity and are also very seeded.

Calamondin

Calamondin is commonly grown in southern China, Taiwan, Japan, the Philippines, and northern India. It is a small mandarin-like fruit of 3–3.25 cm in diameter, weighing 20–30 g. It has a smooth orange-colored peel that is very thin (1–2 mm). Its fruit has an orange-colored acidic flesh with seeds, but the peel is sweet and edible. It is commonly used for making marmalade and for culinary purposes.

Citrus Fruit Development

Citrus fruits follow a typical sigmoid pattern of growth and development, which is divided into three stages. The initial phase, or phase I, is of slow growth including the period between anthesis and June drop. Phase II is the rapid growth period in which the fruit experiences a huge increase in size by cell enlargement during 4–6 months. In the final phase, or phase III or ripening period, growth is mostly arrested and fruits undergo a nonclimacteric process. Citrus fruits are

nonclimacteric fruits and hence there is no remarkable increase of respiration rate and ethylene production during ripening as in climacteric fruits such as mango or banana. Being nonclimacteric, citrus fruits do not ripen after harvest. Proper handling of citrus fruits is needed during harvesting, storage, transportation, and marketing to minimize wounding, stimulation of respiration, and ethylene production, which can induce physiological disorders and fungal rot. Citrus fruits produce a very low quantity of ethylene after harvest and there is no associated rise in respiration. However, fruits respond to exogenous ethylene supply by an increase in respiration, chlorophyll loss, calyx drying, and abscission. During ripening, citrus fruits change color from green to yellow or orange or orange-red according to the variety. This is called natural degreening, or natural color development. In some citrus fruits, if held on the tree beyond maturity, the yellow-orange color again changes to green, which is called regreening. Regreened fruit, although internally mature, loses marketability. The regreening process can occur on the tree and also after harvest. In most citrus fruits, regreening occurs when the fruit is on the tree, but in pomelo, regreening has been observed in harvested fruit stored in natural light or fluorescent light.

Fruit Morphology

Citrus fruits are classified as a hesperidium. Hesperidium is a modified berry resulting from a single ovary. The fruit consists of 8–16 carpels that form the core of the fruit or segments that contain the seeds and juice. Citrus fruits are characterized by the presence of an outer rind or skin. The rind or peel of citrus fruits is divided into an exocarp or flavedo, which is the outer, colored part, and the mesocarp or albedo, which is the inner colorless (white) or sometimes tinted part. The flavedo consists of the epicarp proper, hypodermis, outer mesocarp, and oil glands. Above the epicarp is a multilayered protective skin or cuticle. The edible pulp of a mature citrus fruit is divided into segments with or without seeds or juice sacs by a thick film or endocarp surrounding the soft central axis. Each segment is surrounded by a continuous endocarp membrane. In the segments, juice is contained in closely packed, club-shaped multicellular sacs, also called juice vesicles, which completely fill the segments. A thin wall called the carpellary septum surrounds the segments. Each juice sac also has a very minute oil gland at the center. The seeds (ovules) are also attached to segment walls by means of axial placentation.

The pomological and organoleptic attributes of citrus fruits are quite diverse. The fruit diameter ranges from a few centimeters in Mandarins to more than 25 cm for some pomelos (*C. grandis*). The fruit's shape also varies: fruits are oblate in tangerines, mandarins, and grapefruits, spherical or oval in sweet oranges, oblong in lemons (*C. limon*) and citrons (*C. medica*), and spherical in limes (*C. aurantifolia*). The fruits usually have 8–16 segments with or without seeds. Albedo forms the major portion of the citron fruits, while it is absent in kumquats and poorly developed in mandarins. The fruit pulp color depends on the presence or absence and abundance of carotenoids and anthocyanins in the pulp, and it can be pale, yellow, orange, or red. The size and shape of the seeds are also variable among species. Navel oranges and Tahiti lime (*C. latifolia*) are seedless, while grapefruit and pomelo have 30–50 seeds. The fruit flavors and essential oils are diverse both qualitatively and quantitatively.

Methods of Consumption

Citrus fruits are consumed fresh or processed into various products. Citrus fruits including oranges, mandarins, tangerines, and grapefruits are peeled and eaten fresh or as desserts. A major portion of citrus fruits produced are utilized for processing. The fresh fruit segments are also added to salads and desserts and on cakes. The most common citrus fruit product is fresh or frozen orange juice concentrate made from freshly squeezed and filtered orange juice. Additionally, citrus fruits are also made into marmalade, jams, jellies, candies, or wine. The dried and pulverized fruits are used for preparing confectionaries and flavoring baked products. Fresh or dried peel of citrus fruits has a variety of uses. The grated outermost layer of the rind, zest, is used in cooking and baking. The pulp, obtained after the extraction of orange juice, is dried and used as an emulsifier and binder in the food and beverage industries. Essential oils extracted from the peel of citrus fruits are used commercially for flavoring drinks, ice cream, pudding, desserts, chewing gum, sweetmeats, ice cream, sherbet, and other products. They are also a used by the pharmaceutical industry for the preparation of drugs, soaps, perfumes, cosmetics, and home cleaning products. Dried orange blossoms and leaves are used to make herbal teas. Fresh juices from limes and lemons are made into refreshing drinks. Lime and lemon juices are also suitable for garnishing and for flavoring dishes and curries. The fruit is also made into pickles, salted preserves, and dried limes and processed into beverages, jams, jellies, and marmalade. Essential oils are also extracted from the peel and are extensively used in flavoring soft drinks, confectionery, chewing gum, sweets, ice cream, sherbet, and other food products.

Biochemical Composition of Fruits

Sugars and Acids

The total soluble solids form 10–20% of the fruit fresh weight and are mainly composed of carbohydrates (70–80%) and small quantities of organic acid, proteins, lipids, and minerals. The insoluble portion mainly contains cell structure polysaccharides. The total solid contents in citrus fruit increase with ripeness due to an increase in sugar content. Sucrose, glucose, and fructose constitute the major fruit carbohydrate components. In mandarins and tangerines, sucrose, glucose, and fructose occur in a general ratio of 2:1:1. Sugars are prominent in tangerine, oranges, and grapefruits, while limes and lemons are rich in citric acid. Additionally, trace amounts of mannose, maltose, heptuloses, and galactose have also been identified in citrus fruits. Sucrose is the major nonreducing sugar in citrus fruits. Sucrose, in very small amounts, is present in limes and lemons. Arabinose, a pentose sugar, has been identified in lime and grapefruit. Starch content in citrus fruits is negligible.

Organic acid contributes to the acidic properties of citric fruits. Citric acid forms the major acid in citrus fruits. Malic acid forms the second most acidic component though present in much lower amounts than citric acid. Other organic acids including succinic, lactic, and oxalic have also been detected in fruits. Organic acids exist in free form or in combined form in salts (such as citrates and malates), esters, or glycosides. The titratable acidity or the free acidity of the citrus fruit juice is mainly due to citric acid contents. The total acidity represents the sum of all acids in free and combined forms. Citric acid is the predominant organic acid in juices, while malic, malonic, oxalic, and quinic acids form the major citrus peel organic acids. Acidity varies with fruit maturity and citrus species. It ranges from 0.5% to 1.5% in orange juice, 0.8% to 2.5% in grapefruit, and 4% to 8% in lemons and limes. In many oranges and grapefruit varieties, acidity declines with fruit ripeness due to a decrease in citric acid content. In lemons, a decrease of pH with an increase in acidity occurs with fruit ripeness. Citrus fruits are very low in fat content and are also not a good source of proteins.

Nutritional Value of Citrus Fruits

Citrus fruits have long been valued as important sources of vitamin C. Besides being deficient in cholesterol, citrus fruits also contain an impressive list of health-benefiting nutrients including essential minerals, vitamins, and dietary fibers. Citrus fruits are principal sources of many bioactive phytochemicals with disease-preventive properties including flavonoids and limonoids.

Minerals

Citrus fruits are good sources of dietary potassium and are relatively low in sodium (3–4 mg per 178 ml of orange juice). The ratio of sodium and potassium plays a role in the maintenance of electrolyte balance. Citric acid in citrus fruit can help in the absorption of calcium and other minerals by acting as a chelator.

Vitamin C

Among vegetables and fruits, citrus fruits are particularly popular as excellent dietary sources of vitamin C and can supply vitamin C content ranging from 23 to 83 mg per 100 g fresh weight on an average. Consumption of citrus fruits in moderate amounts may be the best way to meet the 100% of the RDA for vitamin C. Studies showed that intake of orange juice (500 ml day^{-1}) for two weeks (~250 mg ascorbic acid per day) resulted in increased plasma vitamin C concentrations by 40–64% and reduced oxidative markers in adults. A reduction in plasma lipid peroxidation was observed in healthy adults who consumed orange juice (8 oz or 236 ml) daily (70 mg vitamin C) for 2 weeks.

β-Carotene

The only fat-soluble vitamin occurring in citrus fruits in substantial quantity is vitamin A in the form of provitamin A carotenoids. Carotenes and β-cryptoxanthin form the major vitamin A precursors in citrus fruits. β-Cryptoxanthin is the major vitamin A precursor in tangerines, mandarins, and oranges, while α- and β-carotenes represent a minor portion of carotenoids in some oranges. Among various foods, citrus fruits including oranges and tangerines are the most concentrated dietary sources of β-cryptoxanthin. The content of provitamin A carotenoids varies greatly among different citrus fruits.

Folic Acid

Citrus fruits and their juices are good sources of natural folates, and according to a study in Europe, folate was 100% bioavailable from orange juices and is highly stable. There is strong scientific evidence supporting a positive relationship between dietary folate consumption and the prevention of neural tube defects in infants. Citrus fruits (100 g) can provide up to 10–20% of the RDA for adults and children less than 9 years of age, complementing to the dietary folate requirement. Another study reported that the consumption of orange juice (750 ml) daily for four weeks increased the plasma folate concentrations in adults by 18%.

Dietary Fiber

Cellulose, hemicelluloses, and pectins in citrus fruits are a source of dietary fiber. Pectin is the predominant soluble dietary fiber component of citrus fruits constituting about 65–70% of the total fiber content. Pectin occurs both in the edible portions of fruit and in the inedible residues such as peel, rag, and core. Consumption of fresh citrus fruits such as oranges and grapefruits can contribute significant quantities of pectin to the human diet. Insoluble fiber in citrus fruits is composed of polysaccharides and they play an important role in human diet in preventing digestive disorders because of their water-holding capacity.

Limonoids

Limonoids are one of the most health-benefiting bioactive components of citrus fruits owing to their versatile health-promoting and disease-preventing properties. Citrus limonoids were considered as the culprits causing delayed bitterness of the juices at room temperatures lowering the juice quality. Limonoids are highly oxygenated and modified triterpenes classified as tetranortriterpenoids. The term 'limonoid' is derived from limonin, the first limonoid component identified as the bitter component of citrus seeds. Several other limonoid compounds such as obacunone, nomilin, obacunoic acid, isolimonic acid, deacetylnomilin, ichigan, isoobacunoic, and dictomnolide were also identified. Limonin and nomilin are the predominant limonoids of citrus fruit. Limonoids are grouped into aglycones and glucosides. Aglycones are bitter limonoid compounds in the peels of citrus fruits, while glucosides are tasteless components. Both aglycones and glucosides are present in citrus seeds, but fruit tissue contains only glucosides. More than 50 limonoid aglycones and glucosides have been identified from various *Citrus* species. Evidence from several *in vivo*, *in vitro*, and animal studies suggests that

limonoids have anticancer properties and showed potent cytotoxic activities. In studies conducted using animal models and cell lines, limonoids have been shown to inhibit proliferation of the cancers of the stomach, colon, breast, skin, and pancreas. Limonoids including limonin and nomilin were also found to have antibacterial and antiviral properties. Studies also indicated that the anticancer properties of limonoids can be correlated to the induction of glutathione S-transferase, a major detoxifying enzyme system.

Flavonoids

Citrus fruits are known to be rich sources of polyphenolics such as flavonoids and phenolic acids. More than 60 types of flavonoids have been identified in citrus fruits belonging mostly to 4 different flavonoid groups: flavones, flavanones, flavonols, and anthocyanins. In the genus *Citrus*, flavanones are more abundant in high concentrations than flavones. Flavanones are concentrated in albedo and in the membranes than in the juice sacs. Hesperidin, naringin, and neohesperidin are the major flavonoids in citrus fruits. Citrus flavanones occur in the form of aglycones or glycosides. Hesperidin is the prominent flavonoid in orange and it is not bitter, but less soluble in water. Hesperidin also occurs in mandarins, lemons, and limes. Naringin, the major flavonoid in grapefruits and shaddock, has a bitter taste and it is soluble in water. Seeds and peels of citrus fruits are also rich in phenolic compounds such as phenolic acid and flavonoids. Naringin, neohesperidin, and neoeriocitrin are the main neohesperidoside flavanones present in bergamot, grapefruit, and bitter orange juices. Bergamot, orange, mandarin, and lemon juices contain the rutinoside flavanones: hesperidin, narirutin, and didymin. Caffeic, chlorogenic, ferulic, sinapic, and *p*-coumaric acids are the most abundant phenolic acids present in citruses.

Citrus flavonoids are known for their powerful free radical scavenging and for their anti-inflammatory activities. The anti-inflammatory properties of citrus flavonoids, hesperidin and its flavone analog diosmin, are due to their inhibition of the activities of proinflammatory mediators such as prostaglandins E2 and F2 and thromboxane A2. *In vitro* studies have also shown that citrus flavonoids can inhibit the reactions catalyzed by cyclooxygenase, lipoxygenase, and phospholipase A2. Citrus flavonoids have also been shown to possess platelet anti-adhesive and antiaggregation properties. Epidemiological studies have indicated an inverse relationship between regular consumption of citrus fruits and reduced risk of developing cardiovascular diseases, atherosclerosis, and inflammation. Flavonoids also exhibit antibacterial and antiviral activities. Evidences from a number of studies have demonstrated that citrus flavonoids or the purified single citrus flavonoid components (hesperidin, naringin, naringenin, etc.) possess antiproliferative activities and are capable of inhibiting the proliferation of many kinds of cancer cell lines including melanoma, colon, breast, squamous, leukemia, lung, prostate, colorectal, and hepatomas. Although the exact mechanisms explaining the anticancer properties of citrus flavonoids are still largely unclear, a number of mechanisms have been proposed. Flavonoids have been suggested to exert multiple actions and are involved in the inhibition of metastasis, inhibition of tumor progression, inhibition of angiogenesis in tumor cells, arrest of cell cycle progression, protection of DNA against oxidative damage, inactivation of carcinogens, signal transduction, etc.

Clostridium botulinum

A Harris, The Food and Environment Research Agency (Fera), York, UK

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Clostridium botulinum is an anaerobic spore-forming gram-positive bacillus, which is ubiquitous in the environment. *C. botulinum* and in rare cases *C. butyricum* and *C. baratii* can produce neurotoxins that are among the most potent known to man. *C. botulinum* produces eight botulinal neurotoxins (BoNTs), types A–G. Human botulism is usually associated with types A, B, and E and rarely with type F, while animal botulism is usually associated with types C and D. Type G has been reassigned as *C. argentinense*, which has been associated with sudden death but not neuroparalytic illness. Disease from type G is unknown in animals.

C. botulinum can be divided into four subgroups I–IV, differentiated by their biochemical activities. Group I is proteolytic, grows at temperatures between 10 and 45 °C, and can produce toxin types A, B, and F. Group II is nonproteolytic, grows at temperatures between 3 and 45 °C, and can produce toxin types B, E, and F. Those in group II are also termed psychrotrophic because of their ability to grow at temperatures below 5 °C. Groups I and II are the main groups associated with human illness, and those in group I account for almost all reported cases of infant botulism. Group III is nonproteolytic and produces toxin types C and D; and group IV can be weakly proteolytic and produces only toxin type G.

Types of Botulism

There are three main types of botulism, namely, foodborne, infant, and wound. Another two clinical categories are recognized – adult intestinal toxemia and iatrogenic botulism.

Foodborne botulism is the most common form of botulism and is caused from ingestion of foods containing *C. botulinum* toxin. In the case of foodborne botulism, contaminated products may be widely consumed, thus exposing a large number of people to the hazard and may subsequently represent a medical and public health emergency.

Infant botulism affects infants less than 1 year of age and is caused when infants ingest *C. botulinum* spores, which then germinate and produce toxin in the intestine. The spores may come from the environment or from foodstuffs. Honey has been previously implicated in the disease and is no longer recommended for infants less than 12 months. Almost all cases of infant botulism have been due to types A and B.

Wound botulism occurs when *C. botulinum* infects a wound and subsequently produces toxin. It has been associated with major soil contamination through compound fractures or severe traumas/lacerations. The incidence of wound botulism has increased considerably in recent years, particularly among injectors of black tar heroin.

Adult intestinal toxemia is the colonization of the intestine with *C. botulinum* following ingestion of spores and is analogous to infant botulism. Germination, vegetation, and toxin production by *C. botulinum* are not usually supported in the normal adult intestine; however, in a small number of adults who have a bowel abnormality or bowel disease or are undergoing antimicrobial therapy, colonization can occur.

Iatrogenic botulism is the accidental overdose of toxin (e.g., via inhalation by laboratory workers or via injection for therapeutic or cosmetic purposes).

Toxin Action

All of the toxins produced are large single polypeptides (130–150 kDa) of a similar structure. Enzymatic cleavage produces a 100 kDa heavy chain and a 50 kDa light chain linked via a single disulfide bond. In proteolytic strains, the enzymatic cleavage is caused by proteases produced by the cell, while in nonproteolytic strains, an exogenous protease such as trypsin is involved.

The toxin either enters the blood stream directly or is absorbed intact from the gastrointestinal tract. The toxin binds via gangliosides to high-affinity presynaptic receptors. It is then transported into the nerve cell through a receptor-mediated endocytosis process common with dichain toxins.

The toxin acts by blocking the normal release of the neurotransmitter acetylcholine that under normal circumstances triggers contractions of the skeletal muscle. The toxin binds irreversibly, and the recovery of function depends on ultraterminal sprouting of the nerve to form new motor endplates.

Each of the seven toxins (A–F) has different specific toxicities and durations of persistence within the nerve cells.

Symptoms

C. botulinum intoxication in adults is characterized by a descending symmetrical flaccid paralysis. Early symptoms include blurred vision, slurred speech, dry mouth, difficulty in swallowing, and muscle weakness. Botulism, particularly the early symptoms, may be confused with a number of other conditions including poliomyelitis, viral encephalitis and meningitis, myasthenia gravis, Guillain–Barré syndrome, tick paralysis, stroke syndromes, Eaton–Lambert syndrome, alcohol intoxication, drug overdose, antimicrobial-associated paralysis, and atropine, shellfish, or mushroom poisoning.

Early symptoms may vary depending on the route of infection/intoxication. Foodborne botulism has an incubation period ranging from 2 h to 8 days with the majority of cases having an onset 12–72 h postexposure. Nausea, vomiting, abdominal cramps, and diarrhea may precede the neurological symptoms described earlier.

The incubation period for wound botulism is considerably longer than for foodborne botulism and may range from 4 to

18 days. This is due to the organism first causing infection and then the subsequent *in vivo* production of toxin in the wound. Neurological symptoms are as described earlier and may include the presence of a fever.

The incubation period in infant botulism is difficult to ascertain but can be between 3 and 30 days. *C. botulinum* intoxication in infants is characterized by 'floppy baby syndrome.' Infants may be constipated and have feeding difficulties, poor sucking reflex, lethargy, loss of head control, and a feeble cry. In the adult version of intestinal toxemia, clinical manifestations are similar to those observed with foodborne botulism and may include the early gastrointestinal symptoms. In comparison to foodborne botulism, the onset is generally gradual and less dramatic.

In cases of iatrogenic botulism, the incubation period for inhalational exposure is similar to that of foodborne botulism with incubation periods ranging from 24–36 h to several days postexposure. Clinical symptoms are as described earlier while lacking any gastrointestinal symptoms.

In cases of overdose by injection, incubation periods vary depending on dosage. The doses usually recommended for cosmetic purposes are too low to cause disease. However, higher doses injected for treatment of muscle movement disorders have caused systemic botulism like symptoms in patients. Patients who received injections of botulinum toxin at a much higher dose than that recommended for cosmetic purposes have resulted in symptoms of severe botulism and long-term recovery.

In the absence of medical intervention, mortality rates as high as 50–60% have occurred. Mortality rates vary based on the patient age and type of botulism and are generally lower in those aged <20 years. With improvements in critical care management, fatality rates have dropped to *ca.* 16%, and where death does occur, it is often due to delayed diagnosis/treatment. Death is usually via respiratory failure due to paralysis or nosocomial infections (particularly pneumonia) resulting from long-term hospitalization. Mortality rates for foodborne botulism are 5–10%, 15–17% for wound botulism, and $<1\%$ for infant botulism.

Recovery can take weeks to months and full neurological recovery from weakness and fatigue may require as long as 1 year. In 95% of cases, the nerve terminals regenerate and recovery is complete. Extended outpatient rehabilitation is often required.

Complications

Although there are no additional specific complications resulting from botulism intoxication, the potential complications of prolonged paralysis, assisted ventilation, and nutritional support are significant. Nosocomial infections may include pneumonia; urinary tract infections (from indwelling Foley catheters); stress ulcers and sores; thrombophlebitis, cellulitis, and line infections due to peripheral and central intravenous catheters for prolonged periods; fungal infections; and also deep vein thrombosis and pulmonary embolism due to patients being bedridden for weeks to months.

Infectious Dose

The estimated lethal doses for purified crystalline botulinum toxin type A for a 70 kg man are 0.09–0.15 μg when introduced intravenously, 0.7–0.9 μg through inhalation, and 70 μg orally. The precise human toxicities for the remaining BoNTs are uncertain. All seven toxins have been shown to cause inhalational botulism in primates and therefore have the potential to cause human botulism if a significant exposure occurs. It is thought that 1 g of pure toxin dispersed in animal feed would be enough to kill 400 000 adult cows. Type A toxin produces a more severe disease than types B and E because of differences in amount of ingested toxin, absorption, or receptor affinity. Type A intoxication results in respiratory failure occurring more rapidly and more severely than with the other types of botulism. Mortality rates are lower in type B disease than with type A or E, and it has been shown generally that the longer the incubation period, the better the prognosis.

Diagnosis/Confirmation

The early diagnosis of botulinum intoxication is paramount as antitoxin therapy is most effective when administered early. Initial diagnosis is based on clinical history, physical examination, epidemiological history, and electromyography results. Epidemiological histories should include risk factors that may support the diagnosis including black tar heroin injection (wound), laboratory work with botulinum toxins or receiving nonapproved neurotoxin preparations for therapeutic or cosmetic purposes (iatrogenic), and recent consumption of a home-canned product (foodborne).

Diagnosis is confirmed by demonstration of botulinum toxin or the spores in the suspected food or patient specimens (vomit, feces, serum, gastric aspirate, and wound). It has been shown that the toxin may routinely be present in the serum 7–9 days after exposure and in some patients for up to 28 days postexposure.

Infant botulism diagnosis is made on clinical symptoms and confirmed by recovery of the organism or by detection of the toxin in stools.

In cases of inhalational botulism, diagnosis is more difficult as often toxin is not identifiable in the serum/stool.

The definitive diagnosis is made by the mouse bioassay, and positive *in vitro* assays are confirmed using the mouse bioassay.

Treatment

Treatment of botulism required intensive hospital care and may include where necessary mechanical ventilation and administration of antitoxin. The antitoxin is of equine origin and may carry a significant risk of serum sickness, and skin sensitivity testing should always be undertaken before administration. Hypersensitivity is in the region of 10–20%.

Control of the airway and ensuring adequate ventilation are of primary importance, and in some cases, endotracheal intubation may be required.

If exposure is known to have occurred within several hours, then induced vomiting and gastric lavage should be commenced. Even after several days, an emetic agent may be advisable to help eliminate any unabsorbed toxin still present.

Several forms of antitoxin are available and some agencies (e.g., Centers for Disease Control, the United States, and Public Health England, the United Kingdom) recommend the administration of antitoxin based on clinical diagnosis without waiting for laboratory confirmation. The antitoxin neutralizes toxin not yet bound to nerve terminals but does not neutralize toxin already bound.

Additional treatment for wound botulism includes debridement, drainage, and irrigation of the wound. As toxin production may continue until the infection with *C. botulinum* is eliminated, the administration of antibiotics is also likely.

In March 2013, the Food and Drug Administration (FDA), the United States, approved the first botulism antitoxin (BAT) that can neutralize all seven known botulinum nerve toxin serotypes. The BAT heptavalent (A, B, C, D, E, F, and G) (equine) is derived from horse plasma and is now the only drug available for treating adult botulism in the United States. BAT has superseded the use of a licensed bivalent botulinum antitoxin AB and an investigational monovalent botulinum antitoxin E. It is also the only available drug for treating infant botulism that is not caused by nerve toxin type A or B.

In cases of infant botulism, a human-derived botulinum immune globulin (BabyBIG) is available. BabyBIG is obtained from the plasma of immunized adults who have subsequently developed high titers of neutralizing antibodies against BoNTs A and B. BabyBIG is derived of human origin and therefore does not have the high anaphylaxis risk inherent with equine sources or the risk of lifelong equine antigen hypersensitivity. Although supportive intensive care including mechanical ventilation may be required, the use of BabyBIG can significantly reduce the length of hospital stay for infants.

Prevalence in the Environment

C. botulinum is ubiquitous in the environment and can be found in soil; dust; marine and freshwater sediments; intestinal tracts of animals, birds, and fish; vegetables; fruits; leaves; silage; and animal manure.

There is a geographic predilection by *C. botulinum* type with type A spores prevalent in western United States, Brazil, Argentina, and China. Proteolytic type B spores are primarily found in eastern United States and nonproteolytic type B spores in the United Kingdom and continental Europe. Type E spores predominate in aquatic environments and are found in many northern regions such as Alaska, northern Canada, Scandinavia, Russia, and Japan. Types C and D are more associated with the warmer climates of Indonesia, Australia, and South Africa with type C more prevalent in some aquatic environments occupied by waterbirds. Type F, which is found more rarely, has been detected in the soils/sediments of Brazil and Paraguay and in aquatic environments. Type G has been isolated from soil in Argentina and Switzerland.

Prevalence in Foods

Because of the prevalence of *C. botulinum* in the environment, there is potential for a wide range of raw food materials to carry spores. In many cases, the common food vehicles associated with *C. botulinum* are characteristic of the country or culture and the prevalence of the *C. botulinum* type found in that environment. In certain parts of the United States, China, Spain, and Italy, consumption of vegetables contaminated with type A is the most common cause of botulism, while in Alaska, Japan, Canada, and Scandinavia, cases are usually associated with fish/aquatic products contaminated with type E. In central continental Europe, cases are typically from home-cured meats and usually associated with type B spores. In cases of infant botulism, honey has become a recognized source for *C. botulinum* spores.

Group I strains are frequently related to insufficiently processed home-preserved foods such as canned vegetables and cured meats, whereas group II strains are more of a risk in foods processed with mild heat treatments and subject to refrigerated storage (e.g., REPFEDS (refrigerated processed foods of extended durability)).

Commercially prepared foods are rarely implicated in botulinum outbreaks due to stringent controls, but when a failure does occur, mass intoxication may result. In the United Kingdom in 1989, a major outbreak occurred resulting in 27 people affected with one fatality. The outbreak was due to a yogurt containing hazelnut puree, which had been sweetened with aspartame rather than sugar. The processing of the conserve had been inadequate to destroy *C. botulinum* spores. In the United States in 2007, eight people contracted foodborne botulism after eating commercially produced canned food products (including hot dog chili sauce), which had been underprocessed.

The majority of botulism cases today are associated with low-acid home-preserved foods particularly vegetables that have a $pH > 4.6$, for example, peppers, garlic, and carrots. In 2006 in Thailand, 209 people were affected with 42 people developing respiratory failure, neuromuscular failure, and autonomic nervous system failure. The outbreak was due to ingestion of pickled home-canned bamboo shoots.

Global Incidence

In 2010, in 29 of the European Union (EU) and European Economic Area (EEA) countries (all except Liechtenstein), 104 cases of botulism were confirmed. This was a decrease of 21% when compared to 2009 when 132 cases were confirmed. Poland, Romania, Italy, and France accounted for 80% of the confirmed cases. The EU trend has been stable during 2006–10 with the confirmed case rate ranging from 0.02 to 0.03 cases per 100 000 population (European Centre for Disease Prevention and Control, Annual Epidemiological Report 2012). Previous data from the same source indicate similar numbers of cases reported between 2005 and 2010 with 152 cases reported in 2005, 157 cases (109 confirmed) in 2006, 171 cases (129 confirmed) in 2007, and 151 cases (112 confirmed) in 2008. Between 1995 and 2004, there were 2388 reported cases

although not all countries reported for all years. Incidence in Europe (50 countries) is considerably higher than in just the EU/EAA (31 countries).

In the United States, a total of 112 laboratory-confirmed cases of botulism were reported to the CDC in 2010. Of these, foodborne botulism accounted for 9 (8%), infant botulism for 85 (76%), wound botulism for 17 (15%), and botulism of unknown or other etiology for 1 (<1%) cases (Centers for Disease Control and Prevention, Botulism Annual Summary, 2010). Previous data from the same source indicate similar numbers of cases reported between 2005 and 2010 with 145 cases in 2005, 170 cases in 2006, 144 cases in 2007, 153 cases in 2008, and 121 cases in 2009. In general, infant botulism was the predominant cause each year.

Between 1976 and 2007, a total of more than 3000 cases of infant botulism have been globally identified, and as of 2009, infant botulism has been documented in 26 countries representing 4 continents.

In England and Wales, wound botulism accounts for the most cases of botulism with 144 cases between 2000 and 2010. This compares to four cases of foodborne botulism and six cases of infant botulism during the same time period. In the United States between 2005 and 2010, there were 158 cases of wound botulism compared to 573 cases of infant botulism and 101 cases of foodborne botulism. Thirteen cases were of unknown or other etiology.

Survival, Prevention, and Control

In order for foodborne botulism to occur, the food must initially be contaminated with *C. botulinum* spores. The environment provided by the food must be anaerobic and nonacidic with low sugar and salt to enable the germination of the spores into cells capable of growth and toxin production. The food must then be consumed without sufficient prior heating to destroy the toxins (85 °C for >5 min).

To control and prevent botulism, the processing and subsequent storage of the food must be such that it results in either the destruction of the spores or the prevention of their germination, growth, and subsequent toxin production.

C. botulinum produces spores that can survive in a dry state for decades. The spores are highly resistant to heat, desiccation, UV light, and alcohols. They may survive several hours at 100 °C but will not survive exposure to moist heat at 120 °C for 30 min. Spores of the nonproteolytic group II types are more heat-sensitive than the group I types (proteolytic) but can still withstand many of the mild pasteurization techniques currently in use (70–95 °C). In contrast, the toxins are heat-labile and are inactivated by heating at 85 °C for ≥5 min.

Processing/Storage/Shelf Life

The proteolytic group I types cannot grow below temperatures of 10 °C, so are not of concern in cold-distributed foods. These group I types when they grow often cause food spoilage that may indicate to consumers the defective quality of the food. However, the potency of the toxin is such that even tasting a product spoiled by *C. botulinum* may cause intoxication. A case in 2002 occurred where an individual tasted a mouthful of foil-wrapped baked potatoes but did not swallow it due to the spoiled taste. He had however consumed sufficient toxin for botulism to occur and spent more than 6 months in hospital recovering.

The strains of group II are nonproteolytic and can grow at temperatures as low as 3 °C. These strains may show no outward signs of obvious spoilage of the foodstuff and are more of concern in products that are minimally processed and have refrigerated storage, for example, REPFEDS.

The increased consumer demand for fresher less preserved foods has led to the use of milder heat treatments combined with other food preservation hurdles. This includes chilled storage, a controlled shelf life, and occasionally intrinsic preservatives (e.g., reduced pH). Hermetic sealing may be used to create anaerobic conditions that may extend the shelf life, but this may also create conditions favorable for the growth of *C. botulinum* in cases of product abuse. Product abuse (i.e., where there is failure to store a product at a low temperature or to consume within a certain timeframe) may lead to increased consumer risk from group II spores, which can grow and produce toxin at temperatures as low as 3 °C.

C. botulinum spores are resistant to pressure but can be destroyed by combinations of high-pressure and high-temperature treatments. The spores and toxins of all strains are also relatively resistant to the freezing temperatures used for food storage.

Heat Resistance

The proteolytic strains of *C. botulinum* (group I) produce spores that are highly heat-resistant, and these are the principal concern for the safe production of low-acid canned foods. As such, a universal botulinum cook is used in the canning of low-acid foods (pH >4.6). A botulinum cook results in a 12 log reduction of spores at 121 °C for 3 min or an equivalent time/temperature combination. High-acid foods (<4.6) do not support the germination and growth of group I spores, and for these products, the botulinum cook is not required.

The *D*-value or decimal reduction time is the time it takes at a given temperature to reduce a population by 90%. Group I spores are considerably more heat-resistant than group II spores although these still show moderate heat resistance. Group I spores have a $D_{121°C}$ of 0.21 min and a $D_{100°C}$ of 25 min, while group II spores have a $D_{121°C} = < 0.001$ min and a $D_{100°C}$ of <0.1 min. It has been shown that heating group II spores for 5–10 min at 80–85 °C can inactivate their spore germination system due to sublethal injury but that in the presence of lysozyme, germination can still be induced and the heat resistance increased by up to two orders of magnitude.

pH/Sodium Chloride Concentration

The growth of proteolytic *C. botulinum* strains is inhibited at pH <4.6 or by 10% sodium chloride (NaCl), with the minimum water activity to allow growth being 0.96 where NaCl is used as the humectant (Table 1). Growth and toxin production of nonproteolytic *C. botulinum* strains are inhibited at pH <5 or in the presence of >5% NaCl concentration. For these strains, the minimum water activity to allow growth is 0.97 where NaCl is the humectant. It should be noted that water activity

Table 1 Characteristics of *C. botulinum* groups I and II

	C. botulinum *group I*	C. botulinum *group II*
Toxin types	A, B, F	B, E, F
Proteolytic	Yes	No
Minimum temperature	10 °C	3 °C
Optimum temperature	35–40 °C	18–25 °C
Minimum pH	4.3–4.6	5
NaCl	10%	5%
Minimum a_w[a]	0.94	0.97
$D_{121°C}$ spores	0.21 min	<0.001 min
$D_{100°C}$ spores	25 min	<0.1 min

[a]May vary, depending on humectant.

values may vary depending on the humectant used with glycerol permitting growth at lower a_w values. Humectants (salts or sugars) absorb moisture making water less available for microbial growth. The toxins of both groups I and II are stable at low pH.

Disinfectants

C. botulinum spores are readily killed by chlorine-based disinfectants and exposure to formaldehyde. The spores are sensitive to most disinfectants authorized in the food processing sector as long as the correct time/concentration combinations are used.

Detection

A variety of methods exist for the detection of *C. botulinum* toxins and may include ELISA (enzyme-linked immunosorbent assay), PCR (polymerase chain reaction), endopeptidase assays, and lateral flow immunoassays, among others. These methods have been used as screening tools and may provide a rapid result in some matrices. However, the gold standard for the detection of toxin still remains the mouse bioassay. This involves the extraction of the toxin (if required, e.g., from foodstuffs), trypsinization if required (necessary for non-proteolytic strains), and then intraperitoneal inoculation of laboratory mice. Mice are subsequently observed for signs of botulism, which may include ruffled fur, labored breathing, Cheyne–Stokes respiration, and pinching of waist resulting in a 'wasp waist.' The mice are observed for 3 days, but generally, symptoms of botulism will be observed within the first 24 h. The toxin type may be determined by neutralization tests with specific antitoxins. The mouse bioassay is very sensitive and is measured as MLD (minimum lethal dose) with one mouse LD50 corresponding to 5–10 pg and a detection limit of 20–30 pg ml^{-1}. Detection of *C. botulinum* spores usually results from providing a suitable environment, which enables the growth and toxin production of the organism. Detection is then confirmed by the presence of toxin as described earlier.

Therapeutic/Cosmetic Use of Botulinum Toxin

Despite the potency of *C. botulinum* neurotoxins and their involvement in serious disease, their use for therapeutic and cosmetic purposes (particularly of BoNT type A) is increasing. The use of neurotoxins for cosmetic purposes such as reducing the appearance of wrinkles and frown lines is well established but offers only temporary improvement. *C. botulinum* neurotoxin is used in a wide variety of medical conditions associated with muscular hyperactivity, glandular hypersecretions, and pain. These include focal dystonias, spasticity, nondystonic disorders, strabismus, chronic pain and disorders of localized muscle spasms, smooth muscle hyperactive disorders, and sweating and salivary and allergy disorders. The use of neurotoxin does not correct the underlying condition but improves clinical symptoms for a time. The duration and quality of improvement vary depending on the dose, dilution, and method of injection. The effects generally last approximately 3 months after which further injections will be needed. There is a risk of the patient developing resistance, but this has been reduced by giving the lowest effective dose and ensuring long periods between injections.

Clostridium: Occurrence and Detection of *Clostridium perfringens*

R Labbé, University of Massachusetts, Amherst, MA, USA
V Juneja, Eastern Regional Research Center, Wyndmoor, PA, USA

© 2016 Elsevier Ltd. All rights reserved.

Background

Clostridium perfringens was recognized as a potential cause of foodborne illness in the 1950s following the isolation of a large number of the organism from suspect foods involved in foodborne illness. In the United States, it is the second leading cause of bacterial foodborne illness. It was eventually realized that the responsible enterotoxin was produced following the ingestion of a large number of cells from outbreak foods. The cells sporulate in the small intestine and release the enterotoxin. The enterotoxin was subsequently isolated in the early 1970s. Extensive work has been conducted on the mode of action of the toxin using animal models and in cell culture.

C. perfringens is divided into types A–E. Types B–E are typically associated with domestic animals and are responsible for a variety of veterinary illnesses. Type A is associated with foodborne illness and is part of the microflora of soil.

Extensive surveys of the incidence of *C. perfringens* in retail foods were conducted beginning in the mid-twentieth century after realization of its role in foodborne illness. Specialized selective and presumptive media have been developed and modified to take advantage of the special ability of *C. perfringens* for rapid growth at elevated temperature, including in the presence of specific antibiotics.

The Organism

C. perfringens is classified into five types, A–E, depending on their ability to produce four toxins, alpha, beta, epsilon, and iota. Food poisoning is caused by type A, while a more serious gastrointestinal illness, necrotic enteritis, is due to type C but is rare in industrialized countries.

Foodborne illness caused by type A *C. perfringens* is due to the production of an enterotoxin during sporulation in the small intestine following consumption of a large number of vegetative cells in temperature-abused foods. The enterotoxin is encoded by a gene (*cpe*) located on either the chromosome or large plasmids. In the majority of outbreaks, the responsible isolates carry the enterotoxin gene on the chromosome.

C. perfringens is an anaerobe, that is, requires the absence of oxygen for rapid growth. This is readily achieved during cooking procedures in which high temperatures drive off oxygen. In the vegetative (growth) state, the organism possesses the shortest generation time of any bacterium, able to divide in <10 min in protein foods under optimal conditions such as those that may be found following the cooling of large portions of meat, poultry, and gravies.

C. perfringens is a spore-forming organism. Under conditions of limited nutrients, vegetative cells (i.e., those in the growth phase) can enter the spore state, which is a cell from highly resistant to physical insults such as radiation, high temperatures, pasteurization, and sanitizing agents. However, the spores of this organism are inactivated by canning procedures. In the natural environment and in nonoutbreak foods, the organism is often found in the spore state. When placed in conditions of proper nutrients (germinants), such as protein foods, spores can germinate and resume vegetative cell growth.

Occurrence

Reservoirs

The environment

Type A strains have been isolated from most soil samples examined, at levels of up to 10^3–10^4 g. However, soil is not considered a major reservoir as the level of enterotoxin-positive isolates is low.

Feces

C. perfringens is present in the intestinal contents of virtually all animals including most humans examined with great variation in number and between species. Levels may also vary over time. Median counts in healthy individuals range from 10^3 to 10^6 g and are higher in neonates and elderly than adults. There is some uncertainty as to whether humans are reservoirs of foodborne, enterotoxigenic *C. perfringens*.

The widespread presence of *C. perfringens* spores in fecal samples has led to the use of *C. perfringens* as an indicator of fecal pollution of water by certain governmental jurisdictions on several continents. As well, the World Health Organization has also recommended it as a useful indicator of fecal pollution. *C. perfringens* spores were also found to be good indicators of the distribution of sewage sludge on the ocean floor where low temperature and high pressure are less suitable for common indicators of fecal pollution such as coliforms and fecal streptococci.

Food/food animals

Following the identification of *C. perfringens* as an etiological agent of foodborne illness, many surveys of the incidence of the organism in foods were conducted. Early surveys revealed an incidence of approximately 50% (range of 30–80%) of raw or frozen meat and poultry items containing generic (i.e., enterotoxin-positive and enterotoxin-negative) *C. perfringens* (Table 1). Typical ranges in early surveys were at levels up to 10^2 g in meat and poultry, the commodities typically associated with foodborne outbreaks. Certain foods, such as spices, were found to contain the organism at higher levels, even up to 10^3 g. More recent surveys have employed techniques that allow the determination of the presence of the enterotoxin gene. This revealed that enterotoxigenic *C. perfringens* is present at low levels in retail foods (Table 2).

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00169-0

Table 1 Levels of generic *C. perfringens* in retail foods

	% positive	Levels (per gm or cm^2)
Beef, pork, poultry	52–94	1–100
Pork sausage	39	5–93
Ground beef	50	5–100
Pork carcasses	66	20/100 cm^2
'Raw meat'	70	<3
Raw fruits and vegetables	4	10–100
Spices/herbs	5–100	10–10 000
Frozen foods	3	10–20

Compiled from Guran and Oksuztepe; Juneja et al.; Lindström et al.

Table 2 Levels of enterotoxigenic *C. perfringens* isolates from selected sources

Source	% enterotoxin-positive
Soil	7
Healthy adults	8[a]
Meat, fish, poultry, retail	0.1–1.7
'Raw meat,' retail	8–12
Intestine, food animals	10–40

[a]Compiled from Carmen et al.; Guran and Oksuztepe; Lindström et al.; Li et al.; Miki et al.

Taken together, and in spite of many surveys of retail food, food animals, humans, and the environment, the natural reservoir of foodborne, enterotoxigenic *C. perfringens* remains unknown. It is now generally accepted that <10% of global isolates carry the enterotoxin gene (Table 2).

Entry and Growth in Outbreak Foods

High-protein foods, such as meat and poultry, are typically involved in the outbreaks of foodborne illness. These have been prepared in advance often in large amounts in settings such as cafeterias, restaurants, and caterer preparation sites. Spores of the organism are able to survive the heating steps associated with food preparation. Such spores can then germinate and grow during slow cooling procedures. Because outbreaks of *C. perfringens* typically occur in institutionalized settings, the average outbreak size consists of several dozen cases. However, the relatively mild symptoms of most cases result in the involvement of public health officials when only a large number of people have become ill.

Factors Affecting Growth

The temperature limits for growth of *C. perfringens* are between 15 °C (60 °F) and 50 °C (122 °F) with an optimum at about 45 °C (112 °F). Deficiencies in cooling are involved in virtually all cases of foodborne illness caused by *C. perfringens*. Specifically, slow or improper cooling allows the rapid growth of the organism between 37 and 50 °C. This highlights the need to reduce the size of portions of meat or the volumes of gravies after cooking as spores can survive the internal temperatures. The potentially rapid growth of *C. perfringens* during cooling has led to governmental regulations regarding the cooling of commercially produced, processed meat and poultry. For home and institutional settings, the temperatures recommended by governmental agencies for holding of cooked foods during serving or holding should be followed. These are 5–60 °C (40–140 °F).

Detection

Detection of Viable *C. perfringens*

Methods for detection of *C. perfringens* depend on the level of expected cells. The levels in retail foods are expected to be low and the standard technique involves the most probable number (MPN) method (see Section '**Most Probable Number**'), while the cell number in outbreak foods is much higher and requires the use of specially developed selective and differential media.

Criteria for Outbreak

The typical criteria for implicating the role of *C. perfringens* in outbreak foods involve either (a) detection of enterotoxin-positive spores ($>10^6$ g) in feces of ill individuals, (b) detection of elevated ($>10^5$ g) numbers of vegetative cells in outbreak foods, or (c) detection of enterotoxin in feces of ill individuals.

Most Probable Number

An MPN procedure is used when a low number of *C. perfringens* are expected, for example, in routine surveys of retail foods. For this purpose, iron milk medium containing 2% iron powder is used and is inexpensive and simple to prepare. Selection is based on the appearance of a 'stormy fermentation.' In the reaction, casein is precipitated by acid from the fermented lactose followed by fractionation of the curd into a spongy appearance when the milk is incubated at 45 °C. If results are read after 18 h, confirmatory tests are not necessary.

Examination of Outbreak Foods

Many media for enumeration of *C. perfringens* from outbreak foods have been developed over the years. The currently recommended medium in North America and elsewhere is tryptose-sulfite-cycloserine (TSC) agar. Following anaerobic incubation at 37 °C, *C. perfringens* colonies appear as black due to the reduction of sulfite to sulfide and reaction of the sulfide with iron in the medium to form the black iron sulfite precipitate. Because certain other clostridia may produce black colonies on this medium, confirmation of a selected number of isolates is necessary (see '**Confirmatory Tests**' later).

Confirmatory Tests

Confirmatory tests can rule out the possible (though unlikely) presence of other sulfite-reducing clostridia. The media for this purpose are tubes of motility nitrate (MN) and lactose gelatin (LG). The use of TSC agar together with the LG and MN has been adopted as official first action by AOAC (Association of Official Analytical Chemists) International. Details of the laboratory procedures are described as standard methods by the US Food and Drug Administration and by the International Organization for Standardization. Commercial tests kits for

identification of clostridia are also available. Their use has been described in publications from professional organizations such as the American Society for Microbiology.

Enterotoxin Detection

Detection of *C. perfringens* enterotoxin in feces is a method of confirming the role of *C. perfringens* in foodborne illness. The two available commercial assays are an enzyme-linked immunosorbent assay and a reverse passive latex agglutination. Stools of healthy individuals contain undetectable levels of the enterotoxin. The commercial kits for each technique, respectively, are available from TECHLAB Inc. and Oxoid Inc.

Enterotoxin Gene

As shown in **Table 1** versus **Table 2**, the ability of *C. perfringens* to produce enterotoxin is limited to a small percentage of isolates. To confirm the role of the organism in foodborne outbreaks by the presence of a large number of viable cells or spores, it is necessary to demonstrate that suspect isolates (colonies) possess *cpe*. This is performed using the polymerase chain reaction (PCR) assay. The procedure amplifies *cpe* from lysed cells (i.e., isolates confirmed as *C. perfringens*) allowing the determination of its presence. PCR protocols have been developed to determine the location of *cpe*, that is, whether on the chromosome or on a plasmid, though this distinction is not routinely done or required in investigations of outbreaks.

Possible Medical Applications of *C. perfringens* Enterotoxin

As part of its biological activity in cases of foodborne illness, *C. perfringens* enterotoxin binds to membrane proteins called claudins. Certain solid cancer cell lines often overexpress membrane-associated claudin molecules. This has led to a possible use of *C. perfringens* enterotoxin as an anticancer agent. In particular, tumor necrosis and shrinkage against xenografts of human pancreatic cancer tumors growing on the back of mice have been demonstrated. Current research involves limiting immune responses to the enterotoxin and employing particular enterotoxin fragments. Its potential medical application is an exciting possibility for this toxin.

Clostridium: Food Poisoning by *Clostridium perfringens*

K Miyamoto and M Nagahama, Tokushima Bunri University, Tokushima, Japan

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Clostridium perfringens was initially identified as a cause of food poisoning in the 1940s. This bacterium then became known as an important cause of foodborne disease. Many cases of food poisoning due to enterotoxigenic *C. perfringens* are now reported every year, and *C. perfringens* food poisoning ranks among the most common foodborne diseases in industrialized countries. The most important virulence factor is the toxin known as *Clostridium perfringens* enterotoxin (CPE), while the biological properties of this bacterium also contribute to the induction of foodborne disease.

In this article, we described the basic features of *C. perfringens* food poisoning, with a focus on the genetic and biological characteristics of CPE-producing strains, and also introduced novel insights into the molecular mechanism of CPE cytotoxicity.

Characteristics of the Organism

C. perfringens is a Gram-positive, rod-shaped, encapsulated, nonmotile bacterium that causes a broad spectrum of human and veterinary diseases. The virulence of *C. perfringens* mostly attributes its toxin-producing ability; that is, more than 16 different toxins have been identified from human and veterinary disease isolates. Of these toxins, the human gastrointestinal (GI) virulence of *C. perfringens* is known to depend on three toxins, CPE, beta-toxin (the main toxin responsible for necrotizing enteritis in humans), and also possibly beta2-toxin (an additional toxin for human colitis by CPE-producing type A strain). While toxin-producing ability is crucial for human GI diseases, *C. perfringens* food poisoning isolates have several other biological abilities: a rapid doubling time (<10 min for vegetative cells), the ability of vegetative cells to grow in relatively high optimal growth temperatures (43–45 °C), the ability to form environmental stress-resistant spores, and tolerance to air exposure in spite of being classified as an anaerobic bacterium. These properties also play important roles in the induction of *C. perfringens* foodborne illness.

Based on the production of an arsenal of four major toxins (alpha, beta, epsilon, and iota), *C. perfringens* isolates are classified as type A–E. Toxin typing of *C. perfringens* strains was traditionally identified by toxin–antitoxin serum neutralization tests in mice. The recent development of PCR-based schemes permitting toxin genotyping has simplified toxin typing of *C. perfringens* isolates. Food poisoning isolates are most frequently identified as type A, while the most important toxin gene, the *cpe* gene, is rarely found in type C, D, and novel E strains. These type C to E strains have not yet been identified as causative agents of *C. perfringens* food poisoning outbreaks, even though type C to E strains sometimes express an enterotoxin with very similar or almost identical physical, serological, and biological properties to CPE produced by the type A strain. Of these *cpe*-carrying type A–E strains, the CPE-producing type A strain is more widely distributed than the other types of CPE-producing strains. On the other hand, a *cpe*-positive type C isolate was found in some cases of necrotic enteritis (also known as Darmbrand or pigbel), while the *cpe*-positive type C strain may have accidentally been isolated from a patient with type A food poisoning. The *cpe* gene is present on a conjugative transferable large plasmid in most, if not all, type C, D, and E strains. However, genetic organization of the *cpe* region of type C, D, and E strains differs from that of *cpe*-positive type A strains.

Factors Contributing to *C. perfringens* Type A Foodborne Illness

A unique toxin, CPE, plays a major role in *C. perfringens* type A food poisoning. A large number of epidemiological studies confirmed the importance of CPE in GI virulence. First, most type A *C. perfringens* isolates from food poisoning outbreaks produce CPE. Second, a strong positive correlation exists between illness and the presence of CPE, the level of which in a patient's feces is known to cause serious intestinal effects in experimental animals. And third, human volunteers fed highly purified CPE will develop all of symptoms characteristic of *C. perfringens* type A food poisoning.

Animal model experiments revealed that CPE is active on the GI tract; that is, all regions of the small intestine are sensitive to treatment with CPE. In rabbit ileal loops, purified CPE causes the rapid loss of fluid and electrolytes from the GI tract. These effects on rabbit ileal loops can be neutralized with CPE-specific antiserums. Moreover, the ability of CPE-positive *C. perfringens* food poisoning isolates to produce both fluid accumulation and histopathologic damage in rabbit ileal loops is remarkably higher than that of CPE-negative isolates or that of a *cpe* knockout mutant of the food poisoning strain.

The importance of CPE to human GI virulence has been supported by the finding that CPE-producing type A *C. perfringens* strains (most isolates harbor the *cpe* gene on a plasmid) are also isolated from nonfoodborne human GI diseases, including antibiotic-associated diarrhea, sporadic diarrhea, and nosocomial diarrheal outbreak.

The Biochemistry of CPE

CPE is a single polypeptide of 35 317 Da composing 319 amino acids with an isoelectric point of 4.3. This toxin is not a heat-stable enterotoxin; its activity is inactivated by heating for 5 min at 60 °C. It is also sensitive to pH extremes but resistant to some proteases, such as trypsin and chymotrypsin. This toxin is not a secreted toxin because the toxin gene (*cpe*)

does not encode the 5′ signal peptide, which is often associated with secreted toxins.

Native CPE crystal structure analysis revealed CPE to be a three-domain protein with an elongated architecture of beta-sheets. These features of CPE are common among pore-forming toxins, such as *C. perfringens* epsilon-toxin and *Laetiporus sulphureus* hemolytic pore-forming lectin. However, the domain arrangement of CPE is in the opposite order; domain I is composed of the C-terminal region of CPE, whereas domains II and III are formed by the N-terminal region. The C-terminal half of the toxin (domain I) is responsible for specific receptor-binding activity. CPE domain II contains a region that appears to be a transmembrane stem, and this region is crucial for pore formation and cell killing. The CPE region residing in domain II also promotes CPE hexamer formation (~450 kDa SDS (sodium dodecyl sulfate)-resistant large complex, described later). Domain III may undergo structural changes during prepore to pore transition. The N-terminal 37 amino acids of CPE lack a definable structure and are not necessary for toxicity.

Genetics of CPE

Cpe ORF nucleic acid sequences are highly conserved among CPE-positive type A isolates; that is, CPE must have a highly conserved amino acid sequence. Interestingly, the *cpe* gene appears to be harbored on either the chromosome or the large plasmids with a single copy. In the chromosomal *cpe* strain, the *cpe* gene is flanked by insertion sequence (IS) elements (IS*1469* and IS*1470*), which is associated with the putative 6.3-kb *cpe*-containing transposon, Tn*5555*. On the *cpe* region of *cpe*-carrying plasmids, the *cpe* gene is resided by upstream IS*1469* and by downstream IS*1151* or IS*1470*-like elements in almost all type A *C. perfringens* isolates; that is, based on gene arrangement differences in the *cpe* region, most, but not all, CPE-producing type A strains are divided into three *cpe* genotypes: one type of the chromosomal *cpe* strain and two types of the plasmid *cpe* strain. Similar to other toxin genes such as the epsilon-toxin gene, the *cpe* gene is harbored on conjugatively transferable plasmids. Collectively, the *cpe* region in both chromosomal and plasmid *cpe* strains is on a transposon, a mobile genetic element; that is, these IS elements may be related to mobilization or transfer of the *cpe* gene.

Synthesis and Release of CPE

Although CPE-producing *C. perfringens* isolates are divided into three *cpe* genotypes, the amount of CPE expressed by an isolate is not affected by whether that isolate carries the *cpe* gene on the chromosome or a large plasmid. CPE synthesis begins shortly after the induction of sporulation and progressively increases for the next 6–8 h. CPE expression is regulated at the transcriptional level, with significant amounts of *cpe* mRNA being produced during sporulation; however, *cpe* mRNA is not produced during the vegetative growth of *C. perfringens*. This phenomenon is strongly supported by the findings of genetic analyses as follows: expression of the *cpe* gene in type A strains is strictly regulated by sporulation-associated alternative sigma factors, including SigF, SigK, and SigE. SigK and SigE (SigE and SigK are sporulation-associated sigma factors active in mother cells during the sporulation of *Bacillus subtilis*) directly induce the transcription of *cpe* mRNA by binding SigK- or SigE-dependent promoters (P1, P2, and P3) located upstream of the *cpe* ORF. The abundant CPE expression during sporulation also depends on the exceptional stability of *cpe* mRNA (the functional half-life of *cpe* mRNA is approximately 60 min).

Unlike most *C. perfringens* toxins, CPE is not actively secreted; following its synthesis, the CPE protein accumulates in the cytoplasm of the mother cell as a cytoplasmic CPE-containing paracrystalline inclusion body. When sporulation events have been completed, the mother cell lyses with the simultaneous release of CPE into the intestinal lumen, in which then CPE acts as an enterotoxin.

Effects of CPE on the GI Tract

C. perfringens food poisoning is basically a self-limited illness in humans. Therefore, histopathologic studies have seldomly been conducted on humans. Instead, the actions of CPE have been examined using animal models. Using an *in vivo* rat or rabbit ileal loop model, CPE causes the loss of fluid and electrolytes from the GI tract and then produces extensive histopathologic damage to the small intestine; that is, the target organ for CPE is believed to be the small intestine, with the ileum being particularly sensitive to this toxin. CPE-induced histopathologic damage is initially limited to the villus tips of the small intestine; however, the entire small intestinal villus eventually suffers extensive damage over time: desquamation of the villus epithelium, inflammatory cell infiltration (mostly lymphocytes), and slight hyperemia in the mucosa. This CPE-induced tissue damage plays a major role in initiating CPE-induced fluid/electrolyte intestinal transport alterations; that is, the onset of fluid transport changes closely coincides with the development of tissue damage, and CPE levels that produce tissue damage can induce intestinal fluid and electrolyte transport alterations. CPE-induced intestinal damage can develop within 15–30 min of toxin treatment in the rabbit ileum.

The cellular actions of CPE were extensively investigated using a cultured intestinal epithelial cell line. These studies speculated that CPE would act in a multistep process. The current model for the actions of CPE begins with binding to the toxin-specific receptors, claudin-3 and claudin-4, in a temperature-sensitive manner. Claudins are a 24-member family of ~20 to 25 kDa proteins and are the most important proteins in epithelial tight junctions. These tight junction proteins are predicted to consist of four transmembrane domains, two extracellular loops, and cytoplasmic tail-mediating signal cascades. CPE binding to receptor claudin proteins is mediated by the second extracellular loop (at a helix–turn–helix motif) of the tight junction protein. CPE can bind to claudin-3, claudin-4, claudin-6, claudin-7, claudin-8, and claudin-14 (the contribution of claudins-8 and claudin-14 to CPE cytotoxicity is less than that of claudin-4), but not to claudin-1, claudin-2, claudin-5, or claudin-10. CPE–claudin binding rapidly results in the formation of an ~90 kDa small complex, which contains claudin families and claudin receptors along with claudins incapable of binding CPE (nonreceptor claudin(s)).

Within as little as 5 min of CPE binding, six small complexes are then thought to oligomerize into a stable large complex (~450 kDa), which initially assembles as a prepore and rapidly inserts into membranes to form an active pore. The formation of active pores causes the loss of normal plasma membrane permeability properties. These CPE-induced permeability alterations are initially restricted to small molecules of <200 Da, for example, calcium ions and amino acids. As a result of these events, CPE-treated cells die from classical caspase 3-mediated apoptosis at moderate levels of CPE, whereas cells die from oncosis at higher levels of CPE. Thus, large-complex formation is a necessary step in CPE-induced cytotoxicity.

CPE pore formation also leads to morphological damage, which allows the formation of a bigger large complex (~650 kDa). This ~650 kDa large complex contains another ~65 kDa tight junction protein, occludin. This event induces the further disruption of tight junctions.

Collectively, the involvement of tight junction proteins in the actions of CPE causes intestinal paracellular permeability changes. The overall sequence of events on CPE-treated culture cells is believed to lead to CPE's effects on the small intestine both *in vivo* and *in vitro*.

Tolerance of *C. perfringens* to Environmental Stress

Besides its toxin-producing ability, *C. perfringens* type A foodborne illness is commonly the result of inadequate handing of food during cooking, cooling, or holding. The biological properties of *C. perfringens* vegetative cells and spores in these settings contribute to its ability to cause food poisoning by enabling its survival and growth in cooked food; for example, resistance to heat, low temperatures, NaCl, and nitrates (typically used to process and protect foods). Of these tolerant properties to environmental stresses during cooking, extremely high heat tolerance has been a well-established property of *C. perfringens* vegetative cells and spores. The resistance of *C. perfringens* spores to heat is influenced by both environmental and genetic factors. Regarding environmental factors, the spores of *C. perfringens* food poisoning strains can survive boiling in a protective meat-based medium (e.g., cooked-meat medium). Incomplete heating can also induce the germination of *C. perfringens* spores. These resistant properties of spores are genetically based on the products of *ssp* genes, which encode a/b-type small acid-soluble proteins. The three previously identified *ssp* genes (*ssp1*, *ssp2*, and *ssp3*) in *C. perfringens* strains share identical sequences and are also expressed at similar levels in several *C. perfringens* isolates, including strains that produce heat-resistant or less heat-resistant spores. The novel *ssp* gene, *ssp4*, was recently identified. One of the *ssp4* gene products, the Asp Ssp4 variant, is harbored in most chromosomal *cpe* strains, and this variant mostly contributes to the extreme heat resistance of spores made by food poisoning strains with the chromosomal *cpe* gene. This gene product also appears to contribute to sodium nitrate resistance.

Pathogenesis of *C. perfringens* Type A Food Poisoning

Inappropriate cooking and preservation cause the rapid proliferation of the vegetative cells of enterotoxigenic *C. perfringens* in foods. While many ingested *C. perfringens* vegetative cells are likely killed due to the acidity of the stomach, some vegetative cells that survive pass through the stomach and remain viable in a sufficiently contaminated food vehicle (i.e., food containing 10^6–10^7 *C. perfringens* vegetative cells per gram). These surviving vegetative cells multiply and sporulate in the small intestine; hence, this illness is considered to be an infection, not an intoxication. A low-molecular-weight (1000–5000) sporulation factor, produced by both CPE-negative and CPE-positive vegetative cells, may promote *in vivo* sporulation. CPE is expressed during sporulation and then accumulates in the mother cells of *C. perfringens*. After mother cells lyse, CPE is released into the intestinal lumen, in which the CPE quickly binds to intestinal epithelial cells and exerts its action. These events induce fluid and electrolytes losses and also morphological damage to intestinal epithelial cells.

Epidemiology

C. perfringens type A food poisoning annually ranks among the most common foodborne diseases in the United States, Europe, and Japan. Identified outbreaks of *C. perfringens* type A food poisoning commonly involve large outbreaks (the average outbreak size is ~50 to 100 in United States) and often occur in institutions, such as hospitals, school cafeterias, prisons, and nursing homes. This epidemiological feature has largely been attributed to at least four factors. First, large amounts of food are prepared at once in institutions, which is a factor that increases the risk of contamination. Second, the preparation of large amounts of food is associated with insufficient heating, especially the 'core' region of food. Third, large amounts of food are often prepared in advance and held for later serving. These conditions appear to facilitate the growth of heat-tolerant bacterium in prepared food. Fourth, relatively mild and nondistinguishing symptoms develop in most cases of *C. perfringens* type A food poisoning; in other words, *C. perfringens* food poisoning with a small number of cases is not recognized or reported. Therefore, the true prevalence and impact of this foodborne disease appear to be significantly understated.

Molecular Characteristics of Food Poisoning Strains

Isolates from food poisoning outbreaks are mainly classified into three *cpe* genotypes based on the gene arrangement of the *cpe* region, as described earlier. Plasmid *cpe* strains have been identified as the pathogen in human GI diseases such as antibiotic-associated diarrhea, nosocomial diarrhea, and sporadic diarrhea and also as isolates in healthy human feces and environmental samples. Studies using recently developed PCR assays, which allow these '*cpe* genotypes' to be differentiated from each other, revealed that the plasmid *cpe* strain can induce *C. perfringens* type A foodborne outbreaks, similar to the chromosomal *cpe*-positive strains; isolates from approximately two-thirds of outbreak cases harbored the *cpe* gene on the chromosome, and plasmid *cpe* isolates were the causative strain in another one-third of cases. However, as other *cpe*-negative environmental strains, most of these plasmid *cpe* strains produce spores that are less resistant to high and low temperatures, NaCl, and nitrates, than the chromosomal food

poisoning strains. These properties are based on the genetic background of the plasmid *cpe* strains; plasmid *cpe* strains carry the *ssp4* gene, which encodes the less heat-resistant Ssp4 protein the Gly Ssp4 variant.

Source of Enterotoxigenic *C. perfringens* Strains in Food Poisoning Outbreaks

While common food vehicles for *C. perfringens* type A foodborne illness were initially thought to be meat and meat products (notably beef and poultry and gravies) in the United States, various foods have also been identified as a contaminated food in *C. perfringens* type A food poisoning outbreaks. In general, *C. perfringens* is ubiquitous in nature; it is present in soil (at levels of 10^3–10^4 CFU g^{-1}), foods (e.g., approximately 50% of raw or frozen meat contains some level of *C. perfringens*), dust, and the intestinal tract of humans and domestic animals (e.g., human feces typically contain 10^4–10^6 CFU g^{-1}).

In independent surveys investigating various kinds of environmental samples, some surveys identified both types (chromosomal or plasmid-borne) of *cpe*-positive isolates, while other surveys failed to detect *cpe*-positive strains in environmental samples. The reasons for the difficulty in detecting CPE-producing *C. perfringens* in environmental samples are as follows:

(1) Very low number of *C. perfringens* is present in retail food samples, while the *C. perfringens* strain is frequently present in retail food.
(2) Only a small subset of food isolates (less than 5%) can produce CPE, maybe even in putative reservoir(s).
(3) CPE is produced only during sporulation; however, it is sometimes difficult to induce the sporulation of isolates using several kinds of sporulation-specified media (e.g., Duncan–Strong medium).

Results from the limited number of surveys identifying *cpe*-positive strains in investigated samples revealed that *C. perfringens* strains carrying the *cpe* gene on a large plasmid are likely to be the main population in the environment, while the three *cpe* genotypes of the *C. perfringens* strain are broadly distributed. Therefore, foods could be accidentally contaminated with *cpe*-positive strains from the environment in any steps during food processing (Figure 1).

Interestingly, recent studies using molecular assays (multilocus sequence typing and microarray assays) revealed the genetic characteristics of chromosomal and plasmid *cpe* strains. The multilocus sequence typing (MLST) procedure has characterized isolates using the DNA sequences of approximately 450–500 bp internal fragments of multiple housekeeping genes. The different sequences present within isolates of each housekeeping gene have been assigned as distinct alleles, and, for each isolate, the alleles at each of the loci define the allelic profile or sequence type (ST). Using MLST assays, chromosomal *cpe* strains construct a distinct ST from plasmid *cpe* strains, *cpe*-negative strain, and type B to E veterinary strains.

Another molecular assay is a microarray assay, in which the property of nucleic acid sequences specifically pairs with each other between complementary nucleotide base pairs. With a

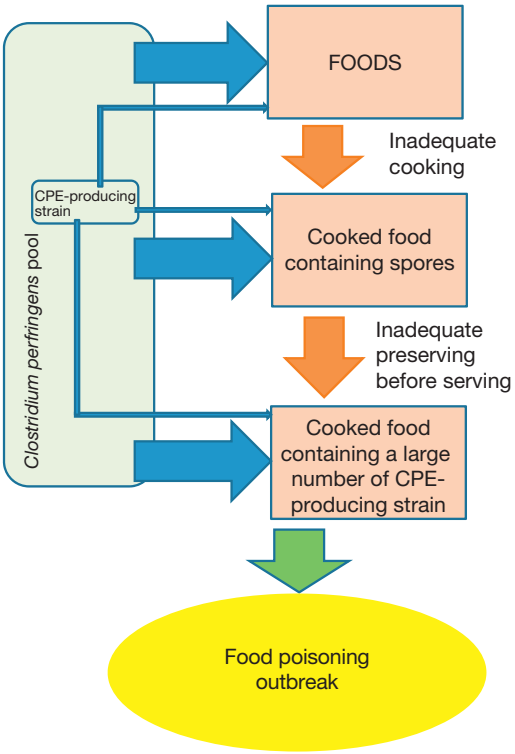

Figure 1 Events leading to *C. perfringens* food poisoning outbreaks, when accidentally contaminated with CPE-producing strain. Foods are more frequently contaminated with non-CPE-producing strains.

completely sequenced *C. perfringens* food poisoning strain genome-based DNA microarray assay, type A chromosomal *cpe* strains have different genetic backgrounds from type A plasmid *cpe* strains and *cpe*-negative type A strains; that is, the gene clusters of myo-inositol, ethanolamine, and biotin synthesis are absent in the variable region of chromosomal *cpe* strains, whereas the gene cluster of cellobiose metabolism is present. Combined with the results of MLST analysis for chromosomal *cpe* strains, chromosomal *cpe* strains and plasmid *cpe* strains are likely to have different habitats in the environment; plasmid *cpe* strains might have adapted to the mammalian intestine environment, while chromosomal *cpe* strain might be present in environments with plant materials.

The principal reservoir(s) of *C. perfringens* type A food poisoning strains has not been examined in detail. The development of a method(s) capable of detecting low numbers of bacterial cells is required to further investigate the source of CPE-producing *C. perfringens* in environmental samples because contaminated samples commonly contain a low number of CPE-producing *C. perfringens* with a small subset of total *C. perfringens* isolates. Unfortunately, the current standard procedures established to diagnose *C. perfringens* food poisoning are only able to detect large numbers of *cpe*-positive strains in samples. Several assays based on the methods of 'microbial source tracking' might be useful for detecting low numbers of vegetative cells and/or spores in environmental samples.

In the future, epidemiological surveys using assays, which can differentiate between the genetic backgrounds of *cpe*-positive and *cpe*-negative strains and are based on microbial

source tracking, help to understand the *cpe*-positive *C. perfringens* habitat in the environment, and based on these epidemiological findings, candidate(s) of native reservoirs of chromosomal and/or plasmid *cpe*-positive *C. perfringens* strains would be identified.

Clinical Features

Food poisoning outbreaks due to type A enterotoxigenic *C. perfringens* typically involve a large number of cases. The primary clinical symptoms associated with food poisoning are moderately severe abdominal cramps, nausea, and watery diarrhea; vomiting and fever are rare. Symptoms of food poisoning by type A *C. perfringens* strains develop 8–24 h after the ingestion of food heavily contaminated with the organism. The illness is generally self-limited but typically lasts 12–24 h. Mild symptoms may last 1 or 2 weeks in some cases.

Fatalities are very rare, occurring in $<0.05\%$ of cases. While everyone is susceptible to *C. perfringens* type A food poisoning, fatalities are commonly caused by dehydration and occur among the very young, very old, debilitated, and chronically ill individuals. Three foodborne outbreaks of CPE-producing strains with fatalities have recently been reported, and isolates in these outbreaks were identified using PCR assays as a type A strain harboring the *cpe* gene on the chromosome. Of these outbreaks, fatalities were attributed to necrotizing colitis, which has features similar to those of necrotizing enteritis caused by the *C. perfringens* type C strain. These fatal cases had nausea and vomiting in addition to abdominal cramps and watery diarrhea.

Diagnosis

A diarrheal disease is difficult to identify as a foodborne illness due to enterotoxigenic *C. perfringens* in a clinical setting. For example, the clinical symptoms and degree of severity of foodborne diseases by *C. perfringens* and *B. cereus* are very similar. Therefore, a laboratory investigation must be performed to identify a diarrheal disease as food poisoning caused by CPE-producing *C. perfringens*.

The most conventional diagnostic criterion to identify *C. perfringens* type A food poisoning outbreaks is the detection of CPE in the feces of patients. However, the usefulness of fecal CPE detection approaches for identifying *C. perfringens* food poisoning outbreaks is limited because fecal samples from suspected cases must be collected soon after the onset of food poisoning symptoms to ensure meaningful results. Serological assays such as the reversed-passive latex agglutination assay and enzyme-linked immunosorbent assay are used to detect CPE in properly collected fecal samples. The detection of CPE in the feces of several patients, who exhibit a common clinical features (common food consumption, typical incubation time, and characteristic symptoms), provides compelling evidence for the occurrence of *C. perfringens* type A food poisoning, while nosocomial type A *C. perfringens* outbreaks rarely occurred via contaminated environments, mainly lavatory equipment.

Further laboratory analyses including bacterial isolation and species identification are reliable approaches to identify *C. perfringens* type A food poisoning. For example, in the United States, bacteriologic criteria used by the Centers for Disease Control and Prevention (CDC) to identify an outbreak include demonstrating the presence of either (i) 10^5 *C. perfringens* organisms per gram of stools from two or more patients or (ii) 10^5 *C. perfringens* organisms per gram of epidemiologically implicated food.

Only demonstrating the presence of *C. perfringens* in suspected food or the feces of patients is insufficient for the unequivocal identification of *C. perfringens* type A food poisoning because *C. perfringens* is ubiquitous and is found in raw food and the GI tracts of healthy individuals. Therefore, to identify food poisoning outbreaks caused by type A *C. perfringens*, isolates from suspected cases should be identified as the type A CPE-producing *C. perfringens* strain. Culture samples using spore-formation medium (such as Duncan–Strong medium) are used to investigate the ability of foodborne disease isolates to produce CPE. However, a definite protocol for CPE expression by food poisoning isolates has not yet been established. Moreover, the *in vitro* sporulation of food poisoning isolates is often difficult to achieve under laboratory conditions.

Instead of investigating CPE-producing ability, molecular assays, for example, simple PCR assays, are available to specifically detect the *cpe* gene. The *cpe* gene must be functional in most, if not all, *cpe*-positive strains because the *cpe* region in the *cpe*-positive *C. perfringens* strains examined, which can produce CPE during *in vitro* sporulation, has almost identical sequences, such as the ORF sequence of the *cpe* gene, upstream sequence of the *cpe* ORF including SigK- and SigE-dependent promoters, and ribosome-binding sites. Developed PCR assays can relatively easily detect the presence of the *cpe* gene carried by *C. perfringens* strains in properly collected contaminated food samples and/or fecal samples from patients with *C. perfringens* type A food poisoning. However, many protocols for the *cpe*-detecting PCR assay also detect the *cpe* gene in type C and type D *C. perfringens* and the *cpe* pseudogene in type E strain; that is, PCR assays detecting the *cpe* gene must be meaningful when combined with PCR assays identifying the *C. perfringens* toxin genotype.

CPE-positive strains must be present, even at very low frequencies, in various foods, healthy human feces, and the environment. Therefore, similarities must be investigated between isolates from feces and suspected food to more strictly diagnose cases and identify contaminated food in foodborne illnesses. To investigate similarities or differences between *cpe*-positive isolates in these samples, identifying the serotype and/or genotype (such as the pulsed-field gel electrophoresis type) of CPE-producing isolates can be an alternative and supplemental approach for diagnosing *C. perfringens* type A food poisoning outbreaks.

Treatment and Prevention

The clinical symptoms of *C. perfringens* type A food poisoning are commonly mild and the clinical course is self-limited. Antibiotic treatment is typically not required. Rehydration

drinks containing important electrolytes are useful for managing the dehydration caused by diarrhea.

CPE-producing *C. perfringens* strains are broadly distributed in the environment, including foods, soil, and kitchen surfaces. Therefore, contamination events to food may occur during the cooking process (food ingredients, cooking, and preserving) (**Figure 1**). For this reason, completely protecting against *C. perfringens* contamination to food(s) is likely to be difficult. Fortunately, a large number of CPE-producing bacterial cells are needed to induce *C. perfringens* food poisoning, which is because many ingested *C. perfringens* vegetative cells are killed when exposed to the acidity of the stomach. Collectively, the most important factors preventing and controlling *C. perfringens* type A foodborne illness are 'careful cooking' and 'careful storage,' which prohibit the vegetative growth of *C. perfringens* in cooked foods. Therefore, reducing the total amount or size of food for heating and cooling (it is difficult to archive high internal temperatures in large amounts of food), appropriate storage at less than 10 °C for cooked foods before serving (growth rates of *C. perfringens* vegetative cells rapidly decrease at temperatures below ~15 °C, with no growth occurring at 6 °C), and the immediate consumption of served foods as soon as possible are the best ways to prevent *C. perfringens* food poisoning.

Biologically, the growth of *C. perfringens* strains is affected by water activity (a_w), reduction potential (E_h), pH (optimal growth at pH 6 to 7), and chemical preservatives (e.g., NaCl). These preservation factors also control the growth of *C. perfringens* vegetative cells and inhibit the outgrowth of germinating *C. perfringens* spores in food.

Clostridium: Occurrence and Detection of *Clostridium botulinum* and Botulinum Neurotoxin

Introduction

Botulinum neurotoxin (BoNT)-producing clostridia normally called *Clostridium (C.) botulinum* are, from the genetic and physiological points of view, a diverse taxonomic group. The group comprises Gram-positive, anaerobic, rod-shaped, spore-forming bacteria that produce the most toxic biological substance known, botulinum neurotoxin (BoNT). Foodborne botulism is a neuroparalytic disease resulting from neurotoxin-induced inhibition of skeletal and autonomic peripheral cholinergic nerve terminals. It results from consumption of food in which *C. botulinum* has grown and produced botulinum toxin. Without prompt diagnosis and treatment, the resulting cranial neuropathy and symmetrical, descending flaccid paralysis may progress to respiratory failure and death.

BoNTs are 150 kDa proteins produced by *C. botulinum* or neurotoxigenic strains of *C. butyricum* or *C. baratii*. Maximal potency of BoNTs is only obtained after cleavage of the 150 kDa polypeptide into a 100 kDa heavy chain (HC) and a 50 kDa light chain (LC) linked by a single disulfide bond. The HC binds to receptors on neurons and enables the internalization of the LC, a zinc metalloprotease, into presynaptic neurons at the neuromuscular junction. The internalized LC cleaves one of the soluble *N*-ethylmaleimide-sensitive attachment receptor (SNARE) proteins. The LC of BoNT type A cleaves synaptosomal-associated protein 25 (SNAP-25), whereas the LC of BoNT type B cleaves synaptobrevin-2. Cleavage of these proteins prevents the docking of small synaptic vesicles with the presynaptic membrane, preventing the release of acetylcholine into the neuromuscular junction and resulting in flaccid paralysis of the corresponding muscle.

Seven serologically distinct BoNTs (A–G) can be distinguished based on neutralization of toxicity with specific antisera. Recently, a strain of *C. botulinum* producing BoNT type B and another BoNT that is not neutralized by antitoxins to BoNTs A–G has been isolated from a case of infant botulism. It has been proposed that this novel neurotoxin is an eighth serotype – BoNT type H. While sequence data have not yet been made available, genomic studies have indicated that BoNT type H differs substantially from the other seven BoNT serotypes. Human botulism, including foodborne, wound, and infant botulism, is associated with types A, B, E, and, very rarely, F. The majority of cases of animal botulism are caused by type C; cattle and sheep are also particularly susceptible to botulism caused by type D. To date, there is no direct evidence linking type G to disease.

Based on physiological differences, and now supported by whole genome sequencing, *C. botulinum* is divided into four groups: (I) all type A and proteolytic strains of types B and F, (II) all type E and nonproteolytic strains of types B and F, (III) type C and D strains, and (IV) type G strains. Strains producing two toxin types have been reported, as have those producing only one type of toxin but carrying a silent gene for a different toxin type. Groups I and II are commonly referred to as 'proteolytic' and 'nonproteolytic' strains, respectively. Proteolytic strains are relatively resistant to heat and preservatives such as salt, acidulants, and nitrite. They are therefore the most likely forms involved in outbreaks from underprocessed canned foods or from salted, pickled, and otherwise cured products. Exceptions are some dry- and brine-cured hams and pickled fish where *C. botulinum* may develop before the diffusion of the main ingredients conferring safety (e.g., salt and acid) is complete. With few exceptions, infant botulism is caused by proteolytic strains of *C. botulinum*. As a result of their sensitivity to heat and ability to grow at refrigeration temperatures, group II, or nonproteolytic, strains present a risk of botulism from minimally processed packaged foods that have extended shelf lives at refrigeration temperatures. In a few exceptional cases, other clostridia (*C. baratii* producing type F toxin and *C. butyricum* producing type E toxin) have been implicated in foodborne botulism incidents. Type E is the prevailing form of *C. botulinum* in aquatic environments and the most likely form of botulism from preserved fish. Type E is also the main cause of botulism involving the indigenous population of Canada and Alaska. The emphasis here will be on groups I and II since they are involved in human illness. Strains belonging to group III are involved with animal botulism. This article discusses the distribution of botulinum spores in the environment and in foods and detection of the organism and its neurotoxin in foods.

Presence of *C. botulinum* in the Environment

Spores of *C. botulinum* are commonly present in soils and sediments, but their numbers and types vary, depending on the location. The possibility of contamination of food with *C. botulinum* depends on the distribution and incidence of spores in the environment where the food originates.

C. botulinum spores are widely distributed in North America, but the spore load varies considerably, as does the predominating type. Soils in the United States west of the rise of the Rocky Mountains usually contain type A spores, while type B spores predominate in the Eastern United States. Most US type B strains are proteolytic. *C. botulinum* type E is found in damp to wet locations. In the region around the Great Lakes, and particularly around Green Bay of Lake Michigan, high numbers of type E are found in shoreline and sediment samples. Type E is also found in the coastal areas of Washington and Alaska. The distribution of types on the Pacific coast changes with latitude; south of 36N, the prevalent types shift from E to A and B.

Type B predominates in the terrestrial environments of Britain, Ireland, Iceland, Denmark, and Switzerland. It is associated with most botulism outbreaks in Spain, Portugal, Italy, France, Belgium, Germany, and Poland, indicating wide

distribution of this type in the European environment. Type B also predominates in the aquatic environments of the United Kingdom. Most European type B strains are nonproteolytic.

C. botulinum type E predominates in marine and freshwater environments in temperate to subarctic regions. High incidences of *C. botulinum* type E have been recorded from the Nunavik region of Quebec, the northwest coast of Alaska, the Great Lakes, and lakes and rivers of North Japan. High levels of type E spores were found in Scandinavian waters, particularly in the Kattegat, between Denmark and Sweden, and in the Baltic Sea. The presence of high numbers of *C. botulinum* type E in these regions suggests a terrestrial origin of the organism and passive accumulation from land drainage. Type E spores also predominate in the Ukraine and most parts of Russia. High numbers of type E botulism outbreaks associated with fish caught from Lake Baikal suggest a high prevalence of *C. botulinum* type E in the Irkutsk region of Russia. In general, surveys of Asia report lower numbers, with the exceptions of a high incidence of type E spores around the Caspian Sea and a high incidence of all types in the Xinjiang district of China.

Fewer surveys have been carried out in the southern hemisphere. Spores of all types have been detected in South America. In a study of over 2000 Argentine soil samples, 23.5% tested positive for BoNT-producing clostridia, with type A being the most frequently detected. *C. botulinum* type E has been found in fish, oyster, and shrimp samples taken off the Brazilian coast.

As a result of its role in outbreaks of avian botulism across the world, the distribution of *C. botulinum* type C has been widely studied. Based on both surveys and recorded cases of animal botulism, *C. botulinum* type C has been found in several countries including Australia, Japan, Korea, Canada, the United States, Costa Rica, Spain, Sweden, Finland, Germany, Ireland, Italy, Norway, Brazil, South Africa, and Turkey. Genetic recombination between *C. botulinum* type C and type D strains has resulted in *C. botulinum* strains producing a mosaic C/D type toxin. Chimeric type C/D toxin is more lethal to avian species than either type C or type D. Type C botulism has become an emerging and serious problem in poultry flocks in Sweden, causing 13 separate outbreaks in 2008. Recent molecular typing evidence indicates the type C/D strain responsible for avian botulism outbreaks in waterbirds in Spain shares a very high level of genetic similarity with the strains responsible for the Scandinavian outbreaks in poultry flocks. *C. botulinum* type D is the cause of botulism outbreaks in cattle in several parts of the world including parts of the United States, Canada, Australia, Israel, Turkey, Germany, South Africa, and the Netherlands.

In summary, type A spores predominate in soils in the Western United States, China, Brazil, and Argentina, and type B spores in the Eastern United States, the United Kingdom, and much of continental Europe. However, most US type B strains are proteolytic, while most European strains are nonproteolytic. Type E is the predominant type in northern regions and in most temperate aquatic regions and their surroundings. Types C and D are found more frequently in tropical environments. The reasons for this distribution pattern are not well understood. Type A appears to favor neutral to alkaline soils with low organic content, consistent with its virtual absence in the highly cultivated soils of the Eastern United States and Europe. Type B strains predominate in heavily farmed soils in Argentina, Denmark, and the United States. Type E is psychrotolerant, which undoubtedly plays a role in its prevalence in the north and in many aquatic environments. Based on outbreaks in wild and domestic animals, *C. botulinum* types C and D can be found over most continents.

Presence of *C. botulinum* in Foods

Spores of *C. botulinum* are widespread in nature and are found in soils, aquatic sediments, and the gastrointestinal tracts of animals. Contamination of food with *C. botulinum* often occurs during growth or harvesting and is most likely to occur when a product originates in an environment with a high incidence of spores. However, contamination can also occur during or after processing. There have been considerably fewer surveys of foods for contamination with *C. botulinum* than environmental surveys, and they have focussed primarily on fish, meats, and infant foods, particularly honey.

Fish may become contaminated with spores of *C. botulinum* in their environment or during processing and handling. The presence of *C. botulinum*, mostly type E, in fish is readily demonstrated, although the incidence is lower than in environmental surveys. For example, 20% of the fish caught in the Baltic Sea and Finnish freshwaters tested positive for *C. botulinum* type E, while 7% of vacuum-packed hot-smoked products marketed in Finland contained spores of the organism. Other studies have indicated a range from 0% to 100% of fishery products testing positive for *C. botulinum* type E. Most fish-borne botulism outbreaks recorded in Canada, the United States, Russia, Europe, Japan, Egypt, and Iran have been linked to the consumption of smoked, salt-dried, canned, or fermented fish usually eaten without further cooking.

The level of contamination of meats is generally very low, relative to the incidence on fish and fishery products. The few studies indicate that the incidence of *C. botulinum* in meat samples is often less than 10%, and several studies have not been able to detect *C. botulinum* in meats. The concentration of spores in meat is typically <1 spore per kg, with the exception of raw pork and vacuum-packed bacon in the United Kingdom, where some samples had up to 7 spores per kg. Survey results reveal that nearly all toxin types identified from cured meat, raw pork, vacuum-packed bacon, and liver sausage were either type A or type B. *C. botulinum* types A and B are the two serotypes most often associated with botulism outbreaks from meat products. The presence of low numbers of *C. botulinum* in pig and cattle's feces indicates carriage of *C. botulinum* by healthy animals and suggests contamination of carcasses with *C. botulinum* during carcass dressing.

C. botulinum types A or B may be present on vegetables, particularly those harvested from the soil. *C. botulinum* is common in soil and organic fertilizers, usually at low concentrations. However, one survey reported 25 000 spores per kg in soil in China. One product of particular concern is cultivated mushrooms, in which up to 2100 type B spores per kg have been detected. As a result of the relatively frequent occurrence of botulism outbreaks resulting from canned vegetables in California in the early part of the twentieth century, an extensive survey of vegetables from markets and gardens was

conducted. Fruits and vegetables, including asparagus, beans, carrots, celery, corn, lima beans, olives, potatoes, turnips, apricots, cherries, and peaches, all tested positive for *C. botulinum*, primarily type A. Improperly processed or temperature-abused vegetable products, including baked potato, potato salad, carrot juice, olives, mushrooms, bean curd, and onions, have all been implicated in foodborne botulism outbreaks. Home-canned vegetables including beans, carrots, asparagus, and vegetable products stored in oil including garlic in oil and eggplant in oil present an especially high risk of foodborne botulism.

Spores in honey and other infant foods pose a unique hazard because, in some infants, the spores are able to colonize the intestines, produce toxin, and cause infant botulism. By 1984, honey had been implicated as the likely source of botulinum spores in 20 cases of infant botulism in California. Surveys for the presence of *C. botulinum* spores in honey suggest that the incidence ranges from 2% to 26% of samples depending upon the geographic source of honey, with spore levels in random samples of honey in the order of 1–10 spores per kg. However, in honey samples associated with infant botulism, the level is approximately 10^4 spores per kg. The pasteurization process applied to honey is used to inactivate osmophilic yeasts and prevent granulation, but is not sufficient to inactivate spores of *C. botulinum*. Other infant foods have also been examined. While *C. botulinum* has been detected in samples of corn syrup and rice cereal, exposure of infants to botulinum spores via these foods seems to be minimal as the spore levels are low and spores are unlikely to multiply during manufacture and storage. Due to the risk for infant botulism, health authorities in several countries recommend that honey should not be given to infants less than 1 year of age.

Dairy products are rarely vehicles for botulism outbreaks. Six reported outbreaks of botulism caused by cheeses, primarily cottage cheese, occurred in California and New York between 1912 and 1951. One of these outbreaks occurred in Albany, New York, in 1914 and resulted in the death of three persons and was one of the first reported outbreaks caused by *C. botulinum* type B. In October 1993, eight cases resulted after eating a potato stuffed with meat and a commercial cheese sauce. In August 1996, an outbreak of botulism in Italy affected eight people after consumption of mascarpone cheese, either alone or as a component of the desert tiramisu.

Detection of *C. botulinum*

Safety Precautions When Working with *C. botulinum* or BoNT

The extreme toxicity of BoNT requires that specific safety procedures be followed when working with cultures containing *C. botulinum* and BoNT. With the rare exception of wound botulism, *C. botulinum* is noninfectious in healthy adults. As a result of its noninfectious nature, *C. botulinum* is a containment level 2 organism. In Canada, procedures generating significant quantities of toxin, or aerosol formation of toxin, require BSL3 laboratory facilities. All personnel engaged in handling toxic materials must be fully informed about the hazards, and all materials to be autoclaved should be contained in stainless steel boxes with handles. Therapeutic antisera must be available in case of accidental intoxication. Potentially toxic materials should always be contained in unbreakable, leak-proof trays or boxes. This is particularly important in the incubation or manipulation of botulinal cultures, which may contain in excess of 10^5 mouse LD per ml. If toxin should be spilled, it must be inactivated immediately with 0.1 N NaOH.

Traditional Culture Methods

Prevalence rates for *C. botulinum* in foods are not readily available, mainly because of the cost and difficulties of detecting the organism in foods. *C. botulinum* is traditionally detected by enriching food or environmental samples for spores, followed by broth culture and detection of BoNT in the culture supernatant. Common enrichment media for detecting viable *C. botulinum* are cooked meat medium (CMM), CMM glucose, chopped meat glucose starch medium, and tryptone–peptone–glucose–yeast extract (TPGY) broth to which trypsin may be added. Trypsin is necessary to activate the toxin produced by group II organisms and may also inactivate potential inhibitors of *C. botulinum* such as bacteriocins in mixed cultures. While foods may be inoculated directly, the sediments of centrifuged samples are preferred because potential growth inhibitors are removed. At least two tubes of media are inoculated. One is heated at 75–80 or 60 °C, depending on whether the suspected type belongs to group I or II, to select for spores. Alternatively, spores of group II may be selected by holding samples in 50% alcohol for 1 h before inoculation. The other tube is incubated without any heating to allow development of vegetative *C. botulinum* cells in cases where few or no spores are suspected. Adding lysozyme to the medium may increase recovery of heat-injured spores. Group I strains grow optimally at 37 °C, while group II strains have an optimal growth temperature of 30 °C. *C. botulinum* is identified after incubation of the enrichment medium by toxin analysis of the supernatant fluid. Botulinal toxin is detected by injecting serum or extracts from foods and clinical specimens into mice, observing these for lethality, and neutralizing the toxin with specific antisera.

It is not necessary to isolate *C. botulinum* in pure culture from foods in order to demonstrate its presence. If the neurotoxin is present in the nonselective culture after incubation, the toxin-producing organism must have been originally present. If an enrichment culture tests positive for either *C. botulinum* type B or F, the organism must be isolated to determine whether the strains belong to group I or group II. *C. botulinum* can be isolated by streaking toxic enrichment cultures onto *C. botulinum* isolation (CBI) agar. CBI agar is supplemented with cycloserine, sulfamethoxazole, and trimethoprim to inhibit background flora and egg yolk for detection of lipase-positive colonies. Suspect lipase-positive colonies showing spreading and an irregular edge may be picked and restreaked for isolation. Many other common clostridia, such as *C. sporogenes*, produce a lipase reaction on agar plates containing egg yolk. Isolates are grown in TPGY or CMM broth, and toxicity of the culture supernatant confirms identity of the isolate as a neurotoxigenic clostridium. It is important to note that *C. butyricum* is lipase-negative; therefore, *C. butyricum* strains producing type E toxin will appear as lipase-negative colonies on CBI agar. Colony immunoblotting to detect

individual botulinum toxin-producing colonies on an agar plate is a sensitive method for isolation from enrichment cultures with a high background flora.

As an alternative to testing enrichment cultures, or pure cultures, with the mouse assay to detect BoNT, polymerase chain reaction (PCR) can be used to detect the presence of genes encoding BoNT. Multiplex PCR assays (both conventional and real-time-PCR) have been developed to allow simultaneous detection of *botA*, *botB*, *botE*, and *botF* genes in a single reaction. These multiplex PCR reactions allow screening of many samples at once, with the advantages of reduced time to detection without a requirement for use of live animals. Application of multiplex PCR to isolated colonies also allows identification of bot-containing colonies, facilitating isolation of botulinogenic clostridia. As PCR does not detect botulinum toxin, the possibility exists that clostridial strains with silent BoNT genes may be detected, resulting in a false-positive result. PCR has also been used for molecular characterization of *C. botulinum* based on the sequences of the neurotoxin and flagellin genes.

When *C. botulinum* is present in food or environmental samples, it is typically present in low concentrations (<1 to 1000 spores per kg). Quantitative estimates of such low numbers require the use of broth cultures and most probable number (MPN) analysis. Depending on the precision required, three or five tube MPN tests are performed in a similar manner described earlier for the detection of *C. botulinum*. Toxicity testing for the large number of samples involved in MPN analysis is facilitated by using an *in vitro* assay, in place of the standard mouse bioassay.

Detection of BoNT

BoNTs are extraordinarily potent with the parenteral human lethal dose estimated to be 0.1–1 ng kg^{-1} and the oral lethal dose estimated at 1 μg kg^{-1}, thereby requiring an extremely sensitive assay for detection.

Mouse Bioassay

BoNTs are recognized by their lethal action in mice and neutralization with specific antisera. The sample, or an extract prepared by homogenizing it in gelatin phosphate buffer, is clarified by centrifugation and filter sterilized. Trypsin treatment may be required to activate low levels of toxin from nonproteolytic strains. The prepared sample is injected intraperitoneally into mice with and without neutralization with antitoxin. Typical symptoms of botulism are ruffled fur, pinched waist, labored breathing, limb paresis, and general paralysis before death. The time required to onset of symptoms is dependent upon the concentration of toxin in the extract, with symptoms typically occurring within the first 24 h postinjection. Definitive results are obtained if mice injected with untreated sample display symptoms within 72 h, while mice injected with neutralized sample do not display symptoms. The use of an end point earlier than death is encouraged, as ruffled fur, pinched waist, and labored breathing are typical and easily observable signs of botulinum toxin. The mouse bioassay has several advantages including high sensitivity (approximately 10 pg of botulinum toxin) and is sufficiently robust to detect botulinum toxins in a wide range of sample matrices including feces, serum, gastric liquid, a wide range of food samples, and supernatants of bacterial cultures. In addition, the mouse bioassay is the only assay capable of detecting all serotypes, including any possible new serotypes, of BoNTs. In addition to the obvious ethical objection of sacrificing animals, the mouse bioassay has the disadvantages of being slow, expensive, and low throughput.

A refinement of the typical mouse bioassay, nonlethal mouse assays involve subcutaneous injection of mice and observation for flaccid paralysis of muscle near the injection site. Subcutaneous injection at the inguinocrural region in mice has been demonstrated to yield sensitivity results comparable to the typical mouse assay. A nonlethal mouse toe-spread reflex model has been used to detect botulinum toxins in buffer, serum, and milk samples at sensitivities similar to the typical mouse bioassay. Preincubation of samples with specific antitoxins prevents development of paralysis, allowing identification of toxin serotype with these methods. *Ex vivo* assays, using rat or mouse phrenic nerve diaphragm, and the rat intercostal muscle strips assay allow several tests from tissues of a single animal.

Immunologic Assays

The earliest immunologic assays used to detect botulinum toxins included passive agglutination and immunodiffusion assays. Enzyme-linked immunosorbent assays (ELISAs) were first developed for BoNT in the late 1970s and were capable of detecting approximately 400 mouse lethal doses (1 MLD is approximately 10 pg of neurotoxin). Improvements in ELISA technology, such as use of capture antibodies in a sandwich ELISA and generation of specific monoclonal antibodies for capture and detection, have increased the sensitivity of ELISA detection of botulinum toxins to less than one mouse lethal dose per ml of food matrix. Traditional ELISAs used alkaline phosphatase or horseradish peroxidase to cleave a chromogenic substrate. Reporters using signal amplification or chemiluminescence have further increased the sensitivities of immunoassays. Lateral flow assays are rapid and easy to perform with minimum requirements for laboratory equipment or skills. The sensitivity of lateral flow assays is in the range of 5–20 ng, approximately 1000 times less sensitive than the mouse bioassay. Some commercial lateral flow assays have been reported to be limited by matrix effects and have been recommended only for rapid detection of botulinum toxin in bacterial cultures.

Endopeptidase Assays

Development of *in vitro* assays to detect botulinum toxins has accelerated as a result of increased investment to defend against biological threat agents, and also assays are used for potency testing for lot release of therapeutic BoNT (e.g., Botox, Dysport,

or Xeomin). The discovery that botulinum toxin is a specific endopeptidase has led to the development of several assays that rely on detection of the endopeptidase activity of the LC. These assays typically employ a peptide containing a sequence from one of the substrate proteins – SNAP-25, synaptobrevin, or syntaxin. Cleavage of the peptide is measured by several methods including generation of a bioluminescent signal through cleavage of a SNAP-25 luciferase fusion protein, changes in fluorescence emission ratios using fluorescence resonance energy transfer (FRET), and detection of cleavage products using mass spectrometry. Most of the assays relying on endopeptidase activity require an initial step to remove interfering substances and concentration of the neurotoxin. This step often employs immunomagnetic 'pulldown' using magnetic beads coated with antibody to the neurotoxin HC. Endopeptidase assays have the advantage over immunoassays of detecting only botulinum toxins with endopeptidase activity, and not inactive toxins.

Cell-Based Assays

Cell-based assays take detection of biological activity even further by providing a model for BoNT detection that provides information on the activity of the BoNT preparation. This includes cell surface binding, endocytosis, translocation of the LC into the cellular cytosol, and enzymatic activity of the LC on SNARE substrates. This makes cell-based assays ideal for high-throughput screening for botulinum toxin inhibitors. In addition, cell-based assays may present a more accurate indication of the biological activity of therapeutic preparations of BoNTs. The drawbacks of cell-based assays are their limited sensitivity in comparison to the mouse assay and *in vitro* endopeptidase assays, and the difficulty in obtaining quantitative results. Cell-based assays also require the maintenance of cell cultures and take much longer to obtain results, when compared to other *in vitro* assays.

Introduction

Vitamin B12 is the largest and most complex of all the vitamins. The name vitamin B12 is generic for a specific group of cobalt-containing corrinoids, also known as cobalamins, with biological activity in humans. Cobalt gives this water-soluble vitamin its red color. The main cobalamins in humans and animals are hydroxocobalamin, adenosylcobalamin, and methylcobalamin, the last two being the active coenzyme forms.

Although vitamin B12 was isolated almost 60 years ago, its metabolism remains incompletely defined. In practice, cobalamin metabolism is complex and requires many processes and steps, any one of which, if not present, may lead to cobalamin deficiency. Table 1 enumerates the elements establishing the definition of cobalamin deficiency.

This article summarizes the current knowledge on cobalamin metabolism and disorders.

Vitamin B12 Ingestion and Related Disorders

Vitamin B12 is produced exclusively by microbial synthesis in the digestive tract of animals. Therefore, animal protein products are the source of vitamin B12 in the human diet, in particular organ meats (liver and kidney). Other good sources are fish, eggs, and dairy products. In foods, hydroxo-, methyl-, and 5′-deoxyadenosyl cobalamins are the main cobalamins present.

A typical Western diet contributes 3–30 μg of cobalamin per day. The recommended dietary allowance set by the Food and Nutrition Board of the Institute of Medicine (the United States) is 2.4 μg day^{-1} for adults and 2.6–2.8 μg day^{-1} during pregnancy.

Table 2 describes through a synthetic view the different stages of vitamin B12 metabolism used in clinical practice and the corresponding causes of cobalamin deficiency. In clinical practice, vitamin B12 deficiency caused by dietary deficiency is rare.

The dietary causes of deficiency are limited to elderly people who are already malnourished, such as elderly patients living in institutions (they may consume inadequate amounts of vitamin B12-containing foods) or in psychiatric hospitals (strict vegetarians). Studies focussing on elderly people, particularly those who are in institutions or who are sick and malnourished, have suggested a cobalamin deficiency prevalence of 30–40%. The Framingham Study demonstrated a prevalence of 12% among elderly people living in the community. Using a stringent definition, a prevalence of 5% had been reported in a group of patients followed or hospitalized in a tertiary reference hospital.

A dietary cause of cobalamin deficit or deficiency was also found in newborns from strictly vegetarian pregnant women.

Vitamin B12 Digestion and Related Disorders

Dietary vitamin B12, which is bound to proteins in food, is released in the acidic environment of the stomach where it is rapidly complexed to the binding protein and transporter haptocorrin (HC), also referred to as the R-binder or transcobalamin I. About 80% of circulating cobalamin is bound to HC, and serum cobalamin levels have been correlated with serum HC concentrations. Although some unexplained low serum cobalamin concentrations were reported to be caused by mild to severe HC deficiencies, these abnormalities were not accompanied by pernicious anemia and are not thought to cause functional cobalamin deficiency.

Cobalamin continues its route in the gastrointestinal tract and dissociates from HC under the action of pancreatic proteases. Then, cobalamin is associated in the intestine with the intrinsic factor (IF, also known as the S-binder). This complex is essential for the ileal absorption of cobalamin (Table 2).

Digestion disorders related to vitamin B12 deficiency are mainly represented by food-cobalamin malabsorption (FCM) syndrome. This syndrome is characterized by the inability of the body to release cobalamin from food or intestinal transport proteins, particularly in the presence of hypochlorhydria (therefore, the appropriated denomination is 'maldigestion'). The principal characteristics of this syndrome are listed in Table 3.

FCM accounted for at least half of subtle or clinical documented cobalamin deficiency in elderly patients (60–70% in our experience). FCM is caused primarily by atrophic gastritis, related or not to chronic carriage of *Helicobacter pylori*. Other factors that mainly contribute to FCM are long-term ingestion of antacids, such as H2 receptor antagonists and proton pump inhibitors, particularly among patients with Zollinger–Ellison syndrome, and biguanides (metformin). In addition, other FCM inducers include chronic alcoholism, surgery or gastric reconstruction (e.g., bypass surgery for obesity), and partial exocrine pancreatic failure.

It is to note that in the case of FCM, patients can absorb 'unbound' cobalamin through IF or passive diffusion mechanisms. Thus, the recognition of the syndrome permits new developments of oral vitamin B12 therapy.

At this level, it is also important to note that several homozygous nonsense and missense mutations in the gene encoding the gastric IF have been reported to cause hereditary juvenile cobalamin deficiency.

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00174-4

Vitamin B12 Absorption and Related Disorders

Absorption depends mainly on IF, which is secreted by the gastric mucosa. IF binds cobalamin forming a complex that is absorbed by the terminal ileum (Table 2). This complex is located at the apical side of brush border membranes (BBMs) of polarized epithelia, such as the intestinal apical BBM. It consists of the IF–vitamin B12 receptor named cubilin, a 460 kDa peripheral membrane glycoprotein, encoded by the *CUBN* gene, which was mapped to chromosomal region 10p12.33-p13, and the 48 kDa amnionless protein encoded by the *AMN* gene, a gene essential for mouse gastrulation and localized on human chromosome 14.

The human megalin/gp330/LRP2 receptor, encoded by the LRP2 gene located on chromosome 2q24-q31, is a giant endocytic receptor (600 kDa) of the low-density lipoprotein receptor family that was strongly suggested to play an important role in the stability of the cubilin–AMN complex.

The mechanism of vitamin B12 absorption through the complex IF–cubilin–AMN is Ca^{2+}-dependent.

Mutations in CUBN 7 were reported to cause hereditary megaloblastic anemia 1 (MGA1). MGA1 is a rare autosomal recessive disorder affecting human subjects with neurological symptoms and juvenile MGA.

Two principal mutations were identified in Finnish patients (FM): a mutation named FM1 changing a highly conserved proline to leucine (P1297L) in CUB domain 8, suggesting that this proline is functionally crucial in cubilin, and one point mutation FM2 in the intron interrupting CUB domain 6, which produced a truncated cubilin. Interestingly, a normal-size cubilin protein was identified in urine samples from homozygous FM1 patients, whereas a complete absence of the protein was reported in a patient homozygous for the FM2 mutation. Other mutations were also uncovered but were subsequently identified as polymorphisms after their

Table 1 Definitions of vitamin B12 (cobalamin) deficiency

- Serum cobalamin levels <150 pmol l^{-1} and clinical features and/or hematologic anomalies related to cobalamin deficiency
- Serum cobalamin levels <150 pmol l^{-1} (<200 pg ml^{-1}) on two separate occasions
- Serum cobalamin levels <150 pmol l^{-1} and total serum homocysteine levels >13 μmol l^{-1} or methylmalonic acid levels >0.4 μmol l^{-1} (in the absence of renal failure and folate and vitamin B6 deficiencies)
- Low serum holotranscobalamin levels <35 pmol l^{-1}

Table 2 Stages of vitamin B12 metabolism and corresponding causes of vitamin B12 deficiency

Stages and actors in vitamin B12 metabolism	*Causes of vitamin B12 deficiency*
Intake solely through food	• Strict vegetarianism and patients who are sick in institutions or in psychiatric hospitals
Digestion brings into play the following:	• Gastrectomies
• Haptocorrin	• Pernicious anemia
• Gastric secretions (hydrochloric acid and pepsin)	• Food-cobalamin malabsorption
• Intrinsic factor	
• Pancreatic and biliary secretions	
• Enterohepatic cycle	
Absorption brings into play the following:	• Ileal resections and malabsorption
• Intrinsic factor	• Pernicious anemia
• Cubilin, amnionless	• Food-cobalamin malabsorption
• Calcium and energy	
Transport by transcobalamins	• Congenital deficiency in transcobalamin II
Intracellular metabolism based on various intracellular enzymes	• Congenital deficiency in various intracellular enzymes

Table 3 Main characteristics of the food-cobalamin malabsorption syndrome

Characteristics of food-cobalamin malabsorption	*Associated conditions or agents*
• Low serum vitamin B12 (cobalamin) levels	• Gastric disease: atrophic gastritis, type A atrophic gastritis, gastric disease associated with *Helicobacter pylori* infection, partial gastrectomy, gastric bypass, vagotomy
• Normal results of Schilling test using free cyanocobalamin labeled with cobalt-58 or abnormal results of derived Schilling test[a]	• Pancreatic insufficiency: alcohol abuse
• No anti-intrinsic factor antibodies	• Gastric or intestinal bacterial overgrowth: achlorhydria, tropical sprue, Ogilvie's syndrome, HIV
• No dietary vitamin B12 deficiency	• Drugs: antacids (H2 receptor antagonists and proton pump inhibitors) or biguanides (metformin)
	• Alcohol abuse
	• Aging or idiopathic

[a]Derived Schilling tests use food-bound cobalamin (e.g., egg yolk, chicken, and fish proteins).

detection in normal individuals in the general population. The cubilin P1297L mutation associated with hereditary MGA1 was reported to cause impaired recognition of the cobalamin–IF complex by cubilin.

In addition, a mutation in AMN was reported in recessive hereditary MGA1 and was demonstrated to be essential for a functional cobalamin–IF receptor. This study demonstrated that homozygous mutations affecting exons 1–4 of the human *AMN* gene translated into selective malabsorption of vitamin B12, a phenotype associated with hereditary MGA1. The essential AMN–cubilin interaction was confirmed *in vitro*, thereby explaining the molecular basis of intestinal cobalamin malabsorption syndrome.

In adults, cobalamin deficiency is classically caused by pernicious anemia or Biermer's disease or Addison's disease. It is an autoimmune disease characterized by the destruction of the gastric mucosa, especially the fundus, associated with a primarily cell-mediated autoimmune process and the presence of various antibodies anti-IF and gastric parietal anticell antibodies that target the H+/K+-ATPase α and ß subunits.

Pernicious anemia is the leading cause of cobalamin deficiency and accounted for 40–50% of cases in adults. In the general population, the prevalence of pernicious anemia is 0.1%; in subjects over the age of 60, it reaches 1.9%. The principal characteristics of pernicious anemia have been reported in detail in several reviews and are listed in Table 4. In practice, the diagnosis of pernicious anemia is based on the presence of IF antibodies in serum (specificity, >98%, and sensitivity, around 50%) or biopsy-proved autoimmune atrophic gastritis. The presence of *H. pylori* infection in gastric biopsies is an exclusion factor.

Genetic susceptibility to pernicious anemia appears to be genetically determined, although the mode of inheritance remains unknown. Evidence for the role of genetic factors includes familial co-occurrence of pernicious anemia and its association with other autoimmune diseases. Thus, a certain number of autoimmune diseases occur at a higher frequency in patients with pernicious anemia – around 30% – or among family members of pernicious anemia patients. They can precede the disease or occur after its onset. The association with autoimmune diseases such as type 1 diabetes (insulin-dependent), autoimmune thyroiditis (particularly Hashimoto's thyroiditis), and vitiligo is common. Other associations have also been frequently described, for example, Sjögren's syndrome, celiac disease, and Addison's disease (adrenal insufficiency). Cases of multiple autoimmune syndrome including pernicious anemia have also been documented.

Table 4 Main characteristics of pernicious anemia

Characteristics of pernicious anemia
● Low serum vitamin B12 (cobalamin) levels
● Hematologic abnormalities or neurological manifestations
● Abnormal results of Schilling test using free cyanocobalamin labeled with cobalt-58
● Presence of anti-intrinsic factor antibodies
● Autoimmune gastritis (*Helicobacter pylori*-negative)
● Associated autoimmune diseases (Sjögren's syndrome, Hashimoto's thyroiditis, type 1 diabetes mellitus, etc.)

Since the 1980s, the malabsorption of cobalamin has become rare, owing mainly to the decreasing frequency of gastrectomy and terminal small intestine surgical resection. Several disorders commonly seen in practice might, however, be associated with cobalamin malabsorption. These disorders include exocrine pancreas' function deficiency following chronic pancreatitis (usually alcoholic), lymphomas or tuberculosis (of the intestine), celiac disease, Crohn's disease, Whipple's disease, and uncommon celiac disease.

Vitamin B12 in Blood and Tissues and Related Disorders

After cobalamin is absorbed at the BBM–blood barrier, it dissociates from the IF and reaches the systemic circulation where it associates with transcobalamin II (TCII) (Table 2).

The kidney represents an essential organ where the body's vitamin B12 stores are maintained, and studies demonstrated that the kidney regulates plasma vitamin B12 levels by maintaining a pool of unbound cobalamin that can be released in the case of vitamin B12 deficiency.

The tissular cobalamin–TCII complex uptake is achieved through megalin (LRP2) and transcobalamin II receptor (TCII-R)-mediated endocytosis, which plays a crucial role in cobalamin homeostasis. It is worth mentioning that TCII is responsible for the cellular uptake of vitamin B12 in most tissues and that TC deficiency is associated with severe MGA. Following cobalamin–TCII cellular uptake, TCII undergoes lysosomal digestion, which allows cobalamin separation from TCII and its cytoplasmic transfer.

It has been estimated that there is a delay of ranging from 5 to 10 years between the onset of cobalamin deficiency and the appearance of clinical manifestations, due to important hepatic stores (>1.5 mg) and the enterohepatic cycle. The average vitamin B12 content is ~1.0 mg in healthy adults, with 20–30 µg found in the kidneys, heart, spleen, and brain. Estimates of total vitamin B12 body content for adults range from 0.6 to 3.9 mg with mean values of 2–3 mg. The normal range of vitamin B12 plasma concentrations is 150–750 pg ml^{-1}, with peak levels achieved 8–12 h after ingestion.

Part of the unbound cobalamin serves as a cofactor for methionine synthase-mediated homocysteine catabolism into methionine and methylenetetrahydrofolate reductase (MTHFR)-mediated formation of the vitamin B9 (folate) biologically active form, tetrahydrofolate, which is then involved in the synthesis of purines and pyrimidines. The other part of free vitamin B12 is transferred to the mitochondria where it is transformed into adenosyl-B12, an important cofactor in the methylmalonyl-coenzyme A mutase-mediated formation of succinyl-CoA from methylmalonyl-CoA, the product of odd-chain fatty acid and some amino acid catabolisms.

Biochemically, cobalamin deficiency will cause homocysteine accumulation, increased methylmalonyl-CoA levels, and decreased MTHFR activity. These changes translate into several abnormalities including folate deficiency and subsequent inhibition of purine and pyrimidine formation essential for RNA and DNA syntheses.

The clinical manifestations of these metabolic abnormalities are MGA, neurological defects, malformations of neurological

structures, increased cardiovascular thrombotic risk and renal disease, and methylmalonic acidemia.

Functional cobalamin deficiency can also be caused by defects in the intracellular processing of cobalamin such as abnormal lysosomal digestion of the TCII–cobalamin complex, and subsequent defective lysosomal release of cobalamin, and abnormalities in intracytoplasmic cobalamin metabolism with all the consequences on biochemical reactions in which cobalamin acts as an important cofactor.

Clinical Manifestations of Vitamin B12 Deficiency

Clinical manifestations related to vitamin B12 deficiency are highly polymorphic and of varying severity, ranging from milder conditions, such as fatigue, common sensory neuropathy, atrophic glossitis (Hunter's glossitis), and isolated macrocytosis or neutrophil hypersegmentation, to severe disorders, including combined sclerosis of the spinal cord, hemolytic anemia, and even pancytopenia.

These later years, the use of strict criteria to define vitamin B12 deficiency (see Table 1) has resulted in more recognition of previously unknown or atypical clinical presentations of cobalamin deficiency. The established manifestations of cobalamin deficiency are described in Table 5.

Vitamin B12 Deficiency Therapy

The treatment of established vitamin B12 deficiency is based upon the administration of intramuscular cyanocobalamin. Its efficacy on the resolution of clinical signs and symptoms has been proved.

The classic treatment for vitamin B12 deficiency is based on parenteral administration – in most countries as intramuscular injections – in the form of cyanocobalamin and, more rarely, hydroxo- or methylcobalamin. Hydroxocobalamin may have several advantages due to a better tissue retention and storage. However, the management concerning both the dose and schedule of administration varies considerably between countries.

In the United States and United Kingdom, doses ranging from 100 to 1000 μg per month (or every 2–3 months when hydroxocobalamin is given) are used for the duration of the patient's life. In France, treatment involves the administration of 1000 μg of cyanocobalamin per day for 1 week, followed by 1000 μg per week for 1 month, followed by 1000 μg per month, again, normally for the remainder of the patient's lifetime.

Likewise, oral cyanocobalamin given at treatment doses has been shown to exhibit a similar efficacy to intramuscular cyanocobalamin, resulting in significantly increased levels of serum vitamin B12 and improvements in hematologic parameters. In fact, about 1–5% of free cobalamin (or crystalline cobalamin) is absorbed along the entire intestine by passive diffusion. A systematic review carried out under the auspices of the *Cochrane Metabolic and Endocrine Disorders Review Group* supports the efficacy of oral cobalamin therapy, with a daily dose of 2000 mg initially and then 1000 mg weekly of vitamin B12. However, the efficacy of oral cobalamin in the treatment of severe neurological diseases has not yet been sufficiently documented. Therefore, in these patients, cobalamin must still be administered via the parenteral route.

Our working group has developed an effective oral treatment for FCM and pernicious anemia using *crystalline* cobalamin (cyanocobalamin). Our principal studies of oral cobalamin treatment (open, not randomized studies) are described in Table 6. These other routes of administration have been proposed as a way of avoiding the discomfort, inconvenience, and cost of monthly injections.

Since the 1990s, at least half of these patients were treated with oral cyanocobalamin, with a dose between 125 and 2000 μg day^{-1}. All of the patients who were treated orally corrected their vitamin B12 levels, and at least 80% corrected their hematologic abnormalities. Moreover, half of the patients experienced a clinical improvement on oral treatment. Table 7 shows our '*façon de faire*' (take home recommendations). The following can be proposed: ongoing supplementation is needed until any associated disorders are corrected (e.g., by

Table 5 Main clinical features of vitamin B12 deficiency

Hematologic manifestations	*Neuropsychiatric manifestations*	*Digestive manifestations*	*Other manifestations*
• Frequent: macrocytosis, neutrophil hypersegmentation, regenerative macrocytic anemia, medullary megaloblastosis ('blue spinal cord') • Rare: isolated thrombocytopenia and neutropenia, pancytopenia • Very rare: hemolytic anemia, thrombotic microangiopathy (presence of schistocytes)	• Frequent: polyneuritis (especially sensitive), ataxia, Babinski's phenomenon • Classic: combined sclerosis of the spinal cord • Rare: cerebellar syndromes affecting the cranial nerves including optic neuritis, optic atrophy, urinary and/or fecal incontinence • Under study: changes in the higher functions, dementia, stroke and atherosclerosis (hyperhomocysteinemia), parkinsonian syndromes, depression, multiple sclerosis, autism	• Classic: Hunter's glossitis, jaundice, LDH and bilirubin elevation ('intramedullary destruction') • Debatable: abdominal pain, dyspepsia, nausea, vomiting, diarrhea, disturbances in intestinal functioning • Rare: resistant and recurring mucocutaneous ulcers	• Frequent: Tiredness, loss of appetite • Under study: atrophy of the vaginal mucosa and chronic vaginal and urinary infections (especially mycosis), hypofertility and repeated miscarriages, venous thromboembolic disease, angina (hyperhomocysteinemia)

Table 6 Experience of oral vitamin B12 therapy in the University Hospital of Strasbourg, Strasbourg, France

Study characteristics (number of patients)	*Therapeutic modalities*	*Results*
Open prospective study of well-documented vitamin B12 deficiency related to food-cobalamin malabsorption ($n=10$)	Oral crystalline cyanocobalamin: 650 μg day^{-1}, during at least 3 months	• Normalization of serum vitamin B12 levels in 80% of the patients • Significant increase in hemoglobin (Hb) levels (mean of 1.9 g dl^{-1}) and decrease in mean erythrocyte cell volume (ECV) (mean of 7.8 fl) • Improvement of clinical abnormalities in 20% of the patients • No adverse effect
Open prospective study of low vitamin B12 levels not related to pernicious anemia ($n=20$)	Oral crystalline cyanocobalamin: 1000 μg day^{-1}, for at least 1 week	• Normalization of serum vitamin B12 levels in 85% of the patients • No adverse effect
Open prospective study of well-documented vitamin B12 deficiency related to food-cobalamin malabsorption ($n=30$)	Oral crystalline cyanocobalamin: between 1000 and 250 μg day^{-1}, during 1 month	• Normalization of serum vitamin B12 levels in 87% of the patients • Significant increase in Hb levels (mean of 0.6 g dl^{-1}) and decrease in ECV (mean of 3 fl); normalization of Hb levels and ECV in 54% and 100% of the patients, respectively • Dose effect – effectiveness dose of vitamin B12 $\geq$ 500 μg day^{-1} • No adverse effect
Open prospective study of low vitamin B12 levels not related to pernicious anemia ($n=30$)	Oral crystalline cyanocobalamin: between 1000 and 125 μg day^{-1} during at least 1 week	• Normalization of serum vitamin B12 levels in all patients with at least a dose of vitamin $\geq$250 μg day^{-1} • Dose effect – effectiveness dose of vitamin B12 $\geq$ 500 μg day^{-1} • No adverse effect
Open prospective study of low vitamin B12 levels related to pernicious anemia ($n=10$)	Oral crystalline cyanocobalamin: 1000 μg day^{-1}, during at least 3 months	• Significant increase in serum vitamin B12 levels in 90% of the patients (mean of 117.4 pg ml^{-1}) • Significant increase in Hb levels (mean of 2.45 g dl^{-1}) and decrease in ECV (mean of 10.4 fl) • Improvement of clinical abnormalities in 30% of the patients

Table 7 Expert opinion recommendations for oral vitamin B12 treatment

	Pernicious anemia	*Intake deficiency and food-cobalamin malabsorption*
Parenteral administration (intramuscular)	Cyanocobalamin: • 1000 μg day^{-1} for 1 week • 1000 μg per week for 1 month • 1000 μg per each month, for life (1000–2000 μg day^{-1} for at least 1–3 months in the case of severe neurological manifestations)	Cyanocobalamin: • 1000 μg day^{-1} for 1 week • 1000 μg per week for 1 month • 1000 μg per 1 or 3 months, until the cobalamin deficiency cause is corrected (1000 μg day^{-1} for at least 1–3 months in the case of severe neurological manifestations)
Oral administration	Cyanocobalamin: • 1000 μg day^{-1} for life[a]	Cyanocobalamin: • 1000 μg day^{-1} for 1 month • 125–1000 μg day^{-1}, until the cobalamin deficiency cause is corrected[a]

[a]The effect of oral cobalamin treatment in patients presenting with severe neurological manifestations has not yet been adequately documented.

halting the ingestion of the offending medication or chronic alcoholism or by treating *H. pylori* infection or pancreatic exocrine failure). This may result in lifelong administration or, when applicable, sequential administration.

Acknowledgments

We are indebted to Professor Marc Imler and Jean-Louis Schlienger who initiated this work. The research on cobalamin deficiency was supported by a grant of the Fondation de France (Prix Robert et Jacqueline Zittoun, 2004).

Cobalt Properties

Cobalt is the 27th element of the periodic table (atomic number 27). It was discovered by Swedish chemist Georg Brandt about 1730. Its symbol is Co, and it is included in group 9 (or VIIB) in the periodic table, thus corresponding to the transition metals. It is a brittle, hard, silver-gray metal with magnetic properties similar to those of iron (ferromagnetic). It is alloyed with aluminum and nickel to make particularly powerful magnets. The abundance of cobalt in the Earth's crust is 0.003%. It has a fusion point of 1493 °C, a boiling point of 3100 °C, an atomic weight of 58.93320, and a relative density of 8.86 g cm^{-3}.

Cobalt has an electronic structure of [Ar] $4s^2 3d^7$, and its most common oxidation states are +2 and +3. Nevertheless, some compounds with oxidation states ranging from −3 to +4 are also known. At temperatures below 417 °C, cobalt exhibits a hexagonal close-packed structure (ε-cobalt). Between 417 °C and its melting point of 1493 °C, cobalt has a face-centered cubic structure (α-cobalt).

Cobalt occurs in nature in a fairly widespread but dispersed form, being detectable in trace quantities in many rocks, soils, and manganese-rich marine nodules. The currently exploited sources of cobalt are mainly those where it originates as a by-product of more valuable metals, particularly copper, nickel, zinc, lead, and platinum. It is distributed in minerals such as erythrite or red cobalt [$Co_3(AsO_4)_2 \cdot 8H_2O$], cobaltite (CoAsS), skutterudite [(Co,Ni)As_3], carrollite [$CuCo_2S_4$], linnaeite [Co_3S_4 (+Ni,Cu,Fe)], cattierite [CoS_2], nickel cattierite [(Co, Ni)S_2], heterogenite [$2Co_2O_3CuO \cdot 6H_2O$], or asbolane (mixed manganese–iron oxide with cobalt). In seawater, the metal is present primarily as the cobalt ion and its chloro, sulfate, and carbonate complexes. In shallow waters, up to 98% of the metal can be found in the sediments and in suspended particulate matter. There are several cobalt isotopes with different half-lives among which are ^{56}Co (77.3 days), ^{57}Co (271.8 days), ^{58}Co (70.9 days), ^{59}Co (stable), ^{60}Co (5.3 years), and ^{61}Co (1.7 h).

The main use of cobalt compounds remained as a coloring agent (a rich blue color) to glass, enamels, and porcelain, right up to the twentieth century. It is also employed to make heat-resistant superalloys. Some alloys of cobalt are used in jet turbines and gas turbine generators, where high-temperature strength is important. Cobalt compounds are also important for nonmetallurgical applications, such as catalysts for the petroleum and chemical industries, a drying agent, or in lithium-ion battery electrodes. Cobalt salts of the higher carboxylic acids (cobalt soaps) are used to accelerate drying in oil-based paints, varnishes, and inks. As a ferromagnetic material, it forms permanent magnets and it can be used as an electromagnet. It has also been used in human medicine in the treatment of certain iron-resistant anemia. Finally, radioactive ^{60}Co is used to treat cancer as a medical device for the precise treatment of brain tumors and deformities of blood vessels. Cobalt–chromium alloys are also used as biomaterials because of its high degree of biocompatibility and the low volume of attrition produced at the articulating surfaces.

Cobalt is essential to hematopoiesis by virtue of the fact that it is the metal confined by the corrin ring of vitamin B_{12}. The ring consists of four pyrrole subunits, linked together to form a macrocyclic ring. It is thus like a porphyrin, but with one of the bridging methylene groups removed. The nitrogen of each pyrrole is coordinated to the central cobalt atom. In ruminants, bacteria present in their digestive tracts are able to convert cobalt ions to vitamin B_{12}. It is also associated with glycylglycine dipeptidase enzyme. In the presence of hydrogen peroxide, cobalt ions are able to produce hydroxyl radicals through a Fenton-like mechanism. Good food sources of cobalt include meat muscles, fish, nuts, oats, and green leafy vegetables such as broccoli and spinach. The bioavailability *in vivo* of cobalt ions is relatively limited, because these cations precipitate in the presence of physiological concentrations of phosphates and nonspecifically bind to proteins such as albumin. Dietary factors that seem to have the greatest effect on the ruminal production of vitamin B_{12} are cobalt concentration, roughage content of the diet, and total feed intake.

Cobalt Analysis

Sample Treatment

Most of the methods used for cobalt determination require the availability of a treated sample solution. Previously, the sample must be subjected to a treatment process where the organic matter and other matrix components are destroyed and metal ions for further analysis are released. During this treatment, the risk of sample contamination or analyte losses is high.

A common practice is the incineration of the sample in a muffle furnace using a time–temperature-controlled program. This process is defined as dry mineralization. Process efficiency and analyte retention mainly depend on the food matrix and the time–temperature program applied. The ash residue is usually dissolved with acids (HCl, HNO_3, etc.) after a blanching step.

An alternative to the earlier technique is wet mineralization. This method is based on the oxidizing action of strong acids either alone or in acid mixtures that sometimes include hydrogen peroxide. These reagents have the capacity to release cobalt ions and other trace elements keeping them in solution.

Dry and wet mineralization procedures are often tedious and time-consuming. Another drawback of the earlier mineralization methods lies on the high risk of volatilization of certain mineral elements such as selenium, mercury, or arsenic, thus causing analyte losses. For cobalt determination, this problem is not initially present unless the final objective of the applied technique is oriented to determine these volatile elements simultaneously.

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00175-6

The microwave digestion procedure could be a faster and more efficient alternative. In this technique, samples are introduced in microwave ovens using pressure vessels. It also allows the use of a smaller volume of reagent. The most significant disadvantage is the risk of explosion due to increase in pressure caused by the destruction of organic matter. The pressure vessels are placed on a turntable to avoid problems arising from lack of homogeneity in the distribution of radiation within the microwave oven.

Despite the discrepancies earlier discussed between these treatment processes, usually, the comparison of dry and wet mineralization and microwave digestion methods did not show statistically significant differences in relation to accuracy and recovery percentage of mineral elements determined.

Preconcentration Methods

In some cases, the cobalt concentration present in food and biological samples could be below the detection limit of the analytic technique used. Another possibility is a strong interfering effect with the food matrix, which impairs the measurement procedure. In these cases, preconcentration and/or separation methods prior to cobalt analysis are needed to improve sensitivity and selectivity. The detection limit of the analyte can be substantially improved if the final volume is reduced. Several procedures, such as solid-phase extraction (SPE), liquid–liquid extraction (LLE), cloud point extraction (CPE), coprecipitation, and membrane filtration, have been proposed and applied for the enrichment and separation of cobalt from a sample matrix. Table 1 summarizes some published papers on cobalt preconcentration techniques in foods.

SPE is an advantageous separation and preconcentration technique for trace metal ions given its simplicity, flexibility, and high enrichment factor. The general procedure is to use a solid phase that separates the analyte of interest from interfering substances of the food matrix. With this purpose, the original sample, previously dissolved or suspended in a liquid phase, is poured on the solid phase on which the analytes are retained. Subsequently, another liquid phase is necessary to elute the retained analytes. Several solid-phase materials have been employed for the preconcentration of cobalt ions. These include chemically modified silica gel with aminothioamidoanthraquinone, cellulose functionalized with 8-hydroxyquinoline, silica gel–polyethylene glycol, β-cyclodextrin cross-linked polymer, Aliquat 336 chloride immobilized in poly(vinyl chloride), glycerol-bonded silica gel, and activated carbon modified by dithiooxamide. Carbon nanotubes have been currently proposed as a novel solid-phase extractant for cobalt determination at trace levels. The hexagonal arrangements of the carbon atoms in graphite sheets, attached to their high surface area, make them a promising solid sorbent for preconcentration procedures. Process parameters such as pH, sample flow rate, and sample volume can influence on the adsorption efficiency as previously studied. Thus, it is shown that the acidity of the solution affects the adsorption process because protons in acid solution can protonate the binding site of the chelating molecules, and hydroxides in basic solution may form complexes causing metal

X. (2014). *Journal of Chromatography A* **1360**, 76–81

precipitation. On the other hand, a lower flow rate of sample produces a longer contact time with the solid phase, thus increasing the percentage recovery. Finally, low sample volumes result in a higher percentage recovery because the contact time between the metal ions and the active sites of the solid phase increases.

LLE is a preconcentration method in which the metal is distributed between two immiscible liquid phases (usually an aqueous phase and organic phase). Cobalt preconcentration is achieved by adding a chelating agent to the aqueous phase, followed by an extraction of the cobalt complexed into the organic phase. For the analytic measurement of the extracted cobalt ion, a back-extraction step to an aqueous medium, usually acid, is recommended. Nevertheless, LLE has several drawbacks, such as emulsion formation and the use of large and contaminated solvent volumes, which make LLE expensive and environmentally unfriendly. Searching for alternatives to the conventional LLE using negligible volumes of extractant and a minimum number of steps has led to the development of liquid-phase microextraction techniques for cobalt preconcentration.

CPE is related to LLE but has emerged as an alternative due to several reasons: (1) its excellent concentration factors, (2) the smaller required sample size, (3) the use of a small volume of organic solvent that is generally toxic, (4) the use of nontoxic surfactants, (5) the reduction of laboratory residues, and (6) being recognized as a safer, simpler, and cost-effective procedure. CPE is based on the following phenomenon: in much diluted solutions of nonionic surfactant, the monomers are dispersed in the solvent. But above the critical micellar concentration of the surfactant, these monomers associate spontaneously, forming aggregates of colloidal dimensions termed micelles, due to the diminished solubility of the surfactant in water. The surfactant solution becomes turbid because it attains the cloud point. This clouding phenomenon can be induced by changing the temperature, surfactant concentration, or the choice of a compatible pH buffer, resulting in the separation of a single isotropic micellar phase into two phases, a surfactant-rich phase of small volume and an aqueous phase. Choosing an appropriate chelating agent that is able to form with the metal ion a hydrophobic complex, which is entrapped by micellar structures, extraction and subsequent preconcentration of cobalt in the surfactant-rich phase can be achieved. Among the nonionic surfactants commonly used, Triton X-114 (octylphenoxypolyethoxyethanol) is the most feasible for preconcentration cloud point extraction. Regarding chelating agents, 2-(5-bromo-2-pyridylazo)-5-(diethylamino)-phenol (5-Br-PADAP), 1-(2-pyridylazo)-2-naphthol (PAN), ammonium pyrrolidinedithiocarbamate (APDC), and 1-(2-thiazolylazo)-2-naphthol (TAN) have been used for the determination of cobalt.

The separation of dissolved substances by precipitation may occur in two ways. Direct precipitation is produced when a reagent creates an insoluble and very selective precipitate. Alternatively, indirect precipitation is formed when a precipitate of a different compound is produced and the desired analyte is retained by coprecipitation on the surface of the formed precipitate. Further, centrifuging, filtering, or washing separates this precipitate. The coprecipitation technique stands out by its ease and the simultaneous preconcentration and separation of the analytes from the food matrix. Hydroxides of various metal ions as inorganic coprecipitants have been used for the preconcentration of cobalt in food and environmental samples such as magnesium(II), thulium(III), zirconium(IV), tin(IV), and scandium(IV) hydroxide. Other organic coprecipitants such as magnesium-8-quinolinate, iron(III) hexamethylenedithiocarbamate, and bismuth(III) diethyldithiocarbamate have been also employed in cobalt coprecipitation studies, giving very high concentration factors.

Finally, another preconcentration technique is membrane filtration in which cobalt ions are collected in the form of metal chelates over a membrane filter from an aqueous solution by filtration. The filter material has a strong affinity for hydrophobic species in water, which allow retention of these species during filtering. Among the materials used as a filter to cobalt ions are cellulose nitrate or cellulose acetate. APDC, poly(ethyleneimine) or carmine has been used as complexing agents.

Atomic Absorption Spectroscopy

In atomic absorption spectroscopy (AAS), electromagnetic radiation at specific wavelength is passed through a cell containing gaseous free atoms. Atoms are produced in two different ways using AAS: flame atomic absorption spectrometry (FAAS) and electrothermal atomic absorption spectrometry (ETAAS) (graphite furnace and a L'vov platform). Thus, the determination of cobalt using an atomic absorption spectrophotometer requires a light source (wavelength $\lambda = 240.7$ nm) and an atomization source. Standard working conditions for analyzing cobalt by AAS are listed in Table 2.

FAAS uses an air–acetylene or nitrous oxide–acetylene as the most common oxidant–fuel mixtures to produce atomization. Preconcentration methods described in the preceding text permit the use of FAAS for cobalt determination in foodstuffs with detection limits of 0.30–2.4 ng ml^{-1}. However, when conventional FAAS proves impractical because cobalt values are below or near the detection limit of the instrument, it is recommended to use ETAAS in which the atomization is produced by the passage of electrical current through a cylindrical graphite tube (called graphite furnace). This process comprises several steps: preheating, drying, pyrolysis, atomization, and cleaning, which are achieved by a temperature–time interval program (ramp heating). During the drying stage, liquid from the sample is evaporated and driven off. In the pyrolysis stage, some of the concomitants in the sample are removed. During this process, the system is flushed with protective gas (usually argon) to exclude air from the sample compartment and to minimize oxidation of the atomizer material at high

Cleaning	1	3	2450(2700)	1.0

temperatures. Finally, the temperature is rapidly increased to quickly vaporize and atomize the sample. Table 3 shows operation conditions used for cobalt determination by ETAAS.

ETAAS combined with preconcentration methods has been used for cobalt determination. It can reach detection limits of 1.2–50 ng l^{-1}. In order to reduce matrix effects when ETAAS is used, various matrix modifiers are added.

Inductively Coupled Plasma Optical Emission Spectrometry (ICP-OES)

The earlier analytic techniques are sensitive enough to determine cobalt and other trace elements. However, as monoelemental techniques, they could become too slow and tedious when trying to analyze a wide range of trace elements. ICP-OES is a multielemental technique able to determine concentrations of multiple elements in a sample with a single aspiration obtaining a high degree of variability and minimum interferences. The technique is based upon the spontaneous emission of light, with a characteristic wavelength, from atoms and ions previously excited in plasma. The particular wavelength leaving the monochromator is converted to an electrical signal by a photodetector.

Plasma may be defined as a luminous volume of partially ionized gas. It is generated from radiofrequency magnetic fields induced by a copper coil wound around the top of a glass torch. The sample solution is converted to an aerosol and directed into the central channel of the plasma. The plasma maintains a temperature of approximately 10 000 °C in its core where cobalt and other elements are released as free atoms and excited. Therefore, argon plasma is needed to produce atomization and excitation. The nearly complete atomization of the sample minimizes chemical interferences.

For cobalt determined by ICP-OES, a solution detection limit of 5 μg l^{-1} and a sample detection limit of 2.5 μg g^{-1} can be achieved. Selectivity is important to minimize the spectral overlap interferences resulting from rich line emission spectra of cobalt and other elements such as tungsten, niobium, and molybdenum. ICP-OES has been used for cobalt determination in dried fruit, coffee, cocoa, and infant formula. The emission spectral lines used for cobalt analysis are 228.616, 230.786, and 238.346 nm.

Inductively Coupled Plasma Mass Spectrometry (ICP-MS): Cobalt Speciation

ICP can also be coupled with a mass spectrometer leading to inductively coupled plasma mass spectrometry (ICP-MS). The inductively coupled argon plasma is once again used as an excitation source for the elements of interest. However, in contrast to ICP-OES, the plasma in ICP-MS is used to generate ions that are introduced in the mass analyzer through a sampler cone, followed by a skimmer cone. Mass spectrometers are instruments that separate ions according to their mass-to-charge ratio (m/z) and then accurately quantify the resulting ions once they pass through a detector.

There are five types of mass analyzers: quadrupoles, ion traps, time-of-flight, magnetic sectors, and Fourier transform-based ion cyclotrons. Quadrupole mass spectrometry has become increasingly popular in recent years, being currently the most used. Sample introduction can be static, through direct insertion probes, or dynamic. The interconnection with chromatographic equipment is implied in the latter. In fact, as it will be discussed later, the use of high-performance liquid chromatography with the mass spectrometry has recently become a routine technique due to advances achieved in the interconnecting interfaces.

ICP-MS is the method of choice for cobalt and other ultratrace element determinations due to its low detection limit, multielement capabilities, fast routine, and wide linear calibration range. For cobalt, it has been widely applied in clinical analysis, reaching quantification limits as low as 0.20 ng ml^{-1} in oral mucosa cells, 0.01 ng ml^{-1} in human serum, and 0.03 ng ml^{-1} in whole blood.

Regarding interferences, spectroscopic interferences are probably the largest ones in ICP-MS and are caused by atomic or molecular ions that have the same m/z ratio as the analytes of interest. In many cases, it can be avoided by using a different isotope of the element of interest or by measuring another isotope of the interfering element and subtracting from the mass of interest on the basis of the known isotope ratio of the interfering element. Current ICP-MS instrumental software makes a correction for all known atomic 'isobaric interferences'; however, they do not provide corrections for most of the polyatomic interferences. Such interferences are caused by polyatomic ions that are formed from precursors having numerous sources, such as the sample matrix, reagents used for preparation, plasma gases, and entrained atmospheric gases. Table 4 shows the main polyatomic interferences for cobalt determination.

Currently, it is necessary to know not only the precise quantity of trace element that is present in a food or biological sample but also in what form it is present (speciation). Chemical speciation comprises the identification and quantification of different trace elements and the biomolecules to which they are associated, their oxidation states, and the coordination

groups involved. In the last years, a novel scientific discipline was arisen, known as metallomics or chemical speciation. To this sense, cobalt can be present in the environment in different forms. The main compounds of toxicological interest are the metallic form (cobalt metal), the oxides (cobalt oxide and tetroxide), and the salts (cobalt chloride, sulfide, and sulfate). On the other hand, there are other forms of nutritional interest such as a wide variety of cobalamins including cyanocobalamin (CNCbl), hydroxocobalamin (OHCbl), methylcobalamin (MeCbl), and 5′-deoxyadenosylcobalamin (AdoCbl).

To carry out these studies, several methods of high-performance liquid chromatography (HPLC) and capillary electrophoresis (CE) coupled with ICP-MS have been reported for cobalt speciation analysis. The separation of cobalt species is based on their retention times. The advantages of using CE as a separation method, in comparison with other chromatographic techniques, are its low cost, applicability to small sample volumes, and high resolving power and low reagent consumption. It has been applied on pharmaceutical preparations of vitamin B_{12} achieving detection limits for the cobalamins ranging from 30 to 70 ng ml^{-1}. Another study using EC-ICP-MS on nutritive supplements and chlorella foods achieved lower detection limits of 0.3, 0.2, and 1.7 ng ml^{-1} for CNCbl, OHCbl, and Co(II) ion, respectively.

In relation to HPLC-IPC-MS, the physical separation capabilities of liquid chromatography with the analytic skill of mass spectrometry are combined yielding high sensitivity and selectivity. It has been used for the analysis of nutritive supplements with detection limits of 0.008, 0.013, and 0.014 ng ml^{-1} for Co(II), OHCbl, and CNCbl, respectively. The following table (Table 5) shows some published studies on cobalt speciation using these hyphenated techniques and on cobalt analysis by ICP-MS.

Table 4 Polyatomic interferences for the determination of cobalt in ICP-MS

Isotope	*Abundance*	*Interference*
^{59}Co	100	$^{43}Ca^{16}O^{+}$, $^{42}Ca^{16}O^{1}H^{+}$, $^{24}Mg^{35}Cl^{+}$, $^{40}Ar^{23}Na^{+}$, $^{40}Ar^{18}O^{1}H^{+}$, $^{40}Ar^{19}F^{+}$

Ion-Selective Electrodes

Ion-selective electrodes are one of the most frequently used potentiometric sensors during laboratory analysis. The main advantage over spectroscopic methods is that most of these spectroscopic techniques are relatively expensive and involve large infrastructure backup and support of expertise. In contrast, ion sensors provide analytic procedures that overcome the earlier drawbacks since they are fast and require minimal sample treatment. Ionophore plays the main role in the sensitivity and selectivity of ion-selective electrodes. A good ionophore shows strong affinity for a particular ionic species than others.

A number of ion-selective electrodes for the determination of cobalt concentration have been reported using materials such as Schiff bases, calixarenes, isothiazoles, and mercapto compounds. However, most of these sensors suffer from disadvantages such as narrow working concentration range, non-Nernstian potential response, high response time, high detection limit, and poor reproducibility.

Recently, PVC membrane electrode (PME) and coated graphite electrode (CGE) have been prepared by using 2-((thiazol-2-ylimino)methyl)phenol as a good ionophore in order to use it as cobalt-selective electrode. The electrodes exhibit a Nernstian slope for cobalt ions with a limit detection of 6.91×10^{-7} mol l^{-1} for PME and 7.94×10^{-8} mol l^{-1} for CGE, which show a proper potentiometric response. Similarly, azines, a condensation product of hydrazine with ketones or aldehydes, can also be used as cobalt-selective electrodes. Thus, palladium(II) dichloro acetylthiophene fenchone azine in a plasticized PVC matrix reveals a good selectivity for cobalt(II) with a detection limit of 8×10^{-7} mol l^{-1}. Finally, the

use of macrocyclic ligands (such as dipyridine–hexaazacyclotetradecane derivatives) with PME and CGE has also been developed with similar results (detection limits of 6.80×10^{-9} mol l^{-1}).

Colorimetric Methods

These types of techniques are less used for cobalt determination; however, they offer some advantages such as less tedious sample pretreatments and more inexpensive instrumentation. Colorimetric methods were introduced during the 1940s for analyzing cobalt in biological materials and achieved detection limits of 0.005 μg ml^{-1} in blood samples. Recently, a simple naked eye colorimetric method has been developed based on controlling the oxidation level of methylene blue. This redox dye could be tuned from blue to colorless, yellow, and green at different oxidation states. The sensing system is just a simple mixture of methylene blue, 2-aminothiophenol, and copper nitrate, forming a complex that resulted in the reduction of methylene blue from blue to colorless in 3 min. The addition of cobalt ions to this system produces a color change from colorless to brown at low cobalt concentrations and green at high concentrations within 2 min. The sensing of cobalt ions can be achieved by UV–visible spectra or by the naked eye. The authors reported a linear range from 0.1 to 1.1 mM with a correlation coefficient of 0.9982 and a detection limit of 0.04 mM.

Nondestructive Techniques

Neutron activation analysis is not a common technique for cobalt analysis. However, it can be used as a multielement technique when determining a large number of trace elements without destroying the sample. Furthermore, it is a well-established technique for multielement determination at ultra-trace levels with high sensitivities (i.e., a detection limit of 0.6 ng g^{-1} was achieved for cobalt in liquid milk samples). The technique principle is that elements can be radioactive by exposure to neutron irradiation. By monitoring the subsequent decay of these radioisotopes, it is possible to identify and accurately quantify the elements in the sample.

There are three main sources of neutrons for irradiation: nuclear reactors, radioactive neutron sources, and electron–ion accelerators. The former provide the highest neutron fluxes and permit the highest sensitivities for detection and quantification of various elements. Currently, this technique is being used to authenticate the geographic origin of certain foods with a quality mark (e.g., foodstuffs belonging to a protected designation of origin).

x-Ray fluorescence (XRF) is another unusual nondestructive technique for cobalt determination. It is based on bombarding a small area of the sample with x-ray photons, which are sufficiently energetic to cause ionization of inner electrons of the atoms. Because of this unstable atomic configuration, an electron from an outer orbital fills the vacancy of an inner electron, which emits the difference of energy between the two orbitals as a 'secondary' (or fluorescent) x-ray photon. The main difference with ICP-OES is that in XRF, emitted radiation from the ultraviolet–visible region of the spectrum is covered. It has achieved a detection limit for cobalt of 1 μg g^{-1} in fruits and of 0.3 μg g^{-1} in dairy samples.

Cobalt Physiology

Cobalt is a trace element widespread in the environment and human exposure is mainly attributed to air breathing and food intake. Skin contact with soil or water containing cobalt may also enhance exposure. This element has both beneficial and harmful effects on human health. From a nutritional point of view, cobalt is part of vitamin B_{12} in which this element is complexed with four nucleic pyrroles joined in a ring called corrin, similar to porphyrins. However, this element may be toxic when human exposure occurs at levels higher than recommended values. The respiratory system is the main target organ as a result of inhalation of high doses of cobalt by metallurgy workers, causing several diseases such as pneumonia, nodular fibrosis, asthma, and lung cancer. It may also cause thyroid damage, high blood pressure, heart effects, vomiting, and diarrhea.

The human body contains an average of 1.1 mg of cobalt, 85% of it being in the form of vitamin B_{12}. Usually, the main source of cobalt in humans is through diet. Its absorption in the digestive tract varies between 5% and 45% in different individuals. This absorption is conditioned by both dietary factors and physiological factors. Cobalt bioavailability is determined by the cobalt intake from diet as well as on its chemical form. Several studies show that cobalt species determine the kinetics of cobalt absorption both through diet and by inhalation routes. Volunteer studies have found that chloride form of cobalt had higher absorption than the oxide form. Moreover, early experiments showed that cobalt urinary excretion is inversely proportional to the dose supply. On the other hand, the digestive absorption of cobalt compounds is also influenced by other concomitants present in the food. The presence of albumin or lactose increases the absorption of the element. Thus, administration of cobalt ions with cow milk may increase the gastrointestinal absorption up to 40%. On the other hand, the bioavailability *in vivo* of cobalt ions is impaired in the presence of physiological concentration of phosphates. Finally, a low iron status promotes cobalt absorption probably by active competition for the same transport mechanism in enterocytes. In relation to physiological factors, gastrointestinal uptake of cobalt differs according to sex, as shown by a research study, where volunteers were supplied with several amounts of soluble cobalt compounds showing significantly higher urinary cobalt levels in women (median, 109.7 nmol $mmol^{-1}$ creatinine) than in men (median, 38.4 - nmol $mmol^{-1}$ creatinine).

Once absorbed, cobalt is mainly present in the organism as cobalt (II) ions and is distributed throughout the body, the liver, kidneys, pancreas, and heart being the main organs where cobalt is accumulated. Most of the cobalt present in serum is bound to albumin, and the free fraction is estimated between 5% and 12%. This latter fraction is in equilibrium with free cobalt present in the interstitial fluid. It has also been identified in serum a histidine-rich glycoprotein that binds cobalt and other elements such as copper, nickel, and zinc. There is not any standard biochemical marker of cobalt accumulation in the human body with age.

Cobalt in the form of vitamin B_{12} is an established treatment for pernicious anemia. It is proclaimed to increase erythropoiesis and physical performance, even in nonanemic subjects. The molecular mechanism by which cobalt stimulates erythropoietin production is not fully understood. It seems that cobalt stabilizes the hypoxia-inducible factors (HIFs), namely, HIF-α-prolyl hydroxylase and HIF-α-asparaginyl hydroxylase, which increase the expression of the erythropoietin gene. Eight non-corrin cobalt-containing enzymes have been identified, which are shown in **Table 1**.

Cobalt may interact with other ion metals. Thus, in human red cells, cobalt shares the same transport mechanism with calcium. The uptake is practically irreversible since cobalt bound in the cytosol is not itself extruded by the Ca pump. Additionally, cobalt *in vitro* can replace iron in the heme group of hemoglobin. Binding to hemoglobin is initially reversible; however, a cobalt fraction starts later to bind strongly probably due to oxidation *in situ* from cobalt (II) to cobalt (III). In acute cyanide poisoning, the capacity of cobalt (II) ions to form stable complexes with cyanide anion may be used to neutralize this toxicant. On the other hand, cobalt can also replace zinc in some enzymes such as alkaline phosphatase and carboxypeptidase.

The main excretion route of cobalt is the urine followed by feces. Studies of whole-body retention of inorganic cobalt in human males after intravenous injection gave an excretion rate after 8 days of 56% in urine and 11% in feces. This cobalt excretion is lower in hemodialysis patients justifying the importance of renal clearance. Urinary cobalt is used in biological monitoring of occupational exposure to cobalt compounds to discriminate occupationally exposed subjects from nonexposed ones and to distinguish subgroups of workers with different degrees of exposure.

Cobalt represents approximately a 4.3% of vitamin B_{12} weight. Considering that daily requirements of vitamin B_{12} are approximately 1 μg and that only 50% of vitamin B_{12} is absorbed by the gastrointestinal tract, the Recommended Daily Allowance (RDA) of vitamin B_{12} is 2.4 μg, which corresponds to 0.10 μg of cobalt.

Exposure Sources

Toxic effects of cobalt may occur as a result of an exposure to high concentrations or through chronic exposure for a long time period at low concentrations (mainly occupational exposure). Among the adverse effects of cobalt toxicity are skin dermatitis and carcinogenic, mutagenic, cardiovascular, and respiratory effects. Although the mechanism of cobalt toxicity

Table 1 Non-corrin cobalt-containing enzymes and its function in the organisms

Enzyme	*Function*
Aldehyde decarbonylase	It is involved in the conversion of a fatty aldehyde to a hydrocarbon. The only case where the enzyme has been purified is from a green alga and this decarbonylase appeared to have cobalt and porphyrin
Bromoperoxidase	Bromoperoxidase from *Pseudomonas putida* catalyzes the formation of a carbon–bromine bond in the presence of peroxides. It is activated by incubation with cobalt ions but not with other transition metals such as iron, nickel, zinc, and vanadate
Glucose isomerase	It catalyzes the reversible isomerization of D-glucose to D-fructose and is of outmost commercial importance for the industrial production of corn syrup
Lysine 2,3-aminomutase	A bacterial enzyme that also contains cobalt ions that catalyzes the interconversion of L-lysine and L-beta lysine, the first step in lysine degradation
Methionine aminopeptidase	It is a ubiquitous enzyme in both prokaryotes and eukaryotes that catalyzes cotranslational removal of N-terminal methionine from elongating polypeptide chains during protein synthesis. It contains two cobalt (II) ions per active subunit that catalyze hydrolysis
Methylmalonyl-CoA carboxyltransferase	It is a multienzyme complex from prokaryote that couples two carboxylation reactions, transferring a carboxyl group from (*S*)-methylmalonyl-CoA to pyruvate to yield propionyl-CoA and oxaloacetate
Nitrile hydratase	It catalyzes the hydration of nitriles to their corresponding amides. This enzyme is also used as biocatalyst in acrylamide and nicotinamide production, as well as in environmental remediation for the removal of nitriles from waste streams
Proline dipeptidase	Also called prolidase. It is an enzyme that catalyzed the cleavage of bonds between aminoacyl and proline groups

remains unknown, it seems that cobalt ions in the presence of hydrogen peroxide are able to produce hydroxyl radicals in a manner possibly similar to Fenton reaction, causing oxidative stress and oxidative damage to lipids, proteins, and DNA. This would be favored by hyperoxic conditions with oxygen acting synergically with cobalt to promote the formation of free radicals. Cobalt also has a strong affinity for sulfhydryl groups causing displacement of divalent cations in the ion center of metal-activated enzymes and inhibition of vital enzymes such as cytochrome P450, peroxidase, and tyrosine iodinase. This effect has also been demonstrated for DNA repair enzymes (incision and polymerization steps) in which cobalt ions interact with zinc finger domains in the protein.

When the toxicity of cobalt compounds is investigated, it is important to consider various factors. Speciation or chemical form of the cobalt compound influences its solubility and bioavailability. As a result, acute toxicity of these compounds varies from each other (see Table 2). The route and the time of exposure should also be considered for evaluating the risk (single, repeated, short- and long-term exposure, oral, inhalation, etc.). The organ or tissue whose damage gives rise to the critical effect, called critical organ, must be selected. Aiming for a quantitative assessment of risks related to toxicant exposure, risk assessment is applied to environmental and occupational health.

Table 2 Median lethal dose (LD_{50}) of several cobalt compounds in rats

Compound	*LD_{50} (mg kg^{-1})*
Cobalt chloride	80
Cobalt oxide	202
Cobalt chloride hexahydrate	766
Cobalt sulfide	>5000
Cobalt metal	6171

Soil, Water, and Air

Cobalt is present in nature in a fairly widespread but dispersed form, being detectable in trace quantities in many rocks, soils, and manganese-rich marine nodules. Currently, the exploited sources of cobalt are mainly those where it exists as a by-product of more valuable metals, particularly copper, nickel, zinc, lead, and platinum. Cobalt is also present in igneous rocks that are rich in iron. The abundance of cobalt in the Earth's crust is 0.003%. In relation to sediments, cobalt concentration was determined in modern sediments in the Bristol Channel (England), a region that receives a significant input of industrial waste from coal mining, smelting, and other industries. A cobalt concentration of 22.8 mg kg^{-1} in suspended particulates, 16.0 mg kg^{-1} in silts, and 6.4 mg kg^{-1} in sands was found. Similarly, sediments from the Ems (Germany) contained 40 mg kg^{-1} of cobalt and there was a significant contribution from industrial discharges. Cobalt concentration in soils is determined by several factors such as the amount of organic matter, clay mineral content, oxidation–reduction state, pH, and translocation to root and foliage plants. Usually, cobalt concentrations in most soils ranged between 0.1 and 50 μg kg^{-1}.

In seawater, the metal is present primarily as cobalt (II) ion and its chloride, sulfate and carbonate complexes. Cobalt values around 0.1–0.7 μg kg^{-1} are reported. An increase in cobalt concentrations with depth in the oceans is related to organic productivity. The low concentration of cobalt close to the continents probably indicates removal through absorption, coprecipitation, and flocculation of solids. Thus, in shallow waters, up to 98% of the metal can be found in the sediments and in suspended particle matter. Several studies have found an average cobalt concentration in drinking water over 2 μg l^{-1}.

Cobalt concentration in the atmosphere depends on anthropogenic activity and other natural sources that include weathering and local geology, volcanic eruptions, and seawater spray. The average concentration of cobalt in ambient air is situated around 0.4 ng m^{-3}. However, levels up to 0.61 μg m^{-3}

have been detected in urban areas. The residence time of cobalt in the atmosphere depends on the particle size and meteorological factors. Rainwater solubilizes the cobalt species present in the atmosphere. Studies have detected a cobalt concentration in rainwater over 0.3 $\mu g\,l^{-1}$ in rural areas against 1.7 $\mu g\,l^{-1}$ in highly industrial areas.

Dietary Sources

The average daily intake of cobalt from food is estimated to be between 5 and 60 $\mu g\,day^{-1}$ varying between countries. Several studies have reported a mean dietary intake of cobalt of 4–29 $\mu g\,day^{-1}$ in France, 11 $\mu g\,day^{-1}$ in Canada and the United Kingdom, and 60–65 $\mu g\,day^{-1}$ in Turkey. Cobalt-rich food sources include meat muscles, liver, fish, nuts, oats, and green leafy vegetables such as broccoli and spinach. Several studies have analyzed this element using ICP-OES or ICP-MS obtaining an average concentration of 0.25–1.03 $\mu g\,g^{-1}$ in dried fruits, 0.06–0.18 $\mu g\,g^{-1}$ in crucifers, 0.02–0.06 $\mu g\,g^{-1}$ in cereals, and 0.17 $\mu g\,g^{-1}$ in fish liver. As it will be seen later, myocardial effects have been observed in heavy beer consumers. This is because in the early 1960s, some breweries added cobalt salts (chloride or sulfate) to stabilize beer foam, resulting in elevated exposures to cobalt. Some people who consumed excessive amounts of beer (8–25 pints per day) suffered from severe heart problems, causing death.

Cobalt content in human milk depends on feeding mothers and their lifestyles (dietary habits during pregnancy and after the birth, taking medications, smoking, etc.). Cobalt concentration in human milk from Central European women has been found between 0.42 and 2.46 $\mu g\,l^{-1}$. A transfer factor from the mothers' daily intake to milk was reported to be equal to 8.4.

Anthropogenic Sources

Significant exposure to cobalt occurs predominantly at work since environmental concentrations are usually low. Cobalt compounds are used as a coloring agent (to enrich blue color) for glass, enamels, and porcelains. It is also employed to make heat-resistant superalloys. Some alloys of cobalt are used in jet turbines and gas turbine generators, where high-temperature strength is important. Cobalt compounds are also important for nonmetallurgical applications, such as catalysts for petroleum and chemical industries, as a drying agent, or as part of lithium ion battery electrodes. Cobalt salts of the higher carboxylic acids (cobalt soaps) are used to accelerate drying in oil-based paints, varnishes, and inks. As a ferromagnetic material, it forms permanent magnets, thus being used as an electromagnet.

Cobalt levels present in the environment are reported to be relatively high during cobalt powder production in grinding processes, hard-metal industry, and ceramics industry. These high levels of cobalt in the environment result in an increased concentration in blood and urine of the exposed workers. Cobalt exposure has also been detected, although to a lower extent, among diamond polishers and dental technicians. Spain has established a workplace exposure limit of 0.02 $mg\,m^{-3}$ for cobalt.

^{58}Co and ^{60}Co are radioactive isotopes produced from routine operations of nuclear power plants. Although the half-life of these isotopes is relatively short ($t_{½} = 71$ days and $t_{½} = 5.27$ years), small amounts can be released into the environment as cooling water pollutants or radioactive waste. Furthermore, small amounts of cobalt could be released to the atmosphere from incinerator plants that use carbon as fuel or from the vehicle exhaust tubes.

As already mentioned, contaminated soils by highway and airport traffic or other types of industrial pollution could contain high cobalt concentrations. The mobility of cobalt present in the soil depends on the acidity of the medium. Thus, cobalt may be transferred from the plants' edible parts, mainly fruits, grains, and seeds, to the food industries. Although animals eating these plants will accumulate this metal, this fact does not seem to increase cobalt transmission and concentration along the food chain.

Finally, over the last years, the use of cobalt alloys as biomaterial in orthopedic joint replacement has created a new source of cobalt exposure. In dental usage, the term 'steel' became a synonym of cobalt–chromium alloys. On the other hand, the use of metal bearings in hip joint arthroplasty may cause a serious concern because of the wide applicability in susceptible patients.

Allergic Effects

The existence of allergenic reactions to cobalt is well known causing an erythematous and papular dermatitis. Cobalt ions can act as hapten and bind to macromolecular components to produce immunogenic products that can account for allergic reactions. Cobalt allergy occurs as a result of exposure to substances containing this element such as detergents, hair dyes, creams, and fertilizers. Also, the body adornments (jewels) may contain cobalt. A sensitivity of 7.6% has been reported by the North American Contact Dermatitis Group in individuals patch-tested from 1998 to 2000. Similarly, a study carried out in Denmark for 10 years (2003–12) has documented a positive association between cobalt allergy and dermatitis caused by nonoccupational exposure to leather goods.

Photosensibilization of cobalt in cement has been described in bricklayers, itself being manifested by severe and diffuse eczematous dermatitis in the body and limbs. A cross-sectional study developed in the Swedish hard-metal industry showed a prevalence of irritant reaction and hand eczema of 15% and 10%, respectively. Usually, skin cobalt allergy is related to other allergic reactions caused by other metals such as chromium and nickel (cross-reaction).

Dental technology students have an increased risk of developing contact dermatitis during their studies, owing to the use for training purposes of alloys that release high amounts of cobalt (0.0047–820 $\mu g\,cm^{-2}\,week^{-1}$). Dental technicians and students mostly have short and repeated contact with tools and alloys containing this element, which may result in the deposition of large amounts of metal on their skin. A severe, generalized pruritic eczematous rash in an 84-year-old woman with cobalt–chromium prosthetic hip for a fractured femur neck has also been diagnosed in Australia. The replacement of the cobalt–chromium hip prosthesis with a titanium-on-polyethylene one

aided to overcome her dermatitis and the serum cobalt levels decreased from 967 to 232 nmol l^{-1} after 3 months. Table 3 shows several investigations performed over allergic effects of cobalt exposure.

Carcinogenic Effects

Studies on carcinogenic effect of cobalt are inconclusive. Although inhalation of cobalt particles could be related to the increased risk of lung cancer, this carcinogenic effect is not so clear when is contacted by other means. In 1990, the International Agency for Research on Cancer concluded that the epidemiological evidence was inadequate in classifying cobalt or cobalt compounds as human carcinogens and that there was sufficient evidence for the carcinogenicity of cobalt metal powder and cobalt oxide in experimental animals.

Sarcomas in rats have been observed at the site of injection of cobalt salts or cobalt metal powder. However, similar injection studies have provided little evidence of cobalt-induced cancer in mice, hamster, and guinea pigs. The chronic exposure (0–3 mg m^{-3}, 6 h day^{-1}, 5 days $week^{-1}$ during 104 weeks) to aerosols containing cobalt sulfate has shown a major incidence of lung tumors in rats and mice of both sexes. The study has also found a major prevalence of liver hemangiosarcoma in male mice. However, in this case, significant correlations could not be established due also to a higher prevalence of infection by *Helicobacter hepaticus*. In relation to the use of cobalt alloys as biomaterial, several studies have evaluated the effects of implanted Co–Cr alloys on the development of tumors in animals. Four out of six studies reported tumors at the implant site, whereas two studies reported no such increase.

Two epidemiological studies were developed in France to observe the incidence of lung cancer among hard-metal workers. In this case, cobalt exposure is associated with tungsten carbide exposure in the hard metal-manufacturing industry. It was found that these workers had an increased mortality from lung cancer due to the simultaneous exposure to cobalt and tungsten carbide. Although occupational risk was highest among smoking workers, this excess mortality could not be attributed to smoking alone. The toxicity of cobalt–tungsten carbide has been also studied using lung epithelial cells *in vitro*. The toxicity was higher in nanoparticles (80 nm) against microparticles (4 μm), suggesting that internalization may play a role in enhancing toxicity. Another research has estimated the risk of cancer, especially lung cancer, among women workers exposed to cobalt aluminate spinel used in the porcelain factories in Denmark. In that study, a woman group was selected to be exposed to cobalt and further was compared with a woman reference group from cobalt-free department in a factory. The results showed a higher risk of lung cancer in both groups if compared with the whole Danish women population, although the risk was only slightly higher for the exposed group than for the reference group. Moreover, a higher risk of cervical cancer was found in the exposed woman group and of corpus uteri cancer in the reference group. Finally, an increase in mortality from lung cancer was reported among cobalt recovery workers in Soviet plants concerned with nickel extraction. However, there was a simultaneous exposure to nickel and arsenic that could explain this finding.

The use of Co–Cr alloys as hip implants has also been studied in humans for long periods (3–7 years). Most of the studies developed in patients showed that there is no evidence that these metal-on-metal bearing surfaces are associated with an increased risk of any cancer diagnosis. Table 3 shows some relevant studies over carcinogenic effects of cobalt exposure.

Cobalt Genotoxicity

Some *in vitro* studies, with human lymphocytes or mammalian cells, indicate that cobalt (II) ions may affect DNA integrity either directly through a Fenton-like mechanism or indirectly, affecting the repair system of DNA damage. Another study, comparing the effect of fine and nanoparticle alloys of cobalt–chromium on human fibroblast cells, noted that the nanoparticles generated free radicals, cell DNA damage, cytotoxicity and aneuploidy. This genotoxic effect has also been shown with cobalt oxide nanoparticles in human hepatocarcinoma cells through an increase in lipid hydroperoxide and reactive oxygen species generation.

In vivo intraperitoneal administration of cobalt (II) ions (50–100 μmol kg^{-1} as cobalt acetate) in rats produced oxidative DNA damage in renal, hepatic, and pulmonary chromatin. Similarly, chromosomal aberrations have also been found in bone marrow cells of mice after a single oral administration of high doses of cobalt chloride (20–80 mg kg^{-1}). With all the previously mentioned, there is considerable evidence to consider that all soluble cobalt (II) salts have genotoxic effects in animals and *in vitro* models. However, there is no evidence available in humans. Thus, a human study realized by Belgian researchers detected no significant increase of genotoxic effects in workers exposed to cobalt-containing dust, at a mean level corresponding to TLV-TWA (20 μg m^{-3}), as compared to controls. Although several epidemiological studies show that occupational exposure to hard-metal particles is associated with an increased risk of lung cancer and despite the increase of reactive oxygen species tested with *in vitro* models, there is no evidence of a genotoxic effect by cobalt compounds in humans. Therefore, further investigation may be developed in this sense in the future.

Respiratory Effects

Several compounds are thought to cause lung damage through the generation of oxygen-derived free radicals and related reactive compounds. The respiratory system is the most affected organ resulting from cobalt exposure by inhalation. In addition to the possible increase of the incidence of lung cancer, different types of toxic reactions related with respiratory system have been reported, including the upper respiratory tract, the bronchial tree, and the alveolar parenchyma.

Upper Respiratory Tract

Animal studies have shown degeneration of the olfactory epithelium, squamous metaplasia of the respiratory epithelium, and nonneoplastic lesions of the nose and larynx of rats and mice exposed to aerosols containing cobalt sulfate hexahydrate. Furthermore, studies performed on humans showed that inflammation of the nasopharynx seems to be frequent in hard-metal workers. However, it is not clear whether the occurrence of these symptoms is produced by particles containing cobalt or from an immunologically mediated reaction (allergic rhinitis). It has also been observed that subjects working in lignite mines have a high prevalence of atrophic rhinitis, which may be related to an excessive pollution caused by airborne contaminants such as chromium, nickel, cobalt, and lead.

Bronchial Tree

Cobalt has been identified as an occupational agent, which is involved in asthma diseases. Exposure to cobalt salts or cobalt metal released from diamond-polishing activities may cause typical bronchial asthma in a small proportion of workers (generally <5%). Similarly, 7% of workers exposed to cobalt dust at a hard-metal plant of Uppsala (Sweden) reported asthma. Another study showed that chromium and cobalt salts (in the form of cobalt chloride) can be responsible for occupational asthma in workers exposed to higher metalworking fluid aerosols of an aerospace manufacturer of Birmingham (the United Kingdom). A higher urinary excretion of chromium and cobalt was observed in the occupational asthma group than in the asymptomatic control group.

The pathophysiology of cobalt asthma may involve both immunologic and nonimmunologic mechanisms. Japanese researchers showed IgE antibodies to cobalt-conjugated human serum albumin in some of the cobalt asthma patients. For the remaining patients, the mechanism of cobalt-induced asthmatic reaction remains unknown. In order to investigate this mechanism, it could be noted that a positive lymphocyte transformation test with cobalt (II) ions has also been reported in hard-metal asthma, suggesting a role for cellular immunity. On the contrary, a study conducted to analyze all the cases of cobalt asthma encountered in a cobalt plant of Kokkola (Finland) used skin prick tests for cobalt and common environmental allergens. None of these patients had a positive reaction against cobalt in skin prick test, indicating a nonimmunologic mechanism.

Lung Parenchyma

In 1950, severe and fatal pulmonary edema and hemorrhage were firstly described in rats treated intratracheally with cobalt metal powder (500 μg per rat). Similarly, intratracheal instillation of 10–50 mg of cobalt metal produced acute pneumonia with diffuse cellular infiltration and bronchiolitis obliterans. Subchronic response assessed 8–12 months after the acute dose was characterized by the presence of multinucleated cells and a lack of cellular reaction within the alveolar walls. Short-term exposure appears to have fewer adverse consequences. Exposure of rats to aqueous suspension of ultrafine metallic cobalt particles (20 nm) during 4 days at 5 h day^{-1} induced slight and reversible pulmonary injury including focal hypertrophy or proliferation of the epithelium in the lower airways.

Hard-metal pulmonary fibrosis has been known for over 70 years, in subjects exposed to dust produced during mixing, shaping, and grinding of hard metals. Several studies have shown a close relationship between cobalt exposure and lung fibrosis. Thus, parenchymal reaction in some hard-metal workers exposed to dust containing cobalt has been observed. Histological changes varied from intense desquamative alveolitis with giant multinucleated cells to end-stage nonspecific pulmonary fibrosis. A weak association of the disease with a

specific human lymphocyte antigen (HLA) polymorphism (glutamate 69 in HLA-DP beta chain) has been reported.

According to the medical literature, bronchial asthma is considered the main etiologic agent inducing hard-metal fibrosis. The essential factor to avoid the progression of the disease is to separate the affected individuals from the work environment. However, in many cases, the disease remains despite the cessation of exposure and not always is managed with steroid treatment. To summarize, Table 4 shows several investigations performed on respiratory effects of cobalt exposure.

Cobalt and Thyroid Function

Animal studies have confirmed that cobalt is a goitrogen (a substance that suppresses the function of the thyroid gland by interfering with iodine uptake). This effect may be related with the capacity of cobalt ions to inhibit tyrosine iodinase enzyme. In a cobalt production plant, a subclinical hypothyroid status has been observed in some workers. Similarly, increased concentrations of total and free serum thyroid hormone have been found in workers exposed to cobalt–zinc sulfate.

Cardiovascular Diseases

Cobalt is considered responsible for a type of myocardiopathy with a specific pathogenesis. As already mentioned, the first cases reported of myocardiopathies associated with the intake of high doses of cobalt were related to beer drinkers. In the second half of the 1960s, in some areas of Canada, the United States, and Belgium, a large number of subjects, all of them great beer drinkers, showed a particular dilatative myocardiopathy associated with other symptoms such as cardiocirculatory insufficiency with dyspnea, hypotension, tachycardia, cyanosis, enlarged heart with reduced cardiac output, and in many cases a large pericardial effusion. The mortality rate of subjects was as high as 50% in some areas. It was observed that these pathologies were attributed to cobalt added as a foaming agent (1 ppm on average) in the form of sulfate or chloride. This meant an estimated daily intake of 6–8 mg of cobalt. Complications in the diagnosis of cobalt myocardiopathy were also related to the possibility that alcohol would also be able to induce such cardiopathy. Thus, cobalt myocardiopathy could be an advanced state or a particular type of alcoholic myocardiopathy. According to some authors, a fulminant form of beriberi due to thiamine deficiency was caused by alcohol and aggravated by cobalt. Finally, other studies claimed the direct toxic role of cobalt.

Several cases of myocardial toxicity have been associated with cobalt industrial exposure. Workers of a cobalt compound plant showed an association between cumulative cobalt exposure and left ventricular isovolumic relaxation time and deceleration time of the velocity of the early rapid filling wave, indicating altered left ventricular diastole. Another study investigated cardiac function of a group of Italian hard-metal workers with or without hard-metal fibrosis. The mean duration of exposure was 10.4 years, ranging from 1 to 40 mg m^{-3}, whereas that level of environmental exposure ranged between 0.009 and 13.6 mg m^{-3} cobalt. An abnormal left ventricular ejection fraction during resting and at exercise was also found, which could be explained by the formation of cobalt deposits in the myocardium after industrial exposure. The subjects also showed ventricular dysfunction and abnormality of the right ventricular function, which could be a manifestation of initial pulmonary artery hypertension or of early occult cor pulmonale.

Several mechanisms about cobalt toxicity on the cardiovascular system have been proposed:

(1) Impairment of antioxidant enzyme activities and myocardial mitochondrial ATP production rate. An experimental study showed a lower activity of manganese superoxide dismutase in rats exposed to a cobalt-supplemented diet for 24 weeks against control group. Activity in the

Cocoa: Composition and Health Effects

DD Mellor, University of Nottingham, Loughborough, UK

Description of Commodity

Cocoa is derived from the 'bean' from the cocoa or cacao tree (*Theobroma cacao*), which is cultivated in the equatorial regions, as it requires a hot climate with high levels of precipitation to grow and produce optimal yields. The cocoa 'bean' develops in large and often colorful pods that contain the bitter seeds used in the manufacture of cocoa and, subsequently, chocolate.

Sources and Production

Postharvest, the 'bean' requires a number of processing steps that, ultimately, can influence many of the potential health benefits and organoleptic properties of end products. Processing can not only degrade polyphenolic compounds, reducing bitter flavors, which may be preferable to consumers, but also reduce the availability of compounds that may be responsible for the beneficial bioactive functions.

The initial step, following harvesting and splitting of the pod to remove the 'beans,' is fermentation. The remaining pulp around the 'beans' is removed, which allows the rich flavors associated with cocoa to develop. The exact method varies from country to country; it can be achieved by simply by covering the piles of beans with leaves or with the use of boxes designed especially for this purpose.

Following fermentation, which can take between 5 and 8 days depending on method and country, the 'beans' are dried and winnowed where the 'bean' is cracked to separate the shell from the nib (the part that is used to make cocoa and chocolate). The nibs are roasted to further develop flavor. These roasted nibs are ground before processing to produce cocoa powder and cocoa butter. This has the effect of separating the fat-rich cocoa butter, which is used in chocolate production along with many applications in the cosmetic industry, and the cocoa powder, also often described as fat-free cocoa mass. The distinction of fat-free cocoa mass from cocoa solids is important, as a chocolate high in cocoa solids is not necessarily high in fat-free cocoa mass, which is the cocoa component rich in potentially beneficial polyphenolic compounds. Chocolate, which typically lists cocoa solids as part of the ingredient labeling information, is a composite of cocoa butter and fat-free cocoa mass (cocoa powder).

The separation of the fat-free cocoa mass from cocoa butter is important as it enhances the stability of final products, reducing any separation of fat that can result in unpleasant 'blooming' where a white fatty layer can be seen on the surface of products, as was the case with eighteenth-century cocoa drinks and poorly stored chocolate today. Separation is achieved using methods such as the Dutch process that uses alkali to produce a mellower-tasting product, which may be lower in polyphenols, prior to hydrolytically pressing the powder from the fat or the Broma process, which is a slower process using a combination of sieving and temperature to produce what is known as natural cocoa. Van Houten developed the former method, while the latter was developed in the United States at the Ghirardelli factory. These processes were accompanied by a number of other technological advances in the nineteenth century that helped change cocoa products from a bitter drink to the modern drinking cocoas and chocolates that are enjoyed by millions today. Cocoa and chocolate are products often consumed for pleasure owing largely to their hedonic qualities and luxury image. Initially, this led to research aimed at understanding potential harms, including tachycardia, but this has changed dramatically over the last decade and a half with the investigation of potential health benefits.

The emergence of potential health benefits from compounds found in cocoa is of great interest to both the scientific community and the food industry. Arguably, a disproportionate amount of work is being undertaken using cocoa and chocolate due to commercial interests, which may not exist to fund work with other plant-based foods containing similar compounds. Alongside potential financial interests, a key property of cocoa and chocolate is that they are rich sources of polyphenolic compounds, which are stable over time. Chocolate has been shown to maintain its polyphenol content 2 years after manufacture, with low levels of contaminants and bacteria growth, characteristics not seen in fruit and vegetables. Whereas other commodities, including teas, appear to be less stable, with a shorter shelf life, they are yet to demonstrate similar levels of bioavailability to the polyphenols found in cocoa or chocolate. This, together with good consumer acceptability and desirability, has resulted in over 2000 peer-reviewed papers describing research on cocoa or chocolate in PubMed by August 2014.

A key challenge in the promotion of any potential health benefits derived from the consumption of cocoa and chocolate is the way it is considered as a food by society and the formulations that are most popular. Many products based on cocoa are energy dense, resulting from high levels of fat and sugar. Chocolate as a formulation varies from country to country; often, cocoa and cocoa butter can have added sugar and, potentially, milk and/or other emulsifiers (typically soy lecithin), which in some countries are accompanied by added vegetable fats; in Europe, only illipe, palm oil, sal, shea, kokum gurgi, mango kernels, and copra oil can be used. But this can mean that chocolate contains around 500–530 kcal per 100 g (2050–2250 kJ), 27–32 g of fat of which 16–19 g is saturated, and 45–64 g of added sugar (typically sucrose). When sold as a powder, cocoa contains around 310 kcal per 100 g (1300 kJ), 22 g of fat of which 13 g is saturated, and only a trace of sugar. However, cocoa is consumed rarely in this form, and often, sugar and fat (often from added dairy fat) are added, which can dramatically alter nutritional composition. So, by definition, in some territories, chocolate cannot be considered as a food with a health claim simply because of its high fat and sugar content.

Availability, Absorption, and Metabolism

The mechanism(s) and exact bioactive compounds responsible for the health benefits observed have also been an area of debate. Epicatechin has been proposed as the key biologically active polyphenol, in part not only due to its relatively low molecular weight but also because it has been detected in plasma following ingestion. However, it is equally likely that many of the polyphenolic compounds found in cocoa and chocolate are metabolized in the gastrointestinal tract, degraded and transformed chemically both by stomach acid and by the microflora of the colon prior to absorption. It has been suggested that many of these metabolites could be responsible for the beneficial effects of cocoa and chocolate rather than the compounds native to cocoa after processing.

The complex nature of cocoa, as a source of polyphenols, alongside other bioactive compounds such as theobromine, a bioactive amine with similar effects to caffeine, has been hypothesized to be responsible for many of the health benefits. This is aside from its unique fatty acid and amino acid profiles and the fact that cocoa is a good source of many micronutrients, including magnesium and iron, which also may impact human health. Potentially, this means that it is difficult to identify if the benefits arise from one active compound or a synergistic mix of compounds. In addition, the hedonistic and socially ascribed qualities given to chocolate since the Aztecs could infer benefits purely from its consumption in a Hawthorne-type effect, where individuals improve or modify an aspect of behavior in response to being observed.

Much of the initial work *in vitro* focussed on the antioxidant properties of the phenolic rings in cocoa polyphenols. This is demonstrated by the very high oxygen radical absorbance capacity (ORAC) value for cocoa. However, the effect of these compounds *in vivo* is less related to their antioxidant properties, as their bioavailability is not sufficient to support this mechanism, than the number of pathways targeted by cocoa polyphenols. The most widely studied is perhaps inducible endothelial nitric oxide synthase (eNOS), a key enzyme involved in how blood vessels respond to the sheer stresses caused by changes in blood flow and pressure. Cocoa polyphenols are associated with an increase in nitric oxide, which improves the capacity of the blood vessel to expand and reduces the risk of damage that might lead to the development of atherosclerotic plaques and, ultimately, cardiovascular disease. Other key enzymes acted on by cocoa polyphenols include AMP-activated protein kinase, which can influence insulin resistance and lipid metabolism in a positive way, and the angiotensinogen-converting enzyme pathway, which is key in determining blood pressure.

History of Consumption and Formulation Including Some of the 'Issues'

The consumption of cocoa can be traced back to the civilizations of Central America, especially the Mayans and Aztecs, although it appears to have originated in South America where a wide variety of native cocoa trees can still be found. Cocoa has been cultivated since about 1500 BC. Historically, a number of physiological effects have been linked to cocoa consumption, with its use initially linked to rituals; it was consumed as a bitter drink mixed with chili or even blood by the ruling classes, priests, and warriors. It was suggested by Montezuma II that a soldier could march for a whole day on a single cup of cocoa without getting fatigued. During the time of the conquistadors, Spanish monks recorded in detail the potential health effects of cocoa, including as a treatment for consumption (tuberculosis), digestive problems, and general fatigue. Following these expeditions, cocoa was brought to Europe, but dismissed in many royal courts at the time as moldy almonds, although in Spain, a culture of cocoa drinking did develop. This spread across Europe, despite the fact that cocoa was bitter and the fat component did not form a stable emulsion upon mixing with water. The culture of cocoa drinking was a concern in France, where it was considered a narcotic, most likely as a result of cocoa houses becoming places where intellectuals would meet and, because cocoa provided an alternative to the alcoholic beverages, began to think more radically. However, it was not until the industrial revolution when methods, such as the Dutch process and conching, developed that modern cocoa and chocolate began to be manufactured. Discovered by Rodolphe Lindt, conching physically redistributes fat in cocoa to improve the texture of the end product, mixing cocoa powder for a long time using a paddle that scrapes the surface of the bowl. Air and friction reduce the amounts of volatile fatty acids and oxidize some of the bitter compounds, thus mellowing the taste of the end product. However, this process and others while mellowing flavor have the potential to reduce further levels of bitter bioactive compounds, including epicatechin and theobromine. During this period, Joseph Fry also discovered that, if cocoa butter was added back to cocoa, the product could be molded allowing the first chocolate bars to be produced.

Within much of northern Europe and North America, milk chocolate is more popular than the bitter plain chocolate, probably because of its mellower and sweeter flavor. Milk chocolate was initially developed in Switzerland following the invention of a process to dry milk. Until then, it was only possible to mix milk with cocoa in a drink: Daniel Peter added the dried milk developed by Henri Nestlé to cocoa liquor, creating milk chocolate.

All these developments needed raw ingredients, namely, cocoa and sugar, which came from plantations and colonies of the Dutch, Spanish, and British empires and depended to a large extent on the slave trade up until its abolition. The combination of global trade and industrialization meant that cocoa and chocolate became not just a rare treat for the wealthy, but a product consumed widely by the whole of society. Its high energy content, including saturated fat and sugar, means that chocolate has been implicated as a cause of a range of problems including obesity, poor skin health, and dental caries. However, epidemiological data do not support a link between chocolate consumption and obesity; if anything, the data suggest the opposite. These findings need to be taken with a note of caution, as such studies are prone to a degree of selection and reporting bias, as they rely on participants reporting what and how much chocolate they eat.

Health Effects

Early work studying the Kuna Indians, an indigenous population inhabiting islands near Panama, provided modern insight

into the health effects of cocoa. This ethnic group has little age-related increase in blood pressure or associated hypertension. However, when members of this group moved to the urban environment of Panama City, they display expected levels of hypertension. This could be said to represent the classic 'migration type' study, suggesting a lack of a genetic effect, and the increase in hypertension must be attributed solely to environmental influences. The island-dwelling Kuna consume large quantities of cocoa daily, both as drinks (up to five cups a day) and as an ingredient in cooking. Those living in Panama City, however, consume very little cocoa. Moreover, the island-dwelling Kuna have a threefold higher level of nitric oxide metabolites in their urine compared with those living in an urban environment. These epidemiological data clearly suggested an association between cocoa polyphenols (mainly flavanols) and improved vascular function and support the view that increased nitric oxide, via the induction of nitric oxide synthase, could be the mode of action.

Epidemiological evidence of the effect of chocolate has largely been derived from studies in which data collection was initially undertaken as part of other studies, and the effect of cocoa or chocolate consumption examined as post hoc analysis. The majority of these data have been derived from European prospective study data sets, which are supported by cross-sectional data from the United States and Spain. The cross-sectional natures of European cohort studies lack predictive power because of their design. European studies, however, reported hard end points, including death and myocardial infarction, suggesting that chocolate consumption is associated with a reduced rate of mortality.

Data from the Zutphen Elderly Study reported by Buijsse et al. considered the effects of consuming foods containing cocoa in elderly men over a period of 15 years. The findings suggested no association between sugar confectionary consumption and mortality but did demonstrate a significant inverse association between habitual intake of cocoa-containing foods and cardiovascular mortality rates (as well as all-cause mortality rates). This was in agreement with the cross-sectional data collected at the start of the study, suggesting a significant inverse association between blood pressure and habitual intake of foods containing cocoa. These data were subsequently confirmed by analysis of the Potsdam cohort from the European Prospective Investigation into Cancer and Nutrition reported by Buijsse et al. In this group, chocolate consumption and blood pressure were assessed at baseline and found to be inversely associated in nearly 20 000 individuals aged 35–65 years of age. When followed up, those who consumed the greatest quantity of chocolate had a significantly lower risk of myocardial infarction and stroke than those consuming the lowest amounts (RR = 0.61 (95% confidence interval 0.44–0.87)), with 12% of this effect (95% confidence interval 3–36%) explained by the effect of chocolate on blood pressure after an average follow-up period of 8 years.

Cocoa polyphenolic compounds have been reported to have beneficial effects on cardiovascular risk, including the lowering of blood pressure, in both animal models and clinical trials with human participants. In rats, the consumption of cocoa polyphenols demonstrated not only a reduction in blood pressure but also an increase in the expression of a number of genes associated with endothelial function, which suggests the potential for an epigenetic effect of polyphenols. Upregulated genes associated with reduced blood pressure acted on endothelial function via increased nitric oxide and prostaglandin production.

Many of the clinical studies demonstrating a reduction in blood pressure attributed to the effect of polyphenols have been credited to changes in endothelial function. However, work in individuals with type 2 diabetes has shown an improvement in endothelial function but no change in blood pressure. The effects of the underlying condition and concomitant medication, which may reduce blood pressure but have minimal effect on endothelial function, could explain this apparent contradiction. It has been suggested that the improvement in endothelial function derives from an increase in redox-sensitive activation of the phosphatidylinositol 3-kinase/Akt pathway, which results in the activation of eNOS. This is thought to be via an increase in intracellular free calcium concentration and activation of estrogen receptors. These changes appear to go beyond just nitric oxide with cocoa polyphenols acting on other endothelium factors. The improvements seen in endothelial function have been linked to insulin signaling and, ultimately, the potential to reduce insulin resistance. In individuals with type 2 diabetes, the results are inconsistent. However, in studies with healthy individuals and those with hyperinsulinemia consuming high doses of chocolate (100 g day^{-1}) for 2 weeks, reductions in insulin resistance have been reported consistently. Alongside the potential for better endothelial function and insulin sensitivity, it has been suggested that activation of the AMPK pathway in both the skeletal muscle and liver could explain improvements in insulin sensitivity.

Cocoa and chocolate polyphenols have also been associated with the beneficial effects on dyslipidemia across a range of clinical and nonclinical groups, including individuals with type 2 diabetes. This is in accordance with data that suggest diets rich in plant-derived foods and polyphenols are associated with more favorable lipid and cholesterol profiles and reduced cardiovascular risk. Data from mice models of diabetes suggest that cocoa polyphenols might act via hepatocellular AMP-activated protein kinase (AMPK) along with its downstream target, acetyl-CoA carboxylase. In 2006, Zang et al. reported that the effects of these polyphenols were approximately 200 times more potent than metformin, the most commonly used pharmaceutical agent in type 2 diabetes, on lipid metabolism. As in the case of blood pressure, there are a number of alternate mechanisms by which cocoa polyphenols might act to improve the lipid profile including the modulation of the ATP-cassette binding protein. In data from human studies, improvements in lipid profiles, specifically increased high-density lipoprotein (HDL) cholesterol levels, have been seen in populations with diabetes. Another research suggests that polyphenols may reduce the overall amount and vulnerability of low-density lipoprotein (LDL) cholesterol to oxidative damage. Some of the data from clinical studies are challenging to interpret, as often cardiovascular risk and LDL cholesterol are calculated, rather than measured, creating a potential for bias and/or confounding factors, meaning interpretation needs to be undertaken with care.

Despite dismissing the potential of cocoa and chocolate as having an antioxidant effect *in vivo* because the data from human

studies are largely equivocal, it is still important to consider what is meant by oxidative stress and how it is measured. A number of methods available can be insensitive to changes in response to diet or can be directly influenced by their presence as components of acute food intake, rather than showing any effect upon endogenous redox biology. The relatively poor absorption of cocoa polyphenols resulting in low plasma concentrations compared with other antioxidant compounds, including uric and ascorbic acids, suggests that any effects are likely to go beyond just antioxidant capacity and act via multiple mechanisms. It is logical that the beneficial effects of polyphenols on endothelium function arise from increased synthesis of endothelium-derived factors, such as nitric oxide and prostaglandins, which are also free radical scavengers, resulting in an enhanced pool of potentially beneficial compounds. Along with the effects of cocoa polyphenols that have been demonstrated on superoxide dismutase, this increase in free radical scavengers might explain the reductions in oxidative stress markers including lipid peroxidation and DNA damage.

Cocoa polyphenols may also have positive effects on coagulation and clotting, having been demonstrated to inhibit platelet aggregation, the potential mechanism being via decreased production of superoxide anions and increased nitric oxide synthesis, which in addition would reduce levels of oxidative stress. A further potential effect of polyphenols on health is as 'an antinutrient' or chelating agent. This could be considered as a 'negative effect' with increased risk of micronutrient deficiencies and disease, such as iron-deficiency anemia. However, this chelating effect could potentially reduce chronic disease risk. Both in the gastrointestinal tract and, potentially, in circulation, by binding metal ions that could otherwise be prooxidants, oxidative stress and oxidation of LDL cholesterol and/or DNA damage might be reduced. Currently, these effects are little more than a hypothesis based on mechanistic work *in vitro*. It is clear, however, that beneficial effects of cocoa are likely to be derived from polyphenols and these compounds appear to have multiple modes of action, with the mechanisms described in this article often interacting and overlapping.

Cocoa and chocolate have been proposed to improve cognition, based on mechanisms associated with nitric oxide metabolism. This has been demonstrated in animals, but work in humans has also reported the potential of improved cognition. This concept has been hypothesized as perhaps reducing progression in dementia, but consistent data are not yet available. The effects of cocoa butter as a cosmetic product have been observed for many years; the effect of chocolate on the resistance of skin to ultraviolet light damage has also shown limited promise in clinical studies.

Chocolate and cocoa drinks have been studied as a potential ergogenic aid in sport, for both professional athletes and the general public. Initial studies have suggested that chocolate might delay perception of fatigue and, thus, improve exercise performance. This has been associated with a reduction in glucose oxidation linked to the effects of polyphenols. Data are yet to demonstrate this effect consistently. Other areas of interest in exercise physiology are the potential of cocoa polyphenols to modulate oxidative stress and inflammation associated with exercise; mechanistic work *in vivo* shows promise, but the practical implications are yet to be demonstrated.

Endeavors to explore the health potential of chocolate are less than 20 years old. From the initial work *in vitro* of Waterhouse, Shirley, and Donovan in the mid-1990s to the first human studies reported in 2000, attempts have been made to see if cocoa has the potential to reverse or prevent disease processing pertaining to cardiovascular disease and cognitive decline. The vast majority of these studies have been undertaken in healthy individuals, with a few undertaken in populations with, or at increased risk of, cardiovascular disease. Only five studies have been undertaken in individuals with diabetes, for example, and two with heart failure or following heart surgery. Some of these studies have combined cocoa, typically in the form of chocolate, with other potentially bioactive compounds, such as soy isoflavones and lycopene. It is possible that favorable palatability and acceptability of chocolate mean that it could be used as a carrier or vector for other less palatable plant-derived bioactives in the future.

The key challenge when attempting to ascertain the potential health effects of cocoa and chocolate lies in the way many studies are conducted. There is little consistency in the formulations or even concentrations/doses of polyphenols being consumed by participants. This reflects that cocoa and chocolate manufacturers have, at least, supported many studies financially and, therefore, are unlikely to share commercially sensitive data with respect to recipes and composition. Additionally, many of the studies are limited in duration and often sample size, with very few studies exceeding 100 participants or lasting greater than 12 weeks. The reliability of many studies is also brought into question as, although many studies state that participants were blinded to the cocoa or chocolate they were given, on closer examination, it is apparent that the control product(s) was milk in studies of cocoa beverages or white chocolate in studies of dark chocolate. Under such conditions, it is highly plausible that informed study participants would be fully aware of the arm to which they had been assigned. In a review, Karen Cooper et al. summarized the first 10 years of research on the health effects of chocolate and proposed an 11-point checklist for planning future trials. These included the design of the trials; need to consider the matrix or formulation used; use of chocolate in preference to cocoa; transparency in terms of both independency of the trial from industry and the need to register human trials publically; careful selection of biomarkers, especially those assessing antioxidant effects; and, finally, publication of null or negative results.

Future and Health Claims

Increasingly, in many countries, claims associating food and health are being regulated. In Europe, for example, the European Food Safety Authority (EFSA) has a rigorous assessment process for assessing health claims whether maintaining health or preventing disease, which can be generic or proprietary. The latter provides sole use for a claim for 5 years protecting the investment in intellectual property. To be awarded a health claim, foods need to have an identifiable, well-characterized component with a defined mechanism(s) of action and effect and clinical trial data to support the effect *in vivo*. In 2012, the EFSA gave a positive opinion for a proprietary health claim by Barry Callebaut (BE) for a cocoa product containing flavanols. This was granted under Article 13.5 and, potentially, allows these cocoa and chocolate products to carry the claim that *Cocoa flavanols help maintain endothelium-*

dependent vasodilation, which contributes to normal blood flow. This claim acknowledges the growing body of data from many sources for chocolate and cocoa that have been shown to demonstrate this effect. However, it is perhaps less clear how the general public would interpret this claim and if it would influence purchasing decisions.

Not all health claims linked to cocoa and chocolate have been as successful. In 2012, the USDA withdrew publication of ORAC values from its Nutrient Data Laboratory website (http://www.ars.usda.gov). This decision was based on mounting evidence suggesting that there was no link between the antioxidant capacity of foods and chronic disease risk. Using the PASSCLAIM criteria, which are the basis for a positive opinion for a health claim, it was found that reduction in cardiovascular risk could not be attributed to the antioxidant capacity of polyphenol-containing foods, such as cocoa. This perhaps explains the EFSA judgment in 2010 that found a causal relationship could not be demonstrated. The panel also stated that any beneficial psychological effect (as with physiological effects) could not be linked to the antioxidant activity, content, or properties.

So, although one health claim has reached the EFSA threshold, many have failed due to poor characterization of the bioactive compounds, the absence of clear mechanism(s) of action, or inadequate clinical trial data. This does not mean that chocolate will eventually be labeled with health claims, as nutritional composition and portion size are also important. The Barry Callebaut claim was for 10 g of a specially formulated chocolate, or 2.5 g of cocoa, containing 200 mg cocoa flavanols, more than twice the more typical levels of polyphenols. Otherwise, the energy content and added sugar would make a health claim for chocolate incompatible with established public health messages.

Many of the negative aspects of chocolate and cocoa consumption have not stood up to rigorous examination, with no apparent weight gain seen in studies or when observing populations. However, the shift in focus to consider the beneficial effect of polyphenols and recommendations of higher intakes, especially in an aging population, should be undertaken with caution owing to the largely under studied potential of food–nutrient–drug interactions. It has been suggested that epicatechins and other flavanols can act on cytochrome P450, including CYP3A4, which are responsible for the conjugation of many organic compounds, including a wide range of drugs. Thus, any compounds altering the action of this and similar enzyme systems could impact the circulating concentration of pharmaceuticals and their half-life and, ultimately, increase the risk of side effects or poor control of symptoms. This could lead, in the future, to as yet undefined negative health effects, which need to be studied before recommendations to increase intakes to above that achieved normally, for example, levels seen among the Kuna of Panama.

Conclusion: Cocoa and Chocolate for Health or Pleasure?

It is of note that the history of cocoa and chocolate consumption has been linked with potential health benefits. However, with industrialization, and the increased availability of sugar, a sweeter product has been created, which is associated with unproved negative health effects. This means that chocolate is likely to remain a luxury, nonessential food. However, it should not necessarily be considered as being inherently harmful and has potential for a number of well-defined health benefits. This does not mean that increasing consumption is wise, from both the perspective of sustainability, as ecosystems would need to be changed to grow more cocoa, and health, as eating more chocolate is likely to lead to increased energy intake, weight gain, and, potentially, long-term health consequences.

Cocoa Tree and Beans

Cocoa beans represent the seeds of the fruits of cocoa tree (*Theobroma cacao* L., order Sterculiacae), which is a native species of tropical humid forests on the lower eastern equatorial slopes of the Andes in South America. Cocoa was domesticated and consumed for the first time by the Mayas and Aztecs. The growth of the cocoa tree requires warm-humid climates with temperatures between 20 and 30 °C and high and constant humidity, conditions found in areas about 20° latitude north and south of the Equator. Abundant and well-distributed rainfalls are essential because the cocoa tree tolerates a dry season of up to 3 months a year. The cocoa tree is a rather delicate plant that does not tolerate direct strong winds and direct sunlight. In fact, it is generally grown in the shade of other tall trees (banana trees and coconut palms). Trees can reach up to 20 m in height, but are usually kept below 5 m. The fruit is 10–30 cm long and 7–10 cm wide and weighs ~400–1000 g. It is an indehiscent drupe called a pod or 'cabosside.' It can be spherical, cylindrical, pointed or blunt, smooth, or wrinkled. The pericarp has a thickness of 10–15 mm and can be of different colors depending on the ripeness and variety, turning from green to yellow, from red to orange. The optimum ripeness of the fruit varies according to the variety and generally lasts from 4.5 to 7 months. The fruit is harvested twice a year (in February/March and April/July). The summer harvest usually produces fruit of better quality. The seeds, in the number of 20–60 per fruit, are arranged in regular rows and immersed in a mucilaginous acidic pulp containing glucose and fructose and are called beans. Cocoa beans are the only economically valuable part of cocoa tree because they represent the raw material for the production of cocoa-based products. Each cocoa bean consists of two cotyledons (nibs) and a small embryo, all enclosed in a skin (shell). The cotyledons contain two types of cells: storage or parenchyma cells, containing fat globules, protein and starch granules, and pigmented cells, containing polyphenols and methylxanthines.

Cocoa Varieties and Geographical Diffusion

Two major botanical groups of cocoa are currently recognized: Criollo and Forastero. Criollo (native) corresponds to the subspecies 'cacao' and represents the original cocoa, previously consumed by pre-Columbian people. Its diffusion resulted from the dissemination through the Andes toward the lowlands of Venezuela, Colombia, and Ecuador and northward to Central America and Mexico, and to a large number of Caribbean Islands. Today the subspecies Criollo is found in Mexico, Colombia, and Venezuela. It represents only 5% of the world's production due to its great susceptibility to disease; making it difficult to cultivate. Criollo pods are green to red; the seeds are pale, ferment easily, have a pleasant and penetrating aroma, and have an optimum taste. Therefore they are considered an excellent quality cocoa. The Criollo is rarely used alone; most frequently it is used to fortify other mixtures having a weak and not persistent aroma. It can be subdivided into Central American Criollo and Venezuelan Criollo. The Forastero cacao (foreigner) corresponds to the subspecies 'sphaerocarpum' and resulted from dissemination toward the Amazon Valley in Northern Brazil and the Guyanas. In the nineteenth century, Forastero cocoa seeds were taken from South America to the islands of Sao Tomé of West Africa, then to Ghana. From Ghana, Forastero spread to other African countries, the most important of which are the Ivory Coast, Cameroon, and Nigeria. In these countries, there was an immediate increase in cultivated area, and they are now the largest producers of cocoa in the world. Forastero represents about 85% of the world's cocoa production because it is very strong, resistant to disease, and easily cultivated, especially in Africa. The seeds have a strong flavor, not very aromatic and of poor quality, and are generally used in a mixture with other more valuable varieties. Forastero cocoa is now a group very differentiated in several subspecies and hybrids. The best-known Forasteros are the 'Amelonados' with pods resembling melon, which were the predominant types traditionally cultivated in West African countries. The Amazonian subgroups show a wide genetic variability. Some Forastero plants growing in particular areas give cocoa of excellent quality (*cru*) such as Arriba, the national cocoa of Ecuador.

Natural hybridization between Criollo and Forastero led to the origin of a third variety of cocoa named 'Trinitario,' not found in the wild. It has been reported that the Criollo population from Venezuela and the Amelonado-type Forastero from Guyana could have been involved in hybridization leading to the production of Trinitario. It is difficult to specify the characters of Trinitarios as they may have pod and bean characters ranging from those typical of Criollos to those of Forasteros.

Cocoa Beans Harvesting, Fermentation, and Drying

These steps of the process are carried out in the countries of origin. Fresh cocoa seeds undergo fermentation and a drying process to be ready and stable for transport to the countries in which they will be processed to chocolate and related products. Local or regional variations in cocoa plant materials, fermentation procedures, and drying processes lead to a traded good typical of the country of origin; therefore, the composition of the fermented cocoa beans, which is one of the most important factors influencing taste and flavor of the cocoa products, depends not only on the cocoa variety but also on the geographic origin.

Cocoa bean fermentation can be considered the first key stage in cocoa products and chocolate production because

the series of biochemical reactions occurring in the beans is necessary for inducing the pleasant characteristics of cocoa-based products.

The fully ripe cocoa pods are carefully cut from the trees, are gathered into heaps, and can be stored for 2–5 days. This enhances prefermentation activity inside the pods. The harvested pods are broken by hitting against a hard surface, and the seeds are extracted from the fruit together with the surrounding sugary mucilaginous pulp (wet beans) and kept for fermentation immediately. The fresh bean is bitter and is not suitable for manufacture of cocoa products because it does not have any flavor, aroma, or taste of cocoa products. All the standard methods of fermentation essentially involve keeping together in heaps, baskets, boxes, or perforated barrels a mass of a reasonable quantity of wet beans for periods ranging from 4 to 6 days and mixing the mass of beans on alternate days. The natural beans' fermentations are generally carried out according to a traditional process. Among the various methods adopted for fermentation in the different cocoa-producing countries, the heap, tray, and box methods are considered the standard, widely adopted methods. The real substrate of the fermentation is not the bean, but the surrounding pulp that contains about 84.5% water, 10% glucose and fructose, 2.7% pentosan, 0.7% sucrose, 0.6% protein, 0.7% acids, and 0.8% inorganic acids and therefore it is a good substrate where a wide range of microorganisms can develop. Wild yeasts (*Kloeckera* and *Saccharomyces* spp.) and bacteria of genera such as *Lactobacillus*, *Bacillus*, *Pediococcus*, *Acetobacter*, and *Gluconobacter*, are involved in cocoa fermentation, determining alcoholic, lactic acid, and acetic acid fermentations.

The first consequence of fermentation is the loss of most of the pulp around the beans because the pulp substrates are broken down through microbial action; however, more important are the biochemical changes inside the cocoa beans that contribute to a reduction of their bitterness and astringency and improve their color and flavor.

In the first stage of the fermentation, yeasts proliferate and convert sugars to alcohol, then the development of lactic acid bacteria occurs, which contributes to sugar breakdown producing lactic acid. After the pulp has run off, the conditions become more aerobic, and the presence of oxygen allows acetic acid bacteria to take over from the yeasts and convert alcohol to acetic acid. Acids that are synthesized from pulp sugars move into the beans and lower the internal pH. The acetic acid diffusing through the beans causes a breakdown of the polyphenol and lipid membranes of the vacuoles of the cell, and the cell contents become mixed, allowing various enzymatic reactions to take place. One of the most important consequences is the oxidation of polyphenols and their conversion to insoluble forms due to the reactions with proteins; these reactions are responsible not only for the removal of the bitter taste from the beans but also for the strong reduction of total polyphenol content, thus affecting the antioxidant and health properties of cocoa. Oxidation of polyphenols is also responsible for the change of bean color, from violet to brown. During and after fermentation, another fundamental biochemical change occurs: internal beans' autolytic enzymes, in particular carboxypeptidase and aspartic endoprotease, are activated by the low pH; the proteins in the cotyledons undergo hydrolysis, giving rise to amino acids and oligopeptides, essential precursors for the development of cocoa aroma, arising from the reaction of amino acids with sugars (Maillard reactions) during the subsequent step of roasting.

The duration of fermentation ranges from 1.5 to 10 days, depending on the cocoa variety, climate, volume of cocoa mass, and the method adopted. Criollo ferments in a relatively shorter period of 2–3 days, whereas Forastero takes 5–7 days.

For the manufacturer of chocolate or cocoa powders the degree of fermentation of the beans is a major quality criterion. Fully fermented cocoa beans have a brown color. It has been shown that too high contents of nonfermented (slaty color) or partly fermented (violet color) beans result in a lack of cocoa flavor in the end product. The slaty beans cause a very acid and astringent flavor profile, whereas the violet beans cause a bitter and harsh flavor.

The fermented beans have a moisture content of about 55%, too high to permit the storage of the beans. The moisture content has to be lowered to about 6% for safe storage and transportation. Immediately after fermentation, cocoa beans are sun-dried or dried utilizing hot air. Depending on climatic conditions, the beans are exposed to the sun for about 12–20 days. This method generally gives good-quality beans in traditional areas of cocoa production where the weather is sufficiently sunny, as in West Africa. In the areas where the climate remains unsuitable for drying, artificial drying methods became necessary, utilizing hot air with a maximum temperature of about 60 °C. The humidity % after drying is 5–8%, with a weight loss of two-thirds with respect to the fresh bean. The dried beans are packed in jute bags of about 60 kg capacity and traded to transformation countries, where all the following steps (Figure 1) for production of chocolate and cocoa products will take place.

Processing of Fermented Cocoa Beans: Roasting and Production of Cocoa Liquor

A key step of chocolate production is roasting. Roasting is performed in the transformation countries, and flavor is formed during this step from the precursors developed during fermentation and drying of cocoa beans. The aroma precursors in cocoa beans, which include free amino acids, low-molecular-weight peptides, and reducing sugars, develop into the cocoa specific aroma through Maillard reactions during roasting.

Before roasting, cocoa beans are cleaned to remove stones, metals, and other extraneous materials. Beans are cleaned by passing through a series of screens and magnets. In some cases a preroasting process is applied. The roasting can be performed on whole cocoa beans or on cocoa nibs. In most cases the traditional roasting is performed on whole cocoa beans by hot air treatment, and cocoa shells are removed by aspiration (winnowing). Temperatures of roasting are generally lower that 150 °C and for times of from 30 to 120 min. Roasted cocoa beans are then lightly crushed to avoid dust formation, obtaining cocoa nibs.

Roasted cocoa nibs are milled to break down the cell walls and expose the cocoa butter. The resulting product is a homogeneous flowing cocoa paste called cocoa liquor containing

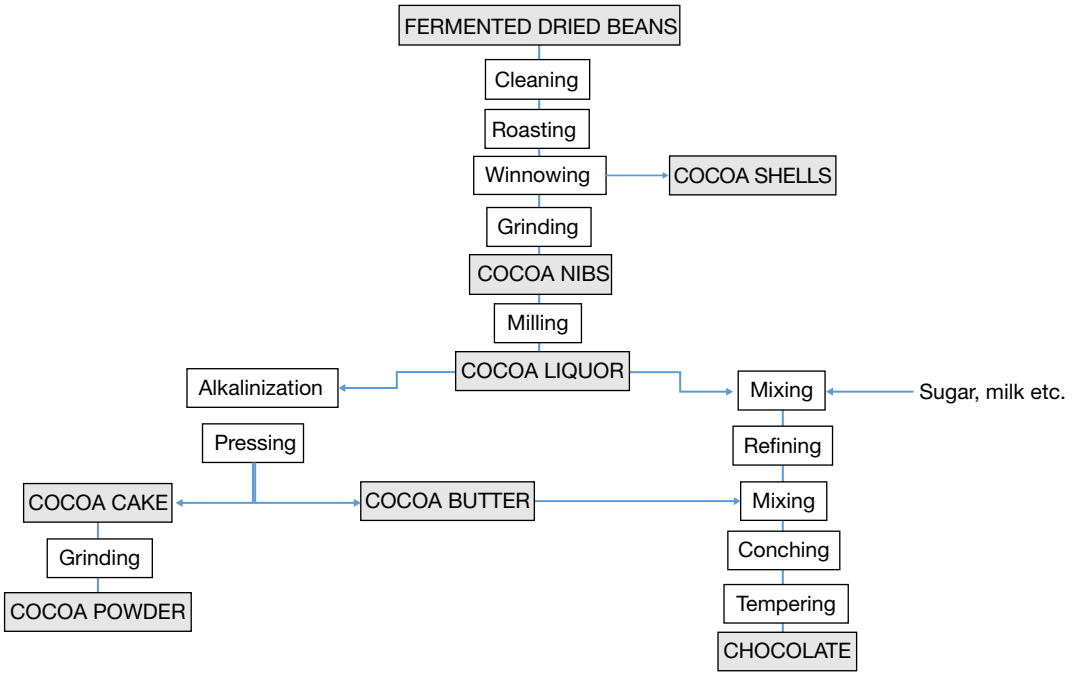

Figure 1 An overview on cocoa bean processing.

about 55% fats. To produce cocoa liquor with improved dispersibility, the cocoa nibs can be subjected to an alkalinization process (Dutch cocoa process): roasted nibs are treated with a diluted alkali solution at 75–100 °C, then neutralized and dried. This treatment causes starch swelling and the formation of porous cell structure of cocoa mass that prevents the formation of sediments in cocoa drinks.

Production of Cocoa Powder and Cocoa Butter

Cocoa powder is widely used in the manufacturing of cocoa-based products as drinks, cake fillings, ice cream, and so on. To convert cocoa liquor (generally alkalinized cocoa liquor) to cocoa powder, a defatting process is performed by pressing liquor in a mechanical or hydraulic press at 400–500 bar and a temperature of 90–100 °C. In this way part of the fat (cocoa butter) is removed, and cocoa cake (compressed cocoa powder) is produced. Cocoa powder is obtained by grinding cocoa cake. Generally the fat content of cocoa powder is 10–24%. Cocoa butter obtained from pressing is separated, filtered, and reused as an ingredient for chocolate and many cocoa-derived products.

Production of Chocolate

Chocolate is obtained from nonalkalinized cocoa liquor mixed with sucrose, cocoa butter, emulsifying agents (lecithins), flavoring compounds (vanillin), and eventually other ingredients (milk, hazelnuts, almonds, etc.). Ingredients are mixed to obtain a homogeneous chocolate paste that is then refined to obtain finer particles of <30–40 μm. The refining step is performed by single or multiple refining rollers. Further key steps in chocolate production are conching and tempering. Refined chocolate paste is powdery and has a harsh and sour flavor, and conching is necessary to obtain fine chocolate of optimal flavor, smoothness, and texture. Conching is performed in round or oblong rotary conche pots in which the chocolate mass is mixed, ground, and kneaded at temperatures of 65–75 °C. Conching times vary from a few hours to many days, depending on the desired final chocolate quality. Generally during conching steps, flavors, emulsifier, and cocoa butter are added. The effect of conching on chocolate paste is a reduction of acidity due to the loss from evaporation of acetic acid and other volatile compounds, loss of moisture, and a more uniform distribution of fats that form a film around each cocoa particle.

Tempering is one of the most critical steps to obtain a product with a stable crystalline form of cocoa butter responsible of the good melting properties and the glossy surface of good-quality chocolate. Tempering is performed by cooling under stirring the cocoa mass derived from conching (from 40–50 to 18–28 °C). Cocoa is maintained at this low temperature for about 10 min, and then is heated to 32 °C. In this way the polymorphic form V of cocoa butter is obtained, with a melting point of 34 °C, close to the human body temperature.

Different chocolate typologies are produced (Table 1) and can be classified according to the different percentages of cocoa liquor and cocoa butter in the final products or according to the addition of ingredients different from cocoa. Today much of the chocolate consumed is in the form of sweet chocolate, with the addition of sugars (sucrose). Milk chocolate is sweet chocolate that in addition contains milk powder. White chocolate contains cocoa butter, sugar, and milk, but no cocoa liquor.

Table 1 Examples of formulations for different kind of chocolate (g/100 g)

Ingredient	*Chocolate (50% cocoa)*	*Chocolate (70% cocoa)*	*Milk chocolate*	*White chocolate*
Cocoa liquor	35	70	12	–
Added cocoa butter	15	–	22	30
Sugar	50	30	51	50
Whole milk powder	–	–	15	20

Chemical Composition

Lipids

Cocoa fat (cocoa butter) represents about 50–58% of the cocoa beans, and its triacylglycerols (97–98% of cocoa butter) mainly consist of palmitic acid (25% of total fatty acids), stearic acid (37%), and oleic acid (34%), with a low amount of linoleic acid (3%). Oleic acid is primarily esterified at the 2-position of glycerol, so the main triacylglycerols are 1,3-dipalmito-2-olein, 1-palmito-3-stearo-2-olein, and 1,3-distearo-2-olein. Cocoa butter is solid at room temperature and melts at temperatures between 30 and 40 °C, depending on the polymorphic form. The amount of cocoa butter in chocolate is 21–35%, depending on the addition of cocoa butter to the cocoa liquor.

Protein, Peptides, Amino Acids, and Amines

Proteins make up 10–15% of the dry weight of cocoa seeds, the second most abundant constituent after cocoa fat. Proteins are the cocoa fraction that undergoes the most intensive modification during fermentation, where microbiological and enzymatic reactions lead to extensive breakdown of cocoa seed proteins, yielding peptides and amino acids that are the important flavor precursors.

Cocoa beans contain four main proteins, albumin, globulin, prolamin, and glutelin. Albumin and globulin are the most important both quantitatively and qualitatively. Globulins are vicilin-like storage proteins consisting of three subunits with molecular masses of 47, 31, and 15 kDa, which are derived from a common 66-kDa precursor. The albumin fraction was identified as a 21-kDa cocoa seed protein having trypsin inhibitory properties. During fermentation, peptide and free amino acids increase and total protein concentration decreases. The globulin protein fraction is the most degraded during fermentation. Cocoa proteins are cleaved to hydrophilic and hydrophobic peptides as well as amino acids through autolysis by two endogenous enzymes, aspartic endoprotease and carboxypeptidase. Fermentation of cocoa beans is fundamental for the activation of these two enzymes by microbial metabolites (such as acetic acid). Changes in the protein composition of cocoa beans have been noted not only during fermentation but also as a consequence of roasting. A decrease in total protein, free amino acids, and albumin are seen during roasting.

Regarding amino acids composition, nonfermented beans contain low levels of free amino acids with a 1:1 ratio between hydrophobic/acidic amino acid, whereas in fermented cocoa seeds this ratio significantly increases to 3:1. The increase in the concentrations of hydrophobic amino acids, such as leucine, alanine, and phenylalanine, is explained by the activity of carboxypeptidase that releases single hydrophobic amino acids and aspartic endoprotease, which hydrolyzes proteins preferentially at the hydrophobic amino acids sites. The free amino acid content recorded in fermented beans ranges from 500 to 1800 mg/100 g, with a prevalence of the hydrophobic amino acids responsible of the formation of Strecker aldehydes and pyrazines, important compounds for cocoa aroma. Among nonprotein amino acids, relevant contents of gamma-aminobutyric acids, ranging from 30 to 100 mg/100 g, were detected in fermented cocoa beans, therefore cocoa can be considered an important natural source of this inhibitory neurotransmitter amino acid.

Low amounts (20 mg kg^{-1}) of biogenic amines deriving from microbial decarboxylation of amino acids occurring during fermentation, as 2-phenylethylamine, tyramine and tryptamine have been found in cocoa. Biogenic amines can be also originated by thermal decarboxylation of amino acids, so their amount is higher in roasted products.

Carbohydrates and Organic Acids

The primary carbohydrates in fermented dried cocoa beans are starch (6%) and cellulose (9%). Soluble carbohydrates include glucose, fructose, sucrose (0.08–1.5%), raffinose, and stachyose. Sucrose is partially hydrolyzed during fermentation, providing reducing sugars precursors of aroma development during roasting. Fiber fraction aside from cellulose contains pentoses (1.5%), galactans, and polymers of galacturonic acid. Fibers are concentrated in cocoa shells.

Organic acids (1.2–1.6%) are primarily formed during cocoa bean fermentation, and the most represented are acetic acid (0.2–0.7%), citric acid (0.4–0.7%), and oxalic acid (0.3–0.5%). Acetic acid is partly lost during cocoa processing, in particular during conching.

Methylxanthines

Cocoa, as coffee and tea, is generally considered a stimulating food, due to the high levels of alkaloids. Theobromine and caffeine in particular are the principal alkaloids found in cocoa. Theobromine (3,7-dimethylxanthine) represents 1.2–2% of cocoa beans, where it is partially bound to tannins in cotyledon cells. During fermentation, the development of acetic acid permits the release of theobromine that migrates from cotyledons to shells. Cocoa shells in fact contain about 1.5% of theobromine, and generally they are reused to extract this alkaloid.

Polyphenols

Cocoa is a rich source of polyphenols: the defatted unfermented cocoa beans contain about 120–180 g kg^{-1} of polyphenolic compounds, representing one of the most concentrated natural sources. The polyphenols in cocoa beans are stored in the pigment cells of the cotyledons. Depending on the amount of anthocyanins, pigment cells are white to deep purple. Three groups of polyphenols can be distinguished: catechins or flavan-3-ols (~37%), anthocyanins (~4%), and proanthocyanidins (~58%). The main catechin is (−)-epicatechin representing up

to 35% of polyphenol content. In smaller amounts, (+)-catechin as well as traces of (+)-gallocatechin and (−)-epigallocatechin have been found. Procyanidins in cocoa consist of oligomers and polymers of catechin and epicatechin. Anthocyanins identified in cocoa include cyanidin-3-galactoside and cyanidin-3-arabinoside. Small quantities of quercetin, quercetin glycosides, naringenin, luteolin, apigenin, clovamide, and phenolic acids such as caffeic, ferulic, gallic, and *p*-coumaric acid have also been found in cocoa products.

The high level of polyphenols in raw cocoa beans is progressively reduced during cocoa processing. During fermentation polyphenols diffuse with cell liquids from their storage cells and undergo oxidation to condensed high-molecular mostly insoluble tannins. These reactions are both nonenzymatic and enzymatic catalyzed by polyphenol oxidase. It is reported that epicatechin and catechin content, respectively, are reduced to ~10–70% during fermentation. Roasting causes a dramatic reduction of some phenolic substances, in particular clovamide, together with an overall decrease of the antiradical and antioxidant properties of cocoa beans/nibs. High temperatures during the cocoa bean roasting process and also the alkali treatments on the cocoa powder induce the epimerization reaction of epicatechin to catechin, reducing its bioavailability. Moreover, some recent works have achieved chiral separations of catechin and epicatechin enantiomers, showing that the prevalent form of catechin in roasted cocoa products is (−)-catechin, a nonnatural in cocoa beans with less bioavailability than (+)-catechin.

Flavor Compounds

Chocolate and cocoa flavors reside in their volatile fraction, which is composed of a complex mixture of up to 500 compounds. The aromatic profile of cocoa beans is very complex and is also dependent on the method and duration of fermentation and drying practices applied. Alcohols, aldehydes, and ketones have been reported as the major groups of compounds found in raw cocoa and at the beginning of the fermentation process (1 or 2 days). Alcohols, esters, and acids (acetic acid mainly) were developed in the middle of fermentation (3–5 days), becoming the most important groups of volatile compounds at the end of fermentation (6–8 days). Alcohols, esters, and pyrazines contents increased during the sun-drying process.

Cocoa fermentation is crucial not only to the formation of significant volatile fractions but also for the development of cocoa–chocolate flavor precursors as amino acids and reducing sugars. *Via* Maillard reactions, cocoa roasting converts flavor precursors formed during fermentation to two main classes of odorant compounds: pyrazines and Strecker aldehydes, and three of these had a strong chocolate flavor: 2-ethylpropanal, 2-methylbutanal, and 3-methylbutanal. Pyrazines were recognized as cocoa/nutty notes: 2,3-dimethylpyrazine, trimethylpyrazine, tetramethylpyrazine, 3(or 2),5-dimethyl-2(or 3)-ethylpyrazine, 3,5(or 6)-diethyl-2-methylpyrazine, and furfurylpyrrole. Conching has an effect on cocoa aroma, although no new key odorant is synthesized during the heating process, and levels of 2-phenyl-5-methyl-2-hexenal, furaneol, and branched pyrazines are significantly increased, whereas most Strecker aldehydes are lost by evaporation.

World Production and Human Consumption

The cocoa-producing countries are all developing countries and localized in Africa, Central America, South America, Asia, and Oceania. World production of cocoa beans is constantly growing: it has increased from 31 000 tons in 1880 to more than 3 000 000 tons in 2002 and about 5 000 000 tons in 2012. Africa is the continent with the highest production (67%). The largest state producer is the Ivory Coast (about 30% of world production). World cocoa production has risen at an average annual growth rate of 3.3% during the period 2002–12.

Between 2002 and 2011/2012, primary cocoa processing growth at an average rate of 2.9% per annum was registered. Europe remained by far the largest cocoa-processing region, followed by the United States. However, with an annual growth rate of 5.6%, the largest regional processing increase occurred in Asia and Oceania. Moreover, in the last 10 years processing in the countries of origin has increased, supported, in some countries, by government policies favoring the export of value-added semifinished products rather than raw cocoa beans.

European regions are also the largest cocoa consumers, accounting for 48% of total world consumption of cocoa followed by the Americas, at 33%. Growing consumption has been observed in Asia and Africa. Consumption of chocolate confectionery products increased by 10% between 2002 and 2010 in selected countries, including the major European countries, the United States, Brazil, Japan, and Australia, corresponding to an annual growth rate of 1.2%. World per capita consumption of cocoa has also seen a similar pattern of growth over the review period, rising from 0.54 kg in 2002 to 0.61 kg in 2010.

Consumer preferences, especially of European and American consumers, has changed over the last 10 years: chocolate aficionados are asking for single-origin premium chocolate and 'high cocoa content' products, with their own distinctive flavors. Cocoa industries are driven to use innovation to appeal to consumers in saturated markets: new flavors, new packaging, and new sizes but also chocolates with health-promoting properties for health-conscious consumers. Sustainable sourcing is also growing in importance for consumers: demand for cocoa grown in a responsible manner is rising, as a consequence of the companies' response to consumer preferences.

About Codex Alimentarius

The Codex Alimentarius, or the food code, is a collection of internationally adopted food standards and related texts developed by the Codex Alimentarius Commission (CAC) and presented in a uniform manner. Codex standards, guidelines, and codes of practice aim at protecting consumers' health and ensuring fair practices in the food trade. Since its beginning, the Codex Alimentarius evolved in the most important international reference point in matters concerning food safety and quality and international food trade.

Codex Alimentarius Commission

The CAC was established by the Food and Agriculture Organization (FAO) of the United Nations and the World Health Organization (WHO), as an intergovernmental body to implement the Joint FAO/WHO Food Standards Programme, which was established by a FAO Conference resolution in 1961 and a World Health Assembly resolution in 1963. Its principal objective is to protect the health of consumers and to facilitate the trade of food by setting international food standards and other texts that can be recommended to governments for acceptance. The CAC also coordinates all food standards work done by international governmental and nongovernmental organizations.

The CAC is open to the governments of all member nations or associate members of FAO and WHO. It currently has 185 members, and more than 200 intergovernmental and international nongovernmental organizations are accredited as observers. Codex members cover 99% of the world's population. More and more developing countries are taking an active part in the Codex process, in many cases assisted by the Codex Trust Fund, which strives to finance and train participants from such countries to enable efficient participation. Being an active member of the Codex helps countries to compete in sophisticated world markets and to improve food safety for their own population.

The body of Codex Alimentarius consists of CAC, Executive Committee, General Subject Committees, Commodity Committees, ad hoc Intergovernmental Task Forces, and FAO/WHO Coordinating Committees. All Codex Committees, their current status, and host governments are presented in Table 1.

The Procedural Manual of the CAC describes the legal foundations and practical functioning of the CAC and its subsidiary bodies. It sets out the basic rules of procedures for the elaboration of Codex standards and related texts, basic definitions, and guidelines for the operation of Codex committees. It is intended to help member governments participate effectively in the work of the joint FAO/WHO Food Standards Programme.

Member countries communicate with the CAC through the Codex Contact Points that act as the link between the Codex Secretariat and member countries in order to coordinate all relevant Codex activities within their own countries. In order to provide better transparency and to facilitate more efficient participation in Codex activities, member countries are encouraged to establish National Committees for Codex Alimentarius that should include representatives of the relevant ministries, technical experts, decision-makers from the industry, and consumer organizations.

FAO/WHO Trust Fund for Participation in the Codex

FAO and WHO help developing countries to apply Codex standards, to strengthen national food control systems, and to take advantage of international food trade opportunities.

In 2002, FAO and WHO recognized that developing countries and countries with economies in transition were not participating fully in the work of the CAC. In response, the director-generals of WHO and FAO launched the FAO/WHO Project and Fund for Enhanced Participation in Codex (Codex Trust Fund) on 14 February 2003 with the objective of helping developing and transition economy countries enhance their level of effective participation in the Codex activities.

Codex Standards, Codes of Practice, Guidelines, and Recommendations

The Codex Alimentarius includes standards for all the principal foods, whether processed, semiprocessed, or raw, for distribution to the consumers, containing provisions with respect to food hygiene, food additives, residues of pesticides and veterinary drugs, contaminants, labeling and presentation, methods of analysis and sampling, and import and export inspection and certification.

For food safety and nutrition matters, the CAC, as a risk manager, establishes its standards using the principles of risk analysis and bases its work on the scientific advice provided by the independent international risk assessment bodies such as the Joint FAO/WHO Expert Committee on Food Additives (JECFA), Joint FAO/WHO Meeting on Pesticide Residues (JMPR), Joint FAO/WHO Expert Meetings on Microbiological Risk Assessment (JEMRA), or ad hoc consultations organized by FAO and WHO. Codex standards also address issues related to food quality to ensure fair practices in the food trade. Food standards, guidelines, and recommendations established by the CAC are recognized as reference points for food under the relevant World Trade Organization (WTO) agreements. While being recommendations for voluntary application by members, Codex standards serve in many cases as a basis for national legislation.

Public concerns about food safety issues are often placing Codex at the center of global debates. Biotechnology, pesticides, veterinary drug residues, food additives, and contaminants are some of the issues discussed in Codex meetings. Creating

Table 1 List of all Codex Alimentarius bodies with their status and host countries

Acronym	*Name*	*Status*	*Host*
CAC	Codex Alimentarius Commission	Active	FAO (Rome) and WHO (Geneva)
CCEXEC	Executive Committee of the Codex Alimentarius Commission	Active	FAO (Rome) and WHO (Geneva)
General subject committees			
CCCF	Codex Committee on Contaminants in Foods	Active	The Netherlands
CCFA	Codex Committee on Food Additives	Active	China
CCFAC	Codex Committee on Food Additives and Contaminants	Renamed and reestablished	—
CCFH	Codex Committee on Food Hygiene	Active	The United States
CCFICS	Codex Committee on Food Import and Export Inspection and Certification Systems	Active	Australia
CCFL	Codex Committee on Food Labelling	Active	Canada
CCGP	Codex Committee on General Principles	Active	France
CCMAS	Codex Committee on Methods of Analysis and Sampling	Active	Hungary
CCNFSDU	Codex Committee on Nutrition and Foods for Special Dietary Uses	Active	Germany
CCPR	Codex Committee on Pesticide Residues	Active	China
CCRVDF	Codex Committee on Residues of Veterinary Drugs in Foods	Active	The United States
Commodity committees			
CCCPC	Codex Committee on Cocoa Products and Chocolate	Adjourned sine die	—
CCCPL	Codex Committee on Cereals, Pulses and Legumes	Adjourned sine die	—
CCFFP	Codex Committee on Fish and Fishery Products	Active	Norway
CCFFV	Codex Committee on Fresh Fruits and Vegetables	Active	Mexico
CCFO	Codex Committee on Fats and Oils	Active	Malaysia

CCNASWP	FAO/WHO Coordinating Committee for North America and South West Pacific	Active	Papua New Guinea
CCNEA	FAO/WHO Coordinating Committee for Near East	Active	Lebanon

standards that at the same time protect consumers and ensure fair practices in the sale of food is a process that involves specialists in numerous food-related scientific disciplines, together with consumer organizations, production and processing industries, food control administrators, and traders. The finalization of food standards and their compilation into a code that is credible and authoritative require extensive consultation and the collection and evaluation of information, followed by confirmation of final results and sometimes objective compromise to satisfy differing sound, scientifically based views.

There are two main groups of Codex standards: Codex general standards such as the General Standard for Food Additives, General Standard for Contaminants and Toxins in Food and Feed, and General Standard for the Labelling of Prepackaged Foods and specific standards of which the largest number is the group called 'commodity standards.' Representatives of some of the major commodity standards included in the Codex with a year of last modification are presented in the Table 2.

Commodity standards tend to follow a fixed format set out in the Procedural Manual of the CAC. The format consists of the following categories of information:

- *Scope* includes the name of the food to which the standard applies and, in most cases, the purpose for which the commodity will be used.
- *Description* includes a definition of the product or products covered with an indication, where appropriate, of the raw materials from which they are derived.
- *Essential composition* includes information on the composition and identity characteristics of the commodity, as well as any compulsory and optional ingredients.
- *Food additives* includes the names of the additives and the maximum amount permitted to be added to the food. Food additives must be cleared by FAO and WHO for their safety, and the use of food additives must be consistent with the Codex General Standard for Food Additives.
- *Contaminants* contains the limits for contaminants that may occur in the product(s) covered by the standard. These limits are based on the scientific advice of FAO and WHO and must be consistent with the Codex General Standard for Contaminants and Toxins in Food and Feed. Where appropriate, reference is also made to the Codex maximum limits for pesticide residues and for residues of veterinary drugs in foods.
- *Hygiene* makes reference to relevant Codex Codes of Hygienic Practice for the commodity concerned. In almost all cases, it is required that the product shall be free from pathogenic microorganisms or any toxins or other poisonous or deleterious substances in amounts that represent a hazard to health.
- *Weights and measures* contains provisions such as fill of the container and the drained weight of the commodity.
- *Labelling* includes provisions on the name of the food and any special requirements to ensure that the consumer is not deceived or misled about the nature of the food. These provisions must be consistent with the Codex General Standard for the Labelling of Prepackaged Foods. Requirements for the listing of ingredients and date-marking are specified.
- *Methods of analysis and sampling* contains a list of the test methods needed to ensure that the commodity conforms to the requirements of the standard. References are made to internationally recognized test methods that meet the CAS's criteria for accuracy, precision, etc.

The Codex Alimentarius contains more than 200 standards in the prescribed format for individual foods or groups of foods.

Codex codes of practice define the production, processing, manufacturing, transport, and storage practices for individual foods or groups of foods that are considered essential to ensure the safety and suitability of food for consumption. For food hygiene, the basic text is the Codex General Principles of Food Hygiene, which introduces the use of the Hazard Analysis and Critical Control Point (HACCP) food safety management system. A code of practice on the control of the use of veterinary drugs provides general guidance in this area.

Codex guidelines fall into two categories:

- Principles that set out policy in certain key areas
- Guidelines for the interpretation of these principles or for the interpretation of the provisions of the Codex general standards

In the cases of food additives, contaminants, food hygiene, and meat hygiene, the basic principles governing the regulation of

Table 2 Representatives of the Codex commodity standards and the year of last modification

CODEX STAN 311-2013	Standard for Smoked Fish, Smoke-Flavoured Fish and Smoke-Dried Fish	2013
CODEX STAN 3-1981	Standard for Canned Salmon	2011
CODEX STAN 219-1999	Standard for Grapefruits (*Citrus paradisi*)	2011
CODEX STAN 260-2007	Standard for Pickled Fruits and Vegetables	2007
CODEX STAN 247-2005	General Standard for Fruit Juices and Nectars	2005
CODEX STAN 89-1981	Standard for Luncheon Meat	1991
CODEX STAN 96-1981	Standard for Cooked Cured Ham	1991
CODEX STAN 207-1999	Standard for Milk Powders and Cream Powder	2014
CODEX STAN 275-1973	Standard for Cream Cheese	2010
CODEX STAN 212-1999	Standard for Sugars	2001
CODEX STAN 86-1981	Standard for Cocoa Butter	2001
CODEX STAN 87-1981	Standard for Chocolate	2003

these matters are built into the relevant standards and codes of practice.

There are free-standing *Codex principles* covering the

- addition of essential nutrients to foods,
- food import and export inspection and certification,
- establishment and application of microbiological criteria for foods,
- conduct of microbiological risk assessment (MRA),
- risk analysis of foods derived from modern biotechnology.

Interpretative Codex guidelines include those for food labeling, especially the regulation of claims made on the label. This group includes guidelines for nutrition and health claims; conditions for production, marketing, and labeling of organic foods; and foods claimed to be 'halal.' There are several guidelines that interpret the provisions of the Codex Principles for Food Import and Export Inspection and Certification and guidelines on the conduct of safety assessments of foods from genetically modified plants and microorganisms.

The uniform Codex procedure for the Elaboration of Codex Standards and Related Texts, according to the CAC Procedural Manual, includes eight steps (**Figure 1**).

An alternative accelerated 5-step procedure for the elaboration of Codex standards and related texts, as a subject of an accelerated

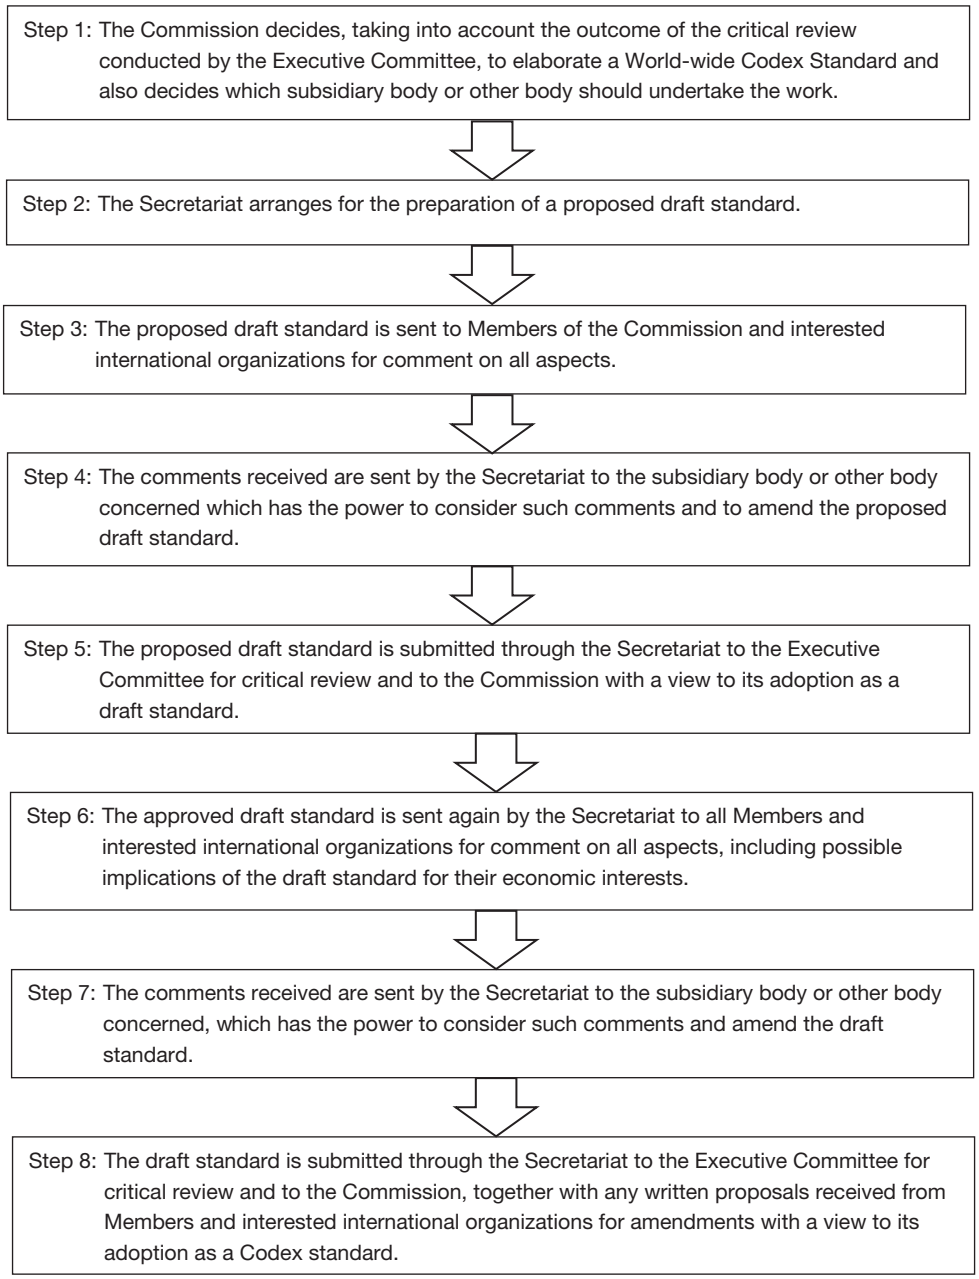

Figure 1 An 8-step procedure for the elaboration of Codex standards.

elaboration process, may also be performed if it is identified by the CAC, or the relevant subsidiary body. The accelerated procedure omits steps 5, 6, and 7 of the regular Codex procedure.

Codex Contact Points are responsible for ensuring that papers are circulated to those concerned within their own country and for ensuring that all necessary action is taken by the date specified.

Risk Analysis

As defined by the CAC, the risk analysis should follow a structured approach comprising the three distinct but closely linked components of risk analysis: risk assessment, risk management, and risk communication, each component being integral to the overall risk analysis. There should be a functional separation of risk assessment and risk management, in order to ensure the scientific integrity of the risk assessment, to avoid confusion over the functions to be performed by risk assessors and risk managers, and to reduce any conflict of interest. Effective communication and consultation with all interested parties should be ensured throughout the risk analysis.

Scientific Basis for Codex Work

Codex committees, when developing standards, apply risk analysis and rely on the independent scientific advice provided by expert bodies organized by FAO and WHO. These bodies also give direct advice to member governments.

From the very beginning, Codex activity is based on the sound science. Experts in a wide range of scientific disciplines have contributed to every aspect of the code to ensure that its standards withstand the most rigorous scientific scrutiny.

The main principles of developing scientific advice are as follows:

- Excellence: Use of internationally recognized expertise, supported by the creation of a platform for global scientific discussions based on best practices in elaborating guidance.
- Independence: Experts contribute in their own capacity and not on behalf of a government or institution. They are required to declare possible conflicts of interest.
- Transparency: Procedures and methods to ensure all interested parties understand the processes for the development of scientific advice and have access to the reports, safety assessments and evaluations, and other basic data.
- Universality: A broad base of scientific data is critical for the elaboration of international standards-setting activities. Therefore, institutions and all interested parties throughout the world are invited to make data available.

Experts responsible for risk assessment should be selected in a transparent manner on the basis of their expertise, experience, and independence with regard to the interests involved.

Risk assessment should incorporate the four steps, hazard identification, hazard characterization, exposure assessment, and risk characterization, and should be based on all available scientific data and on realistic exposure scenarios, with consideration of different situations that include consideration of susceptible and high-risk population groups.

FAO/WHO expert bodies responsible for the scientific advice to CAC and their subsidiary committees are the JECFA, the JMPR, the JEMRA, and other ad hock expert groups conducted by FAO and WHO.

The JECFA is an international expert scientific committee administered by FAO and WHO. It has been meeting since 1956, initially to evaluate the safety of food additives. Its work now also includes the evaluation of contaminants, naturally occurring toxicants, and residues of veterinary drugs in food. JECFA has evaluated more than 2600 food additives, approximately 50 contaminants and naturally occurring toxicants, and residues of approximately 95 veterinary drugs. The committee has also developed principles for safety assessment of chemicals in foods that are consistent with current thinking on risk assessment and take account of developments in toxicology and other relevant sciences.

The JMPR is an expert ad hoc body administered jointly by FAO and WHO in the purpose of harmonizing the requirement and the risk assessment on the pesticide residues. The JMPR has met annually since 1963 to conduct scientific evaluations of pesticide residues in food. It provides advice on the acceptable levels of pesticide residues in food moving in international trade.

The JEMRA began in 2000 in response to requests from the CAC and FAO and WHO member countries and the increasing need for risk-based scientific advice on microbiological food safety issues. JEMRA aims to develop and optimize the utility of MRA as a tool to inform actions and decisions aimed at improving food safety and to make it equally available to both developing and developed countries. JEMRA focuses on the following main areas of work: providing risk assessments for selected pathogens (pathogen–commodity combination risk assessments) to the CAC and to member states, developing guidelines for risk assessment of microbiological hazards in food and water, and providing expert advice on risk management.

FAO and WHO provide expert scientific advice on many aspects of food quality, safety, and nutrition relevant to the work of the CAC. While not officially part of the CAC structure, the FAO/WHO expert consultations provide independent scientific expert advice to the commission and its specialist committees and task forces. The issues being addressed include biotechnology and nanotechnologies.

Codex and International Food Trade

During the last century, a quantity and variety of food traded internationally has grown exponentially. According to FAO statistics, international food trade is more than 500 billion dollars per year market, with billions of tonnes of food produced, transported, and marketed. The increasing global market requires uniform food standards and the Codex international food standards, guidelines, and codes of practice contribute to the safety, quality, and fairness of this international food trade. Consumers can trust the safety and quality of the food they buy and importers and distributers can trust that the quality of food they ordered will be in accordance with their specifications. Reference to the Codex Alimentarius occurs in many bilateral and plurilateral trade agreements.

The WTO Agreement on the Application of Sanitary and Phytosanitary Measures (SPS Agreement) and the Agreement on Technical Barriers to Trade (TBT Agreement) both encourage the international harmonization of food standards, and

Codex standards have become the benchmarks against which national food measures and regulations are evaluated within the legal parameters of WTO agreements. WTO members that wish to apply stricter food safety measures than those set by Codex may be required to justify these measures scientifically.

Codex Alimentarius Commission: Role in International Food Standards Setting

V Kotwal, Telecom Regulatory Authority of India, New Delhi, India

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Since ancient times, food standards have been laid down by competent authorities or governments for the protection of consumers and the facilitation of trade. Food laws are enacted to protect the consumers against unsafe, adulterated, and misbranded food, and also to facilitate the movement of food across borders. With technological advancements in storage and transportation, the twentieth century has witnessed an exponential increase in food trade. However, the independent development of food standards in different countries led to barriers in trade.

The establishment of the Food and Agriculture Organization (FAO) in 1945 and the World Health Organization (WHO) in 1948 led to an increased focus on food and health and thus began a series of joint expert meetings. In 1950, experts at the first meeting of the Joint FAO/WHO Expert Committee on Nutrition stated, "Food regulations in different countries are often conflicting and contradictory. Legislation governing preservation, nomenclature, and acceptable food standards often varies widely from country to country. New legislations not based on scientific knowledge is often introduced, and little account may be taken of nutritional principles in formulation regulations." The Committee noted that the conflicting nature of regulations may be an obstacle to trade and may therefore affect the distribution of nutritionally valuable food and suggested that FAO and WHO study these problems more closely.

The fourth session of the FAO/WHO Expert Committee on Nutrition stated, "The increasing, and sometimes insufficiently controlled, use of food additives, has become a matter of public and administrative concern." It also noted that the means of solving problems related to food additives may differ from country to country, and this fact "must in itself occasion concern, since the existence of widely differing control measures may well form an undesirable deterrent to international trade." In the same year, 1955, the FAO and WHO convened the first joint FAO/WHO Conference on Food Additives. The Joint FAO/WHO Expert Committee on Food Additives (JECFA) began work and, in its first meeting, articulated the general principles for the use of food additives; a text that still forms the framework for the consideration of food additive use.

At the same time, there were other developments taking place at the international level involving food standards. In 1958, the United Nations Economic Commission for Europe (UNECE) established the Geneva Protocol, in which a harmonized layout for food commodity standards was proposed. The layout still forms the basis of most food commodity standards worldwide, including Codex standards. Similarly, the International Dairy Federation, founded in 1903, had worked on standards and labeling requirements for milk and milk products. This work was taken over by the Joint FAO/WHO Expert Committee of Government Experts on the Code of Principles concerning Milk and Milk Products. The Committee developed formal procedures for the elaboration of its standards, which involved consultation with the governments between the meetings of the Committee itself. After the Second World War, there was a regional effort to harmonize the food standards in Latin America and Europe.

In February, 1961, the Director-General of the FAO, B.R. Sen, actively entered into discussion with the WHO, the UNECE, the Organisation for Economic Cooperation and Development, and the Council of the Codex Alimentarius Europaeus, with proposals that would lead to the establishment of Joint FAO/WHO Food Standards Programme. In November, 1961, the eleventh session of the conference of the FAO passed the resolution by which the Codex Alimentarius Commission (CAC) was established.

The Joint FAO/WHO Food Standards Conference, convened in Geneva in 1962, established the framework for cooperation between the two agencies. The CAC was to be the body responsible for implementing the Joint FAO/WHO Food Standards Programme, and it was also endorsed in May 1963 at the sixteenth World Health Assembly.

The first session of the CAC was held in Rome in October 1963, and it was attended by delegates from 30 countries and 16 international organizations. Currently, the CAC has 186 Codex Members, 185 member countries, and 1 member organization (EU); 220 Codex Observers, 50 international governmental organizations, 154 nongovernmental organizations (NGOs), and 16 UN agencies. The thirty-seventh session of CAC, held in 2014 in Geneva, was attended by delegates from 170 countries; one Member organization; and 28 international governmental, and nongovernmental organizations, including UN agencies. The headquarters of Codex Alimentarius is based in Rome and the Codex Secretariat is also located in the FAO building in Rome. However, the meetings of CAC are held in every alternate year in either Rome or Geneva.

Purpose

The Codex Alimentarius is a collection of internationally adopted food standards and related texts presented in a uniform manner. It develops harmonized international food standards, guidelines, and codes of practice to protect the health of consumers, and to ensure fair practices in the food trade. These food standards and related texts aim at protecting consumers' health and ensuring fair practices in the food trade. The publication of the Codex Alimentarius is intended to guide and to promote the elaboration and establishment of definitions and requirements for foods to assist in their harmonization, and, in doing so, to facilitate international trade. The Commission also promotes the coordination of all food standards work undertaken by international governmental and nongovernmental organizations.

Scope

The Codex Alimentarius includes standards for all the principle foods, whether processed, semiprocessed, or raw, for distribution to the consumer. Materials for further processing into foods should be included to the extent necessary to achieve the purposes of the Codex Alimentarius, as defined. The Codex Alimentarius includes standards/guidelines/codes of practices for food hygiene, food additives, residues of pesticides and veterinary drugs, contaminants, commodities (e.g., milk, meat, fruits and vegetables, and processed food), labeling and presentation, methods of analysis and sampling, and import and export inspection and certification. Thus, it looks at both horizontal and vertical standard setting so far as food is concerned.

Codex standards and related texts are not a substitute for, or an alternative to, national legislation. Every country's laws and administrative procedures contain provisions with which it is essential to comply. Codex standards and related texts contain requirements for food aimed at ensuring for the consumer a safe, wholesome food product free from adulteration, correctly labeled and presented. A Codex standard for any food or foods should be drawn up in accordance with the Format for Codex Commodity Standards and contain, as appropriate, the sections listed therein.

In 1995, the Codex standards, guidelines, and Codes of practice became a reference for food safety in the World Trade Organisation (WTO) Agreement on Sanitary and Phytosanitary measures. The only other organizations mentioned are the World Organization for Animal Health for animal health issues and the International Plant Protection Convention for plant health.

Structure of Codex Alimentarius Commission and Its Subsidiary Bodies

The CAC consists of the following main organizational elements, each of which has a role to play in the achieving the mandate of the Commission (Figure 1):

(a) The Commission
(b) The Executive Committee
(c) The Codex Subsidiary bodies
(d) The Codex Secretariat

Codex Alimentarius Commission

While passing the resolutions at the eleventh session of the FAO Conference in 1961 and the sixteenth World Health Assembly in 1963, which led to the establishment of the Codex Alimentarius Commission, the two bodies also adopted the Statues and Rules of Procedure for the CAC, the main decision making body of the Joint FAO/WHO Food Standards Programme. The legal basis for the Commission's work is provided by the Statutes. The Membership to the Commission is open to all Member Nations and Associate Members of the FAO and/or WHO. The Commission meetings, which are held annually (in July) in Rome or Geneva, are chaired by the Chairperson, and he/she is assisted by the three Vice-Chairpersons.

Executive Committee of the Codex Alimentarius Commission

The Executive Committee consists of the Chairperson and three Vice-Chairpersons of the Commission, as well as the

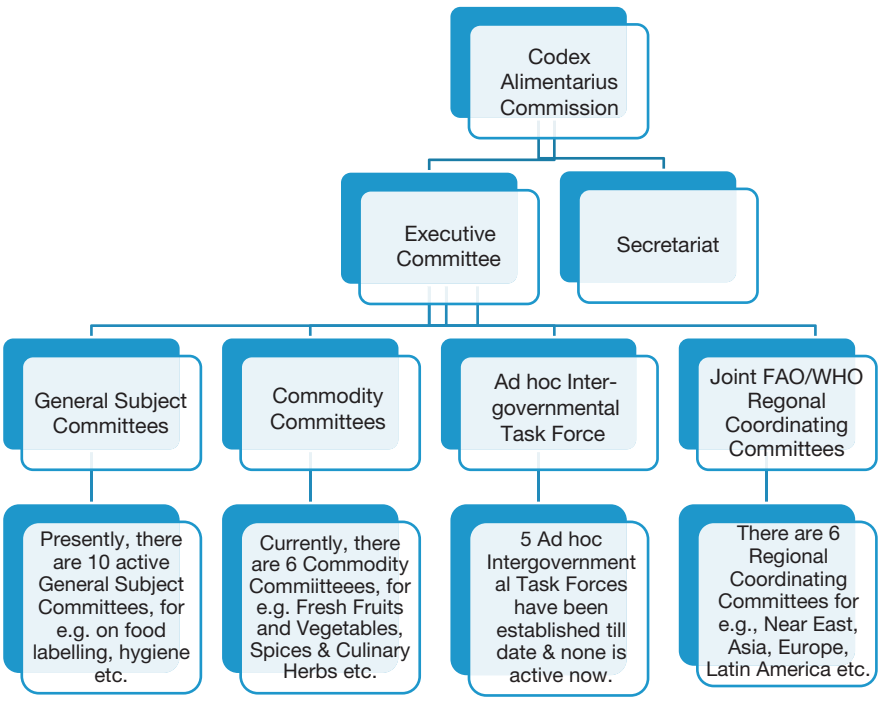

Figure 1 Organizational structure of the Codex Alimentarius Commission.

Regional Coordinators, together with seven further Members elected by the Commission at regular sessions from among the Members of the Commission, one each coming from the following geographic locations: Africa, Asia, Europe, Latin America and the Caribbean, Near East, North America, and South-West Pacific. The Executive Committee acts on behalf of the Commission as its executive organ between sessions of the Commission. In particular, the Executive Committee may make proposals to the Commission regarding general orientation, strategic planning, and programming of the work of the Commission; study special problems; and assists in the management of the Commission's program of standards development, namely by conducting a critical review of proposals to undertake work and by monitoring the progress of standards development.

Subsidiary Bodies Under the CAC

There are two kinds of Subsidiary bodies, the Codex Committees, which prepare draft standards for submission to the Commission and the Coordinating Committees, through which regions or groups of countries coordinate food standards activities in the region. The Commission may also approve a third type of subsidiary body called a Codex ad hoc Intergovernmental Task Force (TF), which is a Codex Committee with very limited terms of reference (TOR), established for a fixed period of time. Section V of the CAC Procedural Manual enlists the table of Committees and their TORs.

The Codex Committees are further divided into the General Subject Committees and the Commodity Committees.

General subject committees

These Committees are so called because their work has relevance for all Commodity Committees, and this work applies across all Commodity Committees. These are sometimes referred to as 'horizontal committees.' Currently, the following ten General Subject Committees are functioning:

- Codex Committee on Contaminants in Foods (CCCF)
- Codex Committee on Food Additives (CCFA)
- Codex Committee on Food Hygiene (CCFH)
- Codex Committee on Food Import and Export Inspection and Certification Systems (CCFICS)
- Codex Committee on Food Labeling (CCFL)
- Codex Committee on General Principles (CCGP)
- Codex Committee on Methods of Analysis and Sampling (CCMAS)
- Codex Committee on Nutrition and Foods for Special Dietary Uses (CCNFSDU)
- Codex Committee on Pesticide Residues (CCPR)
- Codex Committee on Residues of Veterinary Drugs in foods (CCRVDF)

Commodity Committees

Commodity Committees are responsible for developing standards for specific foods or classes of foods based on the composition. They are often referred to as the 'vertical standards.' These Committees convene as necessary and go into recess or are abolished when their work is complete. There are currently six active Commodity Committees, as follows:

- Codex Committee on Fish and Fishery Products (CCFFP)
- Codex Committee on Fresh Fruits and Vegetables (CCFFV)
- Codex Committee on Spices and Culinary Herbs (CCSCH)
- Codex Committee on Fats and Oils (CCFO)
- Codex Committee on Processed Fruits and Vegetables (CCPFV)
- Codex Committee on Sugars (CCS)

The following Commodity Committees work through correspondence or are in recess:

- Codex Committee on Cereals, Pulses, and Legumes (CCCPL)
- Codex Committee on Cocoa Products and Chocolate (CCCPC)
- Codex Committee on Meat Hygiene (CCMH)
- Codex Committee on Milk and Milk Products (CCMMP)
- Codex Committee on Natural Mineral Waters (CCNMW)
- Codex Committee on Sugars (CCS)

The following Commodity Committees that have been abolished are as follows:

- Codex Committee on Edible Ices (CCIE)
- Codex Committee on Meat (CCM)
- Codex Committee on Meat and Poultry Products (CCMPP)
- Codex Committee on Soups and Broths (CCSB)

Joint FAO/WHO Regional Coordinating Committees

The Membership is open to all Member Nations and Associate Members of the FAO and/or WHO, which are also members of the CAC within the relevant geographic location. There are six Regional Coordinating Committees, as given below:

- FAO/WHO Coordinating Committee for Africa (CCAFRICA)
- FAO/WHO Coordinating Committee for Asia (CCASIA)
- FAO/WHO Coordinating Committee for Europe (CCEURO)
- FAO/WHO Coordinating Committee for Latin America and the Caribbean (CCLAC)
- FAO/WHO Coordinating Committee for North America and South-West Pacific (CCNASWP)
- FAO/WHO Coordinating Committee for Near East (CCNEA)

Each Committee meets once in a year or once every 18 months or 2 years, depending upon its nature. The Codex Alimentarius Commission has designated a member country of the Commission, which has indicated its willingness to accept financial and other responsibility, such as appointing a Chairperson of the Committee. This country is referred to as the host country. The host country is responsible for appointing the Chairperson of the Committee from among its own nationals. Should this person for any reason be unable to take the chair, the host country shall designate another person to perform the functions of the chairperson for as long as the chairperson is unable to do so.

Ad hoc Intergovernmental Task Force

As per Statute 7 of the CAC, like other subsidiary bodies, the Commission may establish an ad hoc Intergovernmental Task Force (TF) for a specific purpose and specified period.

Presently, there are no TFs that are active. However, the following TFs were established and then abolished on completion of their assigned work as per their TORs:

- Task Force on Animal Feeding (TFAF): 1999–2004 and 2011–2013
- Task Force on Foods Derived from Biotechnology (TFFBT): 1999–2003 and 2004–2008
- Task Force on Fruit and Vegetable Juices (TFFJ): 1999–2005
- Task Force on the Processing and Handling of Quick Frozen Foods (TFPHQFF): 2006–2008
- Task Force on Antimicrobial Resistance (TFAM): 2006–2011

The Codex Secretariat

The Codex Secretariat is located at FAO headquarters in Rome. The Secretariat organizes the meetings of the Commission and the Executive Committee, and it facilitates the work of the Subsidiary bodies in close coordination with the secretariat of the host country.

Scientific Basis for Codex Work

Within Codex, risk analysis is defined as "a process consisting of risk assessment, risk management, and risk communication" (Figure 2). It is a structured, systematic approach that examines the potential adverse health effect consequential to a hazard, or conditions of food, and it develops options for mitigating the risk. Risk analysis should be:

- applied consistently;
- open, transparent, and documented;
- conducted in accordance with both the Statements of Principle Concerning the Role of Science in the Codex Decision-making Process and the extent to which other factors are taken into account and the Statements of Principle Relating to the Role of Food Safety Risk Assessment; and
- evaluated and reviewed as appropriate in the light of newly generated scientific data.

Figure 2 Process of risk analysis.

Risk analysis is an integral part of the decision-making process of the Codex, and the Commission has adopted the definition of risk analysis, as well as the *Working principles for risk analysis for application in the framework of the Codex Alimentarius*. Risk-analysis principles to be applied by the Committees on Food Additives; Contaminants in Food; Residues of Veterinary Drugs in Foods; Pesticide Residues; Food Hygiene and the Nutrition and Food for Special Dietary Uses have been adopted by the Commission.

Risk Assessment

When developing standards, Codex Committees apply risk analysis and rely on the independent scientific advice provided by expert bodies organized by the FAO and WHO, as illustrated in Figure 3. However, scientific advice may also be provided through a series of ad hoc meetings on a given topic or ad hoc expert consultations that are convened only once to address a specific topic.

These bodies also give direct scientific advice to Member Governments. There are four FAO/WHO expert committees, namely: (1) Joint FAO/WHO Expert Committee on Food Additives (JECFA); (2) Joint FAO/WHO Meeting on Pesticide Residues (JMPR); (3) Joint FAO/WHO Expert Meetings on Microbiological Risk Assessment (JEMRA); and (4) Joint FAO/WHO Expert Meeting on Nutrition (JEMNU), with other scientific advice provided by the FAO and WHO. The funds for Codex Scientific Advice are primarily provided by the FAO and WHO, and several countries also support the FAO and WHO in this important work.

A four-step process for risk assessment (Figure 4) is followed by these bodies.

Advice from the JECFA is considered by CCFA, CCCF, and CCRVDF, as it is responsible for providing scientific advice on:

- Food additives
- Contaminants in foods
- Residues of veterinary drugs in foods

Similarly, the JMPR is responsible for evaluating exposure to pesticides and recommending maximum residue levels (MRLs) for the new and periodic review of compounds for dietary intake purposes. There is well-established criteria for the prioritization of compounds for evaluation by the JMPR by the CAC. It is thus responsible for performing the risk assessment upon which the CCPR and, ultimately, the CAC base their risk management decisions.

The JEMRA are commissioned by the CCFH through the FAO and WHO for performing international risk assessments upon which the CCFH and the CAC base microbiological risk management options. The specific request to the FAO or WHO for microbiological risk assessment by the CCFH will include the risk profile document, a clear statement of purpose and the scope of the work to be undertaken, any time constraints facing the committee that could impact the work, and the specific risk management questions to be addressed by the risk assessors.

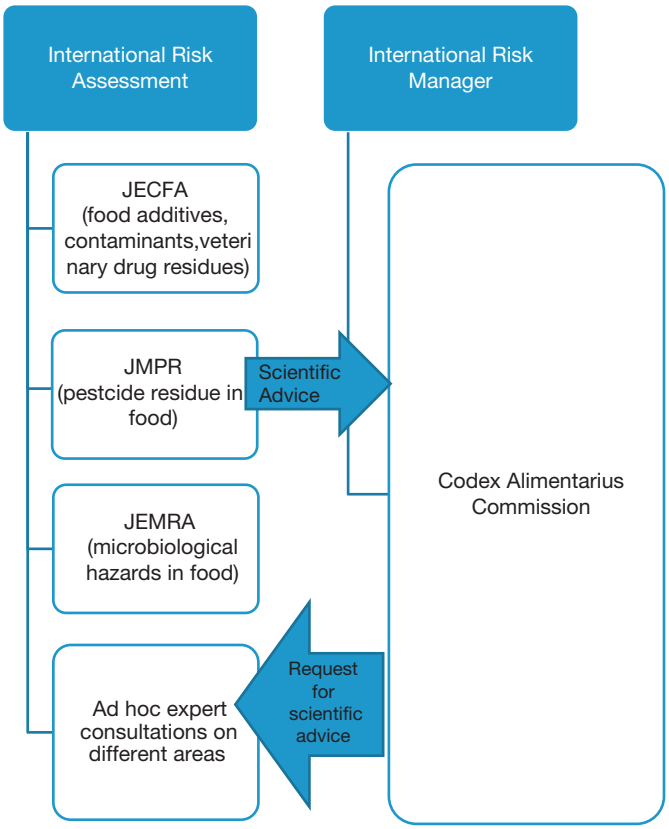

Figure 3 Roles of risk assessor and risk manager.

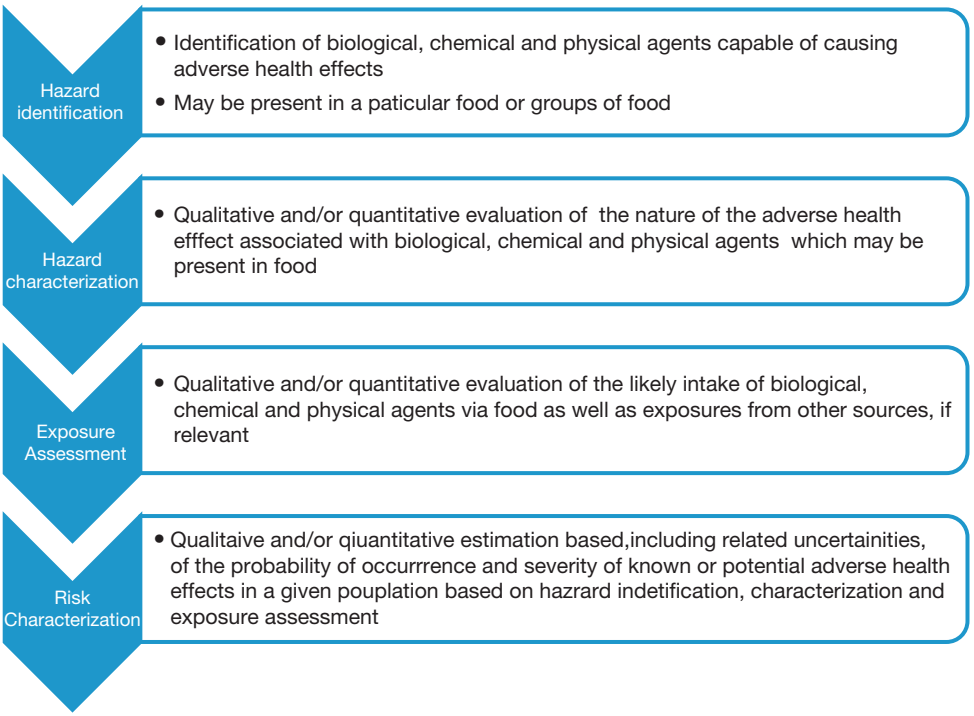

Figure 4 A four-step risk assessment process.

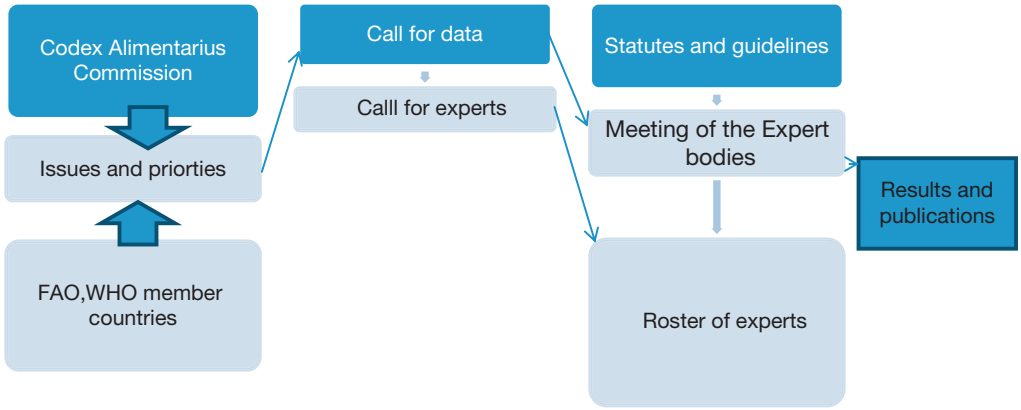

Figure 5 Process for the provision of scientific advice by expert bodies.

So far as the nutritional risk assessment advice to the CCNFSDU and CAC is concerned, the FAO and WHO are acknowledged as the primary sources of this advice.

Procedure for the provision of scientific advice by expert bodies

The steps involved in the provision of the scientific advice are listed in Figure 5.

Identification and prioritization of issues referred by the CAC or by member countries of the FAO and WHO.

- Call for data to facilitate the evaluation of the identified issue: The data can be provided by the industry, wherever applicable, or national data can be provided by the regulatory agencies or scientific institutes.
- The data submitted is examined by a group of experts who are elected in their personal capacity and not as representatives of their country or of the institute where they may be employed. In appointing experts, the FAO and WHO consider the scientific and technical excellence, diversity and complementarity of scientific backgrounds and opinions, and geographical as well as gender balance. The exact composition of the group will depend on the nature of the expert advice required, but it may include representatives of the natural sciences, including chemists, biologists, toxicologists, and public health specialists, as well as experts from other fields.
- Based on the data that has been submitted and the expert group consultations, the outcomes of the risk assessment are published.

Risk Management: Elaboration of Standards by the CAC

When a Codex subsidiary body (i.e., a committee or a task force) proposes to elaborate a standard, code of practice, or related text within its items of reference, it should consider the following:

- Priorities that were established by the Commission in the Strategic Plan of Work
- Any specific relevant strategic project currently being undertaken by the Commission
- Feasibility of completing the work within a reasonable period of time

The CAC has well-established criteria, to be applied in determining priorities for the inclusion of tasks in the program of work of committees and ad hoc task forces. These criteria are generally addressed when a member country makes a submission to a committee for new work or for the review of an existing, or adopted, Codex text. If the proposal falls outside of the committee's terms of reference, the proposal is referred to another committee or reported to the Commission in writing, together with proposals for amendments to the committee's terms of reference.

The initial proposal for a new or ammended Standard or related text comes from a country or group of countries that raises the issue at a Codex committee or an FAO/WHO coordinating committee. A committee proceeds with work on a new standard only once it has been approved by the Commission.

When a committee or task force starts to elaborate a standard whose development has been approved by the Commission, there is a step procedure to be followed. The normal procedure has eight steps, although an accelerated five-step procedure may be used if agreed to by at least two-thirds of the Members of the Commission. Most of the Codex documents are elaborated through this step process. Some Codex documents are developed outside of the step process, such as internal documents to guide the work of a specific Committee.

Project documentation

When a committee or other subsidiary body of the Commission is considering elaborating a standard code of practice, or related text, the committee will prepare project documentation for submission to the Executive Committee and the Commission. This documentation will provide the information required by the Commission to determine whether or not the work should be approved, and will be the basis for the Executive Committee's critical review and monitoring of the progress of the work. This project documentation is not required for individuals maximum residue limits for pesticides

or veterinary drugs, or the maintenance of standards and texts such as the General standard on food additives or international numbering system.

Project documentation should consist of the following:

- Purpose of the proposed standard
- Indication of its relevance to the Codex strategic objectives
- Scope of the proposed standard
- Assessment of the proposed standard against the criteria for the establishment of work priorities
- Proposed time line for completion of the work (including, as a minimum, start date, proposed date for adoption at step 5, and proposed date for final adoption by the Commission)
- Identification of expert advice requirements
- Identification of any issues related to the needs of developing countries.

The preparation of this project documentation is the responsibility of the Member proposing the new work. It should be prepared in sufficient time for the committee to reach consensus on whether or not to recommend the work and subsequent consideration by the Executive Committee and the Commission.

Specific criteria for determining priorities in the work of committees and task forces

The specific criteria that are applied while evaluating a proposal for the elaboration of a standard are different for general and the vertical subject committees as given below:

Criteria applicable to general subject committees

- Contribution to the protection of consumers' health and prevention of fraudulent practices
- Diversification of national legislation and apparent resultant or potential impediments to international trade
- Scope of the work undertaken and the establishment of priorities between the various sections of the work
- Work already undertaken by other international organizations in this field will be considered

Criteria applicable to commodity committees

- Contribution to the protection of consumers' health and prevention of fraudulent practices
- Volume of production and consumption in individual countries and volume and pattern of trade between countries
- Diversification of national legislation and apparent resultant or potential impediments to international trade
- International or regional market potential
- Amenability of the commodity to standardization
- Coverage of the main consumer protection and trade issues by existing or proposed general standards
- Number of commodities that would need separate standards indicating whether raw, semiprocessed, or processed products are to be included in the standard
- Work already undertaken by other international organizations in this field

Procedure for the elaboration of Codex standards

Part 3 and Part 4 of Section II of the *Codex Procedural Manual*, which is updated as and when necessary, lays down the procedures for the elaboration of codex standards and related texts through an eight- or five-step process.

The eight-step uniform procedure for the elaboration is as follows:

Step 1: The Commission decides to elaborate a standard and assigns the work to a committee, after taking into account the outcome of the critical review conducted by the Executive Committee. A decision to elaborate a standard may also be taken by a committee, but it is subject to endorsement by the Commission. In the case of regional standards, the Commission bases its decision on the proposal of the majority of the members belonging to the region or group of countries submitted at the CAC session.

Step 2: The Secretariat arranges the preparation of a proposed draft standard. In the case of MRLs for residues of pesticides or veterinary drugs, as well as MLs in case of the contaminants in food, the Secretariat distributes the recommendations of the JECFA and JMPR and any other information on risk assessment work conducted by the FAO and WHO.

Step 3: The proposed draft standard is sent to members of the commission and interested international organizations for comment on all aspects.

Step 4: The comments received are forwarded by the Secretariat to the concerned subsidiary body or other body concerned, which, as per the TOR, has the mandate to consider the comments and to propose amendments to the draft standard.

Step 5: The proposed draft standard is submitted through the Secretariat to the Executive Committee for critical review and to the Commission for its adoption as a draft standard. The Commission gives due consideration to the outcome of the critical review and the comments that may be submitted by any of its members.

Step 6: The draft standard is sent by the Secretariat to all Members and interested international organizations for comment on all aspects, including possible implications of the draft standard for their economic interests.

Step 7: The comments received are sent by the Secretariat to the concerned subsidiary body or the other body concerned, which has the power to amend the draft standard.

Step 8: The drafts standard is submitted through the Secretariat to the Executive Committee for critical review and to the Commission for adoption as a Codex standard. At this step again, the Commission gives due consideration to the outcome of the critical review and comments submitted by the members, and members may take part in the debate.

The five-step uniform, accelerated procedure for the elaboration

On the basis of a two-thirds majority of votes cast, and taking into account the outcome of the critical review conducted by the Executive Committee, the CAC shall identify those standards that shall be subject to an accelerated elaboration process. While making a decision to use the accelerated elaboration process, relevant consideration could be:

- Matters concerning new scientific information
- New technologies

- Urgent problems relating to trade or public health
- Revision or updating the existing standards

Once the Commission decides to elaborate a standard on the basis of a two-thirds majority of votes cast using the accelerated procedure and assigns the work to a subsidiary body or other body, the Secretariat arranges the preparation of a proposed draft standard, and the proposed draft standard is sent to members of the Commission and the interested international organizations for their comments. During step 2, the recommendations of the risk assessment done by the JECFA, JMPR, and other FAO/WHO consultations are made available. In step 3, the proposed draft standard is sent to the members of the Commission and interested international organizations for their comments, and when standards are subject to the accelerated procedure, members of the Commission and the interested international organizations are notified.

In step 4, the Secretariat forwards comments to the subsidiary body or other body for consideration and amendments to the proposed draft standard, if any. In step 5, the proposed draft standard subject to the accelerated elaborating procedure is sent to the Executive Committee for critical review and then to the Commission through the Secretariat, together with any written proposals from Members and interested international organizations, for adoption as a Codex standard.

Unlike in the eight-step procedure, the proposed draft standard or related text is submitted to the members of the Commission and other international organizations and to the Executive Committee only once.

The final adoption of the Codex standard, either through the eight- or the five-step procedure, can be made only at the plenary session of the CAC.

Measure to facilitate consensus while adopting standards

At the Twenty-sixth Session of the Commission in the year 2003, it was decided that every effort should be made to reach agreement on the adoption or amendment of standards by consensus. All efforts should be made to ensure that the process of standard-setting is open, transparent, inclusive, and science-based.

Risk Communication

After the adoption of the Codex standard by the CAC, it is published and issued to all Member states and Associate Members of the FAO and/or WHO, as well as to international organizations. They are also available on the Codex Alimentarius website (www.codexalimentarius.org).

The documents published by Codex can be classified as:

- Standards and MRLs, which contain mandatory requirements (are identified as CODEX STAN and CAC MRL/ML)
- Codes of practices, which are recommendations in general or for specific manufacturing or handling process (are identified as CODEX RCP)
- Guidelines, directed at the Codex subsidiary bodies and national governments, which are usually advisory texts (are identified as CAC GL)

Methods of analysis are considered as part of the standard or the MRL. Till date, the CAC has adopted the following Codex standards and related texts (Table 1).

Role of Codex Standards in the Framework of International Trade

Following the Marrakesh Agreement in 1994, which led to the creation of the WTO in 1995, the Agreement on the Application of Sanitary and Phytosanitary measures (the SPS agreement) and the Agreement on Technical Barriers to Trade (TBT Agreement) also went into effect. The SPS agreement has recognized and chosen the Codex standards, guidelines, and codes of practices, as well as the recommendations for food additives, veterinary drugs and pesticide residues, contaminants, methods of analysis, and sampling. Similarly, the Codex standards have assumed considerable significance under the Technical Regulations and standards provisions contained in Article 2 of the TBT agreement.

The recognition of the scientifically based Codex standards and the related texts within the framework of the SPS and TBT agreements has given a big flip to the work of Codex and also generated more interest in its Members. There has been increased Member attendance at Codex meetings, particularly from the developing countries.

Conclusion

At its Thirty-sixth Session in 2013, Codex Alimentarius celebrated its fiftieth year of establishment. It is a matter of great satisfaction that the membership has grown from 30 in 1963 to 186. It reinforces the confidence in the organization's work and the extremely important responsibility of laying down the global parameters for the quality and safety of food products for human consumption that the organization is shouldering. However, to maintain relevance in the rapidly changing

Table 1 List of adopted Codex standards and related texts

Type of text	*Number*
1. Codes of practice, both general and for specific production and handling processes	49
2. Guidelines	72
3. Individual food standards	212
4. Miscellaneous	4

The Codex Standards for Food Additives (GSFA, General Standards of Food Additives) list the food additives that have been adopted by the CAC (updated up to 36th session).

Codex MRLs for pesticides (updated up to the 36th session of the CAC), veterinary drugs (updated up to the 35th session of CAC), and residues

Source: www.codexalimentarius.org.

environment, where everyday new scientific developments are taking place, new food safety concerns are emerging, consumer preferences are changing rapidly, and there is increased global trade, the CAC must be more nimble-footed in setting standards. There is a need to make the process of standard-setting more inclusive by making an extra effort to encourage the developing countries to submit the necessary data.

The Codex Strategic Plan for the period 2014–19 that was adopted at the Thirty-sixth Session would need to be followed and monitored to ensure that the twin mandates of the Codex Alimentarius work are followed in letter and spirit.

Coenzymes and Cofactors

Introduction

Metabolism represents an array of chemical reactions that usually involve the transfer of specific functional groups from which substances are produced, maintained, or destroyed; and energy is made available to produce heat or work. Such transfer reactions often depend on aid from cofactors. Herein, cofactors are described that are involved in (1) bond making and breaking steps, (2) redox reactions, (3) the transfer of functional groups, and (4) changes in cellular energy or chemical potentials. In general, cofactors facilitate the coupling of the spontaneous processes of catabolism to the nonspontaneous processes of anabolism. As biocatalysts, cofactors provide the possibility of differing transition states that lower the activation energy of given reactions. As such, cofactors may increase reaction rates or enable reactions at lower temperatures. Cofactors can also affect the reaction environment or bind to substrates to change physical and chemical properties that make them more susceptible to chemical alteration. When associated with a corresponding apoenzyme, the presence of a cofactor extends the catalytic capacity of the resulting holoenzyme or functional enzyme (i.e., an apoenzyme plus cofactor). Moreover, when linked to specific metabolic processes, a cofactor may provide additional regulatory functions by acting as allosteric modulators.

For clarity and organization, the term cofactor will be used throughout to describe both organic and inorganic compounds that are involved as catalysts in enzymatic or biologically relevant chemical reactions. In this regard, it is also important to note that some terms have very specific meanings. For example, 'coenzyme' will be used to define organic cofactors that work in conjunction with apoenzymes. The term prosthetic group will be used when a given cofactor is nondissociable with respect to its corresponding enzyme; cosubstrate will be used when binding is dissociable. When metals serve as cofactors, they usually fall into two categories, that is, metals important to metalloenzymes or metals important to metal–enzyme complexes. The stability of the interaction defines whether the term metalloenzyme or metal–enzyme complex is used. Metalloenzymes have metal binding constants of 10^8–10^9 or greater. Metal–protein complexes have constants of 10^5 or less. To broaden the discussion, comments regarding biofactors that are responsible for nonenzymatic chemical catalysis, such as the tocopherols, are also included. Throughout the article, a number of examples and descriptions of cofactor function are described; however, our primary descriptive goal is to portray the broad range of mechanistic approaches that are involved in biological conversions important to metabolism in various animal species.

Biochemical Functions

Role of Cofactors in Catalytic Processes

Cofactors aid in creating alternative routes for reactions and, as a consequence, aid in reducing the amounts of energy required to reach the reactions' highest activation transition state. Accordingly, more of a given substrate can proceed to the formation of product. Cofactors improve enzyme–substrate interactions by combinations of the following mechanisms: (1) effecting conformation changes that improve interactions and the binding of a substrate to an enzyme, (2) causing bond strain to align a portion of a substrate so it is better positioned to engage in a reaction, (3) altering the nucleophilic or electrophilic properties of a substrate, (4) altering the environment at the active site of an enzyme (e.g., water structure around the active site), (5) forming transient covalent bonds with residues within the active site to lessen the energy of substrate moiety transfers, and (6) enhancing electron tunneling (increasing movement of electrons to an active site). The active site of enzymes is usually found in a 3-D groove or pocket. Cofactors extend chemical options or improve on entropic considerations by providing an extendable arm to place a substrate or an intermediate closer to the active center of an enzymatic process. Cofactors facilitate transition-state formation, a transition in which the targeted molecule is no longer a substrate, but not yet a product.

As shown in Figure 1, one may describe chemical reactions in terms of the 'activation' or 'free energy' needed to initiate a chemical transition or reaction. In this regard, many reactions proceed with multiple steps and reaction intermediate transition states. Note that the activation energy is lowered, but the initial energy of the starting reactants or their final products is not changed.

Listed in Table 1 are well-recognized cofactors derived from water-soluble vitamins and vitamin K, as well as important nonvitamin-derived cofactors. In addition, examples of essential dietary minerals utilized as cofactors are summarized in Table 2, particularly those involved in redox reactions.

Role in Entasis (Facilitation of Energized States in Proteins and Metalloproteins)

The term entasis comes from the Greek meaning 'to stretch or strain tight.' When metal cofactors are involved, the state of entasis (e.g., conformational strain) is relieved by a loss of an electron from metals that are a part of a protein complex. The electron transfer is more thermodynamically favorable. In many enzymes for which elements, such as calcium, magnesium, zinc, sodium, and potassium, are required or influence

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00181-1

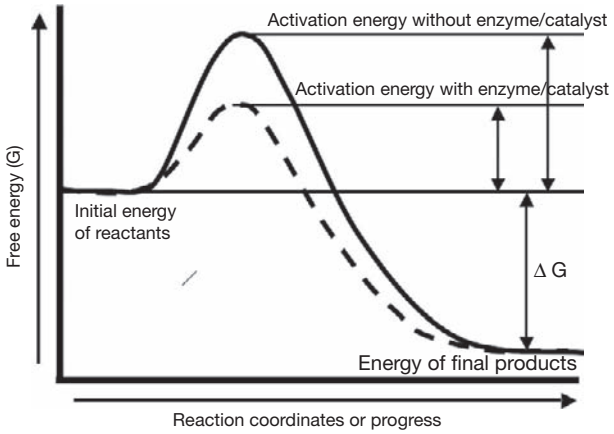

Figure 1 The relationship between reaction progress, activation energy, and the function of enzymes as catalysts. The activation energy (also known as the Gibbs free energy (G) or free enthalpy) is the minimum energy required to start a reaction. With respect to enzyme-catalyzed reactions, simply stated, an enzyme (often with the aid of a cofactor) acts to lower the activation energy needed to start the reaction.

catalytic activity, their roles are often to facilitate entasis-like processes.

In contrast, cofactors derived from organic compounds are less capable of hydrolyzing or changing the chemical character of biological compounds, because of their lower redox potentials. The typically higher reduction potentials of metal-containing complexes and/or the energy associated with entasis circumvent this problem. Metalloenzyme complexes are often several orders of magnitude more proficient as redox catalysts than organic-derived cofactors capable of redox. As it relates to 'entasis,' simple metal complexes tend to equilibrate quickly with substrates and products and other components in the reaction environment. However, when combined in a complex protein structure (i.e., an enzyme), entatic strain caused by the inclusion of metal cofactors makes the initial phases of the reactions much more energetically favorable. The reaction center is also less compromised by nonspecific interactions. Accordingly, an active site of an enzyme can be thought of as existing more in isolation than a component that is in equilibrium with cellular compounds and compounds not directly related to the reaction.

Table 1 Coenzymes and cofactors

Vitamin-derived coenzymes and cofactors

Cofactor name	*Common abbreviations for the cofactor*	*Precursor*	*Modifications leading to cofactor formation*	*Chemical group(s) transferred or types of reactions catalyzed*
Ascorbic acid		Vitamin C	The biosynthesis of ascorbic acid in many animals starts with the formation of UDP glucuronic acid in a pathway important for D-glucuronic acid synthesis. L-gulonolactone, a product of the pathway, reacts with oxygen, catalyzed by the enzyme L-gulonolactone oxidase, to produce ascorbic acid. In humans, L-gulonolactone oxidase is missing; thus, a dietary source of ascorbic acid is required	Ascorbic acid is a reducing agent and antioxidant. It often is utilized as a cofactor for monooxygenase (hydroxylase)-catalyzed reactions
Biotin; coenzyme R		Biotin (vitamin H and vitamin B_7)	Biotin as a cofactor is covalently linked. The enzyme biotinidase catalyzes the cleavage of biotin from biotinyl peptides (the proteolytic degradation products of holo-(biotin-requiring) carboxylases, which allows recycling and reutilization of biotin)	Biotin is essential for carboxylation reactions involving the addition of CO_2, important in the synthesis of fatty acids, isoleucine, and valine and in gluconeogenesis
Cobalamins: Hydroxocobalamin Methylcobalamin Adenosylcobalamin	B_{12}, OHCbl, or B_{12a} MeCbl or MeB12 AdoCbl	Vitamin B_{12}, cyanocobalamin (commercial preparation of B_{12} in which a CN moiety	In humans, the various forms are rapidly interconverted	Together with folic acid, cobalamins are essential for DNA synthesis. Methylcobalamin serves as a source of transferable 'CH_3—' groups.

(*Continued*)

Table 1 (Continued)

Vitamin-derived coenzymes and cofactors

Cofactor name	*Common abbreviations for the cofactor*	*Precursor*	*Modifications leading to cofactor formation*	*Chemical group(s) transferred or types of reactions catalyzed*
		replaces the methyl group)		Adenosylcobalamin serves as a cofactor for isomerization reaction, rearrangements in which a hydrogen atom is directly transferred between two adjacent atoms (e.g., the conversion methylmalonyl-CoA to succinyl-CoA by methylmalonyl-CoA mutase)
Coenzyme A	CoASH	Pantothenic acid (vitamin B_5)	Coenzyme A is synthesized in a multistep process that requires four ATPs, pantothenate, and cysteine	CoASH aids in the transfer of acetyl group and other acyl groups (e.g., TCA-related oxidations and fatty acid metabolism)
Flavin adenine dinucleotide	FAD	Riboflavin (vitamin B_2)	FAD consists of a riboflavin moiety bound to the phosphate group of an ADP molecule	Catalyzes high-energy electron transfer reactions important in oxidative phosphorylation, common cofactor for enzymes with reductase activity
Flavin mononucleotide or riboflavin-5-phosphate	FMN	Riboflavin (vitamin B_2)	Produced from riboflavin by the enzyme riboflavin kinase	Functions as a prosthetic group for various oxidoreductases including NADH dehydrogenase
Nicotinamide adenine dinucleotide or, in older notation, diphosphopyridine nucleotide	NAD or DPN	Niacin (vitamin B_3)	In animal cells, *de novo* tryptophan degradation plus ATP addition or, alternatively, ATP addition to diet-derived niacin	As a cofactor, catabolic oxidative/reduction reactions; as a cosubstrate, polyribosylation reactions
Nicotinamide adenine dinucleotide phosphate or, in older notation, triphosphopyridine nucleotide	NADP or TPN	Niacin (vitamin B_3)	Conversion of NAD into NADP by NAD kinase (requires ATP)	Most often anabolic oxidative/reduction reactions
Pyridoxal-5′-phosphate	PLP	Pyridoxine	Conversion of pyridoxine into PLP by pyridoxal kinase (requires ATP)	Carries out transamination, decarboxylation, and racemization reactions (also see **Table 2**)
Tetrahydrofolic acid	THFA, H_4FA, MTHF	Folic acid (vitamin B_9)	The synthesis of THFA and derivatives (N^5, N^{10}-methylene-THFA, N^5-methyl-THFA, N^5-formimino-THFA, N^{10}-formyl-THFA, N^5, and N^{10}-methenyl-THFA) starts with dihydrofolate reductase (essential to THFA formation from H_2FA). The reactions that lead to derivatives are FA → H_2FA → THFA ↔ methylene-THFA → methyl-THFA	Transfer of methyl, formyl, methylene, and formimino groups and the so-called one-carbon transfers, essential for amino acid, purine, and DNA synthesis
Thiamine pyrophosphate (i.e., thiamine diphosphate)	TPP, TDP, ThDP	Thiamine (vitamin B_1)	Thiamine is converted into TPP by thiamine kinase (requires ATP)	Carries out two-carbon group transfer reactions, α-carbon cleavage (e.g., oxidative decarboxylations), transamination reactions

Table 1 (Continued)

Vitamin-derived coenzymes and cofactors

Cofactor name	*Common abbreviations for the cofactor*	*Precursor*	*Modifications leading to cofactor formation*	*Chemical group(s) transferred or types of reactions catalyzed*
Thiamine triphosphate	TPPP, TTP, ThTP	Thiamine (vitamin B_1)	ThTP is currently suggested to be synthesized by apparent chemiosmotic mechanisms, analogous to ATP synthesis	Nerve cell energy metabolism, sodium gating in nerve cells; in E. coli, TTP is used in metabolic processes induced during amino acid starvation
Vitamin K; 2-methyl-1, 4-naphthoquinone derivatives: phylloquinone, menaquinone	Vitamin K_1 (phylloquinone), vitamin K_2 (menaquinone, also MK-n, where M stands for menaquinone, K stands for vitamin K, and n represents the number of isoprenoid side chain residues)	Vitamin K	Vitamin K_1 is synthesized by plants: the menaquinones are synthesized in the intestinal lumen by bacteria	Vitamin K (in animals) is involved in the carboxylation of certain glutamate residues in proteins to form gamma-carboxyglutamate (Gla) residues. Gla residues facilitate subsequent calcium binding that causes activation of enzymes important to blood coagulation and regulation of calcification in bone and smooth muscle

Nonvitamin-derived coenzymes and cofactors

Cofactor name	*Common abbreviations for the cofactor*	*Chemical modifications leading to cofactor formation*	*Chemical group(s) transferred or types of reactions catalyzed*
Adenosine triphosphate	ATP	ATP is formed by the action of ATP synthase. ATP synthase is a mitochondrial membrane enzyme that uses transmembrane electrochemical proton potential differences facilitate the phosphorylation of adenosine diphosphate (ADP) to ATP	Adenosine triphosphate (ATP) is a coenzyme involved in energy transfer reactions including biosynthetic reactions, motility, and cell division
Adenosine 3,5-cyclic monophosphate	cATP	cAMP is derived from ATP, synthesized by adenylyl cyclase	cATP is important in cell signaling and cell signaling transduction
Cytosine triphosphate	CTP	CTP synthetase catalyzes the last committed step in pyrimidine nucleotide biosynthesis: $ATP + UTP + glutamine \rightarrow ADP + P_i + CTP + glutamate$	CTP is a high-energy molecule similar to ATP but is limited to a smaller subset of metabolic reactions (e.g., synthesis of glycerophospholipids and glycosylation of proteins)
Coenzyme Q, ubiquinone	CoQ, CoQ_{10}	Biosynthesis occurs in 3 major steps: (1) creation of the benzoquinone structure (using phenylalanine or tyrosine), (2) addition of isoprene side chain units, and (3) condensation of the isoprene chain with benzoquinone	CoQ_{10} is found in the membranes of many organelles; the highest concentration is found on the inner membrane of the mitochondria, where it facilitates electron flow. CoQ also has antioxidant potential
Glutathione (GSH)	GSH	GSH is a tripeptide (Gly-Cys-Glu) with a gamma peptide linkage between the carboxyl group of the glutamate side chain and the amine group of cysteine, which is attached by peptide linkage to glycine. Glutathione reduces disulfide bonds formed within cytoplasmic proteins to cysteines by serving as an electron donor. In the process, glutathione is converted to its oxidized form, glutathione disulfide (GSSG). Once oxidized, glutathione can be reduced back by glutathione reductase, using NADPH as an electron donor	Major reducing agent in cells (e.g., is maintained at mM levels). A cosubstrate for glutathione peroxidases and glutathione S-transferase. It is a key component of the glutathione–ascorbate cycle, a system important to maintaining safe hydrogen peroxide levels in cells
Guanosine-5′-triphosphate	GTP	The synthesis and regulation of GTP are complex and involve enzymes, such as inosine-5′-monophosphate dehydrogenase, GMP synthase, GMP kinase, and nucleoside-diphosphate kinase	Analogous to ATP, GTP acts as a substrate for the synthesis of RNA during the transcription process or DNA during DNA replication. It is used as a

(*Continued*)

Table 1 (Continued)

Nonvitamin-derived coenzymes and cofactors

Cofactor name	*Common abbreviations for the cofactor*	*Chemical modifications leading to cofactor formation*	*Chemical group(s) transferred or types of reactions catalyzed*
			source of energy for specific steps in protein synthesis and gluconeogenesis
Guanosine 3,5-cyclic monophosphate	cGMP	cGMP is derived from GTP, synthesized by adenylyl cyclase	cGMP is essential to signal transduction, in particular with G proteins, in second-messenger mechanisms where cGMP is converted to guanosine diphosphate
Heme (various types)	Heme	Heme consists of an Fe ion located at the center of heterocyclic organic ring, called porphyrin. Porphyrins consist of four pyrrolic groups joined together by methine bridges	Hemes are components of hemoglobin and are at the active sites in numerous enzymes and protein important to oxygen metabolism (e.g., myoglobin, cytochromes, catalase, and nitric oxide synthase)
α-Lipoic acid or thioctic acid	ALA	ALA is an organosulfur compound derived from octanoic acid. As a cofactor, ALA is covalently attached by an amide bond to a terminal lysine residue in the lipoyl domain component of the active site of lipoic acid requiring enzymes	Essential for the transfer of acetyl groups in pathways important to energy regulation and production
Molybdopterin, molybdenum cofactor	Mo cofactor	Molybdopterins are synthesized utilizing guanosine triphosphate as a principle substrate	The molybdenum cofactor is used by sulfite oxidase, xanthine oxidoreductase, and aldehyde oxidase. The absence of molybdenum cofactor leads to the accumulation of toxic levels of sulfite
3′-Phosphoadenosine-5′-phosphosulfate	PAPS	PAPS is a derivative of adenosine monophosphate that is phosphorylated at the 3′-position with a sulfate group attached to the 5′ phosphate	PAPS is a coenzyme in sulfotransferase reactions
Pyrroloquinoline quinone	PQQ	Tricyclic quinone derived from the annulation of glutamic acid with tyrosine	PQQ is utilized as a dehydrogenase redox cofactor in many bacteria and recently discovered to serve a similar role in lower eukaryotes. Although it is not currently viewed as a classical cofactor important to enzymatic functions in animals, it is ubiquitous in nature and is present in all tissues. It appears to play a role as a redox agent in cell signaling by interaction with receptors important to Janus kinase (JAK) and signal transducer and activator of transcription (STAT) pathways and mitogen-activated protein kinase (MAPK) pathways
S-Adenosylmethionine	SAM-e, SAMe, SAM	SAM is made from ATP and methionine by methionine adenosyltransferase	Serves as a cosubstrate in methyl group transfer reactions. Transmethylation, transsulfuration, and aminopropylation are the metabolic pathways that use SAM as a cosubstrate
Tetrahydrobiopterin	BH_4, THB	Tetrahydrobiopterin is synthesized by reactions involving GTP as a substrate and GTP cyclohydrolase as an important enzyme associated with the synthetic pathway	THB serves as a cofactor for 3 aromatic amino acid hydroxylase enzymes, which are important to the degradation of phenylalanine and synthesis of serotonin, melatonin, norepinephrine, and epinephrine. BHT is also a cofactor for the production of nitric acid by nitric oxide synthases

Table 2 Cofactors involved in redox reactions

Cofactor	*Description*
Metals	
Manganese	Utilized in the mitochondrial antioxidant system (e.g., Mn-dependent superoxide dismutase) and enzymes, such as malic enzyme and pyruvate dehydrogenase
Iron	Utilized in numerous oxidases, mono- and dioxygenases, and reductases, as well as cytochrome P450 enzymes, important in secondary metabolism and mitochondrial function. Iron is also found in heme proteins, such as hemoglobin and myoglobin. Hemoglobin binds oxygen cooperatively via coordination with iron. Active sites containing iron often exist as iron–sulfur clusters containing sulfide-linked di-, tri-, and tetrairon centers in variable oxidation states. For example, both mitochondrial complex I and complex II have multiple Fe–S clusters
Zinc	Utilized in various enzymes such as alkaline phosphatase, alcohol dehydrogenase, matrix metalloproteinase, carboxypeptidase A, and carbonic anhydrase
Cobalt	Utilized in corrin-containing proteins (e.g., as cobalamin) and enzymes, such as methionine aminopeptidase 2 (eukaryotes) and nitrile hydratase (bacteria)
Nickel	Utilized in plant urease, the NiFe hydrogenases in bacteria, and the nickel-tetrapyrrole coenzyme, cofactor F430, which is used by methyl coenzyme M reductase, and minor forms of bacterial superoxide dismutase and glyoxalase
Copper	Utilized in numerous oxidases: superoxide dismutase, mono- and dioxygenases, and reductases. Copper is also used in hemocyanins that transport oxygen in some invertebrate, for example, crustaceans living in environments with low oxygen pressure (e.g., hemocyanins bind oxygen noncooperatively and less efficiently than hemoglobin). Terrestrial arthropods (e.g., spiders and scorpions) also utilize hemocyanins
Molybdenum	Utilized in aldehyde, sulfite, and xanthine oxidases
Nonmetals	
Selenium	Utilized in glutathione peroxidase (reaction: $2\,GSH + H_2O_2 \rightarrow GSSG + 2H_2O$) and Se-dependent deiodinases that convert T_4 to T_3 (the active hormone) by removing an iodine atom from the outer tyrosine ring
Sulfur	Utilized in redox (cysteinyl residues at the active site of proteins). Inorganic sulfur is a part of iron–sulfur clusters in proteins with redox activity (cf. Fe and ferredoxins), which serve as electron shuttles in cells. In bacteria, nitrogenase enzymes contain Fe–Mo–S clusters (important in nitrogen fixation)
H, C, N, O	Utilized in all biologically important organic compounds. Distinguished by being the smallest of the elements that can form stable multiple bonds
Vitamin-derived cofactors	
Ascorbic acid/vitamin C	Utilized in oxidation reactions catalyzed by monooxygenases (hydroxylases), dioxygenases, and oxidases. Such enzymes are often iron- or copper-containing. Ascorbate acts as a reductant to maintain Fe and Cu in their reduced states
Niacin	Utilized as a precursor of the coenzymes: nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP). Reactions involve the removal of two hydrogen atoms from the reactant in the form of a hydride ion (H:) and a proton (H+). The proton is released into solution, while the reductant RH2 is oxidized and NAD^+ is reduced to NADH by transfer of the hydride to the nicotinamide ring of NAD or NADP. As a general observation, NAD is used mostly in catabolic processes and NADP in synthetic processes
Pyridoxine (vitamin B_6)	Utilized in the hydrolysis of ether linkages in glycogen by glycogen phosphorylase. The phosphate group on the pyridoxal-5′-phosphate donates a proton to an inorganic phosphate molecule, allowing the inorganic phosphate to in turn be deprotonated by the oxygen forming the α-1,4 glycosidic linkages in glycogen
Riboflavin	Utilized as a component of the cofactors FAD (flavin adenine dinucleotide) and FMN (flavin mononucleotide) utilized by a variety of oxidases. During the catalytic cycle, a reversible interconversion of the oxidized, semiquinone, and reduced forms of flavin occurs. FMN is a stronger oxidizing agent than NAD and is particularly useful because it can take part in both one- and two-electron transfers; importantly, because oxygen as a reactant prefers one-electron transfers.

Types of Cofactor-Catalyzed Reactions

Many cofactors, particularly those derived from vitamins, are designed for highly specific chemical modifications and reactions. Some of the more important types of reactions are outlined in this section.

Oxidation–reduction reactions

Redox chemical reactions occur with a transfer of electrons (appreciating that some redox reactions occur with no apparent electron net gain or loss in electrons, e.g., reactions involving covalent bonds). When redox reactions occur, the process involves one of the following mechanisms: (1) direct electron transfers, (2) hydrogen atom transfers, (3) hydride ion transfers, and (4) direct combinations with oxygen. Cellular energy release is controlled by means of redox reactions. In this regard, redox proteins and metabolic steps in the regulation of their associated cofactors are often linked or colocated, which provides regulatory continuity, for example, the positioning of mitochondria in cells and the interdependence of mitochondrial and nuclear genes in energy regulation.

Of the vitamin-derived cofactors, flavin adenine dinucleotide (FAD) and riboflavin-5′-phosphate (flavin mononucleotide (FMN)) derived from riboflavin and nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP) derived from niacin are perhaps the most common (cf. Tables 1 and 2). However, in animals, more than a dozen metals, nonmetals, nonvitamin-derived cofactors, and ascorbic acid and pyridoxal-5′-phosphate (PLP) play important roles in redox.

Generation of leaving groups

As noted, cofactors function in part by allowing the possibility of differing transition states that lower the activation energy of given reactions. With regard to the generation of leaving groups, this usually implies enriching the nucleophilic or electrophilic character of transition-state intermediates to better engage in nucleophilic or electrophilic substitutions. The vitamin-derived cofactors, thiamine pyrophosphate (TPP) and PLP, serve as excellent examples of such functions.

Thiamine pyrophosphate (TPP) consists of aminopyrimidine and thiazole rings linked by a methylene bridge. The thiazole moiety acts as an ylid (a neutral dipolar molecule containing a negatively charged atom attached to a heteroatom with a formal positive charge). The carbanion character of TPP's thiazole ring is retained in transition-state intermediates. Examples of enzymes in which TPP is used for this purpose are pyruvate, α-ketoglutarate, or branched-chain amino acid dehydrogenase complexes and 2-hydroxyphytanoyl-CoA lyases (see Figure 2). TPP catalyzes the reversible cleavage of a substrate at the carbon–carbon bond connecting a carbonyl group to an adjacent reactive group (usually a carboxylic acid or an alcohol). In the reverse reactions, the TPP–substrate bond is broken, reforming a TPP ylid and substrate carbonyl.

TPP is also a cofactor for transketolases, enzymes associated with the pentose phosphate pathway in all organisms and the Calvin cycle of photosynthesis. In transketolases, TPP accepts a 2-carbon fragment from a 5-carbon ketose (e.g., D-xylulose-5-P) and then transfers the fragment to a 5-carbon aldose (e.g., D-ribose-5-P) to form a 7-carbon ketose (e.g., sedoheptulose-7-P). The second reaction catalyzed by transketolase in the

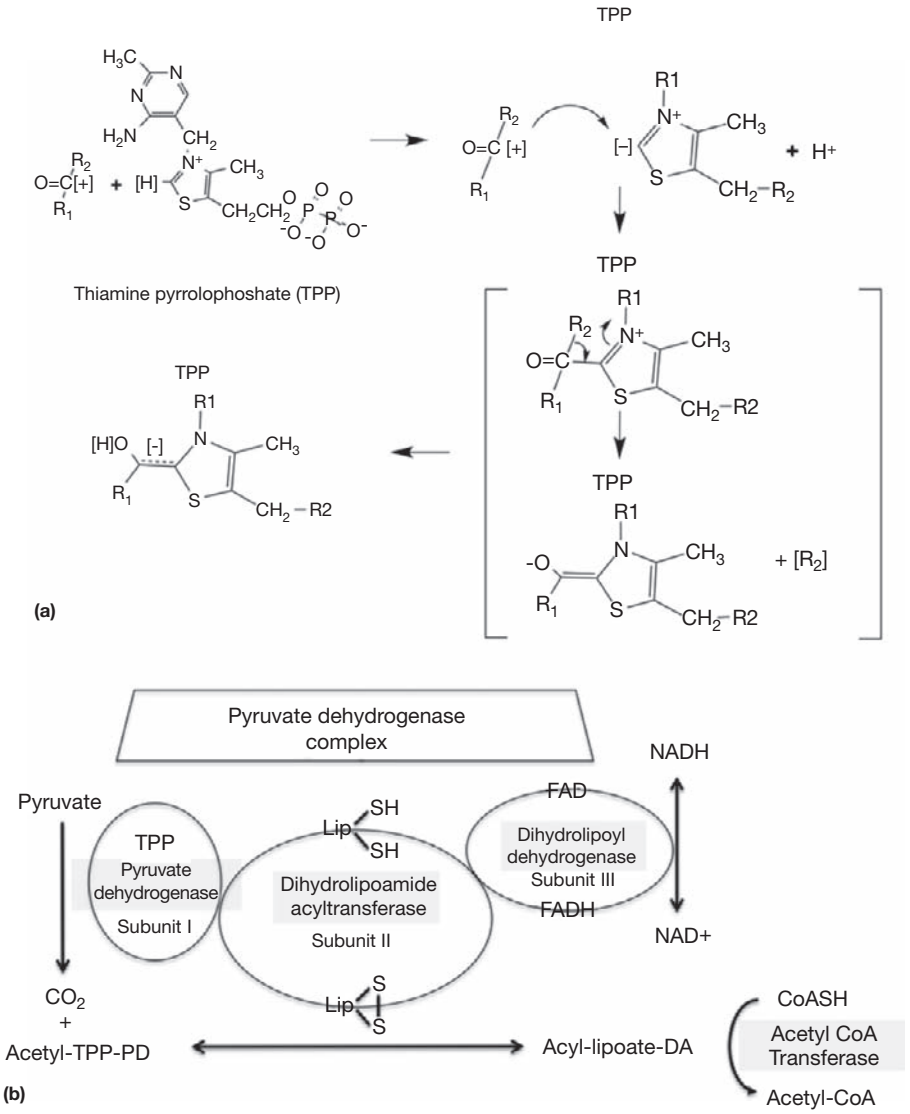

Figure 2 Thiamine. Thiamine (2-[3-[(4-amino-2-methyl-pyrimidin-5-yl) methyl]-4-methyl-thiazol-5-yl] ethanol) as the pyrophosphate derivative, TPP, is exquisitely designed to facilitate the metabolism of carbohydrates. The thiazole moiety of thiamine has carbonium ion character, which is retained in transition-state intermediates. As a consequence, decarboxylation of α-ketoacids derived from glucose may enter energy-generating cycles, such as the tricarboxylic acid (TCA) cycle and citric acid cycle (a). As an example, thiamine pyrophosphate is an essential cofactor for pyruvate dehydrogenase, a component of the pyruvate dehydrogenase complex (b).

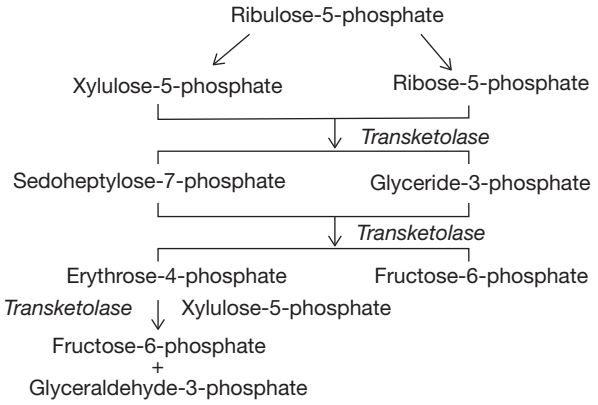
pentose phosphate pathway involves the transfer of a 2-carbon fragment from D-xylulose-5-P to erythrose-4-phosphate, which results in fructose 6-phosphate and glyceraldehyde-3-P. This reaction connects the pentose phosphate pathway to glycolysis (Scheme 1).

PLP-dependent enzymes are particularly critical in the metabolism of amino acids. The 4-formyl substituent of PLP condenses with the α-amino group of an amino acid, to form an azomethine (Schiff base) linkage. Next, the conjugated double-bond system extends into PLP's pyridinium nitrogen. This weakens bonding around the α-carbon of the amino acid substrate, which, depending on the enzyme, can lead to transaminations, decarboxylations, or subsequent substitutions at the carbon adjacent to the α-carbon. In PLP-dependent enzymes, the moiety is often attached to a lysyl group within the enzyme. This has the advantage of setting the stage for an initial transimidation with an amino acid, which is a faster reaction than an aldehyde with an amino acid, that is, a classical transamination. Further, the transimidation mechanism allows PLP to be retained in its original state in association with the enzyme at the conclusion of a catalytic cycle. Accordingly, although the binding of PLP to transaminases can be viewed as potentially dissociable, the net result is more covalent in character (Scheme 2).

Acyl activation and transfer reactions

Cofactors involved in the transfer of acyl and acetyl groups include coenzyme A (CoA), lipoic acid, and small molecular weight proteins, acyl carrier proteins (ACPs), that are associated with fatty acid and polyketide synthesis complexes. A phosphopantetheinyl moiety serves as the principle functional component within the structure of CoA and ACP. The phosphopantetheinyl moiety provides a thiol group that reacts with the carboxylic acid group associated with acetate or acyl functions to form thioesters. This step is a prelude to numerous acetyl and acyl group transfers and enolizations. The carbonyl carbon of a thioester is more positively polarized than a corresponding oxy ester, because oxy esters are more stabilized by resonance than thioesters. Activation as a thioester sets the stage for eventual acetyl and acyl transfers. The phosphopantetheinyl moiety also provides a flexible arm to move substrates from one site to the next in complexes, such as those designed for fatty acid and polyketide synthesis (Scheme 3).



Scheme 1 Transketolase reactions.

In an analogous fashion, lipoic acid, α-lipoic (thioctic) acid, provides a functional sulfhydryl group with an extended flexible arm attached via a peptide bond to lysyl residues in subunits usually associated with dehydrogenase enzyme complexes. For example, the role of lipoic acid in pyruvate dehydrogenase is in part outlined in Figure 2. Given that lipoic acid has two adjacent sulfhydryl groups, which are oxidized to form a dithiolane ring, oxidized lipoic acid is sufficiently electronegative to catalyze the transfer of TPP intermediates with carbanion character. The resulting thioester can then be transferred to form CoA intermediates.

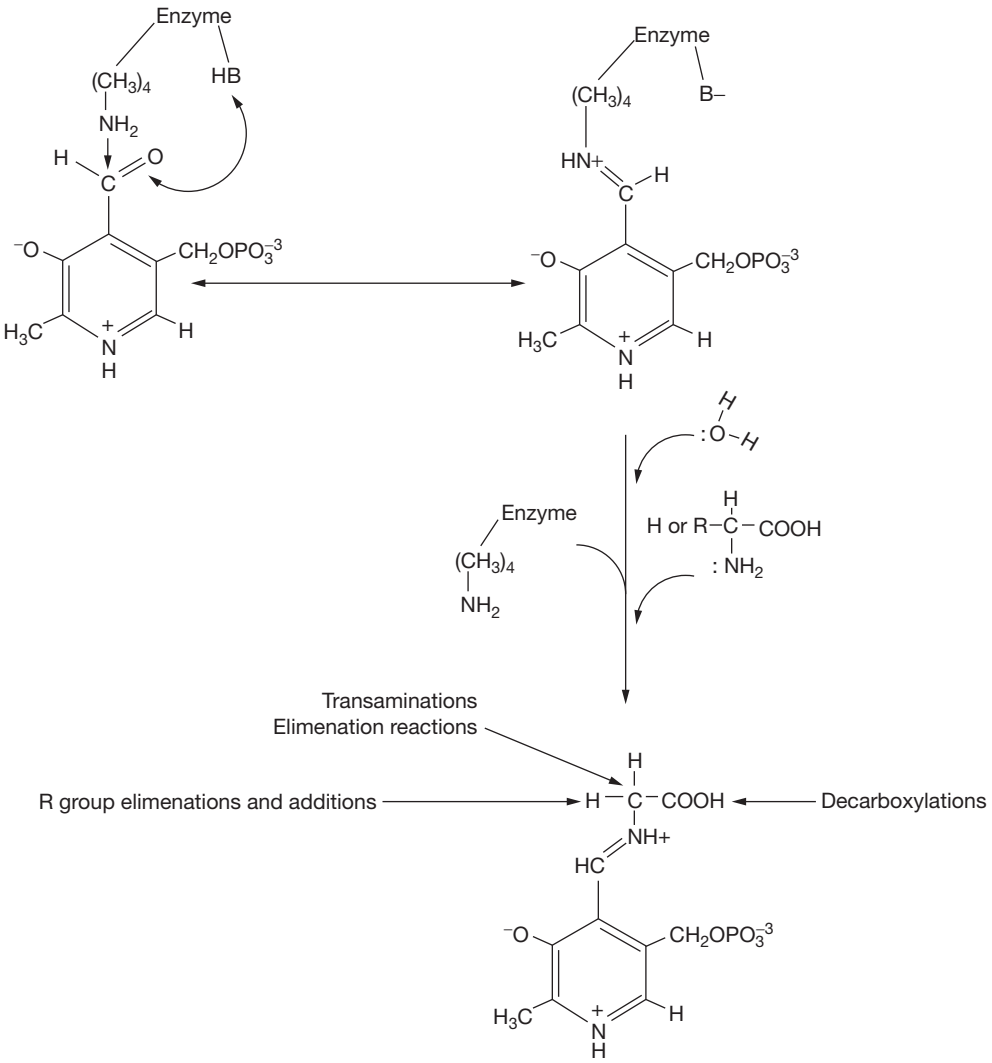
Carboxylations

D-(+)-Biotin is a cofactor designed for the transfer of CO_2 in carboxylase and transcarboxylase enzymes, such as acetyl-CoA carboxylase-α, acetyl-CoA carboxylase-β, and methylcrotonyl-CoA, propionyl-CoA, and pyruvate carboxylases. Biotin is covalently attached to the epsilon-amino group of specific lysine residues at the active site in such enzymes, which are essential to fatty acid synthesis, branched-chain amino acid catabolism, and gluconeogenesis.

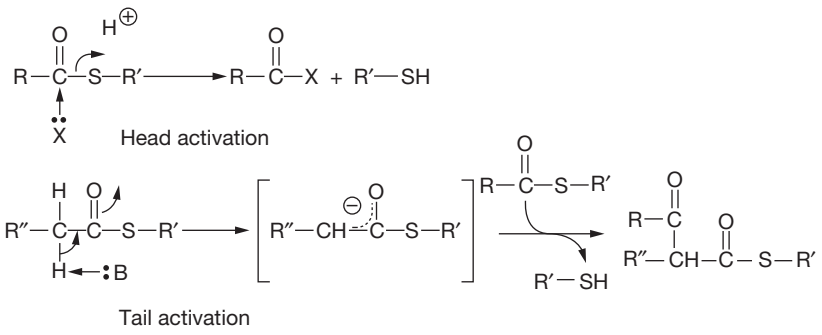
The mechanism involves tautomerization of the ureido nitrogen, a process that enhances its nucleophilicity. Phosphorylation of bicarbonate by ATP represents an independent step to produce carbonyl phosphate, an electrophilic mixed-acid anhydride. The carbonyl phosphate then reacts to generate an active carboxylbiotinyl enzyme. These reactions change the carbon in CO_2 to one with carbanion character, which facilitates subsequent reactions as the conversion of acetate to malonate or pyruvate to oxaloacetate (Scheme 4).

In addition to biotin, the active forms of vitamin K acts as a cofactor that is essential for certain types of carboxylation reactions, particularly those involved for posttranslational modifications of proteins utilized in blood coagulation cascades (e.g., thrombin) and pathways important to the regulation of extracellular matrix (ECM) calcification. Vitamin K-dependent carboxylases catalyze the carboxylation of glutamyl residues to γ-carboxyglutamyl (GLA) residues. The presence of GLA residues facilitates the binding of calcium ions, important to the activation of GLA-containing enzymes (i.e., those involved in blood coagulation) and GLA-containing ECM proteins, such as osteocalcin, important to the control of ECM mineralization. In contrast, in plants and bacteria, vitamin K either functions as an electron acceptor in photosystem I or is important to anaerobic respiration. Compounds with vitamin K activity are derived from 1,4-naphthoquinone derivatives that are combined with varying numbers of isoprenoid units to form the so-called phytyl side chains. Vitamin K includes two natural vitamers designated vitamin K_1 (phylloquinone, synthesized in plants) and vitamin K_2 (menaquinone, present in animal tissues) (Scheme 5).

Vitamin K-dependent carboxylases use vitamin K epoxidation to drive the carboxylation reactions that lead to GLA formation. GLA formation occurs in two independent steps: (1) deprotonation of a targeted glutamic acid residue to form a carbanion intermediate, followed by (2) the addition of CO_2. The mechanism is facilitated by a histidyl residue at the carboxylase active site, which acts as an electrophile that accepts the negative charge on the γ-carbon of the modified glutamyl residue carbanion (Scheme 6).



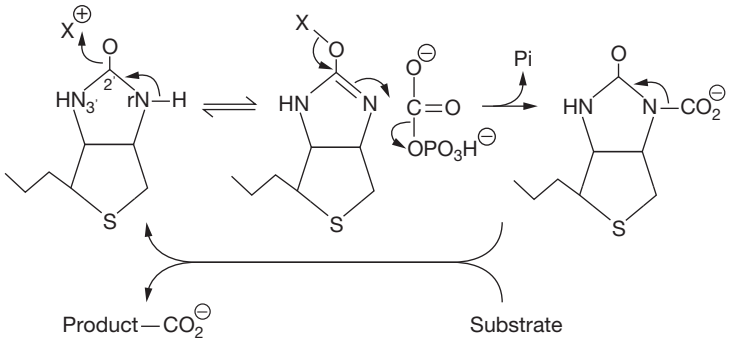
Scheme 2 Pyridoxal-5'-phosphate reactions.



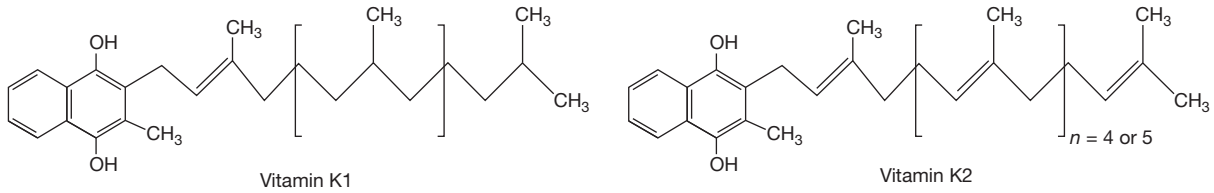
Scheme 3 Thiol-facilitated acyl transfer reactions.

Single-carbon transfer reactions

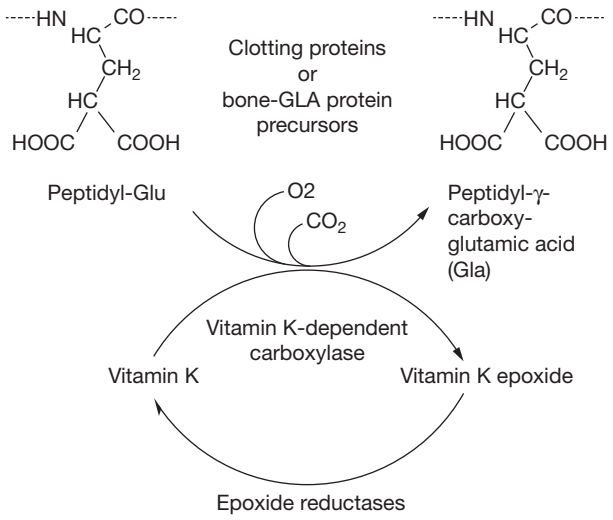
A number of cofactors are involved in single-carbon transfer reactions, in higher organisms, namely, derivatives of folic acid, the cobalamins, and S-adenosylmethionine (SAM). The cofactors derived from folic acid are heterocyclic compounds composed of 4-(pteridin-6-ylmethyl)-aminobenzoic acid that is conjugated with one or more L-glutamate units. The reactions that involve folic acid derivatives include the generation and utilization of formaldehyde, formimino, and methyl groups. For these conversions to



Scheme 4 Biotin activation.



Scheme 5 Forms of vitamin K.



Scheme 6 Vitamin K-dependent carboxylase reaction.

occur, folic acid must be reduced to tetrahydrofolic acid (THFA) (Scheme 7).

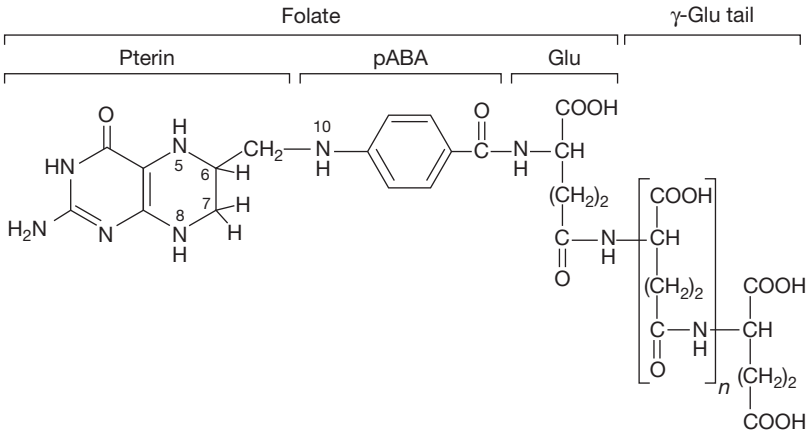
Reduction of the pteridine ring brings the two nitrogens at positions five and ten closer together, which changes their electrochemical properties to facilitate the formation of THFA single-carbon derivatives. The potential derivatives of THFA are N^5-methyl-THFA, N^5-formimino-THFA, N^{10}-formyl-THFA, $N^{5,10}$-methylene-THFA, $N^{5,10}$-methenyl-THFA, and N^5-methyl-THFA. The differing oxidation states of a carbon unit are needed for the range of reactions catalyzed by THFA. For example, the formyl, methanyl, and methylene forms of THFA are utilized for purine and thymidylate (i.e., DNA-related) synthesis. Methylated forms of THFA participate in reactions important to the interconversion and catabolism of amino acids (Scheme 8).

Further, the relative binding of THFA derivatives to given enzymes appears related to the number of the glutamyl residues attached to the 4-(pteridin-6-ylmethyl)-aminobenzoic acid moiety of folic acid. The number of glutamyl residues also dictates specificity and partitioning into given THFA apoenzymes.

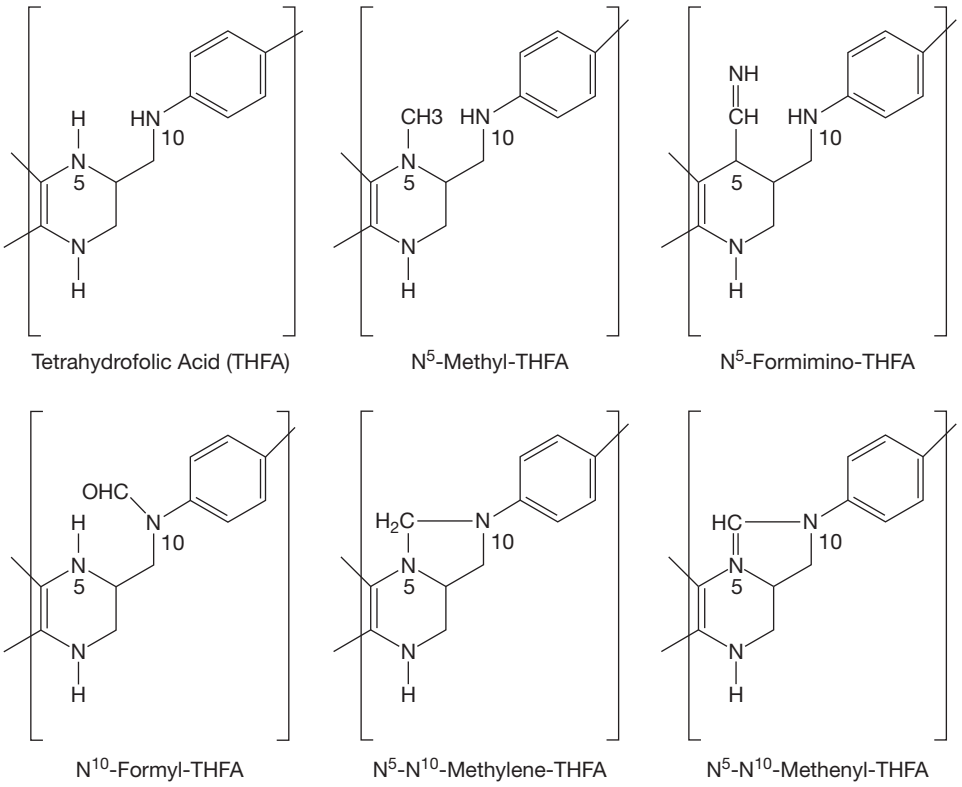
The biochemical basis of the interrelationship between THFA and cobalamin is the maintenance of two functions: (1) nucleic acid synthesis and (2) methylation reactions that are involved in reactions that range from the silencing of genes (DNA methylations) to the synthesis of lipotropic agents and compounds involved as methyl donors, such as choline, betaine, or methylated derivatives of glycine. The most important linkage between folate and vitamin B_{12} occurs at the methionine synthetase step, where 5-methyl-THFA serves as a substrate with homocysteine to form methionine.

There are two forms of vitamin B_{12}. Both forms of vitamin B_{12} consist of a porphyrin-like structure of tetrapyrrole rings containing cobalt at its center. A 5′,6′-dimethylbenzimidazole nucleotide may also linked to the tetrapyrrole rings via a phosphate sugar linkage (see F, Rearrangements on vicinal carbons). Methylated vitamin B_{12} (cobalamin) catalyzes the conversion of homocysteine to methionine by transferring a methyl moiety derived from methyl-THFA to methionine. In effect, vitamin B_{12} in this reaction acts somewhat analogous to a Grignard reagent (e.g., an organometallic complex involved in the transfer of an alkyl group) (Scheme 9).

As noted, for the transfer of methyl groups, SAM also plays a predominate role. SAM is essential to the methylation of phospholipids and production of methylated forms of various amino acids and carbohydrates. SAM serves as the principle methyl source in DNA methylation. The methyl group attached



Scheme 7 Folic acid.



Scheme 8 Derivatives of tetrahydrofolic acid.

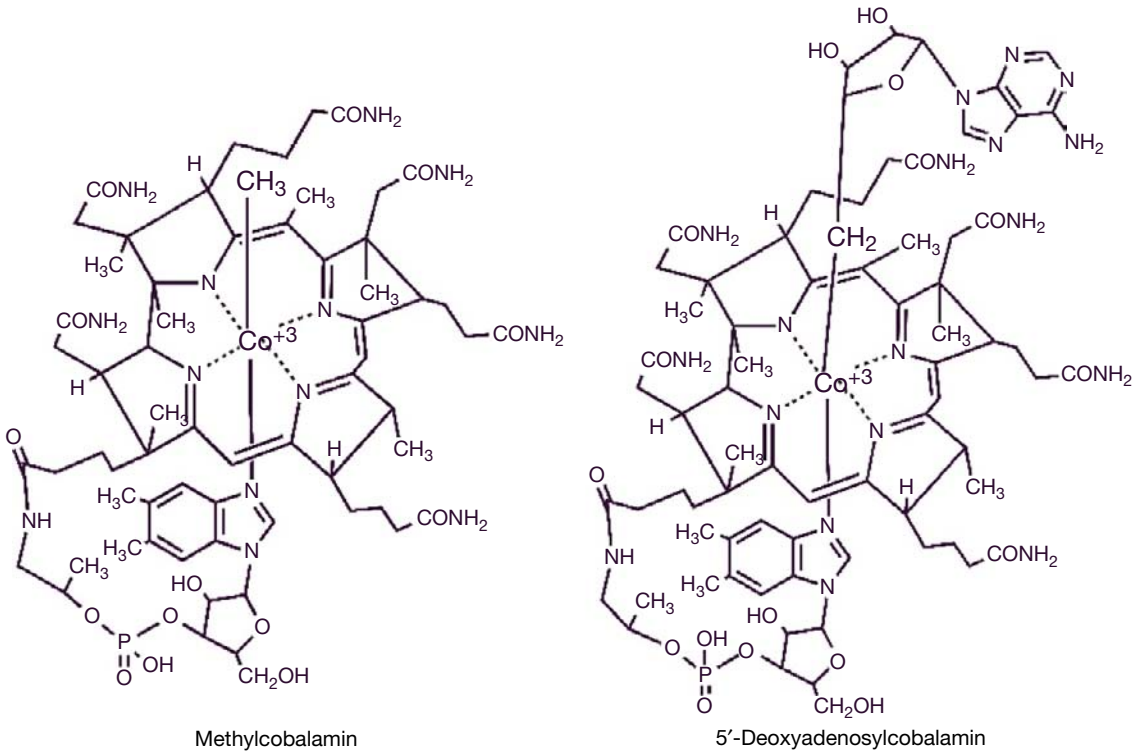
to the methionine sulfur atom in SAM is chemically reactive. This allows donation of this group to an acceptor substrate in transmethylation reactions (Figure 3; Scheme 10).

Rearrangements on vicinal carbons

The rearrangement of vicinal carbon atoms (e.g., an ethenyl group minus one hydrogen atom [$-CH{=}CH_2$] or $R-CH{=}CH_2$ where R can be any other group of atoms) depends on the 5′, 6′-dimethylbenzimidazolyl nucleotide form of vitamin B_{12}. Examples include reactions catalyzed by methylmalonyl-CoA mutase that allows for the oxidation of odd-chain fatty acids and methylation of branched-chain fatty acids, which is important to neural membrane assembly (Figure 4).

Control of reactive oxidants

Reactive oxidant species (ROS) are reactive oxygen ions and peroxides that include superoxide anion, hydrogen peroxide, hydroxyl radicals, and their derivatives (e.g., hypochlorous acid, HOCl). ROS are by-products of the normal metabolism of oxygen, particularly related to mitochondrial oxidations and reactions catalyzed by cytochrome P450 oxidases. High levels of ROS initiate reactions that may alter the structures of important molecules, such as DNA, RNA, proteins, and lipids,



Scheme 9 Derivatives of cobalamin.

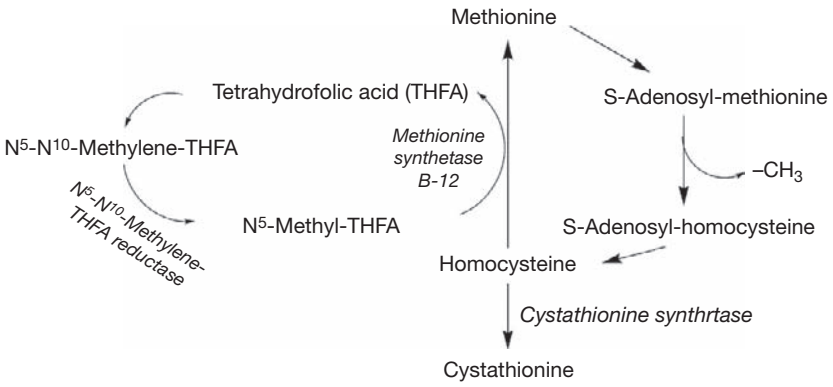


Figure 3 One-carbon metabolism pathway involves the interaction between folic acid, vitamin B_{12}, and S-adenosylmethionine (SAM). Reduced folic acid serves as donors of single carbons in any one of its three forms: 5-methyl-THFA, 5,10 methylene-THFA, and 10-formyl-THFA. The single-carbon donor, 5-methyl-THFA, is used to convert homocysteine into methionine, which can then go to form S-adenosylmethionine, the key substrate in methylation reactions. 5,10-Methylene-THFA is important for the conversion of deoxyuridylate into thymidylate (not shown), and the donor 10-formyl-THFA is used *de novo* purine synthesis (not shown).

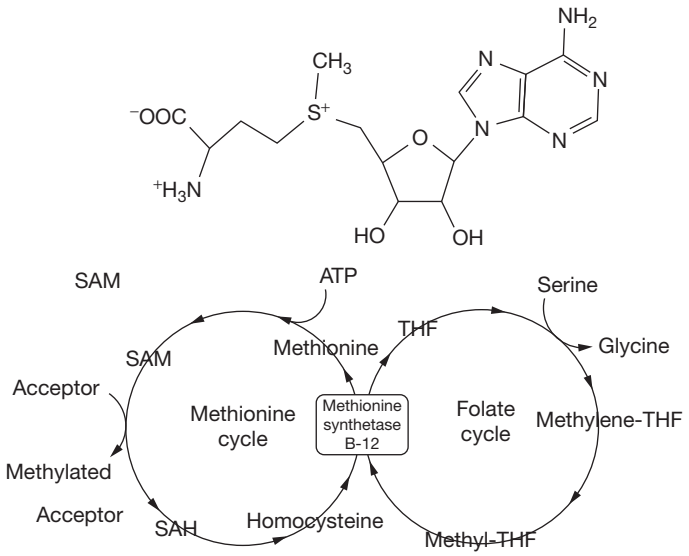
particularly lipids comprising cellular membranes. As a consequence of the potentially destructive nature of ROS, a number of systems and compounds have evolved to counteract potentially destructive ROS reactions. A partial list of antioxidant cofactors including some dietary biofactors is given in Table 3.

Of the vitamins and related derivatives, many are apolar and reside mostly in the lipid membranes of cells or cellular organelles. The best example of an essential nutrient that acts as an antioxidant is vitamin E, a group of ten lipid-soluble compounds that includes both tocopherols and tocotrienols. Of the differing forms of vitamin E, γ-tocopherol is the most common (found in many plant oils), and α-tocopherol is considered to be the most biologically active. Compounds with antioxidant activity are often referred to as the first line of defense with respect to cellular membrane protection. Of the other small molecular weight compounds (vitamin-derived cofactors and related metabolites), most appear to act as reductants.

ADP-ribosylation reactions

About half the niacin present in cells as NAD or NADP is used as a substrate for mono- and polyribosylation reactions, that is,



Scheme 10 Relationship between the methionine and folate cycles.

multiple groups of ADP-ribose moieties are transferred to proteins to form long branched chains, in a reaction called poly(ADP-ribosylation). Mono- and polyribosylations are important in the regulation of a broad range of enzymes. In the nuclei of cells, polyribosylation of specific histones is an essential part of DNA repair. ADP-ribosylation is the addition of one or more ADP-ribose moieties to a protein (Scheme 11).

Cofactor Regulation and Generation

Transport and Transporters

The transport of organic cofactors, their intermediates, and metals in and out of cells is an important regulatory mechanism. Integral membrane proteins with specific permeability and/or affinity for cofactors control cellular transport. With regard to metals, given that metal ions are already at their chemically basic level, intracellular metabolism is focused on direct interactions between the metal and its transport pathways. Indeed, in most cases, simple diffusion plays a very minor role. For example, it has been estimated that the 'free' cellular copper and zinc concentrations in cells are no more than a few atoms per cell, because of binding to highly specific intracellular transporters. In general, absorption of metals from intestinal lumen cells into circulation or from circulation into targeted cells occurs through association with protein complexes, such as in the case for iron and transferrin through the transferrin receptor and cobalamin and intrinsic factor through the receptor cubilin, or through a transporter with permeability for the cofactor, as in the case for the SLC39 family of zinc transporters or sodium-ascorbate cotransporters SVCT1 and SVCT2.

For nonmetal-, vitamin-, or nonvitamin-derived cofactors, the processes are also highly regulated and complex. For example, for the vitamin-derived cofactors, disassembly is required for intestinal absorption. Appreciate that vitamins in foods are usually present as cofactors or in highly modified forms. Pancreatic and intestinal cell-derived enzymes (nucleosidases, phosphatases, and peptidases) are key factors in the initial digestive process with the goal of creating smaller or more soluble moieties designed to increase the statistical probability of interacting with luminal receptors for transport out of the intestinal compartment. In circulation, cofactors or their precursors may be specifically bound to transport proteins or loosely associated with proteins, such as albumin and immunoglobulins.

In addition to dietary deficiencies of given precursors (e.g., essential vitamins and minerals), impairments in absorptive mechanisms, through genetic disorders or other pathophysiological conditions, can also lead to cofactor deficiencies. For example, pernicious anemia in the elderly can result from impaired cobalamin absorption in spite of adequate intake due to insufficient gastric intrinsic factor secretion from gastric parietal cells. Vitamin B_{12} absorption is directly dependent on the interaction between intrinsic factor-bound cobalamin and the cubilin receptor, which binds this nutrient–protein complex.

Because various gene products handle the intracellular and whole body metabolism of cofactors, mutations or polymorphisms in such genes can lead to disruptions in cofactor metabolism with significant health consequences. For example, mutations in genes required for intestinal absorption of cofactors can result in a phenotype with close resemblance to symptoms of the corresponding dietary deficiency. Elemental iron absorption is mediated through DMT1, which is encoded by the gene SLC11A2. Mutations in SLC11A2 in both rats and mice lead to microcytic anemia, which is also present in iron deficiency anemia. Likewise, at the cellular level, as would be expected, transporters also play essential and important roles in cofactor regulation. Some examples are listed in Table 4.

Further, mutations in the biosynthesis, recycling, or restoration pathways can resemble the dietary deficiency. For instance, L-gulono-gamma-lactone oxidase is a critical enzyme in the L-ascorbic acid biosynthesis pathway, and mutation of this gene in rats leaves it prone to scurvy. Interestingly, humans and many other primates cannot synthesize their own vitamin

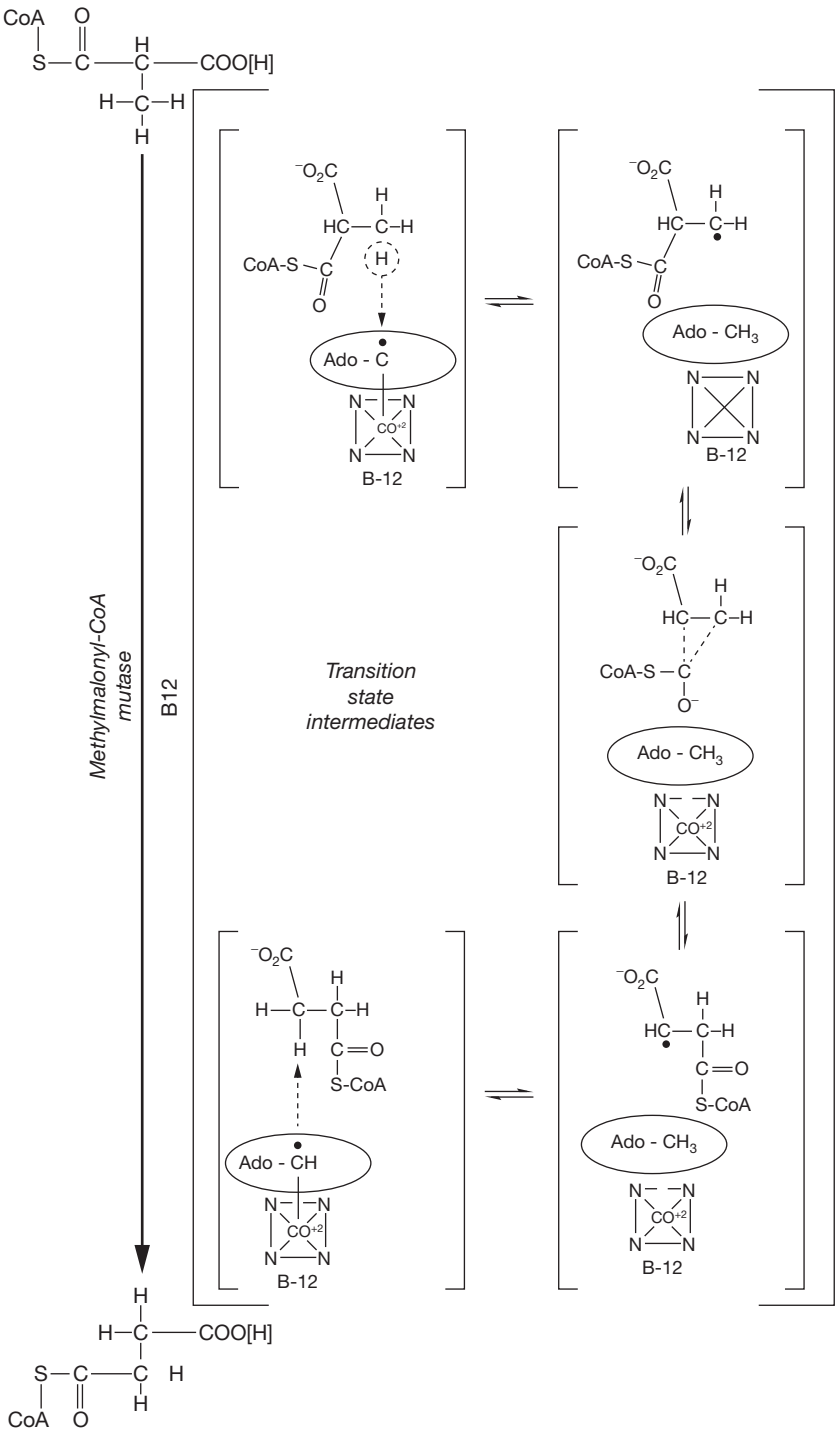


Figure 4 Mutase reactions begin with the homolytic cleavage of the bond between the 5′, 6′-dimethylbenzimidazolyl nucleotide form of B-12 and the Co^{3+}. A free radical is formed; accordingly, coenzyme B-12 in the catalytic process acts as a free radical generator. A free radical is then formed on the vicinal carbon of the substrate, which sets the stage for rearrangements, such as the isomerization of methylmalonyl-CoA to succinyl-CoA.

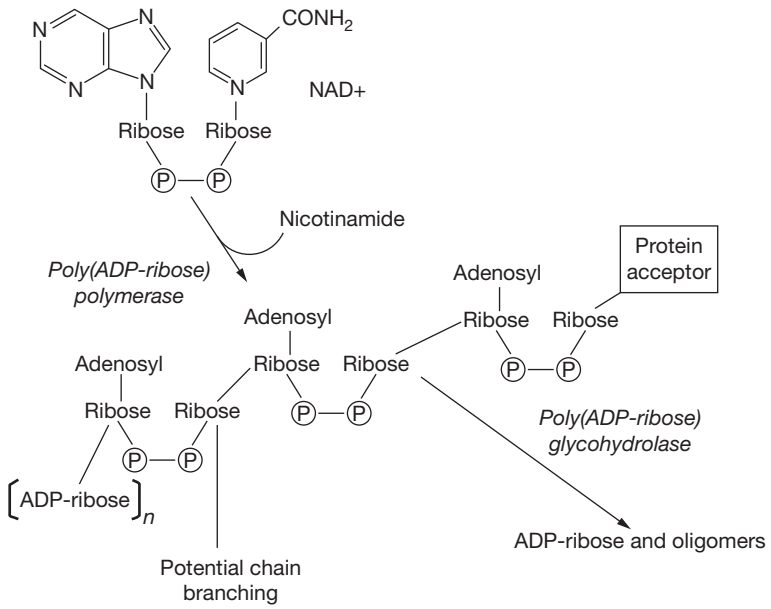
C because of mutations in the gulonolactone oxidase and as a consequence are sensitive to dietary vitamin C deficiency. Another example of a mutation in cofactor biosynthesis leading to a cofactor deficiency is X-linked sideroblastic anemia, which is caused by a mutation in 5-aminolevulinate synthase gene ALAS2. Mutations in ALAS2 affect the heme biosynthesis pathway, and impairment in 5-aminolevulinate synthase leads to impaired heme synthesis and microcytic anemia concomitant with iron overload due to ineffective use of available iron. It is also important to note that the phenotype because of

Table 3 Cofactors, related enzymes, and selected biofactors with antioxidant activity

Essential compounds (vitamins) and related derivatives	*Function*
α-, β-, γ-, and δ-Tocopherols (vitamin E)	Lipid peroxide initiated chain reaction breakers
β-Carotenes	Singlet oxygen quencher
Lycopene	Singlet oxygen quencher
Ubiquinol (CoQ-10)	Radical scavenger
Ascorbic acid	Reductant
Glutathione	Reductant
Urate	Radical scavenger
Bilirubin	Radical scavenger
NADH, NADPH, $FADH_2$, $FMNH_2$	Sources of reducing potential
Proteins and enzymes	
Superoxide dismutase, depending on the organism, utilizes metals (Cu, Zn, Mn, and Ni) as cofactors	Dismutation of superoxide anions: $[M_{(n+1)+}]\text{-SOD} + O_2^- \rightarrow [M_{n+}]\text{-SOD} + O_2$ $[M_{n+}]\text{-SOD} + O_2^- + 2H^+ \rightarrow [M_{(n+1)+}]\text{-SOD} + H_2O_2$. where M = Cu ($n=1$); Mn ($n=2$); Fe ($n=2$); Ni ($n=2$)
Glutathione peroxidase (utilizes Se as a cofactor and glutathione as a cosubstrate)	Reduces lipid hydroperoxides to their corresponding alcohols and H_2O_2 to water: $2GSH + H_2O_2 \rightarrow GSSG + 2H_2O$
Myeloperoxidase (utilizes Fe as a cofactor)	Controls hypochlorous acid production from hydrogen peroxide and chloride anion
Hydrogen peroxidases (utilizes Fe as a cofactor)	Converts hydrogen peroxide to water
Catalase (utilizes Fe as a cofactor)	Catalyzes the decomposition of hydrogen peroxide to water and oxygen
α-1-Microglobulin (utilizes a critical cysteine residue at its active center to facilitate reactions)	Degrades heme and is a radical scavenger as well as a reductase
Metal binding proteins (e.g., metallothionein, chaperones, and ceruloplasmin)	Sequestration, transport, and regulation of transition metals capable of nonspecific redox when not protein bound
Diet-derived antioxidants/nutraceuticals	
Polyphenol antioxidants (e.g., pyrroloquinoline quinone, hydroxytyrosol, and flavonoids like various flavones; flavanols, such as catechins or epicatechins; flavanones; isoflavone phytoestrogens, such as daidzein and genistein; flavonols such as quercetin (like rutin); and stilbenoids such as resveratrol)	Over 4000 distinct species, many have antioxidant activity; others can effect changes in cell-to-cell signaling, receptor sensitivity, inflammatory enzyme activity, or gene regulation
Phenolic acids (e.g., cinnamic acid, caffeic acid, salicylic acid, and vanillin)	Redox cycling, general antioxidant activity
Carotenoids (e.g., lutein, zeaxanthin, and carotenes)	Over 600 known carotenoids in two classes xanthophylls (which contain oxygen) and carotenes (which are hydrocarbons and contain no oxygen) quench singlet oxygen



Scheme 11 Poly(ADP-ribose) polymerase reactions.

Table 4 Examples of transporters important to the regulation of vitamins and minerals

	Transporter name/symbol	*Solute carrier*	*Genetic disease*
Vitamin examples			
Thiamine (vitamin B_1)	Organic cation transporter 1/OCT1	SLC22A1	Thiamine-responsive megaloblastic anemia
	Thiamine transporter 1	SLC19A2	Lethal encephalopathy, basal ganglia disease
	Thiamine transporter 2	SLC19A3	
Riboflavin (vitamin B_2)	Riboflavin transporter 1/RFVT1	SLC52A1	Brown–Vialetto–Van Laere syndrome, motor neuron disease
	Riboflavin transporter 1/RFVT2	SLC52A2	
	Riboflavin transporter 1/RFVT3	SLC52A3

[a]PCFT/HCP1 can transport both folate and heme.

mutations in cofactor transporter genes can also be lethal. For example, mutation of SLC23A1, which encodes the ascorbic acid transporter SVCT2, in mice leads to perinatal lethality and symptoms that do not resemble scurvy or vitamin C deficiency. The differences (lethal vs. nonlethal) may be due to the developmental timing of the mutations. Mutations that occur very early in development are often more likely to be lethal.

Another consideration is that the some minerals and vitamins may have other biological roles than strictly cofactor functions, in which case the phenotype evident in the mutation of transporter genes may reflect a combination of a lack of cofactor activity and the noncofactor associated effects caused by the reduced transport of the same nutrient. For example, zinc is a cofactor for some enzymes such as carbonic anhydrase and alcohol dehydrogenase, and zinc is also present in many DNA-binding proteins as zinc fingers and can modulate cell signaling.

Cellular Synthesis Pathways and Chemical Modifications Important to Cofactor Cellular Regulation or Modulation of Activity

The regulation of given cofactors occurs at a number of levels. In addition to regulation at the level of transport, many vitamins are subject to chemical modifications that transform them into coenzymes. Thus, the amounts of available cofactors may be controlled by chemical modifications and some cases synthesis. The following sections focus on specific chemical modifications important to organic cofactor activations to highlight the range of cellular strategies used.

Phosphorylation. The addition of a phosphate (PO_4^{3-}) group is often used as a major homeostatic control. In many proteins and enzymes, phosphorylation serves as a type of 'on/off' switch, thereby altering function or activity. Enzymes designated as kinases usually catalyze phosphorylation reactions using ATP as a cosubstrate. Phosphorylation can serve to (1) alter hydrophilic charter and size so that the cofactor is less likely to be transported out of a cell or cellular compartment, (2) improve or alter binding of the cofactor to given enzymes, (3) change a given chemical characteristic of the cofactor, or (4) contribute to overall cellular control because of linkages to the cell's chemical potential, as defined by ADP/ATP concentrations. Some important examples include the following:

- Phosphorylation of ascorbic acid to ascorbate-2-phosphate, which renders the molecule less likely to act as a redox initiator by inhibiting keto–enol tautomerism (e.g., [−COH═COH−] ↔ [−CO−CO−])
- Phosphorylation of vitamin B_6 to PLP, which allows PLP to act as an acid catalyst in glycogen phosphorylase, that is, in addition to its role in transaminases and other PLP-requiring enzymes
- Phosphorylation of NAD to NADP, which results in a cofactor that is more likely to function in a synthetic process (NADP) than catabolic process (NAD)
- Phosphorylation of TPP to thiamine triphosphate, in which neural tissue is involved in ion gating and transport
- Phosphorylation of pantotheine, which facilitates covalent attachment of pantotheine-4′-phosphate to other moieties,

such as intermediates in the coenzyme A synthesis pathway or to ACP subunits

Adenylylations. Examples of adenylylation reactions include conversion of niacin to NAD(P), pantothenic acid to CoA, and vitamin B_{12} to adenosyl B-12 and also the formation of non-vitamin-derived cofactors, such as SAM and 3′-phosphoadenosine-5′-phosphosulfate (an activated form of sulfate). The presence of an adenylyl function can improve binding to targeted protein/enzyme binding domains. Analogous to certain types of phosphorylations, adenylyl transfers represent another way of linking cofactor generation to changes in a cell's chemical potential.

Methylations and Amidations. Examples of methylations include the following:

- Methylation of ascorbic acid to 2-methyl-ascorbic acid. This type of modification can be important in the regulating ascorbic acid's redox activity (inhibits keto–enol tautomerism).
- Methylation of niacin to 1-methylnicotinamide, which facilitates the removal of excess niacin from cells.
- Methylation of aromatic cofactors, which can change the location of reactions on resonating ring structures. For example, the presence of a methyl group can direct electrophiles to attack aromatic molecules at ortho- and/or para-positions relative to the location of the methyl group.

With regard to amidations, the conversion of nicotinic acid to nicotinamide changes the –[COO-] moiety from an acid to a weak base. The hydrogen bonding potential with water and other protic solvents is altered. Similar to methylation, the presence of a $-[CONH_2]$ group is *ortho–para* directing, that is, incoming electrophiles are directed to ortho- or parapositions, which results in the stereospecific transfer of hydride ions from NAD or NADP.

Conjugations utilizing glutamate and isoprene units. As noted, folic acid in cells is a pteroyl derivative containing polyglutamyl residues in γ-linkage. The number of γ-linked glutamyl residues in part determines the binding of folic acid (i.e., pteroylpolyglutamates) to given enzymes. For example, liver thymidylate preferentially binds pteroylpolyglutamates with four glutamyl residues, but derivatives with two to seven glutamyl residues all bind at least 30-fold more tightly than pteroylmonoglutamate. Polyglutamylation can also influence folic acid solubility. For transport in fluids and in and out of cells, the principle form of folic acid is monoglutamylated, which is the most soluble form. In the intestine and cells, conjugated forms of folic acid in foods are converted to the monoglutamyl folic acid by enzymes with γ-linked peptidase activity in order to increase solubility and eventual transport into the body and into cells.

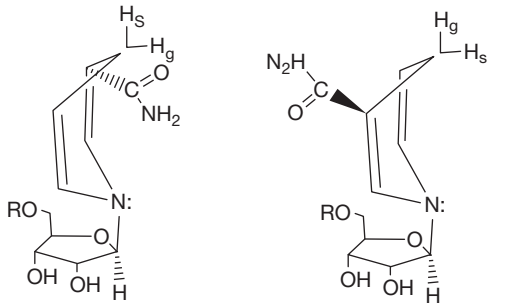
Isoprene conjugation is important to the synthesis of phytyl side chains for numerous biological active biofactors and cofactors (e.g., carotenoids, tocopherols, and phyllo- and menaquinones). As an example of a dietary biofactor, prenylated flavonoids are produced in plants with varying degrees of phytoestrogenic and antioxidant activity. Isoprene units (2-methyl-1,3-butadiene, $CH_2{=}C(CH_3)CH{=}CH_2$) are converted to dimethylallyl diphosphate and isopentenyl diphosphate in pathways designed for synthesis of compounds that have highly divergent functions (e.g., from rubber to biologically actives sterols). For the fat-soluble vitamins, a hydrophobic (phytyl) side chain composed from isoprene units allows such vitamins to partition into lipid membranes of the hydrophobic domains of targeted proteins.

Isomerism. The isomeric form of a cofactor also plays a role in the regulation of given catalytic activities. As an example, dehydrogenases and reductases often show preferences for one or the other of the two isomeric forms of NAD[P]H (the A or pro-R form or B or pro-S form). The two hydrogen atoms of niacin at the 4-position are prochiral. The binding of NAD to dehydrogenases or reductases is such that hydride transfer involves only one side of the nicotinamide moiety. Binding of the nonpreferred form is generally weaker, and the maximum velocity is slower. Examples of dehydrogenase and reductases that prefer the A or pro-R form are alcohol, lactate, and isocitrate dehydrogenases and dihydrofolate reductase, whereas glyceraldehyde-3-phosphate, 3-phosphoglycerate, glutamic acid, and glucose-6-phosphate dehydrogenases and glutathione reductase prefer the B or pro-S form (Scheme 12).

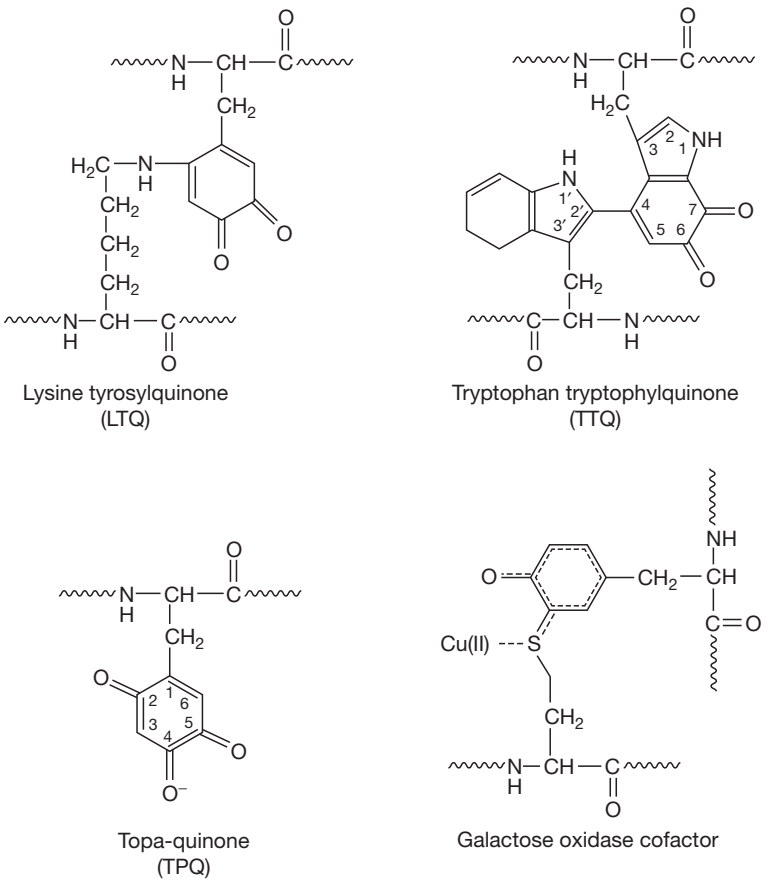
Covalent Attachment and In Situ Cofactor Formation. Many cofactors are covalently attached to the enzymes that they serve. Of the vitamins and vitamin-like compounds, good examples are biotin, lipoic acid, pantothenic acid (as pantotheine), and riboflavin-derived cofactors, FMN and FAD. Indeed, more than 20 flavoenzymes have been described, for which five novel FAD or FMN covalent linkages have been identified (e.g., the covalent linkages to histidyl, tyrosyl, or cysteinyl residues). PLP could also be included, because as noted, imine bonds, although capable of dissociation, are also covalent.

Covalent binding has obvious impact on cofactor metabolism (e.g., metabolic turnover of the cofactor becomes more dependent on protein catabolism before it can be released and potentially reutilized). The thermodynamics constraints of reactions can also be significantly altered (e.g., changes in entropic considerations).

With regard to *in situ* cofactor formation, in the past two decades, the best examples come from the discovery of four novel redox cofactors derived from posttranslational modification of specific amino acids within corresponding enzymes. These include the topa quinone cofactor, found in copper amine oxidases; lysine tyrosyl quinone, found in lysyl oxidase; tryptophan tryptophylquinone, found in bacterial methylamine dehydrogenases; and cysteine-cross-linked tyrosine,



Scheme 12 Isomeric forms of NADH.



Scheme 13 Quinone cofactors.

found in galactose oxidase. The topa quinone cofactor of copper amine oxidase is generated by copper-assisted self-processing of the precursor protein (Scheme 13).

Conclusion

Many of the aforementioned cofactors are found and used in all forms of life. This suggests that they were present in our earliest of ancestors. The recent assignment of quinone derivatives as the main compound class composing 'interstellar' dust grains is important in this regard. For example, one of the quinones that was identified, pyrroloquinoline quinone, is an important redox cofactor used by methylotrophic bacteria and present in all biological tissues examined to date. Further, considerable evidence supports the notion that the formation of RNA was a dominant process in the eventual evolution of life. RNA is capable of self-replication and catalyzing specific biochemical reactions. Accordingly, it is not difficult to envision that cofactors, such as ATP, evolved by a process similar to the formation of RNA (and DNA) as major components of reactions important to sustaining energy relationships.

With regard to the discovery and conceptual understanding of cofactors as catalyst, most of the advances have come in this century. NAD was the first organic cofactor to be identified extending from the early work of Arthur Harden and William Young. They observed that a boiled and filtered yeast extract accelerated alcoholic fermentation in yeast capable of fermentation. As methods important to the study of protein structure and enzyme kinetics improved, the relationships that cofactors play in influencing induced fit and the so-called 'lock and key' mechanisms, as well as entropic parameters, entasis, and quantum tunneling, became more apparent.

Although detailed discussions of specific catalytic mechanisms are beyond the scope of this article, our goal nevertheless was to provide basic descriptions of cofactor functions. Many of which represent the bases for biochemical lesions associated with nutritional deficiency syndromes and conditions. For more detailed discussions of mechanisms, the reader should consult the references listed in section 'Future Readings.' For additional physiological and nutritional descriptions, the articles that are cross-referenced should be consulted, particularly those related to vitamins and minerals that serve as cofactors.

Coffee: Analysis and Composition

MC Cid and M-P de Peña, University of Navarra, Pamplona, Spain

Introduction

Coffee is the most traded commodity in the world after oil. Although native to Africa (Ethiopia (Abyssinia)), nowadays, it is cultivated in regions between the Tropic of Cancer and the Tropic of Capricorn.

The generic name *Coffea* covers approximately 70 species, but only two of them are economically important: *Coffea arabica*, commonly arabica coffee, which accounts for three-quarters of world production, and *Coffea canephora* var. *robusta*, commonly robusta coffee. Differences between these two species include ideal growing climate, physical aspects, chemical composition, and characteristics of the brew made with the ground roasted seeds.

Coffee is one of the most consumed beverages in the world and a rich source of antioxidants. The amounts of these antioxidants are influenced by several technological factors. Besides, the antioxidants identified in coffee (chlorogenic acids (CGAs) and volatile and nonvolatile Maillard reaction (MR) products) contribute in different proportions to the overall antioxidant capacity. Several chronic diseases, such as cancer, cardiovascular, inflammatory, and neurodegenerative pathologies, are associated with oxidative stress. The antioxidants present in coffee, together with caffeine, have been proposed as those compounds that mainly contribute to its health properties.

Green Coffee

Composition of Green Coffee

Arabica and robusta green coffees show both qualitative and quantitative differences in their composition (Table 1).

Green coffee composition is dominated by carbohydrates (~60% dry matter), more abundant in arabica coffee than in robusta. Most carbohydrates present in green coffee are insoluble polysaccharides (cellulose and hemicellulose, arabinogalactan, and galactomannan) accounting for ≈50%. The soluble fraction (≈10%) includes disaccharides (sucrose) and monosaccharides (glucose, galactose, arabinose, fructose, mannose, mannitol, xylose, and ribose) in traces.

Proteins, peptides, and free amino acids account for 10–15% of the green coffee dry matter. The main amino acids, both protein-bound and free, are asparagine, glutamic acid, alanine, aspartic acid, and lysine. Several other *N*-compounds are present in coffee, such as caffeine, trigonelline, and nicotinic acid. The caffeine concentration in robusta coffee is approximately double that in arabica.

Lipid contents in green coffee account for 8–18% of its dry matter. The total content in arabica seeds is approximately twofold than that in robusta. Fatty acids in coffee are found primarily in combined forms; most are esterified with glycerol in the triacylglycerol fraction (75%), 20% esterified with diterpenes, and a small proportion esterified in sterol esters (sitosterol (54%), stigmasterol, and campesterol). Most fatty acids in coffee are unsaturated, being linoleic, oleic, and linolenic acids the most abundant. Also, palmitic, stearic, araquidic, lignoceric, and behenic acids and pentacyclic diterpenes (methylcafestol, cafestol, and kahweol) are present.

Regarding minerals, potassium accounts for approximately 40% of the mineral content of ground coffee, and phosphorus, for 4%. The remaining mineral content consists of approximately 30 different elements, including sodium, magnesium, calcium, and sulfur. Trace minerals in coffee include zinc, silicon, manganese, iron, copper, and aluminum, among others.

Green coffee also contains a large amount and variety of polyphenols. The main components of the phenolic fraction of green coffee are CGAs (7–12% dry matter), which are more abundant in robusta coffee. These phenolic acids are formed by the esterification of one molecule of quinic acid and one to three molecules of *trans*-hydroxycinnamic acids in different positions. The main groups of CGA are caffeoylquinic acids (CQAs), dicaffeoylquinic acids (diCQAs), feruloylquinic acids (FQAs), *p*-coumaroylquinic acids (*p*CoQAs), and mixed diesters of caffeoylferuloylquinic acids (CFQAs; Figure 1). CQAs are the most abundant CGAS in coffee, being 5-*O*-CQA the most abundant. More recently, numerous minor CGAs were found in coffee including isomers of dimethoxycinnamoylquinic acids, dimethoxy-hydroxycinnamoylquinic acids, dihydroxy-methoxycinnamoylquinic acids, diferuloylquinic acids, di-*p*CoQAs, and mixed diesters of the earlier described hydroxycinnamic and methoxycinnamic acids. In addition, at least three free cinnamic acids were also identified in green coffee, namely, caffeic acid, ferulic acid, and 3,4-dimethoxycinnamic acid.

Phenolic compounds different from CGAs and related compounds, such as cinnamoyl glycosides, cinnamoyl amino acids, anthocyanidins, and lignans, have also been identified in green coffee in minor amounts.

Roasting Coffee

Roasting Process

The characteristic properties of the coffee beverage, such as flavor and aroma, are developed during the roasting of coffee. The beans are heated to 180–250 °C, from 2 to 25 min, depending on roast technique and desired roasting degree (light, medium, or dark). The initial changes occur at or above 50 °C when the protein in the tissue cells denatures. Three major phases are drying, pyrolysis, and cooling. During the drying phase, most of the free water evaporates keeping the bean temperature at 100 °C. Temperature rise indicates the second phase. At about 150 °C, there is a release of volatile products (water, CO, and CO_2), which results in an increase of 50–80% in bean volume. At 170–200 °C, pyrolytic reactions drastically modify the chemical composition of the bean by the formation of hundreds of substances that give coffee its characteristic aroma and taste. At the

Table 1 Chemical composition of green *Coffea arabica* and *Coffea robusta* seeds

	Concentration[a] (g/100 g)	
Component	*Coffea arabica*	*Coffea robusta*

5-*O*-Caffeoylquinic acid	3.0–5.6	4.4–6.6

Content varies according to cultivar, agricultural practices, climate, soil composition, and methods of analysis.
[a]%Dry matter; water content of raw coffee 7–13%.

end of roasting, the beans then burst due to the increase of internal pressure, and the popping of the beans indicates that roasting must be stopped by cooling (quenching). Despite chemical changes, also, the physical parameters of coffee change considerably. The bean color changes to cinnamon brown, an 11–20% loss in weight occurs, and the specific gravity falls from 1.2 to 0.6 due to volume increase.

Torrefacto is a roasting process in which sugar is added to coffee, usually robusta. This roasting technique is used in several countries of southern Europe and South America where some segments of the population prefer coffees with a dark-brown color, intense aroma, and a strong taste with a tendency to bitterness. This kind of roasting process was initially used to mask negative sensorial attributes in robusta coffees. Nowadays, torrefacto-roasted coffee is usually blended with conventional roasted coffee (robusta) for commercial use.

The degree of roast is reflected on the external color of the beans (from light to dark brown due to pyrolysis of organic compounds). Despite visual evaluation, color analysis is traditionally carried out on ground roasted coffee using techniques based on the reflectance of the light in the visible or in the NIR range of the color spectrum. The use of a standardized tristimulus colorimeter provides lightness (L^*) and chromaticity (a^* and b^*) parameters that can also be applied to calculate the hue angle (H°) and chroma (C^*). The lower the lightness, the darker the roast. Similarly for the Agtron-type spectrophotometer, which uses NIR illumination, other techniques using lasers have been developed to be used directly on coffee beans without grinding.

Influence of Roasting Process in the Composition of Coffee

The roasting process causes several changes to the composition of the coffee beans, because some compounds are degraded or modified, resulting in the development of the characteristic color, aroma, and flavor of coffee. These transformations have been extensively studied, but the composition of roasted coffee is still far from being elucidated. Table 2 provides a rough overview of the main components of roasted arabica and robusta coffee.

Roasting leads to profound changes in the chemical composition of coffee with a simultaneous decrease in the naturally occurring substances in green coffee and the generation of many other compounds derived from the MRs, carbohydrate caramelization, and pyrolysis of organic compounds. Although some compounds formed during roasting might be responsible for the health properties of the coffee brew, potential carcinogenic compounds, such as acrylamide and furan, can also be formed.

Most of the carbohydrates present, such as cellulose and polysaccharides of mannose, galactose, and arabinose, are insoluble. During roasting, some of them are degraded to low-molecular-weight carbohydrates, which are soluble. Sucrose present in raw coffee is decomposed in roasted coffee up to half.

Phenolic compounds suffer great changes during the heating processing of coffee due to their thermal instability. The content of CGAs drops during roasting as shown in Table 3. During the drying phase, when there is still adequate water content, isomerization of CGAs occurs, leading to an increase in 4- and 3-CQAs in roasted coffee. Additionally, some of the CGAs are hydrolyzed to cinnamic acids and quinic acid. The cinnamates may be decarboxylated and transformed into low-molecular-weight compounds. Later in roasting, part of the CGAs lactonize giving rise to several isomers of caffeoylquinic, feruloylquinic, and diCQA lactones (Figure 1). Decomposition of CGAs has a great impact on the quality attributes of roasted coffee and is directly related to flavor development.

The MR involves the condensation of the carbonyl group of the reducing sugars with the amino group of amino acids and proteins. It consists of a complex network of chemical reactions during which a myriad of products of different chemical compositions are formed, commonly known as Maillard reaction products (MRPs). The polymeric brown-colored final products of the MR are called melanoidins and result from the cyclizations, dehydrations, retroaldolizations, rearrangements, isomerizations, and condensations of other MRPs. Melanoidins are one of the major components of roasted coffee, accounting for up to 25% of dry matter. These compounds have different chemical compositions, which are still not fully elucidated, and consequently different properties: nutrient or contaminant binding, antioxidant or prooxidant, and mutagenic or antimutagenic. Because phenolic compounds also participate in the MR, they are at least partly incorporated in coffee melanoidins through noncovalent or covalent bonds. Besides color development, the MR plays a key role in aroma generation. For example, pyrazines, resulting from the degradation of instable MRPs, are potent odorants in roasted coffee. Other main classes of aromatic compounds formed during the MR are aldehydes, ketones, pyridines, oxazoles, thiazoles, and thiophenes.

Furthermore, the addition of sugar at the end of the torrefacto roasting process might intensify the development of MRs and, consequently, increase the antioxidant capacity of coffee.

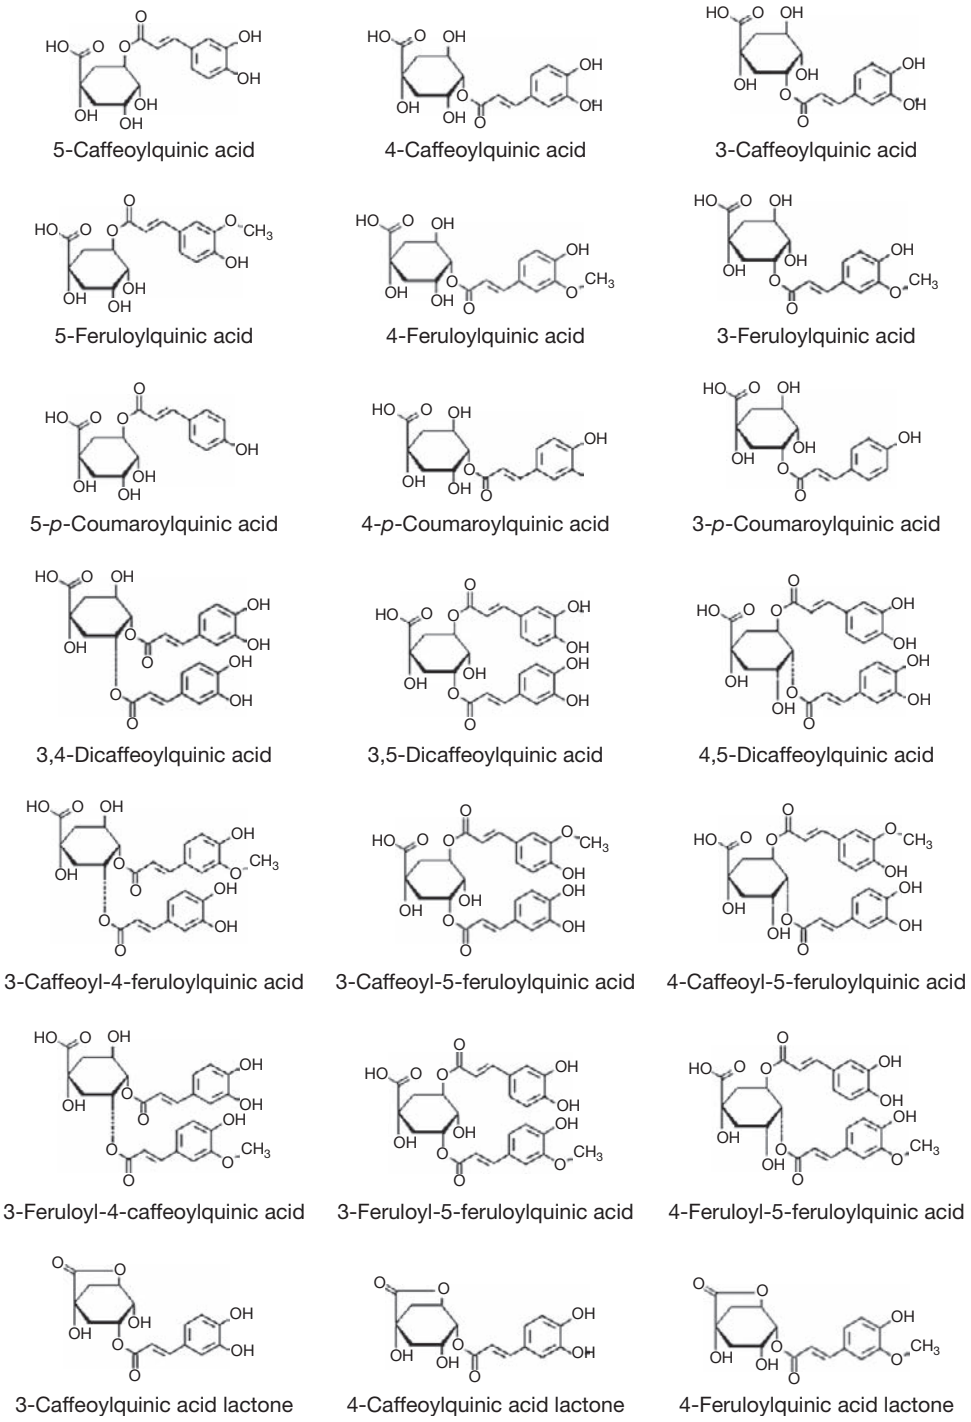

Figure 1 Main chlorogenic acids in coffee.

Protein is subjected to extensive changes when heated in the presence of carbohydrates. There is a shift of the amino acid compositions of coffee before and after bean roasting. The total amino acid content of the hydrolysates drops by about 30% because of considerable degradation. Arginine, aspartic acid, cysteine, histidine, lysine, serine, threonine, and methionine, being especially reactive amino acids, are somewhat decreased in roasted coffee, while the stable amino acids, particularly alanine, glutamic acid, and leucine, are relatively increased. Free amino acids occur only in traces in roasted coffee because they are involved in a series of reactions, for example, the MR, giving rise to potent aroma compounds. Mercaptans, thiophenes, thiazoles, alkylpyrazines, pyrroles, pyridines, and pyrrolizines result from the degradation of sulfur amino acids, hydroxy amino acids, and proline.

The caffeine content of raw arabica coffee is 0.8–1.4%, whereas in the robusta variety, it is 1.7–4.0%. Caffeine is quite thermostable and decreases only slightly during roasting.

Table 2 Chemical composition of roasted *Coffea arabica* and *Coffea robusta*

	Concentration[a] *(g/100 g)*	
Component	*Coffea arabica*	*Coffea robusta*

In contrast, trigonelline, which is present in green coffee up to 1.2%, is 50–80% proportionally decomposed to roasting temperature. The main degradation products are nicotinic acid, pyridine, and several alkylpyridines and pyrroles.

The lipid fraction appears to be very stable and survives the roasting process with only minor changes. Linoleic acid is the predominant fatty acid, followed by palmitic acid. The major compounds in roasted coffee beans (coffee oil) are triacylglycerols (78.8%) and diterpene esters (15%). The main diterpenes are cafestol, 16-*O*-methylcafestol, and kahweol. Cafestol and kahweol are partially degraded by the roasting process. Sitosterol and stigmasterol are the major compounds of the sterol fraction.

The potassium is predominant in coffee ash (1.1%), followed by calcium (0.2%) and magnesium (0.2%). The predominant anions are phosphates (0.2%) and sulfates (0.1%). Many other elements are present in trace amounts.

The aroma of roasted coffee is very complex, being composed of a large number of volatiles with different odor qualities, some pleasant, but many others probably below their detection threshold. The concentration, proportion, and synergistic and antagonistic effects among volatile compounds influence the final aroma quality.

The *volatile composition* of roasted coffee depends on many factors, including coffee species/variety, growing and harvesting conditions, storage prior to roasting, degree of roast, and type of roasting machine. The formation of volatile compounds depends on the stability of their precursors and location within the seed. More than 900 compounds with a wide variety of functional groups have been identified until now after roasting in different types of coffee.

The classes of volatile compounds found in roasted coffee are furans, pyrans, pyrazines, pyrroles, aldehydes, ketones, phenolics, hydrocarbons, alcohols, acids, esters, lactones, thiophenes, oxazoles, thiazoles, pyridines, amines, and various sulfur and nitrogen compounds. Not all the volatiles in coffee are odorants, and their contribution to flavor is not usually directly related to their abundance.

The complex aroma is formed during the roasting process by pyrolysis of the water-soluble components, such as sugars, amino acids, and trigonelline. A number of them may be produced by more than one route. The main pathways by which the aroma precursors are degraded are the MR; Strecker degradation and formation of pyrazines and oxazoles; degradation of trigonelline, phenolic acids, lipids, and sugars; breakdown of sulfur and hydroxy amino acids; and proline and hydroxyproline degradation. Generally, carbohydrates produce furans, aldehydes, ketones, and phenols; proteins, peptides, and amino acids produce ketones, pyrroles, and pyrazines; lipids are responsible for only small amounts of aldehydes and ketones given their resistance to changes during the roasting process; CGAs produce phenolic volatile compounds (e.g., catechols, pyrogallol, and phenol); trigonelline produces pyrroles, pyridines, and pyrazines. Almost all thiophenes, oxazoles, and thiazoles are formed during roasting, since they are not usually detected in green coffee.

2-Furfurylthiol is the most important contributor to the aroma of coffee. Its precursors are polysaccharides containing arabinose, for example, arabinogalactans, and cysteine in the free and bound forms. Part of furfurylthiol and the other thiols are present in roasted coffee as disulfide bound to cysteine, SH-peptides, and proteins.

Robusta coffees contain alkylpyrazines and phenols in significantly higher concentrations than arabica, being earthy and smoky/phenolic notes in the aroma profile more intensive. Arabica coffees are usually richer in the odorants of the sweet/caramellike group. In torrefacto coffee, where coffee is roasted with sugar, pyrazines, pyridines, and furans are formed in greater quantity than in conventional roasted coffee due to increases in the Maillard and caramelization reactions.

At least 28 volatile compounds are reported as key odorants of ground and brewed coffees and contribute to the aroma. Most of these odorants have been assigned to sweet/caramel, earthy, sulfurous/roasty, and smoky/phenolic notes. The remaining odorants have a fruity or spicy odor. Several authors suggested that only those compounds which concentrations surpass their odor thresholds are odor-active in food. However, the evaluation of the odor activity values for all of the volatiles in coffee is very laborious because concentration and odor threshold data must be determined by a large number of compounds (Table 4).

One of the first practicable methods to convert the results of instrumental analysis of the volatiles into sensory data was combined hedonic aromatic response measurement analysis and aroma extract dilution analysis. In both procedures, serial dilutions of an extract containing the volatile fraction of a food

are analyzed by gas chromatography–olfactometry (GCO). In this technique, the separated compounds at the effluent from a GC column are evaluated qualitatively one by one by human assessors. An integrated approach involving the joint determination of the volatile compounds by gas chromatography–mass spectrometry (GC–MS) and GCO provides useful information about the most important active contributors to the aroma of different coffees.

One of the key factors in the analysis of the profile of volatile compounds is their extraction. Several methods have been used to study the aroma fraction of roasted coffee and coffee brews. One of the first was the preparation of coffee extracts where volatile compounds were dissolved with organic solvents, as in steam distillation extraction. This method should be performed under mild conditions. The temperature, in particular, is a critical point, due to the instability of, for example, thiols and disulfides. To avoid the formation of artifacts, the temperature during the isolation of the volatiles may not exceed 50 °C for a longer period.

As an alternative to the injection of an organic solvent extract, the vapor phase surrounding the coffee sample (headspace) can be directly analyzed. This method gives the most accurate composition of volatiles. However, under the usual operating conditions, the headspace gas sample is considerably diluted by the carrier gas. This problem can be solved by the injection of the headspace gas directly into the interior of the capillary column (on-column injection), using a purge-and-trap system with an adsorbent or using a static headspace (SH) sampler. Headspace sampling has progressively replaced techniques such as steam distillation or solvent extraction because it is the most suitable for studying high volatile compounds and because its composition represents better the aroma perceived by the consumer. The direct and accurate analysis of volatiles in coffee by SH (SH-GC) requires a careful standardization of instrumental parameters such as sample size, equilibration time and temperatures, and chromatographic conditions required for the separation of volatile compounds. As the injection procedure can be automated using a headspace sampler, errors associated with manual handling are removed.

Solid-phase microextraction has been extensively applied to the study of coffee aroma as a simple, rapid, solvent-free, and inexpensive method. The selection of fibers and optimization of both extraction and desorption parameters are necessary. Polydimethylsiloxane (PDMS)/divinylbenzene (DVB) coating had the highest overall sampling sensitivity, whereas carboxen (CAR)/PDMS was the most effective for small molecules and acids. In coffee, the DVB/CAR/PDMS fiber has been chosen because its three-component composition gives high recoveries for analytes with different structures and polarities.

The separation of volatile compounds is usually achieved by GC. The components eluting from the GC can be detected with an FID, although specific detectors, including the NPD and FPD, are also widely used for coffee volatiles, but MS is nowadays the most common detector used to identify and also to quantify (by total ionic current) coffee volatiles.

The change in the flavor profile from the ground coffee to the brew is caused by a change in the concentrations of these compounds and not by the formation of new odorants. The aroma of coffee is not stable; the fresh note is rapidly lost. Of the highly volatile odorants, methanethiol evaporates the fastest, followed by acetaldehyde.

CGA contributes to body and astringency; sucrose contributes to the color, aroma, bitterness, and sourness; proteins remain perfectly stable, but minor protein components, such as free amino acids, are highly reactive. Trigonelline generates pyridine and may consequently be responsible for some objectionable flavors. Caffeine has no function other than a contribution to the bitterness.

Coffee Brew

The brewing process is essential in brew composition, because the contact of water with roasted coffee grounds is the crucial step for the extraction of coffee compounds. Other factors, such as origin or variety of coffee beans, blending, roasting degree, and grinding, also play a key role in coffee brew composition.

Among the several brewing techniques, filter coffee (drip filter) is the most widely used coffee brew obtained by infusion method, whereas espresso coffee (EC) is the most appreciated coffee brew produced by pressure method. Moreover, in southern European countries such as Italy and Spain, the use of the mocha coffee maker is much extended at domestic level, and the plunger coffee maker is being used more often for coffee aroma lovers. In each case, the technical conditions applied, such as the coffee/water ratio, water temperature, and water pressure, also contribute to the different chemical compositions of coffee brews.

In drip filtration methods, water at 92–96 °C flows through a hardly compressed ground coffee bed, and the extract drips from the brewing chamber into the pot. Turbulence in the brewing chamber prevents water from becoming saturated. This method involves extracting water-soluble compounds, but most of the lipophilic fraction remains in the filter with the solid materials.

In pressure methods, water at approximately 9 bar and 88–92 °C is forced to go through coffee grounds compacted in a small brewing chamber (coffee cake). Rapid brewing time and fine particle size are necessary. In this case, the composition and quality of the brew also depend on the water pressure.

Usually, the extraction of water-soluble components including CGAs, caffeine, nicotinic acid, trigonelline, soluble melanoidins, and hydrophilic volatile compounds is greater at higher temperature and pressure. Galactomannans and arabinogalactans are the predominant polysaccharides that pass into the brew.

Caffeine is the single most frequently determined compound in coffee products, and the methods applied to its analysis have changed dramatically over the last 25 years. Caffeine absorbs strongly in the ultraviolet region (272 nm in water and 276 nm in chloroform), and this provides the basis of countless spectrophotometric methods. At present, chromatographic methods, and mainly reversed-phase HPLC, provide the most reliable way to quantify caffeine in coffee products. A simple aqueous extraction produces very complex extracts, which cannot be directly used. A similar chloroform extract is significantly cleaner but still contains interfering compounds that absorb at 276 nm. The level of these interfering components may be reduced by simple clarification with lead acetate and filtration to remove polymeric materials in samples, solution cleanup with a C18 Sep-Pak cartridge, and the column chromatography. In many cases, the chromatographic conditions allow the simultaneous determination of trigonelline and caffeine. A smaller number of papers have described alternative liquid chromatographic techniques, for example, ion-exchange and even gel-filtration.

The most abundant *phenolic compounds* of coffee are CGAs. The main hydrophilic antioxidant compounds in coffee are 3-, 4-, and 5-monocaffeoylquinic acids and 3,4-, 3,5-, and 4,5-diCQAs. Also, little amounts of caffeic acid, ferulic acid, *p*-coumaric acid, 4-hydroxybenzoic acid, and sinapic acid can be found in coffee. Traditionally, the Folin–Ciocalteu colorimetric method has been used to routinely measure the total phenolic compounds. Although this is the most popular method to evaluate the total phenolic compounds, the Folin–Ciocalteu reagent can be reduced by many electron donors, not only phenolic compounds. Furthermore, to identify and quantify single phenolic compounds is necessary to apply HPLC analysis. Detection of phenolic compounds is usually recorded at 325 nm. Quantification of 5-caffeoylquinic acid (5-CQA) is made by comparing the peak area with that of the standard. Because of the lack of commercial standards, in many cases, quantification of the other caffeoylquinic acids (and other CGAs) is performed using the area of 5-CQA standard combined with the molar extinction coefficients of the respective CQA. Also, in recent years, MS has become the most suitable method to identify and quantify phenolic acids.

The *lipid fraction* (not water-soluble) of coffee is partially extracted due to the high temperature of the water and is present in the brew as an emulsion. However, oil particles are likely to be retained in filters made of paper or similar types of materials. The high pressure used to make espresso and the absence of a filter made of paper, or another lipophilic material to retain the lipids, facilitate their extraction into the brew. Thus, unfiltered coffee and EC brews contain higher amounts of these compounds, including bioactive diterpenes and sterols. The emulsified lipid fraction can be determined by liquid–liquid solvent extraction with, for example, trichloromethane. Total lipids are quantified by weight after evaporation of the solvent. Different amounts have been reported in both espresso and non-EC beverages. For an EC prepared with a 100% arabica coffee, ~5% of the total solids may be considered as typical. Within the unsaponifiable fraction of coffee lipids, two compounds belonging to the diterpene family – cafestol and kahweol – are of relevance to blood cholesterol level; present in roasted arabica beans at levels around 0.6%, they are transferred to the espresso brew in small amounts.

Browned compounds are quantified by measuring the absorbance of the sample at 420 nm after exactly 1 min with a spectrophotometer connected to a thermostatically controlled chamber (25 °C).

Caffeine and the quinic acid lactones are the main bitter substances in the coffee brew. Also, acidity of coffee beverages is an important organoleptic parameter. The presence of acetic, formic, malic, citric, and lactic acids has been detected in the brew, along with quinic acid and CGAs. The content of the last ones is of course smaller when using dark roasted coffee, in which they have largely disappeared. A mineral acid – phosphoric acid – has also been found in brews, deriving from the thermal degradation of phytic acid, the phosphoric acid ester of inositol. Coffee brew acidity cannot be described just by the pH. The measurement of this variable, obtained using electrode-type instruments, reports values ranging from 4.8 to 5.8 (optimum 4.9–5.2), showing an increase with roasting degree and depending on extraction time.

EC is an increasingly popular drink. By definition, EC is a "polyphasic beverage prepared from roast and ground coffee and water alone, constituted by a foam layer of small bubbles with a particular tiger-tail pattern, on top of an emulsion of microscopic oil droplets in an aqueous solution of sugars, acids, protein-like material and caffeine, with dispersed gas bubbles and solids." These characteristics of EC are responsible for their peculiar sensorial properties. A fine EC should have a great amount of persistent, consistent, and hazelnut foam with 'tiger-skin' effect, a bitter/acid balance taste, and a strong body. A good EC cup could be prepared from approximately 7.5 g of finely ground roasted coffee for a volume of 40 ml of water at 9 atm of pressure and 96 °C temperature.

The quality of a good cup of EC is initially evaluated by the quality of its foam. The *foam index* is defined as the ratio, in percentage, of EC foam and liquid volumes measured immediately after the extraction of EC using a 100 ml graduated cylinder. The *persistence of foam* is defined as the time (in minutes) that the liquid phase below the cream layer took to appear during cooling at room temperature. Foamability seems to be influenced by a protein fraction, while foam persistency depends more on a polysaccharide fraction.

Density is little influenced by coffee solids. Differences with respect to pure water are limited to the second decimal digit; this could be explained by the presence of coffee lipids dispersed as an emulsion, which are less dense than water and decrease the overall density. The addition of sugar can raise density to around 1.08 g ml^{-1}. *Viscosity* is influenced by the presence of dispersed phases, related to the amount of lipid droplets in emulsion. Increased viscosity has been associated

with improved body. *Surface tension* is a property of interface, due to the tendency of molecules to diffuse from one material to another: pure water–air interfaces.

The brewing method may influence the hydrolytic degradation of insoluble carbohydrate polymers, adding to the soluble content. Total solids content is the most important characteristic in the chemical composition of EC, often perceived by consumers as 'strength'; a typical figure for soluble carbohydrates is 8 g l^{-1}, corresponding to around 15% of total solids. The *total solids* are determined by oven-drying 40 ml of EC to a constant weight (14 h, 102 ± 3 °C) without filtering. Accordingly, suspended solid materials, emulsified lipids, and solutes are included. The *extraction* is defined as the percentage of total solids with respect to ground roasted coffee dose (7.5 g). The *concentration* is defined as the percentage of total solids with respect to the EC volume (40 ml). The *total solids on filtrate* are determined by oven-drying 40 ml of EC after filtering with Whatman 1 to a constant weight (14 h, 102 ± 3 °C). The true soluble fraction, typically 90% of the total solids, can be determined by oven-drying after filtering the liquid.

Antioxidant capacity. During very intense heat treatments, such as the roasting of coffee, the loss of antioxidant activity of natural antioxidants – mainly represented by polyphenols – by progressive thermal degradation has been found to be minimized by the formation of MRPs. The antioxidant activity of coffee can be measured using different methods. Colorimetric reactions are developed to evaluate the ability of a food compound or product to quench and/or reduce radicals or metals using DPPH, or ABTS radicals, or the FRAP assay, respectively. The antioxidant capacity is usually compared with that of a very well-known antioxidant, such as vitamin E, using Trolox (a water-soluble vitamin E analog). For this reason, these methodologies are usually called Trolox equivalent antioxidant capacity (TEAC) assays. These colorimetric methodologies are currently the most widespread, but all of them are based on similar electron transfer redox reactions and evaluate more than phenolic compounds. Other methodologies like the electron spin resonance spectroscopy have been proposed as much more specific techniques, capable of distinguishing the contribution of phenolic and nonphenolic antioxidants in coffee by means of different stabilized radicals such as Frémy's salt and TEMPO. The basis is the absorption of microwave energy by unpaired electrons, such as those of free radicals, when they are in a magnetic field. Mainly, phenolic compounds can be detected when Frémy's salt is used as the stabilized radical, whereas TEMPO is mainly scavenged by MRPs, such as melanoidins.

ABTS: 2,2´-Azino-bis(3-ethylbenzothiazoline-6-sulfonic acid) diammonium salt. DPPH: Potassium persulfate, 2,2-diphenyl-1-picrylhydrazyl. Trolox: 6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid. Frémy's salt: Dipotassium hydrogen phosphate, potassium dihydrogen phosphate, sodium chloride, Frémy's salt (potassium nitrosodisulfonate). TEMPO: 2,2,2,2-Tetramethyl-1-piperidine-1-oxyl.

Coffee: Decaffeination

AS Franca, DEMEC/Universidade Federal de Minas Gerais, Belo Horizonte, Brazil

© 2016 Elsevier Ltd. All rights reserved.

Introduction

The term coffee is mostly employed in association with the consumable beverage obtained by extracting roasted coffee with hot water, but it actually comprises a wide range of intermediate products, starting from the freshly harvested fruit (coffee cherries), then to green and roasted coffee beans, to the final product of consumption, the beverage itself. Decaffeinated coffee is defined as 'coffee from which caffeine has been extracted' and, as a commercially available product, corresponds to roasted and ground coffee. The decaffeination process is usually performed on coffee beans prior to roasting (green coffee beans).

Background

Caffeine (1,3,7-trimethylxanthine) is an alkaloid that occurs naturally in coffee, cocoa beans, kola nuts, and tea leaves. It is the most widely consumed and studied psychoactive substance in history, but the general conclusions on its effects on human health are still controversial. Increased alertness and learning capacity and better exercise performance have been cited as some of the positive effects of low to moderate caffeine intake. While some studies have associated caffeine intake with high blood cholesterol, coronary diseases, and cancer, others suggest that its consumption may lower the incidence of suicide and hepatic cirrhosis. Nonetheless, excessive caffeine intake has been associated with a wide variety of health problems, including aggravated heartburn and acid indigestion, anxiety, tachycardia, insomnia, and accelerated osteoporosis. It has also been reported to cause mutation, inhibition of DNA repairs, adrenal stimulation, cardiac arrhythmias, and increased heart output. In light of some deleterious effects and the general controversy around this specific compound, a great deal of effort has been devoted to providing caffeine-free beverages, especially coffee.

Roasted coffee beans contain ~1–2% of caffeine by weight. The decaffeination process removes up to 97% of the caffeine, so that a cup (150 ml) of decaffeinated coffee contains from 1 to 5 mg of caffeine, as opposed to 60–180 mg for the same cup with regular coffee.

It should be kept in mind that coffee is a complex mixture of chemical compounds, and, although earlier studies on the effects of coffee on health have been mostly associated with caffeine consumption, it should be emphasized that this compound is just one of the several bioactive substances that are present in coffee. Unfiltered coffee is a significant source of cafestol and kahweol, and such diterpenes have been implicated in the cholesterol-raising effects of coffee. Some results of epidemiological research indicate that coffee consumption may help prevent several chronic diseases, including type 2 diabetes, Parkinson's disease, and liver disease. Overall, there are little evidence of health risks and some evidence of health benefits for adults consuming moderate amounts of coffee (3–4 cups per day).

Decaffeination Procedures

In the production of coffee, green beans are roasted to generate the coffee soluble solids and volatiles that impart flavor to the brewed beverage. In order to avoid coextraction of aroma components in the decaffeination process, green beans are generally extracted. The conventional methods employed for coffee decaffeination are organic solvent extraction, water decaffeination, and supercritical carbon dioxide extraction. A schematic overview of these procedures is displayed in Figure 1, and a more detailed discussion on each specific procedure is presented as follows.

Solvent Decaffeination

The original processes employed for coffee decaffeination were based on solvent extraction from the green coffee beans. Solvent extraction relies on the solubility of caffeine in various organic solvents including acetone, benzene, ethyl acetate, ethyl alcohol, ethyl ether, and methylene chloride. It can be accomplished either by direct solvent extraction of the beans or indirectly, employing water extraction of the beans, followed by solvent extraction of the caffeine from the water extract.

The first commercial process was developed in Germany (1905), established by the firm Kaffee HAG. Chlorinated compounds were the first caffeine extractants used in this process. Trichloroethylene was commonly employed as the solvent of choice until it became the subject of US Food and Drug Administration investigations and was eliminated in 1977, because of its suspected carcinogenicity, and then replaced by methylene chloride. A wide variety of solvents have been tested over the years, with dichloromethane (DCM) and ethyl acetate being the most employed up to date. DCM has also been recently tested as a caffeine extractor for coffee bean waste, that is, spent coffee grounds. DCM is not selective as other solvents, including methanol and water, although in this specific application, the coffee was roasted as opposed to the green beans used in the traditional processes. Also, caffeine levels will be much lower in this type of waste because most of the caffeine will be transferred to the beverage, given its high solubility in water at elevated temperatures (>90 °C).

The conventional decaffeination process can be divided into four major steps: (1) steaming the beans, (2) extracting caffeine with an organic solvent, (3) driving off the solvent by steam to a tolerable level, and (4) drying the coffee beans. It was early determined that direct organic solvent extraction was either not very effective or rather slow, regardless of the high solubility of pure caffeine in the specific solvent employed. In order to improve extraction and expedite caffeine removal,

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00183-5

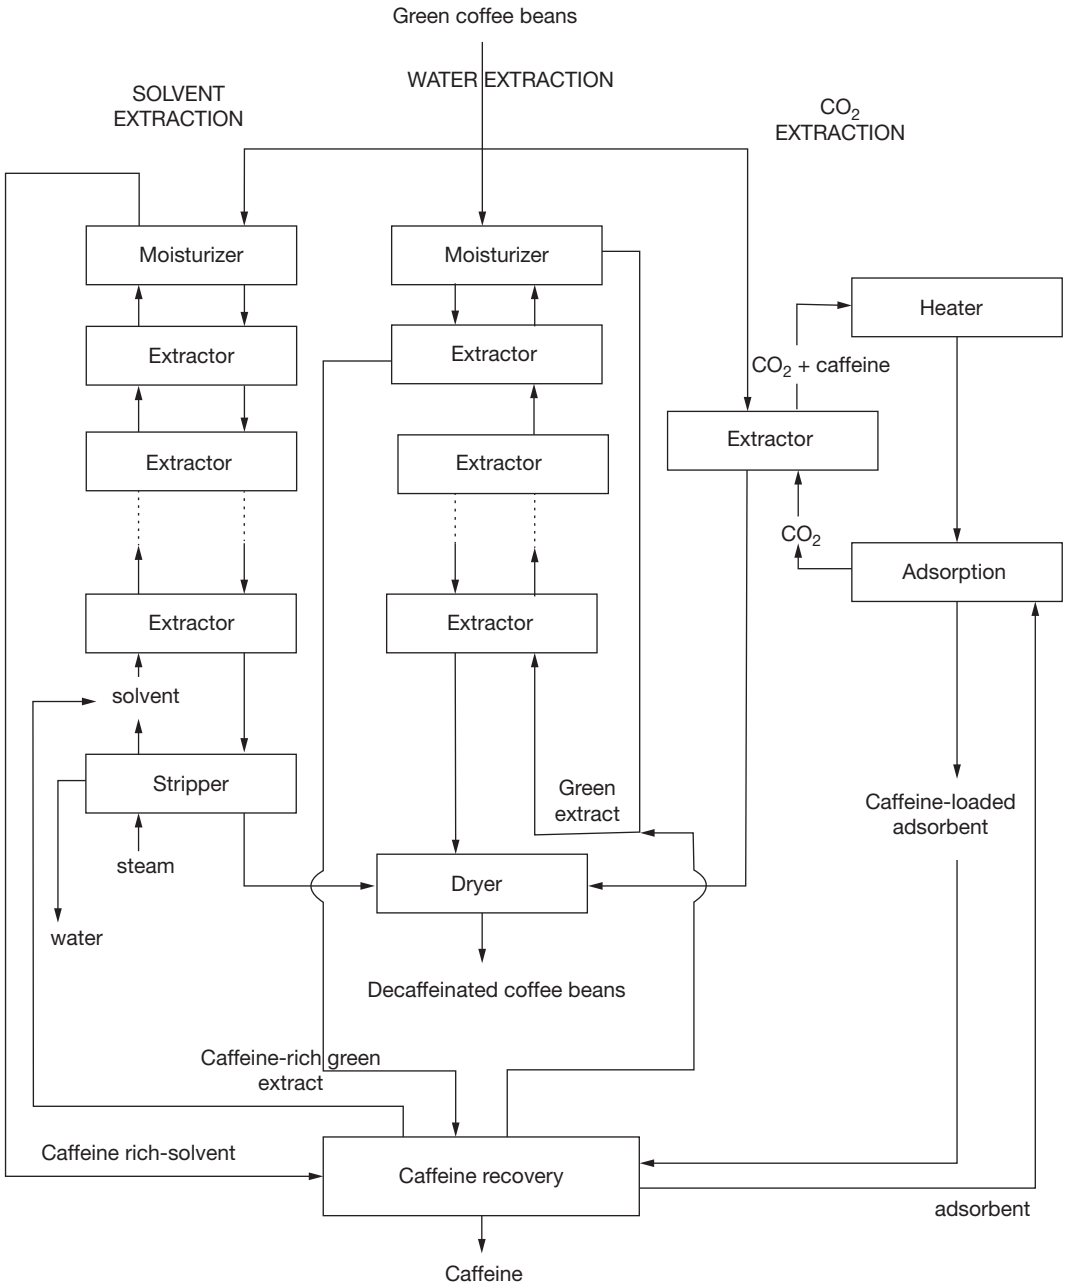

Figure 1 Schematic overview of conventional decaffeination processes.

coffee beans are thus steamed. This will promote swelling of the beans and improve solvent permeability and also break down caffeine complexes. A process patented in 1939 suggested that the coffee beans should be first contacted with water (20 °C) for approximately 1 h prior to steaming. This immersion of the beans is intended to wet the outside surface of the beans and also provides a so-called surface absorption of water, since the water content is raised from 10% to 22%, approximately. Other processes suggested a wetting step after steaming in order to raise the moisture content of the beans up to 40%.

The extraction itself is carried out in a battery of several fixed bed columns with the solvent, at temperatures ranging from 25 to 120 °C, being contacted countercurrently with the bed of beans, for a period of up to 10 h. The column that contains the coffee beans with the lowest caffeine content is separated and solvent-drained. It is then steam-stripped in order to remove all the residual solvent. The decaffeinated coffee beans are then discharged and dried prior to storage. The caffeine-rich solvent that exits the first column of the batch is sent to a caffeine recovery stage, and the resulting caffeine-free solvent is returned to the process. See Figure 1 for a schematic view of the process.

There are some studies introducing modifications over the basic solvent extraction procedure. The extraction time can be reduced down to 3 h by employing a solvent in turbulent flow.

The step of moisturizing the coffee beans can be skipped when dimethyl sulfoxide is employed as a solvent. However, other compounds including sugars are also dissolved, and thus, their concentration must be kept near their saturation point. Some experiments indicate that mixing a suspension of caffeic acid crystals in water with methylene chloride or ethyl acetate provides a significant increase in extraction capacity. A caffeine–caffeic acid complex is rapidly crystallized at room temperature, and the extent of decaffeination is much higher in comparison with the same solvents mixed with water. A patent from 1988 (General Foods Corporation, the United States) proposed that contacting any type of caffeine-containing extract solution with caffeic acid should result in an insoluble caffeine–caffeic acid complex. Several types of extracts/solvents (oil, water, and organic) were tested, employing both green and roasted coffees.

Water Decaffeination

In 1941, a process that aimed at the removal of caffeine from coffee employing the universal 'green' solvent was devised. The so-called water decaffeination (Swiss Water process) consists basically of replacing the commonly employed organic solvents by water, taking advantage of the temperature-dependent solubility of caffeine in such nontoxic solvent. However, there are other water-soluble constituents that should not be extracted in order to maintain flavor qualities. Therefore, in order to prevent their extraction, the extracting water must contain equilibrium quantities of these solubles, with little or no caffeine. Claimed advantages of this process over solvent decaffeination include increased extraction rates, elimination of the solvent stripping system, purer extracted caffeine, and elimination of undesirable compounds extracted by the organic solvents. Also, the pre-steaming and pre-wetting steps are eliminated. The extraction process itself is similar to the one employed for solvent decaffeination, with a battery of columns containing the green beans being contacted countercurrently with the water extract (containing up to 15% green coffee water solubles), for a period of up to 8 h (see Figure 1). The decaffeinated beans are washed with water and air-dried. The wash water is mixed with the caffeine-free water extract in order to maintain the required equilibrium composition of noncaffeine solubles. The caffeine-rich extract is also recycled after caffeine removal. Caffeine recovery is performed by either solvent extraction or adsorption by activated carbon.

CO_2 Decaffeination

The use of supercritical CO_2 extraction for coffee decaffeination started in Germany in 1970. The major advantage of this method is the use of an inert gas as solvent, while the disadvantages are the costly high-pressure equipment and batch processing. The process is usually carried out at pressures ranging from 180 to 300 bars and temperatures of 40–90 °C. Initially, the coffee beans are brought to a moisture content of up to 50% (by wetting, steaming, or both) as in the case of solvent extraction. The beans are then loaded into the extraction vessel, while a solid adsorbent (activated carbon) is loaded into the adsorption vessel. As the CO_2 is circulated through the vessels, caffeine is extracted from the beans and retained by the activated carbon (see Figure 1). The extracted caffeine may also be removed from the supercritical fluid by reducing pressure, thereby decreasing its solubility, or by passing the CO_2 into a washing tower, where the caffeine is absorbed by the water. An alternate of the method represented in Figure 1 consists in placing both the green coffee beans and activated carbon into a pressure vessel, being contacted with CO_2 at 220 bar and 90 °C. The coffee beans are separated from the granular activated carbon by a vibrating sieve. Decaffeinated beans are then dried down to 10% moisture as in the other types of decaffeination procedures.

There are several patents introducing a few modifications and variations over these methods. If a decaffeination rate of over 97% is required, the caffeine/CO_2 mixture can be passed first through a washing tower and then through a column containing the activated carbon. The use of supercritical nitrous oxide has been proposed as a replacement for CO_2, given its higher solvent power under similar pressure and temperature conditions. The use of a CO_2-saturated caffeine-free green coffee extract has also been proposed. After contacting the beans for several hours at high pressures (up to 300 bar) and temperatures (up to 100 °C), there is a rapid drop in pressure, and the beans are washed with the liquid for up to 2 h. The CO_2-saturated caffeine-containing green coffee extract is then decaffeinated with supercritical CO_2 (the caffeine is separated from the CO_2 in a water absorption tower). Other proposed modifications include (i) elimination of the pre-wetting step by employing a varying temperature profile during extraction, (ii) acidification of the beans during the pre-wetting step in order to compensate for acidity losses, and (iii) replacement of the activated carbon by ion exchangers or zeolites. A recent study proposed simultaneous extraction of caffeine and chlorogenic acids from coffee beans by employing both water and supercritical CO_2 flowing countercurrently through the extractor filled with the beans. The nonpolar recovery section height was varied (increased) by adding glass beads to the bottom of the extractor. It was observed that caffeine recovery in the supercritical CO_2 increased with increasing height of the nonpolar recovery section, because it allowed caffeine already dissolved in the water phase to be transferred to the supercritical CO_2 phase.

Although the majority of CO_2 decaffeination processes employ supercritical conditions in order to obtain satisfactory extraction, there is a patent from 1989 (Hermstein & Still, Germany) that proposes the use of liquid CO_2. Moisturized green beans (45–55% moisture) are contacted with water-saturated CO_2 at relatively lower pressures (65–70 bar) in comparison with supercritical extraction. Extraction time is quite high, 60 h, but it is claimed that the flavor quality of the decaffeinated coffee is very good. Caffeine is recovered by decompression of the CO_2–caffeine mixture.

Roasted Coffee Decaffeination

The major drawback of applying the aforementioned methods directly to roasted coffee is the simultaneous extraction of volatiles and aroma components. Nonetheless, a few procedures have been proposed. A patent from 1984 (from Kaffee HAG) described the application of supercritical CO_2 decaffeination to roasted coffee. Extraction takes place in two steps, the

first employing dry CO_2 to extract aroma components and then employing CO_2 to remove the caffeine itself from wetted roasted coffee. Afterward, the water-soluble components are extracted from the decaffeinated coffee and mixed with the aroma-containing CO_2. The resulting extract can then be freeze-dried to produce decaffeinated instant coffee. A few years later, the same company proposed a procedure employing liquid CO_2 to remove caffeine from roasted and ground coffee with minimal extraction of aroma volatiles. Moistened roasted coffee is placed in a pressure vessel connected in a closed cycle with another pressure vessel filled with a strong acid ion exchanger that is selective for adsorption of caffeine. Extraction takes about 2–3 h in a closed system and the CO_2 is kept at low temperatures (15–30 °C). The small amount of roasted coffee components that are absorbed by the CO_2 can be separated by CO_2 evaporation and returned to the roasted coffee. It is claimed that the flavor of the decaffeinated roasted coffee obtained by this procedure is similar to regular roasted coffee.

Other Developments

Water-immiscible oils or fatty materials have also been proposed as extractants for decaffeination processes. Examples include sunflower, soybean, corn, peanut, and coffee oils. The procedure consists basically of the conventional multistage countercurrent extraction, with the coffee beans previously moistened (40–60% water content). Caffeine extraction is carried out at temperatures ranging from 90 to 120 °C. The oil is separated from the green beans by steaming and regenerated by liquid–liquid water extraction. This type of caffeine extractant can also be employed for caffeine removal from the caffeine-rich green extract obtained during water extraction.

Other 'green' solvents have been recently evaluated as alternatives for caffeine removal. A recent study showed the potential of ethyl lactate (ethyl 2-hydroxypropanoate) for such purpose. Accelerated solvent extraction was employed at temperatures ranging from 100 to 150 °C and 10 min extraction time. The recovery of caffeine was in the range of 50–90%. Further studies are mentioned aiming at the use of supercritical CO_2 with ethyl lactate as a cosolvent.

Caffeine Recovery

Large amounts of caffeine are required for addition to beverages and for pharmaceutical uses. Market needs are met either by recovering and refining caffeine from the decaffeination of coffee or via synthetic route. Caffeine removed from coffee decaffeination processes is usually obtained from a caffeine-rich solvent mixture, either an organic solvent or water, or from a caffeine-loaded adsorbent. Caffeine mixed with a volatile solvent can be recovered by solvent evaporation or distillation. If the solvent presents a high boiling point, a countercurrent water liquid–liquid extraction system can be employed. Removal of caffeine from the water–caffeine mixture coming from either this type of process or water decaffeination can be accomplished by (a) liquid–liquid extraction with a volatile solvent (that will be later evaporated) or (b) adsorption by an activated carbon. As previously mentioned, caffeine recovery from processes employing supercritical CO_2 is also based on adsorption.

Recovery of caffeine from the saturated adsorbent can be performed in several ways. The most common procedure is contacting the caffeine-loaded adsorbent with a chemical agent that will provide desorption, usually an acidic solution. Employed acids include acetic, formic, benzoic, citric, dichloroacetic, and lactic, either pure or combined. Other desorption agents include organic solvents such as methyl ethyl ketone, ethyl acetate, and dichloromethane. Caffeine can then be recovered from the resulting solution by employing several methods such as solvent evaporation or distillation, membrane separation, and crystallization. Both water and CO_2-based decaffeination procedures claim the major advantage of employing 'green' solvents. Naturally, such advantage can no longer be claimed if the previously mentioned solvent-based caffeine recovery systems are also employed. Thus, some solvent-free processes have also been devised. In a process developed by Kaffee HAG, in 1985, desorption is accomplished by treating the caffeine-loaded activated carbon with hot pressurized water (300 °C and 90–200 bar) for 1–3 h. The activated carbon is then ready to be reused in the decaffeination process without further treatment. As the adsorption capacity decreases slightly after each cycle of use, the activated carbon must be eventually reactivated at high temperatures. The caffeine is recovered from the aqueous solution by membrane separation or evaporation.

The so-called 'direct caffeine desorption' process, based on two patents from HAG (1986 and 1994), also avoids the use of solvents in caffeine recovery. The caffeine-loaded adsorbent is processed in a three-stage fluidized bed reactor. In the first (upper) stage, caffeine desorption takes place by contacting the adsorbent with an inert gas from combustion (oxygen-depleted) at 360 °C. In the second (middle) stage, nondesorbed caffeine and inorganic impurities are decomposed at a higher temperature. In the third (lower) stage, the activated carbon is regenerated by the gas entering the reactor at 800 °C. The adsorbent is then water-quenched and returned to the decaffeination plant. The caffeine-saturated gas stream is treated in a scrubber system, in which the caffeine is absorbed by water and later crystallized.

Future Trends

There are a few available reports on attempts to produce genetically decaffeinated coffee beans. Transgenic coffee plants with suppressed caffeine synthesis using RNA interference (RNAi) technology have been obtained. Overall, it was concluded that RNAi seemed to confer a global effect on expression of several relevant genes, indicating that reduction of caffeine levels was not due to the suppression of a single enzyme but instead attributed to a disturbance of the whole biosynthetic pathway. It was also concluded that theobromine is the major intermediate in caffeine biosynthesis. Both theobromine and caffeine contents of the plants were reduced by up to 70%, indicating that it should be feasible to produce coffee beans that are intrinsically deficient in caffeine. However, given that caffeine offers protection to young leaves and fruits from predators like larvae and also avoids competition by preventing the growth of neighboring plant species, producing decaffeinated plants through genetic manipulation still presents a few challenges.

Recent innovations in food technologies have led to the use of traditional technologies, such as fermentation and enzyme technology, to produce new health food ingredients, reduce or remove undesirable food components, add specific nutrients or functional ingredients, modify food compositions, mask undesirable flavors, or stabilize ingredients. With that in mind, understanding the mechanisms involved in the degradation of caffeine by either microorganisms or enzymes can help in the development of a bio-based process for caffeine removal.

Bacterial strains found capable of degrading caffeine belonged to *Pseudomonas* and *Serratia* genera, and there is an indication that they can be used for reduction of the caffeine content in bearing plants. A method has been proposed for producing tea leaves with less caffeine content by growing caffeine-degrading bacteria on the surface of the leaf, but no studies on coffee have been reported. Many of the available studies on caffeine degradation by biological action means have focussed on lowering the caffeine content of coffee pulp and husks (residues generated during the wet and dry processing of coffee, respectively) so they can be employed as a supplement for animal feed. A few have focussed on the use of these residues as fermentation substrates for the production of value-added chemicals, and caffeine degradation was merely a consequence of microorganisms' growth. Anaerobic fermentation of coffee pulp resulted in about 13–63% reduction of caffeine in 100 days, whereas aerobic fermentation resulted in 100% degradation of caffeine in 14 days. Bioremediation of coffee pulp and husks to reduce the caffeine content has been mostly studied in fungal systems. Among the microbial communities present in coffee pulp, only a few species like *Aspergillus*, *Penicillium*, and *Rhizopus* were found capable of degrading caffeine. *Aspergillus* and *Penicillium* species degraded caffeine almost with 100% efficiency at 25 °C, whereas the efficiency of degradation decreased to 30% at 30 °C. An effective method has been reported using coffee pulp and husks as substrates for the growth of molds. Caffeine was degraded during the growth of *Lentinus edodes*, whereas caffeine was accumulated in the fruiting bodies of *Pleurotus* sp. Thus, *Pleurotus* sp. could be used to recover caffeine from coffee.

Though the search for a caffeine-degrading microorganism began over 40 years ago, studies in this research area are still needed. The degradation pathway in fungi is still not clearly known. Even in microbial systems, studies have to be performed to ensure that toxic metabolites are not formed by the strain during its growth. More microorganisms that could degrade caffeine need to be isolated. Also, studies employing coffee beans or plants as growth substrates have yet to be conducted. Biological detoxification of coffee pulp by solid-state fermentation using fungi seems promising. However, the initial caffeine concentration and external nitrogen concentration are very crucial for caffeine degradation to be effective. Though the enzymes involved in the degradation of caffeine are known, *in vitro* enzymatic studies for caffeine degradation are not yet available. Also, such enzymes are not very stable, and thus, more studies on enzyme stability and biochemical characterization are required. Such enzymes could be purified and immobilized in a bioreactor, so their caffeine-degrading ability could be studied and optimized. In time, such studies can lead to the development of a biological process for caffeine degradation.

Introduction

Beverages are an important component of our diet. Coffee occupies an important place among beverages, since it holds the second position in consumption after water. On average, people consume 500 billion cups of coffee annually, with a global production of 8 million tons per year. The major consumers are the United States, Brazil, Europe, and Japan.

Coffee (*Coffea* L.) is considered as a valuable and enjoyable beverage, and often, it is consumed due to its stimulatory effects, mainly related to the presence of caffeine (1,3,7-trimethylxanthine): generally, 240 ml of instant coffee contains approximately 100 mg of caffeine. Caffeine content can be, however, influenced by the different technologies used. For instance, green bean dewaxing and wet processing can reduce its content, which remains in the range of 0.65–2.30%.

In addition to caffeine, coffee contains more than a thousand different chemicals, including carbohydrates, lipids, nitrogenous compounds, vitamins, minerals, alkaloids, and phenolic compounds. Some of them, such as trigonelline, nicotinic acid, chlorogenic acid (5-*O*-caffeoylquinic acid, CQA), melanoidins, and diterpenes (cafestol and kahweol), together with caffeine feature relevant nutritional or functional properties.

The coffee fruit (also called berry or cherry) is an oval drupe of about 10 mm in size. Coffee beans present an outer skin called pericarp, which is green in unripe and red-violet, deep red, yellow, or orange, depending on the cultivar, in ripe fruits. The pericarp covers the mesocarp (the soft yellowish, fibrous, and sweet pulp), a pectin adhesive layer, which is a highly hydrated layer of mucilage, and the endocarp, called the parchment (Figure 1). Finally, a silverskin covers each hemisphere of the coffee bean (endosperm).

Many factors influence coffee quality, among which the action of microorganisms. Microbial metabolites produced during coffee fermentation can diffuse into the grains and influence the beverage's final quality. There are different kinds of coffee beverages, characterized by different nuances in terms of body, aroma, acidity, and astringency.

Coffee is a complex array of biologically active components that can influence many metabolic processes. The main components are alkaloids (caffeine and trigonelline), phenolic compounds (chlorogenic acids), and diterpenes (cafestol and kahweol) (Table 1).

The main mechanism of action of caffeine is to antagonize adenosine receptors (with its A1 and A2A subtypes); a secondary effect is the inhibition of phosphodiesterases, with the subsequent accumulation of cyclic adenosine monophosphate and an intensification of the effects of catecholamines. Coffee is metabolized in the liver by enzymes known as cytochrome P450 1A2 (CYP1A2). Caffeine effects translate, in most people, in a psychoactive response, which includes increased alertness and attention, through the stimulation of the central nervous system, and in a complex cardiovascular response, mainly consisting of an acute increase in blood pressure. Some benefits related to its consumption include mood enhancement, better exercise performance, and shorter reaction times. Caffeine also produces negative effects, such as sleeplessness, anxiety, restlessness, tension, nervousness, palpitations, tremulousness, and psychomotor agitation. Moreover, the risk of rheumatoid arthritis and osteoporosis increases when coffee is consumed on a regular basis. Some other negative effects can arise strictly related to some special risk groups: for such subjects, a reduced consumption of coffee is recommended (Table 2).

Cafestol and kahweol are also present in coffee. They can increase blood cholesterol and also feature some chemopreventive activity. The way of action of these compounds on lipoprotein metabolism is not completely understood. The only scientific evidence available is that they are absorbed intestinally. The positive association between coffee consumption and serum cholesterol has been observed mainly in Scandinavia and in the United States, where boiled coffee and filtered coffee are very popular. Therefore, the brewing method is probably critical to the cholesterol-raising effect of coffee. Also, French press (cafetière) coffee contains relatively high levels of cafestol and kahweol (6–12 mg/cup).

Genus	*Coffea*
Species	*Arabica; Canephora*

Figure 1 Coffee fruit structure and botanical classification of coffee plant.

Table 1 Main physiological actions of coffee components

Compound	*Molecular formula*	*Amount (mg/100 ml)*	*Physiological action*
Trigonelline		0.4–1.2 nicotinic acid	Antioxidant and antiinflammatory activities
Kahweol		0–0.1 (filtered coffee) 0.7–10 (boiled coffee)	Increased low density lipoprotein cholesterol and total cholesterol Free radical scavenging
Caffeine		30–54	Central nervous system stimulation Elevation of blood pressure Increased alertness Increased metabolic rate Decreased DNA degradation and reduced hydroxyl radicals Antioxidant properties
Chlorogenic acid (CGA)		35–175 CGA 17–87 caffeic acid	Antiinflammatory and antiangiogenic activities Antioxidant properties
Cafestol		0–0.1 (filtered coffee) 0.5–8 (boiled coffee)	Increased low density lipoprotein cholesterol and total cholesterol Free radical scavenging

Chlorogenic acids and caffeic acids are other important healthy components present in coffee. Chlorogenic acids are a family of esters formed between quinic and *trans*-cinnamic acids, which are an important group of dietary phenols. Caffeoylquinic acid (CQA) is the main compound among chlorogenic acids. The content of chlorogenic acids has been reported to range from 70 to 350 mg, which would provide about 35–175 mg of caffeic acid. These compounds show antioxidant activity *in vitro*. Probably, their action *in vivo* is reduced, because the metabolites deriving from their catabolism have lower antioxidant activity than the parent compounds.

Finally, coffee contains some micronutrients, such as magnesium, potassium, niacin, and vitamin E, which may contribute to the health effects of coffee consumption.

Antioxidant and Antibacterial Properties of Coffee

Lifestyle factors play a key role in human health. Traditional diets rich in bioactive components are associated with a lower risk of different illnesses; for example, the consumption of antioxidants or antioxidant-rich foods induces a lower risk of cancer (colorectal, hepatic, renal, ovarian, pancreatic, esophageal, endometrial, and pharyngeal cancers), as demonstrated by several meta-analyses.

Coffee is known as a dietary source of antioxidants and free radical scavengers, such as caffeine, hydroxycinnamic acids (caffeic, chlorogenic, coumaric, ferulic, and sinapic acids), Maillard reaction products, and melanoidins. Compared to other beverages, coffee stands out for its antioxidant potential; some authors reported levels of phenolic compounds in several beverages,

Table 2 Main groups subjected to caffeine's adverse effects and safe limits

Groups	*Risks*	*Limit (mg day^{-1})*
Women of childbearing age	*Conception*: High intakes of coffee or caffeine ranging from 400 to 800 mg day^{-1} are associated with delays in conception *Pregnancy complications*: Levels of at least 300 mg day^{-1} of caffeine increase the risk of spontaneous abortion. This association could be explained by the relationship between nausea and fetal viability *Fetal growth*: Caffeine intakes ranging from 200 to 400 mg day^{-1} induce a decrease in mean birth weight of about 100 g. Mothers of small for gestational age (SGA) infants had higher caffeine intakes in the third trimester of pregnancy than mothers of non-SGA infants *Lactation*: High maternal caffeine intakes cause irritability and poor sleeping patterns in infants	300
Children	Caffeine doses higher than 3 mg kg^{-1} of body weight can result in some behavioral effects (nervousness, anxiety, and sleep disturbances)	45 for 4–6 years old, 62.5 for 7–9 years old, and 85 for 10–12 years old
Older adults	Higher plasma caffeine concentrations could increase the risk of drug interactions and fracture risk, particularly in the presence of calcium and vitamin D insufficiency	400

drinks, and infusions in concentrations ranging from 0.07 to 4.16 mg l^{-1} in the following order: black tea > instant coffee > coke > red wine > violet carrot juice > apricot nectar > Turkish coffee > white wine. Coffee components exhibit some degree of antioxidant activity, so that coffee has the potential of reducing inflammation by decreasing oxidative stress.

Coffee antioxidant potential is associated with the presence of both natural compounds and substances developed during roasting. The temperature and time of the roasting process can impact on total antioxidant activity. Melanoidins, which are high-molecular-weight nitrogenous and brown-colored compounds, are formed during the roasting process. They show antioxidant, antimicrobial, anticariogenic, anti-inflammatory, antihypertensive, and antiglycative activities. Melanoidins from coffee showed higher antioxidant activity than those isolated from other sources, such as beer. All types of coffee preparations (filter, espresso, and Italian style) show antioxidant capacity, since all are effective free radical scavengers. Decaffeinated coffee has lower antioxidant capacity than regular coffee. The antioxidant capacity is about 6–7% after each 200 ml of coffee consumption, resulting in a reduction of inflammation through the reduction of free radicals and other reactive oxygen species.

Roasted coffee extract also features activity against some microorganisms, such as *Staphylococcus aureus* and *Streptococcus mutans* and several species/strains of Enterobacteriaceae (*Serratia marcescens*, *Enterobacter cloacae*, and *Salmonella enterica*). This activity is related to some coffee characteristic components, such as caffeic acid, trigonelline, caffeine, chlorogenic acid, and protocatechuic acid, all melanoidins with well-known natural antimicrobial activity.

Cardiovascular Effects of Coffee

The effects of coffee on the cardiovascular system are largely debated because the underlying mechanisms are complex and because of the considerable variability in individual responses. Many effects of coffee on the cardiovascular system have been attributed to caffeine, although coffee contains hundreds of chemical substances, many of which, such as polyphenols, are pharmacologically active.

Several epidemiological studies have examined the association between coffee consumption and the risk of coronary heart disease, but the findings have been equivocal. Experimental data from short-term and animal studies have suggested detrimental effects of caffeine on blood pressure, insulin resistance, and arrhythmia and have implicated coffee as a potential cardiovascular risk factor. Moreover, cross-sectional studies have shown an association between coffee and plasma cholesterol concentrations. Additionally, evidence from case–control studies has suggested that coffee consumption is associated with a higher risk of cardiovascular disease.

On the other hand, prospective cohort studies generally have not supported the existence of an association between coffee consumption and a higher risk of cardiovascular diseases, indicating that for most healthy people, moderate coffee consumption is unlikely to adversely affect cardiovascular health. Furthermore, several studies have suggested that also for patients with established coronary heart disease, it is safe to continue their habitual coffee consumption. A randomized clinical trial involving patients with acute ST segment elevation myocardial infarction (MI) has evaluated the effects of an acute ingestion of coffee on the autonomic function and cardiovascular health. Coffee ingestion was associated with an increase in parasympathetic tone, and coffee did not increase cardiac arrhythmia. The authors concluded that coffee ingestion is safe and not associated with adverse cardiovascular outcomes in postmyocardial infarction patients.

The relation between coffee consumption and the risk of arrhythmias has also been investigated. Although early animal studies indicated that coffee appeared to cause arrhythmias in a canine model, more recent studies have suggested that coffee does not increase arrhythmias. Actually, long-term coffee drinking might reduce the risk of abnormal cardiac rhythms, including atrial fibrillation.

Controlled interventional studies have shown that in normal adults, even acute high-dose caffeine did not affect cardiac

rhythm and rate and did not cause clinically significant ventricular or supraventricular arrhythmias. Moreover, prospective cohort studies did not find significant association between coffee consumption and the risk of atrial fibrillation. Mechanisms involved in this potential protection against arrhythmias are still largely unknown, but it has been hypothesized that caffeine attenuates negative effects of endogenous adenosine on cardiac electrical conduction.

The cardiovascular risk factor more extensively studied in relation to coffee is blood pressure: an elevated blood pressure is a risk factor for coronary heart disease, congestive heart failure, stroke, kidney disease, and all-cause mortality, and the relation between blood pressure and subsequent outcomes is direct and progressive throughout the usual range of blood pressure, including the nonhypertensive range. Therefore, even a small change in average blood pressure levels may have a major public health effect. Evidence that caffeine is an antagonist of adenosine receptors suggested the biological plausibility that coffee induces vasoconstriction and elevates systolic and diastolic blood pressure acutely. However, whether coffee consumption has chronic effects on blood pressure and cardiovascular disease is far from obvious and remains controversial. Dietary and other lifestyle factors play an important role in hypertension and blood pressure control: excess intake of salt or alcohol, suboptimal dietary pattern, physical inactivity, and excess body weight are here the most important factors. Coffee drinking might add as another dietary factor causing hypertension, but whether coffee intake per se is associated with detrimental long-term blood pressure changes or increases the risk of hypertension remains debated. A recent meta-analysis of 20 randomized, controlled trials and five cohort studies has shown no clinically important effects of long-term coffee consumption on blood pressure or the risk of hypertension in coffee consumers.

Various confounding factors may have influenced the equivocal results of different studies, including differences in the study design, populations examined (age, sex, usual frequency of coffee drinking, and smoking), types of coffee blend, and types of preparations used. Particularly, the design of epidemiological studies may affect findings about the relation between coffee and blood pressure or cardiovascular risk. Observational (cohort) studies usually have a large sample size and can provide insight into the long-term effects of different doses of coffee on blood pressure and possible changes in the effects by gender, age, race, cardiovascular risk profile, and other characteristics. However, observational evidence does not demonstrate causality, because coffee drinking is part of an individual's lifestyle and is related to many other factors, such as alcohol intake, mental stress, and dietary habits, which may also influence blood pressure.

Randomized clinical trials may provide insight into causality, because both the intervention (e.g., the use of coffee or caffeine in tablets) and the control treatment (e.g., decaffeinated coffee or placebo) are randomly assigned to participating subjects, and any confounder that could distort the relation between coffee and blood pressure should be equally distributed in both groups. The limitation of currently available randomized clinical trials on this subject is however that only fixed doses of coffee or caffeine have been studied, and for a relatively short period of time, the number of participating subjects has been limited; and there have often been problems of poor adherence to the assigned treatments. Furthermore, trials may have suffered from unsuccessful randomization or lack of blinding of the participants and/or investigators, which could introduce bias. Therefore, any conclusion on the cardiovascular effects of coffee has to rely on the overall evidence deriving from multiple sources of information.

The variability observed in the results of coffee studies and meta-analyses may be in part explained by the development of tolerance. For example, tolerance to caffeine-induced pressor effects quickly develops in habitual coffee drinkers, and blood pressure may be increased only temporarily in occasional coffee drinkers, while it is usually not elevated in heavy drinkers. It is possible that the complex set of counterregulatory hormones maintaining blood pressure causes tolerance to the humoral and hemodynamic effects of caffeine. In addition, above a certain level of consumption, caffeine's pressor effect might be counterbalanced by other coffee ingredients, including chlorogenic acid, flavonoids, melanoidins, quinide, magnesium, cafestol, and kahweol. Also, potassium, contained in coffee, may lower blood pressure. This may help explain the observed inverse 'J-shape' relation between habitual coffee drinking and the risk of hypertension, which increased up to three cups per day and then slightly decreased at higher amounts of consumption.

Another reason underlying the heterogeneity of responses to coffee drinking is the interaction between coffee components and the individual genetic constitution (nutrigenetics). For example, the enzyme accounting for approximately 95% of caffeine metabolism (the CYP1A2 isoform) has a wide interindividual variability in activity, resulting in rapid or slow metabolism of caffeine. It has been observed that subjects with slow metabolism have an increased risk of MI. Also, blood pressure responses are variable between subjects, with most subjects experiencing an increase in blood pressure, others showing no change, and some even showing blood pressure reductions. An association between gene variants in the adenosine and adrenergic receptors and blood pressure responses to caffeine has been observed. In principle, the exposure to higher blood pressure values as the result of such nutrigenetic interactions in some genetically predisposed individuals may expose such individuals to a higher coffee-related cardiovascular event. Moreover, it has been observed that genetic variants of adenosine receptors may also explain the interindividual variability in the susceptibility to anxiety and sleep changes induced by caffeine.

Besides blood pressure, other cardiovascular risk factors may be affected by coffee consumption. Some coffee compounds other than caffeine also have insulin-sensitizing and anti-inflammatory effects, and recent evidence from prospective cohort studies has suggested an inverse association between coffee and the risk of type 2 diabetes mellitus. This relationship is consistent across age, obesity, and study location (the United States and Europe), independent of potentially confounding dietary and lifestyle factors. Some proposed mechanisms able to explain this association include effects on insulin sensitivity and/or insulin secretion modulated by different minerals, antioxidants, and phytochemical compounds found in coffee. The role of caffeine in increasing or decreasing the risk of type 2 diabetes mellitus is still poorly understood. Most findings indicated a dose–response relation, with diabetes risk reduction for

higher levels of coffee consumption. Generally, four or more cups of coffee per day have generally been associated with a lower risk of type 2 diabetes mellitus, whereas for lower levels of consumption, results are controversial. Cross-sectional studies have highlighted that high coffee consumption is associated with lower postload plasma glucose concentrations among persons without diabetes and a lower incidence of impaired glucose tolerance and type 2 diabetes mellitus. In short-term metabolic studies, caffeine intake acutely reduces insulin sensitivity, exaggerating the blood glucose response to glucose loads. This action is probably related to the ability of caffeine to exert adenosine receptor antagonism or increase catecholamine levels. Also, decaffeinated coffee consumption has been associated with a reduction of risk of type 2 diabetes mellitus. Caffeinated and decaffeinated coffee consumption has a beneficial effect on insulin sensitivity because both reduce plasma C-peptide concentrations. However, the beneficial effect of decaffeinated coffee on glucose metabolisms requires further study. Chlorogenic acid and quinides are also probably involved in the reduction of risk of type 2 diabetes mellitus because they act on glucose homeostasis in animal models of diabetes. In humans, the components of coffee other than caffeine may exert beneficial effects on glucose metabolism. However, long-term studies on glycemic control are needed.

The previously considered harmful effects of coffee on the lipid profile depend on how the beverage is prepared. In fact, boiled coffee has higher concentrations of cholesterol-increasing compounds, classified as diterpenes, such as cafestol and kahweol. They are extracted from coffee beans by prolonged contact with hot water, while brewed/filtered coffee has a much lower concentration of cafestol and kahweol because of the much shorter contact with hot water and the retention of diterpenes by filter paper. Accordingly, it has been observed that the consumption of boiled coffee dose-dependently increase serum total and low density lipoprotein (LDL) cholesterol concentrations, whereas the consumption of filtered coffee results in very little change in serum cholesterol.

Regarding the association between coffee consumption and the risk of stroke, various findings have led to inconsistent results. Two recent meta-analyses have concluded that moderate coffee consumption has a preventive effect on stroke, and this is probably due to the healthy effect of coffee on the main risk factors for stroke, including hypertension, cardiovascular diseases, and diabetes mellitus. Regarding heart failure, a meta-analysis has indicated that there is a modest inverse association between moderate coffee consumption and the incidence of heart failure. Although potential modifiers of the coffee–heart failure relationship are not known, it is possible that the beneficial effects on blood pressure and other cardiovascular risk factors contribute to positively affect the risk of heart failure. In light of these findings, the current heart failure prevention guidelines have suggested a revision of the warning about coffee consumption, due to the evidence showing that coffee may provide a moderate protection against the incidence of heart failure.

Effects on Cancer

The relationship between coffee and cancer raises great interest, and in fact, more than 500 papers in the last decades have estimated the association between coffee consumption and the occurrence of cancer at 11 organ sites. Some studies found out that coffee consumption is associated with a reduced risk of hepatocellular, kidney, and, to a lesser extent, premenopausal breast and colorectal cancers, while it is unrelated to prostate, pancreas, and ovarian cancers. Since the results obtained are often controversial, in 2007, the World Cancer Research Fund (WCRF) conducted a comprehensive analysis of diet and cancer, using a standardized approach to review the overall evidence. This report showed an inverse relationship between coffee and the risk of pancreatic cancer and kidney cancer. This influence on cancer development appears to be related to the chemical composition of coffee and probably due to compounds able to influence the risk of cancer. For instance, caffeine can both stimulate and suppress tumors, depending on the species and the phase of administration. The consumption of caffeine is inversely related to hepatocellular injury. A population-based case–control study in the United States highlighted that caffeine was associated with a lower prevalence of abnormal alanine aminotransferase activity. Some other compounds, such as cafestol and kahweol, show anticarcinogenic properties, including the induction of phase II enzymes involved in carcinogen detoxification and the reduction of bile acid secretion associated with colon carcinogenesis. Polyphenols and chlorogenic acid are characterized by antioxidant effects. In particular, chlorogenic acid reduces blood glucose levels in rats and increases insulin sensitivity. Chronic hyperinsulinemia and insulin resistance are confirmed markers of high risk for some cancer sites. Moreover, caffeic acid inhibits DNA methylation in human cancer cells: this epigenetic regulation represents an important mechanism, because tumor cells are hypermethylated. In fact, DNA hypermethylation is often associated with the inactivation of genes and pathways involved in the tumorigenic process, including cell cycle regulation, inflammatory and stress response, and apoptosis. In addition, coffee-mediated stimulation of the Nrf2/ARE signaling pathway induces an increase in defense mechanisms against chemical stresses.

The influence of coffee consumption on the main types of cancer is reported in **Table 3**.

Effects on Neurodegenerative Diseases

Coffee has been shown to reduce the risk of Alzheimer's dementia and other diseases of the central nervous system, including Parkinson's disease.

A trend towards a protective effect of caffeine on Alzheimer's dementia has been frequently reported. Coffee may be the best source of caffeine to protect against Alzheimer's dementia due to a component in coffee that synergizes with caffeine to selectively enhance plasma cytokines. A quantitative review of four studies, despite heterogeneous methodologies and results, indicated that coffee consumption is inversely associated with the risk of Alzheimer's dementia, compared to nonconsumers.

Coffee and caffeine intake have also been associated with a reduced risk of Parkinson's disease, especially in men, in a number of prospective and case–control studies. Caffeine reduces the loss of dopaminergic neurons in animal models,

Table 3 Coffee influence on cancer development

Type of cancers	*Coffee effect*
Breast cancer	Coffee consumption has an inverse association with breast cancer, in particular among premenopausal women. Premenopausal women with a breast cancer 1, early onset (*BRCA*1) or breast cancer 2, early onset (*BRCA*2) gene mutation who habitually drank six or more cups of coffee per day experienced a 70% statistically significant reduction in breast cancer risk
Colorectal cancer	Coffee is a protective factor against colorectal cancer. This action is due to the presence of cafestol and kahweol that regulate the excretion of bile acids and neutral sterols into the colon
Prostate cancer	No association between prostate cancer risk and cumulative lifetime daily coffee consumption, duration of daily drinking, and age when daily drinking was started has been established
Ovarian cancer	No association between coffee and ovarian cancer has been found. However, some studies showed a modest inverse relationship between caffeine intake and ovarian cancer. This effect is probably related to caffeine modulation of estrogen level circulation
Pancreatic cancer	No association between coffee and pancreatic cancer has been found. A reduced risk was apparent among men who drank at least three cups of coffee per day
Liver cancer	Coffee consumption appears to reduce the risk of liver cancer. Probably, coffee polyphenols may maintain a relatively lower iron status and therefore reduce the risk of liver injury
Kidney cancer	Coffee consumption is associated, but not significantly, with a lower risk of kidney cancer. This action is probably due to the fact that caffeine has a diuretic effect by blocking antidiuretic hormone and antioxidant compounds reduce oxidative damage to DNA, proteins, and other molecules. Moreover, coffee consumption may reduce the risk of kidney cancer by improving insulin sensitivity

and its neuroprotective function is attributed to the antagonism on adenosine 2A (A2A) receptors in the brain, which are being increasingly targeted by anti-Parkinson therapies in clinical trials.

Other Effects

Coffee consumption is also associated with various other health effects. For instance, coffee may reduce the risk of depression. Additionally, coffee may improve asthmatic symptoms, probably through caffeine, which is a methylxanthine bronchodilator. Coffee may also enhance physical performance in sustained high-intensity exercise. Coffee may also prevent symptomatic gallstones and its consumption is associated with protection against some infectious and malignant diseases, particularly of the liver.

High levels of caffeine may increase urine output and urinary calcium and magnesium excretion, which have implications for bone health. Caffeinated coffee increases the risk of bone loss and fractures.

Effects on Mortality

Some studies have also investigated the association between coffee consumption and major causes of death, including heart diseases, respiratory diseases, stroke, injuries and accidents, diabetes, and infections. The results of these studies have been variable, and data are lacking to clarify the association between coffee drinking and mortality, to determine whether there is a dose–response relationship, and to assess whether associations are consistent across various subgroups. In a large, prospective cohort study, a dose-dependent inverse association between coffee drinking and total mortality was observed, after adjusting for potential confounders (smoking status in particular). Although the observational nature of the study does not prove a cause/effect relationship, the authors speculated that a plausible mechanism by which coffee consumption might have health benefits is the presence of antioxidant compounds, including polyphenols. The significant inverse associations of coffee consumption with death from all causes provide reassurance with respect to the concern that coffee drinking might adversely affect health.

Conclusions

The currently available overall evidence on cardiovascular effects related to habitual coffee consumption is largely reassuring. Moreover, coffee has a protective effect on cancer and neurodegenerative disease. Therefore, coffee can be included as part of a healthy diet. Many of coffee benefits probably derive from its caffeine content, but other substances may have an important role in health protection, particularly for their antioxidant effect.

It is very difficult to establish the factors responsible for coffee's beneficial or harmful effects. In order to better understand the function of these compounds, they should be isolated and utilized in a controlled experimental situation, using a well-established chemical balance of coffee components and at doses nutritionally achievable. Finally, it is also possible that coffee drinkers differ in other important dietary and sociological aspects from nonconsumers, and coffee use may be a surrogate marker of some other dietary or lifestyle risk factor.

Clinical trials need to verify the relationship between coffee and diseases, controlling coffee type, the original coffee beans, the roasting process, serving sizes, brewing process, and duration over a long period of time, with specific quantitative information (in mg kg^{-1} day^{-1}) on caffeine intake.

Coffee Types

Coffee cultivation is spread all over the world, starting in Arabia (one species is called *Coffea arabica*, and a variety is 'Moka', named after an Arab village), passing through many countries, such as Ceylon (Sri Lanka), Java, India, the Philippines, Hawaii, and Vietnam, among others, some of which are important producers to this day. Coffee was introduced in America from plants previously adapted to the climate in Amsterdam and Paris and planted in Martinique, Suriname, and French Guiana, from where it was brought to Brazil. Nowadays, coffee is the second beverage widely consumed in the world, being overcome only by water, and Brazil is the largest producer in the world.

After oil, coffee is the most valuable traded commodity worldwide, with global retail sales estimated to be US$ 90 billion. Coffee is the major export product of some countries such as Brazil, Uganda, Burundi, Rwanda, and Ethiopia. About 70% of the world crop is grown on smallholdings smaller than 10 ha, and hence, it is often a family business that provides maintenance for over 25 million people worldwide. On a broader scale, the international coffee trade involves about 500 million people in its management, from cultivation to the final product for consumption.

The coffee tree belongs to the tribe Coffeeae in the family Rubiaceae. One hundred species are associated with the genus *Coffea*, but only two species are agroeconomically important, *Coffea arabica* and *C. canephora*. *C. dewevrei*, *C. congensis*, *C. eugenioides*, *C. kapakata*, *C. salvatrix*, *C. stenophylla*, *C. liberica*, *C. racemosa*, and others are primarily used in genetic crosses. Presently, arabica coffee accounts for about 63% of coffee produced, and robusta coffee 37%.

Coffea arabica (Arabica Coffee)

Coffea arabica was first described by Linnaeus in 1753. The best known varieties are 'Typica' and 'Bourbon,' but from these, many different cultivars have been developed, such as 'Caturra' (Brazil and Colombia), 'Mundo Novo' (Brazil), 'Tico' (Central America), the dwarf 'San Ramon', and the 'Jamaican Blue Mountain'. Arabica plant is a large bush with dark-green oval leaves. It is genetically different from other coffee species, having four sets of chromosomes rather than two. The fruits are oval and mature in 7–9 months; they usually contain two flat seeds (the coffee beans) – when only one bean develops, it is called a peaberry. Compared with robusta, arabica trees are generally less vigorous and productive with a higher cost of production and produce beans that contain about half the amount of caffeine. Arabica coffee produces a beverage with a typical sweet aromatic taste that can be consumed alone or blended with *C. canephora*.

'Catuai' and 'Mundo Novo' are the most traditionally cropped cultivars of *C. arabica*, but many others are also economically important worldwide. Since arabica coffee is often susceptible to attack by pests and diseases, resistance is a major goal of plant-breeding programs. Arabica coffee is grown throughout Latin America, in Central and East Africa, in India, and to some extent in Indonesia.

Coffea canephora (Robusta Coffee)

The term 'robusta' is actually the name of a widely grown variety of this species. It is a robust shrub or small tree growing up to 10 m height, but with a shallow root system. The fruits are round and take up to 11 months to mature; the seeds are oval in shape and smaller than those of *C. arabica*. Robusta coffee is harvested in West and Central Africa, throughout Southeast Asia, and to some extent in Brazil, where it is known as conilon. Robusta coffee constitutes a relatively new commercial crop, so there is a great potential for genetic improvement. 'Robusta' is the most widely cultivated variety of *C. canephora* in the world, so that the name of this variety is used to designate the common name of the species. Nevertheless, in Brazil, 'Conilon' (also known as 'Kouillou') is practically the sole cultivated variety of *C. canephora*.

Coffea canephora, produces a beverage that qualifies it to be used for soluble coffee production and to be blended with arabica coffee. Current research shows that in spite of giving beverage with different sensory characteristics of the arabica, robusta coffee produced and processed properly can be a source of desirable characteristics in the composition of blends with arabica.

Coffea liberica (Liberian Coffee)

Liberian coffee grows as a large strong tree, up to 18 m in height, with large leathery leaves. The fruits and seeds (beans) are also large. Liberian coffee is grown in Malaysia and in West Africa, but only very small quantities are traded.

Early planning of a coffee plantation has an important meaning and can ensure the success of the activity to be started. Because it is a permanent culture, mistakes in implementation may be impossible to fix, seriously compromising the venture. Thus, important aspects should be considered, such as available resources, proper choice of the area and cultivar, and the planting system and management.

Coffee cultivation and treatment involve the following steps: tree abatement; soil preparation; planting (small plants are usually grown in nurseries in the same or in external properties); treatment (soil correction, fertilizing, pest control, and terrain cleaning manually or with herbicides); fruit picking (ripe fruit is usually red and therefore called a berry; Figure 1); sieving to get rid of impurities; transportation; washing to remove pulp and membranes; sun drying, revolving grains with a rake, or mechanical drying through hot air blasting; hand separation of grains; and storing in silos and bagging.

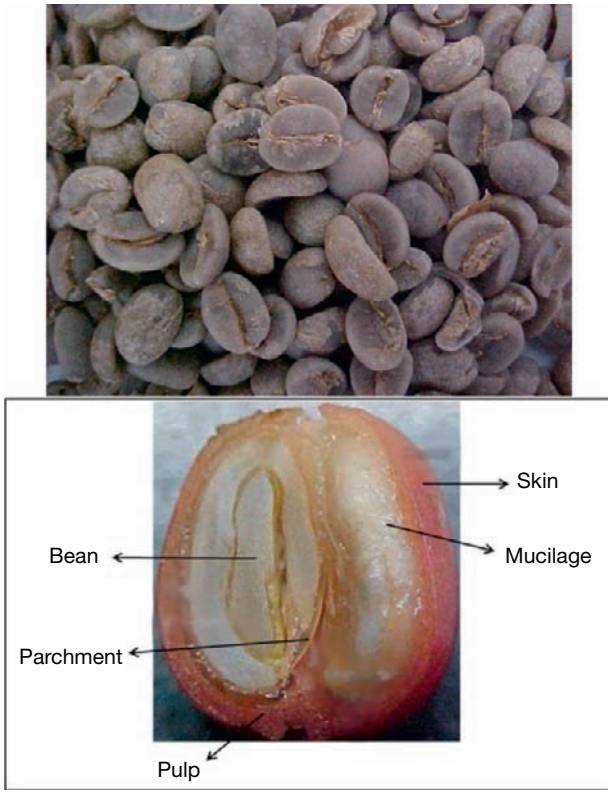

Figure 1 Green coffee (top) and longitudinal cut of the mature fruit coffee (cherry) (bottom) showing all the parts present in the coffee fruit.

Planting

One of the most important factors in coffee planting is the production of well-developed healthy plants of good quality. Seedlings must have a well-developed root system, have good root/shoot ratio, be acclimated to the sun, since coffee is grown in full sun, and be free of pest problems and nutritional deficiencies. However, the formation of good quality planting material depends primarily on the quality of the seeds.

Coffee Plant Propagation

Propagation by Seeds

Ripe red cherries of arabica coffees are collected and pulped, and the mucilage is removed by fermentation. The freshly picked coffee seeds (typically referred to as beans) can be either planted immediately or dried for later use. Coffee drying takes place on wire mesh trays in the shade. Coffee seeds with approximately 10–15% of humidity can be used up to a year or more if properly stored. Storing coffee beans correctly is essential for a longer seed life.

Growing Coffee Seeds in Poly Bags

Poly bags, made of black diothene (200 gauge), are commonly used and filled with a mixture of topsoil, well-rotted cattle manure, coarse sand, gravel, coffee pulp, and coffee husks. A ratio of three parts topsoil to one part coarse sand and one part cattle manure is often used. A top dressing of nitrogen is applied by incorporating 20 g urea in 5.0 l of water per meter of bed. The seedlings of arabica coffee can still be grafted franc or foot type. A variety of *C. canephora* is most commonly used as rootstock considering its resistance to nematodes. Tubes are conical containers, made of hard plastic (polypropylene). The production of seedlings in plastic pots in a greenhouse facilitates isolation of the nursery in relation to insects, reduces pest, preserves the integrity of the root system, and increases the ease of handling in producing grafted seedlings.

Coffee Cultivation

The basis of the success of the coffee activity relies on the adoption of good agricultural and processing practices, which can be considered as production processes based on recommendations predetermined aimed at satisfying performance of coffee farms, in an efficient way generating satisfaction and safety for the whole production chain.

Good agricultural practices for cultivation are based on three principles: food security; social and environmental responsibilities, necessary for the development of a solid strategy for the integration of production; and farm management capable of monitoring and controlling over the production process and when necessary making adjustments in the system (inputs, safety procedures, and management training).

On the other hand, consumers are concerned with aspects beyond the sensory quality of the product such as the preservation of the environment, improvement of income of the growers, and rural workers' safety. Aiming to attest if these requirements are met, several certifiers are responsible for guiding, inspecting, and certifying the compliance of these coffee requirements. The certification movement is growing by promoting improvements in the entire coffee production chain. Examples of accreditation in the culture of coffee are Fairtrade, Rainforest Alliance, Organic, and others.

The trend towards a global economy, a growing competition, and the search for technologies with higher productivity also has effects upon coffee cultivation. Mechanization is being disseminated and updated. Moreover, new methods of cultivation are introduced, among them being high-density cultivation, in which the distance between plants is being reduced. This modern method increases the number of coffee trees from 3000 or 4000 to 100 000 plants per hectare, with an increase in productivity of around 50% over the traditional method. This procedure is important for workers' health, since lower risks are involved and less herbicide is applied, especially after the third year. On the other hand, there is an increase in the frequency of tree cutting and higher demand for control of fungus disease in the plants.

Coffee Harvesting

Depending on the variety, it takes approximately 3–4 years for newly planted coffee trees to begin to bear fruit. The fruit (coffee cherry) turns a bright, deep red or yellow when it is ripe and ready to be harvested.

Harvesting is one of the most important steps influencing the coffee quality. Coffee processed from ripe cherries is naturally sweet and shimmering with floral and fruit notes. Coffee processed from unripe cherries may taste grassy, green, thin, or astringent and finally processed from overripe, shriveled cherries (sometimes called raisins) runs the risk of tasting fermented, musty, or moldy.

Harvesting coffee is particularly challenging because coffee fruit typically does not ripen uniformly; presenting more than one bloom, the same branch may simultaneously display ripe red cherries, unripe green cherries, and dry, overripe black cherries. Studies with coffee fruits in various stages of maturation showed that the highest quality of cherry fruit occurs in stage, ideal harvest. The coffee harvested early with a high percentage of green causes damage in the type of the coffee (quality) and drink and can also achieve a rate of 20% of losses on the final yield, in addition to affecting the appearance, roasting, type, and drink. On the other hand, the longer it stays in the coffee tree, the greater incidence of black rot grain or loss of dry mass and quality.

In regions where labor is inexpensive, where families pick their own small plots, or in mountainous areas, trees may be picked repeatedly, and only ripe fruits are harvested during each pass. In parts of the world where labor is scarce or expensive, coffee may be stripped from the trees in a single picking. Ripe, unripe, and overripe cherries are all gathered together, along with some leaves and twigs. Although sophisticated sorting methods can compensate to some degree for mass picking, no expedient is quite as effective as repeated, skillful handpicking.

Machines have been developed that selectively pick ripe cherries by vibrating the tree just vigorous enough to knock loose the ripe fruit while leaving the unripe fruit still attached to the tree. Such machines do not approach the selectivity of a good handpicker and are used only in regions of the world – Brazil, Australia, and parts of Hawaii – where labor is too costly to support handpicking. The main exception is Brazil, where the relatively flat landscape and immense size of the coffee fields have permitted mechanization of the process. Almost all fine coffee is still picked selectively by hand.

Harvesting Methods

Strip picked – the entire crop is harvested at one time. This can be done either by machine or by hand. In either case, all of the cherries are stripped off of the branch at one time.

Selectively picked – only the ripe cherries are harvested and they are picked individually by hand. Pickers rotate among the trees every 8–10 days, choosing only the cherries that are at the peak of ripeness. Since this kind of harvest is labor-intensive, and thus more costly, it is used primarily to harvest the finer arabica beans. At the end of the day, each worker's harvest is carefully weighed and each picker is paid on the merit of his or her work. The day's harvest is then combined and transported to the processing plant.

Coffee Processing

Coffee beans are the seeds of fruits that resemble cherries, with a red skin (the exocarp) when ripe. Beneath the pulp (the mesocarp), surrounded by a parchment-like covering (the endocarp), lies two beans, flat sides together. When the fruit is ripe, a thin, slimy layer of mucilage surrounds the parchment. Underneath the parchment, the beans are covered in another thinner membrane, the silver skin (the seed coat). Each cherry generally contains two coffee beans; if there is only one, it assumes a rounder shape and is known as a peaberry. Coffee beans must be removed from the fruit and dried before they can be roasted; this can be done in three ways, known as the dry, wet, and semidry fermentation methods. When the process is complete, the unroasted coffee beans are known as green coffee (Figure 1).

Dry Method

The dry method (also called the natural method) is the oldest and simplest method and requires little machinery. The method involves drying the whole cherry and the process is environmentally friendly because it produces low amounts of solid and liquid wastes, with no production of effluents with high organic matter content (Figure 2). The beverage quality depends of the proper processing. This coffee has their own market because the beverage is full-bodied and less acidic than coffee from wet process.

The method involves drying the whole cherry and, most often, is used after nonselective harvesting of different maturation stages of the coffee fruit. There are variations on how the process may be carried out, depending on the size of the plantation and the facilities available that interfere in the final quality obtained. The three basic steps, cleaning, drying, and hulling, are described later in the text.

Firstly, the harvested cherries are usually sorted and cleaned, to separate the unripe, overripe, and damaged cherries and to remove dirt, soil, twigs, and leaves. This can be done by winnowing, which is commonly done by hand, using a large sieve. Any unwanted cherries or other materials not winnowed away can be picked out from the top of the sieve. Ripe cherries can also be separated by flotation (by different density) in washing channels close to the drying areas.

The coffee cherries are spread out in the sun, either on large concrete or brick patios or on matting raised to waist height on trestles. As the cherries dry, they are raked or turned by hand to ensure homogenous drying. It may take up to 4 weeks before the cherries are dried to the 12.5% maximum moisture content, depending on the weather conditions. On larger plantations, machine-drying is sometimes used to speed up the process after the coffee has been predried in the sun for a few days.

The drying operation is the critical stage of the process, since it affects the final quality of the green coffee. Coffee that has been overdried will become brittle and produce too many broken beans during hulling (broken beans are considered defective beans). Coffee that has not been dried sufficiently will be too moist and prone to rapid deterioration caused by the attack of fungi and bacteria during the storage time.

The dried cherries are stored in bulk in special silos until they are sent to the mill where hulling, sorting, grading, and bagging take place. All the outer layers of the dried cherry are removed in one step by the hulling machine.

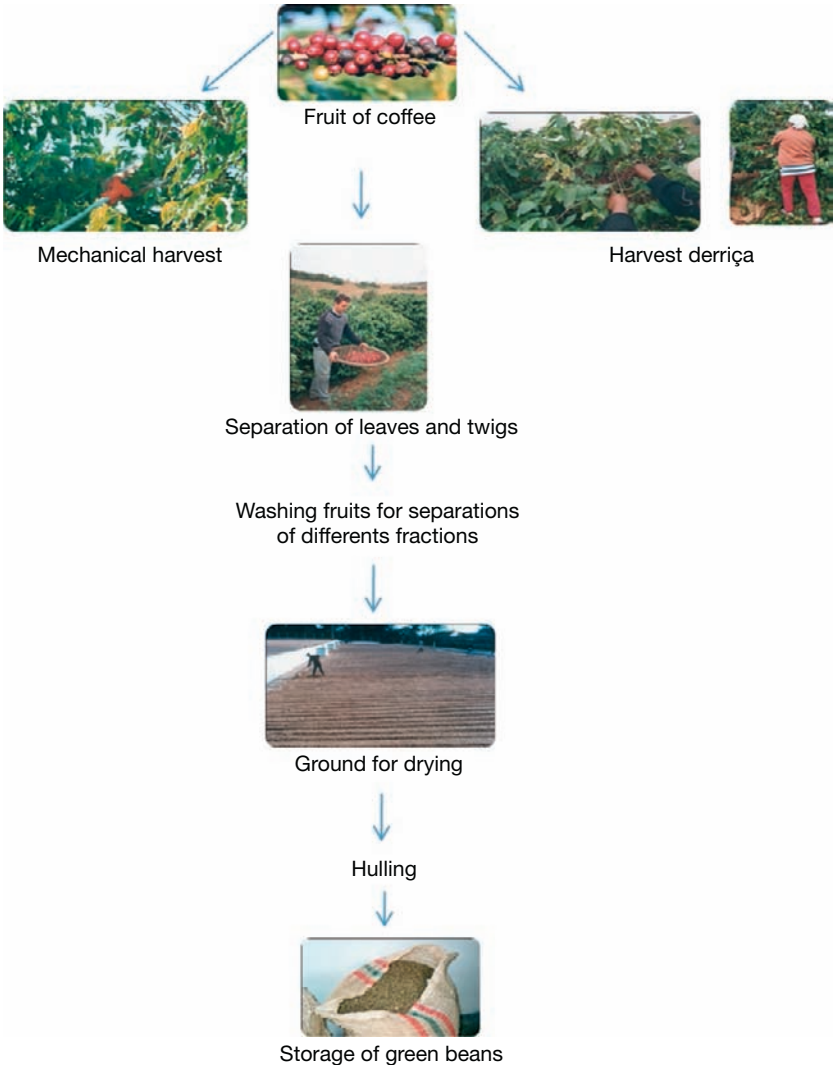

Figure 2 Main steps involved in dry or natural coffee fermentation. Reproduced from Schwan, R. F., Silva, C. F. and Batista, L. R. (2012). Coffee fermentation. In: Hui, Y. H. (ed.) *Handbook of plant-based fermented food and beverage technology*. Boca, Raton, FL: CRC Press, Chapter 42.

The dry method is used for about 90% of the arabica coffee produced in Brazil; Ethiopia, Haiti, and Paraguay; and India and Ecuador. Almost all robusta coffees are processed by this method. It is not practical in very rainy regions, where the humidity is too high or where it rains frequently during harvesting.

Wet Method

The wet method (also called the washed method) requires the use of specific equipment and substantial quantities of water (Figure 3). When properly done, it ensures that the intrinsic qualities of the coffee beans are better preserved, producing a green coffee, which is homogeneous and has few defective beans. Hence, the coffee produced by this method is usually regarded as being of better quality and commands higher prices. This method is used for all arabica coffee, except in Brazil, Ethiopia, and Yemen arabica. Just a few percentage of robusta coffee is processed in this way.

Even after careful harvesting, a certain number of partially dried and unripe cherries, as well as some stones and dirt, will be present among the ripe cherries. As in the dry method, preliminary sorting and cleaning of the cherries are usually necessary and should be done as soon as possible after harvesting. This operation can be done by washing the cherries in tanks filled with flowing water. Screens may also be used to improve the separation between the ripe and unripe, large and small, cherries.

After sorting and cleaning, the pulp is removed from the cherry. This operation is the key difference between the dry and the wet methods, since in the latter, the pulp of the fruit is separated from the beans before the drying stage. The pulping is done by a machine, which squeezes the cherries between fixed and moving surfaces. The flesh and the skin of the fruit are left on one side and the beans, enclosed in their mucilaginous parchment covering, on the other. The clearance between the surfaces is adjusted to avoid damage to the beans. Pulping operation should also be done as soon as

Figure 3 Main steps involved in wet coffee fermentation. Reproduced from Schwan, R. F., Silva, C. F. and Batista, L. R. (2012). Coffee fermentation. In: Hui, Y. H. (ed.) *Handbook of plant-based fermented food and beverage technology*. Boca, Raton, FL: CRC Press, Chapter 42.

possible after harvesting to avoid any fruit deterioration, which might affect the bean quality.

The pulped beans go on to vibrating sieves that separate them from any unpulped or imperfectly pulped cherries, as well as from any large pieces of pulp that might remain. From the screens, the separated pulped beans then pass through water-washing channels where a further flotation separation takes place before they are sent to the next stage.

Because the pulping is done by mechanical means, it normally leaves some residual flesh as well as the sticky mucilage adhering to the parchment surrounding the beans. The parchment has to be completely removed from the coffee beans to avoid contamination of products resulting from the mucilage degradation. The newly pulped beans are placed in large fermentation tanks in which the mucilage is broken down by natural and microbial enzymes until it is dispersible, when it can be washed away. Unless the fermentation is carefully monitored, the coffee can acquire undesirable, sour flavors. For most coffees, mucilage removal takes place between 24 and 36 h, depending on the temperature, thickness of the mucilage layer, and concentration of the enzymes; the end of the fermentation is assessed when the parchment surrounding the beans loses its slimy texture and acquires a rougher 'pebbly' feel. When the fermentation is complete, the coffee is thoroughly washed with clean water in tanks or in special washing machines.

Another version of this method is when the mucilage is mechanically removed obtaining the coffee called demucilated without the fermentation stage consequently with less final flavor. An intermediary process consists in obtaining the pulped beans with part of the mucilage and directly drying them (dry fermentation), obtaining the coffee called dehulled.

The wet parchment coffee at this stage has of approximately 57% moisture. To reduce the moisture to a maximum 12.5%, the parchment coffee is dried either in the sun, in a mechanical dryer, or by a combination of the two. Sun drying is done on extensive flat concrete or brick areas, known as patios, or on drying tables made of fine mesh wire netting. The beans are laid out in a layer of 2–10 cm and turned frequently to ensure even drying. Sun drying should take from 8 to 10 days, depending upon ambient temperature and humidity. Coffee dries more quickly if raised on tables because of the upward draft of warm air. The use of hot air drying machines becomes necessary to speed up the process in large plantations where, at the peak of the harvesting period, there might be much more coffee than can be effectively dried on the terraces. However, the process must be carefully controlled to achieve satisfactory and economical drying without any quality damage.

After drying, the wet-processed coffee, or parchment coffee as it is commonly known, is stored and remains in this form until shortly before export.

The final stages of preparation of the coffee, known as 'curing,' usually take place at a special plant just before the coffee is sold for export. The coffee is hulled, to remove the parchment, and then passes through a number of cleaning, screening, sorting, and grading operations, which are common to both wet- and dry-processed coffee. Electronic sorting machines may be used to remove defective beans that cannot be distinguished by eye.

The wet method is generally used for arabica coffees, with the exception of those produced in Brazil and the arabica-producing countries mentioned earlier in the text as users of the dry method. This method is rarely used for robusta.

Semidry Method

The semidry process (or pulped natural) is a variation of wet processing. It is an intermediate process between dry and wet processing and results in what are called pulped natural coffees. It combines a wet mechanical process to remove the pulp and the spreading out of depulped beans as a thin layer on cement patios for a period to allow further aerobic degradation of mucilage (dry process; Figure 4). Some studies have focused on the chemical properties of coffee beans under semidry processing and the correlation between those properties and beverage quality. No study has yet presented conclusive evidence of the level of influence of this process on the final quality of the beverage. However, it is possible to say that the qualities of coffee beverages made from pulped natural coffee lie somewhere between those obtained using dry and wet processing. The green beans produced via semidry processing are usually used in espresso blends.

Figure 4 Main steps involved in semidry coffee fermentation. Reproduced from Schwan, R. F., Silva, C. F. and Batista, L. R. (2012). Coffee fermentation. In: Hui, Y. H. (ed.) *Handbook of plant-based fermented food and beverage technology*. Boca, Raton, FL: CRC Press, Chapter 42.

Microorganisms: Quality and Safety in Coffee

The method of coffee processing impacts on the native microbiota and, therefore, with the groups of microorganisms involved during fermentation. In some regions or in certain producing years, because of the environmental conditions of coffee, the quality can be inferior because the microbiota changes to deteriorative microorganisms (like butyric and propionic acid bacteria). Nevertheless, in all processing methods (dry, wet, and semidry), the objectives of fermentation, involving bacteria and yeasts, are to remove the mucilaginous layer rich in polysaccharides (pectins) and to reduce the water content present in the fruits. Coffee seeds have all the precursors needed to generate typical flavor and aroma during the roasting operation but the natural microbiota during the fermentation/drying step confer special flavor in the coffee beverage. The microorganisms naturally present in the production environment use sugars in the pulp and mucilage and excrete organic acids and other metabolites that may affect the final sensory characteristics of the beverage. In addition, coffee fermentation and drying must be managed in order to control the growth of filamentous fungi that can give off-flavors and produce mycotoxins.

The three different methods for processing the fruit show quantitative and qualitative differences on the microbiota. The dry process has more microbial species than the other two processes (wet and semidry) because the whole fruits are processed. On the other hand, in the wet process, the skin and pulp are removed, and consequently, the epiphytic microorganisms are mechanically removed. The microbiota of the semidry processing is still not well known but bacteria, yeast, and filamentous fungi are detected in Brazil and India. The review for this topic has been published by Silva.

Microorganisms Present in Dry Process

The presence of organic acid from fermentation (acetic, lactic, butyric, and propionic acids) confirms the microbial action in the fermentation process for natural coffees. In the beginning of the process, the bacteria species predominate over yeast and filamentous fungi, but this changes when the water activity and physical–chemical conditions alter in the media and final phase of the fermentation. Some species identified were *Tatumella ptyseos*, *Pseudomonas putrefaciens*, *P. mirabilis*, *Enterobacter aerogenes*, *Acinetobacter*, *B. subtilis*, and *Paenibacillus amylolyticus*.

The bacteria present on the surface of the coffee cherries synthesize the acid that can migrate to the pulp and mucilage and can interfere with the organoleptic quality of the beans. The negative influence of bacteria on the quality of the coffee beverage is linked to the species present and not to population density. In natural coffee fruit rated very soft (i.e., as having optimal sensory quality), the bacterial population can represent up to 80% of the total microbiota during this process.

Yeasts become predominant as the water activity declines during the fermentation and drying periods, which can last up to 20 days. Twenty-one species of yeasts have been identified, including seven pectinolytic species (*Debaryomyces hansenii*, *D. polymorphus*, *Pichia anomala*, *P. holstii*, *P. burtonii*, *P. guilliermondii*, and *Arxula adeninivorans*). The presence of yeasts during the whole process contributes to the availability of the substrate and action of pectinases over the pulp and mucilage. The role of yeast may be related not only to the fermentation process but also to the control of filamentous fungi growth. Isolates belonging to the genera *Debaryomyces* and *Pichia* have demonstrated the ability to inhibit the growth of toxigenic fungi and may therefore have the potential for biological control.

Studies of natural coffee microbial populations always emphasize filamentous fungi isolation and identification, but the microorganisms present during the fermentation and drying periods are predominantly bacteria and yeasts. Therefore, the presence of filamentous fungi is not involved in the fermentation process, and in general, their presence decreases the sensorial and sanitary quality during the mycotoxin production, especially ochratoxin A (OTA).

Microbiota Present in Wet and Semidry Processing

The microbial diversity of coffee beans in wet processing is smaller compared with that in dry processing, because the

fermentation time is shorter (up to 48 h) and there is a more rapid pH decline from 6 to 4.3. This microbiota comprises few bacterial and yeast species. There is no report of filamentous fungi involved in wet fermentation. The mucilage adhered to beans is the substrate used by bacteria and yeast during fermentation. Higher microbial diversity in washed coffee fruits could be observed using molecular identification techniques that allow the detection of cultivable and uncultivable microorganisms.

The molecular identification of microorganisms associated with coffee showed that, in semidry process, the microbial succession occurred: bacteria dominated at the beginning of the process, but after 72 h, bacteria and yeast populations reach similar values (average 10^6 CFU g^{-1}) and after 192 h of fermentation, the yeast population predominates.

Currently, there is still doubt regarding the apparent bacterial role on coffee fruit fermentation. Recently, it was observed, in wet process, that the predominant population was lactic acid bacteria (LAB), especially *Weissella*, *Lactobacillus*, and *Leuconostoc* (*W. cibaria* and *W. soli*, *Lb. plantarum* and *Lb. brevis*, *L. mesenteroides*, *L. pseudomesenteroides*, and *L. citreum*). Thus, it is possible that the LAB in the wet processing are responsible for the degradation of the mucilage; however, this group of bacteria does not participate in the coffee fermentation in dry fermentation. It is possible that the anaerobic or low oxygen conditions present in wet fermentation favor the LAB development. The action of LAB allows the pH to fall, preventing the proliferation of other bacteria and promoting yeast growth. About the role of yeast in the fermentation of the depulped beans, some researchers do not believe the yeast action on the mucilage degradation. However, pectinolytic yeasts have been isolated during the wet processing of coffee in both robusta and arabica coffees. The fermentation also occurs due to the action of yeast, namely, *Kluyveromyces* sp., *Saccharomyces cerevisiae*, *Candida parapsilosis*, *C. tropicalis*, *C. pelliculosa*, *Torulopsis famata*, *Pichia anomala*, *P. kluyveri*, and *Hanseniaspora uvarum*. Some species like *Pichia kluyveri*, *P. anomala*, and *H. uvarum* showed an inhibitory effect on the growth of *Aspergillus ochraceus*, a fungus that is potentially toxigenic and is often isolated in coffee fruits and beans. Therefore, it is possible that yeasts play a dual role during the processing of coffee fruits: they facilitate mucilage degradation during fermentation and afford biological control.

The microbiota of the semidry processing is still not well known. A great diversity of prokaryotes and eukaryotes was detected using polymerase chain reaction–denaturing gradient gel electrophoresis (PCR-DGGE) in addition to conventional techniques. PCR-DGGE allowed the detection of species not isolated from conventional techniques, such as *Enterobacter cowanii*, *Lactobacillus plantarum*, *Pantoea agglomerans*, *Bacillus macerans*, and an endophytic bacterium that could not be cultivated and the yeasts *S. cerevisiae* and *H. uvarum*. The presence of filamentous fungi was detected with populations below 10^3 CFU g^{-1} and only in recently harvested fruits, washed fruits, and washed fruit fractions and in the skin + pulp portion. The filamentous fungi species found were *Aspergillus* sp., *A. chevalieri*, *A. foetidus*, *A. niger*, *A. ochraceus*, *A. tubingensis*, *A. versicolor*, *Cladosporium* sp., *C. cladosporioides*, *C. macrocarpum*, *Cylindrocarpon* sp., *Eurotium chevalieri*, *Fusariella* sp., *Fusarium* sp., *F. chlamydosporum*, *F. lateritium*, *F. nivale*, *F. solani*, *F. sporotrichioides*, *Geotrichum* sp., *Mucor hiemalis*, *Penicillium* sp., *P. brevicompactum*, *P. commune*, *P. decumbens*, *P. fellutanum*, *P. implicatum*, *P. roqueforti*, *Phoma* sp., and *Ulocladium* sp.

Ochratoxin in Roasted Coffee

In agricultural products, such as coffee, interactions between different fungal species represent a natural phenomenon that affects the development of these microorganisms and their subsequent production of mycotoxins. Several studies have been undertaken to assess the growth of mycotoxigenic fungi and mycotoxin degradation. These interactions are influenced by environmental conditions, microorganism diversity, agricultural products, the type of processing, and the cultivation system used. Interactions between mycotoxigenic and nontoxic species can lead to the appearance of diseases and the production of different types of mycotoxins and their degradation. The results of these interactions are influenced by environmental conditions. OTA has been detected in various agricultural products, including coffee. Coffee drinks significantly contribute to the ingestion of OTA in the human diet. OTA is primarily produced by *Aspergillus* section *Circumdati* (*A. westerdijkiae* and *A. ochraceus*) and section *Nigri* (*A. carbonarius* and *A. niger*) species.

Coffee bean contamination with OTA may occur throughout the entire production chain and is directly related to the care and quality of the crop management, harvest, postharvest storage, and type of roasting.

The toxic effects of OTA appear to be related to its ability to inhibit protein synthesis by competing with phenylalanine in the reaction catalyzed by phenylalanyl-tRNA synthetase and other systems that require this amino acid. OTA also increases lipid peroxidation, leading to greater mitochondrial and cell damage. Furthermore, this mycotoxin is also considered nephrotoxic, cytotoxic, carcinogenic, teratogenic, and immunosuppressive and was classified by the International Agency for Research on Cancer (IARC) as a member of group 2B, that is, a possible human carcinogen.

Several studies have shown that the process of roasting is effective in reducing the OTA concentration, but there is still a lack of more conclusive studies about the effects of the various stages of roasting and grinding and methods of preparing the beverage on toxin stability. The type of roasting and particle size interfere with the residual content of OTA in the beverage. Therefore, the study helps to establish quality requisites for roasted and ground coffee production within national and international standards of quality, enabling value to be added to a traditional product of Brazilian agriculture.

Functional Disorders Affecting the Colon

Constipation

Constipation is the most common gastrointestinal complaint in the general population. It is particularly prevalent in women, children, and older adults. The definition of constipation varies, but based on epidemiological studies, it is commonly defined as having a bowel movement frequency of 3 or less per week. However, reports of bowel movement frequency are usually inaccurate and often do not correlate with complaints of constipation. This observation led to a more extensive definition or the Rome III criteria (Rome III, last revised in 2006) for constipation that includes the presence of the following for a period of at least 6 months:

1. Must include two of the following:
   - Straining during at least 25% of defecations
   - Lumpy or hard stools in at least 25% of defecations
   - Sensation of incomplete evacuation for at least 25% of defecations
   - Sensation of anorectal obstruction/blockage for at least 25% of defecations
   - Manual maneuvers to facilitate at least 25% of defecations
   - Fewer than three defecations per week
2. Loose stools are rarely present without the use of laxatives.
3. There are insufficient criteria for irritable bowel syndrome.

The prevalence of constipation varies according to the criteria utilized for estimation. Overall, the prevalence of constipation in North America varies between 2% and 27%. In children, the worldwide prevalence ranges from 0.7% to 29.6%. In adults, the prevalence rises dramatically, especially after 65 years of age. In general, constipation can be regarded as disordered movement of stool through the colon or anorectum. However, secondary causes include neurological, metabolic, and endocrine disorders. Risk factors associated with constipation include advanced age, female gender, lower level of education, low socioeconomic status, nonwhite ethnicity, and use of certain medications. Cross-sectional studies, however, have failed to link low intake fiber and constipation.

The initial evaluation of the patient with constipation includes a careful history and physical examination. Laboratory evaluation, endoscopic evaluation, and radiological studies should be performed only in selected individuals if indicated.

Treatment of chronic constipation begins with lifestyle modifications, if indicated, and therapy with fiber. Osmotic and stimulant laxatives, stool softeners, emollients, and enemas sometimes are required to treat refractory intractable constipation. It is well recognized that fiber is important for normal defecation. This is due primarily to the ability of fiber to increase stool weight. The increased weight is secondary to the physical presence of the fiber, water held by the fiber, and increased bacterial mass from fermentation. Larger and softer stools increase the ease of defecation and reduce transit time through the intestinal tract, which may help to prevent or relieve constipation. In general, cereal fibers are the most effective at increasing stool weight. Wheat bran is considered the gold standard when it comes to fecal bulking. Overall, the recommended amount of dietary fiber is 20–35 $g\,day^{-1}$ coming from meals and supplements. The effect of fiber and low-digestible carbohydrates on gastrointestinal tolerance is a concern due to the development of symptoms like bloating and distention, leading to low compliance.

Irritable Bowel Syndrome

Irritable bowel syndrome (IBS) is a functional gastrointestinal disorder characterized by chronic abdominal pain and disturbed defecation without evidence of an organic etiology that explains the symptoms. IBS can be associated with significant emotional distress, impaired health-related quality of life, disability, and high health care costs. Psychosocial factors have an important role in modulating the illness experience and its clinical outcome.

The estimated prevalence of IBS in North America is approximately between 10% and 15%. Although it can affect both men and women of different age ranges, women and younger patients are more likely to be diagnosed. The clinical diagnosis of IBS is based on the Rome III criteria, which includes recurrent abdominal pain or discomfort for at least 3 days per month in the last 3 months associated with two of the following:

1. Improvement with defecation
2. Onset associated with a change in frequency of stool
3. Onset associated with a change in form (appearance) of stool

The clinical presentation of IBS comprises a history of chronic abdominal pain with variable intensity, locations, and periodic exacerbations; altered bowel habits ranging from diarrhea and constipation; and other gastrointestinal symptoms like bloating and increased gas production. Based on the symptoms, IBS is classified in four different types:

- IBS with constipation: hard or lumpy stools $\geq$25%/loose or watery stools <25% of bowel movements
- IBS with diarrhea: loose or watery stools $\geq$25% of bowel movements/hard or lumpy stools <5% of bowel movements
- Mixed IBS: hard or lumpy stools $\geq$25%/loose or watery stools $\geq$25% of bowel movements
- Unsubtyped IBS: insufficient abnormality of stool consistency to meet the previously mentioned subtypes

If performed, with the purpose of ruling out other conditions with similar symptomatology, routine laboratory workup is usually normal in IBS. Further workup should be done in the

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00188-4

presence of alarming symptoms like unexplained weight loss, rectal bleeding, nocturnal symptoms, and abnormal laboratory results or family history of inflammatory bowel disease, celiac disease, or colorectal cancer.

The treatment strategy is based on the nature and severity of symptoms, their correlation with food intake and/or defecation, the degree of functional impairment, and the presence of psychosocial difficulties and psychiatric comorbidity affecting the course of the illness. If symptoms are mild and intermittent with low impact on the quality of life, treatment is usually aimed towards lifestyle and dietary modifications. However, if symptoms are moderate to severe in intensity or have a significant impact on the patient's quality of life, then adjunctive pharmacological therapy should be considered. Dietary modifications include the exclusion of gas-producing foods or foods that increase flatulence; the avoidance of lactose in patients with lactose intolerance; a diet low in fermentable oligo-, di-, and monosaccharides and polyols in IBS patients with bloating; and a gluten-free 2-week trial in patients with diarrhea-predominant IBS. Although the benefit of a high-fiber diet in IBS is controversial, its use should be considered in patients with constipation-predominant IBS. Lifestyle modification includes an increase in daily physical activity. If adjunctive pharmacological therapy is indicated, then it should be tailored according to the predominant IBS symptom. Treatment options in constipation-predominant IBS include osmotic laxatives (polyethylene glycol) and agents that enhance intestinal fluid secretion and transit, like intestinal chloride channel agonist (lubiprostone) and guanylate cyclase C agonist (linaclotide). In the case of diarrhea-predominant IBS, antidiarrheal medications, like loperamide or bile acid sequestrants, should be considered. As-needed basis antispasmodic agents are indicated for short-term relief of abdominal pain in patients with IBS. Patients with unremitting symptoms with associated psychiatric impairment may benefit from behavior modification techniques in conjunction with antidepressants.

Colonic Diverticulosis and Diverticular Disease

A diverticulum is a saclike protrusion or a herniation of the mucosa and submucosa through a defect of the muscularis. Location is over the mesenteric border of the colonic wall and its origin corresponds to the four sites of penetration of the bowel wall by the major branches of the vasa recta. Strictly speaking, it is truly a pseudodiverticula since it does not contain all four layers of the colonic wall, only the mucosa and submucosa. Diverticulosis is the term used to define the presence of colonic wall diverticulum. Diverticular disease is a broader term used to define symptomatic diverticulosis.

The exact incidence and prevalence of diverticulosis are not exactly known because the majority of patients are asymptomatic. It is known, however, that the prevalence of diverticulosis is age-dependent, $<20\%$ at age 40 and increasing to $>60\%$ by age 60. In addition, the distribution of diverticulosis also varies by geography. Around 95% of patients in Western countries have sigmoid diverticula. In Asian countries, the prevalence of diverticulosis is predominantly right-sided.

Environment and lifestyle are important factors associated with the development of diverticulosis. Increasing age, obesity, diet rich in meats and low in fiber, living in Western countries, and connective tissue diseases are factors that increase the risk of developing diverticulosis. On the other hand, high-fiber intake and living in predominantly rural areas decrease the risk. Equivocal or factor that do not affect the risk include gender, alcohol and coffee consumption, colorectal cancer, and polycystic kidney disease. Smoking has been associated with increased risk of perforated diverticulitis when compared with nonsmoking.

As mentioned earlier, diverticula develop at well-defined points of weakness in the colonic wall that correspond to where the vasa recta penetrate the muscularis. Although still unclear, abnormal colonic motility seems to be a predisposing factor in the development of diverticula. Diverticula can vary in number from one to literally hundreds. The typical size of a diverticulum is 3–10 mm in diameter, but they can exceed 2 cm. Gross descriptions of the diverticula show a thickened inner circular wall and shortening of the taeniae. Electron microscopy studies have demonstrated a normal size and number of muscle cells, but demonstrated an increase in elastin and collagen deposition between the muscle cells in the taeniae.

Clinically, most patients with diverticulosis remain asymptomatic throughout their lifetime, and many cases go undetected. On the other hand, diverticular disease is defined as symptomatic diverticulosis due to diverticular bleeding, diverticulitis, segmental colitis associated with diverticula, or symptomatic uncomplicated diverticular disease. Diverticular bleeding is characterized by painless hematochezia due to segmental weakness of the vasa recta associated with a diverticulum. Diverticulitis is defined as inflammation of a diverticulum that may be acute or chronic and uncomplicated or complicated by a diverticular abscess, fistula, bowel obstruction, or free perforation. Segmental colitis associated with diverticula or diverticular colitis is characterized by inflammation in the mucosa without involvement of the diverticular orifices. Symptomatic uncomplicated diverticular disease is characterized by persistent abdominal pain attributed to diverticula in the absence of macroscopically overt colitis or diverticulitis.

The diagnosis is based on clinical history and physical examination and aided by the use of laboratory workup, imaging, and endoscopic tools. Acute diverticulitis should be suspected in patients with lower abdominal pain and abdominal tenderness on physical examination, keeping in mind other causes like appendicitis, ischemic or infectious colitis, inflammatory bowel disease, and neoplasia.

Patients with acute diverticulitis can present with uncomplicated or complicated disease. The management of uncomplicated diverticulitis includes outpatient treatment with an oral antibiotic aiming at Gram-negative rods and anaerobe coverage, dietary modifications including a clear diet for 2–3 days, high-fiber intake and avoiding nuts and seeds, and if possible the use of topical anti-inflammatory medications. Generally, the elderly, immunosuppressed, patients with significant comorbidities, and patients with high fever or significant leukocytosis should be hospitalized. The treatment of acute complicated diverticulitis is based upon the specific complication: bleeding, perforation, obstruction, peritonitis, abscess, or fistula formation. Management involves hospitalization, bowel rest, and intravenous hydration and empiric antibiotics. Failed medical management and recurrent episodes of acute diverticulitis are indications for operative management.

Colonic Inflammation (Colitis)

Inflammatory bowel disease is discussed in a separate article.

Infectious Colitis

Infectious colitis or infectious diarrhea is a lethal but preventable problem that poses a significant health and economic burden. The majority of deaths occur in developing countries where sources of clean water and adequate sanitation amenities are not readily available. In addition, these are regions where the prevalence of malnourishment is high. In developing countries, most of the cases occur in travelers or secondary to outbreaks from food and water contamination. In these circumstances, mortality is rare and generally occurs in immunocompromised patients. Clinically, inflammation of the infected colon results in frequent, small-volume bowel movements, which may contain mucous and blood. Other presenting symptoms include fever, dyschezia, and tenesmus. Onset is often times acute, but can have a chronic duration. Treatment is frequently guided according to the identified pathogen. A description of the most common microorganisms responsible for infectious colitis is shown in Table 1. A detailed depiction of specific pathogens is described elsewhere.

Table 1 Common pathogens associated with infectious colitis

	Risk factor	*Symptoms*	*Diagnosis*	*Treatment*	*Complications*
Bacteria					
Campylobacter jejuni	Foreign travel	Fever; malaise; abdominal pain; diarrhea; hematochezia	Stool culture	Ciprofloxacin	Guillain–Barré; cystitis; pancreatitis; reactive arthritis; toxic megacolon; postinfectious IBS
Clostridium difficile	Antibiotic use; hospitalization	Diarrhea; fulminant colitis; asymptomatic carrier	Selective anaerobic stool culture; toxin immunoassay; PCR; cell culture cytotoxicity assay	First-line outpatient: metronidazole. First-line hospitalized: metronidazole, vancomycin	Ileus; toxic megacolon; postinfectious IBS; protein-losing enteropathy
Escherichia coli O157:H7	Contaminated food	Hematochezia; abdominal pain; fever	Toxin assay	Supportive care	HUS; ischemic colitis; TTP; toxic megacolon
Salmonella typhimurium	Contaminated food; foreign travel	Fever; abdominal pain; diarrhea; weight loss; hematochezia	Stool, blood, and urine culture	Ciprofloxacin; penicillin; quinolones; supportive care	HUS; toxic megacolon
Shigella spp.	Travel to endemic area	Fever; abdominal pain; diarrhea; tenesmus; hematochezia	Stool culture; PCR; DNA probe; serology	TMP/SMX; third-generation cephalosporins, fluoroquinolones; nalidixic acid; supportive care	HUS; appendicitis; erythema nodosum; meningitis; postinfectious IBS; toxic megacolon; protein-losing enteropathy; TTP; perforation
Yersinia spp.	Cold climate; winter months; contaminated food/water; undercooked pork	Abdominal pain; hematochezia	Stool culture; serology	Aminoglycosides; TMP/SMX; supportive care	Erythema nodosum; exudative pharyngitis; glomerulonephritis; carditis; polyarthritis; reactive arthritis; sepsis; perforation; appendicitis; toxic megacolon
Virus					
Adenovirus	AIDS; immunosuppression	Diarrhea	Viral culture; immunohistochemistry	Supportive	
Cytomegalovirus	IBD; immunosuppression	Nonspecific	Urine culture; immunohistochemistry; PCR	Ganciclovir; valganciclovir	

(*Continued*)

Table 1 (Continued)

	Risk factor	*Symptoms*	*Diagnosis*	*Treatment*	*Complications*
Herpes simplex virus	Anal intercourse; immunosuppression	Anorectal discharge; nonspecific	Intranuclear inclusion bodies on biopsy; PCR; immunohistochemistry; antibody in formalin-fixed tissue	Acyclovir; valacyclovir; famciclovir	
Protozoa					
Balantidium coli	Food/water contamination with pig excrement	Nonspecific	Identification of stool cyst, precyst, or trophozoites; trophozoites in muscle biopsy	Tetracycline; iodoquinol	Perforation; peritonitis
Cryptosporidium spp.	Public swimming pools; HIV; malnourishment; age <2 years	Chronic diarrhea	Microscopic stool analysis	Paromomycin; metronidazole; nitazoxanide	
Entamoeba histolytica	Foreign travel; pregnancy; malnourishment; immunosuppression	Diarrhea	Identification of stool trophozoites	Metronidazole and iodoquinol; paromomycin; nitazoxanide	Perforation; appendicitis; strictures; abscesses
Parasite					
Strongyloides stercoralis	Living in endemic areas	Hematochezia	Microscopic stool analysis; serology; biopsy	Thiabendazole	Perforation; emphysematous gastritis; appendicitis
Trichuris trichiura	Living in endemic areas (tropic/subtropics)	Diarrhea; abdominal pain; tenesmus; weight loss	Identification of eggs in stool	Mebendazole	Rectal prolapse; neurotoxicity

AIDS, acquired immunodeficiency syndrome; DNA, deoxyribonucleic acid; HIV, human immunodeficiency virus; HUS, hemolytic uremic syndrome; IBD, inflammatory bowel disease; IBS, irritable bowel syndrome; PCR, polymerase chain reaction; SMX, sulfamethoxazole; TMP, trimethoprim; TTP, thrombotic thrombocytopenic purpura.

Drug-Induced Colitis

Certain medications are often associated with gastrointestinal adverse effects ranging from nausea to severe colitis. Many medications are known to cause colitis and only a few will be discussed in this section.

Chemotherapy and radiation for underlying neoplastic conditions are well-known causes of neutropenia. In this setting, neutropenic colitis, necrotizing enteropathy, or typhlitis can occur. This is a serious condition clinically manifested as severe right lower quadrant abdominal pain and bloody diarrhea. Fever is indicative of sepsis, intestinal perforation, and peritonitis. The pathology of the affected colonic segment features transmural edema, mucosal inflammation, ulcerations, denuded epithelium, hemorrhage, and necrosis. Treatment includes supportive care in the intensive care unit, intravenous fluids and antibiotics, and surgical resection if indicated.

Drug-induced hypomotility is associated with the use of opioids, tricyclic antidepressants, and anticholinergic medications. The use of vincristine is associated with paralytic ileus. Intestinal hypomotility leads to luminal stasis and bacterial overgrowth.

Nonsteroidal anti-inflammatory drug-induced colitis has a clinical presentation similar to inflammatory bowel disease, presenting with generalized abdominal pain and diarrhea. The use of these drugs is also associated with the development of strictures and ulcerations, particularly in the right colon. Mucosal healing and symptom relief is usually seen after discontinuing the offending drug.

Alosetron, a serotonin receptor antagonist, is associated with the development of ischemic colitis (see the succeeding text). Dihydroergotamine is also associated with ischemic colitis secondary to prolonged vasoconstriction.

Chemical Colitis

Several agents are well-known causes of colonic inflammation. The type of damage is thought to occur from a hypertonic or direct toxic effect over the mucosa. The severity of damage is related to the concentration of the substance, the duration of exposure, and the presence of an underlying colonic disease. The classic example is the use of detergents or soaps for enemas. Other implicated substances include acetic acid, lye, hydrogen peroxide, water-soluble contrast agents, formalin, alcohol, vinegar, and glutaraldehyde. Soaps are alkaline agents that produce liquefactive necrosis, inflammation that ranges from mild to severe, as well as saponification of the colon. Damage from water-soluble contrast agents, mainly in the proximal colon, is thought to be secondary to its hypertonicity. Acute inflammation can be self-resolving without permanent damage. However, scarring, fibrosis, transmural inflammation, and perforation have been reported. Treatment is mainly supportive with intravenous fluids and antibiotics. Surgery is indicated in severe cases of extensive necrosis.

Ischemic Colitis

Intestinal ischemia is caused by a reduction in blood flow, which can be related to acute arterial embolic/thrombotic occlusion, venous thrombosis, or hypoperfusion of the

mesenteric vasculature causing nonocclusive ischemia. Colonic ischemia is a common disorder of the large bowel in the elderly and is the most common form of intestinal ischemic injury. The reason why the colon is more vulnerable to injury is because it receives less blood flow compared to the rest of the gastrointestinal tract. Perfusion to the colon can be compromised by changes in the systemic circulation or by anatomic or functional changes in the local mesenteric vasculature. The three main mechanisms responsible for colonic ischemia are as follows:

1. Nonocclusive ischemia: this is the most common cause comprising ~95% of the cases. This type of ischemia tends to affect the 'watershed' areas of the colon that include the splenic flexure and rectosigmoid colon.
2. Embolic and thrombotic ischemia: this is either from spontaneous emboli from proximal sources or from aortic instrumentation.
3. Mesenteric vein thrombosis: this is a rare cause of colonic ischemia, but when involved, it tends to affect the proximal colon.

The injury to the colon following an ischemic event is due to hypoxia and damage from reperfusion. The hypoxic component causes rapid injury over the colonic mucosal surface. Irreversible damage results from transmural necrosis and complete injury to the tissue. Reperfusion injury usually takes place in the setting of partial ischemia and it is secondary to the release of free oxygen radicals that promote further injury.

Patients with acute colonic ischemia present with a history of abdominal pain and tenderness of rapid onset, usually over the left lower quadrant, as well as increased urgency to defecate. Hematochezia is usually present within 24 h after the onset of pain. Laboratory work results suggestive of ischemia are leukocytosis, decreasing hemoglobin levels, and metabolic acidosis. Plain abdominal films are usually nonspecific, but the 'thumbprint' sign can be seen. Abdominal computed tomography is commonly the first test ordered. The typical finding of thickening of the bowel wall in a segmental pattern is suggestive but not specific for ischemia. The finding of hepatic portal venous gas, although rare, is associated with extensive bowel necrosis and predicts a high risk of mortality. Colonoscopy is another test modality that should be performed early and with minimal insufflation. Colonoscopy findings in the acute setting frequently include pale mucosa with petechial bleeding. Bluish hemorrhagic nodules may be seen representing submucosal bleeding; these are the equivalent to the 'thumbprint' sign detected on radiological studies. Ulcerations and cyanotic mucosa are indicative of chronicity. Arteriography is rarely helpful in the diagnosis of colonic ischemia. It is not always readily available, and patients with nonocclusive colonic ischemia are often markedly dehydrated and acidotic; therefore, if used, it should be after careful fluid resuscitation.

Supportive care including bowel rest, intravenous fluids, and continuous monitoring is the initial therapy in patients with colonic ischemia. Although there is no strong evidence for the use of antibiotics, they are recommended in cases of moderate to severe ischemia. Anticoagulant therapy is indicated for patients who develop ischemia due to mesenteric venous thrombosis or due to cardiac embolization. Urgent abdominal surgical exploration is required in patients with colonic infarction and necrosis followed by postoperative hemodynamic support and observation in the intensive care unit.

Microscopic Colitis

Microscopic colitis is an uncommon chronic inflammatory disease of the colon clinically manifested as chronic watery diarrhea, histological changes of chronic mucosal inflammation, and normal colonoscopy findings. Microscopic colitis is classified into two subtypes according to their microscopic findings:

1. Lymphocytic colitis: intraepithelial lymphocyte count >20 per high-power field
2. Collagenous colitis: colonic subepithelial collagen band >10 μm in thickness

The two subtypes are more common in patients aged 50–70, but cases have been reported in children and adolescents. Both also have a female predilection. Associated conditions include celiac disease, arthritis, and other autoimmune disorders like autoimmune thyroiditis and type 1 diabetes mellitus. Medications implicated as causative agents or triggers include nonsteroidal anti-inflammatory drugs. Smoking may play a role in the development of microscopic colitis due to its effect on colonic blood flow. The pathogenesis of microscopic colitis is unclear; however, it is likely to be multifactorial, involving mucosal immune responses to luminal factors in a genetically predisposed individual. Although both subtypes have a similar inflammatory cell response, it is uncertain whether they are related. Abnormal collagen metabolism leading to increased deposition and a defect in epithelial barrier function predisposing to increased intestinal permeability have been proposed as possible pathogenic explanations for collagenous and lymphocytic colitis, respectively.

Clinically, patients with microscopic colitis present with a history of chronic, watery, nonbloody diarrhea. Onset is often insidious. Bowel movement volume and frequency tend to decrease with fasting. Other symptoms include abdominal pain, urgency, incontinence, weight loss, and dehydration. Extraintestinal manifestations, like uveitis and arthralgia, can be encountered. Physical examination is usually unremarkable and routine laboratory studies are also normal. Colonoscopy examination is usually normal. Nonspecific abnormalities including patchy edema, erythema, friability, and an abnormal vascular pattern have been reported, whereas mucosal ulcerations in the ascending and transverse colons have been reported in a few patients with collagenous colitis.

Treatment is largely empiric. Evaluation of therapy is difficult, because both disorders usually exhibit a relapsing and remitting course over many years. No single agent works in all cases. Antidiarrheal agents like loperamide or bulking agents like psyllium and methylcellulose are associated with clinical improvement, but not histological remission. Other medications like 5-aminosalicylate, glucocorticoids, and bile acid resins, alone or in combination, improve diarrhea and inflammation in some patients. Trial with a 6–8 week course of budesonide has shown good results in patients with collagenous colitis. Ileostomy should be considered only as a last resort, but it appears to be effective in patients with disabling and refractory symptoms.

Diversion Colitis

Diversion colitis is an inflammatory process that occurs in the diverted segment of the colon and rectum after surgical diversion of the fecal stream. Although it has been reported to occur more commonly in patients with inflammatory bowel disease, diversion colitis has been found in patients who have undergone surgical diversion for many indications. The prevalence of diversion colitis is unknown and probably underestimated since a proportion of patients with histological changes of the diverted segment are asymptomatic.

The pathogenesis of diversion colitis is related largely to lumen nutrient deficiency in the form of short-chain fatty acids. Other luminal elements besides short-chain fatty acid deficiency are likely to play a role, but the nature of such factors is unknown.

The diagnosis is based on clinical history and endoscopic findings of erythema, friability, nodularity, edema, aphthous ulcerations, exudates, and frank bleeding. Histological findings range from lymphoid follicular hyperplasia and mixed mononuclear and neutrophilic infiltration to severe inflammation with crypt abscesses, mucin granulomas, and Paneth cell metaplasia. Crypt architecture tends to be preserved. Caution must be taken in patients with recurrent inflammatory bowel disease and *Clostridium difficile* infection should be ruled out.

The treatment of choice is restoration of colonic continuity that reverses symptoms and histological changes. If reanastomosis is not feasible and symptoms are moderate to severe, short-chain fatty acid enema with propionate, acetate, and butyrate mixed in a saline solution has been described as a treatment option.

Colonic Neuropathies: Hirschsprung's Disease

Hirschsprung's disease (HD) is an intestinal motor disorder that results from the congenital absence of ganglion cells in the rectum and distal colon. As a consequence, the affected aganglionic segment lacks receptive relaxation resulting in a functional obstruction clinically manifested as constipation.

The incidence of HD is ~1 in 5000 live births. The overall male to female ratio is of 4 to 1, although it can be nearly 1 to 1 when the entire colon is involved. In ~85% of the cases, the aganglionic segment is limited to the rectum and distal colon; in other cases, longer segments can be affected, and in 5%, the entire colon is affected, including the distal ileum.

HD results from a defect in the craniocaudal migration of neural crest cells during the first 12 weeks of migration. In addition, defective differentiation of neuroblasts into ganglion cells and accelerated ganglion cell destruction may also play a part. The etiology of HD also has a genetic basis. Hereditary patterns are not straightforward and at least eight genetic mutations have been identified. The predominantly affected gene is the RET proto-oncogene, accounting for nearly 50% of familial and 20% of sporadic cases with long-segment disease. Other involved genes include Down's syndrome cell adhesion molecule, endothelin 3, endothelin receptor type B, endothelin-converting enzyme, SOX10, PHOX2B, and the neuregulin genes.

Up to one-third of patients with HD suffer other syndromes or congenital anomalies. Down's syndrome affects up to 2–3% of patients with HD. Other monogenic syndromes include multiple endocrine neoplasia type 2, congenital central hypoventilation syndrome, cartilage–hair hypoplasia, Mowat–Wilson syndrome, Waardenburg syndrome type 4, Smith–Lemli–Opitz syndrome, and Bardet–Biedl syndrome. Approximately 20–25% of patients with HD have associated congenital anomalies that involve the heart, kidney, or urinary tract.

HD is usually diagnosed during the neonatal period in patients with symptoms of distal intestinal obstruction, but can present at any age. Delayed passage of meconium passed the first 48 h of life should raise the suspicion of HD. Abdominal distention, feeding intolerance, bilious emesis, and explosive expulsion of gas and stool after digital rectal exam are other clinical presentations in infants with HD. Some infants with HD may have normal stooling initially, especially if they are breast-fed, and then develop severe constipation when other foods are introduced into the diet. A life-threatening presentation is HD-associated enterocolitis, a severe diarrheal illness that requires a high index of suspicion and prompt management with aggressive fluid resuscitation, intravenous antibiotic anaerobic coverage, and rectal irrigations. In extreme cases, a diverting colostomy may be indicated. Older children with less severe disease may present with a chronic history of intractable constipation, abdominal distention, or failure to thrive. Interestingly, there appears to be no correlation between the severity of symptoms and the length of aganglionic segment.

The diagnostic steps depend on the level of suspicion for HD. Abdominal radiographs may show signs of distal intestinal obstruction. A contrast enema with barium may reveal a more dilated colon proximal to a narrower distal aganglionic colon. This radiological finding is called a 'transition zone' and it may not be evident in patients with long-segment HD. If not clearly identified, a postevacuation film 24 h later may reveal residual barium in the colon. Anorectal manometry is a useful screening test if performed by experienced personnel. The presence of internal anal sphincter relaxation, or rectoanal inhibitory reflex, with balloon distention excludes the diagnosis of HD. To confirm the diagnosis, a rectal biopsy should be done, safely using a mucosal suction technique. If tissue sample is inadequate, then a repeat full-thickness biopsy under anesthesia is warranted. The diagnosis is confirmed if submucosal ganglion cells are absent on light microscopy. Hypertrophied nerve trunks, positive acetylcholinesterase, and negative calretinin immunostains are supportive histopathologic findings.

Treatment is aimed at resecting the affected aganglionic segment, the creation of a neorectum in close proximity with the anus, and preserve sphincter function. Several surgical techniques have been developed over time and are performed in different stages. The decision depends on experience and clinical characteristics of the patient. Currently, the majority of cases are done over one stage with an operation known as the Soave endorectal pull-through.

The majority of patients usually do well after surgical correction having normal to near normal anorectal function and have a good quality of life. However, some bowel function abnormalities are commonly encountered. Constipation or intermittent obstructive symptoms can be caused by mechanical obstruction, residual aganglionosis, or increased internal anal sphincter pressure. Fecal incontinence is usually encountered after surgery. However, continence tends to improve with

age. Finally, despite surgical repair, patients are still at risk for developing HD-associated enterocolitis. Risk factors include the presence of a mechanical obstruction like an anastomotic stricture and patients with long-segment disease, suggesting that intestinal stasis may be a predisposing factor.

Structure

Embryology

During embryogenesis, the mature intestine develops from all three germ layers: the endoderm that gives rise to the simple columnar epithelial cell lining of the surface of the small and large intestines, the mesoderm from which cells of the lamina propria and muscularis layers originate, and the ectoderm that gives rise to the enteric neurons and other components of the enteric nervous system.

The primitive gut develops around the fourth week of gestation from the primitive yolk sac, which is further divided into three parts: foregut, midgut, and hindgut. The embryological origin of the colon is dual. The midgut gives rise to the appendix, cecum, ascending colon, and proximal two-thirds of the transverse colon. The distal third of the transverse colon, the descending colon and sigmoid colon, the rectum, and the upper portion of the anal canal originate from the hindgut. The distal hindgut further divides into a ventral component that becomes the urogenital sinus and a dorsal component that forms the lower portion of the anal canal.

During the fifth week of gestation, the midgut rapidly elongates with the formation of the primary intestinal loop. The cecum originates as a small dilation of the caudal limb of the primary intestinal loop by the sixth week of gestation. It initially lies in the right upper quadrant and then descends to the right iliac fossa, placing the ascending colon and hepatic flexure in the right side of the abdominal cavity. The appendix originates from the distal end of the cecal bud, and its final position is frequently retrocecal or retrocolonic. When the caudal limb of the primitive intestine moves to the right side of the abdominal cavity, the dorsal mesentery twists around the origin of the superior mesenteric artery. After the ascending and the descending portions of the colon reach their final destinations, their mesenteries fuse with the peritoneum of the posterior abdominal wall, and they become retroperitoneal organs. The appendix, cecum, and descending colon retain their free mesentery. The transverse colon fuses with the posterior wall of the greater omentum.

Anatomy

Macroscopic features

The colon is a tubular structure that is continuous with the small intestine proximally at the ileocecal valve and ends distally at the anal verge. In the full-term newborn, the colon is ~30–40 cm in length, increasing approximately to 150 cm in adults. The caliber is greatest in the cecum and gradually diminishes as it reaches the rectum. The appearance of the colon differs from the small intestine in several ways. The outer longitudinal muscle fibers of the colon coalesce into three distinct bands termed taeniae coli that extend continuously from the base of the appendix to the rectum. The haustra are outpouchings of the colon that give it a characteristic sacculated appearance. The plicae semilunares are intermittent creases that are visualized as irregular folds over the luminal surface of the colon. In addition, small sacs of peritoneum filled with adipose tissue, the appendices epiploicae, are found on certain areas of the external surface of the colon.

The colon, as the small intestine, is enclosed by the mesentery. However, most of the colon is fixated in a retroperitoneal fashion, and only a small portion is suspended by mesentery. The transverse colon and sigmoid colon are suspended by mesentery. A small portion of mesentery termed mesocecum fixes the mobility of the cecum. The ascending colon, descending colon, and rectum are partially covered by mesentery on their anterior surfaces.

The cecum is the most proximal part of the colon. It lies in the right iliac fossa and projects downward as a blind pouch below the entrance of the ileum and projects superiorly to the ascending colon. It is a saclike structure ~6 cm long and 8 cm wide in adults. The vermiform appendix is a blind, narrow, elongated outpouching of the cecum, and its lumen is found ~2.5 cm inferior to the ileocecal valve. Its length varies from 2 to 20 cm, being longest during childhood.

The ascending colon extends from the cecum in a distal manner toward the posterior lobe of the liver where it makes a sharp turn and forms the hepatic flexure. It is covered in peritoneum; therefore, it is a retroperitoneal organ. The diameter of the ascending colon is narrower than the cecum, and its length reaches ~20 cm in adults.

At the hepatic flexure, the colon emerges medially and anteriorly into the peritoneum as the transverse colon. Distally, it curves acutely and inferior to the lower pole of the spleen, forming the splenic flexure. The transverse colon is the longest segment of the colon with measured lengths from 40 to 50 cm. It lies anteriorly to the stomach and small intestine. It is completely covered in mesentery termed the transverse mesocolon. It is the most mobile segment of the colon; in fact, it can lie at the level of the pelvis when a person assumes an upright position.

The descending colon, about 25–45 cm in length, arises distal to the splenic flexure. It travels downward and posteriorly and assumes a retroperitoneal position ending at the level of the left iliac crest.

Distally, the descending colon emerges at the pelvic brim from a retroperitoneal position as the sigmoid colon. This is an S-shaped segment of the colon that varies in length and is very tortuous and mobile. It is suspended by mesentery termed sigmoid mesocolon that shortens and disappears as it reaches the rectosigmoid junction.

The rectum extends distal to the sigmoid colon at the level of the third sacral vertebrae toward the anal canal, 2–3 cm in front and below the coccyx. In adults, the rectum measures 10–12 cm in length. It lies below the peritoneum and in close proximity to the pelvic structures.

The anal canal is ~5 cm in length in the adult and has a discrete upper and lower demarcation. The anorectal ring is located proximally and is composed of the upper portion of the internal anal sphincter, the longitudinal muscle of the rectum, the deep portion of the external sphincter, and the puborectalis portion of the levator ani muscle. Distally, the anal verge represents the transition of anoderm to true skin. The mucosa of the distal 3 cm of the rectum and the anal canal contains 6–12 redundant longitudinal folds called the columns of Morgagni. These columns are joined together by mucosal folds called the anal valves, which are situated at the dentate line. The muscularis mucosae disappears in the anorectal canal, and the inner circular coat of muscularis propria thickens to form the internal anal sphincter. The external anal sphincter surrounds the anal canal, and its fibers blend with those of the levator ani muscle to attach posteriorly to the coccyx and anteriorly to the perineal body.

Vascular supply

The superior mesenteric artery, a direct branch of the abdominal aorta, supplies oxygenated blood to the cecum, ascending colon, and proximal two-thirds of the transverse colon. The inferior mesenteric artery, also a branch of the abdominal aorta, supplies the distal third of the transverse colon, the descending colon and sigmoid colon, and the superior portion of the rectum as the superior hemorrhoidal artery. The middle and inferior hemorrhoidal arteries, which are branches of the hypogastric and internal pudendal arteries, respectively, supply the rest of the rectum and anal canal.

The superior and inferior mesenteric veins drain the same regions of the large intestine supplied by the corresponding arteries. The venous system of the anal region drains into the systemic and portal systems. The internal hemorrhoidal plexus drains the proximal anal region into the superior rectal veins and then into the inferior mesenteric vein, which then, together with the superior mesenteric vein, joins the splenic vein to form the portal vein. The external hemorrhoidal plexus drains the distal anal region through the middle rectal and pudendal veins into the internal iliac vein.

Lymphatic drainage

The lymphatic drainage of the large intestine follows their respective blood supply, first draining to the pericolic nodes, intermediate nodes, and ultimately preaortic nodes that surround the superior and inferior mesenteric arteries. The rectum and anal canal drain into the perirectal nodes, which then further drain into the iliac and inferior mesenteric nodes.

Innervation

The innervation of the large intestine, as well as the rest of the gastrointestinal tract, comes from the intrinsic nervous system and the extrinsic nervous system. The enteric nervous system constitutes the intrinsic nervous system of the gastrointestinal tract. It is derived from the neural crest cells and consists essentially of an equal to the 100 million neurons in the spinal cord. The nerve cell bodies of the enteric nervous system are located in different plexuses of the gastrointestinal wall, mainly in the submucosa and muscularis externa. The sympathetic and parasympathetic nerves constitute the extrinsic nerve supply. The proximal colon receives its sympathetic neuronal innervation from the celiac and superior mesenteric ganglia. The parasympathetic innervation comes from the vagus nerve. In the distal colon, the sympathetic innervation comes from the branches of the lumbar segment of the sympathetic trunk, whereas the parasympathetic nerves originate from the pelvic splanchnic nerves. The sources of innervation of the internal and external sphincters are different. In the anal canal, the internal anal sphincter receives inhibitory innervation from the intrinsic nervous system and from extrinsic input from the lumbar sympathetic and sacral parasympathetic nerves. The pudendal nerve innervates the external anal sphincter and other pelvic floor muscles.

Microscopic features

In general, the intestinal wall of the gastrointestinal tract is composed of the following four layers:

1. Mucosa
2. Submucosa
3. Muscularis externa
4. Serosa

Mucosa

The mucosa is the innermost layer of the colon. It is further subdivided into three distinct sublayers: the glandular epithelium, lamina propria, and muscularis mucosae, the outermost sublayer. Compared with the small intestine, the mucosa of the colon lacks villi. However, the glandular epithelium does contain crypts of Lieberkühn that extend down through the lamina propria to the muscularis mucosae. The glandular epithelium is composed of the following several cell types:

- Stem cells are pluripotential cells located at the base of the intestinal crypts. These cells give rise to all types of mature intestinal epithelial cells and additional stem cells to maintain their numbers. Cell differentiation is regulated by different signaling pathways (Wingless, Notch, bone morphogenetic protein, and Hedgehog) between epithelial cells and cells in the lamina propria. In the colon, terminal differentiation occurs in the upper one-third of the crypt, and most cells migrate onto the mucosal surface. On the surface of the colon, older cells are extruded to the intestinal lumen by a process termed anoikis and expelled out of the body by defecation.
- Absorptive cells, generally called enterocytes, are high columnar cells located at the base near the lamina propria. They have oval basal nuclei, an eosinophilic cytoplasm, and a periodic acid–Schiff-positive free surface. Enterocytes are composed of superficial microvilli that are more numerous on the small intestine compared with the colon and contain membrane-bound digestive proteins, transport proteins, and other cellular elements necessary for nutrient absorption. In the colon, absorptive cells are termed principal cells.
- Goblet cells are mucin-producing cells located in the crypts characterized by a narrow base and oval apical surface, flattened basal nucleus, and basophilic cytoplasm with mucin-containing granules. They are much larger in number in the colon compared with the small intestine. The ample amount of mucin produced by goblet cells in the

colon provides lubrication for adequate stool passage. Goblet cells also provide a protective barrier against shear stress. This same barrier is thought to bind surface antigens and inhibit their attachment to the epithelial surfaces.

- Paneth cells are pyramid-shaped cells located exclusively at the base of the crypts. They have a basal nucleus and a cytoplasm rich in eosinophilic granules. Their primary function is to secrete antimicrobial products conferring protection from enteric infection and contributing to the maintenance of the gastrointestinal antimicrobial barrier. In response to luminal bacteria and bacterial antigens, they secrete different substances like phospholipase A2, lysozyme, and α-defensins, the latter being the principal antimicrobial molecule secreted by Paneth cells.
- Enteroendocrine cells, also known as gut endocrine or neuroendocrine cells, are specialized, tall, columnar cells located in the crypts of the colon. They have a large nucleus and prominent cytoplasmic secretory granules, distributed mainly in the basal region of the cell. The enteroendocrine lineage consists of at least 15 different cell types that are categorized based on their morphology, specific regional distribution, and peptide hormone expression.

The lamina propria is a thin layer of connective tissue that provides support to the mucosal epithelial cell basement membrane. In the colon, the lamina propria contains solitary lymphoid follicles that extend to the submucosa, being more developed in the rectum. Furthermore, the lamina propria is rich in arterioles, veins, lacteals, and nerve fibrils and various cell types, including fibroblasts, lymphocytes, macrophages, eosinophils, mast cells, and neutrophils.

The muscularis mucosae is the outermost layer of the mucosa. It lies next to the submucosa and consists of an inner circular layer and outer longitudinal layer of smooth muscle cells (~3–10 cells thick). The colonic muscularis mucosae is thicker when compared with the small intestine, and the thickness increases progressively from the cecum to the anal canal.

Submucosa

The submucosa, located between the outermost layer of the mucosa and the muscularis externa, is made of connective tissue and several different cell types that include fibroblasts, lymphocytes, eosinophils, macrophages, plasma cells, and mast cells. The submucosa has a rich vascular supply and lymphatic drainage, and, because of its close proximity to the mucosa, it supports its electrolyte, fluid, and nutrient absorption. The enteric nervous system nerve cell bodies are located in the submucosal plexus, which is divided into two networks, Meissner's plexus, which lies closer to the mucosa, and Schabadasch's plexus, which lies adjacent to the inner circular muscle.

Muscularis externa

The muscularis externa is composed of smooth muscle cells arranged in two distinct layers: the outer longitudinal layer and the inner circular layer. As mentioned earlier, the outer longitudinal layer fibers form the taeniae coli, which run in parallel to the long axis of the colon throughout its entire length. Within the two smooth muscle layers, there is a nerve fiber plexus of ganglionated cells, termed Auerbach's plexus, that also forms part of the enteric nervous system.

It is important to mention a specific group of cells, the interstitial cells of Cajal, that are involved in the coordinated activity between the enteric nervous system, autonomic nervous system, and smooth muscle cells that direct gastrointestinal motility. The interstitial cells of Cajal are modified smooth muscle cells and are regarded as the pacemaker cells of the gastrointestinal tract. These cells form networks that are widely distributed within the submucosal, intramuscular, and intermuscular layers. Contractions of gastrointestinal smooth muscle are initiated by these specialized pacemaker cells. Propagation of contractions occurs as waves of membrane depolarization spread via gap junctions between adjacent smooth muscle cells.

Serosa

The serosa, an extension of the visceral peritoneum, is the outermost layer of the colon. It is formed by a layer of mesothelial cells supported by connective tissue or adventitia. Occasionally, scattered different cell types are found within the serosa like macrophages, fibroblasts, and mast cells.

Functions

Water and Electrolyte Transport

The colon plays an integral role in intestinal homeostasis by regulating the balance between water and electrolyte absorption and secretion. In general, colonic epithelial cells are primarily responsible for absorption, and the crypt cells are involved in both absorption and secretion.

The colon is a very efficient water-preserving organ. Normally, the colon receives between 1000 and 1500 ml of water daily. Approximately 90% of this volume is reabsorbed by the colon, and 100–150 ml is excreted in the feces. Passive diffusion along an osmotic sodium luminal gradient is the main mechanism in which water is transported along the colon via paracellular pathways. However, the transmembrane protein channels, termed aquaporins, also play a role in the transcellular movement of water. Of the colonic segments, the ascending colon has the greatest absorptive capability because of its longer exposure time to the large volume of small intestinal fluid.

Under normal conditions, the colon reabsorbs sodium and chloride and secretes potassium and bicarbonate. The recovery of sodium is one of the main functions of the colon. Approximately 130–140 mmol l^{-1} of sodium is delivered daily to the colon, and only 40 mmol l^{-1} is excreted in the stool. Under certain circumstances, the colon is able to salvage up to 800 mmol l^{-1} day^{-1}, preventing hyponatremia. Throughout the colon, the mechanism by which sodium is reabsorbed varies. The proximal colon exhibits sodium/hydrogen exchanger channels located in the apical surface of the epithelial cells. These channels are coupled with a chloride/bicarbonate exchanger channel. The distal colon and rectum have electrogenic sodium-specific channels. Both types of transport channels allow the passive diffusion of sodium along an electrochemical gradient. Once inside the cell, sodium is then exchanged for potassium via an energy-dependent pump on

the basolateral membrane of the epithelial cell. Aldosterone, short-chain fatty acids, α2 adrenergic agents, and somatostatin further enhance the absorption of sodium.

Chloride is also recovered from the colon. As mentioned earlier, the proximal colon has chloride/bicarbonate exchange channels that absorb chloride and secrete bicarbonate. The acidic environment of the colon enhances the absorption of chloride, and the secretion of bicarbonate is responsible for the alkaline pH of the feces.

Potassium is passively transported along a sodium gradient. However, potassium is actively secreted in the proximal colon via a transport channel and absorbed in the distal colon via an energy-dependent hydrogen/potassium exchanger. The final concentration of stool potassium is $\sim$50–90 mmol l^{-1}.

Urea entering the colon from the small intestine is metabolized by colonic bacteria and converted to ammonia, which is passively absorbed by the epithelial cells. Other sources of ammonia that is further absorbed come from dietary nitrogen, sloughed cells, and bacteria. Absorbed ammonia reaches the enterohepatic circulation and is delivered to the liver where it is reconverted to urea.

Colon Flora, Nutrient Absorption, and Fermentation

The human colon is one of the most diversely colonized and metabolically active organs in the human body. Up to 1000 different species of bacteria reside in the colon with microbial populations comprising $\sim 10^{11}$–10^{12} colony-forming units per gram of content. The colon provides a favorable environment for bacterial growth due to its slower transit time, readily available nutrients, and favorable pH. Generally, bacteria having an almost exclusive saccharolytic metabolism can be considered potentially beneficial. Such a metabolic profile is typical for lactobacilli and bifidobacteria.

The colonic flora salvages energy via fermentation of undigested carbohydrates that reach the colon. These substances include resistant starches, nonstarch polysaccharides, nondigestible oligosaccharides, and sugar alcohols. The end products of bacterial fermentation – mainly of soluble plant residues – are the short-chain fatty acids butyrate, propionate, and acetate and the formation of odorless gases, including hydrogen, methane, and carbon dioxide. Approximately 90% of these short-chain fatty acids are absorbed by the mucosa in the proximal colon via short-chain fatty acid/bicarbonate transport channels and other electrolyte-coupled transporters. An average of 400 mmol day^{-1} of short-chain fatty acids is produced in the colon, providing 5–15% of the total caloric needs. Although butyrate is the least abundant of the short-chain fatty acids, it acts as the primary energy source for colonic cell health, supplying up to 90% of its energy needs. In addition, butyrate serves as an antidiarrheal agent as it promotes the absorption of water, sodium, and chloride. Propionate and acetate reach the liver via the bloodstream and participate in gluconeogenesis and long-chain fatty acid synthesis, respectively.

The colon is also involved in the metabolism and absorption of other nutrients. Proteins, via fermentation, are converted in the distal colon to short-chain fatty acids, branched-chained fatty acids, amines, ammonia, phenols, indoles, and sulfurs. The human colon cannot absorb long-chain triglycerides. In turn, they bind to luminal calcium making oxalate readily available for absorption. In patients with short bowel syndrome, medium-chain fatty acids from supplements can be absorbed in the remaining colon providing caloric energy. Absorption of calcium is highest in the cecum. Calcium requires solubilization of calcium salts enhanced by the acidic environment of carbohydrate fermentation. In addition, propionate and acetate also enhance the direct absorption of calcium in the colon. Vitamin K, in its K_2 form, comprises a group of bacterial products termed the multiprenyl menaquinones. Vitamin K_2 is passively absorbed in the colon.

Motility of the Colon

The other important function of the colon is the transport of unused material into the rectal area where it can be expelled in a socially acceptable manner during defecation. Although undigested food takes <2 h to reach the colon, it may take as long as 2–5 days for it to be expelled as stool. The propelling function of the colon is accomplished by haustrations (segmental contractions) and mass movement (high-amplitude peristaltic contractions (HAPCs)).

HAPCs are defined as contractions of at least 80–100 mmHg, lasting 10 s and propagating for at least 30 cm (see Figure 1). HAPCs can reach amplitudes >200 mmHg. HAPCs originate in the proximal colon and migrate distally >95% of the time, usually stopping in the distal sigmoid colon.

Food ingestion has an important influence on colonic motility. The response lasts 2–3 h and is mostly composed of segmental contractions, accompanied by an increase in colonic smooth muscle tone and HAPCs, which have been described in pediatric patients. The colonic response to eating is influenced by the caloric content and meal composition. Fat and carbohydrate represent an important stimulant, whereas protein may have an inhibitory effect (Figure 2).

Defecation

Normal defecation is a complex process that involves a sequence of events initiated by the entrance of stool in the rectum. When the rectal wall becomes stretched by stool or gas, the internal anal sphincter relaxes (also known as the rectoanal inhibitory reflex), permitting a small amount of stool to enter the anal canal. An enteric descending inhibitory reflex mediates this process. At the same time, there is a brief contraction of the external anal sphincter, maintaining continence. Extrinsic cholinergic parasympathetic pathways in the pelvic nerves mediate this process. Sensory receptors in the proximal anal canal provide a distinction between solid or liquid stools and gas. The internal anal sphincter has a relaxation of longer duration when the rectal wall is distended by a larger volume, producing a conscious voluntary contraction of the external anal sphincter until the individual decides when it is socially appropriate to evacuate the intraluminal contents. Suppression of the defecation urge and rectal receptive accommodation allows for temporary storage of stool or gas in the rectum or retrograde transport back to the sigmoid colon.

When socially appropriate, an individual may voluntarily relax the external anal sphincter to allow defecation to proceed. Intra-abdominal pressure is elevated to aid in the expulsion

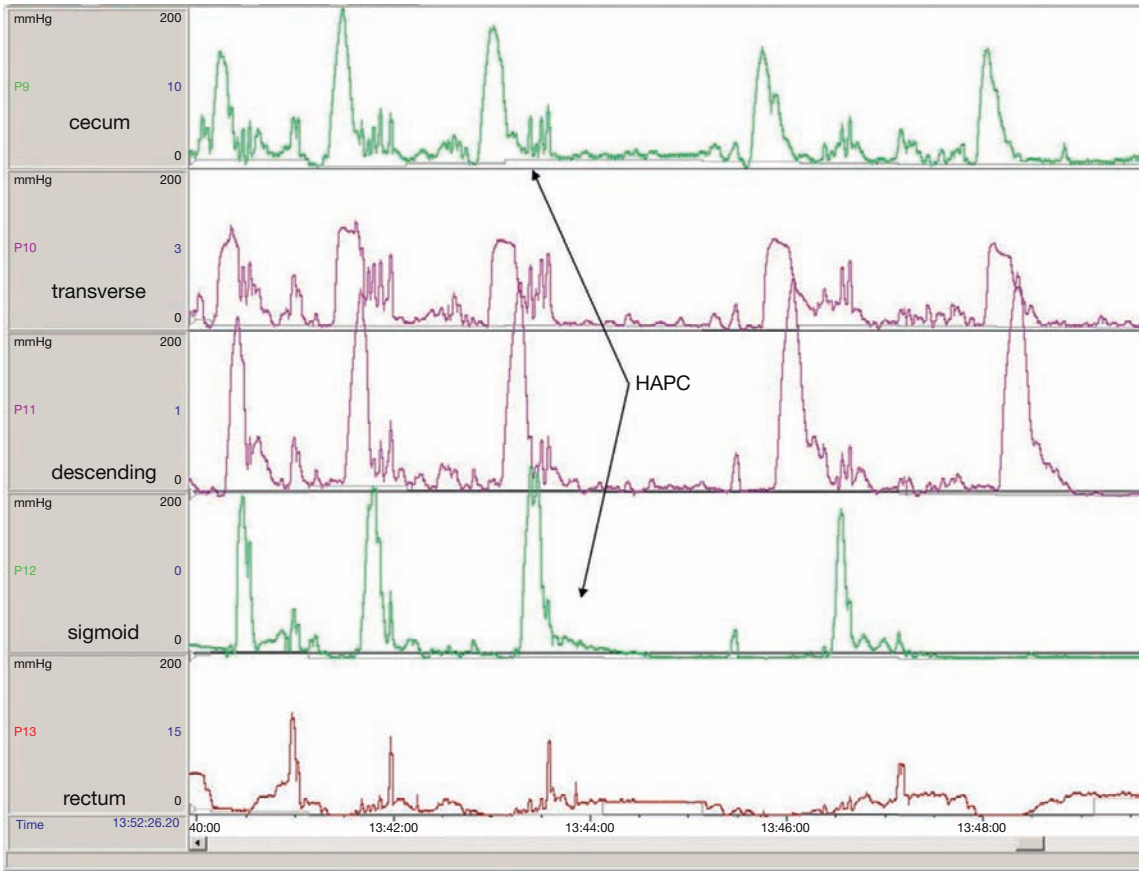

Figure 1 Normal colonic motility. Colonic motility in a child with functional constipation. Note the high-amplitude peristaltic contractions (HAPCs) that resulted after bisacodyl administration. (eds.) *Pediatric gastrointestinal and liver disease* (4th ed.), pp. 686–698. Philadelphia, PA: Elsevier.

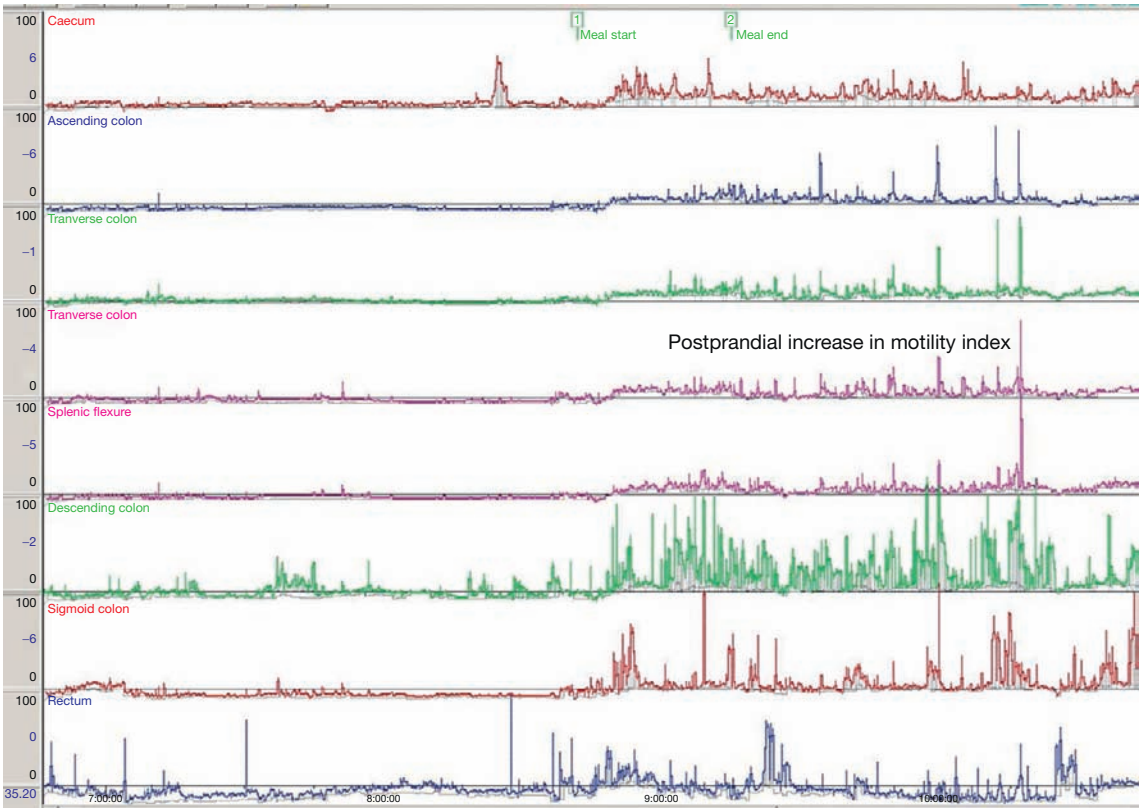

Figure 2 Normal postprandial colonic motility. This colonic motility shows the normal postprandial increase in the motility index. Adapted and modified from Rodriguez, L. and Nurko, S. (2011). Gastrointestinal motility procedures. In: Wyllie, R., et al. (eds.) *Pediatric gastrointestinal and liver disease* (4th ed.), pp. 686–698. Philadelphia, PA: Elsevier.

of feces. Evacuation is usually preceded by a deep breath, which moves the diaphragm downward. The glottis then closes, and contractions of the respiratory muscles on full lungs and abdominal muscles elevate both intrathoracic pressure and intra-abdominal pressure. Both activities serve to increase the anorectal angle, thereby reducing resistance to outflow. At the same time, the puborectalis muscles relax, further increasing the angle, the levator ani muscles contract, the perineum descends further, and stool is expulsed.

Introduction

It is well known that color is one of the first criteria for identification and perception of food quality. This color is provided by pigments, natural in fresh foods and natural or synthetic in manufactured products. Even more, consumers associate food color with safety, quality, and good food processing, a reason why food industries spend high proportion of the product's cost to preserving or adding color.

Food colors or colorants are food additives added in order to make foodstuffs more visually appealing; to restore their original appearance if the visual acceptability has been damaged as a consequence of processing, storage, packaging, and distribution; and/or to add color to those foodstuffs otherwise colorless or colored differently.

Nevertheless, even if color is the obvious property for pigments, it is important to note that these molecules may have other biological properties. Due to this, natural pigments from plants are of growing interest as substitutes for synthetic dyes in the food and pharmaceutical industry, and they increase their added value if they possess positive effects on health. In most countries, the use of food additives (including colorants) is governed by strict regulation. The legislation specifies which colorant may be used, the source, the purity, and to which food and at what level they may be added.

This article reviews the main aspects of natural pigments and food colorants dealing with human health.

Food Natural Pigments

Different food natural pigments can be identified:

- Anthocyanins
- Betalains
- Carotenoids
- Chlorophylls
- Curcumin
- Myoglobin and hemoglobin

Pigments naturally formed during food processing have also been included in this section, as the melanoidins and the *Monascus* pigments (Figure 1).

Anthocyanins

The anthocyanins are part of a widespread group of plant constituents, known as flavonoids. The structure is based on a C15 skeleton consisting of a chromane ring bearing a second aromatic ring B in position two (anthocyanidin). The structure is complemented by one or more sugar molecules bonded at different hydroxylated positions (anthocyanins).

Six anthocyanidins (aglycones) are the most common in nature and consequently used as natural colorants (viz., pelargonidin, peonidin, petunidin, malvidin, cyanidin, and delphinidin).

Regarding their chemical stability, it is important to mention that the color of these pigments is highly affected by pH and four structures exist in equilibrium: the flavylium cation (colored) at low pH, displaced toward the uncolored forms (carbinol pseudobase and chalcone) or the quinoidal form (red/blue) as the pH value increases (Figure 2).

Anthocyanins provide the red to purple or blue color to pome fruits (apples, pears, chokeberries, etc.); stone fruits (apricots, cherries, peaches, and plums); small fruits (currants, strawberries, and all other berries); some tropical fruits (acerolas, lychees, mangos, etc.); other fruits such as grapes, pomegranates, and red oranges; cereals (rice, barley, sorghum, etc.); legumes (e.g., beans); roots, tubers, and bulbs (onions, potatoes, etc.); brassica crops (broccoli, red radish, etc.); and other crops (eggplant, perilla, rhubarb, tamarillo, etc.).

Due to the aforementioned chemical properties, anthocyanins, as food colorants, are used for red fruit drinks, sorbets, water ices, jellies, jams, gums, etc., at pH values below 4.

In recent years, several studies have shown that anthocyanins display a wide range of biological activities, including antioxidant, anti-inflammatory, and antimicrobial, and their consumption is associated with a diminished risk for different types of cancer owing to their antiproliferative, proapoptotic, and antiangiogenic effects. Also, they play an important role in blood vessels, platelets, and lipoprotein, able to reduce the risk of coronary heart diseases. Nevertheless, the absorption and metabolic fate of these pigments are still under study.

Their influence on prevention in visual performance and ocular diseases, their role in skin aging and UV-induced skin damage, and their neuronal and cognitive brain functions have also been reported, being of special interest as they are one of the fewer secondary metabolites able to cross the blood–brain barrier.

Betalains

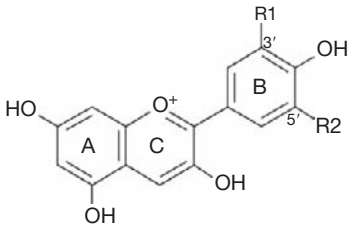
Betalains are water-soluble nitrogen-containing pigments, which provide red-violet (betacyanins) and the yellow (betaxanthins) colors to some fruits and vegetables. They are ammonium conjugates of betalamic acid with cyclo-DOPA and amino acids or amines, respectively.

With a focus on food, the scarce attention toward betalains may be due to the fact that red beet has long been considered the only edible betalainic source. However, other sources of betalains are species of the genus *Amaranthus*; other Cactaceae such as cactus fruits from *Opuntia* sp., *Hylocereus polyrhizus*, or *Myrtillocactus geometrizans*; and Swiss chard.

The most interesting applicable feature of betalains is the stability in the pH range from 3 to 7, when processed at low pasteurization, in the presence of ascorbic acid, and stored at low temperature, which makes these pigments suitable for their application in a wide range of low-acid and neutral foods.

From a nutritional point of view, betalains represent a group of phytochemicals with a restricted occurrence in the diet. Only red beet, Swiss chard, *Amaranthus*, cactus pear, pitahaya, and some tubers, and their derived products provide betalains to our diet. However, the use of betanin as food colorant and the plant betalain-enriched extracts in functional foods increases the consumption of this type of phytochemicals.

Betalains are bioavailable molecules, present as intact forms at systemic level, but new studies should be carried out in order to identify the complete pool of circulating compounds derived from betalain biometabolism once they are consumed.



Anthocyanidin	R1	R2
Pelargonidin	H	H
Cyanidin	OH	H
Peonidin	OCH_3	H
Delphinidin	OH	OH
Petunidin	OCH_3	OH
Malvidin	OCH_3	OCH_3

Figure 1 Structure of the main dietary anthocyanins.

Preliminary experiments on the biological and health-promoting properties of betalains have been focussed on their antioxidant properties due to their chemical and *in vitro* antiradical properties. However, their real physiological relevance has not been fully unraveled in intervention or clinical trials in humans. New studies conducted at the right physiological concentrations about the action of betalains and their circulating metabolites may open new ways of biological actions of these phytochemicals against human disorders.

Carotenoids

Carotenoids are the most widespread group of pigments in nature, responsible of the red, orange, or yellow colors of many vegetables and fruits. These molecules are isoprenoids that consist of eight isoprene units in a long polyene chain, which may extend from 3 to 15 conjugated double bonds.

β-Carotene is the most prominent member of the group of carotenoids. It belongs to the class of carotenoids named carotenes, together with lycopene. The group of xanthophylls is formed from the hydrocarbon carotenes by the introduction of oxygen functions, as lutein, α- and β-cryptoxanthin, and zeaxanthin.

Around 60 different carotenoids have been identified in fruits and vegetables.

At least 85% of our dietary lycopene comes from tomato fruit and tomato-based products. Major sources of β-carotene include green leafy vegetables, carrots, red peppers, oranges, potatoes, and broccoli. In a lesser extent, carotenoids are also present in eggs, poultry, and fish, especially when included in the animal feed. Lutein and zeaxanthin are highly present in spinach and kale, broccoli, peas, and Brussels sprouts, and they are the major carotenoids of corn and egg yolk; astaxanthin is the red pigment of crustaceans, salmon, and trout. Capsanthin and capsorubin are present in paprika flavoring. Bixin and norbixin are apocarotenoids present in annatto, a natural food coloring.

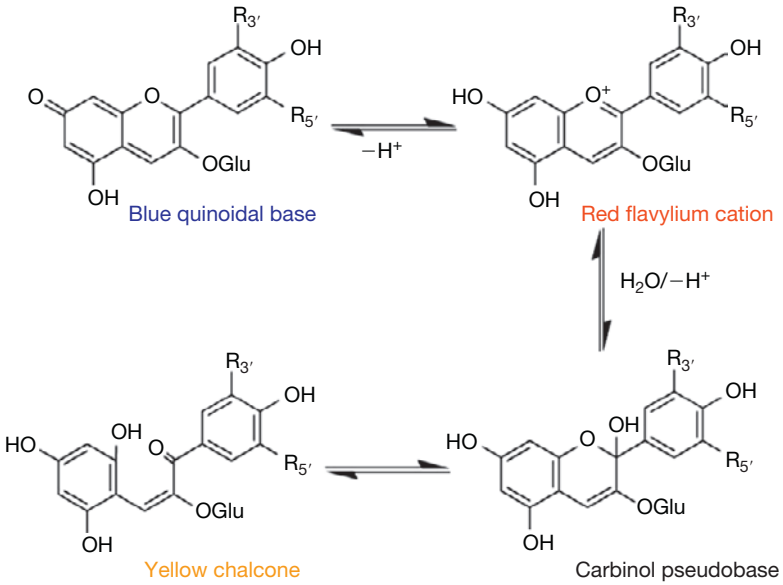


Figure 2 Structural transformations of anthocyanins depending on pH changes.

Bioaccessibility of carotenoids is limited and conditioned by different factors, as food processing and the composition and structure of the food matrix. Pressure cooking and stir-frying increase their bioaccessibility, whereas the presence of dietary fiber has a negative effect. Because of their lipophilic nature, the absorption of carotenoids is enhanced from a fatty diet.

Carotenoids have a broad range of positive effects on human health. The best established function is the provitamin A activity (vitamin A is important for many functions in the human body, being essential for normal growth and development, immune function, and vision), restricted to those molecules with β-ring end groups, as β-carotene, zeaxanthin, and β-cryptoxanthin.

Lutein and zeaxanthin are present in eye macula and might protect from light-induced damage and scavenge free radicals formed. Besides, UV protective effects have been reported in the skin after supplementation of β-carotene, due to the protection against photooxidation. Consumption of tomato products, rich in lycopene, is associated with reduced low-density lipoproteins (LDLs) oxidation implicated in vascular lesions, and low serum levels of lycopene have been related to increased risk of atherosclerotic events in middle-aged men. In relation to cancer, carotenoids have shown to inhibit cell proliferation and increase gap junctional communication. Epidemiological studies demonstrate that an increased consumption of a diet rich in carotenoids is associated with a diminished risk for different types of cancer, as it occurs with the high lycopene consumption and prostate cancer and lung and stomach cancer. However, the CARET (Beta-Carotene and Retinol Efficacy Trial) study showed that lung cancer was alleviated with β-carotene supplementation. It seems that the dietary consumption of a combination of carotenoids and other phytochemicals in fruit and vegetables is more effective in the protection against cancer than the intake of single supplements of any carotenoid.

Chlorophylls

Chlorophyll is the green pigment found in cyanobacteria and chloroplasts of algae and plants and is critical in photosynthesis as it allows plants to absorb energy from light.

The basic skeleton is composed of a large planar structure of four pyrrole rings joined together with a central metal atom of magnesium and a phytol hydrophobic group.

At least six chlorophyll molecules are known: chlorophylls a, b (higher plants), c, d, and e (algae) and bacteriochlorophylls (photosynthetic bacteria). The most widely distributed in plants is chlorophyll a.

Chlorophyllins are molecular analogs of chlorophyll more stable and also available as food colorants. They are hydrophilic, due to hydrolysis of the phytol tail, and the magnesium atom is replaced with other metal complexes as copper.

Chlorophylls are abundant in leafy fresh vegetables, as spinach and kale, lettuce, and basil. They are highly susceptible to degradation during processing. The most common reactions involve the loss of magnesium by heat or acidic conditions, forming pheophytin, and the green color turns to an olive green. Further decarbomethoxylation leads to the conversion of pheophytin into pyropheophytin. These changes are perceived by the consumer as a loss of quality. Storing the product at low temperatures and the immediate processing help to preserve the green color.

Native chlorophylls are poorly absorbed as such and are easily converted into Mg-free pheophytins during the gastric phase of digestion. Pheophytins are transferred to micellar fractions for their optimal uptake by human intestinal cells and likely represent the biologically relevant forms of these pigments.

Natural chlorophylls and chlorophyllins have been reported to display antioxidant activity, in models of lipid peroxidation, and antimutagenic and chemopreventive activities. Their porphyrin cycle can either scavenge free radicals or form a complex with carcinogens. Human studies on populations at high risk of developing carcinoma, because of toxin ingestion, have shown a reduction of urinary excretion of damaged DNA catabolites, without reported toxicity effects, possibly due to the formation of adducts of chlorophylls and mutagen, interfering in the bioavailability of the latter.

Curcumin

Curcumin is a natural colorant extracted from the rhizomes of *Curcuma longa* plant (turmeric). Three compounds have been isolated: curcumin, demethoxycurcumin, and bisdemethoxycurcumin that impart the yellow pigmentation to the plant and the products added, for example, curry.

The main pattern of consumption is in powder form, containing a mixture of the three curcuminoids, used as spice in Indian cuisine, to improve palatability and preservation of foods and to impart color to condiments and dressings.

Curcumin exhibits poor bioavailability, a major limit for its therapeutic efficacy and use in clinic. The major factors are its poor absorption due to insolubility in water, fast metabolism, extensive enterohepatic recirculation, and rapid systemic elimination in the bile and urine. The 40% of orally administered curcumin is excreted unchanged in the feces.

Curcumin is believed to have a wide range of biological effects. It has been shown to directly interact with numerous signaling molecules and activate/inhibit multiple regulatory proteins, including transcription factors, enzymes, and cytokines. In this way, curcumin may reverse conditions as insulin resistance, hyperglycemia, hyperlipidemia, and other inflammatory symptoms associated with obesity and metabolic diseases.

Because of its multitargeting properties, curcumin has exhibited activities against some types of cancer as colorectal and breast cancer. Histological improvement of precancerous lesions has been observed in bladder cancer, oral leukoplakia, and intestinal metaplasia of stomach, and a decrease in the number and size of polyps in skin lesions has been observed in phase I and phase II human clinical trials. In proinflammatory diseases as ulcerative colitis, Crohn's disease, pancreatitis, or arthritis, curcumin has shown promising effects, with high tolerability and scarce adverse effects. Efforts must be done to improve its poor bioavailability.

Melanoidins

Melanoidins are brown-colored compounds, with high-molecular-weight heterogeneous polymeric structure. These

products are formed through the Maillard reaction of sugars and amino acids at high temperatures and low water activity.

Information about the structure of melanoidins is scarce due to the high complexity and diversity of structures and the difficulty of isolation of pure compounds.

Melanoidins are present in a large range of products, such as barley malts, bread crust, bakery products, balsamic vinegar, tomato sauce, and coffee.

Little is known about the metabolic fate of melanoidins. They are largely resistant to digestion in the human gastrointestinal tract. The microbial gut degradation occurs for the less complex melanoidin structures that are absorbed and can be detected in urine in quantities up to 30% of intake.

Human studies have reported antioxidant activity of coffee or beer melanoidins after ingestion. Melanoidins protect against radical stress in the colon and behave as dietary fiber by promoting the growth of gut bifidobacteria. Besides, inhibitory effects of melanoidins on matrix metalloproteases implicated on tumor growth and development have been reported. They also have antibacterial activity against *Staphylococcus aureus*, *Escherichia coli*, and *Salmonella enterica* and could prevent the adhesion of *Streptococcus mutans* to the tooth surface playing a role inhibiting the development of dental caries.

Better knowledge of melanoidin structures would benefit the understanding of their biological properties.

Monascus

Monascus-fermented rice, also referred as red yeast rice (RYR), is a food product that is produced by inoculating fungi of the genus *Monascus* into steamed rice. *Monascus* fungi produce different main pigments: red colorants (rubropunctamine and monascorubramine), orange colorants (rubropunctatin and monascorubrin), and yellowish colorants (monascin and ankaflavin).

RYR (known as beni-koji in Japan) has been used for centuries in Eastern countries as China and Japan as natural food colorant and flavor as well as food preservative of meat and fish. Food examples are red rice vinegar, some types of tofu, Peking duck, Chinese pastries and rice wines as Japanese sake, imparting reddish color. The RYR is most often powdered and sold as such but the pigments may also be extracted.

Healthy effects have been reported for RYR as cholesterol lowering, antidiabetic activity, anti-inflammation, and prevention of osteoporosis, and some of these activities have been related to the pigments contained.

The red and orange pigments possess antibiotic activity against bacteria, yeast, and filamentous fungi. Both orange (rubropunctatin and monascorubrin) and yellow pigments such as monascin and ankaflavin have shown immunomodulatory and anti-inflammatory properties. In addition, *Monascus* pigments could prevent obesity development. Monascin and ankaflavin might reduce triglyceride accumulation and proliferation of preadipocytes. Cancer-chemopreventive activity has been reported for all pigments, specially monascin and ankaflavin, by inhibition of cancer cell progression and cytotoxicity of tumoral cells.

However, the RYR can be contaminated by citrinin, a hepatotoxic metabolite of *Aspergillus* and *Penicillium* species that has led to the prohibition of *Monascus* pigments use as food additive colorants in EU and United States, while in Asian countries, it is accepted under monitoring and the establishment of maximum limits for citrinin in foods.

Myoglobin and Hemoglobin

Meat color is due to the concentration of the pigments myoglobin and hemoglobin. Myoglobin is a metalloprotein composed of a polypeptide globin and a heme residue with iron ion.

Color changes in meat occur because of the susceptibility of myoglobin to alterations. Under low oxygen tension, iron in myoglobin exists in Fe^{2+} state and meat is visually purple-red. When it is exposed to oxygen for a short time, myoglobin binds oxygen producing oxymyoglobin, which is bright pink or red. Oxidization of iron to Fe^{3+} state produces metmyoglobin, visually brown or gray-brown. Further degradation of metmyoglobin gives green and dark brown pigments.

Biological function of myoglobin is related to storage of the oxygen brought by the hemoglobin for the requirements of living tissues. It binds reversibly O_2 and facilitates its transport to mitochondria. Myoglobin also scavenges reactive O_2 species and facilitates oxygen diffusion. An additional role of this protein is to bind nitric oxide in skeletal muscle as nitric oxide inhibits cytochrome c oxidase and thus impairs mitochondrial respiration.

Colorants Used as Additives in Food Industry

Fruit and vegetable juices can be added to foodstuffs but are considered ingredients rather than additives. Because of this, they do not carry an E number in the European Union (EU) market, turning the foodstuff into a more natural product. Accepted food colors and quantities allowed to be added to each foodstuff are regulated by national laws (except for the EU countries that share a common legislation).

According to the US Food and Drug Administration (FDA), all color additives shall be declared. Food colorings exempt from certification are those having generally a mineral, plant, or animal origin and are declared as 'artificial color,' 'artificial color added,' or 'color added.' Colors subject to certification are usually identified by the terms 'FD+C No.' All the 'FD+C' color additives have to be declared, and in order to save labeling space, they can appear with their names without the prefix 'FD+C No.'

This section will focus on natural pigments that are not a food in itself and are not normally used as a characteristic ingredient of foods, such as riboflavins, cochineal, vegetable carbon, and some minerals. Artificial food colors, which are produced by chemical synthesis, will also be reviewed.

Riboflavins

Riboflavin, also known as vitamin B2, occurs as yellow to orange-yellow crystals. It is designated by the E number E 101 and can be found both in its free form (E 101i) and as riboflavin-5′-phosphate (E 101ii). Riboflavin or vitamin B2 is present naturally in animal products (meat, milk, and eggs), vegetal ones (malted barley, nuts, and almonds), and yeast.

It is also used as food color in order to confer yellow shades to some foodstuffs such as dairy products and confectionary. It may be produced by chemical synthesis, biosynthesis from *Eremothecium ashbyii* (aka *Ashbya gossypii*), *Saccharomyces cerevisiae*, and *Bacillus subtilis*, among other microorganisms, or isolated from natural sources. Riboflavin-5′-phosphate is prepared.

The health effects of riboflavin are mainly determined by its role as a vitamin. Its physiological functions are described in other articles of this Encyclopedia.

Cochineal, Carmine, and Carminic Acid

Carminic acid is a red-crimson anthraquinone coloring matter that occurs naturally in some insects like cochineal (*Coccus cacti* L.). The food color cochineal or cochineal extract is obtained after hydroalcoholic extraction of bodies of insects. Carmine is a more concentrated solution containing, at least, 50% of carminic acid.

Cochineal-derived dyes are mainly used to confer red shades in alcoholic beverages, yogurts, juices, ice creams, and confectionary, although it can be also found in jams and some processed meat products.

Concerning its health properties, carminic acid may cause allergic reactions and even anaphylactic shock to a sensitive subset of populations. Nevertheless, it is not a significant hazard to the general population.

Vegetable Carbon

Vegetable carbon or carbon black is produced by steam activation of carbonized plant material. It is mainly used in confectionary and desserts, including dairy products.

No ADI has been established for vegetable carbon owing to its scarce toxicological data, despite evidence on its safety has been confirmed by the European Food Safety Authority (EFSA).

Food Colors from Mineral Origin

There is a group of food colors that are obtained mainly from mineral sources by diverse extraction processes. These food colors are titanium dioxide that provides white color and opacity; iron oxides, conferring yellow, red, or black shades; aluminum; silver; and gold. These colors are mainly used as surface coatings (e.g., iron oxides are present in sausage coatings). Gold and silver can also be included in expensive eccentric beverages. Calcium carbonate can also act as coating colorant providing white color, although its principal role as additive is to serve as anticaking agent, stabilizer, and acidity regulator. Although they are accepted in the EU, most of these cannot be used within the American market as they are banned by the FDA. On the contrary, some color additives as ferrous gluconate and ferrous lactate are accepted in the United States, but not at the EU, for the coloring of ripe olives.

Information on the dietary exposure to these minerals when used as food additives is very scarce (Table 1). Nonetheless, their contribution to the daily consumption of minerals may be considered as negligible attending to their restricted use. The absorption, distribution, metabolism, excretion, and safety of these mineral food colors follow the same patterns as when they are contained naturally in foods or they are present as contaminant due to food processing operations.

Azo Food Colors

Most of the synthetic additives used as food colors share a common chemical structure characterized by the presence of an azo functional group. In addition, many of these colors are sodium salts of sulfanilic acid. Tartrazine, Sunset Yellow FCF, Azo Rubine, amaranth, Ponceau 4R, Allura Red AC, Brilliant Black BN, Brown HT, Lithol Rubine BK, Orange B, and Citrus Red No. 2 are part of this group.

Tartrazine is the trisodium salt of 5-hydroxy-1-(4-sulfonatophenyl)-4-[(*E*)-(4-sulfonatophenyl)diazenyl]-1*H*-pyrazole-3-carboxylate. It provides orange-yellow color to some desserts and sweets, potato and corn chips, muesli, corn flakes, noodles, tartar sauce, mustard, bouillon cubes, and energy and sport drinks. Tartrazine is also available for consumer, as it is one of the few food additives that can be purchased at grocery stores. Sunset Yellow FCF, Orange Yellow S, or FD+C Yellow No. 6 is an orange-yellow azo dye present not only in soft drinks and desserts such as jellies but also in confectionary, jams, chips, biscuits, ice creams, instant noodles, and food decorations and coatings. Azo Rubine or carmoisine, a red dye, is present in nonalcoholic flavored drinks, sugar confectionary, and yogurts. Amaranth provides dark, reddish brown color to alcoholic beverages like aperitif wines just as to candied fruit, other confectionary products, yogurts, and ice creams. Ponceau 4R, Cochineal Red A, or New Coccine is a red color used mainly in soft drinks, confectionary, coatings, biscuits, ice creams, and fine bakery wares. Allura Red AC can be found in crisps, biscuits, nonalcoholic flavored drinks, drinks, desserts and yogurts, sweets, ice creams, and jams. Brilliant Black BN or Black PN and Brown HT are bisazo colors used to confer dark shades in a broad array of foodstuffs that are banned in many other countries outside the EU. Lithol Rubine BK is a red dye used exclusively in cheeses as surface coating. Orange B, banned in the EU market but allowed in the United States, is only used in sausage coatings. Citrus Red No. 2 is only for use in the United States to color orange skins.

Dietary exposure to azo food colors vary notably among these additives because of their differences regarding quantities used and pattern of consumption of foodstuffs containing them (Table 1).

Azo food colors are extensively metabolized by the gut microbiota to sulfanilic acid and aminopyrazolone after oral administration. On the basis of this fact, urine excretion of intact azo colors is negligible or very low (e.g., <5% for tartrazine), while their metabolites, mainly free and conjugated sulfanilic acid, are absorbed to a greater extent.

Regarding health effects of azo colors, controversial literature has been reported. Some cell/animal studies pointed out how tartrazine, Ponceau 4R, Allura Red AC, Brilliant Black BN, and Brown HT might affect neurodevelopment or exert carcinogenic properties. Nevertheless, adverse effects of these food colors on neurobehavioral development or cell proliferation should not be expected to occur in humans, according to EFSA. In general, there are no indications of any genotoxic/carcinogenic potential of (bis)azo dyes or their metabolites. On the

[a]Data according to the Commission Regulation (EU) No 1129/2011 of 11 November.
[b]MLU, maximum level of use by EU laws; R, regulated on the basis of the foodstuff considered; q.s., 'quantum satis,' which means that no maximum level is specified and substances shall be used in accordance with good manufacturing practice.
[c]Data according to the Code of Federal Regulations Title 21 (Parts 73 and 74).
[d]If the color does not require certification, it follows the rules established at the Part 73 of the Code of Federal Regulations Title 21; if it requires, it follows Part 74 of Title 21.
[e]Acceptable daily intake (ADI) based on recent EFSA reevaluations of selected colors as food additives. Data with asterisk refer to values based on the Joint FAO/WHO Expert Committee on Food Additives (JECFA).
[f]Data based on the mean dietary exposure considering the maximum permitted levels (Tier 2) established by EFSA Panels after reevaluations of selected colors as food additives and on Lok et al.

other hand, the effects of Sunset Yellow FCF on the testis, sperm morphology, and sperm mobility remain unclear nowadays, which motived the reduction of the ADI for this azo dye.

Tartrazine has been identified to cause migraine, asthma, and certain cutaneous conditions (i.e., urticaria) in a very small fraction of the population due to intolerance reactions. Sensitive reactions after Sunset Yellow FCF, Azo Rubine, amaranth, Ponceau 4R, or Allura Red AC consumption may also take place in some individuals, overall when it is taken within blends of other synthetic food colors. Finally, behavior changes (hyperactivity, restlessness, and sleep disturbance) might appear in children following exposure to some azo colors in combination with other food additives like sodium benzoate. This fact would be restricted to specific sensitive individuals, and its clinical significance remains unclear.

Quinoline Yellow

It is a greenish yellow food dye, produced by chemical synthesis that can be found in sport and energy drinks, ices, and confectionary, among other products.

It has a limited absorption in mammal animal models, and the bulk of the dose is excreted unchanged via the feces. Nonetheless, this color additive is to some extent bioavailable, concerning some systemic effects found in long-term toxicity studies. Adverse sensitivity reactions (urticaria and rhinitis)

after intake of Quinoline Yellow have been reported although no conclusive results on the induction of sensitivity by this food color have been achieved. It may also have an adverse effect on activity and attention in children, similarly to some azo dyes.

Caramels

Caramel is a complex mixture of compounds resulting in a dark brown liquid or solid material formed by the controlled heat treatment of sugars. Caramelization is produced in the presence of ammonia, sulfite, alkalis, or combinations thereof, and caramels are classified, according to their processing, into plain caramel, caustic sulfite caramel, ammonia caramel, and sulfite ammonia caramel. Caramels are present in a plethora of foodstuffs such as beer, biscuits, chocolate, confectionary, cookies, crisps, ice creams, sauces, soups, vinegar, wood-aged spirits, and, overall, colas.

The main contributors to mean exposures (Table 1) to caramels in children through European countries are flavored drinks, bakery, and desserts, including dairy products. Non-alcoholic beverages, beer, cider, and confectionary account for the higher amounts of the four caramel colors in adults. Some population groups having high exposure to caramel color could exceed the ADI of this color.

Caramels are complex mixtures of poorly characterized compounds, and their bioavailability remains unclear.

Caramel food colors present low toxicity/carcinogenicity both in short-term tests and in chronic studies. However, certain low-molecular-weight compounds being part of these additives, such as furan and 5-hydroxymethyl-2-furfural (5-HMF), might have chemotoxic potential though their contribution to the toxicity of caramel colors has not been fully elucidated. There are no data concerning the long-term toxicity or carcinogenicity of caramel colors so far. In contrast to other synthetic additives, there are no reported cases of sensitivity reactions.

Triarylmethane Colors

Brilliant Blue FCF, Erioglaucine disodium, Green S or Lissamine Green B, and Fast Green FCF are synthetic triarylmethane dyes. They can be found mainly in ice creams and other dairy products, peas, and drinks. According to the higher level of intake of these dyes (Table 1), some adults may be above the ADI of Brilliant Blue FCF and Green S. Anyway, triarylmethane colors are poorly absorbed and mainly excreted unchanged in feces. Brilliant Blue FCF lacks significant genotoxicity effects, while data related to Green S are not available.

Other Synthetic Food Colors

Indigotine or Indigo carmine is a synthetic color, although it used to be extracted from plants of the genus *Indigofera*. Together with Patent Blue V, it is used in order to confer blue coloration to foodstuffs. Both blue colors are mainly used in coatings, ice creams, and confectionary. Erythrosine is exclusively used for cherry products in the EU and used also for sweets in other countries. In general, these food colors have low absorption and limited availability and are excreted almost completely via feces. Health effects of these colors are not worth mentioning as they are recognized as safe under proper manufacture practices and normal intakes.

Anthocyanins

Anthocyanins are water-soluble vacuolar flavonoid pigments. They are responsible for the orange, magenta, violet, and blue color of plant organs, including leaves, stems, roots, flowers, and fruits. Until now, 600 different anthocyanins are known mainly in the form of heterosides. The aglycone form, or anthocyanidin, is a polyhydroxy and polymethoxy derivative of flavylium (2-phenyl-1-benzopyrylium), which is usually bonded to a sugar moiety and can be possibly acylated by a phenolic or aliphatic acid (Figure 1). Among the 23 types of known anthocyanidins, only six are common in higher plants: pelargonidin, cyanidin, peonidin, delphinidin, petunidin, and malvidin.

Many factors, that is, pH, heat, light, metals, and copigmentation, may affect their stability, color, hue, and density. Under acidic conditions, the eight conjugated bonds in anthocyanin structures carrying a positive charge on the heterocyclic oxygen ring are responsible for the intense red-orange to blue-violet color. They show a wavelength of maximum adsorption between 465 and 550 nm and a significant absorption in the UV range between 270 and 280 nm.

In vitro, under mildly acidic conditions (pH 3–6), the red and stable flavylium cation form predominates, while at pH 6 and above, it changes into the colorless carbinol pseudobase or chalcone forms and finally into the bluer and unstable quinonoidal base form (Figure 2). The larger the number of hydroxyl groups on the B-ring, the bluer the color is. Aromatic acylation causes a blueshift and stabilizes anthocyanins, whereas aliphatic acylation increases the stability and solubility. Self-association with flavonoids stabilizes anthocyanins and causes bluing and intensifying of color.

Sources and Production

Cyanidin, delphinidin, and pelargonidin glycosides are the most common in nature, being present in 80% of pigmented leaves, 69% of fruits, and 50% of flowers. The distribution of the six more common anthocyanidins in fruits and vegetables is the following: cyanidin (50%), delphinidin (12%), pelargonidin (12%), peonidin (12%), petunidin (7%), and malvidin (7%). 3-Glycosides occur about two and a half times more frequently than 3,5-diglycosides.

The major sources of anthocyanins are red fruits, some cereals, and root vegetables (aubergines, beans, cabbages, radishes, and onions).

Berries such as black currants and blackberries contain up to 2–4 g kg^{-1} fresh weight anthocyanins mainly in the skin. They are also present in apples, plums, and pears and in the flesh of cherries and strawberries. In particular, red grapes can contain up to 250 mg/100 g, while the concentration in red wines varies in accordance with the varieties of grapes employed and with the type of vinification and, especially, with aging. However, a medium value of around 500 mg l^{-1} of anthocyanins could be established in young wines.

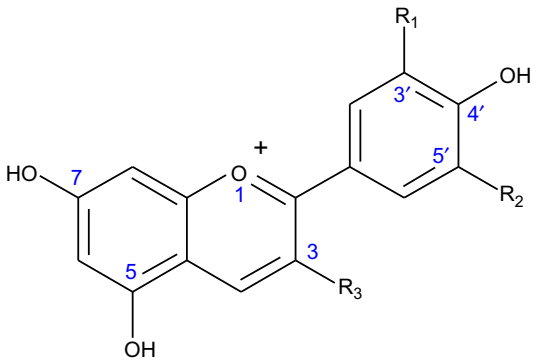
Actually, the European Union allows the use of anthocyanins as food colorants named E163 in acidic food or beverages including soft drinks, fruit preserves, sugar confectioneries, dairy products, frozen products, dry mixes, and alcoholic drinks. In particular, grape skins, a by-product of the wine industries, are the most common source for economic reasons along with the concentrated juice of black currants, strawberries, cranberries, elderberries, cherries, and red cabbages. Other less familiar sources include radishes, black carrots, and red and purple sweet potatoes.

Moreover, berry, grape skin, and seed extracts are commercialized as nutraceuticals and as dietary supplements for their antiaging effect.

Despite their great potential of application, anthocyanin extraction from natural sources is complex due to their relative instability.

Determination of Anthocyanins

Usually, anthocyanins are extracted under mild conditions with cold acidified polar organic solvents (i.e., methanol, ethanol, and acetone) at a composition of 70–80% in water. The acid employed is usually acetic acid, trifluoroacetic acid, or sulfured water in order to minimize the pH effects on the flavylium equilibriums. Then, the concentrated extract is purified by washing with hexane, petroleum ether, or diethyl ether to remove unwanted lipophilic compounds. Alternative techniques that reduce the use of organic solvents and maximize recovery with minimal degradation of the pigments are solid phase extraction and elution by solvent with increasing polarity, supercritical fluid extraction using CO_2 and polar organic modifiers as cosolvents, pressurized hot water



Anthocyanins	R1	R2
Pelargonidin-3-glucoside	H	H
Peonidin-3-glucoside	OCH_3	H
Cyanidin-3-glucoside	OH	H
Malvidin-3-glucoside	OCH_3	OCH_3
Petunidin-3-glucoside	OCH_3	OH
Delphidin-3-glucoside	OH	OH

extraction, microwave-assisted extraction with polar solvents, and countercurrent chromatography that allows fractionation and isolation of pure compounds for direct identification by mass spectroscopy (MS) and nuclear magnetic resonance.

Recently, enzyme-assisted extraction has been carried out for anthocyanin extraction from cherry, red grape, strawberry, black currant, and blueberry juice processing wastes and grape residues. Nowadays, some researchers have also developed cell cultures within plant species for the production of anthocyanins.

The analysis of anthocyanins is commonly carried out through high-performance liquid chromatography (HPLC) on octadecylsilane, polystyrene, or phenyl-bonded columns in reversed phase using gradient solvent systems of acetonitrile–water or methanol–water with a small amount of acid and a UV detector. Anthocyanins have a unique maximum absorption at 520 nm, and a diode array detector (DAD) performs a complete spectrophotometric scan on each peak as it elutes and provides a unique chromatogram for each compound. Recently, electrospray ionization–MS (ESI–MS) detection has been used allowing very low fragmentation and exact molecular weight determinations. Another common technique used for the separation of anthocyanins is capillary zone electrophoresis (CZE) with UV or ESI–MS detection using acidic media optimized via a phosphate buffer and a cationic surfactant.

Patterns of Consumption

Depending on the diet, the daily intake of anthocyanins in humans has been estimated to range between a few and 100 mg. The average anthocyanin intake in adults within the United States is about 12.5 mg day^{-1}. A higher consumption has been reported in European countries with a North–South gradient. This result is consistent with the Mediterranean diet including berries, other red- and blue-colored fruits, and red wine. Considerably, enhanced anthocyanin consumption of commercially available extracts is also suggested.

Availability, Absorption, and Metabolism

Anthocyanins are rapidly absorbed in the stomach and small intestine reaching a maximum plasma concentration (C_{max}) of between 1.4 and 200 nm for doses of 10–720 mg of anthocyanins. The C_{max} is reached between 45 min and 4 h after ingestion of an anthocyanin-containing meal depending on its composition. In addition, anthocyanins are rapidly eliminated in urine after 1.5–6 h of ingestion. Since the proportion of absorbed and excreted anthocyanins is $<0.1\%$ of the ingested amount, there is a paradox about the metabolic fate of a very high percentage of the ingested anthocyanins that needs to be explained.

In both blood and urine, they appear as intact, methylated, glucuronide derivatives and in sulfoconjugated form. Interestingly, the glycosides do not appear to be easily hydrolyzed to aglycones.

The reasoning of the paradox is that the bioavailability of anthocyanins compared with other flavonoids is influenced by physicochemical characteristics such as size, lipid/water solubility, and pK_a; by food matrix effects like the presence of lipids; or by interaction with other compounds in the meal. Moreover, the changes of pH and the presence of digestive enzymes, biliary acids, and microbiota along the gastrointestinal tract can greatly affect the chemical stability of anthocyanins and their metabolism.

Anthocyanins occur under cationic form in the gastric lumen, but whether they are adsorbed through binding to some specific protein transporters, it is still unknown. On the other hand, the absorption of anthocyanin glycosides in the small intestine, mainly in the form of carbinol pseudobase, may involve specific glucose transporters. Another possible mechanism could be the hydrolyzation of anthocyanins by brush border enzymes prior to passive diffusion of the aglycone. Finally, large amounts of unabsorbed anthocyanins and derivatives excreted in the bile from the enterohepatic circulation can reach the colon. Enzymes of the gut microbiota can also induce metabolization including methylation, sulfation, and conjugation with glucuronic acid and breaking of glycoside linkages. These compounds may undergo adsorption and further metabolization in the liver.

Moreover, the low stability of anthocyanins in the pH of the intestine and the activity of the intestinal microbiota are at least partially responsible for the conversion of anthocyanins into more stable small phenolic acids, such as protocatechuic acid, or other molecules of unknown structure.

Therefore, the overall anthocyanin bioavailability should result from the contribution of the amount that crosses all physiological barriers in all their possible forms: native, degradation products, metabolites, and anthocyanin derivatives.

Moreover, several intact anthocyanins and some metabolites have been detected in many animal tissues including the liver, the kidneys, the brain, the lungs, and the eyes.

As a consequence, what is left to explore is whether the biological effects associated with anthocyanins are due to their native forms or to some specific metabolites arising after adsorption.

Betalains

Betalains are water-soluble nitrogen-containing pigments responsible for the yellow-orange-red colors of flowers and fruits belonging to the angiosperm order Caryophyllales. However, in Caryophyllaceae and Molluginaceae, they are replaced by anthocyanins, and interestingly, the two pigment families are mutually exclusive. Betalains comprise 55 structures: the red-violet betacyanins and the yellow-orange betaxanthins that are ammonium conjugates of betalamic acid with *cyclo*-DOPA and amino acids and amines, respectively. Although more than 50 types of betacyanins are known, betanidin is the most common aglycone that can be glycosylated or acetylated on one or both C5 or C6 hydroxyl groups (**Figure 3**). Further glycosylation of the 5-*O*-glucoside and esterification with hydroxycinnamic acids are also very common.

Betacyanins display a wavelength of maximum absorption in the UV range between 270 and 280 nm due to the *cyclo*-DOPA structure and a second adsorption maximum in the visible range at about 535–538 nm depending on the solvent system. Acylation with hydroxycinnamic acids produces a third maximum at about 300–330 nm, whereas aliphatic acid

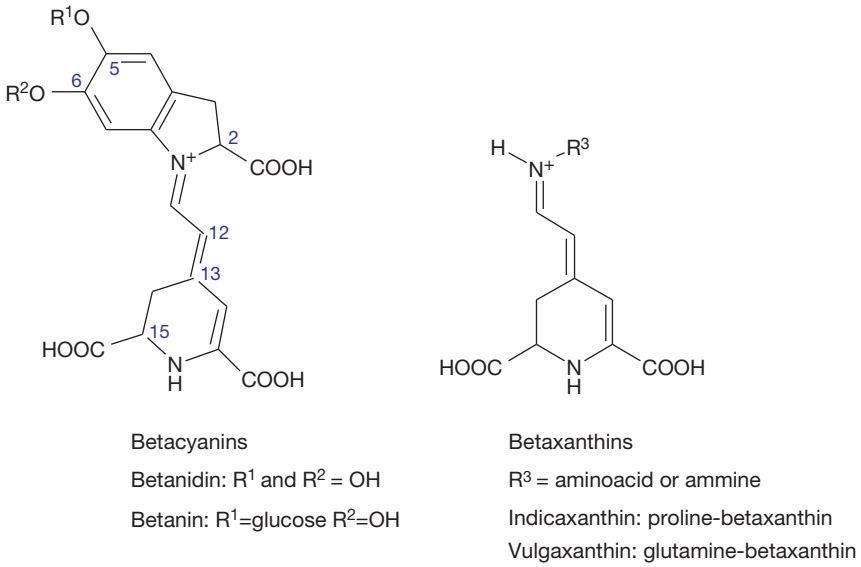

Figure 3 Basic structure of betacyanins (left) and betaxanthins (right).

derivatives are not distinguishable from their corresponding betanidin glycosides. Betacyanins and betaxanthins are cations below pH 2.0, zwitterions at pH 2.0, monoanions between pH 2.0 and 3.5, and stable bisanions above pH 3.5 and 7.5.

Sources and Production

The major dietary sources of betalains are not only cactus pear and red and yellow beetroot but also colored Swiss chard and grain or leafy amaranth (Table 1). The major commercially exploited betalain crop is red beetroot (*Beta vulgaris*) because the extract contains mainly betanin, which is approved as a red food colorant E162 in different low-acid and neutral food commodities (pH 3–7) from beverages to candies and from dairy to cattle products by both the European Union and the United States. Betalains are more stable as food colorants over a broader pH range than anthocyanins, although their use is still limited, being not always edible.

For example, cactus fruit betalains cover a broader color spectrum without negative flavor impact as compared with red beet. An additional advantage to cactus fruits is their minimal soil and water requirements, as it is regarded as an alternative culture for the agricultural economy of arid and semiarid regions.

Determination of Betalains

Plant cells and tissue cultures are alternative sources of betalains that ensure continuous supplies of easily extractable products with uniform quality and yield, independently from their geographic location and minimizing risks of political interference. The most widely used plant *in vitro* systems are cell suspensions, hairy roots, and tissue cultures. Extraction of betalains is commonly performed with an aqueous organic solvent (i.e., methanol); however, the addition of ascorbic acid in the extraction medium is recommended to slightly lower the pH, which stabilizes betacyanins and inhibits possible oxidation by polyphenol oxidases.

HPLC with C18 in reversed phases and UV detection is the method of choice for the analysis of betalains. Elution is performed by a gradient solvent system using methanol and phosphoric acid at pH 2.75 in ion suppression mode. Two different wavelengths were used to monitor selectively the red and yellow pigments (538 and 476 nm). Another common method of detection is ESI–MS in positive mode.

Patterns of Consumption

Betalains represent a group of phytochemicals with a restricted occurrence in the diet since their plant food sources are quite reduced. Only red beet, Swiss chard, amaranth, cactus pear, pitaya, and some tubers and their derived products provide betalains to our diet.

However, the use of betanin as a food colorant and the plant betalain-enriched extract in functional foods may increase their consumption.

Availability, Absorption, and Metabolism

Despite the scarce studies on bioavailability and metabolism of betalains, they all show that these pigments are bioavailable. In particular, cactus pear fruit or red beet juice indicaxanthin and betanin, which represent the adducts of betalamic acid with proline and cyclo-DOPA-5-*O*-β-glucoside, respectively, are reported to reach plasma concentrations of mM order, which is quite higher compared with that of polyphenols. Simulated gastrointestinal adsorption studies have indicated that indicaxanthin and betanin are absorbed passively by solvent drag through paracellular junctions of intestinal epithelial cells without any metabolic transformation and circulate as unconjugated molecules. However, in the case of betanin, its bioavailability appears to be limited by a digestive instability and

Table 1 Dietary natural pigments and their occurrence in food expressed as mg of compound per 100 g of fresh weight (FW) of food

Natural pigments	*Dietary sources*	*Concentration mg/100 g FW*

by an intestinal efflux mechanism, thus reducing the absorption by around 35% of betanin intake. Moreover, its intestinal permeation may be influenced negatively by the food matrix. Since unknown metabolites that may fit with conjugates or microbial metabolites are also detected in urine, there is the need to develop further studies on their effects on health.

Carotenoids

Carotenoids comprise more than 700 lipid-soluble, yellow-orange-red pigments with a broad distribution from bacteria to higher plants. They are found in chloroplasts of leaves and green fruits along with chlorophylls and in chromoplasts of flowers, fruits, roots, and seeds. The carotenoid backbone consists of eight isoprenoid units linked covalently to create a symmetrical polyene chain with multiple conjugated double bonds (Figure 4). Cyclization of the end groups occurs in hydrocarbon carotenes, whereas the introduction of oxygen functions gives rise to xanthophylls. Carotenoids are highly prone to chemical degradation during food processing and storage due to the effects of light, oxygen, and heat.

Sources and Production

Green vegetables, such as broccoli, spinach, and lettuce, contain lutein as their main pigment (45%), β-carotene (35–30%), violaxanthin (15%), neoxanthin (10%), and small amounts of α-carotene, β-cryptoxanthin, zeaxanthin, and antheraxanthin. Yellow and red fruits and vegetables (carrots, watermelon, potatoes, and tomatoes) have a more distinctive carotenoid distribution with high amounts of β-carotene. Tomatoes and watermelon are rich in red lycopene. Yellow and orange fruits (pumpkins, oranges, and peaches) contain primarily xanthophyll esters and β-carotene.

Vegetable oils, in particular palm oil, and some spices like red pepper (capsanthin and capsorubin) and saffron (crocin and crocetin) are good sources of carotenoids.

Animal tissues (salmon, trout, and shrimp) contain the orange-pink astaxanthin depending on their intake of phytoplankton (macro- and microalgae), which biosynthesize carotenoids. Egg yolk is also rich in lutein and zeaxanthin depending on their foraging.

Actually, few carotenoids are used as food colorants: α-, β-, and γ-carotene (E160a), bixin, norbixin, annatto (E160b), capsanthin, capsorubin, paprika (E160c), lycopene (E160d), β-apo-8-carotenal (E160e), ethyl ester of β-apo-8′-carotenal (E160f), lutein, and astaxanthin.

Some plant and seafood by-products, algae, and microorganisms are eco-friendly and low-cost sources of carotenoids. Moreover, production from algae and microalgae has many advantages, such as easier extraction with higher yields and no lack of raw materials or limited seasonal variation. The main carotenoids derived from algae are listed in Table 2.

Determination of Carotenoids

The extraction of carotenoids is generally carried out with organic solvents or supercritical fluid extractions. In recent years, in order to increase the recovery efficiency, a novel approach based on enzymatic extraction has been developed for marigold (lutein) and tomato products (lycopene). Recently, biotechnological productions or metabolic engineering of carotenoids using microorganisms and crop plant's cell cultures such as potatoes, tomatoes, rice, and maize has also been exploited.

The most common method for the analysis of carotenoids is HPLC with UV detection on a C18 or C30 reversed phase in isocratic or gradient elution mode using various mixtures of solvents (methanol, acetonitrile, and tetrahydrofuran) with the addition of butylated hydroxytoluene. Carotenoids absorb strongly between 400 and 500 nm (all-*trans* isomers), while *cis* and *cis–trans* isomers also exhibit absorption at around 320 nm. Another sensitive detection technique employed is

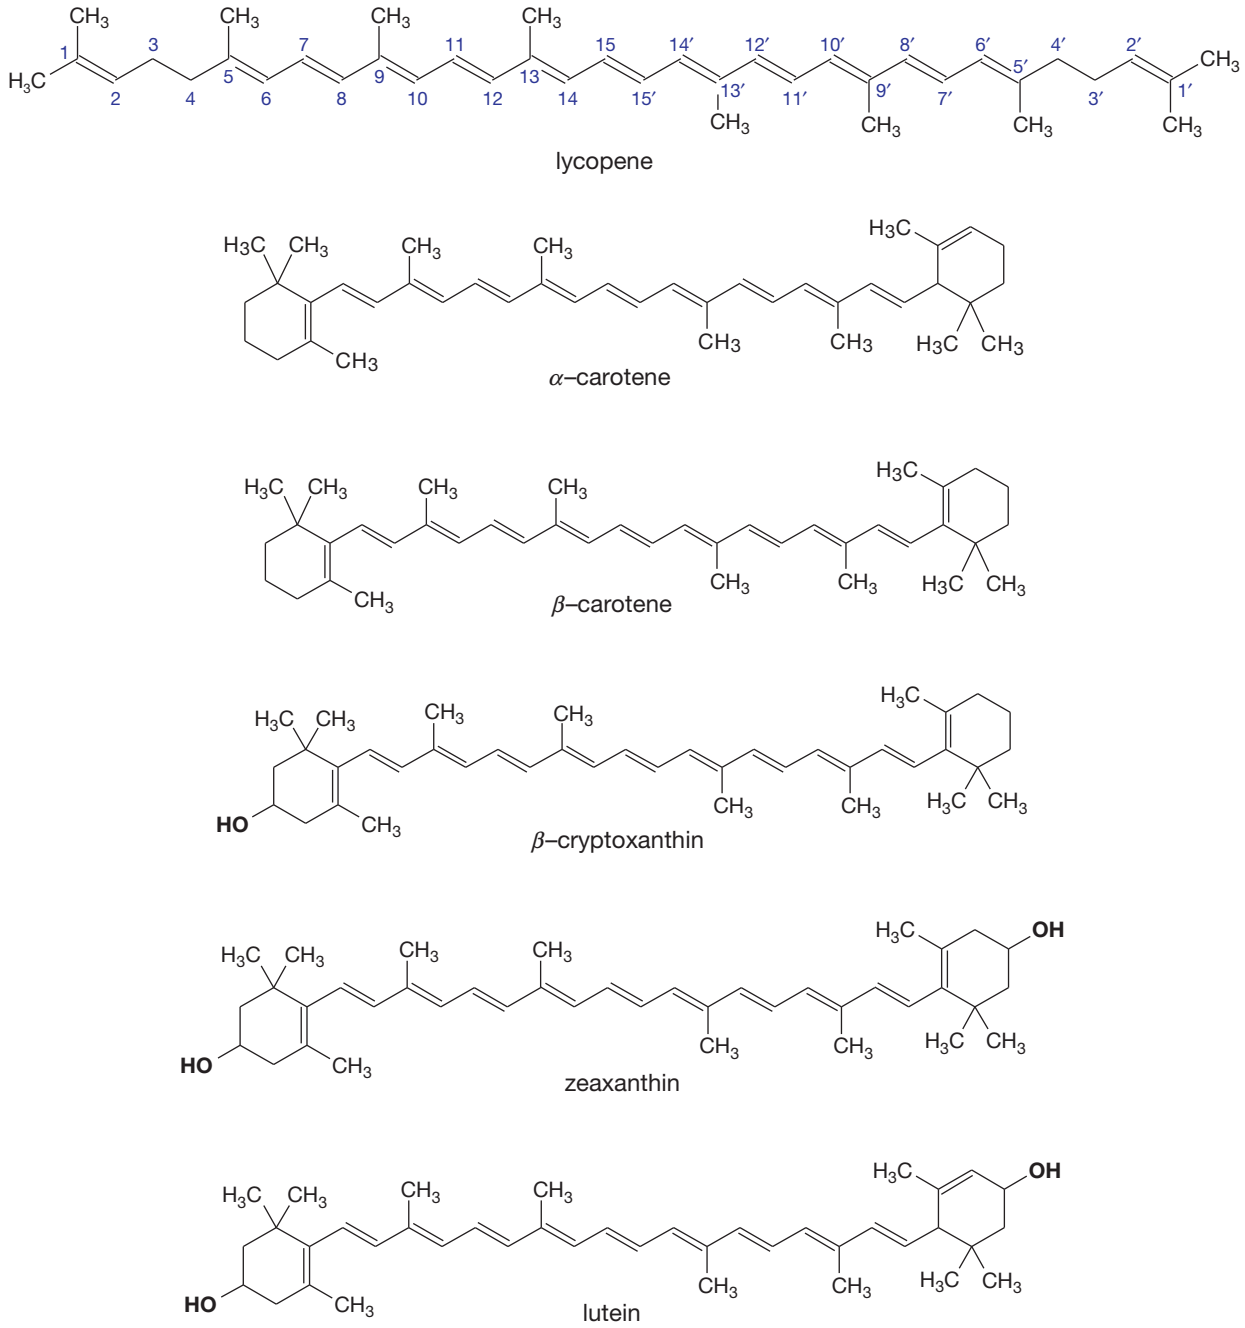

Figure 4 Chemical structure of the most common dietary carotenoids.

the atmospheric pressure chemical ionization (APCI)–MS in positive and negative mode. A very promising method for fast analysis of carotenoids is capillary electrochromatography on stationary phases similar to those of HPLC.

Patterns of Consumption

In developed countries, 80–90% of carotenoid intake comes from vegetable and fruit consumption. A European North–South gradient for the intake of some carotenoids within and among European countries has been reported since southern (Mediterranean) countries (i.e., Greece, Italy, Portugal, and Spain) consume greater amounts of fruits and vegetables than northern countries (i.e., the United Kingdom, Ireland, and Scandinavian countries).

Availability, Absorption, and Metabolism

The carotenoid bioavailability is affected by the food matrix, because fruit carotenoids seem to be more bioavailable than

Table 2 Natural pigments (mg/kg of dry weight (DW)) in seaweed

Natural pigments	*Sources*	*Concentration mg/kg DW*
Carotenoids

Chlorophylls		
Chlorophyll a and b	*Laminaria digitata*	1250
	Ascophyllum nodosum	565–1030

those in vegetables where they are linked to proteins. Moreover, ripening, food processing, and cooking increase their availability due to the disruption of the food matrix. Heating also induces isomerization from the *trans*-form, which is mostly found in raw vegetable materials, to the *cis* one that is easily adsorbed.

Being lipophilic compounds, carotenoid absorption takes place in the small intestine and requires the formation of mixed micelles with biliary salts. As a consequence, carotenoid bioavailability is enhanced by dietary fat, while it is decreased by soluble fiber. It is estimated that the consumption of at least 5 g of fat in a meal is required for suitable adsorption.

The chemical structure of carotenoids plays an important role in micellization. As a matter of fact, xanthophyll esters exhibit more fat solubility and are more available than free xanthophylls and apolar carotenes.

The intestinal assimilation of carotenoids seems to occur by simple or facilitated diffusion involving a membrane receptor. The bioavailability of lutein (79%) was found to be higher than that of lycopene (40%) and β-carotene (27%), and it was suggested that about 90% of β-carotene, lutein, and lycopene contained in fruits and vegetables are adsorbed. The increase of bioaccessibility of carotenoid formulations in hydrophilic matrices has also been developed.

After the intestinal uptake, carotenoids are packed into chylomicrons, which are then excreted into lymphs. Once taken up by the liver, carotenoids are exported to various tissues by lipoproteins like low density lipoproteins (LDLs) or high density lipoproteins (HDLs). In particular, carotenes are transported by LDLs, whereas xanthophylls by HDLs, so they will accumulate differentially in certain tissues depending on the receptor density for LDLs or HDLs.

Chlorophylls

Chlorophylls are green lipid-soluble pigments consisting of a substituted tetrapyrrole with coordinated magnesium in the center. The skeleton of chlorophyll derives from further esterification of the porphyrin macrocycle by phytol, a diterpene alcohol (Figure 5). Chlorophyll a and b are predominant in

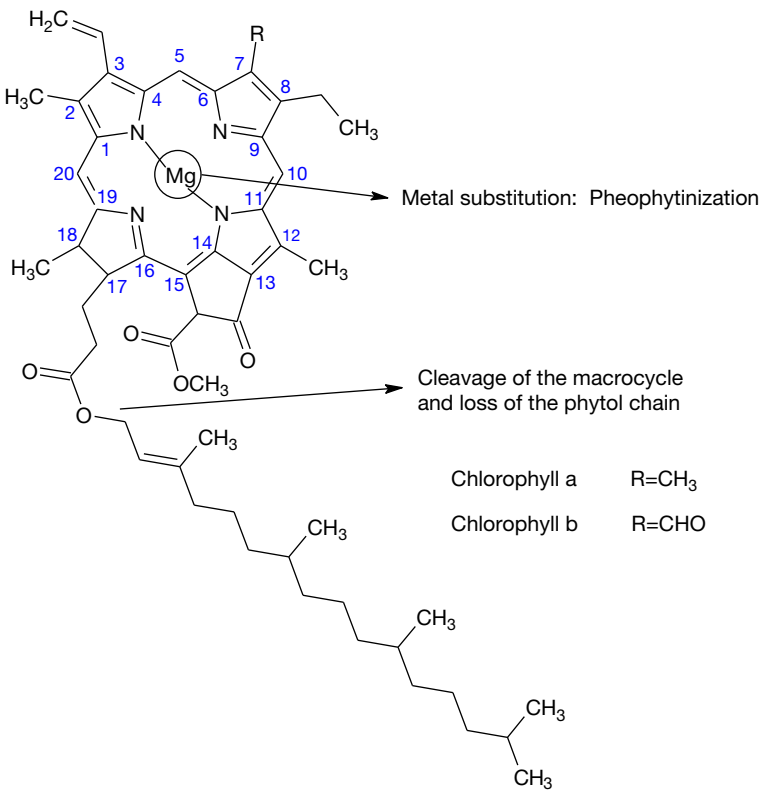

Figure 5 Chemical structure of dietary chlorophyll derivatives.

higher plants, whereas chlorophyll c, d, and e derivatives are found throughout various photosynthetic algae and diatomic species (brown, red, and yellow-green algae). Furthermore, several additional classes of bacteriochlorophylls have been isolated in photosynthetic bacteria. In plants, chlorophyll a is typically found in higher amounts than chlorophyll b by a 3-to-1 margin. The difference between chlorophyll b and a is the presence of an aldehyde residue instead of a methyl group at position 7. As a consequence, it results in chlorophyll a being a blue-green pigment with a λ_{max} of 660–665 nm and chlorophyll b being a green-yellow pigment λ_{max} of 642–652 nm. Chlorophylls occur in chloroplasts where they act as light-harvesting pigments during photosynthesis. Their distribution and content in fruits and vegetables depend on several factors including species, agroclimatic conditions, pre- and postharvest treatments, and type and degree of food processing. In fact, chlorophylls are relatively unstable and easily oxidized and converted to numerous derivatives responsible for the yellow discoloration of processed products.

Sources and Production

Commonly consumed green vegetables contain chlorophyll concentrations by up to fivefold higher than carotenoids. In some species, chlorophylls can exceed 1000–2000 mg kg^{-1} wet weight. Dietary chlorophylls include a large number of derivatives with structural differences affecting the color and the commercial and nutritive values of foodstuffs.

Fresh fruits and vegetables contain mainly chlorophylls a and b, which are both converted to olive-brown Mg-free pheophytin and yellow pyropheophytin during severe thermal processing or acidification common in canning operations. During blanching operations, chlorophyll undergoes the endogenous enzymatic cleavage of phytol forming the water-soluble chlorophyllide that can further degrade to Mg-free pheophorbide. However, in order to overcome the yellow discoloration of vegetables before thermal processing, metal-free derivatives can be converted to the stable Zn chlorophylls via the regreening process.

Chlorophyll extracts can be added as food colorants in jam, jelly, candy, ice cream, and several other products, although its application is limited because of the lability of the coordinated magnesium and the associated color change. To overcome this problem, a commercial-grade sodium copper chlorophyllin (SCC) has been developed. This is a mixture of Cu–chlorine derivatives prepared by the saponification of chlorophyll with NaOH, followed by a replacement of the Mg^{2+} atom by Cu. Since the copper complex is not absorbed by the body and is removed in its entirety as an excretion product, it is considered to be safe and is permitted to be used in most countries as the food additive E140. However, the concentration of free ionizable copper in the coloring must be kept below 200 mg kg^{-1} under current regulations.

Determination of Chlorophylls

Chlorophylls are commonly extracted from edible plants, nettle, grass or alfalfa, silkworm droppings and mulberry leaves, and, recently, marine microalgae. Traditionally, chlorophyll is extracted with organic solvents (methanol, ethanol, and acetone) under mild conditions. The chlorophyll extract is then mixed with dioxane and then precipitated through a dropwise addition of water in order to remove carotenoids. An alternative and safer technique is the supercritical fluid extraction with carbon dioxide, which is suitable for the isolation of thermolabile compounds and provides a solvent-free highly pure extract.

Chlorophyll pigment separation and identification are commonly achieved by HPLC with DAD (660 nm) and fluorescent detection (excitation 440 nm and emission 660 nm) on a C18 reversed phase using a gradient solvent system starting with methanol and ending with an ether–methanol mixture. Ammonium acetate is usually added as a suppression ion and ion-pairing reagent for the analysis of polar chlorophyll derivatives. An improved technique of detection is APCI–MS in both positive and negative modes. CZE with laser-induced fluorescence detection offers selectivity and sensitivity for the identification of the fraudulent addition of E140 to refined olive oil.

Patterns of Consumption

Compared with other food pigments, the dietary consumption of chlorophyll is really significant if we consider its natural abundance in green fruits and vegetables, the derivatives formed through food processing and cooking, and the increasing use of commercial-grade chlorophylls. In Mediterranean countries, a good source of chlorophylls is also virgin olive oil, although its chlorophyll content and profile are affected by both agronomic and technological factors, whereas, in East Asian culture, edible marine algae are an important source accounting for more than 10% of the Japanese diet with an average consumption of 1.4 kg per person per year.

Availability, Adsorption, and Metabolism

Considering that chlorophyll derivatives span a broad range of polarity from lipophilic (natural chlorophylls) to highly water-soluble (SCC) and have variable sensitivities to pH, they have different digestive behaviors and routes of absorption.

In vitro digestion models revealed that, due to the acid pH of the gastric lumen, both chlorophyll a and b are converted into pheophytins as the rate of pheophytinization is higher for chlorophyll a (97% of pheophytin a and 61% of pheophytin b). However, the type of food matrix also affects the digestive stability, and it seems that oily matrix exerts a slightly protective effect against pheophytinization. During the gastric phase, allomerization reactions involving C13 oxidation by triplet molecular oxygen can also take place, whereas de-esterification of pheophytins to give pheophorbides does not occur.

As for carotenoids, the adsorption of lipophilic chlorophylls by the small intestinal epithelium requires dispersion and solubilization into micelles for transport and incorporation through enterocytes. The bioavailability of the dephytylated chlorophyll derivatives is up 65-fold higher than that of the phytylated pigments. Where phytylated chlorophyll derivatives show passive absorption by simple diffusion, the dephytylated ones are passively absorbed by facilitated diffusion in the lower range of concentrations tested. In contrast to the lipophilic chlorophyll derivatives, the water-soluble SCC derivatives do not require association with bile

salt micelles, and the subsequent intestinal cell uptake seems to proceed predominantly by a facilitated process with absorbed SCC derivatives efficiently effluxed back to the luminal compartment.

The extent in which both natural lipophilic chlorophyll and SCC derivatives are metabolized and secreted into circulation is, however, currently unknown.

Curcumin

Curcumin is a yellow oil-soluble pigment found in the popular Indian spice turmeric deriving from the rhizomes of *Curcuma longa*. Curcumin, along with desmethoxycurcumin and bisdesmethoxycurcumin, belongs to curcuminoid, a group of polyphenolic pigments distributed not only in the *Curcuma* but also in the *Zingiber* species. Curcumin is a bis-α, β-unsaturated β-diketone and exists in at least two tautomeric forms, keto in acidic and neutral solutions and stable enol in alkaline medium. It is practically insoluble in water at acidic and neutral pH but soluble in alkali. It is stable at high temperatures and in acids but unstable in alkaline conditions and in the presence of light.

At pH 3–7, curcumin acts as an extraordinarily potent H-atom donor and it is a potent antioxidant, while above pH 8, curcumin acts mainly as an electron donor, a more typical mechanism for the scavenging activity of phenolic antioxidants. Due to the presence of two phenolic groups and one active methylene group, it also binds metals, particularly iron and copper, and can function as an iron chelator.

Sources and Production

Curcumin (diferuloylmethane) has been identified as the most bioactive constituent (2–8%) of the turmeric herb extract along with the other two curcuminoids. Curcumin is used as a food preservative and as a yellowish colorant. Turmeric has been also used in traditional medicine as a household remedy for various diseases. Nowadays, the health properties (neuroprotection and chemoprevention and cancer prevention) of curcumin and curcuminoids are gaining an ever-growing attention also in medicinal and clinical industries.

Commercial curcumin, generally extracted from the dried root of *Curcuma longa*, contains ~77% diferuloylmethane, 17% desmethoxycurcumin, and 6% bisdesmethoxycurcumin.

Determination of Curcumin

The extraction of curcuminoids is generally carried out using organic solvents. In particular, the efficiency of the solvent extraction presents the following pattern: methanol > acetonitrile > ethyl acetate. The efficient extraction of curcuminoids is obtained by also using supercritical CO_2 modified with 10% ethanol. On a massive scale, the microwave-assisted extraction technique allows the rapid and selective recovery of curcuminoids in a few minutes. Recently, there is an increased interest in the isolation of the individual curcuminoids and study of their various biological activities.

In this context, a high-speed countercurrent chromatography preparation with or without pH zoning has been developed in order to separate multigram quantities of curcumin and other curcuminoids from curcumin or turmeric powder while maintaining a high level of purity.

The main methods for the quantitative determination of curcumin include UV spectrophotometry (curcuminoids exhibit strong absorption between 420 and 430 nm in organic solvents), HPLC, and capillary electrophoresis. HPLC with diode array detection at 420 nm on C18 reversed phase in a gradient elution mode is the most widely used method without considering its limited sensitivity and low selectivity. HPLC–MS is very sensitive and has advantages over other methods in obtaining the structural information of analytes. However, it requires nebulization and vaporization steps, ionization of samples, and expensive instruments, which make this procedure unavailable in many laboratories. Therefore, a simple method with high sensitivity and low costs is still needed for the determination of these curcuminoids. HPLC coupled with electrochemical detection (ECD) is a highly sensitive and selective technique for the determination of redox substances. In recent years, the ECD method has also been reported for curcuminoid detection.

Patterns of Consumption

Curcuminoids have a restricted occurrence in nature; however, a higher consumption has been reported in Korean diets. Curry (37.24–617.98 $\mu g\,g^{-1}$), especially curry powder, mustard, candy, pickle, and snack food types, exhibits the highest curcuminoid content among various food items in Korean markets.

In Europe, curcumin is known as E100 food additive (turmeric or curcumin), which is widely applied to several food items (e.g., smoked fish, savory snacks, sauce, mustard, and seasoning) and to fabrics.

Availability, Absorption, and Metabolism

Many clinical studies have shown that curcumin has a very low bioavailability after oral assumption because of its poor solubility in aqueous media and its rapid metabolism and elimination. When orally administered, curcumin is absorbed in the gut and is present in the general blood circulation after being largely metabolized as glucuronide/sulfate conjugates. Unfortunately, whether curcumin metabolites are as active as curcumin itself remains unclear. In order to improve the bioavailability, novel delivery strategies such as lipid and polymeric nanoparticles, liposomes, and phospholipid complexes have been developed. Concomitant administration of adjuvants like piperine that interferes with glucuronidation has been undertaken.

Hemoglobin and Myoglobin

Myoglobin and hemoglobin are both hemeproteins responsible for the storage and transport of oxygen in many aerobic organisms, respectively. The characteristic red color of these proteins is due to the heme group (iron protoporphyrin IX) consisting of a porphyrin ring with a centrally located iron atom (Fe^{2+}). Myoglobin is a globular protein of about 153 amino acids (about 17 000 $g\,mol^{-1}$), holding the heme in a

protein pocket, while hemoglobin consists of four myoglobin-like subunits each containing a heme. The porphyrin ring structure held in the confines of the protein accounts for four of the six coordination sites available on the iron atom. These four bonds are with pyrrole nitrogens, while the fifth coordinates with the proximal histidine 93. A sixth site is available to reversibly bind oxygen and other small ligands. The presence of the ligand and the valence of iron dictate the pigment color of myoglobin and hemoglobin. A distal histidine 64 also influences the color dynamics by affecting space relations within the hydrophobic heme pocket.

Myoglobin is the dominant pigment in muscles and hence responsible for most lean meat color of land mammals. Therefore, four major chemical forms of myoglobin influence meat color: oxymyoglobin, deoxymyoglobin, metmyoglobin, and carboxymyoglobin.

Deoxymyoglobin occurs when no ligand is present at the sixth coordination site and the heme iron is ferrous (Fe^{2+}). This results in the purplish-red or purplish-pink color typically associated with vacuum-packaged products and muscles immediately after being cut.

Oxygenation occurs when myoglobin is exposed to oxygen and is characterized by the development of a bright cherry-red color.

Discoloration or browning results from oxidation of both ferrous myoglobin derivatives to ferric iron (Fe^{3+}) myoglobin called metmyoglobin. Reduction of metmyoglobin is crucial to meat color life and greatly depends on muscle oxygen scavenging enzymes, thus reducing enzyme systems, and the NADH pool, which is limited in postmortem muscles. Carboxymyoglobin is a relevant chemical state of myoglobin because of the current increased interest in packaging with low levels of CO. Moreover, combustion during cooking in a gas oven generates small quantities of CO or NO that bind to the myoglobin, forming stable pink compounds.

Sources and Production

The myoglobin concentration varies widely among different types of muscles, and it correlates with the oxidative capacity of the muscle cells within the species. Muscles involved in sustained repetitive actions, like breathing (diaphragm), contain higher concentrations of myoglobin than less-used muscles. The lateral line muscles of fish, which are used for sustained, low-power movement, are redder than the muscle groups used for short bursts of high-power movement. The pectoralis muscles of chickens, used for power takeoffs, are paler than the leg muscles. Moreover, the myoglobin concentration differs from species to species according to the age of the animals. The meat from older animals will be darker in color because of the myoglobin level increase with age due to the myoglobin loss of its affinity for oxygen.

Moreover, the processing and packaging conditions of meat also affect the concentration of myoglobin, thus the color of meat.

Determination of Hemoglobin and Myoglobin

The main methods for the quantitative determination of myoglobin and hemoglobin include UV spectrophotometry (myoglobin and hemoglobin exhibit absorption peaks between 400 and 600 nm) and colorimetric analysis. Colorimetric CIE (L*, a*, and b*) values are largely used to monitor color changes on meat surfaces. Moreover, size-exclusion HPLC combined with reversed-phase HPLC has been applied in order to obtain the separation of hemoglobin and myoglobin peptic hydrolysates.

Colors: Properties and Determination of Synthetic Pigments

E Diacu, University "Politehnica" of Bucharest, Bucharest, Romania

© 2016 Elsevier Ltd. All rights reserved.

General Considerations

Food industry has developed rapidly in recent years by producing a large amount of processed foods for consumers. These consumers select processed foods, having little time to prepare them. The main challenge today for the food industry is to satisfy the growing consumers' demands, who want food to be attractive, to taste good, to be healthy, and to be at a reasonable price. This has led food manufacturers to develop technologies, in which there is almost no food recipe that does not contain food additives.

Synthetic pigments (SPs) are among the first listed food additives, standing out as one of the widest used additive classes for food industry. Apart from providing important properties to the finished product, such as color uniformity and stability during processing and storage, SPs are used to enhance sensory response in concordance with consumers' desire. This is leading to a state of good mood, with the desire to consume more. SPs have been introduced as food colorants once they were synthesized by chemists, at first without any suspicion of their negative health effects. Produced on industrial scale, they could be used in a variety of purposes and areas, including food processing, often without taking into account the possible threat posed to human health, especially when they are present in excess or consumed for a long period. Until a few decades ago, there was no a rigorous control on the use of these pigments in foods. Over the years, due to health side effects arising from the consumption of foods containing pigments, in the population appeared a great concern over their possible adverse effects. Inevitably, laws were issued to protect the consumer and to regulate the addition of SPs in foods. Therefore, only a short list of SPs was compiled under certain condition and limits in use; a maximum daily intake was also established, either for each SP alone or in their binary mixtures.

To check the fulfillment of the laws relating to the addition of SPs in food and to take action when problems arise, advanced analytic methods able to determine with accuracy these compounds at low concentrations are needed. This article will present an overview of properties and determination of SPs, where the term 'pigment' refers to any synthetic compound that can give color to food and nonfood.

Short History

Pigments have been known to people since prehistoric times, at that time being used to decorate the walls or to mark their passing. In the very beginning, the number of pigments was limited, because most of them were obtained only from natural sources (earth, plants, animals, etc.). Earth pigments, *yellow ochre*, *red ochre*, *white chalk*, and *black*, were the most famous ones, being easily accessible from their environment and with a very simple technology for their preparation. Only by grinding these colored earths to a fine powder and then mixing them with some animal fats, people could apply these materials on different surfaces, resulting in latter paintings.

Even around 3000 BC in Egypt, pigments were used for painting. Also mineral *malachite*, *azurite*, and *cinnabar* pigments followed by a new color obtained by mixing more natural minerals, *Egyptian blue*. The Egyptians also were able to produce insoluble pigments by mixing organic dyes extracted from plants with hydrated clay or tannin, the procedure that was called lake making. Almost at the same time, the Chinese civilization developed *vermilion* (mercury sulfide), a new bright red pigment produced by burning mercury and sulfur.

In antiquity, Greeks manufactured two new pigments based on lead: first full white opaque color, the *white lead*, and the *red lead*, which was used also in cosmetics as powder. Today, lead pigments were banned for use by the general public due to their toxic potential. Romans have benefited from the existing pigments obtained before, fortifying the palette with a very expensive pigment obtained from small mollusks, the *Tyrian purple*, affordable only by the very rich people, being also used to dye the togas of Roman emperors. In the same period of time, the cinnabar was brought from the Spanish mined and used by Romans.

During the Middle Ages, the palette of pigments was enriched by discovering innovative combination and processing for other ores and rocks. Thus, a wide range of pigments were created, such as *bone white*, *green malachite* or *green earth*, and *lazulite* (*Lapis Lazuli*). In this period, the most important blue in the Middle Ages was ultramarine and also the most expensive pigment known so far. Due to its price and having a strong blueness, ultramarine has been predominantly used to decorate sacred subjects, especially for the Virgin Mary who was graced in blue.

In the eighteenth century, the synthetic chemistry revolutionized the field of pigments. The chemically synthetic pigment *Prussian blue* (blue lake) manufactured in 1704 by Heinrich Diesbach can be considered as the first modern pigment. However, it must be also related the synthesis of picric acid in laboratory almost in the same time (1771), used as yellow dye in a silk fabric. Since then, the chemistry has spent almost three centuries and succeeded to synthesize thousands of organic pigments in the finest quality ranges, which are very much used in a variety of industries. So, early in nineteenth century, once the Industrial Revolution started, the pigment industry has flourished and new permanent pigments were produced: cobalt pigments (in blue, green, violet, yellow, and red colors), synthetic ultramarine (less expensive than genuine ultramarine, but with identical properties), chrome yellow, genuine emerald green (a copper acetoarsenite compound, potentially lethal), synthetic iron oxides (known as Mars colors), and synthetic organic pigments mauveine, discovered by Perkin in 1856, alizarin crimson, and others.

Throughout the twentieth century, continuing apace until today, many new pigments – based on the discovery of new

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00191-4

chemical elements and on complex organic synthesis – were produced. An important place is taken by azo pigments, known especially by commercial names (Hansa Yellows, Winsor Yellow, Monastral Blue, Allura Red, etc.), because the scientific definition has been quite difficult to practice.

With strict reference only for foods, they were colored since ancient times by using naturally occurring pigments from vegetable and mineral sources, Egyptians, around 1500 BC being the first who used plant extracts as pigments in order to improve the appearance of candy. Three millennia ago, saffron, spice with a high nutritional value, was used to color certain foods and to cure some diseases in Greece. In early 300 BC, wine was also colored with saffron, and in the next period, many other food have improved their appearance by adding various natural pigments, like flower petals, marigold, spinach, parsley, and indigo. Starting with the twentieth century, SPs began to be produced on industrial scale and gradually started to be also used for food. At the very beginning, SPs were used without any regulation, although some of them presented a great toxic potential and were even poisonous (pigments based on lead, arsenic, and mercury complexes). As a result of such findings, a careful assessment of the SPs used in food started, their use was regulated, and only some of them were considered safe and approved for use in food. First foods for which the use of artificial pigments was authorized (yellow *pigments)* were butter and cheese in 1881 in the United States. Today, worldwide, more than ever in history, SPs are used for all kinds of food, drugs, and cosmetics. Nevertheless, as chemical substances, they are strictly regulated and monitored, being the subject of many clinical studies.

Synthetic Food Pigments Used in Food Industry

Color is the attribute most commonly used as base for the quality assessment, a natural color showing to the consumer a high-quality food product, while a pale color may indicate an inferior-quality product. For example, orange in its various forms is associated with aroma, pleasant taste, and energy. Therefore, SPs, provided by industry in a full range of colors, have gained great importance. Making food more attractive for consumers, SPs became always present components in almost every processed food, starting with fruit juices, fast food, dressings, ice cream, cakes, and so on. More than that, added color serves as a kind of code that allows to identify in the easiest way the food products such as candy flavors.

Standing out as one of the widest food additive classes, synthetic food pigments are used in food processing for many specialized applications, especially to keep or to improve the perceived color of fresh and processed foods, being known that colors are a clue to the flavor to be savored. In particular, synthetic food pigments are used not only to provide color to colorless food but also to produce 'fun' foods for children, who are thus exposed, without being aware, to the most undesirable effects of this type of food consumption.

In food processing, manufacturers are tempted to use synthetic food pigments because they are more attractive than natural ones, with a number of advantages: high stability during food processes, exposure to light or storage, more intense and uniform color, easy production by synthesis, a wide variation of colors, and convenient prices. Unfortunately, these colors were sometimes used not in a reasonable quantity, without taking into consideration the possible harmful effects on human health, in particular to most vulnerable members of the population (children). Moreover, cases have been identified when the synthetic dyes were used to disguise grave defects of the low-quality food.

Despite possible adverse effects on human health and on the environment, today, SPs are widely used in the food production and other goods, representing more than 60% of all the dyes produced annually.

Effects of Synthetic Food Pigments on Human Health

The dangers on human health through using SPs in food have been a source of controversy for decades, which continues today. On one hand, nowadays, the use of SPs by food industry has grown constantly, becoming a necessity with the increasing need for processed food. The manufacturers' opportunity to use a wider range of SPs considerably increased due to high complexity of food matrices, notwithstanding possible harmful effects on the health of humans. On the other hand, a growing concern of all consumers regarding food safety relates to the presence of the SPs in food and drinks, because these chemical compounds have been suspected to cause serious health troubles, complaints regarding their mutagenic and carcinogenic risks being also reported.

The most incriminated synthetic compounds as carcinogenic are azo pigments, due to the presence in their molecule of azo linkage, which do not occur naturally. This linkage is the most labile portion of azo dye molecule and can be easily broken enzymatically (i.e., metabolic cleavage), inducing the oxidative stress that leads to formation of free radicals in mammals, including man. Therefore, numerous toxicological and metabolic researches on animals and humans have been performed to assess the effects of food colors on human health, and almost all these studies have shown that synthetic food pigments are unhealthy substances for consumers, especially for children. Many research results show that SPs may cause mainly DNA damage, which then manifests differently. Thus, allergies and changes in hepatic and renal parameters, behavioral problems and attention disorder (particularly in children), respiratory problems (asthma), and heart troubles have been reported especially if azo dyes were present in food (Tartrazine-E102, Sunset Yellow-E110, Allura Red AC-E129, Ponceau 4R–E124, etc.). Azo dyes are also incriminated for their mutagenic potential, especially in the development of intestinal and kidney cancers. Also, there are some SPs that have been banned for food use due to toxic side effects of the breakdown products of these chemicals.

Studies on the dangerous effects of the presence of synthetic food pigments on humans are nonconclusive, and some of them are contradictory. Most toxicological studies showed that adverse health effects are observed when foods containing SPs are consumed in large quantities or when there is an extended exposure over a period of time. But effects on certain sensitive groups of children cannot be excluded.

Although a lot of issues still remain unknown, the majority of toxicological research results agree that the presence of color

additives in foods, in limited amounts, as required by law, does not present serious health hazard. On the other hand, there are highly sensitive people to the presence of unnatural food ingredients that often exhibit severe negative reactions, even in a very limited exposure to such chemicals. Therefore, it is necessary to create consumer awareness regarding the possible ill effects of these food azo dyes and, generally, to pay attention to the type and concentration of each chemical substance added to food, which is compulsory to be written clearly on the respective label.

Current Legislation

Globally, there is a growing consumers' concern surrounding food quality, the food naturalness, the ecological origin of raw materials, the processing technology, packaging, labeling, transportation, and storage. However, in recent decades, there has been an increasing demand of processed foods, and along with it is a high increase in the use of food additives, including SPs. Under the circumstances, the consumer's anxieties regarding the presence of SPs in food were stressed, and the legislation came into force to prevent their unsafe and fraudulent uses. Strict rules were imposed, and the most dangerous SPs were banned in most countries. It was established that the introduction of any SP in food must be subject to premarket approval, and only a limited number of permitted SPs were certified. For each food color, a maximum admitted limit per unit of food was established, and furthermore, limits for simultaneous presence of two or more pigments were foreseen.

There is no common legal framework valid in all countries for the use of SPs in food. In the European Union, the legislation for the use of food additives has been harmonized across all countries, the Council Directive 94/36/EC (1994) being the major law on food colors. Among other food safety regulations, in this directive, the color additives are termed as *E numbers* (from E 102 to E181), abbreviation given to their easy usage as shorter than chemical denominations. A list of permitted colors with maximum allowable levels in various food categories and of colors that have restricted application is annexed here. For example, the maximum accepted level in food for tartrazine is of 100 ppm ($\mu g\,ml^{-1}$) and for Sunset Yellow is 50 ppm, when used individually and no more than 100 ppm in binary mixtures. The purity criteria for colors must also be taken into account by law, these aspects being stipulated in Commission Directive 95/45/EC. In the United States, the Code of Federal Regulations is the body that restricted the use of color food additives in a number of seven water-soluble dyes and six insoluble lakes. Here, SPs are denoted as FD&C colors; for example, tartrazine is known as FD&C Yellow 5.

It should be mentioned that most other countries have their own rules and regulations for the use of synthetic food colors in various applications. For example, Sunset Yellow and Allura Red AC are permitted food pigments by European law, but there are European countries where these colors are banned due to their potential allergic reaction.

Moreover, the synergetic effect due to the simultaneous presence of all types of additives in food has not been investigated yet. Nor the prolonged consumption of synthetic foods containing multiple additives with disastrous consequences on the health of humans, an effect that may occur immediately or over time, was not taken in the study to date.

The establishment of a general legal framework for the use of SPs in foods to be available around the world is a difficult task, although it would be particularly useful. Also, a cumulative additive food content regulation (in terms of synergy effects) is not yet covered so far.

SP Classification and Properties

SPs are substances that absorb the light in the visible spectrum and have the ability to uniformly impart color to a food or nonfood due to the presence in their molecule of at least one chromophore group and of conjugated system with double and single bonds. They are liquid or powdered chemical substances, many of which are petroleum by-products. For thousands of pigments produced through chemical synthesis, in literature, there are reported several types of classification, taking into account various criteria.

As chemical compounds, SPs may be inorganic or organic compounds. These two categories can be further subdivided into other classes. Thus, organic SPs, as the main topic of this work, can be classified in four main classes, according to their chemical structure: azo, nonazo, fluorescent, and miscellaneous pigments. SPs can be also divided into 'lakes' or 'dyes.' But the most common classification system for SPs is drawn according to their use: artwork and industrial paints, architectural, automotives, textiles, cosmetics, printing inks, plastics, pharmaceuticals, foods, etc.

Synthetic organic pigments display a wide variety of physical and chemical properties such as color, light and heat stability, solubility in water or organic solvents, and reactivity; depending on the class they belong to, but generally, SPs within a chemical class display similar properties. However, in the same class, there is the possibility to create some differentiations intentionally through fine synthesis for quality improvement, especially for artwork.

Synthetic Food Pigments

Synthetic food pigments, also called dyestuffs, have the capacity to give color to the food in a stronger and longer-lasting manner than natural pigments. They can be easily identified in food in several ways. Each pigment is listed at international level with five-digit C.I., according to Color Index Generic Numbers, and at European level, through 94/36/EC Directive, by an *E number*, which has the correspondent FD&C colors in the United States. Synthetic food pigments are also represented by their meaningful commercial names, such as Patent Blue V and Indigo carmine.

Synthetic food pigments could be subdivided into two major classes: azo food pigments and nonazo food pigments, but often, they are categorized by their predominant shade, such as pigments yellow, red, or blue.

Azo food pigments

Azo pigments are synthetic compounds that contain in their molecular structure one or more azo groups (—N═N—), being the oldest and most used pigments in food. The base

for the development of azo pigments was the discovery of diazo reaction in the laboratory of Peter Griess in 1858, when the first azo compound was produced, and very rapidly after these, organic chemists have discovered new azo pigments.

The most representative food monoazo pigments permitted by the EU are the following: *tartrazine* E102, C.I. 19140; *Sunset Yellow* E110, C.I. 15985; *carmoisine* E122, C.I. 14720, *amaranth* E123, C.I. 16185, *Ponceau 4R* E124, C.I. 16255; *Red 2G* E128, C.I. 18050; and *Allura Red AC* E129, C.I. 16035 (Figure 1).

Azo pigments are purely of anthropogenic origin, being generally obtained through a relatively simple organic synthesis carried out in two steps, when two organic compounds are required for the coupling and azo linkage formation, respectively, the diazotization of a primary aromatic amine is followed by coupling. Because they have a long scientific name, in most of the cases, azo pigments are known by their market name. For example, the azo pigment 3-carboxy-5-hydroxy-1-(4′-sulphophenyl)-4-(4′-sulfophenylazo) pyrazole trisodium salt is known as tartrazine, disodium 6-hydroxy-5-[(4-sulfophenyl)azo]-2-naphthalenesulfonate is Sunset Yellow, disodium 6-hydroxy-5-((2-methoxy-5-methyl-4-sulfophenyl) azo)-2-naphthalenesulfonate is Allura Red AC, and so on.

Class of nonazo food pigments allowed in the European Union (EU) includes four main groups: the triarylmethanes (with *Patent Blue V* E131, C.I. 42051; *Brilliant Blue* FCF E133, C. I. 42090; and Green S E142, C.I. 44090), the chinophthalon derivative (*Quinoline Yellow* E 104, C.I. 47005), the xanthenes (*Erythrosine* E127, C.I. 45430), and the indigo colorants (*Indigo Carmine* E132, 73015). But the representative class for food colorants is azo food pigments, and they are currently the market leaders.

Synthetic food pigments can be used either alone or in binary mixtures for obtaining a large spectrum of colors, such as *tartrazine* and *Sunset Yellow*, *tartrazine* and *Erythrosine*, and *Allura Red AC* and *Ponceau 4R*. Usually, manufacturers choose a pigment that is very effective, or they choose a pigment as a base for other color combinations, as appropriate for the type of food product.

Synthetic Food Pigment Determination

Potential health hazards due to the presence of SPs in food have attracted considerable attention, and much effort has been devoted to the development of methods for their detection and analysis. These issues have become very topical in terms of current legislative constraints, the literature reporting an impressive number of papers dealing with the determination methods for synthetic food pigments. From the outset, it must be said that the determination of SPs is often a difficult task not only because they are complex chemical compounds of relatively low concentration in food but also because they are in a very complex food matrix sample. The analysis becomes more difficult, or even impossible, for those synthetic

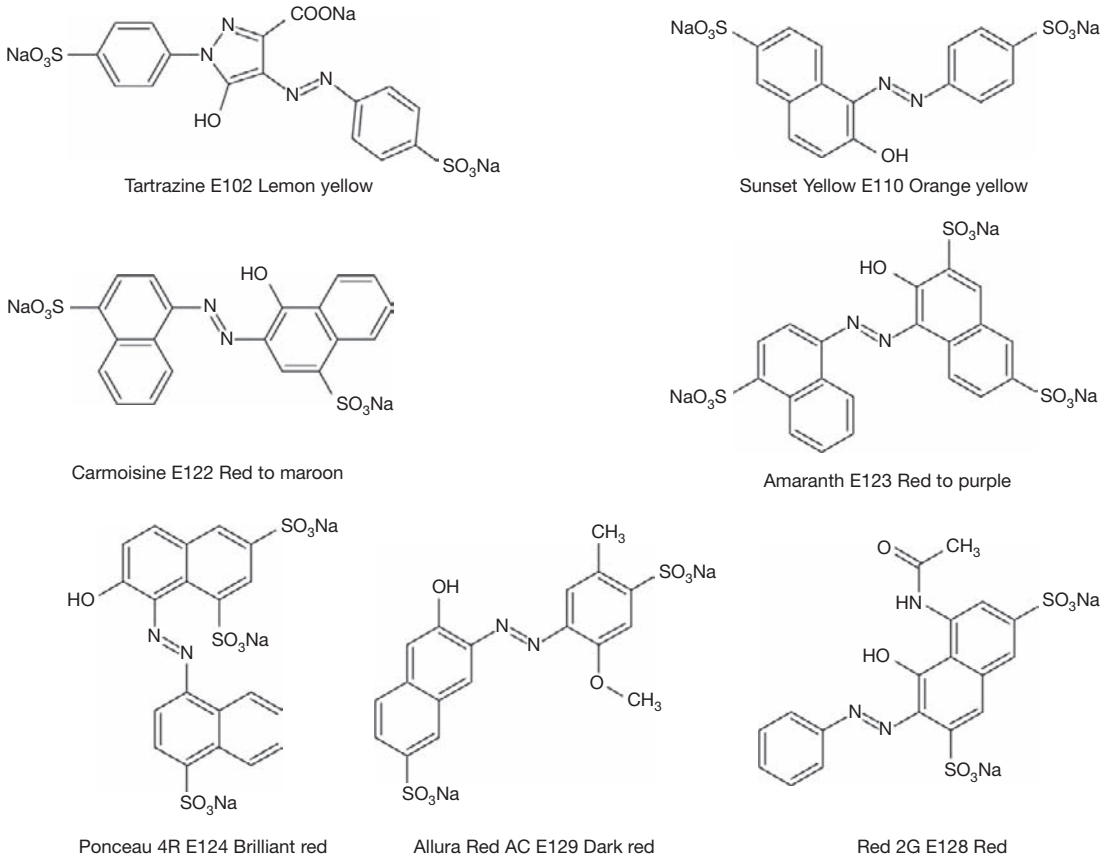

Figure 1 Chemical structures and predominate color for seven most important food azo pigments.

organic pigments that differ only in terms of structure, with a different position of their substituents on the benzene ring. Nevertheless, a variety of analytic techniques for the identification and determination of SPs have been developed, traditional analytic techniques and most advanced ones being reported in the literature. In the following, the most commonly used of these methods in SPs analysis will be briefly reviewed.

Spectral Methods

Spectral methods were the first methods used in SP examination; the analysis of pigments from tube paints was and is commonly performed by ultraviolet–visible spectrometry. Due to the possible presence in the same sample of the natural pigments and of other numerous interferences, absorption molecular spectrometry, in its classical form, was applied mainly to individual pigment analysis and had a relatively small number of applications for analyzing mixtures of SPs. Thereafter, this method has supported numerous improvements in terms of selectivity, especially by the application of chemometrics, and simultaneous analysis of two or more SPs has been reported. From the beginning, infrared spectroscopy had a bigger potential to be used in the analysis of SPs, dry or in solution, although the presence of fillers and extenders as main components in sample matrix makes analysis particularly difficult. Therefore, more important results have been reported after improving sensitivity of IR method by using, as sample, the extracts of SPs. Undoubtedly, the most important achievement in the field was the development of new FTIR technique, by which nearly all SPs could be identified against the spectra of pure compounds that have a characteristic molecular *fingerprint*. Further studies have recommended Raman spectroscopy as a good technique when analyzing synthetic organic pigments from artworks, either individually or in mixtures (up to twenty-one dry azo pigments can be analyzed simultaneously). Compared with FTIR, Raman spectroscopy has the advantage of sharper peaks that do not overlap each other, making much easier the identification of each pigment from a complex sample. However, FTIR and Raman spectroscopies are complementary techniques, together succeeding to overcome almost any problem that may arise in the pigment analysis.

Spectral methods described in the preceding text have reported just few applications in the determination of SPs in real food samples, which include especially the analyses in soft drinks. The reason for this is the high complexity of food samples; almost always, an additional extractive step in sample preparation is needed in order to avoid the spectral overlap, and therefore, more time for analysis is required. New achievements in the simultaneous determination of SPs, such as Sunset Yellow, tartrazine, and Allura Red AC, in soft drink powders have been recently reported by the use of derivative signals of the ratio spectra and the involvement of chemometrics. The obtained linear response covers tens of ppm ($\mu g\ ml^{-1}$) starting with 2 $\mu g\ ml^{-1}$ up to 60 $\mu g\ ml^{-1}$, so the spectral methods may be used for SP control in soft drinks.

Electrochemical Methods

Many SPs possessing electroactive properties have led researchers to develop electrochemical methods for their determination, especially for azo pigments. Differential pulse voltammetry (DPV) and cyclic voltammetry, using different working electrodes, are the most common electrochemical techniques used for the investigation of SPs. Depending on the respective pigment, voltammograms show specific anodic or cathodic peaks that allow the identification and quantification, the peak current being in directly proportionality to the pigment concentration. Figure 2 presents the DPV curves for tartrazine at different concentrations ($mmol\ l^{-1}$) on glassy carbon electrode at pH = 3, where linear dependence of anodic and cathodic peaks with the tartrazine concentration is observed in the upper inset.

Numerous studies revealed that voltammetric methods are selective and sensitive techniques, with very good detection limits of 0.80 $mmol\ l^{-1}$ for common azo pigments. Also, voltammetric techniques have proved to be not only powerful

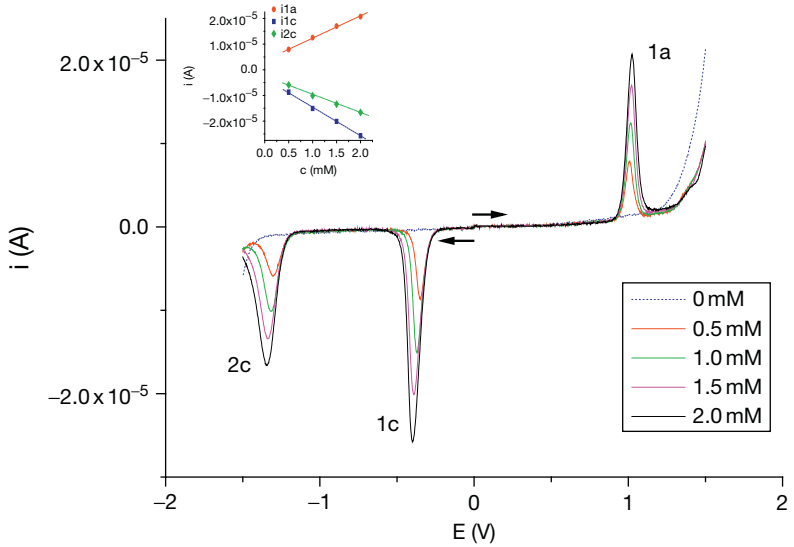

Figure 2 DPV curves for tartrazine; upper inset – dependences of anodic (i1a) and cathodic peaks currents (i1c) on tartrazine concentration (c).

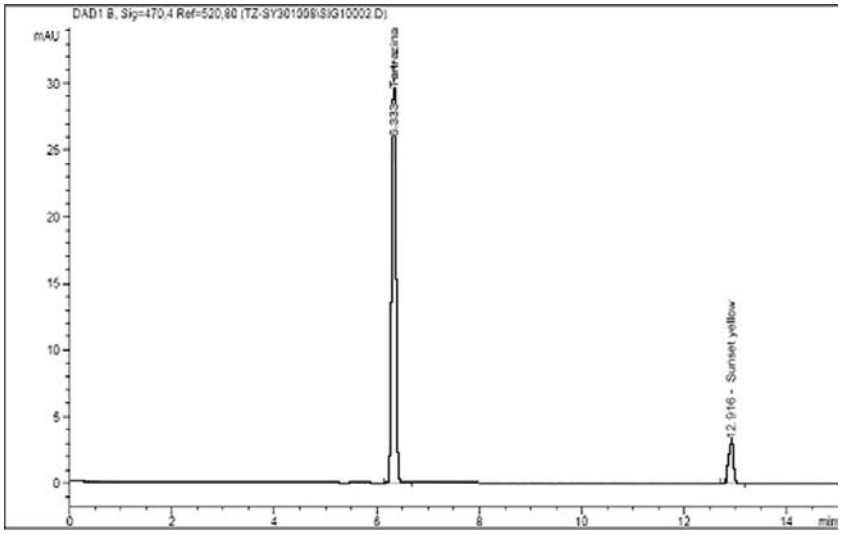

Figure 3 Chromatogram for an orange juice sample on Hypersil 5 μ MOS C_8 column. HPLC system *Agilent Series 1100*-DAD detection.

tools in the SP investigation that offer analytic options for their analysis but also good way to determine the degradation products because they are able to establish certain degradation processes that are likely. Moreover, they can make distinction between synthetic and natural pigments of the same color because the latter are not electroactive (do not have azo group in their molecule).

Although voltammetric methods are simple, sensitive, and less expensive than spectrometric ones, they do not have a broad use in the control of SPs in food, mainly due the same reasons as mentioned in the preceding text. However, the latest breakthroughs in the use of new materials for electrodes are a promising outlook in simultaneous determination of SP in food, particularly in beverages, and these methods are a hopeful alternative to classical approaches to the analysis of SPs.

Chromatographic Methods

Compared with other analytic methods used in the analysis of SPs in food, chromatographic methods are by far the most attractive for achieving the requested performance criteria, either under research requirements or under routine analysis. These methods offer the possibility to analyze SPs with high accuracy and precision, with a very good detection limit ($\mu g\ ml^{-1}$), without a prior step of sample preparation. In order to detect the presence and content of SPs in foodstuff, many separation techniques have been developed and applied, such as thin-layer chromatography (TLC), high-performance thin-layer chromatography (HPTLC) capillary electrophoresis, gas chromatography, high-performance liquid chromatography (HPLC), including ion chromatography and ion-pair chromatography, reporting valuable results. Among these methods, TLC and HPLC have been widely used for food pigment analysis in various food samples, such as fruit-flavored drinks, alcoholic drinks, fruit yogurts, jams, sweets, sugar confectionery, spice, and brightly colored foods. Mainly, TLC aimed to develop rapid methods for the separation and identification of complex mixtures of pigments. This method, with new improved version of reversed-phase HPTLC, has been successfully applied in the analysis for mixture up to 9 pigments on the same chromatographic plate. Recently, HPTLC has been used in the investigation of chili, paprika, and curry powders for the presence of illegal pigments, such as Sudan I–IV, Sudan Red B, Sudan Red G, Para Red, Butter Yellow, and Toluidine Red. All these pigments are classified as carcinogenic substances and are unauthorized substances in foodstuffs under the EU Food Regulations. Reversed-phase HPLC method with diode-array detection in the isocratic elution mode became one of the most valuable approaches for simultaneously determination of complex mixtures of SPs from food matrices and only requires a simple pretreatment of the sample. This can consists in a solvent extraction or in a filtration and sonication. A chromatogram for tartrazine and Sunset Yellow determination in an orange soft drink sample is presented in Figure 3.

HPLC method has reached today a new level of performance by further advances in instrumentation and column technology, this method being known as ultrahigh-performance liquid chromatography (UHPLC). This chromatographic technique brought significant increases in speed, with a very good resolution and sensitivity, UHPLC technology having the capacity to solve almost every problem raised in food pigment analysis.

In this brief overview of methods for determining the SPs, a special role is played by analytic methods based on liquid chromatography coupled with mass spectrometry, considered as unrivaled techniques in the identification and quantification of SPs in food. Performance criteria of these coupled methods, especially the selectivity, provide unambiguous identification and accurate determination of SPs in complex matrices at trace levels, without the need of laborious pretreatment procedures.

Conclusions

Dangers to human health caused by synthetic food pigments are in the spotlight, food safety experts raising numerous

concerns regarding the use of SPs as food colorants. Consequently, the European authorities have established the legal framework for reevaluation of azo pigments as food additives. The aspects raised in this article have highlighted few issues regarding safety and quality of food and drinks that are of high priority worldwide:

1. The need to reduce as much as possible the human health risks due to the presence of chemical ingredients in food by using natural ones. More and more people have become increasingly aware of the dangers of foods that contain artificial pigments, and such foods became less popular, polls indicating global preference for natural food colors.
2. The requirement to test and evaluate the safety of any SP before being used in food with the strict revision of already permitted SPs in food and the law enforcement for taking action if problems are found.
3. The necessity to review the food additive science by running projects on the subject and to develop advanced analytic techniques for the presence of the colors additives in food. It is unanimously recognized that determination of synthetic organic pigments is not easy to perform because of their high coloring power and of similarity in the structure; therefore, there is a critical demand for new development of analytic procedures addressed to improve the determination of SPs in food. Thus, an accurate assessment of SPs in foods can ensure the compliance of legal requirements, in many countries, synthetic food colors being banned in the interest of public health. However, it should be understood that actually, food technology passes through colors, but at the same time, it must go to people's health. Therefore, it is necessary to try to make sense of SPs by setting universal standards.

Introduction

Since ancient times, people have been aware that milk could only be kept fresh for a short while and that it was only available in the immediate vicinity of a cow. In the thirteenth century, Marco Polo reported that the Tatars were able to condense milk. He stated that 10 pounds (4.5 kg) of milk paste was carried by each man, who would subsequently mix the product with water. However, this report probably refers to the soft Tatar curd *katyk*, which can be made into a drink (*ayran*) by diluting it, and therefore it refers to a fermented, not fresh, milk concentrate. Nicolas Appert condensed milk in France in 1820, and Gail Borden Jr. did the same in the United States in 1853, in reaction to the difficulty of storing fresh milk for more than a few hours. While returning from a trip to England in 1851, Borden was devastated by the death of several of his children, apparently from poor quality milk obtained from shipboard cows. Borden was inspired by the vacuum pan he had seen being used by Shakers to condense fruit juice, and he was at last able to reduce milk without scorching or curdling it. Even then, his first two factories failed, and only the third, built in New York with his new partner, Jeremiah Milbank, produced a usable milk derivative that was long-lasting and needed no refrigeration.

The first person to preserve milk in a concentrated form was Nicolas Appert, who, in the early nineteenth century, concentrated milk by boiling it in a water bath over a fire, then pouring it into glass bottles after cooling, and sterilizing the final product by heating the bottles for 2 h in a boiling water bath. Two inventions made in the second half of the nineteenth century resulted, essentially, in the process that is still used today. Gail Borden (1856) patented the process to evaporate milk, which uses low pressure to make sweetened condensed milk. In 1884, John B. Meyenberg patented a process for sterilizing concentrated milk in tinned cans, which were rotated under pressurized steam, allowing for a relatively short sterilization time. A brief account of the historical developments of condensed milk manufacturing is conveyed in Table 1.

Condensed Milk

Condensed dairy products are value-added milk products with extended shelf life. Fresh milk is clarified and standardized to a suitable level of fat, and it is then heat treated at 85–90 °C for several seconds. This heating process acts as a hurdle, which destroys the majority of microorganisms. It also decreases fat separation and inhibits oxidation. The water content of the milk is reduced due to evaporation. Condensed milk products have several advantages over fresh milk, such as they require less storage space, they retain high quality, they preserve milk's valuable surplus nutrients, and they reduce transportation costs. These products can be used under adverse conditions such as wars, epidemics, or earthquakes or other natural disasters when fresh milk is unavailable. They are also suitable for specialty food products designed for people such as sportsmen, convalescents, or older individuals.

Evaporated milk (EM) is sterilized unsweetened condensed milk, and this product is available commercially. It is prepared from fresh milk from which a sizable (almost half) amount of water is evaporated. Then the product is homogenized and canned, and the cans are subjected to the thermal process of sterilization (Figure 1). In the event of limited availability of fresh milk, milk powder is used in part or all of the solids-not-fat (SNF). Similarly, the fat portion can be obtained from anhydrous milk fat (AMF). If the product is prepared using only milk powder and AMF, it is called *recombined evaporated milk* (REM). In addition to milk, skim milk, and cream, sweet cream buttermilk is also frequently used as a source of some of the milk solids. Because sweet cream buttermilk contains a large portion of the fat globule membrane lipids in milk, it improves the heat stability and the flavor of products, particularly REM. The properties of REM resemble those of EM.

There is no provision under the Codex Alimentarius standards to distinguish a product made from milk powders and AMF from that made from fresh milk. But legislation in some nations has set limits on the use of powders (e.g., EU legislation requires that no more than 25% of the milk solids in regular unsweetened condensed milk are derived from milk powder). There is an emerging trend in some countries to prepare EM using vegetable fats (most frequently, palm oil) instead of milk fats; this trend could be due to an attempt to reduce costs or simply a local preference to not use milk fats. The product thus prepared is called 'filled' EM. Oils high in polyunsaturated fatty acids, such as soybean or sunflower oil, are used in food products to lower blood cholesterol. The oxidation stability of the fats used in REM is of paramount importance.

To improve milk's heat stability during thermal processing, sodium orthophosphate is added. In addition, calcium carbonate, soy lecithin, or calcium chloride is added to help improve milk's heat stability. Polyphosphates are also added to ultra-high-temperature (UHT)-sterilized evaporated milk to control defects such as age gelation of the product. The Codex sets a maximum limit for an addition of 0.2% on an individual basis, or 0.3% if a combination is used.

When the liquid product is mixed with a proportionate amount of water, EM becomes the rough equivalent of fresh milk. However, it requires half the space of its nutritional equivalent (fresh milk), which makes EM attractive for transportation purposes as it can have a shelf life of months or even years, depending on the fat and sugar content. EM is a safe and

Table 1 Historical developments in condensed milk manufacture

Year	*Developments in condensed milk manufacturing*
1357	Marco Polo (Mongolia) described the method for preparing a pasty milk concentrate, which was mixed with water
1809	Nicolas Appert (France) described a method for preserving milk by condensing it
1856	Gail Borden Jr. commercially developed a method of condensing milk; he is known as 'the Father of the process of milk condensing'
1858	Borden's milk, sold under the Eagle Brand, gained popularity for its purity, durability, and affordability
1864	Borden's New York Condensed Milk Co. constructed the New York Milk Condensery, the largest and most advanced condensery, in Brewster, New York
1883	The vacuum pan was markedly improved due to advancements in scientific knowledge in the field of sterilization
1884	John B. Meyenbarg (Switzerland) experimented to create the process to sterilize condensed milk using steam under pressure. He conceived the idea of making condensed milk without the addition of sugar or other preservatives and without storing it under refrigeration
1906	The Federal Food & Drug Act of 1906 changed the name 'evaporated cream' to 'evaporated milk'
1911	Nestlé constructed the world's largest condensed milk plant in Dennington, Victoria, Australia
1914	Professor O. F. Hunziker, Head of the Department of Dairy at Purdue University published a book titled *Condensed Milk and Milk Powder*. Professor Hunziker and others with the American Dairy Science Association standardized and improved condensery operations in the United States and other countries
1958	Plate-type evaporators were developed
1961	Anand Milk Producer's Union Ltd. (AMUL), in India, started the first ever commercial production of sweetened condensed milk in that country

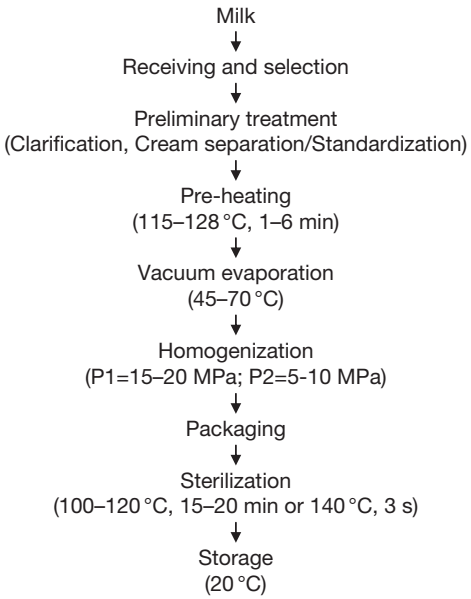

Figure 1 Flow diagram for the preparation of condensed milk.

reliable substitute for perishable fresh milk, and it was very popular before the invention of refrigeration. It can be easily shipped to locations devoid of resources for safely producing or storaging milk. Today, households across the world use it most often to prepare desserts and in baked goods due to its characteristic flavor.

The Codex Alimentarius standards, which are the most common in international trade, prescribe a minimum of 7.5% milk fat and 25% total milk solids (TMS) in EM. Similarly, legislation in various nations has set limits for the composition of EM. According to the traditional British standard, EM requires a minimum of 9% milk fat and a minimum of 31% TMS, while the U.S. standard prescribes a minimum of 7.9% milk fat and 25.9% TMS. Thus, the concentration of EM ranges from 2.0 to 2.5. The Codex allows the protein content in the SNF to be adjusted, with a minimum of 34%, by adding lactose, milk permeate, or milk retentate. However, additions that change the ratio of casein-to-whey protein are not allowed, with the local legislations in some countries still forbidding standardization of the protein.

Method of Evaporated Milk Preparation

The method to manufacture sterilized and UHT-sterilized EM is shown in Figure 1. The major processing steps are discussed in the following sections.

Preheating

Fresh milk is heat treated before it is concentrated. This treatment is mainly to increase the concentrated milk's heat stability. The homogenized full-cream EM cannot be sterilized if the milk is not subjected to preheating. Generally, milk is preheated at 110–130 °C for about 1–3 min in a continuous flow to yield EM with the highest heat stability. Preheating also acts as an important hurdle for microbial growth as it inactivates microbial spores. For REM, preheating is carried out by the powder manufacturer, before concentration and drying. This allows the powder to be reconstituted at the predetermined concentration for REM.

Concentration of milk

Modern multistage falling film evaporators with energy efficient designs are invariably used for milk concentration. Overconcentration should be avoided to prevent the risk of lowering the milk's heat stability. Similarly, overconcentration also requires higher energy use and lowers the production capacity. Based on the continuous measurement of the refractive index or density of the concentrate, the total solids (TS) content is adjusted at the point where the product leaves the evaporator. The final standardization of fat and TS is usually carried out between the concentrating and sterilizing processes. The milk, which is concentrated by reverse osmosis (RO), can also be used to prepare unsweetened condensed milk. EM produced by RO has virtually the same composition and properties as that produced by evaporation, but the industrial application of RO for this purpose appears to be very limited.

Homogenization

The milk is homogenized as this process prevents coalescence of fat globules and reduces the rate of creaming while the product is stored. The homogenization pressures up to about 5 MPa generally have little effect on or slightly increase heat stability, but higher pressures result in a large decrease in heat stability. The concentrated milk is homogenized immediately after it leaves the evaporator. A higher homogenization temperature results in a smaller fat globule size at the same pressure with better heat stability.

Heat stability test

During preparation of EM, it is obvious that the heat stability of the product varies from batch to batch. Stabilizers are added to regulate the heat stability. The amount of stabilizer needed also varies to a great extent. The quantity of stabilizers to be added is determined by adding different amounts of the stabilizers to a series of cans containing the product. The cans are subsequently sterilized, and the contents are checked for heat stability. The amount of stabilizer that results in the optimum properties is added to the total batch.

Cooling and cold storage

After homogenization, EM is cooled and stored, and then a predetermined quantity of stabilizer (dissolved in water) is added; this quantity is determined by the results of the stability test. At this stage, prolonged storage should be avoided to prevent microbial growth. Final standardization of fat and TS can be carried out at this stage, taking the amount of water that is added with the stabilizer into account. The cold storage of unsterilized EM for more than 24 h considerably increases the risk of the sterilized product's age gelation.

EM is expected to be stored for longer period, which requires various conditions so that the product's quality does not deteriorate during storage. The storage temperature is one major factor determining the shelf life of the product. Condensed milk and EM are stored at about 10–15 °C. Storage at low temperatures such as 0 °C or below may lead to sugar separation in the condensed milk, leading to sandiness; this sugar separation is caused by the formation of very large lactose crystals. A very low storage temperature also increases the viscosity of the product, which may be beneficial up to a certain point, but it also affects the product's body and texture characteristics. It has been shown that commercial EM remains acceptable even after 2 years when stored below 15 °C, but it deteriorates rapidly when stored at 21 °C or above. The humidity of the storage space should also be kept low (below 50%) to check the spoilage of cans and labels. Inversion of the cans during storage minimizes fat separation in EM.

Packaging

One of the characteristic features of EM is its long shelf life at ambient temperatures; this feature places high demands on the packaging materials. The packaging materials should meet the criteria of mechanical resistance and permeability to water, light, gasses, and hydrophobic components. Those parts that are in direct contact with the product must be made of food-grade materials. The can is the most widely used container for EM, with a standard content of 170 or 411 g (6 or 14.5 oz, respectively). Mechanically sealed cans are widely used for the packaging of concentrated milk products. Modern tinned plate is coated with a layer of a polymer to prevent the dissolution of the tin and iron into the product. In some Western European countries, glass bottles with twist-off caps are used to package EM used as a coffee creamer. Aluminum foil-lined milk cartons and single-portion cups made of aluminum or polystyrene are also widely used. The EM packaged in translucent (white) polystyrene single-portion cups usually develops an oxidized flavor due to the permeability of this material to both oxygen and light.

Sterilization

Sterilization not only kills all microorganisms but also inactivates all microbial spores that may germinate during the storage of EM. The native milk enzymes are inactivated during preheating. While selecting the milk to prepare as concentrated milks, its excellent microbiological quality should be noted. The enzymes produced by microorganisms (especially psychrotrophs) should be absent because they are thermostable, and even sterilization is insufficient to inactivate them. Heating is carried out in continuous sterilizers. Several machines have been designed to fill cans with concentrated milk. In a commonly used system, known as 'vent hole type,' concentrated milk flows through a small aperture (3 mm or 1/8 in. diameter) into cans. After filling, the cans are sealed carefully because the seal has to withstand the heat of the sterilization process. It is also essential that the cans be filled as quickly as possible to avoid contaminating the milk. The opening in the cans is usually soldered by a mechanical finger. The filled and sealed cans are then tested for leaks by plunging them into a hot water tank. If any of the cans rise or give off air bubbles, they are discarded as unfit for sterilization. Modern sealing processes are carried out so rapidly that a large number of cans may be sealed in 1 min. In this process, open or sanitary-type cans are used. The concentrated milk fills the open can, one end of which is already seamed, and, after filling, the other end of the can is seamed by an automatic seaming machine. Cans are sterilized in a horizontal rotating system with rotary air locks, while the bottles are sterilized in hydrostatic sterilizers. These are highly energy-efficient systems because they have considerable heat regeneration.

Defects in Evaporated Milk

Condensed milk and EM are products with a prolonged shelf life. They have typical body, texture, and sensory properties by which they are identified. These properties must be such that the product is fit for sale immediately after production and does not alter during a reasonable period of storage. The product should be physically, chemically, and microbiologically fit for human consumption until the end of the storage period. Routine examination of the product soon after its manufacture as well as during its storage may be carried out to judge the quality of the product. If a defect is noted, care should be taken to eliminate the defect in subsequent batches. Therefore, it is important to know the expected defects, the probable reasons for their occurrence, and the preventive measures used to avoid these defects. The defects that may occur in condensed milk are classified as microbial defects and nonmicrobial defects.

Microbial defects

For all sterilized milk products, there is continuous risk of postprocessing contamination. It may be through microleaks in the cans or during the filling process. The growth of *Bacillus stearothermophilus*, a thermophilic spore-forming bacteria, in an evaporator is one of the most important causes of product defects. Prolonged running time of the evaporator or improper cleaning of the equipment may lead to an appreciable spore count in the concentrated milk. Inactivation of these spores during sterilization is limited, and the residual spores may germinate and grow if the product is sold in tropical countries, where storage temperatures may exceed 40 °C. A brief account of microbial defects follows.

Gassy fermentation/bloats: Gas can form in cans and barrels of condensed milk, causing them to bulge or burst. Gas-producing yeasts are the cause of many types of gaseous fermentations. The source of the contamination may be the raw milk, inferior quality sugar, or unhygienic factory conditions (e.g., improperly cleaned and sanitized equipment and filling machines). To avoid this microbiological defect, good quality raw milk and a proper preheating temperature should be used. In addition, only good quality sugar without any yeast contamination should be used. Proper sanitary conditions should be maintained during the manufacture and packaging of condensed milk. The containers should be filled fully, with little space for air or oxygen.

Bacterial thickening: Condensed milk thickens progressively during storage because of microorganisms, which produce rennet-like enzymes. These organisms are easily destroyed during the preheating process. An optimum sugar ratio also inhibits the growth of the microorganisms. In addition, low-temperature storage helps to reduce the bacterial thickening.

Mold buttons: This defect occurs during storage due to mold contamination. Small reddish-brown pieces of curd about ¼ in. to ¾ in. in diameter form on the product's surface, causing localized coagulation. These pieces of curd are caused by the mold *Aspergillus repeno*, which produces a rennet-like enzyme that causes localized clotting. High-temperature storage promotes the growth of the organism. The milk may be infected with the organism during the concentration process. To avoid this defect, scrupulous cleaning and care of dairy equipment is essential. Because this organism does not grow at low temperatures, storing condensed milk at a lower temperature will prevent this defect.

Nonmicrobial defects

These defects are of chemical or physical origin, and they are briefly described in the following paragraphs.

Sandiness: Good quality condensed milk should possess a smooth homogenous texture and be pleasant to the palate. Sometimes, however, the milk may be gritty and contain a large number of large lactose crystals. The solid particles are so large that the product lacks smoothness. This defect is readily detected by an average consumer. *Sandy*, *rough*, *grainy*, *granular*, and *gritty* are the terms used to describe this defect. If an excess amount of sugar is used to manufacture condensed milk, the sugar particles may also crystallize out and cause sandiness. To check this defect, condensed milk must be cooled so that a large number of minute sugar crystals are formed, which results in a smooth texture. An optimum storage temperature is also essential to avoid this defect. High viscosity also delays crystal formation; therefore, it is necessary to rapidly cool the condensed milk in the initial stages. Correct cooling and induced rapid crystallization with the correct amount of seed lactose will help to avoid this defect.

Age thickening: Thickening of the condensed milk is the most common defect seen in sweetened condensed milk. This defect varies markedly in its intensity from slight gelation to a firm and thick consistency. The defect becomes progressively more intense with storage, especially at room temperature or above. The preheating temperature of the milk and the degree to which the milk is concentrated have been observed to have profound effects on age thickening. With high packaging and heating temperatures, there is a greater tendency for the product to thicken early. With increasing concentration of milk solids, the thickening tendency becomes more marked. To avoid early thickening of condensed milk, an optimum preheating temperature should be maintained. Sugar should only be added at the end of the milk condensing process, and the product should preferably be stored at a temperature below 15 °C. With the addition of the proper type of stabilizers, age thickening may be decreased to a great extent.

Brown color: Usually brown color discoloration is associated with age thickening, both of which become progressively more intense with storage. The acidity and storage temperature determine the rapidity of this change. This defect may be avoided by storing the condensed milk at reasonably low temperatures.

Other defects in condensed milk include some flavor defects such as rancid, tallowy, and metallic. Following good manufacturing practices; using good quality raw materials, good quality milk, and good packaging; and storing the product at a low temperature may help to avoid these defects.

Uses of Condensed Milk

Milk is converted into EM to preserve its nutrients, which should not perish during months or even years of storage without refrigeration, and EM can be easily transported over long distances. For countries with low milk production, especially in the tropics, EM is a general-use milk product. In other markets, EM is used for specific purposes such as in coffee and tea or for cooking. As fluid milk, EM is consumed after 1:1 dilution with boiled water. This yields a product with a slightly higher SNF content and fat:SNF ratio than those of the regular 3.5% fat full-cream milk. Some consumers prefer the flavor of sterilized milk to that of pasteurized or UHT-sterilized milk. The quantity of EM required to give coffee, cocoa, or tea a milky flavor and a white appearance is relatively small. The products of the Maillard reaction in EM give coffee, cocoa, or tea a yellowish hue, which is preferred over the grayish hue obtained if UHT-sterilized or pasteurized milk is added. EM is obtained from homogenized milk, so it is recommended for infant feeding because of the formation of a soft curd in the stomach. The smooth consistency of EM makes it an important ingredient in several types of puddings, sauces, and gravies. Owing to its high TMS content, it is used to manufacture ice

cream. It is also used to prepare chocolate, as well as bakery and confectionery products. In addition, it is diluted with milk and cream to produce coffee creamer.

Consumer Protection Legislation

K Purnhagen and B van der Meulen, Wageningen University, Wageningen, The Netherlands

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Access to safe food is an essential precondition for the life of every human being. In this respect, the United Nations (UN), the Food and Agriculture Organization (FAO), and the World Health Organization (WHO) recognized that access to safe and adequate food in terms of nutritional values forms a right of each individual (Article 11, International Covenant on Economic, Social and Cultural Rights). Complex legal frameworks are needed to ensure the functioning of food markets and protect consumers from risks associated with food.

As exposure to health risks in food as well as consumer expectations varies vertically (e.g., from nation to nation, culture to culture, and region to region) and horizontally (according to the scientific knowledge on risks available), the amount of regulation needed for the effective realization of the right to food largely depends on the circumstances of the respective food markets and available scientific knowledge. Consumer protection regulation on food and health has to be different in different countries and regions and react to new insights from science. In addition, different legal cultures with a view of enforcement and application of the law require nuanced solutions according to the respective legal context.

Food safety is becoming more and more a global challenge by virtue of its economic implications as well as its public health impact. Effective regulation of consumer protection on markets is hence under threat, as consumer protection regulation designed for a specific regional food market increasingly governs other food markets, which are not necessarily embedded in the same prerequisites.

In order to realize the right to food, states and increasingly private standard setters have on the one hand to find an optimal level of regulation and on the other hand to design regulation that attracts safe foodstuffs to their markets.

Food Law and Consumer Protection

Consumer protection legislation takes various forms, which cut across commonly known distinctions in law, and are applied according to their own distinct economic policies and access to justice policies. When protecting from risks involved with foods, this legislation forms consumer protection legislation in the functional area of food law:

(1) Classical state-centered regulation encompasses civil law, criminal law, and administrative law. Civil law protection provides consumers rights within a contractual relationship, for example, by allowing consumers to remedy a contract for unsafe foods. Criminal law imposes sanctions, for example, on food producers for selling unsafe foods. Administrative law typically imposes market entry restriction, for example, by demanding an authorization procedure for foodstuff.

(2) In a market-driven global food sector, the importance of governments as regulators decreases and is increasingly replaced by private standard setters and enforcers. The law of private standards has hence become an increasingly important area for consumer protection legislation in the global food chain.

(3) In consumer protection legislation in federal, supranational, or international legislation such as in the EU or World Trade Organization (WTO), consumer protection on food markets typically follows a subordinate role. In these regimes, protection of the consumer is used primarily to satisfy other objectives such as the fostering of cross-country trade or forming the product of a spillover from legislation of the supply side of markets. However, the more these legislative systems mature into autonomous systems, the more state-centered their regulation becomes.

Consumer Protection in Food Law

As consumer protection legislation differs according to the legal regime in foods to be applied, consumer protection food legislation needs to be viewed according to the logics of the underlying legal regime. According to constraints of space, this piece will hence present an overview of consumer protection legislation of what we consider to be the most important legal food regimes in the world as well as the area of private standards.

Consumer Protection Legislation in International Food Law

In International Food Law, consumer protection in food markets is mainly sought by establishing food safety standards. These are then incorporated and enforced in other regulatory regimes such as national law or private standards. To this end, the FAO and the WHO established in 1963 the Codex Alimentarius Commission (CAC). The work of the CAC has resulted in a vast collection of internationally agreed food standards that are presented in a uniform format, the 'Codex Alimentarius.' Most of these standards are of a vertical (product-specific) nature. They address all principal foods, whether processed, semi-processed, or raw. Standards of a horizontal nature are often called 'general standards,' like the General Standard for the Labelling of Prepackaged Foods.

According to this general standard, the following information shall appear on the labeling of prepackaged foods:

- The name of the food (this name shall indicate the true nature of the food)
- List of ingredients (in particular if one of a list of eight allergens is present)
- Net content
- Name and address of the business

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00194-X

- Country of origin where omission could mislead the consumer
- Lot identification
- Date marking and storage instructions
- Instructions for use

In addition to the formally accepted standards, the Codex Alimentarius includes recommended provisions called codes of practice or guidelines. Most notably are, for example, the 'Code of Ethics for International Trade in Food' and a set of hygiene codes like the 'Recommended International Code of Practice, General Principles of Food Hygiene' and the 'Hazard Analysis and Critical Control Point System and Guidelines for its Application.'

The 'constitution' of the Codex Alimentarius is the procedural manual. The procedural manual gives not only the procedures and format for setting Codex Alimentarius standards and guidelines but also some general principles and definitions. The principles relate among other things to the scientific substantiation of the work of the Codex Alimentarius and the use of risk analysis for food safety.

Consumer Protection Legislation in WTO Law Concerning Food

The WTO is primarily concerned with removing barriers to trade between its member countries. (The WTO was established on 1 January 1995 by the Agreement Establishing the WTO as the result of the so-called Uruguay Round of trade negotiations and signed in Marrakesh on 15 April 1994 (WTO Agreement). The WTO is the institutional continuation of the General Agreement on Tariffs and Trade (GATT, 1947).) It does so by establishing equal treatment of all trading partners as the norm. As different consumer protection legislations form barriers to trade, they require an exception from the general application of liberalizing the WTO law. To this end, Art. XX(b) of the GATT recognizes that certain exceptions to free trade can be necessary to protect social values like health and (food) safety. This opens up a leeway for members of the WTO to legitimately regulate consumers' health and safety of foods. The Agreement on Technical Barriers to Trade (the TBT Agreement) and the Agreement on the Application of Sanitary and Phytosanitary Measures (the SPS Agreement) further substantiate these requirements. The SPS Agreement ensures that countries only apply measures to protect human and animal health (sanitary measures) and plant health (phytosanitary measures) based on the assessment of risk or, in other words, based on science. The measures must be scientifically justified and they may neither be discriminating nor constitute disguised barriers to international trade. The SPS Agreement incorporates, therefore, the main safety aspects of foods in trade. The TBT Agreement covers all technical requirements and standards (applied to all commodities), such as labeling, that are not covered by the SPS Agreement. Therefore, the SPS and TBT Agreements can be seen as complementing each other.

If the measures are in conformity with international standards, no scientific proof of their necessity is required. These measures are by definition considered to be necessary. The most important international standards regarding SPS are set by the so-called three sisters of the SPS Agreement: the Codex Alimentarius Commission, the International Office of Epizootics (OIE) (the abbreviation follows the French spelling), and the Secretariat of the International Plant Protection Convention. The standards on food and food safety are mainly found in the Codex Alimentarius. (The agreement on TBT treaty has similar articles.)

Consumer Protection in Private Food Law

Private standards stipulate rules that food businesses impose upon each other in contractual relations (from a strategic business viewpoint). Legal food safety systems limited by national borders and political compromise are often ill-suited to reflect consumers' and suppliers' demands in the food chain. For this reason, corporations increasingly choose to develop their own food safety standards. These standards form 'uniform' food safety management systems, which lay down detailed requirements for service providers and producers. Such private food standards have been so widely adopted by retailers in particular that they have emerged as the primary mode of governance in global food supply chains. While voluntary, the widespread adoption of private food standards means that these standards have become *de facto* mandatory as a precondition for participation in the majority of global supply chains. This initially applied primarily to export markets. In the developing world retailer capture of food markets in recent years has left few alternatives, even in a domestic context.

Under such private standard regimes, suppliers have to obtain certification and demonstrate compliance with the respective quality management system, verified by independent audits. The variety of standards demanded by customers often requires suppliers to obtain multiple certificates. As their differences are mainly bureaucratic in nature, this is an unnecessary and costly burden. In order to cope with this shortfall, the Global Food Safety Initiative (GFSI) makes a move to level or mutually recognize these different standards as far as possible. To this end, the GFSI approves certification regimes, which then lead to worldwide acceptance ('certified once, accepted everywhere').

Consumer Protection Legislation in American Food Law

The United States of America

In the United States, consumer protection legislation in food law is shared between the federal and the state level. However, since President Roosevelt signed the Pure Food and Drug Act and the Meat Inspection Act into law in 1906, consumer protection in food law became increasingly federalized. Along with the federalization of consumer protection law, the federal Food and Drug Administration (FDA) matured into an ever more powerful regulative body in the United States. However, as the power of criminal law remains with the States, federalization of consumer protection food laws embraced private and administrative laws only.

Consumer protection food legislation in the United States was to a large extent triggered by the cheating practices of the food industry. As a reaction to this, US consumer protection

food legislation is largely occupied with the prevention of adulteration of foods in order to 'promote honesty and fair dealing in the interest of consumers' (21 U.S.C. Sec. 341). This is why the concept of 'adulteration,' unlike, for example, in EU law, takes a prominent position in consumer protection legislation in the United States (21 U.S.C. Sec. 342). The large bunch of legislation hence seeks to prevent such adulteration by ensuring that consumers can trust in the information they receive about the properties of the respective food. To this end, the FDA first and foremost regulates the labeling of food (see especially 21 U.S.C. Sec. 343 and the health claims requirements). Adulteration shall also be prevented by regulating, for example, the manufacture, processing, or packing of foods (see, e.g., 21 U.S.C. Sec. 348–350).

Important legislation (selection): Federal Food, Drug, and Cosmetic Act (FD&C Act); Federal Meat Inspection Act; Federal Trade Commission Act; Filled Milk Act; Import Milk Act; Public Health Service Act; Trademark Act of 1946; Reorganization Plan 1 of 1953; Poultry Products Inspection Act; Fair Packaging and Labeling Act; National Environmental Policy Act of 1969; Controlled Substances Act; Controlled Substances Import and Export Act; Egg Products Inspection Act; Lead-Based Paint Poisoning Prevention Act; Federal Advisory Committee Act; Government in the Sunshine Act; Federal Anti-Tampering Act; Sanitary Food Transportation Act; Mammography Quality Standards Act (MQSA); Bioterrorism Act of 2002; Project BioShield Act of 2004; FDA Food Safety Modernization Act (FSMA) (still pending).

Internet reference address: http://www.fda.gov/RegulatoryInformation/Legislation/default.htm.

Canada

As Canada is a federal system, it is in this respect in many ways comparable to the US legal system. Consumer protection legislation in food law is likewise shared between the federal and the state level. However, with the enactment of several federal laws with regard to consumer protection in food law (most notably, the Canadian Food and Drugs Act (CFDA) and the Safe Food for Canadians Act; for an overview, see list at the end of this subarticle), food legislation became increasingly federalized. Along with the federalization of consumer protection law, the Canadian Food Inspection Agency matured into an ever more powerful regulative body in Canada. Unlike in the United States, the federalization of consumer protection food legislation embraces also criminal law.

The main concern of the early consumer protection food legislation was adulteration of liquor. Hence, like US consumer protection food legislation but for a different reason, Canadian consumer protection food legislation is historically likewise occupied with the prevention of adulteration of foods. However, after modernization, Sec. 3 and Sec. 4 of the CFDA (R.S.C., 1985, c. F-27) are much more up to date than its US counterpart: such as in many other jurisdictions, Sec. 4 obliges food sellers as a general rule to ensure that the food on the market shows certain properties. In particular, food needs to be not poisonous or harmful or unfit for human consumption. If it is, Sec. 22 et seqq. of the act empowers several Canadian authorities to take action.

Important legislation (selection): Agriculture and Agri-Food Administrative Monetary Penalties Act; Appropriation Acts; Canada Agricultural Products Act; Canadian Food Inspection Agency Act; Consumer Packaging and Labelling Act; Feeds Act; Fertilizers Act; Fish Inspection Act; Food and Drugs Act; Health of Animals Act; Meat Inspection Act; Plant Breeders' Rights Act; Plant Protection Act; Safe Food for Canadians Act; Seeds Act.

Internet reference address: http://www.inspection.gc.ca/about-the-cfia/acts-and-regulations/eng/1299846777345/1299847442232.

Latin America

Consumer protection legislation in food law in Latin America is as diverse and vivid as the continent. Although there have been several attempts made in the past decade, however, until the time of writing, only some countries such as Brazil have developed a fully fledged food regulation. However, an all-encompassing Latin American approach to consumer protection food law that one could present in an encyclopedia such as this is nonexistent.

Consumer Protection Legislation in European Food Law

In Europe, consumer protection food legislation has to be evaluated in view of the specific features of different legal entities. Food law is largely harmonized at the supranational level of the EU with the result that member states of the EU do not have a strong say in consumer protection food legislation. Countries such as Switzerland, which are not part of the EU, also increasingly follow the example of EU regulation in food.

The European Union

There is no general authorization procedure for foodstuffs in the EU. Art. 14 (1) of the General Food Law (Regulation (EC) 178/2002, GFL), however, stipulates that "food shall not be placed on the market if it is unsafe." Hence, liability of producers as well as legitimate intervention of authorities depends on whether the respective food passes an 'unsafety' test. The Unfair Commercial Practices Directive 2005/29/EC ensures that consumers are not subject to fraudulent or deceptive practices, adulteration, and other practices, which may mislead the consumer (Art. 8 GFL). Product liability for foodstuffs is regulated by Directive 85/374/EEC (see Art. 21 GFL). If there is scientific uncertainty about the unsafety of foods, authorities may nonetheless take precautionary measures according to the precautionary principle (see Art. 7 GFL).

Compliance with numerous food processing and other market regulation is generally monitored by member state authorities. They are, however, interwoven in a dense communication network between member state authorities and the European Food Safety Authority (EFSA). The EFSA monitors the work of member state authorities. Together with the Commission, it has also extended competences in food crisis management and information regulation.

According to the principle of mutual recognition (also known as the *Cassis de Dijon* principle), foods that are lawfully put on the market in one member state can and should be

allowed access to the markets in other member states if member states cannot provide good justifications why they should not. In this sense, consumer protection food law is local and travels with the food. However, with the enactment of the horizontal General Food Law, the principle of mutual recognition is increasingly on the decline. In case intervention is needed in order to enforce consumer protection rules, the Court of Justice of the European Union has established a preference for information-related over content-related measures. That is why a wide array of measures available to authorities are information-related in nature. Health claims and novel foods even need authorization.

Genetically modified foods and other novel foods fall under a different regulatory regime. They need authorization as a general rule. The authorization decision is taken by the European Commission. It is based on risk assessment by the EFSA.

Important legislation (selection): Regulation (EC) No 178/2002 laying down the general principles and requirements of food law; Regulation (EC) No 510/2006 of 20 March 2006 on the protection of geographical indications and designations of origin for agricultural products and foodstuffs; Regulation (EC) No 852/2004 on the hygiene of foodstuffs; Regulation (EC) No 853/2004 laying down specific hygiene rules for food of animal origin; Regulation (EC) No 854/2004 laying down specific rules for the organization of official controls on products of animal origin intended for human consumption; Directive 2002/99/EC laying down the animal health rules governing the production, processing, distribution and introduction of products of animal origin for human consumption; Regulation (EC) No 882/2004 on official controls performed to ensure the verification of compliance with feed and food law, animal health and animal welfare rules; Regulation (EC) No 1829/2003 on genetically modified food and feed; Regulation (EC) 1924/2006 on nutrition and health claims made on foods.

Internet reference address: http://europa.eu/legislation_summaries/food_safety/general_provisions/index_en.htm.

Switzerland

Since 2010 and pursuant to Art. 16a (1) of the Loi fédérale sur les entraves techniques au commerce, products lawfully marketed in the EU or the European Economic Area may also be marketed in Switzerland. Switzerland has thereby autonomously expanded the Cassis de Dijon principle to their home country. However, in order to successfully market foodstuffs marketed in the EU in Switzerland, they still require authorization by the competent Swiss authority.

Internet reference address: http://www.bag.admin.ch/themen/lebensmittel/10380/index.html?lang=en.

Consumer Protection Legislation in Asian Food Law

China

China is a multilevel system, whereby state laws interplay with local regulation. However, there are strong desires and preparatory works for a basic food law modeled after EU or US standards. Although since 2009 China has enacted horizontal food laws after the model of Western legal systems, at the time of writing, food legislation in China is nonetheless still primarily scattered along the different levels of Chinese legislation. Although the food legislative system in China is modernizing fast, consumer safety regulation still mainly follows the classical approach of administrative control.

China knows three different levels of regulation. The first and highest level concerns laws passed by the National People's Congress. Here, the main act concerned with consumer protection in foods is the horizontal Food Safety Law of the People's Republic of China. The China FDA is the main focal point of the administration and supervision of food (including food additives and health food, the same in the succeeding text) safety at this level. Other important legislations include the Food Hygiene Law, Product Quality Law, Agricultural Product Quality and Safety Law, and Consumer Rights Protection Law. The second level embraces legal instruments issued by the State Council or the provincial People's Congress. They are primarily concerned with the administration of pesticides and veterinary drugs, inspections of slaughterhouses and abattoirs, and the regulation of genetically modified organisms. Third-level regulation embraces decrees or provisions formulated by ministries of the national or provincial government(s). The most important decrees concern practices on food processing, decrees on foods for particular populations, and decrees specific to the management of food poisoning and street foods.

Important legislation (selection): Food Hygiene Law; Product Quality Law; Agricultural Product Quality and Safety Law; Consumer Rights Protection Law.

Internet reference address: http://eng.sfda.gov.cn/WS03/CL0756/ (CFDA); http://www.fas.usda.gov/gainfiles/200903/146327461.pdf (unofficial translation of the Food Safety Law of the People's Republic of China).

India

Indian food law focuses on strengthening both food security and food safety. In 2013, the Indian National Food Security Act was signed into law. This act creates legal entitlements to subsidized food grains for large parts of the Indian population.

In 2006, a new Food Safety Standards Act was put in place. The Ministry of Health and Family Welfare implemented this act through the Food Safety and Standards Regulation, 2011. The act and the regulation are the domain of the Food Safety and Standards Authority of India (FSSAI).

The law covers topics such as prevention of adulteration, hygiene, and labeling for packaged food including health claims, permitted food additives and colors, and microbiological requirements.

All domestic food operators are required to be licensed by the FSSAI.

Important legislation (selection): Food Safety Standards Act, 2006; Food Safety and Standards Regulation, 2011; Indian National Food Security Act, 2013.

Internet reference address: http://www.fssai.gov.in/

Japan

Consumer protection food regulation is based on the Food Safety Basic Act such as other more specific legislations. Food safety policy in Japan is conducted in accordance with the

general internationally recognized deviation of risk management and risk assessment. While the Food Safety Commission is responsible for scientific risk assessment, the Ministry of Health, Labour, and Welfare and the Ministry of Agriculture are in charge of risk management.

Important legislation (selection): Food Safety Basic Act, 2003; Food and Sanitation Law; Business Control and Poultry Inspection Law.

Internet reference address: http://www.fsc.go.jp/english/index.html

Consumer Protection Legislation in South African Food Law

South Africa is governed by not only a pluralist system, whereby state laws interplay with local regulation at a vertical level, but also by the laws of different societies, tribes, and governmental regulation, which interplay horizontally. This is reflected in legal acts as well as control of consumer protection food legislation. The most important act is the Foodstuffs, Cosmetics and Disinfectants Act, 1972. Several other acts accompany the regulatory framework in this respect.

Important legislation (selection): Foodstuffs, Cosmetics and Disinfectants Act, 1972; Meat Safety Act, 2000; Agricultural Products Act, 1990; Liquor Products Act, 1989; Health Act, 1977.

Controlled Atmosphere Storage: Applications for Bulk Storage of Foodstuffs

Z Escobedo-Avellaneda and J Welti-Chanes, Tecnológico de Monterrey, Monterrey, Mexico

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Fruits and vegetables are biological systems that once harvested deteriorate rapidly because they continue metabolic processes. To diminish the rate of senescence, vegetable products must be handled adequately. Low-temperature storage is the most effective and simplest way to reduce metabolic processes causing deterioration. Nevertheless, the combination of low temperatures with preservation factors that avoid the action of oxygen involved in many enzymatic reactions is recommended to extend shelf life while preserving the quality of foods. Although the use of packages under normal atmospheric conditions protects foods from environmental factors such as light, physical, and biological contaminants, vegetable products are still in contact with oxygen.

Controlled atmosphere (CA) and modified atmosphere (MA) are two technologies used to change the gas composition of the surrounding environment with the aim of reducing metabolic reactions, maintaining the freshness, and extending the shelf life of foods. In these technologies, the concentration of oxygen, carbon dioxide, ethylene, and/or nitrogen of the surrounding atmosphere of foods is changed. While in CA the CO_2 and O_2 levels are constantly monitored and adjusted, in MA, the gas concentration changes due to metabolic processes of the fruits and vegetables, and this concentration is not controlled during storage. As a consequence, in MA, the rate of change depends on the respiration rate of the product, package permeability, and storage conditions. Due to the gas control in CA, it is a more costly method, but it is more appropriate for long-term storage products.

CA and MA can be applied once the product is packaged or also be used during the bulk storage where the gas composition inside the storage rooms is changed according to the requirements of foods stored. The use of CA in bulk storage extends the shelf life of foods, avoids microbiological reactions, and controls pests including insects, rats, and mice. Some of these effects are achieved due to the capacity of CA to reduce ethylene biosynthesis retarding ripening. During the storage of fruits and vegetables, the level of O_2 is generally lowered to diminish ethylene production, and the level of CO_2 is often increased to decrease the action of ethylene. The concentration of gases in CA storage rooms is monitored by infrared gas analyzer to measure CO_2 and by a paramagnetic analyzer for O_2.

The use of inadequate preservation conditions in CA storage can cause negative effects on the quality of foods; very low levels of O_2 can result in fermentation causing off-flavors related with ethanol and acetaldehyde production. This can also decrease the synthesis of volatile compounds affecting the sensory quality of foods. This contribution is focussed on the preservation of foods by CA bulk storage.

Metabolic Processes of Fruits and Vegetables Affecting Their Shelf Life

After harvesting, fruits and vegetables continue having metabolic processes like respiration, transpiration, and production of ethylene. These physiological activities are responsible for the ripening and senescence of vegetable products; thus, adequate postharvest handing is necessary to delay changes maintaining quality. The rate of these processes determines the shelf life, and they depend on food composition, physiological characteristics, and storage conditions such as temperature and relative humidity. Respiration oxidizes carbohydrates by using the atmospheric oxygen generating ATP, CO_2, and water. The ATP produced is used in many ripening reactions; thus, the control of the respiration rate is a way of controlling the rate of senescence. Storage at low temperatures decreases the activity of enzymes involved in ripening. Diminished levels of oxygen reduce respiration and the action of enzymes like polyphenol oxidase and peroxidase. The application of CA at low O_2 levels combined with reduced temperature is a way of decreasing senescence of foods. Transpiration is the process of water loss causing wilting, shriveling, shrinkage, softening, flaccidity, limpness, loss of crispness, juiciness, and loss of nutritional quality in fruits and vegetables. Ethylene regulates many aspects of growth, development, and senescence of vegetable products and can be physiologically active at very low concentrations. Transpiration and ethylene production can be controlled by adequate storage conditions.

CA Storage Definition and Principles

The desired atmosphere in CA storage is first achieved by replacing the normal gas composition by purging some gas or by the metabolism of fruits and vegetables, and then, it is maintained by lowering the rate of gas input. The gas input rate is determined by the room capacity, its degree of gas tightness, humidity, temperature, and metabolism of the stored foods.

CA technology generates products that remain turgid because the lower O_2 concentration inhibits or retards the activity of enzymes that act on cellular membranes avoiding texture changes. CA also expands the climacteric and postclimacteric periods; delays senescence during storage due to the reaction between O_2 and ethylene; reduces microbial degradation due to the decreased O_2 levels and the increased CO_2 concentrations; improves the color stability due to a low effect on chlorophylls; allows obtaining foods with similar nutritional and sensory characteristics than the fresh product due to the low effect on acidity, sugars, and vitamins; and controls proliferation of pests and molds at low O_2 or high CO_2 atmospheres.

CA constraints are related with the high costs of storage, the special seals required in the storage room to avoid gas leakage, and the longtime of exposure needed (8–12 days). Another disadvantage is the variability in the concentration of gases required for the storage of foods that depends on many factors such as the type of fruit or vegetable, species, stage of maturity, medium, and climate in which they were grown. Biochemical and anatomical differences, including the size of intracellular spaces and the rate of gas diffusing through the food structure, also influence the variability in gas concentrations. Another disadvantage of CA is that at inadequate storage conditions, undesirable changes like fermentation can appear. For example, apples and pears stored at very low O_2 concentrations presented changes in flavor and color and changes in hardness and darkness of skin due to high concentrations of CO_2. The need for low temperature and high relative humidity to enhance CA effectiveness is also considered as constraints of CA storage.

Main Gases Used in the CA Storage of Foods

There are many gases to be controlled in order to reduce the metabolic processes of foods, microorganisms, or pests in CA storage. The control of both O_2 and of CO_2 levels can be used in order to have synergetic or additive effects to extend the shelf life of foods. The election of either low level of O_2 or high concentrations of CO_2 depends on factors such as the time of treatment, design of the room used, cost of gases, and systems available to control them.

The use of CO_2 prevents the growth of aerobic bacteria and fungi and avoids the oxidation of some compounds. The increase in CO_2 level has different effects in fruits and vegetables such as decrease of synthetic reactions in climacteric fruit, delay in the initiation of ripening, inhibition of some enzymatic reactions, decrease of production of some organic volatiles, modification of the metabolism of some organic acids, reduction in the rate of pectin breakdown, inhibition of chlorophyll breakdown, production of off-flavor, induction of physiological disorders, retarding of fungal growth, inhibition of the effects of ethylene, inhibition of postharvest development, retention of tenderness, and decrease of color loss. Oxygen is necessary for the growth of aerobic bacteria and enzymatic or chemical reactions in foods. Therefore, its concentration may affect the product quality. However, it should not be completely eliminated because it would cause the growth of anaerobic bacteria causing fermentation. Decreasing O_2 levels reduces respiration rate, decreases oxidation, delays ripening of climacteric fruit, extends shelf life, delays breakdown of chlorophyll, reduces rate of ethylene synthesis, changes fatty acids synthesis, reduces degradation rate of soluble pectin, decreases off-flavors, and alters texture. Nitrogen is another gas used in CA, normally as filler instead of CO_2. It is innocuous and when it is used in packages, it may prevent the collapsing. It is also used in some cases instead of oxygen as a nonreactive gas to avoid decomposition and oxidation of lipophilic compounds.

Methods Used to Control Gas Levels in CA Storage

CA storage rooms are built with structures capable of supporting the gases used, and they are provided with the adequate system to produce the atmosphere and the best-available method to maintain the atmosphere composition for the required time. In CA storage, foods are placed into an insulated store room whose walls and doors are gastight. CA rooms are made from metal-faced insulated panels, which are fitted together with gastight locking devices. Doors are usually sealed by having rubber gaskets around the perimeter, which correspond to another rubber gasket around the door jamb of frame to avoid leaks. Static and dynamic are the two ways used to produce the atmosphere needed in CA storage rooms. In the static method, the product generates the atmosphere and it is maintained by ventilation and scrubbing. In the dynamic system, the gas concentrations are supplied by flushing gases. There are also different ways to control the gas levels in CA rooms. Systems such as external burners, liquid or gaseous nitrogen, gas separator systems, and hypobaric storage can be used to control the O_2 levels. For the removal of CO_2 scrubbing systems based on NaOH, hydrated lime ($Ca(OH)_2$), water, activated charcoal, and molecular sieves have been implemented. Heated catalyst scrubbers, ethylene-absorbing beads, and UV light are used to control the ethylene levels (Table 1).

CA Storage of Fruits and Vegetables

The recommended storage conditions for fruits and vegetables under CA are highly variable because they depend on many factors. Factors such as species, cultivars, anatomical differences, initial gas concentration in the storage room, temperature, humidity, degree of ripeness, ethylene concentration, and pre- and postharvest conditions influence the level of gases used. Thus, there are many recommended conditions for the storage of foods.

Temperature is one of the factors that more influence the required concentration of CO_2 and O_2 for the CA storage of foods. The effect of temperature on delaying the ripening of foods by decreasing the rate of reactions is well known. Nevertheless, due to the diversity of factors influencing, when selecting the conditions for the storage or certain food, it will be necessary to evaluate their effects on food quality in terms on color, texture, nutritionals changes, and microbiological safety.

Increasing the CO_2 levels can have different effects on the biochemical and physiological changes associated with ripening such as the production of ethylene that can be inhibited, increased, or not altered. In the first case, CO_2 acts by displacing ethylene from its receptor side, delaying fruit ripening; CO_2 concentration lower than 1% favors ethylene production. The oxygen levels also influence the effects of CA storage on ripening of fruits by inhibiting or lowering the action of ethylene and also altering its synthesis. Lowering O_2 to more than 8% reduces the binding of ethylene to its receptor influencing its actions and therefore ripening. O_2 is required in the final step of ethylene biosynthesis from methionine. Oxygen levels below 5% greatly reduce ethylene production of fruits by inhibiting the ACC oxidase enzyme activity. Very low levels of O_2 can cause fermentation of foods with consequent development of off-flavors, while very high levels of CO_2 can cause texture changes. It was reported that apple (Delicious) stored at 1 °C in 0.5% O_2 + 0.2% CO_2 for 30 days developed high concentrations of ethanol and acetaldehyde and that at 0% O_2, the respiration rate of cucumber stored at 10 °C or 20 °C increased because of fermentation. CA storage of mango in 1% O_2 produces off-flavors and skin

Table 1 Systems used to control the O_2, CO_2, and ethylene levels in CA storage

System	*Characteristics*
O_2 control	
External burners	The level of O_2 in the storage room is reduced by the combustion of propane or natural gas generating CO_2 and water vapor. They usually require a CO_2 scrubber to control the levels of this gas and cooling systems to reduce the temperature of air before and after combustion. They are classified as open flame or catalytic burners. The open flame burner does not allow air recirculation because of the risk of extinguishing the flame by the O_2 depleted recirculating airstream. Catalytic burners provide more complete combustion reducing O_2 levels to 3%; in addition, they have lower operation cost despite being more expensive to install
Flushing with liquid or gaseous N_2	O_2 levels are reduced by directly flushing N_2 in the storage room until the desired O_2 level is achieved. Liquid N_2 is injected into the room through spray headers that atomize the N_2
Gas separator systems	Gas separator systems decrease the O_2 levels while increasing the N_2 concentration from 97% to 99%. They are classified as pressure swing absorption (PSA), hollow fiber membrane separators (HFMS), and high-temperature ammonia cracking systems (HTAC) PSA system compresses dry air and once filtered forces it through a bed of pelletized carbon material, which absorbs O_2 and enhances the N_2 levels HFMS systems are based in the different diffusion rates of gases through membranes. CO_2 and O_2 have much higher permeation rates than N_2; thus, the levels of CO_2 and O_2 decrease, while the level of N_2 increases In the HTAC system, high-temperature anhydrous NH_3 gas reacts with air from the CA room, yielding hydrogen and inert N_2 gas. Further, hydrogen reacts with the O_2 to yield water vapor
Hypobaric storage	Hypobaric pumps are used to reduce the pressure of the room with consequent decreasing in O_2 levels
CO_2 control	
NaOH	NaOH dissolved in water can be used to remove CO_2 in the storage room by circulating the air in open tubes. The amount of CO_2 removed is proportional to the NaOH exposure time
Hydrated lime scrubber ($Ca(OH)_2$)	$Ca(OH)_2$ is one of the simplest and most effective systems for controlling the level of CO_2. $Ca(OH)_2$ is placed in an insulated and airtight box outside the storage room to which it is connected by two pipes in which one of them allows air from the storage room to enter the box that contains the lime $Ca(OH)_2$ can also be placed on bags or pellets that react with CO_2 yielding calcium carbonate, water, and heat maintaining it at level lower than 1%. This methods required space to place the bags and is inefficient because 80% of the lime is not used
Water CO_2 scrubbers	A brine solution is pumped or sprayed over the evaporator coils in the CA room. The brine absorbs CO_2, due to the pressure difference between the incoming water and the atmosphere in the CA room. The corrosion caused by the brine solution may be prevented by using dry cooling units
Activated charcoal and molecular sieve scrubbers	The air from the CA room is blow through an absorbing unit reducing the CO_2 levels, and then it is forced back to the CA room. When saturated with CO_2, the absorbent must be reactivated by pursing it with air
Ethylene control	
Heated catalyst scrubber	The air is forced thought ceramic pickings used as heat exchangers removing up to 87% of the ethylene from the air. The catalyst is electrically heated and the high temperature promotes the oxidation of ethylene to CO_2 and water vapor. This system requires energy for heating and cooling
Ethylene absorbing beads	Small particles of aluminum silicate impregnates with potassium permanganate are placed in a sealed unit. Air from the CA room is circulated through the unit and the ethylene reacts with the permanganate changing the color of the beds when saturated with ethylene
UV light	The UV light reacts with O_2 to form ozone, which eliminates ethylene

J., Vigneault, C., Deell, J. R. and Raghavan, S. G. (2003). Cooling and storage. In: Ramaswamy, H. S., Vijaya Raghavan, G. S., Chakraverty, A. and Mujumdar, A. S. (eds.) *Handbook of postharvest technology: cereals, fruits, vegetables, tea, and spices*, pp. 505–538. New York: CRC Press.

discoloration, but the storage at 12 °C in 5% CO_2 + 5% O_2 was possible for 20 days. With 3% O_2 + 6% CO_2, mango did not present significant fermentation.

CA including either reduced O_2 or elevated CO_2 not only generally decreases the loss of provitamin A but also inhibits the

biosynthesis of carotenoids. Concentration of 5% CO_2 caused loss of carotenes, while 7.5% CO_2 or higher favors their synthesis. CA storage with 2% O_2, air + 12% CO_2, and 2% O_2 + 12% CO_2 had no effect on quality attributes of sliced peaches over 7 days of storage, while the visual quality in color of persimmon slices was slightly enhanced by the treatments containing 12% CO_2. Peach slices stored in 12% CO_2 had a lower content of β-carotene and β-cryptoxanthin. The various carotenoids found in persimmon slices responded differently to the tested atmospheres; storage in 2% O_2 or 12% CO_2 tended to result in lower retinol equivalents after 8 days storage at 5 °C, but the loss was not significant for fruit stored under 2% O_2 + 12% CO_2. In the case of other vitamins like vitamin C, it was noticed that 2% O_2, air + 12% CO_2, or 2% O_2 + 12% CO_2 had no significant effect on total ascorbate content for both fresh-cut strawberries and persimmons.

The effects of CA on texture and other sensorial attributes of some fruits and vegetables have also been evaluated. CO_2 concentrations above 4% with 15–20% O_2 retard the softening of kiwifruit, and this effect increased as the CO_2 content increased from 4% to 10%, but without additional effects at CO_2 content above 10%. Low O_2 levels (2–3%) with 3–5% CO_2 further delayed the rate of kiwifruit softening and increased storage life up to 3–4 months. Although CA increases storage life of kiwifruit, the magnitude of the effects varied from year to year. Contamination of the storage atmosphere by as little as 0.1 μl^{-1} ethylene severely reduced the effectiveness of controlled atmosphere storage in maintaining kiwifruit firmness, even at 0 °C. It was showed that Valencia oranges can be treated with 0.5%, 0.25%, or 0.02% O_2 at 5 °C or 10 °C for up to 20 days without detrimental effects on their appearance, nutritional value, and flavor, while 60% CO_2 at 5 °C could injure oranges, and 7–12% O_2 + 0–5% CO_2 retards decay and toughening of asparagus. Elevated CO_2 concentrations resulted in firmer strawberries, while low O_2 did not affect texture demonstrating that although strawberry is highly perishable, under high CO_2 condition, the firmness and shelf life could be maintained. Off-flavor developed after 3 days of storage at 20% CO_2, but it decreased when fruit was subsequently held for 24 h at 20 °C. Similar results were obtained using low O_2 (2%, 1%, and 0.5%) or elevated CO_2 (10%, 15%, and 20%) concentrations, and their combinations reduced respiration and ethylene production rates of strawberry stored at 2 °C and fruits maintained their color and firmness. The rate of color change in cucumber could be delayed with high CO_2 and low O_2 in the storage atmosphere, but 10% CO_2 could impair their flavor.

The storage of mamey at 15 °C in 1% CO_2 + 5.6% O_2 + 89.3% N_2 for 2 weeks retarded their maturation, and it was recommended to store onion at 5% CO_2 + 3% to reduce sprouting and root growth. The use of 1–5% O_2 + 14% CO_2 allows to reduce the levels of crown rot in bananas as compared with those stored in air, and this effect continued even during subsequent ripening in air at 25 °C, and the storage of cauliflower at 10%, 15%, or 20% O_2 the leaf yellowing and rot caused by *Alternaria brassicicola* is delayed, but it caused injury inside the stem and vegetables developed off-flavors and odors after cooking. Some other recommended CA storage conditions for fruits and vegetables are present in Table 2.

Some products are also classified according to the minimum concentrations of O_2 and maximum level of CO_2 required for storing. Most fruits and vegetables have a threshold level of O_2 and CO_2 to cause injury that includes problems such as off-flavor development, discoloration, off odors, alcoholic taste, browning, and softening. Some minimum concentrations of O_2 and maximum level of CO_2 required for storage of some foods are presented in Table 3.

Table 2 Recommended CA storage conditions for some fruits and vegetables

Product	*O_2 (%)*	*CO_2 (%)*	*Temperature (°C)/relative humidity (%)*	*Shelf life*	*Variety*
Apple	0.02			12 days	
	1.5	Up to 3			
	1.5	<0.5	0	9 months	Gala

CA Storage of Grains and Animal Products

CA can be also used to store grains and cereals for the control of insect's proliferation. Similar to CA storage of vegetable products, CA storage of grain involves the alteration of the proportion of normal atmospheric gases to give an atmosphere inadequate for the development of insects. CA in grain can cause lethal and sublethal effects. Sublethal effects include delayed or disturbed development, other deleterious phenotypic effects, and behavioral phenomena. Thus, the low levels of O_2 and high concentrations of CO_2 used in CA represent an alternative way to the use of poisonous gases for the control of

Table 3 Minimum O_2 level and maximum CO_2 concentration (%) recommended for the CA storage of some foods

Minimum O_2 level	*Examples*
0.5	Nuts, dried fruits, and vegetables
1.0	Pear, apple, broccoli, mushroom, garlic, onion, and minimally processed vegetables
2.0	Apple, pear, kiwi, apricot, plum, cabbage, peach, cherry, nectarine, papaya, strawberry, pineapple, melon, cabbage, lettuce, and cauliflower
3.0	Avocado, carrot, tomato, persimmon, pepper, cucumber, and artichoke
5.0	Citrus fruits, pea, asparagus, potato, and sweet potato
10	Potato
Maximum CO_2 level	*Examples*
2	Apple (Golden Delicious), pear, grapes, tomato, pepper, and lettuce
5	Apple, peach, nectarine, orange, avocado, banana, mango, kiwi, couliflower, pear, and papaya
10	Grapefruit, lemon, lime, pineapple, cucumber, zucchini, broccoli, asparagus, potato, onion, and garlic
15	Strawberry, raspberry, blueberry, cherry, mushrooms, brocoli, and spinach

insects. CO_2 in high concentrations kills insects acting directly as fumigant, while low O_2 levels have asphyxiate effects acting on all the development stages of the insect without detrimental effects on foods but with dangerous results to human, especially low levels of oxygen and high contents of carbon dioxide. High levels of CO_2 are often more effective to control insect than low levels of O_2 because they act more quickly and in addition require a less stringent standard of gastightness. The time required to kill insects depends on the species and developmental stage, temperature, O_2 and CO_2 levels, and air humidity; an initial level of 70% CO_2 maintained above 35% for 10 days is appropriate for complete insect control at temperatures above 20 °C. Oxygen level below 1.2% for 1 week at temperatures above 35 °C or more than 24 weeks at 15 °C has been proposed for complete insect control in Hass avocados. Sunrise papayas and Keitt mangoes can be stored at 0.5% O_2 and 50% CO_2 for 1, 2, and 5 years at 20 °C. These treatments could have some potential application as insecticides for quarantine insect control, on the basis of fruit tolerance, insect mortality, and cost. There are some studies about the CA storage of animal products; for whole pork loins divided into roasts and subjected CO_2 at 1 °C for up to 21 days, a strong inhibition on microbial growth as well as a marked residual effect during posttreatment storage in air was observed. In the evaluation of the quality of whole ungutted bigeye tuna during bulk storage in CA with 60% CO_2 + 15% O_2 + 25% N_2 and 40% CO_2 + 40% O_2 + 20% N_2, at day 33 of storage, none of the lots were rejected based on pH, trimethylamine nitrogen, total volatile base nitrogen and histamine, or the tasting panel scores. The control and CA lots were rejected after inspection (sensorial analysis) at 13 and 22 days, respectively. Fish muscle undergoes a series of changes during storage under atmospheres and conventional chilled storage, resulting in deterioration and loss of quality.

Legislation

Act No. 228 of 1959 for fruit and vegetable storage by CAs from the State of Michigan, the United States, indicates some definitions, specifications for the construction of storage room, and general conditions for the adequate handling of fruits and vegetables stored under CA. The regulation No. 530 of this act specifies the conditions for the CA storage of apples. The Ontario Regulation 95/97 also gives some specifications for the CA storage of apples. Section 3–502.12 of the Food Code (FDA Food Code 2009: Annex 6 – Food Processing Criteria) provides the criteria that are to be met in the HACCP plans of those operators who are conducting reduced oxygen packaging operations. According to the European Union directive No. 95/2/EEC, food stored under CA must have that indicated in the label and gases used must be treated as additives.

Controlled Atmosphere Storage: Effect on Fruit and Vegetables

A Valdez Fragoso and H Mújica-Paz, Instituto Tecnológico y de Estudios Superiores de Monterrey, Monterrey, Mexico

Introduction

Controlled atmosphere (CA) storage of fruits and vegetables refers to storage in atmospheres with reduced levels of oxygen and/or relatively high carbon dioxide concentrations, at low temperature and high relative humidity (RH). The modified atmospheres are created in an air tight room, and they are continuously monitored and maintained throughout the storage period.

CA storage is an appropriate and practical technology for prolonging the shelf life and maintaining the quality of fruits and vegetables on a large scale. CA storage reduces the metabolic activity of the produce, allowing the control of ripening and senescence, which reduces weight loss, delays softening and anthocyanin formation, inhibits browning and decay, and favors flavor and chlorophyll retention.

CA storage is most effective on climacteric fruit such as apples, pears, apricots, mangos, tomatoes, bananas, and papayas, and it has great potential for preserving vegetables with high respiration rates. It is less effective on nonclimacteric fruit and horticultural products with slow respiration rates. Climacteric fruits should be subjected to CA at the earliest possible stage after harvest. Nonclimacteric fruits, such as pineapples, grapes, and limes, have greater flexibility in the afterripening process.

Oxygen concentration is lowered to the desired level in the storage room by first flushing with nitrogen gas or liquid nitrogen, and then injecting carbon dioxide from a gas generator. The overall result is that oxygen concentration declines and carbon dioxide concentration increases in the atmosphere around the stored commodities.

CA Storage Variables

The response of fruits and vegetables to CA storage varies with species, cultivar, growing conditions before harvest, prestorage treatments, maturity or ripeness stage at harvest, ethylene sensitivity, concentration of gasses, temperature in the storage room, and storage time.

The distinctive characteristic of the CA technique is that the storage variables must be rigorously controlled. Thus, to achieve optimum storage conditions for fruits and vegetables, the main variables to be considered are temperature; RH; the concentrations of oxygen, carbon dioxide, and ethylene; and storage duration (Figure 1).

Temperature

Cold storage is the most used method for maintaining the quality of fruits and vegetables. Lower temperatures lead to slower respiration rates and reduce other metabolic or degradation reactions. Temperatures are usually kept between 1 and 3 °C in CA storage, but the accurate optimal temperature depends on the produce and cultivar, as well as other characteristics of the produce.

The storage of fruits and vegetables at the lowest temperatures would seem to be the most beneficial for long-term storage. However, some products, especially tropical and subtropical fruits, show cold stress (termed 'chilling injury') when exposed to low but not freezing temperatures. Chilling injury implies physiological and biochemical disorders. It causes membrane breakdown and the release of metabolites, such as amino acids, sugars, and mineral salts, and enzymes from cells, resulting in enzymatic reactions and the development of harmful microorganisms. Some chilling injury symptoms are surface pitting, discoloration, internal breakdown, flesh browning, failure to ripen, loss of flavor, and decay (Table 1). The severity of the injury increases with lower temperatures and longer durations of chilling exposure.

The beneficial effects of using low-oxygen and high-carbon dioxide atmospheres to reduce the development of chilling injury have been reported. The effectiveness of CAs in reducing chilling injury varies with the commodity, maturity, gas composition, and, above all, the storage temperature. The critical temperature for chilling injury varies with the commodity and cultivar. For instance, it occurs at temperatures below about 12–13 °C in tropical produce and close to 0 °C in the majority of the other products.

Relative Humidity

The RH is also an essential CA storage factor to maintain the quality of fruits and vegetables. Most of these products should be maintained at high RH in the CA room, close to the saturation point (95%), to delay the ripening of different commodities; to maintain the freshness, flavor, and commercial weight of the commodities; and to restrict the development of chilling injury symptoms in sensitive tropical fruits.

However, low RH in the storage room induces the loss of moisture from living tissues (transpiration) that, in turn, causes weight loss in the stored fruits and vegetables. These changes deteriorate the produce appearance (color), texture (shrinking, wrinkling), juiciness, flavor, and nutritional quality. The impact of RH on the water loss of the stored product is strongly related to the temperature and air velocity in the storage room. Other factors, such as variety and maturity, are also important, however.

On the other hand, at high RH (100%), water condensation on the product may occur, providing an ideal environment for the growth of decay organisms. An RH between 85% and 95% is recommended for the storage of fresh produce, in order to restrict weight loss and microbial spoilage. Apples, cherries, peaches, pears, plums, apricots, lemons, berries, litchi, and avocados are among the fruits that need high humidity levels, and the vegetables that require these conditions include asparagus, broccoli, cabbage, carrots, cauliflower, celery, beans, peas, radishes, and corn.

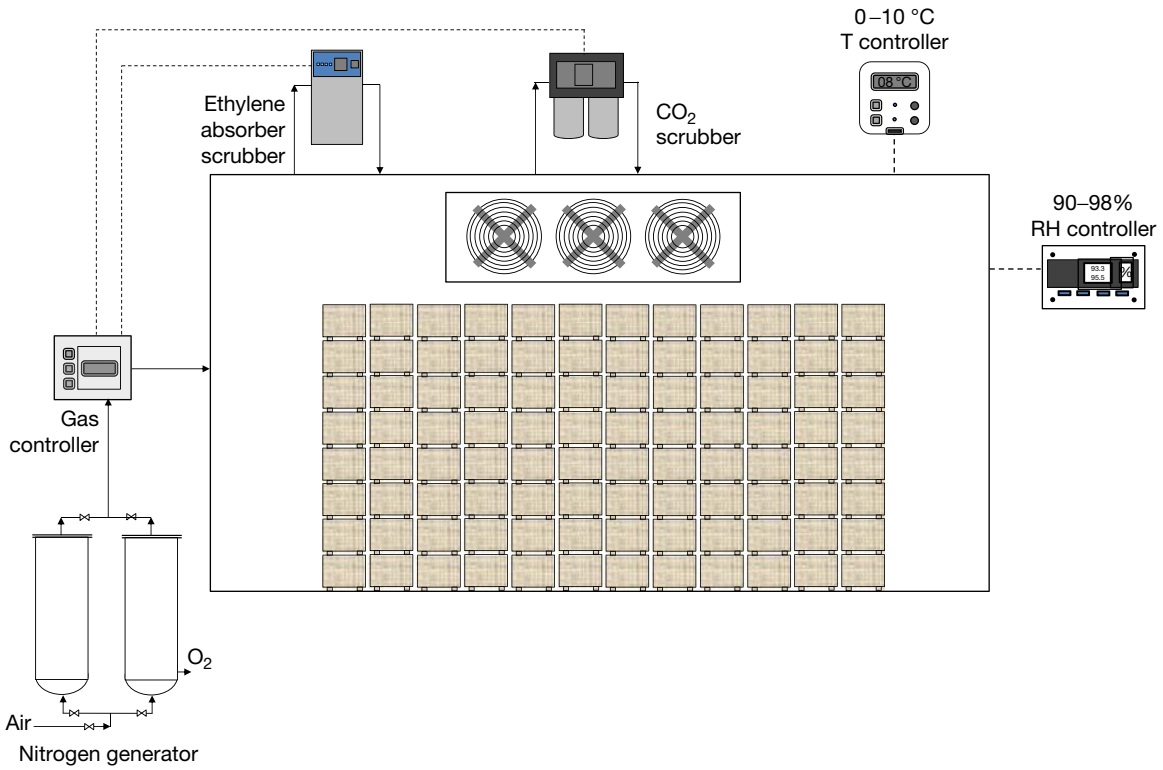

Figure 1 Cold storage room.

Table 1 Possible effects of CA storage conditions on fruits or vegetables

	Effect of storage condition	
Storage condition	*Optimal condition*[a]	*Out-of-range condition*
Decrease temperature	● Minimizes metabolic activity ● Minimizes respiration rate	Very low temperature causes: ● Chilling damage ● Freezing damage ● Browning ● Decay
Decrease O_2 level	● Reduces aerobic respiration rate ● Reduces degradation of color, texture, flavor, and vitamins ● Reduces production rate and action of ethylene ● Delays ripening of climacteric fruit	Very low concentrations induce: ● Fermentation ● Off-flavor ● Alcoholic taste ● Failure to ripen
Increase CO_2 level	● Minimizes aerobic respiration ● Inhibits the effect of ethylene ● Delays ripening ● Reduces discoloration due to enzymatic reactions ● Decreases the production of some organic volatiles ● Reduces the rate of breakdown of pectin and chlorophyll ● Retards fungal growth on the crop	Very high concentrations induce: ● Fermentation ● Drowning of tissue ● Softening ● Off flavor ● Decay

[a]Optimal and out-of-range O_2 and/or CO_2 concentrations depend on the commodity, cultivar, duration of storage, and interactions between O_2 and CO_2.

To assure the beneficial effects of CA storage, the RH needs to be monitored and controlled. Humidity is monitored with a hygrometer or psychrometer, and it is controlled by different means: operating a humidifier in the produce environment, wetting the storage room floor, regulating air movement, maintaining a difference between the air and the evaporator of 0.5–1 °C. At high RH, a small fluctuation in temperature can induce water condensation on the product surface and promote decay.

Oxygen and Carbon Dioxide

It has been demonstrated that, when the storage conditions of fruits and vegetables change from the normal air composition (78% N_2, 21% O_2, and 0.03% CO_2) to an environment with low concentrations of O_2 (1–10%) and high concentrations of CO_2 (1–20%), a reduction in the rates of metabolic activity, respiration, and ethylene production is induced. The effects of reduced oxygen and elevated carbon dioxide on metabolic

changes and respiratory activity are additive. The prime result of the metabolic modification is that the stored commodity maintains the quality characteristics (color, firmness, soluble solids, acidity, vitamins, and freshness) for a longer storage time. In addition, properly maintained levels of O_2 slow down microbial deterioration and inhibit enzymatic browning for some products, such as apples, lychees, and bananas.

However, storage in a CA environment may have adverse effects at too high carbon dioxide concentration (e.g., >3% for red delicious apples and apricots; >30% for cherries) or too low O_2 concentration (e.g., <1% for avocados and bananas). If the O_2 and CO_2 levels are not tolerated by fruits and vegetables, physiological disorders and loss of product may occur. For instance, low O_2 concentration changes the respiration of apples, pears, and tomatoes from aerobic to anaerobic, producing an accumulation of alcohols and aldehydes, which are responsible for undesirable flavors. The extent of these injury symptoms is also a function of exposure time and temperature.

On the other hand, elevated CO_2 concentrations (>5%) may affect the anthocyanin stability and color in red fruits such as strawberries, or it may inhibit the enzymatic activity, due to the high solubility of CO_2 in water and the consequent generation of carbonic acid and lowering of pH. Thus, the success of CA storage technology depends on convenient levels of gas being achieved and maintained in room storage.

Ethylene

Ethylene (C_2H_4) is a natural gaseous plant hormone, which is produced by fresh fruit and vegetables and released into the atmosphere around the fresh product. It increases the respiratory activity of most fruits and vegetables, which, in turn, determines the evolution of their physical and chemical characteristics (appearance, texture, taste, and color) and, consequently, their storage-life.

Controlling ethylene gas in the storage room preserves the commodity quality parameters and freshness, and it extends the life cycle, allowing the produce to be maintained for a longer storage time.

The rate of ethylene production in fruits undergoing ripening is determined by the ability of the fruit to synthesize 1-aminocyclopropane-1-carboxylic acid (ACC) and to convert ACC to ethylene, which is controlled by the activity of ACC synthase and ACC-oxidase.

The ethylene-releasing rate of commodities is highly dependent on the temperature and the concentrations of oxygen and carbon dioxide. For instance, the optimum temperature for ethylene production is 30 °C for apples, 32 °C for some plum cultivars, and 20 °C for peaches, nectarines, and pears.

The O_2 and CO_2 concentrations in the fruit play important roles in the biosynthesis and action of ethylene. Ultra-low oxygen and elevated carbon dioxide concentrations inhibit the activity of ACC synthase and ACC oxidase and suppress ethylene production in fruits such as apples and pears.

Ethylene induces the quality attributes of fruits and vegetables: color development and softening in apples and pears, the greening of citrus, and increases in soluble solids, organic acids, aroma, and flavor in honeydew melons. However, reduced produce quality can be related to the ethylene hormone. For example, this hormone promotes chlorophyll destruction in lettuce and cucumbers; yellowing and dropping of leaves in *Brassica* species; softening, pitting, and development of off-flavor in peppers and watermelons; and browning and discoloration in eggplant pulp.

The removal of ethylene from the CA room can retard the development of undesirable disorders. Preventing ethylene accumulation or ensuring an environment free of ethylene can be accomplished through the ventilation of the cold room, through the use of oxidizing agents (potassium permanganate or ozone), or through the filtration of the air.

Recommended CA Storage Conditions

The inherent variability of fresh commodities and their responses to storage conditions complicate the establishment of the optimal CA. Tables 2 and 3 show recommended temperature, RH, and oxygen and carbon dioxide concentrations for the storage of several fruits and vegetables. However, the recommended CA storage conditions found in literature for a specific fresh produce should be refined through experimentation, empirical observations, and mathematical modeling.

Table 2 Controlled atmosphere conditions for some fruits

Fruits	T *(°C)*	*RH (%)*	*O_2 (%)*	*CO_2 (%)*
Apricot	−0.5 to 0	90–95	2–3	2–3
Apple	0–1	90–95	1–3	1–4
Avocado	5–13	90–95	2–5	3–10
Banana	12–15	90–95	2–5	2–5
Fig	−1 to 0	90–95	5–10	15–20

Lettuce	0–5	98–100	1–3	7–10
Mushrooms	0	95–98	3	10
Onions	0	65–70	3	5–7
Peas	0	95–98	2–3	2–3
Radish	0	95–100	1–2	2–3
Tomatoes	13–15	90–95	4	5

Conclusions

To date, controlled atmosphere storage is the unique technology that can assure long-term storage of fresh fruits and vegetables. Quality of fruits and vegetables is maintained through the application of specific CA storage conditions to each commodity, and control of the gas composition, temperature, and relative humidity of the environment. In addition to these factors, metabolism changes of fruits and vegetables are been considered to establish the optimal storage conditions. This is leading to the development of interactive storage systems, the next generation of storage systems.

Convenience Food

TA Brunner, Bern University of Applied Sciences, Zollikofen, Switzerland

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Convenience food is one of the major food trends in Western societies. However, it is not a new phenomenon. In Ancient Rome, the urban population mainly ate convenience food. The Romans did not even have a choice; their apartments did not include a kitchen so they had to obtain their food from cook shops in the streets. One reason for such a lifestyle was the high cost of firewood; a more practical reason was to prevent fires that could destroy whole quarters or cities. Today, there are different reasons for using convenience food: People want to save time and minimize their physical and mental efforts, and an increasing number of people no longer know how to cook a meal from scratch, so they are dependent on convenience food products.

Definition

There are many definitions of convenience food in the literature. However, most of them include the three aspects of time, effort, and skills. An early definition from 1979 by Traub and Odland defines convenience food as: "Any fully or partially prepared foods in which significant preparation time, culinary skills, or energy inputs have been transferred from home kitchen to the food processor or distributor." Today, the definition of convenience food not only includes the preparation stage of planning, buying, and preparing meals but also incorporates the following stages of consumption and cleanup.

The meaning of using convenience food products has changed dramatically over the decades. In 1950, for example, Haire presented two identical shopping lists to his participants, with the exception of ground coffee on one list and instant coffee on the other. Participants had to characterize the women who bought the items on the lists. Women who bought instant coffee were described as lazy, unable to manage their household, unthrifty, and just not good wives in general. It would be very interesting to replicate this study today; the results would certainly be quite different.

Classification Systems

Several different classification systems for convenience foods have been proposed, for example, classifying them on a scale ranging from zero convenience to full-service convenience, on the basis of the level of prior processing, or on the level of preparation required after industrial processing. Later classification systems have become more complex, for example, a matrix with two levels of prior processing and three levels of preparation and an even more complex matrix with four levels of shelf life and four levels of preparation. All of these classification systems were developed theoretically, and some of them were subsequently validated with consumer data. In the author's own research, the opposite approach was used. They started with food frequency data from consumers and conducted a principal component analysis to identify convenience food categories. Four components emerged: (1) highly processed food products (e.g., frozen ready-made meals), (2) moderately processed food products (e.g., chilled fresh tortellini), (3) single components (e.g., marinated meat), and (4) salads (e.g., cut and washed salad in bags).

Most of these classification systems show that the overall category of convenience foods is very heterogeneous, with some products being only slightly processed and others being heavily processed. There is a continuum of products being processed, and every convenience food product can be indexed at some level of processing. What level of processing is required for consumers to label a product a convenience food is not clearly defined. Today, hardly anybody would label bread, yogurt, and cheese convenience foods, although according to most definitions, they fall into this category. There are other products, such as gravies and soups, that some consumers would call convenience foods, while other consumers would not. And then, of course, there are products like ready-to-heat meals or frozen pizzas that every consumer considers convenience foods.

Overriding Trends

A major trend fostering convenience food consumption that is often discussed in the literature is the increasing participation of women in the workforce. The reason seems plausible: dual-income households have higher incomes but less time. Thus, they are willing to trade some of their money back into time by purchasing convenience food products. Surprisingly, most studies investigating the relationship between female participation in the workforce and convenience food consumption have found no evidence for a positive correlation. Only by applying attitudinal measures it was possible to find some evidence. For example, it was shown that meal preparers with a workload of more than 30 h per week were more convenience-oriented than those with a workload of less than 9 h a week.

Another overriding trend that results in higher convenience food intake is the increasing number of single-person households that can be observed in most Western countries. Although single people have more time available, they are not inclined to use that time cooking for themselves. An unpublished analysis by the author confirms that people living in single-person households consume more highly and moderately processed convenience food products than people living together with at least one other person. For salads, no significant difference was found, indicating that almost everyone buys cut and washed salads in bags. Finally, people from multiperson households consume more single components than those living in single-person households. This seems plausible, since with single components, one still has to cook

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00198-7

and prepare a meal. Together with less-structured mealtimes and the replacement of traditional meals with snacks for all households, the increase in single-person households gives convenience foods a strong boost.

Whereas the causalities for the effects of the increasing female participation in the workforce and the increasing number of single-person households are straightforward, the causality for the decline of cooking skills is not clear. Do people use convenience foods because they lack cooking skills, or did the emergence of convenience foods cause the decline in cooking skills? The fact is that today, many consumers lack cooking skills and therefore depend on convenience foods. The author's own research shows that a lack of cooking skills is indeed a significant driver for convenience food consumption. The more people lack cooking skills, the more they consume highly and moderately processed food items. For salads and single components, cooking skills did not reach significance, which makes sense, as foods from these two categories require much less skill if one wants to prepare them from scratch than foods from the former two categories.

Drivers of Convenience Consumption

To identify the drivers of convenience food, the author conducted a comprehensive study. A sample of $N = 918$ participants completed a survey that included 17 common convenience food items and 14 potential drivers and seven sociodemographic questions. Usage of the various convenience food items differed greatly ranging from salad cut and/or washed, which was consumed on average 73 times per year, to instant pasta, which was only used 2.6 times per year. As mentioned in the preceding text, convenience food items were grouped into four categories based on a principal component analysis: highly processed items, moderately processed items, single components, and salads. For each category, the potential drivers were analyzed separately using regression analysis.

Age is the most important driver for convenience food consumption. The older the consumer, the less convenience food is eaten. This was true for all four categories. There might be two reasons for this: First, after retirement, people have more time available and might spend that time cooking, and second, older people are more accustomed to cooking from scratch from their younger days and may simply continue this habit. Another important driver is an affinity for naturalness. People who pay attention to the naturalness of food do not like processed food items. Naturalness was significant for all categories but salads. This seems plausible since cutting and washing do not affect the naturalness of a food item and, thus, people concerned with food's naturalness can buy these convenience products. Another strong driver is nutritional knowledge. This was significant for highly processed foods, single components, and salads. People with a high level of nutritional knowledge are capable of evaluating what is good for their health. Most highly processed foods and single components contain many additives and preservatives that concerned consumers might judge as unhealthy. For salads, the reason might be the cut and/or washed salad's sensitivity to fungi and bacteria. Most moderately processed foods, on the other hand, are fresh products (e.g., readily bought sandwiches and warm pizza bought/delivered) that are equivalent to self-prepared foods. Therefore, consumers with a high level of nutritional knowledge have no reason not to buy them.

Three more drivers turned out to be significant for two of the four categories: the presence of children in a household, a desire to avoid waste, and cooking skills. Having children reduces the consumption of highly and moderately processed food items. In these categories, one finds the typical ready-made meals that are convenient for single-person households. In a family household, it might be more efficient to prepare meals from scratch because of the higher number of persons living in these households. Another reason might be that parents are concerned about their children having health issues and therefore try to avoid processed foods containing a great deal of additives and preservatives. People who try to avoid food and packaging waste consume less moderately processed food items and less single components. For moderately processed foods, the issue of food waste may be the motivating factor, as these foods usually come in portions that are too large for one person. For single components, it might be the packaging waste, as most of these items are extensively wrapped. A lack of cooking skills is again a driver for highly and moderately processed food items. People with a lower level of cooking skills are not able to prepare the foods in these two categories by themselves and therefore depend on processed foods.

Each category features several drivers that are specific to it. For highly processed food items, these are working status and sociability. People working only part-time or not working at all consume more highly processed foods than people working full-time. This phenomenon has been observed in other studies as well. For example, a snacking consumer segment was identified that was less likely to be well educated and more likely to be unemployed. Sociability refers to an attitude of enjoying eating together with others. The more people display such an attitude, the fewer highly processed food products they consume. This is because in most households, it is still not appropriate to serve ready-made meals when inviting, for example, friends for dinner. For moderately processed food items, education is a specific driver. The more well educated people are, the more moderately processed food products they consume. This seems plausible since well-educated people are likely to have busy jobs but still want to eat rather healthy. Therefore, they go for the moderately processed foods that are freshly prepared, like a sandwich or other to-go foods. For single components, there are three specific drivers: value for money, household size, and physical effort. Value for money refers to a smart shopper mentality, that is, consumers who try to get the best value for their money. It seems that single components, such as marinated or crumbled meat and fish, have good value for their money since smart shoppers buy more of these food items. Household size is also positively related to the consumption of single components. This category also contains foods like frozen french fries and croquettes, things that are prepared easily and things that children really like. This might explain the correlation with household size. Physical effort is the third specific driver for single components. Everyone who has prepared french fries from scratch can understand why people who want to minimize the physical effort of preparing meals buy more foods from the single components category. Finally, two specific drivers emerged for

salads. Consumers who think that convenience foods are too expensive for what one gets buy fewer convenience salads. It seems that, particularly for salads, the surcharge does not seem justified. Some people are not willing to pay extra for merely having their salad already cut and washed. The second driver for salads is an attitude of considering the kitchen to be the woman's domain. The more people think that housekeeping is the woman's responsibility, the more convenience salads they consume. Salads might be regarded as a rather female food product, and therefore, people with such an attitude might want to avoid preparing these foods.

It is also just as interesting to look at the potential drivers that did not turn out to be significant. Surprisingly, variables related to time and effort, such as time-saving, time pressure, and mental effort, did not predict convenience food consumption, with the exception of the physical effort for single components, as discussed earlier. The reason for this might be that convenience foods are now omnipresent. They have crept into our daily lives without us noticing; think of gravy, for example. Today, everyone uses convenience food products. Therefore, these time- and effort-related variables do not differentiate consumers' convenience consumption. Of course, this does not mean that time and effort are not important reasons to use convenience foods; it is just that they do not differentiate consumers and therefore do not turn out to be significant predictors. Instead of having reasons to use convenience foods, it seems that all consumers use them and only consumers who have explicit reasons not to use these items, such as an affinity for naturalness and concerns resulting from a high level of nutritional knowledge, will abstain from consuming them. In other words, the standard is to use them, and people only avoid using such products if they have reasons not to consume them. Besides these time- and effort-related variables, three more potential drivers did not prove significant. For cooking involvement, the same reasoning mentioned earlier might apply. Regardless of the level of cooking involvement, convenience food products are used. Income was also insignificant. One explanation could be that many convenience foods are not really that expensive. For example, a ready-made frozen pizza is usually even cheaper than a self-made pizza when adding up the costs of the ingredients. If one includes the preparation time required to cook a pizza from scratch, it is even worse. More surprising is that concerns about a healthy diet did not predict convenience food consumption. Many researchers found that consumers have an unfavorable image about convenience food. However, it seems that when it comes to a single convenience food product, consumers might not judge it to be unhealthy; they only have an unhealthy image when they think about the marketing category of convenience food in general.

Consumer Segments

In 2007, Buckley and colleagues conducted a comprehensive survey to identify convenience food lifestyle segments. A total of $N=779$ respondents were included in the cluster analysis that was run over 20 factors related to convenience food consumption. The authors identified four convenience food lifestyle segments: (1) food connoisseurs, (2) home meal preparers, (3) kitchen evaders, and (4) convenience-seeking grazers.

For food connoisseurs, convenience is not important. They like to experiment in the kitchen, and eating for them is a social event that is done together with family or friends. They eat proper meals and do not snack in between these meals. They like to take their time when cooking, they are not in a hurry, and they do not feel time pressure. Therefore, they are less likely to buy and consume convenience foods. Food connoisseurs are not very price-sensitive; in fact, they like to spend money on food. For them, cooking is not only a woman's task; male food connoisseurs like to cook either alone or together with their wives. Consumers belonging to this segment think that convenience foods are rather unhealthy and not very attractive in terms of their value for the price. This segment comprises 26% of all consumers, has an average age of about 40 years, and includes the highest proportion of men.

Home meal preparers are similar to food connoisseurs but even less convenience-oriented. They have plenty of time resources to shop and prepare foods and to clean up after a meal. This is the segment that purchases the fewest convenience food products; they prefer preparing a meal from scratch. Home meal preparers are well organized when it comes to shopping for food. They pay attention to freshness, and they try to get good value for the price they ought to pay. Meal preparation activities are a family endeavor as is the intake of meals. A microwave is usually not found in these households. As with food connoisseurs, home meal preparers regard convenience food products as rather unhealthy and expensive. This segment makes up 25% of consumers, most of whom are older and retired, and is more or less balanced in regard to gender.

Kitchen evaders comprise the first of two highly convenience-oriented segments. They use convenience foods to make their lives easier and to avoid food waste. With convenience food, they just buy what they need so nothing is spoiled. If they cooked from scratch, they would have ingredients left that they would have to then throw away. Kitchen evaders are busy people who are always under time pressure. Therefore, they do not want to plan their meal preparation activities; they decide what to eat spontaneously while they are shopping. They are neither interested in product information, nor do they want to try new foods. Instead of having proper meals, they often snack during the day. They are used to eating alone and display a high level of individualism in their consumption behavior. Kitchen evaders have a positive attitude toward convenience food products and think that these products offer good value for their price, are healthy, and save them a lot of time. This segment consists of 16% of all consumers, is below the population's average age, and is rather balanced when it comes to gender.

The last segment is the convenience-seeking grazers. Similar to kitchen evaders, they are very convenience-oriented and are also similar in many other aspects. Unlike kitchen evaders, they are organized in their meal preparation activities and more price-sensitive. Although this segment has the highest proportion of females, convenience-seeking grazers are more likely to think that the kitchen is the woman's task. When it comes to the trade-off between freshness and convenience, they opt for convenience. Similar to kitchen evaders, they are time-stressed, use the microwave, often eat alone, and snack in between meals. Interestingly, convenience-seeking grazers perceive convenience foods as the least beneficial for time-saving. However, they have a positive attitude toward convenience

foods and think that they have good value for their money. One-third of consumers fall into this segment, and most of them are between 30 and 50 years of age.

Healthy Convenience Food

Convenience food has a reputation of being unhealthy. However, the food industry has recently started combining the convenience food trend with the trend of healthy eating by producing healthy convenience foods and healthy ready-made meals. In a tasting test of two rather healthy ready-to-heat meals – one with chicken and rice and the other with salmon and pasta and both with a large portion of vegetables – overall liking was found to be the strongest predictor of the likelihood of buying for both meals. Sociodemographic variables were only relevant for the salmon meal, whereas for the chicken meal, no such effects were observed. It seems that consumers are not ready to make trade-offs when it comes to taste. The food industry's challenge will be to develop healthy and tasty convenience foods, not just one or the other.

Another study segmented consumers based on their health-related motive orientations and found two segments to be particularly inclined to choose ready-made meals. For the first segment, vitality and energy were the main terms used to describe health. They want to keep their bodies in good condition to live active lives and to explore new things. The second segment perceives health mainly in terms of achievement and outward appearance. They want to look good, stay slim, and be successful. Individuals from both segments were rather young, with most of them having no children. This paints a picture of who will be buying healthy convenience food products. It is the young, busy consumers who are successful in what they are doing and who lead active lives.

Convenience food products will surely become healthier in the years and decades to come. Consumers' demand for healthy food is steadily rising, and the trend toward increased convenience will not stop. The ability to bring these two major trends together will be decisive for the success of a particular convenience food producer. Consumers will benefit from this development by obtaining healthy food and saving time, which will improve their work–life balance.

Cooking: Domestic Techniques

AJ Rosenthal, Oxford Brookes University, Oxford, UK

This article is reproduced from *Encyclopedia of Food Sciences and Nutrition*, volume 3, pp. 1622–1627, © 2003, Elsevier Ltd.

Introduction

As with all forms of cooking, domestic cooking is intended to improve the palatability of the food, making it more appetizing. Unlike industrial food preparation and catering or food service, people who may not have any technical knowledge of what is happening from an engineering or biochemical point of view carry out domestic cooking in the home. By definition, cooking raises the temperature of the food, which results in a number of simultaneous and interrelated processes that influence flavor, texture, appearance, nutrient content, and food safety. The different techniques for domestic cooking reflect the way in which the temperature of the food is raised (Figure 1).

Clearly, there are two basic ways in which energy can be applied to a foodstuff to achieve a rise in temperature. The traditional route is by contact with a heated medium, which causes heat to flow to the surface of the food and, subsequently, to the center through conduction. An alternative route is to apply electromagnetic radiation. Of the two types of electromagnetic radiation commonly used in domestic cooking, infrared radiant heating (grilling) employs short-wavelength radiation that is only able to penetrate a couple of millimeters below the surface of the food. The inner regions of the food are heated by conduction. Microwaves have longer wavelengths that are able to penetrate deep into foods, generating heat *in situ*, albeit in nodes requiring food to be rotated during cooking to ensure even distribution of heat.

In many cases, energy transfer during cooking is not via a single mechanism. For example, ovens absorb and emit infrared energy and baked food heat through a combination of convection and radiation. Similarly, barbecues emit infrared radiation and generate hot combustion gases, which flow around the food, heating it by convection.

General Considerations

Surface Heat Transfer

The crucial difference between the different techniques is what happens at the surface of the food.

When a solid food is placed in a hot fluid, there is a stagnant layer of fluid around the food. This boundary layer acts as an insulating barrier that slows the flow of heat from the fluid to the food.

Air is a good insulator (thermal conductivity, 0.024 W m^{-1} K^{-1}); thus, a boundary layer consisting of air slows significantly the flow of heat from an oven to the food (Figure 2(a)). One way of reducing the thickness of this boundary layer is to agitate the heating medium. In the case of fan-assisted ovens, air is forced to circulate, thereby impinging on the surface of the food and physically reducing the thickness of the boundary layer (Figure 2(d)). The surface heat transfer coefficient in a fan-assisted oven is about 10 times greater than in a conventional oven.

Heat travels by conduction through static boundary layers. Heating media that are better conductors of heat than air will increase the rate of heat flow to the surface of the food. Water has a thermal conductivity of 0.573 W m^{-1} K^{-1}, and the rates of convective heat transfer during boiling and simmering are, therefore, considerably faster than in ovens at the same temperature (Figure 2(e)). However, the maximum temperature attainable with water is limited by its boiling point. Alternative liquid heating media, such as oil, have thermal conductivities in the same region and can operate at temperatures around 180 °C. Hence, rates of heat flow to the surface in frying are considerably greater than in boiling. This is also attributable in part to physical agitation of the boundary layer caused by generation of water vapor at the surface of the food, which is in contact with the hot oil (Figure 2(g)).

When saturated steam is used as the heating medium, heat flow to the surface of the food is simultaneously accompanied by condensing of the steam. The dramatic volume change during condensation results in fresh steam flowing to occupy the void, thereby maintaining a virtually negligible boundary layer (Figure 2). However, if the steam is not saturated, the non-condensing air accumulates at the surface of the food, forming an insulating layer. In fact, as little as 6% air in steam reduces surface heat transfer by 90%.

Rate of Heating

During heating, the rate at which heat flows into any food depends on its shape and size and the temperature difference between the food and the heating medium as well as the rate of heat transfer between the food and the heating medium.

Obviously, large surface areas allow more heat flow than small surfaces. Shapes with a higher surface-to-bulk ratio, such as spherical foods, will heat quicker than other shapes (e.g., slabs). Consequently, considering how rapidly heat penetrates to the center of two 'spherical' potatoes of different sizes, evidently, it takes longer for heat to penetrate to the center of a larger potato. There are two reasons for this: greater distance for heat to flow and a smaller area to mass ratio.

The driving force in any heating operation is the difference in temperature between the food and the heating medium. The greater the differences, the faster the rates of heat transfer. In the case of domestic cooking, foods heat by unsteady-state heat transfer. That is to say, the temperature difference reduces as the temperature of the food rises, and hence, the driving force lessens as the process ensues.

The physical properties of the food and the heating system contribute to the heating rate. Factors such as how easily the heat is able to flow through the insulating surface boundary

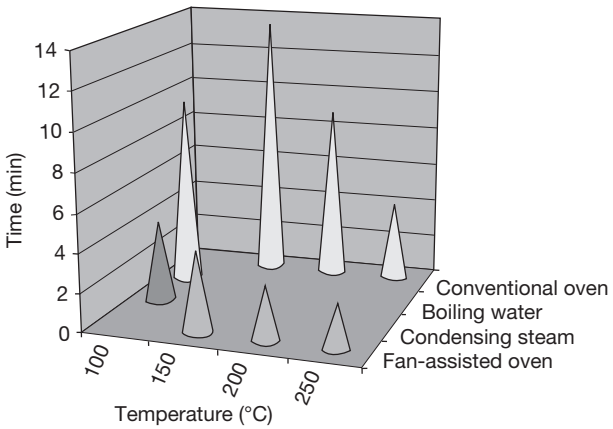

Figure 3 Predicted time for the center of 2 cm diameter potatoes to reach 80 °C.

layer and through the bulk of the food by conduction toward the center are influential.

There are methods for predicting rates of heating based on the physical properties of materials and heating systems. Figure 3 illustrates factors that influence the rate of heating. Time taken for a food of fixed shape and size to reach a particular temperature has been used as a measure of heating rate. In Figure 3, 2 cm diameter spherical potatoes starting at 5 °C have been used. Identical potatoes are placed into different heating media at designated temperatures and the time taken for the core temperature to reach 80 °C predicted. The temperature (80 °C) has been chosen as a realistic temperature for many types of meat and vegetables and one that will achieve gelatinization of starch in a food like a potato.

Clearly, short cooking times can be achieved in a number of ways; working at higher temperature achieves more rapid cooking, as does selecting a cooking process with a high surface heat transfer coefficient. Hence, a fan-assisted oven is faster than conventional ovens because they reduce the thickness of the insulating surface boundary layer around the food.

Cooking by Electromagnetic Radiation

Infrared

As with the other traditional forms of cooking, grilling (broiling) causes the surface of the food to heat, and the center heats by conduction. Absorption of infrared radiation at the surface is proportional to the difference between the fourth power of the radiation source temperature and the surface of the food. However, foods absorb infrared radiation to differing extents depending on their absorptive capacity (e.g., black body, 1; perfect reflector, 0; and water, 0.96).

Conventional grilling and barbecuing are restricted by the fact that radiant energy is supplied from one direction; cooking of all sides is only achieved by frequently turning the food, for example, on a spit.

In practice, infrared heating is involved in many cooking techniques, such as baking and roasting. In these cases, oven walls heat up by convective heat transfer and then emit infrared radiation.

Microwaves

Microwaves penetrate deep into most foods; their sinusoidal electromagnetic waveform causes dipoles (e.g., water) to oscillate, which in turn generates heat (Figure 2(h)). As microwaves pass through a food material, energy is lost; although heating occurs within the food, it is greatest at the surface. The actual temperature achieved within the food depends on several factors, including the frequency of the radiation, strength of the field, dielectric loss factor of the food, free moisture present, and the shape of the food.

Quality Changes during Cooking

General Considerations

Arguably, there are only two basic cooking methods: wet and dry. Wet cooking includes boiling, simmering, steaming, pressure cooking, stewing, and poaching. During wet cooking, the surface temperature of the food does not exceed the boiling point of water (usually 100 °C, but up to about 120 °C in domestic pressure cookers); consequently, the surface remains moist. Dry cooking includes frying (deep and shallow), baking, roasting (in an oven with natural or added fat), grilling (broiling), barbecuing, and griddling. The surface temperature during dry cooking may well exceed 100 °C, leading to evaporation of moisture and a dry or crisp surface.

Whatever is being cooked, it is worth bearing in mind that most foods are biological in origin and many are still respiring up to the time of cooking. The rise in temperature during cooking can result in a disruption of structural integrity and the termination of normal metabolic activity.

We eat a diverse range of foods, each with unique quality criteria. Since changes that occur during cooking are dependent on both the temperature achieved and how long food is held at each temperature, product quality is constantly changing. Most of the changes taking place during domestic cooking can be described by first-order Arrhenius kinetics (i.e., after a finite activation energy is reached, rate of change is proportional to a rate constant, which is affected exponentially by temperature). Activation energy and the rate constant vary for different quality factors; moreover, any particular factor may behave differently in each food (e.g., thiamine is destroyed more rapidly during cooking of rainbow trout than in a buffered solution with the same time–temperature profile). If a food is cooked on the basis of one quality characteristic (e.g., color or texture) and if the time–temperature treatment is varied from an established procedure, other quality parameters may be suboptimal. For example, microwaved meat may not develop the same flavor as conventionally roasted meats.

Textural Changes

No single mechanism is responsible for the texture of foods, yet changes in protein structure and solubilization of polysaccharides (and some proteins) are the two primary phenomena involved.

Heat causes the tertiary structure of proteins to unwind. Heating for long periods or at high temperatures frequently results in irreversible changes in tertiary structure, termed denaturation, which causes changes in functional properties that may or may not be desirable. If the protein is highly charged, the uncoiled amino acid chains tend to repel one another increasing the affinity for water and enhancing solubility.

If the protein is reasonably close to its isoelectric point, the amino acid chains tend to attract one another, with hydrophobic interactions and hydrogen bonds, forming a network of chains. This association behavior results in a reduction in the amount of water associated with protein and the following consequences: a loss of protein solubility; precipitation of the protein from solution, a solid structure (thermal setting or gelation); loss of water-holding capacity accompanied by an aqueous exudate from the product (often observed when cooking meats); shrinkage as both the aforementioned occur; and increased opacity of the food (e.g., egg white).

Some proteins undergo reversible thermal transitions when heated. For example, collagen (and its partially hydrolyzed derivative, gelatin) is solubilized when heated. Its prevalence in connective tissue means this has important implications in the tenderness of cooked meat and is responsible in part for the softening action of long-duration stewing.

Solubilization is also a process that affects polysaccharide material between cell walls of plants. Dissolution of pectin results in softening of plant tissues. Addition of sodium bicarbonate enhances solubilization of pectin, through production of the sodium salt, and displaces calcium ions that are naturally chelated in the structure. Another mechanism commonly involved in providing rigidity in plant tissues is turgor. Denaturation of proteins present in the cell membranes causes termination of osmoregulation and softening of the tissues. Deliberate protein denaturation is the aim of blanching, brief

exposure to temperatures around 85 °C with the intention of destroying flavor-modifying enzymes prior to home freezing.

Starch is present in many plant foods, and heating starch with an ample supply of water leads to gelatinization. The granules swell as they absorb water and the crystalline regions are disrupted. This has both a softening effect and a thickening effect, which is why gelatinized starch provides the viscosity of many sauces. The light, open texture of baked flour products is due to the presence of gas or air cells in the prebaked dough or batter. During heating, the gases expand aided by the generation of additional gas from chemical leavening agents (e.g., sodium bicarbonate) and increased vapor pressure of the water present. Finally, the liquid matrix is heat-set by denaturation of proteins and starch gelatinization. In the case of popcorn, the impervious grain coat acts like the wall of a pressure vessel. As the grain is heated, the water vapor pressure increases until the wall ruptures. The vapor flashes off, opening out the endosperm, which then heat-sets.

A crisp outer surface is often associated with dry cooking because temperatures in excess of 100 °C result in moisture being lost from the surface.

Color and Flavor Changes

With the exception of added colors sometimes used in domestic cooking (e.g., saffron or cochineal), two types of color change result from domestic cooking: modification of natural pigments present in the raw materials and browning reactions. Most natural colors tend to be relatively unstable when cooked. In addition to these chemical reactions, in wet cooking, loss of natural color may result from leaching of water-soluble pigments into the cooking medium.

Metalloporphyrin colors are found in foods of both animal origin and plant origin. Myoglobin, the pigment found in muscle, undergoes changes color from red purple to brown when heated; this is as a result of certain amino acids in the globin protein becoming coordinated with the central iron atom. Chlorophylls are also prone to lose their color when heated in acid conditions. The change from bright green to a grayish green is the result of demineralization of the central magnesium atom from the molecule. Other natural pigments exhibit sensitivity to pH. Anthocyanins, for example, change from red (in acid conditions), to colorless (when neutral), to blue (when alkaline). This can result in color changes when heat disrupts cells and allows these water-soluble pigments to mix with the cooking water.

Browning reactions tend to occur at low levels of available water. They are, therefore, common in dry cooking where the surface layers may dry out. Caramelization occurs when sugars are heated, particularly in the presence of acids or alkalis, and is important in both sugar and flour confectionery. The most famous of these reactions is the Maillard browning, which comprises the reaction between carbonyl groups (as found in reducing sugars) and amino groups. The reaction gives rise to a variety of brown compounds and characteristic aromas. Simple mixtures of one amino acid and one reducing sugar have been shown to produce distinctive aromas, reminiscent of particular foods (e.g., glucose and cysteine heated at 180 °C for 30 s smells of puffed wheat, yet after 3 min, it smells of overroasted meat). Generally speaking, volatile components are lost during cooking, and this can result in a loss of the uncooked flavor. Since the end user carries out domestic cooking, loss of volatiles is not completely wasted and may act as an appetizer.

Sustained heating of dry surfaces can result in carbonization, usually accompanied by smoke. In such circumstances, the surface browns and then blackens as the food burns; such products are usually regarded as spoiled.

Nutritional Changes

Although the act of cooking involves raising the temperature of the food, the term is frequently undifferentiated from other food preparation procedures, many of which commonly precede cooking. Peeling and trimming are two such operations that can lead to substantial loss of available nutrients, by cutting unsightly portions off the food and throwing them away.

Nutrient loss during cooking is attributable to two basic routes: thermally induced chemical reactions and leaching of nutrients into the cooking medium.

Many nutrients are thermally unstable, and when heated, concentrations fall exponentially with time. Obviously, different nutrients have unique rates of destruction. The most sensitive are ascorbic acid (vitamin C) and folic acid, both of which can be completely destroyed by domestic cooking. Of the essential amino acids, lysine is the least stable and up to 40% may be lost by domestic cooking practices. In general, rapid cooking methods, using high temperatures for short periods or microwaves, cause less nutrient destruction than long-duration, low-temperature cooking methods such as stewing. High-temperature short-time processes, such as frying, can result in similar levels of vitamin C as in raw potatoes.

In addition to thermal decomposition, nutrients can be lost through reactions with each other. For example, proteins will participate in the Maillard reactions, particularly when ε-amino groups are present.

Sodium bicarbonate is sometimes added to vegetables for its softening effect. Unfortunately, its addition leads to the destruction of vitamin C as well as chemically modifying proteins, lowering their biological value.

Cooking processes are not entirely detrimental from a nutritional point of view. For example, frying can result in an uptake of oil, resulting in increased energy density of foods.

Safety Aspects

A common misconception is that domestic cooking is performed purely to improve the gastronomic experience to the detriment of biological value. In fact, domestic cooking can make safe products that would otherwise contain harmful or toxic components.

Harmful components in foods arise in the form of naturally present toxins (e.g., cyanides in kidney beans and cassava) or compounds that interfere with digestion, effectively making the food less nutritious (e.g., trypsin inhibitors found in many legumes). The presence of pathogenic microorganisms may lead to infections, while other microorganisms produce toxins, both of which result in food poisoning. Cooking is

effective at destroying or removing many of these harmful components. However, some toxins are relatively heat-stable (e.g., the toxin produced by *Staphylococcus aureus*) and may not be destroyed by temperatures and times incurred during domestic cooking. Domestic cooks without formal training may be unaware of the risks involved in eating particular foods or to the neutralizing effects of cooking. A further risk arises from cross contamination of cooked food by raw ingredients, resulting in the potential for fresh growth of pathogenic microorganisms.

Properties, Production, and Industrial Uses of Copper

Copper (Cu) is a transition metal with atomic number 29. Cu has 29 isotopes, two stable isotopes (^{63}Cu and ^{65}Cu), and 27 radioisotopes. The most abundant isotope is ^{63}Cu that accounts for approximately 69% of naturally occurring Cu. Cu has a face-centered cubic crystal structure. Pure Cu is reddish orange in color, malleable, and a good conductor of heat and electricity.

Cu is naturally present in the Earth's crust and is found in the environment as a metal and in various minerals (e.g., cuprite and malachite). Concentrations can vary from less than 50 ppm to more than several thousand ppm in certain areas. Most of the extracted Cu comes from sulfide ores. Both natural and anthropogenic activities release Cu into the environment. Natural events include volcanic eruptions, windblown dusts, forest fires, and decaying vegetations. Mining, milling, and metal productions are common human activities that discharge Cu into the environment. Mean Cu concentrations in air range from 5 to 200 ng per cubic meter in rural and urban areas. Combustion of fossil fuels is a major contributor to airborne Cu.

In 2013, the largest producers of Cu were Chile, China, Peru, the United States, and Australia. Chile was the top producer with an estimated production of 5 700 000 tons. Cu is used in a variety of industrial applications. Major uses are in electrical wires, plumbing, roofing, and industrial machinery. Cu is also combined with other elements such as zinc and tin to make the alloys brass and bronze, respectively. These alloys are used in applications that require a harder material than pure Cu.

Analytic Measurement of Copper

The most commonly used methods for determining Cu content in food and environmental and biological samples are flame or graphite furnace atomic absorption spectrometry (AAS) and inductively coupled plasma–atomic emission spectroscopy (ICP-AES). In AAS, the sample is atomized by a flame or graphite tube (electrothermal). Quantification of Cu (or other elements) is made by determining the absorption of element-specific optical radiation (light) by free atoms in the gaseous state. ICP-AES produces excited atoms and ions using inductively coupled plasma. The atoms emit electromagnetic radiation at characteristic wavelengths and the intensity of the emission is related to the concentration of the atoms in the sample. For both AAS and ICP-AES, standards with known analyte concentration are used to derive the concentration of the analyte in the sample. Prior to Cu determination by AAS or ICP-AES, samples often need to be prepared for analysis. The sample preparation procedure depends on the specific sample and can involve acid digestion, filtration, and acidification. Additional methods that can be used for the measurement of Cu include inductively coupled plasma-mass spectrometry (ICP-MS), anodic stripping voltammetry, x-ray fluorescence, neutron activation analysis, photon-induced x-ray emission, and gas/liquid chromatography.

Reference Values for Copper

Nutrient reference values for Cu have been established by scientific bodies. Table 1 shows recommended intakes and tolerable upper intake levels (UL) for Cu by life stage group established for North America (i.e., Canada and the United States) and the European Union. Depression in Cu status induces a number of quantifiable physiologic changes. Despite this, no single indicator was deemed sufficient for deriving the estimated average requirement (EAR) for Cu as part of the North American Dietary Reference Intakes due to inconsistencies in results from studies measuring similar biomarkers. For adults aged $\geq$19 years, four indicators were used to establish the EAR: serum Cu concentration, serum ceruloplasmin concentration, erythrocyte Cu/Zn superoxide dismutase (SOD1) activity, and platelet Cu concentration. The EAR for adults range from 0.7 to 1 mg day^{-1} and the recommended dietary allowances (RDA) range from 0.9 to 1.3 mg day^{-1}. EAR and RDA are the same for males and females and these reference values are higher for pregnancy and lactation. It was determined that there were inadequate data to separately establish EAR for infants, children, and adolescents. For infants 0–12 months, adequate intakes were established based on mean Cu intake of infants fed with mainly human milk. For children and adolescents aged 1–18 years, the EAR were derived by extrapolation from the adult EAR. The European Union established population reference intakes that are slightly higher than the North American RDA.

There are limited data on the effects of high intakes of Cu in healthy people. Chronic high intakes of Cu result in the accumulation of Cu in the liver that can lead to liver damage. Acute ingestion of large amounts of Cu salts in drinking water has been reported to cause gastrointestinal symptoms; however, liver damage was selected as the more relevant endpoint to establish the UL for Cu. A no observed adverse effect level (NOAEL) of 10 mg day^{-1} was established for adults based on data showing no liver injury in adults consuming 10 mg of supplemental Cu daily. North America applied an uncertainty factor (UF) of 1 to the NOAEL to derive a UL of 10 mg day^{-1} because of the low prevalence of liver damage from Cu exposure in human populations with normal Cu homeostasis and other evidences indicating the absence of adverse effects with Cu intakes of 10–12 mg day^{-1} from foods. The European Union set a more conservative UL of 5 mg day^{-1}, applying a UF of 2 to account for variability to Cu toxicity within the normal population. It was also concluded that the UL is not

Luxembourg: Office for Official Publications of the European Communities.

applicable during pregnancy and lactation because of limited data relating to these life stages. Given the paucity of data on Cu toxicity in healthy infants, children, and adolescents, a UL was not set for infants and UL for children and adolescents were derived by extrapolation from the adult UL.

Sources of Copper Exposure

For humans, the main sources of Cu exposure are food, Cu-containing supplements, and drinking water. Intake of Cu through dermal routes or inhalation is minimal for most people. Table 2 shows the Cu content of foods rich in Cu obtained from the Canadian Nutrient File. Foods have been separated into different food categories, and the Cu content per serving size and 100 g of the food source have been provided. Organ meats, seafood, nuts, and seeds are rich in Cu. Consumption of one serving of foods highest in Cu content is sufficient to meet the daily Cu requirements for an adult.

Usual Cu intakes from food and supplements for the US population were determined in the third National Health and Nutrition Examination Survey (1988–1994). For men and women aged 19–70 years, mean Cu intakes from food alone ranged from 1.54 to 1.70 and 1.13 to 1.18 mg day^{-1}, respectively. Mean Cu intakes increased to 1.79–1.85 mg day^{-1} for men and 1.32–1.45 mg day^{-1} for women when Cu intake from supplements was also considered. Cu intakes for most people were above recommended intakes and below the upper limits. However, usual intake of Cu from food and supplements at the 5th percentile was below the EAR for women of several age groups. Mean Cu intakes from food for adults in European countries range from 1.0 to 2.3 mg day^{-1} for men and 0.9 to 1.8 mg day^{-1} for women.

Health-based and aesthetics-based guidelines for Cu in drinking water have been established. The US Environmental Protection Agency (US EPA) has set a maximum contaminant level goal of 1.3 mg l^{-1} to protect against gastrointestinal symptoms. The World Health Organization (WHO) has set a guideline value of 2.0 mg l^{-1} to protect against acute gastrointestinal effects and to provide a margin of safety for populations with normal Cu homeostasis. Canada has set an aesthetics-based guideline for Cu in drinking water of $\leq$1.0 mg l^{-1} to ensure palatability and to minimize staining of laundry and plumbing fixtures. The European Union standard for maximum concentration of Cu in drinking water is 2 mg l^{-1}.

Cu concentrations in natural water (e.g., rivers, lakes, and oceans) are relatively low (median: 4–10 μg l^{-1}). Drinking water in some instances can make a substantial contribution to total Cu intake. Tap water from dwellings with Cu piping can contain much higher concentrations of Cu. A number of factors can affect the amount of Cu dissolution from Cu piping accounting for the large variability in Cu concentrations. Tap water of a first-draw sample is more likely to contain higher amounts of Cu than a flush sample since the water has sat in the plumbing for some time. In a monitoring survey carried out in Ontario, Canada, communities, the Cu concentration in consumed water averaged 0.176 mg l^{-1} with a range of 0.020–2.02 mg l^{-1}. It can be estimated that an adult consuming 1.5 l of water would have a daily Cu intake of 0.264 mg

Table 2 Copper content of foods

Food	*Serving size*	*Copper per serving (mg)*	*Copper per 100 g (mg)*
Organ meats			
Veal/beef/lamb/pork/chicken liver (cooked)	75 g	0.476–11.3	0.635–15.1
Pork kidney (braised)	75 g	0.500	0.683
Beef kidney (simmered)	75 g	0.423	0.564
Liver pate	75 g	0.300	0.400
Seafood			
Oyster (boiled or steamed)	75 g	1.10–5.68	1.47–7.57
Lobster (boiled or steamed)	75 g	1.46	1.94
Squid (breaded and fried)	75 g	1.41	1.89
Crab, octopus, clam, crayfish (boiled or steamed)	75 g	0.466–0.886	0.621–1.18
Nuts and seeds			
Sesame seeds (whole, dried)	60 ml	1.5	4.08
Flaxseeds (whole and ground)	60 ml	0.809	1.90
Cashew nuts (dry roasted)	60 ml	0.771	2.219
Pumpkin/squash/sunflower seeds	60 ml	0.623–0.734	1.08–1.28
Brazil nuts, hazelnuts, walnuts, pine nuts	60 ml	0.413–0.619	1.16–1.74
Legumes			
Meat substitutes	1 serving	1.10–1.34	0.733–0.893
Fermented soybean products (natto, tempeh)	175 ml	0.863	0.667
Pink lentils (boiled)	175 ml	0.714	0.399
Soy/white/kidney/navy beans	175 ml	0.283–0.507	0.166–0.283
Peanuts (oil-roasted)	60 ml	0.438	1.30
Meats			
Quail (cooked)	75 g	0.444	0.592
Veal (varied cuts)	75 g	0.161–0.360	0.215–0.480
Cured pork (ham, bacon)	75 g	0.115–0.313	0.153–0.417
Vegetables			
Mushrooms (cooked)	125 ml	0.415–0.686	0.504–0.895
Heart of palm (raw)	85 g	0.547	0.644
Potato with skin (boiled or baked)	1 potato	0.379	0.253
Fruit			
Prunes	60 ml	0.205	0.612
Avocado	½ fruit	0.191	0.190
Raisins	60 ml	0.133	0.362
Milk and alternatives			
Soy beverages	250 ml	0.424	0.165
Goat cheese	50 g	0.366	0.732
Chocolate milk	250 ml	0.172	0.065
Grains			
All bran ready-to-eat cereal	30 g	0.318–0.343	1.06–1.14
Kamut (cooked)	125 ml	0.225	0.248
Quinoa (cooked)	125 ml	0.14	0.191
Others			
Dark chocolate	40 g	0.408–0.704	1.02–1.760

from drinking water. A Swedish study found that the median daily intake of Cu from drinking water for young children was 0.32 mg. It should be noted that considerably higher Cu concentrations that exceed standards have been reported in drinking water from a small percentage of dwellings. Consuming water with high concentrations of Cu concomitant with a Cu-rich diet could result in total Cu intakes exceeding the UL.

Copper Bioavailability

Dietary interactions of Cu with a number of food constituents have been described, yet under most circumstances, Cu bioavailability is minimally affected by the composition of the diet. It is well established, however, that consumption of large quantities of zinc can decrease Cu absorption and lead to Cu deficiency. In fact, decreased Cu status was the endpoint selected by the Institute of Medicine in establishing the UL for zinc for adults. High iron intakes may also interfere with Cu absorption in infants. The amount of Cu ingested greatly affects Cu absorption. When a diet is low in Cu (0.4 mg day^{-1}), up to 75% of the Cu is absorbed, whereas only 12% is absorbed when the diet is high in Cu (7.5 mg day^{-1}). Notably, even though fractional Cu absorption decreases with higher Cu intakes, the absolute amount of Cu absorbed is greater.

Whole-Body Copper Metabolism

In healthy people consuming a balanced diet, overt Cu deficiency and toxicity are rare because of the body's elaborate systems that maintain Cu homeostasis over a moderate range (~10-fold) of exposures. The intestine is the primary site for Cu absorption. Ingested Cu from foods and Cu from digestive fluids (e.g., pancreatic and biliary secretions) present in the intestinal lumen are absorbed by enterocytes by the Cu permease, Cu transporter 1 (Ctr1). Ctr1 is present on the brush-border surface and transports reduced Cu^{1+}. The reduction of Cu^{2+} to Cu^{1+} prior to transport by Ctr1 is not well understood, but may involve Dcytb or Steap2. Cu exits the basolateral side of absorptive enterocytes in a process mediated by the action of the P-type ATPase, ATP7A. Once absorbed, Cu is transported bound to carrier proteins (albumin and α2-macroglobulin) to the liver where it is subsequently released into the circulation for transport to tissues.

The liver is a main organ for controlling Cu balance and maintaining circulating Cu concentrations. The body responds to increases in Cu by eliminating endogenous Cu into the bile in a processed mediated by the P-type ATPase, ATP7B. Biliary Cu excretion is a key homeostatic mechanism for ridding the body of excess Cu and preventing Cu overload. Renal excretion plays a minor role. In healthy people consuming a normal Cu diet, urinary Cu excretion is low (<0.1 mg day^{-1}).

Intracellular Copper Trafficking

Cu is a redox-active metal. Free Cu can participate in Fenton-type reactions and lead to the production of reactive oxygen species that can damage cellular components. The cell has evolved an overcapacity to sequester Cu and it has been estimated that there is less than one free Cu atom per cell. Ctr1 plays a major role in the uptake of cellular Cu, although Ctr1-independent Cu uptake systems exist. Once inside the cell, Cu is transferred to a family of proteins called Cu chaperones and possibly other small Cu-binding proteins (e.g., metallothioneins and GSH). Cu chaperones deliver Cu to specific Cu-requiring enzymes by directly transferring the Cu to the apo-cuproprotein by protein–protein interaction. This direct transfer prevents the accumulation of free Cu that can otherwise engage in deleterious reactions. Metallothioneins provide the cell with additional capacity to bind Cu under conditions of high Cu exposure.

The Cu chaperone for SOD1 (CCS) transfers Cu to SOD1 in the cytoplasm and intermitochondrial space. COX17 is required for incorporating Cu into cytochrome *c* oxidase (CCO) in the mitochondria along with other Cu chaperones including Cox11, Sco1, and Sco2. ATOX1 delivers Cu to ATP7A and ATP7B. When cellular Cu levels are normal, ATP7A and ATP7B are largely localized to the trans-Golgi network and function to transport Cu into the lumen of the trans-Golgi network for incorporation into nascent secretory cuproenzymes such as ceruloplasmin, lysyl oxidase, peptidylglycine α-amidating monooxygenase, and dopamine β-hydroxylase. When cellular Cu levels rise, ATP7A and ATP7B translocate in cytoplasmic vesicles from the trans-Golgi network to the cell surface to expel Cu from the cell.

ATP7A is expressed in the intestine and most other tissues. The tissue expression pattern of ATP7B is more restricted, with high expression in the liver. ATP7A mediates Cu efflux from enterocytes into the plasma by a process that involves fusion of Cu-loaded vesicles with the basolateral membrane of enterocytes. ATP7B mediates Cu excretion into the bile by a mechanism involving fusion of Cu-loaded vesicles with the canalicular membrane of hepatocytes. Cu metabolism MURR1 domain-containing protein 1 (COMMD1) has been shown to interact with ATP7B and may facilitate the excretion of Cu by ATP7B into the bile canaliculus. Mutation of the *COMMD1* gene in dogs has been associated with Cu toxicosis.

Cu transporter 2 (Ctr2) shares sequence similarity with Ctr1 although its function in mammalian cells is less understood. Ctr2 is localized to cytoplasmic vesicles and a small proportion has been detected on the plasma membrane. Studies in yeast support a role for Ctr2 in the mobilization of Cu from intracellular vesicles to the cytosol. Recently, Ctr2 has been shown to play an important role in regulating the function of Ctr1 by controlling the accumulation of a truncated form of Ctr1 lacking the Cu-binding ectodomain. $Ctr2^{-/-}$ mice were found to be defective in the accumulation of the truncated form of Ctr1 and showed increased tissue Cu that accumulated as intracellular foci.

The role of other Cu-binding proteins such as the prion protein (PrP^c) and amyloid precursor protein (APP) in Cu metabolism is not well understood. Some data suggest that the APP may be involved in regulating Cu levels in the brain.

Copper-Dependent Enzymes

Cu has been known to be an essential nutrient for almost a century. Cu is required by organisms in small quantities and therefore considered a trace mineral. Total body Cu content in an adult is approximately 80 mg and most (half to two-thirds) is located in the skeleton and muscle because of their relative size. The brain, liver, heart, and kidneys have the highest Cu concentrations.

The ability of Cu to cycle between its oxidized cupric (Cu^{2+}) and reduced cuprous (Cu^{1+}) forms is critical for its biological function. As an essential component of Cu-dependent enzymes (also called cuproenzymes), Cu functions as a catalytic cofactor carrying out single-electron transfer reactions. Cuproenzymes present in mammals and their physiological function are listed in Table 3. Cuproenzymes function in various physiological processes such as antioxidant defense (SOD1 and extracellular superoxide dismutase (SOD3)), iron homeostasis (ceruloplasmin, hephaestin, and zyklopen), mitochondrial respiration (CCO), development of connective tissue (lysyl oxidase), melanin biosynthesis (tyrosinase), catecholamine production (dopamine β-hydroxylase), peptide hormone processing (peptidylglycine α-amidating monooxygenase), and oxidative deamination (amine oxidases).

Copper Deficiency and Toxicity

Symptoms of Cu deficiency are a result of reduced activity of cuproenzymes. Symptoms of overt Cu deficiency in mammals

Table 3 Physiological function of mammalian cuproenzymes

Cuproenzyme	*Physiological function*
Amine oxidases	Oxidative deamination
Ceruloplasmin (ferroxidase)	Ferrous iron oxidation
Cytochrome *c* oxidase	Reduction of molecular oxygen
Dopamine β-hydroxylase	Norepinephrine production
Hephaestin	Ferrous iron oxidation
Lysyl oxidase	Elastin cross-linking
Peptidylglycine α-amidating monooxygenase	Peptide C-terminal α-amidation
Superoxide dismutases (SOD1 and SOD3)	Superoxide disproportionation
Tyrosinase	Dopaquinone production
Zyklopen	Ferrous iron oxidation

include hypochromic anemia, neutropenia, thrombocytopenia, and hypopigmentation. Structural and functional abnormalities occur in the skeleton and cardiovascular system and depressed immune function and neurological abnormalities are also observed. Overt Cu deficiency is rare in humans consuming a balanced diet. Subpopulations at increased risk for Cu deficiency included preterm infants fed with cow's milk (or other milk-based formulas low in Cu), individuals with malabsorption syndromes (e.g., celiac disease), and gastric bypass patients. Cu deficiency has also been observed in patients receiving total parenteral nutrition. Consumption of high amount of zinc can also predispose individuals to Cu deficiency. Cu toxicity has been observed with overzealous use of Cu-containing supplements and following ingestion of contaminated water with high concentrations of Cu.

Genetic Disorders of Copper Metabolism

The best characterized genetic disorders of Cu metabolism are Menkes syndrome and Wilson's disease. Menkes syndrome is an X-linked recessive disorder that results from mutations in the *ATP7A* gene leading to impaired intestinal Cu absorption and a systemic Cu deficiency. Symptoms include growth failure, mental retardation, weak muscle tone, and brittle hair. A milder form of the disease termed occipital horn syndrome has been described. Occipital horn syndrome is characterized by calcium deposits in the occipital bone, coarse hair, and loose skin and joints.

Wilson's disease is an autosomal recessive disorder that is caused by mutations in the *ATP7B* gene. In Wilson's disease, Cu accumulates in tissues, namely, the brain and liver, resulting in neuropsychiatric symptoms and liver damage. Indian childhood cirrhosis, idiopathic Cu toxicosis, and endemic Tyrolean infantile cirrhosis are rarer diseases of hepatic Cu accumulation in infancy and childhood that have a genetic predisposition. Manifestation of these diseases is often associated with high intakes of Cu from contaminated food or water.

Evaluation of Copper Status

The most commonly used biomarkers for routine assessment of Cu deficiency are plasma Cu concentration and plasma ceruloplasmin (Cp) protein concentration or activity. Most Cu in the circulation is bound to Cp (>90%) and therefore changes in plasma Cu closely follow changes in Cp. A limitation of both these biomarkers is that they are affected by conditions unrelated to Cu status including inflammation, age, gender, hormone use, and pregnancy. In addition, strong homeostatic mechanisms act to maintain plasma Cu and Cp within a normal range, which likely makes these indicators insensitive to mild reductions in Cu status. Several studies have shown changes in biochemical indicators in response to Cu restriction in the absence of changes in plasma Cu or Cp.

Erythrocyte SOD1 enzymatic activity and protein content decrease in experimental animals with Cu deficiency. Enzymatic activity is a better measure of Cu deficiency than protein level given that inactive apo-SOD1 accumulates in Cu-deficient cells. Erythrocyte SOD1 activity has been shown to be lower in Cu-deficient patients, in subjects consuming a low Cu diet and in people taking high-dose zinc (a Cu absorption antagonist) supplements. Limitations of erythrocyte SOD1 activity as an indicator of Cu deficiency are the absence of a simple, standardized assay with a reference interval and the high intra-individual variation. Erythrocyte SOD1 activity is also affected by certain diseases and conditions.

Platelet Cu concentrations may response more quickly to change in Cu intakes and be more sensitive to changes in Cu status compared to other conventional biomarkers. In establishing requirements for Cu in North America, diets that decreased serum Cu and Cp concentrations were considered deficient in Cu. If the diet did not alter serum Cu and Cp, but reduced platelet Cu concentration, the diet was considered to be marginally adequate in Cu.

The search for more sensitive, specific, and noninvasive biomarkers of Cu status that can be easily measured in humans is ongoing given that traditional biomarkers may be insensitive to small changes in Cu status and have other disadvantages. Cu deficiency induces many biochemical changes. Changes in cuproenzymes, Cu-binding proteins, and markers of immune function and bone metabolism have been proposed as potential indicators for assessing Cu status. One promising biomarker is CCS. Studies in rodents and cattle have shown that CCS protein increases in cells in response to Cu deficiency. The mechanism by which CCS is regulated by Cu has been elucidated. Cu binding to CCS decreases its stability and increases its rate of degradation by the 26 S proteasome. Under Cu-deficient conditions, CCS is more stable and protein levels increase. Since CCS is responsive in erythrocytes, it can be measured in a small blood sample and is therefore appealing for use in humans. Since SOD1 protein decreases and CCS protein increases with Cu deficiency, the CCS:SOD1 protein ratio has been proposed as a measure of Cu deficiency. The CCS:SOD1 ratio has the advantage of increasing the magnitude of the change in some situations compared to assessing CCS alone. A study in rats has shown that erythrocyte CCS protein decreases with Cu overload suggesting that CCS may also be useful as a biomarker for Cu excess. Furthermore, CCS mRNA in peripheral blood mononuclear cells has been shown to decrease in response to Cu supplementation in people with high Cp concentration. Other promising biomarkers for assessing Cu deficiency include serum and tissue activity of peptidylglycine α-amidating monooxygenase and CCO activity in platelets.

Presently, liver Cu concentration is considered the 'gold standard' for diagnosing Cu overload, but the invasiveness of a liver biopsy precludes its use in routine assessment. The non-Cp-bound Cu and protein-free Cu in plasma are promising indicators for assessing Cu excess. Protein-free Cu in serum or plasma was found to be higher in patients with untreated Wilson's disease compared to treated patients. New research has revealed that the relative exchangeable Cu, defined as the exchangeable Cu to total serum Cu ratio, is a promising test for diagnosis of Wilson's disease.

Cream: Clotted Cream

RS Chavan and A Kumar, National Institute of Food Technology & Entrepreneurship Management (NIFTEM), Kundli, India
S Bhatt, Anand Agricultural University, India

Introduction

Clotted cream is a thick dairy cream with a nutty flavor, a golden crust of grainy texture, and high fat content (a minimum of 55%, but an average of 64%). Historical records have it that the clotted cream was first produced in Afyon province (Western Turkey) known as Afyon Kaymag in which buffalo milk was used to manufacture the same. British clotted cream also has a long and intriguing history, and it was suggested by Alan Davidson that the arrival of Phoenician traders to Cornwall around 2000 years ago may have introduced the tradition of clotted cream. In the nineteenth century clotted cream was considered a better source of nourishment as compared to 'raw' cream because the latter was liable to go sour easily and when consumed without any heat treatment caused several health problems. Consumers used to prefer clotted cream over raw cream due to its nutritive value, characteristic aroma, and flavor. The European Union made an application in 1993 called 'Cornish clotted cream' to obtain a protected designation of origin for the production of cream by the traditional method in Cornwall. Clotted cream is produced on a day-to-day basis in many parts of European countries, which gives a regular income to many small producers. Clotted cream is creamier than ordinary cream, with a unique flavor developed as a result of milk sugar caramelization and perhaps a slight butteriness. Buffalo milk is preferred over cow's milk for manufacturing of clotted cream as it is high in fat, protein, lactose, total solids, mineral, and vitamin contents, which gives the final products its characteristic rich aroma and flavor. Qashta is a type of thick cream from the Eastern Mediterranean region where, due to its higher amount of fat and protein than buffalo milk, ewe's milk is preferred.

Traditionally, clotted cream was produced by straining cow's or buffalo milk. After filtration, the milk was left to stand in a shallow pan in a cool place for several hours, which facilitated the cream to rise to the surface, which is followed by heating either over hot cinders or in a water bath for hours and then cooled. Yellow clots that formed on the surface of the milk were then skimmed off with the help of a long-handled cream-skimmer known as a reamer or raimer in Devon. By the mid-1930s, the modern processing technique had become famous in Devon because using a cream separator actively separated the cream from the milk using centrifugal force, which helped to produce a larger quantity of clotted cream than the traditional method from the same amount of milk in much less time. English luxury clotted cream has a lower fat content of 48% and is generally used as a topping for desserts, cakes, and muffins, but it is also suited for savory recipes, including pasta and sauces. In bakery products like 'butter shortbread' and 'clotted cream biscuits' clotted cream along with butter is used in the formulation to give the bread and biscuits their distinctive rich and soft texture.

The characteristic flavor of clotted cream is developed due to slow heating of cream for longer duration. The color of the clotted cream can vary from a pale off-white to golden yellow color, with a smooth texture similar to cream cheese. Clotted cream production provides a lot of employment. Clotted cream is called 'malai' in India and 'Devonshire cream' in the Western world. Malai is made by the heating of nonhomogenized milk to about 80 °C (180 °F) for about an hour and then cooled a long time in undisturbed condition. Finally, a thick yellowish layer of fat and coagulated proteins are formed on the surface, which are skimmed off, and the process is repeated to recover most of the fat until it reaches a minimum fat content of about 55%.

Regular consumption of clotted cream was usually believed to be bad for health due to its higher amount of fat. According to the United Kingdom's Food Standards Agency, a 100 g cup of clotted cream provides 586 kcal, roughly equivalent to a 200 g cheeseburger.

Manufacturing Methods of Clotted Cream

In the traditional manufacturing technique, raw buffalo milk, which is preferred for producing clotted cream, is bolted by cheesecloth twice and transferred into copper containers. The milk is heated on a low flame and is continued until the milk reaches temperature of about 90 °C and the milk is held for 30 min; this stage is called 'göbek baglama.' After heating and holding of milk at 90 °C for 30 min, the milk is cooled at room temperature overnight. The cream layer formed on the top of the milk is collected by releasing the milk by perforating the side of the container with a pin. Fresh milk is again added to the previous day's heat-treated cream, which is again slowly heated to 90 °C for 45 min and again slowly cooled to room temperature and left in the cool room for about 4–6 h, followed by refrigeration for 6–8 h. The clotted cream layer formed on the surface is separated out and then inverted into a plastic can, which is packed and sealed before sale.

Today, manufacturers are following two methods for production of clotted cream, that is, (1) farmhouse production method and (2) commercial production method. In the farmhouse production method, milk is usually strained into a rectangular stainless steel tray followed by centrifugal separation of cream with the help of a centrifugal separator. The cream obtained after centrifugal separation is then subjected to heat treatment either by using a forced air convection oven maintained at 80–90 °C for 50–60 min or by scalding the cream in a 'bain marie' type equipment, which operates like a huge water bath in which the hot water is circulated until the final temperature of about 77–88 °C is reached with a holding period of 45–50 min. After slow heating of cream, the cream is allowed to cool for the next 24 h without any disturbance. Finally a golden-color crust that has a fat content of 55–60% is formed on the surface and is separated out with great caution (Figure 1).

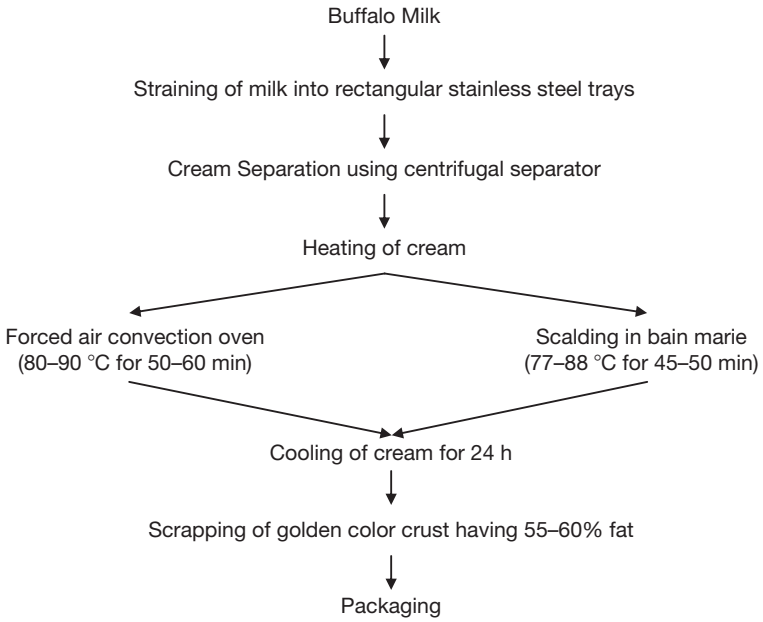

Figure 1 Farmhouse production method for manufacturing of clotted cream.

Commercial manufacturers of clotted cream produce the product by using either a 'float method' or 'scald method.'

In the float method, double cream is floated on milk or skim milk in large jacketed trays and are heated up to 80–85 °C by circulating steam or hot water into the jackets, and the cream is given a holding period of 40–60 min. After slow heating of cream, it is allowed to cool followed by refrigeration to set a golden-color crust, which is scrapped off and packaged into containers (Figure 2).

Cream with a fat content of about 56% is usually used as a starting material for producing clotted cream by the 'scald method.' The cream is heated at 80 °C for 40–60 min with the help of a plate heat exchanger and cooled to below 7 °C and left undisturbed for 12–14 h. It is then packaged for sale in polystyrene or polypropylene pots (Figure 3).

The scald cream method is very similar to float method, but the milk layer is removed and a layer of cream that has been mechanically separated to a minimum fat level is used. In the United Kingdom the resultant cream is allowed to be equivalent to pasteurized cream for legal purposes. A high level of hygiene standards is to be maintained when the processing temperatures are lower than those used in the standard pasteurization process.

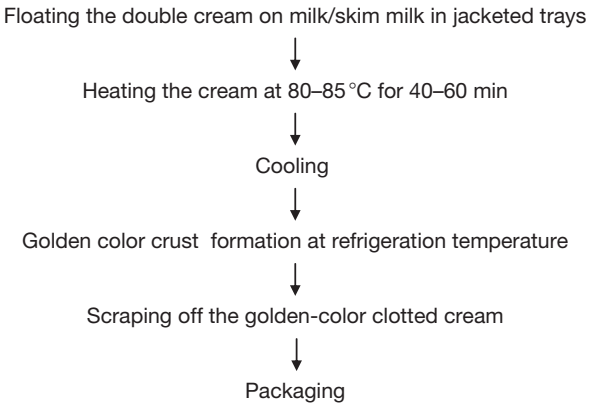

Figure 2 Float method for manufacturing of clotted cream.

Chemistry of Flavor and Golden Crust

As clotted cream is a traditional product, the literature available is limited, but several scientists have studied different aspects, which include microbiological quality, chemical properties, and suitability of packaging materials for enhancing the shelf-life. One interesting study on clotted cream was reported by Senel in which he discussed the effect of carbonyl compounds and free fatty acids on aroma and flavor. The formation of aroma and flavor compounds is the result of the chemical and biochemical transformations of milk components and may be divided into four categories: (1) nonvolatile acids (lactic and pyruvic); (2) volatile acids (formic, acetic, and butyric); (3) carbonyl compounds (acetaldehyde, acetone, and diacetyl); and (4) miscellaneous compounds (certain amino acids, constituents formed by thermal degradation of protein, fat, or lactose). Apart from imparting characteristic flavor to the clotted cream, carbonyls, lactic acid, and free fatty acids also play a vital role in imparting shelf-life of the product. Carbonyl compounds and free fatty acids in clotted cream produced from buffalo milk were found to be much different when compared with other dairy products. The characteristic flavor of clotted cream may also be attributed to the slow heating treatment of cream for a long time, which causes caramelization of milk sugar. Golden-color crust of clotted cream may be attributed to high carotene levels in the milk, which is normally present in the grass eaten by buffalo.

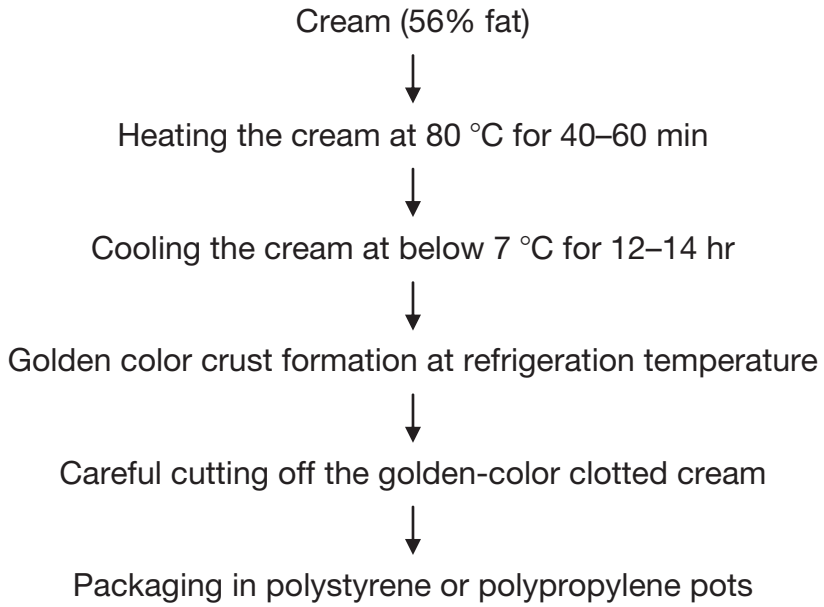

Figure 3 Scald method for manufacturing of clotted cream.

Figure 4 MasoSine pump ideal for clotted cream.

Recent Status of Clotted Cream

The largest commercial producer of clotted cream in United Kingdom (Cornwall) is Rodda's, founded in 1890, which is now able to produce more than 25 tons per day. Clotted cream is believed to have quality as it requires longer manufacturing time. Commercial manufacturers of clotted cream are using modern equipment to manufacture the product under hygienic conditions, both at a large and small scale. Rodda's company in 2012 installed a MasoSine sanitary process pump (Figure 4) supplied by Watson Marlow Pumps Group to carry out the production of clotted cream under hygienic conditions. As a by-product, from every 100 imperial gallons of milk, 94 imperial gallons of skimmed milk are produced, which can be further used to manufacture different dairy products.

Uses of Clotted Cream

Clotted cream is also known as 'baked cream' and is mostly used in the bakery industry as a topping and also in culinary dishes.

Cream Tea

In most of the countries, an essential part of the 'cream tea' is a clotted cream. In Cornwall, clotted cream is served on scones with different fruit flavors of jam, along with a cup of tea. Langage Farm in Devon has started a campaign for the protection of origin of 'Devon cream tea' as similar to 'Cornish clotted cream,' where scones are spread with jam or lemon curd and then topped with clotted cream, which is served with afternoon tea and known as 'Devonshire tea.'

Confectionery

On many occasion clotted cream is used as a supplement to hot or cold desserts. Clotted cream, especially Devon clotted cream, which is less yellow in color due to the lower carotene levels, is regularly used in different baked products. Clotted cream is used in most of the southwest part of England for ice cream and fudge production. One of the products, in which bread is topped with clotted cream and golden syrup honey, is called 'thunder and lightning.' Clotted cream can be spread as a topping over any baked treat, like English muffins, biscuits, croissants or muffins, ice cream, cake, trifle or pudding, or crusty bread, and it also serves a purpose of filling in cakes.

Savory Dishes

Clotted cream is used in savory dishes and can also be incorporated into mashed potatoes or scrambled eggs. Clotted cream, along with rich cheddar sauce and mustard, can be used as a dip with its unique richness of flavor and texture. A moist scone can be split like a shortcake biscuit, topped with berries and clotted cream, and served as a dessert. Clotted cream is also used in some of the creamy savory dishes like risotto, pasta, curry, quiche, or gratins. In some parts of England, barley is used instead of rice for preparing risotto or rice pudding, which adds a unique texture and slightly nutty flavor. The addition of clotted cream to this dish enriches and enhances the creamy texture.

Risks Associated with Consumption of Clotted Cream

Clotted cream might be quite delicious, but on health grounds it cannot be suggested as a daily diet due to its high amount of saturated fat. The market for clotted cream has not expanded beyond certain parts of the world as it has a very short shelf-life and hence is difficult to export. Clotted cream is often associated with a high number of microbiological counts, which makes it vulnerable for its consumers. To obtain a good quality of clotted cream apart from hygienic conditions, factors like status of healthy animals, hygienic milking, manufacturing tools and equipment, and hygienic practices during production and storage of clotted cream must be considered. *Brucella abortus* was first reported in March 1966 from a market sample of clotted cream, and aerobic spore-forming bacteria like *Bacillus subtilis* are more prominent. Researchers have found that cooling for a long time during manufacturing of clotted cream and contamination during handling of packing are the main reasons for such a high number of microbial load. To deliver a safe product to the consumers and to reduce the level of spoilage bacteria, acceptable heat treatment must be applied during the production of clotted cream, and apart from this the clotted cream must be produced in a clean environment under hygienic conditions.

Introduction

Cream is one of the most important dairy products. It was traditionally considered a luxury product, but it is now readily used in many forms and for a variety of purposes. For example, it is a primary raw material for the manufacture of table butter and for preparing *ghee*, a fat-rich Indian dairy product. It is also used as an ingredient in sweet and savory dishes, such as ice cream, soup, custard bases, and cakes. Cream is a concentrated emulsion of milk lipid globules in skimmed milk, and it is separated from milk either by gravity or centrifugal force. Different types of creams are primarily classified according to their fat content (g/100 g) as double cream (45–50%), cream or full cream (30–40%), single or half cream (15–25%), coffee cream (15–18%), and light coffee cream (<10%). According to the standards of the United Nations Food and Agriculture Organization (FAO), cream is classified as followed, based on fat content:

(a) Cream: 18–26%
(b) Light cream (or coffee cream): >10%
(c) Whipping cream: >28%
(d) Heavy cream: >35%
(e) Double cream: >45%

The fat-based standards for various types of cream vary in individual countries, and diverse names are used to describe different creams. So, it is not possible to provide a uniform international definition or universally accepted classification system. However, Table 1 provides the regulations for the fat content of cream products in major cream-producing countries. Cream products are also classified according to their final uses (e.g., whipping cream, coffee cream, or cream liqueur) or by processing method (e.g., pasteurized cream, ultra-high-temperature (UHT)-treated cream, frozen cream, dried cream, and cultured or sour cream).

The physicochemical properties of cream are affected by several factors, such as the state of the lipid globules and the milk lipid globule membrane, the concentration of lipid globules, the type and concentration of nonfat milk solids in cream (e.g., proteins, salts, and added emulsifiers and stabilizers), the temperature of the cream, and the physical handling of the cream (e.g., pumping, aeration, and agitation), which can cause the disruption or agglomeration of the globules. Table 2 provides the chemical composition of cream.

Technology of Cream Separation

The basic principle of cream separation, whether by gravity or centrifugal methods, is based on the fact that milk fat is lighter than the skim milk portion. At 16 °C, the average density of milk fat is 0.93 and skim milk 1.036. Thus, when milk, which is a mixture of fat (as cream) and skim milk, is subjected to either gravity or centrifugal force, the cream and skim milk stratify or separate from one another by virtue of their differing densities. Separating the cream phase from the milk, standardizing the cream to the desired fat content, and heating the cream to increase its shelf-life are universal to the manufacture of (almost) all industrially processed cream products.

Gravity Methods

When milk is allowed to stand for some time, there is a tendency for the fat to rise. The velocity, or rate, at which the fat globules rise is described by the following equation, which is known as Stoke's Law

$$V = 2G/9^{*}(ds - df)r^{2}/n$$

Where,
V=velocity or rate at which a single fat globule rises, G=acceleration due to gravity, ds=density of skim milk, df=density of fat, r=radius of fat globule and n=viscosity of skim milk.

According to Stoke's Law, the velocity is increased by:

(i) An increase in the radius of the fat globule
(ii) An increase in the difference in the densities of skim milk and fat
(iii) A decrease in the viscosity of skim milk

However, in practice, the important factors affecting the rate of cream rise using gravity methods are as follows:

Table 1 Standards for the lipid content of cream in some countries

Country	*Cream type*	*Lipid content (g/100 g)*
Australia and New Zealand	Cream	18–40
France	Light cream	12–30
	Cream	30–40
Germany	Coffee cream	10–30
	Whipping cream	30–40
The Netherlands	Cream	10–30
	Whipping cream	30–40
United Kingdom	Half cream	12–18
	Single cream	18–35
	Whipping cream	35–48
	Double cream	48–55
United States	Half and half cream	10–18
	Light cream	18–30
	Light whipping cream	30–36
	Heavy cream	36–45

Table 2 Chemical composition of cream

Constituents	*Percentage*		
Fat	30	25.00	50.00
Water	64	68.20	45.45
Serum: protein	02.4	02.54	01.69
Lactose	03.5	03.71	02.47
Minerals/ash	00.4	00.56	00.37
Total solids	36	31.80	54.55
Nonfat solids	06	06.80	04.55

(i) *Size of fat globules*: As the size of the fat globules increases, the rate at which the cream rises also increases. (Thus gravity creaming occurs faster for buffalo milk than it does for cow milk because of the larger size of fat globules in buffalo milk.)
(ii) *Temperature*: As temperature increases, viscosity decreases and, in turn, velocity increases.
(iii) *Clumping*: A clump or cluster acts like a single globule, in so far as movement through skim milk is concerned. Therefore, the effective r^2 is increased, which then increases velocity.
(iv) *Addition of adhesives*: Adhesives ultimately help increase the rate at which fat globules rise.

Centrifugal Methods

When milk enters the rapidly revolving bowl of the cream separator, it is immediately subjected to a tremendous centrifugal force, which is 3000–6000 times greater than gravitational force. While both the fat and skim milk are subjected to the centrifugal force, the difference in density affects the heavier portion (i.e., skim milk) more intensely than the lighter portion (i.e., cream). Centrifugal separators contain stacks of conical disks with vertically aligned distribution holes through which whole raw milk is introduced. Under the influence of a centrifugal force, the sediment and lipid globules in the milk settle radially outward or inward, respectively, in the separation channels. Solid milk impurities of high density rapidly settle out to the outside of the separator, and they are then collected in the sediment space. Because the cream is less dense than skimmed milk, it moves inward toward the axis of rotation, and it is removed through an axial outlet. Skimmed milk moves outward beyond the disk stack and is removed to a skimmed milk outlet through a channel between the top of the disk stack and the conical hood of the separator bowl. Therefore, the separation of cream from whole milk involves the concentration of lipid globules, followed by the removal of the cream from the skim phase to produce two streams, skimmed milk and cream, the latter of which commonly amounts to 10% of the total throughput. This method allows rapid and efficient separation, and although very high centrifugal forces are applied, not all lipid globules are removed. Skim milk usually has a residual fat content of ~0.1 g/100g, which primarily consists of lipid globules <1 μm in diameter (Figures 1–3).

Factors Influencing the Fat Percentage of Cream

A brief summary of the factors influencing the fat percentage of cream by centrifugal separation is given below:

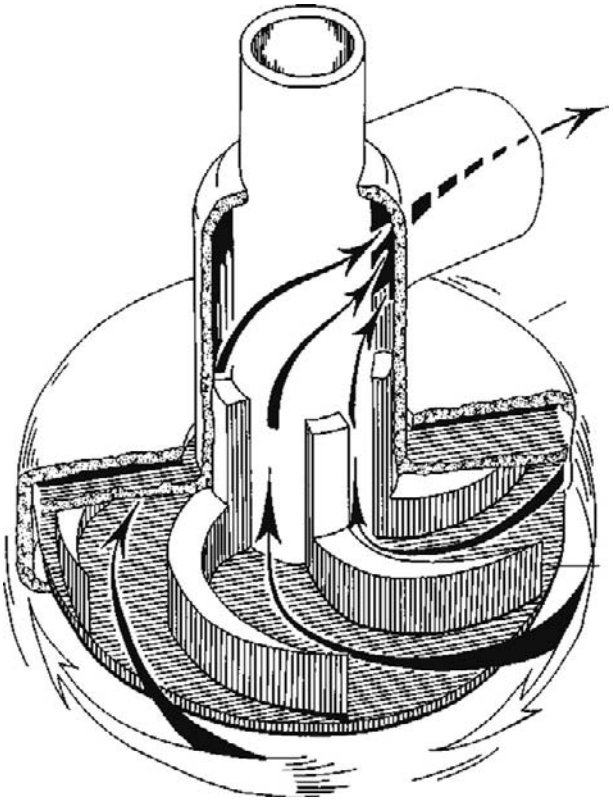

Figure 1 Paring chamber and disk of a semienclosed separator.

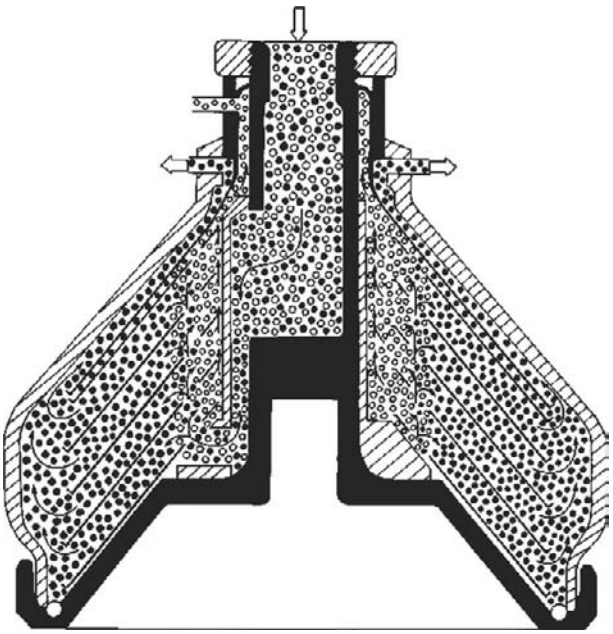

Figure 2 Open-design cream separator.

(a) *Position of the cream screw*: The cream screw/outlet consists of a small, threaded, hollow screw pierced by a circular orifice through which the cream emerges. This screw can be driven IN or OUT, thus bringing it nearer to, or away from, the center of rotation. Under normal conditions, the

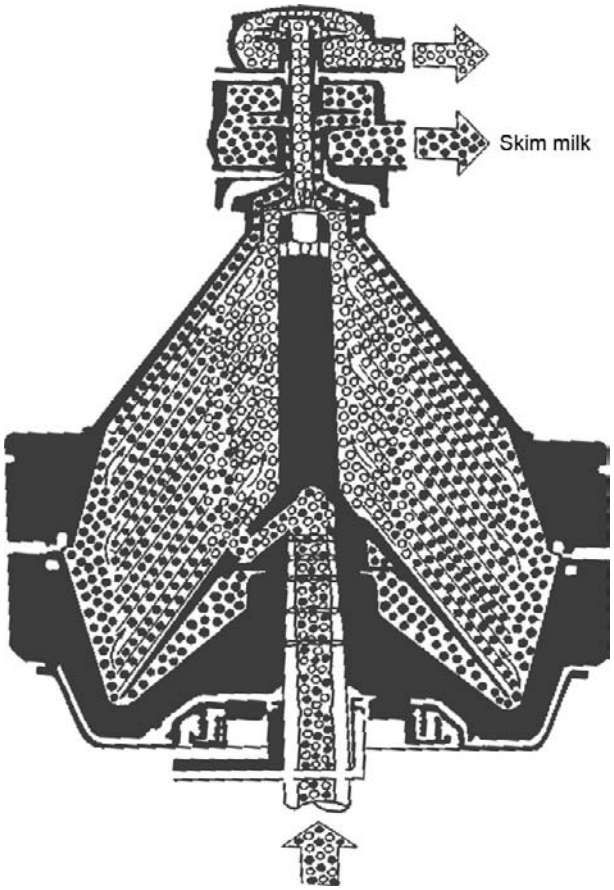

Figure 3 Hermetic-design cream separator.

ratio of skim milk to cream is 90:10. Changes in the separation procedures affect the fat percentage in the cream. Altering the position of the cream screw can change the ratio of skim milk to cream. Therefore, when the cream screw is moved IN toward the axis of rotation, a higher fat percentage in the cream is obtained, and vice versa; this is because the force that tends to discharge cream through the orifice is decreased.

(b) *Fat percentage in milk*: Because all of the fat in milk is present in cream, the cream from the separation of high-fat milk has a higher fat content than that from low-fat milk. Higher fat content in cream is obviously consistent with higher fat percentage, and vice versa.

(c) *Speed of the bowl*: Higher bowl speeds exert a greater centrifugal force, resulting in the rapid flow of skim milk from the bowl. An increase in bowl speed increases the skim milk discharge, leading to a higher fat percentage in the cream.

(d) *Rate of inflow of milk*: When the rate of inflow increases, the discharge from the cream outlet increases, as the skim milk discharge remains constant (with constant centrifugal force); more cream containing the same amount of fat results in a lower fat percentage and vice versa.

(e) *Temperature of milk*: Lowering the temperature increases the viscosity of both cream and skim milk, but the viscosity of cream increases more than that of skim milk. Thus, the quantity of cream discharged is reduced because of bowl-clogging, resulting in a higher fat percentage.

(f) *Amount of water or skim milk added to flush the bowl*: The addition of more water or skim milk will cause an increase in the amount of cream produced, which, with the same fat content, will show a lower fat percentage.

Standardization of Cream

Because traditional cream separators cannot be accurately operated to produce a cream of specific fat content, it is usually necessary to produce cream with a higher fat content. This cream is collected and mixed in cream tanks from which the cream was sampled for fat percentage. The fat percentage is determined and then reduced via the addition of skimmed milk in a process called standardization, which is necessary for producing cream with a fat content close to a predefined value. Direct in-line standardization is usually combined with separation, and equipment that automatically monitors and controls the fat content of cream is used for this purpose. On discharge from the separator, the skim and cream streams are mixed, and the proportion of cream included determines the fat content of the cream prepared.

Fat content must be as close to the stipulated value as possible; too high a fat content results in economic losses for the processor, whereas too low a fat content may result in cream products not meeting legal requirements. During standardization, the temperature of cream can be over 40 °C, so bacterial growth may occur. Thus, it is essential that standardization is carried out rapidly, to prevent cream being held at these temperatures for unnecessarily long periods. Subsequent pasteurization and cooling steps must also follow rapidly.

Pasteurization of Cream

Cream is pasteurized chiefly to inactivate enzymes and microorganisms, thus extending the shelf-life of cream. It renders a safe product for the consumer. The effects of heating largely depend on the intensity of the treatment. To pasteurize cream, either high-temperature short-time (HTST) pasteurization or UHT sterilization is commonly applied. The high fat content of cream protects microbes during heating, necessitating a more severe heat treatment than that required for the pasteurization of milk. For the HTST pasteurization of cream, the International Diary Federation recommends heating at 75 °C, for 15 s for cream containing $<$ 20 g fat/100 g, or to $>$80 °C for 15 s, for cream containing $>$20 g fat/100 g.

When cream is UHT-treated, the quality of the raw material is particularly important, owing to the longer shelf-life of this product. The UHT processing of cream involves heating the product to 135–150 °C for a few seconds, whereby minimal chemical, physical, and organoleptic changes occur in the cream, but spoilage and pathogenic microorganisms are inactivated. The UHT treatment of cream does not necessarily produce a sterile product, as some bacterial spores, especially those of *Bacillus* spp., can survive UHT treatment. The indigenous milk enzymes, lipoprotein lipase and proteinase, cause lipolysis and proteolysis, respectively, during storage.

Neutralization of Cream

The neutralization of sour cream refers to the partial reduction of its acidity. It is done to avoid the excessive fat loss in butter milk that results from churning highly acid pasteurized cream. When pasteurizing sour cream, the casein curdles, thereby entrapping fat globules, and as a bulk of curd goes in buttermilk, this causes high fat loss. Neutralization also guards against the production of an undesirable off-flavor in cream.

In addition, neutralization improves the storage quality of the product. The neutralizer used should never be dried when added to cream. So it is dissolved in clean potable water and then diluted to a 10% solution, before being distributed with vigorous steering at 29–32 °C. The cream acidity is checked to know whether it is correctly neutralized or not.

Homogenization of Cream

The main objective of homogenization is to prevent, or at least minimize, the creaming phenomenon. However, the alteration of the characteristics of cream products or the production of new product structures is also possible by selecting the appropriate homogenizing parameters. Although homogenization is essential for all types of single and half cream, and may be applied to double cream, it can have negative effects on cream functionality.

Ripening of Cream

Ripening is a process for fermenting cream, and it may be coupled between pasteurization and churning, during which cream undergoes changes in flavor, aroma, and texture. Ripening cream results in the improved and uniform flavor of butter and enhances churning. Diacetyl is a major flavor compound in the ripened cream, and a large number of other compounds also contribute at levels above and below the individual sensory threshold where synergistic interaction may occur.

Cream Products

Whipping Cream

Whipped cream is valued by consumers for its taste and texture, and it is often considered a luxury product. The whipped product is created by beating air into cream to form a stiff-foamed product, which has many applications, including those in desserts and cakes.

Cream is first standardized to the desired fat content, which is generally between 30 and 40 g/100 g. Stabilizers may be added to the standardized cream before heat treatment. The pasteurization of cream is commonly carried out at 80 °C, and then the cream is cooled, aseptically packaged, and distributed. Pasteurized cream has a shelf-life of <3 weeks at refrigeration temperature. The need for a cream with an extended shelf-life has led to the production of UHT whipping cream, which, after the optional addition of stabilizers, is heated at >135 °C for a few seconds. As a result, a shelf-life of several months can be obtained.

However, the physical shelf-life of such cream is limited, owing to the fact that the creaming of lipid globules occurs, so a homogenization step needs to be applied to reduce lipid globule size and minimize the separation of the globules during storage. However, homogenization impairs the whipping properties of cream, so choosing the optimal conditions for the homogenization of UHT whipping cream represents a trade-off between maintaining optimal whipping characteristics and minimizing the separation of lipid globules during storage. Following homogenization, UHT-treated whipping cream is cooled, packaged aseptically, and distributed.

Process of whipping

Whipping involves beating air into the cream, resulting in the formation of a coarse foam, which contains air bubbles with an average diameter of 150 μm. These are rapidly covered by milk proteins, which stabilize them against collapse. A large proportion of the protein absorbed on the bubble surface is formed by the surface-active β-casein, which is present in large quantities in nonmicellar form at the low temperatures at which cream is commonly whipped, but other caseins and whey proteins are also found at the bubble interface. On further whipping, air bubble size is reduced approximately threefold, and milk lipid globules displace some of the proteins from the bubble interface. On adsorption at the bubble interface, the globules shed their globule membrane material from the contact area with the air bubble in the process, thereby creating an air–lipid interface.

Prolonged whipping leads to the stiffening of the cream, as a result of the creation of a network of partially coalesced lipid globules. Partial coalescence may be induced as a result of mechanical damage to the milk lipid globules during whipping. This process is enhanced by the presence of large lipid crystals in the globules. The partial coalescence of the lipid globules can also result from the collapse of air bubbles in the foam. Because the globules have shed their original membrane material on the area that interacts with the bubble interface, the collapse of air bubbles leads to partially uncovered globules, which are extremely susceptible to partial coalescence. Eventually, a stiff foam results, in which the air bubbles are surrounded and stabilized by a network of coalesced lipid globules. A network of coalesced lipid globules in the serum phase of the foam adds structure and stability and prevents the collapse of the whipped cream.

Effect of processing parameters on whipping characteristics

Various processing steps can significantly affect the whipping characteristics of cream. These characteristics of cream obtained from the same milk can vary considerably, just by use of a different separator for separating the cream, and the overrun of whipped cream increases with the increasing temperature of separation in the range 25–50 °C. Homogenization is required to prevent the creaming of lipid globules in UHT whipping creams. It increases the whipping time of the cream and reduces the overrun and stiffness of the whipped cream. These changes are related to the membrane of homogenized lipid globules primarily composed of caseins. Compared to globules, they are less susceptible to absorption onto the air

bubble interface and shear-induced aggregation, however. A thickening agent such as K-carrageenan is generally added at around 0.01% to prevent creaming during storage.

To improve the whipping characteristics of homogenized cream, emulsifiers may be added to the cream. Heat treatment does not drastically affect the whipping properties of cream per se, but it is commonly applied in conjunction with homogenization because highly heat-treated creams generally have poor whipping properties.

Sour Cream

Sour cream is a heavy-bodied, ripened cream of high acidity (0.6% lactic acid), clean flavor, and smooth texture made by inoculating sweet, pasteurized, and homogenized cream with a culture of lactic acid bacteria and allowing fermentation to proceed until these desired qualities are obtained. It should have a white-to-yellowish, slightly creamy appearance; clean, slightly acidic, rich flavor; and clean, milk-sour, flavorful taste.

Method of manufacture

Sweet cream is standardized to get 18–20% milk-fat. It is then pasteurized, homogenized, and chilled to 15–20 °C, and the final fat content is set. It is inoculated with a lactic acid bacterial starter (i.e., lactic acid/butter culture) at 2–4% and 24 °C, before being fermented until the desired qualities are obtained. During the acid production, the homogenization clusters flocculate, resulting in a highly viscous cream. To increase the firmness, rennet or permitted thickening agents are sometimes added to the sweet cream. When the pH reaches 4.5, the cream is further cooled with gentle stirring and then chilled to 2–4 °C and packed. Alternatively, souring may be applied to the package. Fermentation, which takes 14–24 h, may occur in filled cream containers to produce set-style cultured cream, or in a fermentation tank from which cream containers are subsequently filled. Both types of fermentation have disadvantages. Following in-tank fermentation, the cream has to come in contact with the production equipment again, because it has to be further processed, thereby increasing the possibility of recontamination and reduction in the viscosity of the cream. Consequently, the need for the addition of hydrocolloids increases. Although set-style cultured cream is thicker, it tends to become inhomogeneous during the long fermentation at ambient temperatures.

Cream may also be chemically acidified, using glucono-δ-lactone or food-grade acids. This method has several advantages over conventional culturing practices, including the elimination of culture-handling problems, improved production efficiency, and quality control. Chemically acidified sour creams have a similar appearance and texture to those of cultured sour creams, but the latter have superior flavor characteristics. Sour cream is mainly used in prepared foods.

Coffee Cream

Coffee cream is a shelf-stable product with a fat content of >10%. It is homogenized and UHT-processed, filled aseptically, or sterilized in the container. It is a popular product that is mainly used for whitening coffee, as well as for imparting a pleasant flavor to coffee. It is also used in the preparation of food and drinks, and for direct consumption. Coffee cream has a minimum shelf-life of 4 months at room temperature, and it normally contains 10–12 g fat/100 g, and, less often, 15–20 g fat/100 g. Its shelf life is similar to the shelf life of UHT milk. The important quality attributes of coffee cream are taste, whitening power, and stability in hot coffee.

Following separation and standardization, the cream is heat-treated at 90–95 °C and cooled to 6 °C. Stabilizers such as phosphates or citrates may be added to increase the pH and to reduce the concentration of ionic calcium, thereby reducing the susceptibility of casein micelles to aggregation during the sterilization process or on addition to hot coffee. Cream is subjected to two-stage homogenization and sterilization. Traditionally, coffee cream was sterilized in cans or bottles, but since 1996, continuous-flow sterilization in a UHT plant, followed by aseptic packaging, has largely replaced the former process. Both homogenization steps operate at a total pressure of 20 MPa and a temperature of 70 °C. Flow-sterilized coffee cream is subsequently cooled to 25 °C and aseptically filled, usually into plastic cups (7.5–15 g capacity) or preformed cups or cans (100–200 g capacity).

Importance of homogenization

Coffee cream must be homogenized. This prevents a fat layer or fat plug from forming in the container, thus improving taste, whipping power, and stability. It has a direct influence on the flocculation stability of coffee cream. When sterilizing cream in the pack, homogenization has to take place before the sterilization, which again is a double stage process (20 MPa) using the same pressure. Flocculation of cream in hot coffee is due to casein precipitation.

Desirable attributes of coffee cream

In addition to good sensory properties, the two main criteria for assessing the quality of coffee creams are as follows:

Stability of the emulsion: This is the ability of the particulate constituents (primarily lipid and protein particles) to remain evenly dispersed throughout the coffee cream during its long shelf-life.

Whitening effect: This is the ability to form a milky, homogenous mixture on addition to coffee, irrespective of the composition, brewing conditions, and temperature of the coffee.

Like UHT milk, homogenized UHT creams exhibit a gelation phenomenon, generally attributed to the activity of heat-resistant proteolytic enzymes, after prolonged storage.

One important defect with respect to coffee creams is the phenomenon known as 'feathering.' Feathering is the formation of macroscopic aggregates containing proteins and lipids through the acid-induced flocculation of partially protein-covered lipid globules in hot coffee drinks. Although aggregates always form in hot coffee, the visible aggregates (i.e., ≥100 μm) render the coffee cream defective, because the consumer commonly perceives such aggregates as an indication of the sourness of the product. The susceptibility of coffee cream to feathering is often referred to as its coffee stability.

Cream Liqueur

Cream liqueurs are a group of liqueurs that contain milk cream as an ingredient. The roots of cream liqueur lie in home-made products that can be traced back for centuries, such as the Scottish product Atholl Brose. Atholl Brose consists of milk cream and honey, to which whisky, steeped with oatmeal to impart a pleasant nutty flavor, is added. In the second half of the twentieth century, commercial-scale attempts to produce Atholl Brose and other home-made cream liqueurs largely failed, until 1974, when Baileys Irish Cream Liqueur became the first commercialized cream liqueur. The most famous cream liqueurs are the Irish product Baileys Irish Cream and the South African product Amarula.

Composition of cream liqueur

In terms of commercial practice, a standard cream liqueur does not exist. Each manufacturer decides the preferred components and their concentrations. This flexibility enables a product of desired organoleptic properties and a sufficiently long shelf-life. Table 3 shows the composition of a standard cream liqueur, which appears to represent most commercially available products. The 14 g/100 g concentration of ethanol in the product equates to 17 g/100 ml ethanol. Of the ingredients, sodium caseinate is used as an emulsifier, and citrate is added to prevent serum separation during storage.

Technology of cream liqueur

Although there is no universal manufacturing process for cream liqueur, the principle steps of mixing the ingredients and homogenizing the cream base are universal. The sodium caseinate can be dissolved in hot water (85 °C), after which time the other ingredients are added to produce the cream base. Ethanol may be added to the cream base either before or after homogenization. The function of homogenization is to reduce the lipid globule size, thereby prolonging the physical stability of the product by preventing creaming and/or the formation of the cream plug on storage. A general rule-of-thumb for homogenization efficiency is that >98% of the milk lipid globules should have a diameter <0.8 μm.

Maintaining the quality of cream liqueur

As with other cream products, the shelf-life of cream liqueurs has two dimensions, the microbiological shelf-life and the physicochemical shelf-life. The microbial shelf-life of cream liqueurs causes little concern, because human pathogens are unable to grow in this medium of high ethanol and sugar content.

Table 3 The composition of a standard cream liqueur

Component	*Concentration (g kg^{-1})*
Milk fat	160
Sucrose	195
Sodium caseinate	30
Nonfat milk solids	14
Total solids	399
Ethanol	140
Water	461

Source: Banks, W. and Muir, D. D. (1988). Stability of alcohol-containing emulsions. In: Dickinson, E. and Stainsby, G. (eds.) *Advances in food emulsions and foams*. London: Elsevier Applied Science.

Physicochemical defects in cream liqueurs

Different types of physicochemical defects have been noted in cream liqueurs:

(a) *Cream plug formation*: Cream plug formation refers to the accumulation of fat in the neck of the bottle during storage, with the fat unable to be redispersed into the product through shaking or agitation. Cream plug formation results from insufficient homogenization. As a result, lipid globules rise to the top, which may ultimately lead to a cream plug. Because the plug cannot be redispersed on shaking or agitation, it is likely that the creamed lipid globules have aggregated or coalesced. The extent of cream plug formation correlates positively to the proportion of large lipid globules in the product, and it can be prevented by increasing the homogenization pressure. Homogenization efficiency may also be increased, reducing creaming, by the inclusion of low levels (0.5 g/100 g) of low-molecular-weight surfactants in the cream liqueur. Cream plug formation is likely enhanced at low pH levels (<6.0), high concentrations of ionic calcium, and low concentrations of emulsifier, and it can also be increased by temperature fluctuations during storage.

(b) *Serum separation*: The gelation of cream liqueur results in syneresis, leading to the separation of a serum layer. The shelf-life of cream liqueur is the number of days the product can be stored at 45 °C before noticeable serum separation, and it increases in a sigmoidal manner with increasing pH. The use of washed cream or anhydrous milk fat improves the shelf-life of cream liqueurs, and the same is true for the addition of the calcium-chelating agents such as trisodium citrate. The addition of citrate reduces the concentration of ionic calcium and accordingly increases the shelf-life of cream liqueurs by up to two orders of magnitude. Replacing caseinate with whey protein concentrate also increases product stability. Furthermore, the use of sorbitol as a carbohydrate component significantly increases the shelf-life of cream liqueurs.

(c) *Precipitation*: Although the addition of citrate to cream liqueur enhances its stability against serum separation, it also causes a defect in the form of a slightly granular precipitate, consisting primarily of calcium and citrate, at the bottom of the bottle. The precipitate is particularly noticeable on storage at above ambient temperatures, because the solubility of calcium citrate decreases with increasing temperature. As a result, the amount of citrate added to cream liqueur becomes a trade-off between preventing serum separation and minimizing the risk of precipitate formation.

Other Cream Products

Clotted Cream

Clotted cream is prepared by heating cream to 77–88 °C (170–190 °F) in shallow pans and then allowing it to cool

slowly. The surface layer consists of dotted cream, which is skimmed off and strained. Clotted cream is exceedingly rich, containing 60–70% milk fat. This fat is in a finely emulsified condition, which renders it easily digestible. The product has a peculiar boiled taste and rough appearance, and it exhibits a white-flaked surface. The average composition of clotted cream is 67.50% milk fat, 4.90% protein; 1.00% lactose, 0.50% ash, and 26.10% water.

There is no standardized method for preparing clotted cream. Several systems differ in obtaining the raw cream, thus resulting in considerable variation in the texture, flavor, and appearance of the finished product. The flavor and physical consistency of cream depend on the acidity of the original milk, the temperature of scalding, and the time allowed for scalding.

Canned or Sterilized Cream

Canned or sterilized cream generally possesses a peculiar flavor because of its processing, as well as a high viscosity due to homogenization. The texture should be smooth, and the cream should be free from lumpiness and separation of serum. Sterilization spoils its whipping quality. The fat content is about 20–25%, and the nonfat solids content may vary between 6.5% and 9.5%. The various steps in manufacture are as follows:

(i) Fresh, sweet cream is standardized to 20% fat.
(ii) Pre-Standardized cream is heated to 80 °C, without holding.
(iii) Cream is double-homogenized at 80 °C, using 2500–3000 psi in the first stage and 500 psi in the second stage.
(iv) Cream is immediately cooled to 16 °C, preferably over a surface cooler using brine.
(v) Cream is filled into tin cans (or bottles) and immediately sealed.
(vi) Filled cream is sterilized in retorts employing 15 min for coming-up, 12–15 min for holding at 118 °C, and 15 min for cooling to room temperature.

Plastic Cream

Plastic cream is more viscous than any other type of cream. Its texture resembles paste. Its fat content is between 65% and 85%, and it can be used directly for the manufacture of butter-oil. Plastic cream is obtained by (i) reseparating normal cream (30–40%) in a normal cream separator or (ii) separating milk in a specially designed plastic cream separator. In both of the above cases, the initial product is pasteurized at about 71–77 °C for 15 min and cooled to 60–66 °C before separation.

Conclusion

Cream is an extremely versatile product with applications that extend far beyond the dairy sector. Cream products have been traditionally regarded as luxury products, and their popularity may be affected in the current climate by consumer concerns about high fat intake. Given recent advances in our understanding of milk and cream constituents and their interactions with other ingredients, the development of reduced fat cream products with properties equivalent to their traditional high-fat counterparts should be possible.

Cured Foods: Health Effects

J Ruiz-Carrascal, University of Copenhagen, Copenhagen, Denmark

Introduction

Curing refers to the technological process involving the addition of salt and nitrates and/or nitrites to different types of raw materials to produce the so-called cured food products. The origin of the word 'curing' roots in the Latin word 'cure,' translating as 'means of healing, remedy,' and was used for products processed that way because they were known to be safer and no longer capable of transmitting any disease. Curing is no doubt one of the earliest processing technologies for preservation of different foodstuff, whose origin probably dates backs to ancient Egypt, being well known and described by the ancient Greeks and Romans. In even earlier times, basic processing technologies consisted of adding salt to different raw food materials, such as fish, cheese, and meats, thereby leading to a stable food product that could be preserved at room temperature. The main preserving effect of salt relies on the decrease of water activity; however, in the past, the addition of sea salt involved the unintentional addition of nitrates, whose effects on preservation were not understood until later. Nevertheless, 'saltpeter,' a salt efflorescence very rich in nitrates, was used in ancient China and India, and its effects on producing a stable meat color were also well known. Nowadays, curing is undoubtedly the technological process most commonly used for transforming meats, including fermented, dry-cured, smoked, cooked, or canned products.

The technological and safety effect of curing salts is well known and appreciated, and it is thoroughly explained elsewhere in this encyclopedia. To synopsize, curing leads to the development of a stable red color in meats due to the formation of a stable pigment through the reaction of myoglobin with nitric oxide (NO), which in turn is formed from nitrite. Furthermore, the antioxidant effect of nitrites is well known, and its addition helps to control the formation of compounds showing rancid flavors involved in warmed-over off-flavor development in cooked and reheated meats. In addition to this effect on flavor, nitrates and nitrites are known to positively influence the overall flavor of cured products, although their exact involvement has not been entirely elucidated yet. But it is perhaps the antimicrobial effect associated with nitrate/nitrite usage that is the most outstanding property. The presence of a certain amount of nitrites inhibits the germination of *Clostridium botulinum* spores and also helps in the control of the growth of other pathogenic and spoilage bacteria in meat products. Therefore, nitrate and nitrite addition is among the most effective and reliable hurdles for avoiding some of the most serious microbial poisonings.

However, in spite of all these positive effects, the use of nitrate and nitrite in food processing has been controversial over the past 40 years, and this has been mainly due to the toxicity of nitrite itself and to the further reaction with amino compounds to form *N*-nitroso compounds, some of which, like nitrosamines (NAs), have been shown to be potential carcinogens. On the other hand, the intake of nitrate and nitrite, through their transformation into NO, has also been shown to have a protective role in some cardiovascular diseases.

The balance between all these effects has been thoroughly researched for quite some years, but still, there is no clear final scientific outcome supporting either the total avoidance of these preservatives or their indiscriminate use. Accordingly, food legislations in most countries have restricted their use to some specific products and to limited amounts. While meat companies claim that their use is absolutely necessary for obtaining safe products, other groups ask for their total banning from food processing.

This article attempts to collect evidence pertaining to the potential harmful or health-promoting effects of the addition of nitrate and nitrite to food (especially meat) products.

Formation of *N*-Nitroso Compounds

The major concern for the use of nitrate/nitrite in food is related to the involvement of nitrite in the formation of carcinogenic *N*-nitroso compounds, especially NAs, and their subsequent effect as known carcinogenic compounds. These *N*-nitroso compounds can be formed either in the food during processing and prior to consumption or in the human body, due to the ingestion of nitrates or nitrites. The basic chemistry for the formation of NAs is explained elsewhere, but basically, it involves the formation of a nitrosating agent, typically formed from nitrites, which further reacts with a secondary or a tertiary amine (Figure 1). This takes place faster in acidic conditions, although it can also happen in an alkaline medium in the presence of some carbonyl compounds. In the case of added nitrates, it would involve a previous reduction of nitrates to nitrites, which is also favored not only under acidic conditions but also by microbial activity. Such kind of routes can be produced not only in the food itself but also in the human body, as a consequence of the ingestion of amines and the nitrite from the food or through interaction with saliva.

The concern about the involvement of curing salts in the formation of carcinogenic compounds commenced in the 1950s and 1960s, with several studies highlighting the potential implication of nitrite in the formation on NAs. This fact was also linked to the occurrence of different types of cancer. In 1970, a report paper published in Nature by Lijinsky and Epstein reviewed the role of NAs in the development of cancer. Due to the implication of nitrite and amino compounds in the formation of these carcinogenic compounds, the authors concluded that the best way to avoid the risk of NA intake was to eliminate any of these precursors. Since amino compounds are hardly avoidable in most foods, the final indication toward a banning of curing salts was quite clear.

Thus, there are different aspects that should be considered within the controversy of nitrates/nitrites as food additives.

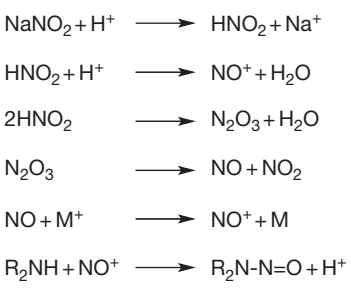

Figure 1 Formation of nitrosamines (M/M^+ are transition metals ions like Fe^{2+}/Fe^{3+} or others). Adapted from Honikel, K. O. (2008). The use and control of nitrate and nitrite for the processing of meat products. *Meat Science* **78**, 68–76, with permission.

First, it seems clear that several *N*-nitroso compounds have been characterized as being potential carcinogenic compounds, but it is important to know which ones and at what level. Then, the actual involvement of nitrates and nitrites in the formation of NAs, both in the food and in the human organism, and other factors affecting their formation in the food, should also be considered as very few compounds can be considered totally harmless. It is the dose and the intake conditions that make them more or less dangerous. Furthermore, the actual contribution of cured foods as a source of nitrates, nitrites, and *N*-nitroso compounds in the diet should also be taken into consideration. Finally, there is the question about the link between consumption of cured products and the incidence of cancer.

As far as the role of NAs in the development of different types of cancer, their high carcinogenic potency has been proven in animal experiments on many different species, and virtually no species has been found to be resistant to their cancer-inducing potential. In fact, the metabolic activation of NAs into DNA-damaging electrophilic agents is very similar in all animals and tissues, resulting in the induction of similar mutagenic DNA lesions. So, although direct proof of carcinogenicity to humans is not available, the evidence for these compounds to be considered human carcinogens is overwhelming. However, each NA seems to have a different ability to induce cancer. In fact, the volatile NAs seem to be more carcinogenic, while nonvolatile ones appear to be not as carcinogenic, or not directly carcinogenic; nevertheless, some of them can be further transformed into volatile versions. Among those frequently found in cured products, *N*-nitrosodimethylamine (NDMA), *N*-nitrosodiethylamine (NDEA), *N*-nitrosopyrrolidine (NPYR), *N*-nitrosopiperidine (NPIP), *N*-nitrosomorpholine, *N*-nitrosomethylbenzylamine, and *N*-nitrososarcosine have shown strong evidence of being carcinogenic, while *N*-nitrosothiazolidine, *N*-nitrosoproline, or *N*-nitrosothiazolidine-4-carboxylic acid seems to either be noncarcinogenic or show a low carcinogenic potential. Despite the type of compound, the maximum allowed level for the sum of all NAs in cured meat products has been set to a limit of 10 $\mu g\ kg^{-1}$ of total volatile NAs in the United States, while no maximum limits have been established within the EU as of yet. Nevertheless, the actual levels leading to the development of a cancerous lesion can be very different from one NA to another, and in the case of humans, it is mostly unknown. To make things even more complex, it seems that NAs show a higher effect as carcinogens in laboratory animals when applied in repeated small doses as compared with larger single applications. This situation would in fact mimic the exposure of humans to traces of NAs on a daily basis.

The presence of nitrate and nitrite enables the formation of NAs in cured products, not only cured meats but also cheese and some fish products. The level and type of NAs found in cured products are very variable. In cooked cured meat products, the amount of secondary amines produced when the product is heated is rather low, since they are processed using fresh meat. The presence of free secondary amines in meat is mainly due to microbial metabolism, and thus, their formation involves high microbial counts, the presence of specific conditions, and the factor of time. On the other hand, due to the high reactivity of nitrite, in raw cured meat products, the amount of residual nitrite is rather low, and moreover, there is no heating step during processing, which would otherwise boost nitrosation reactions. As a consequence of all this, in meat products, the two most frequently determined NAs (NDMA and NPYR), with the production conditions and additive levels allowed nowadays, are found at levels rarely higher than 5 $\mu g\ kg^{-1}$. Other common NAs in cured meat products are NDEA and NPIP, and they also reach similar or slightly lower levels. Cured fish products and cheese usually show lower levels of these same NAs, even though some specific fermented and salted fish products, especially from Southeast Asia, may show very high amounts of NDMA, NPIP, and NPYR, most likely due to their elevated content of biogenic amines. There have been several attempts to address how much the different types of food consumed in a regular diet contribute to the total intake of nitrate, nitrite, and *N*-nitroso compounds (or NAs). Beer, cured meats, and fish products have been highlighted as the main sources of NAs in several countries. Nevertheless, the levels found in cured products are usually low and within established safe limits, except for exceptional circumstances (whether these limits are actually safe in the long term for humans is largely unknown, but they have been established using animal model systems).

Different processing factors may enhance the NA content in cured products: nitrate and nitrite content, pH, cooking temperature, presence of secondary amines or presence of ascorbate or tocopherols, etc. A deep knowledge about how these factors influence the formation of NAs may enable the development of processing protocols aimed at controlling the formation of such carcinogenic compounds.

It seems clear that the amount of nitrate and especially nitrite positively influences the formation of NAs, and in fact, it has been suggested that their formation is proportional to the square of the nitrite concentration. As far as nitrate is concerned, an almost linear relationship between the amount of added nitrate and the content of NDMA and other volatile NAs has been found in several cured meat products and in cured cheese. Such a relationship between nitrate and nitrite content and amount of NAs is the reason behind the limitation in the use of these curing salts in most food products all around the globe and also the voluntary reduction by many food manufacturers. These controls have led, over the past 20 years, to a reduction in the NA content of many common cured meat

products. Nevertheless, when comparing the actual levels of NAs in commercial cured meat products in Denmark, where the national normative only allows a maximum level of 60 mg kg^{-1}, with those in meat products from other EU members, in which the maximum allowed level is more than twice the Danish level (Table 1), differences were very scarce. In fact, some studies have indicated that there is a positive, but not necessarily linear, correlation between the amount of nitrite added into the food and the amount of NAs formed in the final product.

In some countries, the legislation for organic products does not allow the use of nitrates and/or nitrites in the processing of cured meat products. In fact, consumer preferences for organic and natural foods are largely based on concerns about additives used in conventionally produced foods. Consumers are willing to pay significantly higher prices for organic foods. Strangely, many of these organic processed meats (the term 'cured' is not allowed in US legislation, because of the lack of nitrate and nitrite addition) show similar properties to the conventional ones in terms of color and oxidative stability. In most of these products, producers are using spices or plant extracts naturally rich in nitrates, like celery, spinach, and beetroot. Among these, celery is perhaps the most popular, due primarily to its lack of negative impact in relation to color and flavor tainting. The nitrate content of celery powder may be higher than 20 g kg^{-1}. Nevertheless, in this type of product, the actual final amount of curing salts is usually lower than in conventional cures, which could be a concern relative to microbiological safety.

Considering that nowadays the addition of nitrite to cured products remains one of the only plausible strategies to ensure the inhibition of *C. botulinum* spore germination, a further reduction in allowed nitrite levels for cured meat could imply a safety risk. Therefore, other strategies for reducing the formation of NAs would be of enormous interest from a public health perspective. Indeed, ascorbic acid, erythorbic acid, and tocopherols have shown to have a remarkable decreasing effect on the formation of NAs in different types of cured meats. They are capable of inhibiting NA formation by competing with the precursor amine for available nitrosating agents. During curing at a regular meat pH, ascorbic acid reacts faster than secondary amines, such as proline, with the nitrosating agent N_2O_3, thereby preventing the manner in which NA formation occurs. Ascorbate reacts with nitrite 240 times more rapidly than ascorbic acid, and it is, therefore, the preferred candidate of the two. In fact, ascorbate is commonly used in the processing of cured meat products, with the aim of helping both the formation of a stable red pigment through its positive effect on the nitrosation of myoglobin and the prevention of the formation of NAs during processing and subsequent storage. Some lipid-soluble salts of ascorbic acid have been shown to have an even better effectiveness in preventing the formation of NPYR during the frying of bacon. Gamma irradiation has also been shown to have promising effectiveness in reducing the NA content in cured meat products. However, this type of technology is far from being popular in most countries right now, particularly within the EU.

Heating is well known to be one of the factors boosting the formation of NAs during the processing of cured meat products and also during cooking before consumption. For example, raw bacon is mostly free of NAs, but after cooking, and especially after frying, their levels considerably rise. In fact, when analyzing the effect of heating on the NA content of different foodstuffs, a general trend of higher levels of NAs in products with higher processing temperatures has been found. However, in a recent study in which NA content was corrected for moisture loss, the trend was not the same for all NAs: while NPIP increased in almost all cured meat products due to heating, other volatile NAs showed either an increase or a decrease depending on the product. Such varying results could be due to the specific temperatures used for cooking, since very high temperatures could lead to a decrease in the content of certain NAs due to evaporation.

Cured products with a high initial level of secondary amines, usually present due to microbial metabolism, run a higher risk for the formation of NAs during processing. In many of these products, such as meat, cheese, or fish, there is no additional heating of the product before consumption, which in a way limits the formation of NAs. However, it should be considered carefully that some of these products are actually heated when being used as part of the recipe of another foodstuff, such as pizza, pasty, and soups. In some fish products in

Table 1 Maximum allowed levels for nitrate and nitrite (mg kg^{-1}) in some cured products by the EU legislation (EU Commission Regulation, No. 1129/2011)

Type of product	*Nitrite (E249/E250)*	*Nitrate (E251/E252)*	*Observations*
Non-heat-treated processed meat	150	150	
Heat-treated processed meat	150		Except sterilized meat products ($F_o > 3.00$)
Heat-treated processed meat	100		Only sterilized meat products ($F_o > 3.00$)
Wiltshire bacon and similar products	175	250	Maximum residual amounts
Dry-cured bacon and similar products	175	250	Maximum residual amounts
Dry-cured ham	100	250	Maximum residual amounts
Salchichón, chorizo, saucisson sec		250	
Ripened cheese		150	Only hard, semihard, and semisoft cheese
Whey cheese		150	Only cheese milk of hard, semihard, and semisoft cheese
Cheese products		150	Only hard, semihard, and semisoft ripened products
Dairy analogues		150	Only dairy-based cheese analogue
Pickled herring and sprat		500	

In all cases, it refers to the maximum added amount, except when otherwise specified.

which the initial content of free amines is enormous, curing implies a very high risk for the formation of unacceptable amounts of NAs. In fact, addition of nitrites to fish and seafood is banned or severely restricted by most food legislation.

Some unusual NAs, such as *N*-nitrosodi-*n*-butylamine and *N*-nitrosodibenzylamine, have also been detected in cured meat products packaged in elastic rubber nettings, formed as a result of the interaction of the residual nitrite in the cured meats with amine additives in the rubber nettings. NPIP in cured products due to the simultaneous presence of nitrite and pepper can occur either by the oxidative cleavage of the amide bond of piperine and a subsequent nitrosation of piperidine or by a direct nitrosation of the already available piperidine.

In addition to the formation of NA in the food, nitrates and nitrites are also involved in their formation *in vivo* in the human body, mainly due to the acidic conditions of the stomach. Gastric nitrosation proceeds through reaction between amines from the food and nitrosating agents derived from the diet, both nitrites present directly in the food and nitrates reduced to nitrites in the mouth. In fact, nitrate is resorbed in the intestine and excreted through the saliva; thereafter, it is partially reduced to nitrite by nitrate reductase-containing bacteria in the oral cavity. Some studies have suggested that around 90% of ingested nitrite comes from the saliva. Nitrite intake in most countries mainly comes from cured meats, while the main source of nitrates is green leafy vegetables. In fact, most global food legislation has limited the use of nitrates for cooked cured meat products, so that the actual amount of nitrite can be more precisely controlled (**Table 1**). Moreover, there has been a trend toward a reduction in allowed levels of nitrate and nitrite in cured meats, so that nowadays, the residual levels are much lower than they used to be 30 years ago. Nevertheless, EU legislation still allows the use of nitrate in several traditional cured meat products and in cured cheese (**Table 1**). In the case of traditional cured meat products, processors claim that without the addition of nitrates, it would be difficult to achieve the features that consumers expect in this type of products, while in cheeses, the allowance is based in the prevention of early blowing during the processing of less acidic varieties. The use of such high levels of nitrates allowed in pickled herring by the EU normative is remarkable, and as such, usage entails a risk for NA formation.

Nitrosation in the intestinal track seems to be markedly diminished by the presence of ascorbate, so that its presence in the food would limit the *in vivo* formation of NAs. However, some findings suggest that in the presence of fat, ascorbate could actually enhance the formation of NA in the stomach. The parallel intake of polyphenols or other plant compounds with antioxidant activity could also help in the reduction of *in vivo* nitrosation, while other studies suggest that heme from meat could play a role in boosting nitrosation in the large intestine. Without question, more research is needed in this area, which will potentially allow designing cured food product formulas targeted at reducing nitrosation of amines, both in the food and *in vivo*.

As discussed previously, the potential involvement of cured products in the development of cancer caused by *N*-nitroso compounds could be due to both the formation of NAs (and other *N*-nitroso compounds) during product processing and storage and their contribution to the total nitrate and nitrite intake, which would be in turn related to *in vivo* nitrosation. Indeed, the role of NAs in cancer was already described in the 1950s. Later, in the 1960s and 1970s, several papers linked the consumption of cured meats to the development of different types of cancer. Although subsequent studies failed to confirm that nitrite intake caused cancer, the Assembly of Life Sciences in the United States was prompted to commission a report on the toxicity of nitrate and nitrite, which was only partially reassuring. In 2003, the Joint FAO/WHO Expert Committee on Food Additives stated that the epidemiological studies showed no consistently increased risk for cancer with increasing consumption of nitrate. Subsequent epidemiological studies have similarly failed to show a convincing link between nitrate or nitrite intake and cancer. Nevertheless, the International Agency for Research on Cancer (IARC) published a monograph in 2010 in which it was concluded that ingested nitrate or nitrite under conditions that result in endogenous nitrosation is probably carcinogenic to humans. However, this statement does not specifically refer to cured products. In fact, and as explained earlier, the major sources for nitrate and nitrite intake in most countries are saliva, vegetables, and water.

More specifically related to cured products, different epidemiological studies relating the consumption of cured meats or fish with a higher risk for the development of different types of cancer have been published and have been widely communicated in the media. Moreover, the World Cancer Research Fund published guidelines for cancer prevention, one recommendation being to limit the consumption of red meat and eliminate processed meat consumption entirely. Although not specifically mentioned, it is assumed that such a risk is attributed to curing, although other factors specifically linked to the processing of meats could also be involved. Such claims have been very controversial, and a number of papers and articles have been published highlighting the fact that such published claims have lacked epidemiological evidence. In fact, it has been pointed out that studies linking the consumption of processed meat to cancer seriously failed to completely consider several additional factors that can contribute to chronic disease, including participants' behavior as to alcohol and tobacco use, exercise, weight, and access to health care.

At any rate, if processed meats are truly involved in a higher risk of colorectal cancer, it is unlikely that this is due to residual nitrate or nitrite, because green leafy vegetables show much higher levels and seem to show no epidemiological relationship to cancer. Moreover, both nitrate and nitrite are formed endogenously and recycled with the saliva. Nevertheless, some studies suggest that the concomitant ingestion of heme and nitrosation agents could boost the endogenous formation on *N*-nitroso compounds in the colon. Others have hypothesized that *N*-nitrosamides, rather than NAs, could be related to the development of some types of cancers, but little is known about their actual content or their specific involvement in this type of disease.

Other Potential Harmful Effects of Cured Foods

Cases of infant methemoglobinemia as a consequence of well-water with a high nitrate content occurred in the past, and that is the reason why the maximum allowed amount of nitrates in

water is regulated in most countries. In fact, it is nitrite that causes methemoglobinemia, and in this sense, it could be thought that the consumption of food containing residual nitrite, like cured foods, could somehow be related to this type of disease. Nevertheless, the levels of dietary nitrites causing this condition are much higher than those that can be found in cured foods. Yet, there are reports linking cases of methemoglobinemia to the consumption of cured products with high levels of nitrites. For example, in one such incidence dating from the 1950s, an outbreak of methemoglobinemia occurred after consuming wieners and bologna containing more than 5000 ppm of nitrite. At any rate, episodes of cured food involved in cases of acute nitrite poisoning are most likely due to processing mistake.

Potential Beneficial Effects of Nitrate and Nitrite

Nitrate conversion into nitrite, and subsequently into NO, is behind the potential positive health effects of intake of these inorganic salts. Most of these possible effects have been shown for vegetable extracts, very rich in nitrates, and it is unlikely that any significant effect could be due to the residual levels of nitrate or nitrite found in cured products. Nevertheless, as a part of the diet, cured products no doubt contribute to the total intake of nitrate and specially nitrite, since they are estimated to be the third source of these salts, after vegetables and water.

NO is an endogenously produced modulator of vascular tone. Indeed, as a consequence of eating a meal rich in nitrates, a subsequent fall in both systolic pressure and diastolic pressure has been described. It seems clear that the reduction of ingested nitrate into nitrite is behind this effect, since in an experiment in which subjects had to eliminate their saliva after nitrate ingestion, the nitrite peak in blood disappeared and so too did the effect on blood pressure. NO also plays a key role in vascular homeostasis by maintaining vessels in their relaxed state; in experiments carried out in humans, dietary nitrate supplementation attenuated the impairment in endothelial function seen in ischemia reperfusion injury. NO also plays a role in the inhibition of platelet adhesion and aggregation. In this sense, dietary supplementation with either nitrate or beetroot juice has resulted in significant inhibition of platelet aggregation.

Widespread media attention has focussed on the positive effect of nitrate on muscle efficiency and fatigue resistance. In different experiments, a short-term dietary supplementation with sodium nitrate resulted in improved muscular efficiency and a reduction in oxygen consumption during submaximal exercise in healthy subjects. NO has numerous physiological signaling functions that may impact on muscle fatigue and performance: regulation of blood flow, muscle contractility, glucose and calcium homeostasis, and mitochondrial oxygen consumption. The reduction of nitrite to NO is facilitated when oxygen availability is limited, which agrees with the fact that nitrate supplementation appears to be particularly effective in enhancing performance in hypoxia and ischemia. Recent studies suggest that nitrate supplementation may specifically improve calcium handling and force production in type II muscle fibers and result in preferential distribution of blood flow to type II muscles. Given the importance of type II fiber recruitment and metabolism to performance in high-intensity intermittent exercise, and the likelihood that tissue hypoxia develops to a greater extent during such exercise compared to continuous low-intensity exercise, these recent studies therefore provide a clear rationale for nitrate supplementation to enhance performance during multiple sprint sport.

Cystic Fibrosis, Nutrition in

S Sabharwal, Boston Children's Hospital, Boston, MA, USA

© 2016 Elsevier Ltd. All rights reserved.

Definition

Cystic fibrosis (CF) is a multiple organ system disease, affecting the lungs and pancreas. Nutritional status is impaired by inadequate intake, increased energy needs, and pancreatic insufficiency. Pancreatic insufficiency results in maldigestion and malabsorption of nutrients and fat-soluble vitamins. Pancreatic enzyme supplementation and optimizing nutritional deficiencies prevent growth failure and improve other outcomes in patients with CF, including quality of life, resistance to infection, and chronic lung disease prevention, leading to longer life expectancy in patients with this disease.

CF is a result of the defects in the CF transmembrane conductance regulator (CFTR), which is responsible for the excretion of salt, in turn creating viscous secretions in multiple organ systems. For decades, CF was thought to be a disease only of childhood given the lower life expectancy. Largely because of improvements in nutrition, the average life expectancy of patients with CF has advanced well into adulthood.

Clinical Manifestations

Defects in the CFTR result in multisystem disease including lung, liver, and gastrointestinal (GI) diseases, notably pancreatic insufficiency. While the majority of CF mutations cause lung disease, growth and nutritional status are closely tied to lung disease and affected by the type of CF mutation. Body mass index (BMI) being maintained at $\geq 50\%$ for age has been shown to correlate with the percent predicted forced expiratory volume in 1 s of greater than or equal to 90%, which is an excellent marker of lung function. For CF patients ages greater than or equal to 20 years, it is recommended that women maintain a BMI at or above 22 and that men maintain a BMI at or above 23.

Nutritional failure in CF is multifactorial. Insufficient production of pancreatic enzymes leads to fat malabsorption, which can be exacerbated by bile salt abnormalities if there is concurrent liver disease. Progressive pulmonary infection leads to increased work of breathing and therefore increased caloric needs. Chronic lung infection can reduce appetite and lead to an inflammatory catabolic process in the body. Other factors affecting nutrition include CF-related diabetes mellitus, altered motility of the GI tract, and small bowel bacterial overgrowth.

Management

CF derived its name from the cysts and fibrosis noted in the pancreas of patients with CF. The pancreas is responsible for secreting enzymes that aid in the absorption of nutrients including fat-soluble vitamins A, D, E, and K. In order to counteract this malabsorption, pancreatic enzyme replacement therapy is used. Lipase is the enzyme responsible for fat absorption. Pancreatic enzyme replacement is based on the dosage of lipase in the supplement (500–2500 lipase units per kilogram of body weight per meal or $<10\,000$ lipase units per kilogram of body weight per day). In addition, fat-soluble vitamin supplements are routinely given. The CF Foundation (CFF) supports that higher energy intake is needed for improved weight gain. In order to achieve energy intake of 110–200% of the healthy population, the CFF makes several recommendations with the goal being a high-calorie unlimited fat meal.

For children ages 1–12 with CF, intensive behavioral and nutritional counseling is recommended to promote weight gain. For those with growth deficits and adults who are having difficulty with maintaining weight gain, oral or enteral nutritional supplements are recommended.

Fat-soluble vitamins A, D, E, and K are supplemented in all children with CF. Supplements are started at diagnosis including asymptomatic infants and those without pancreatic insufficiency. Standard ADEK supplements tend to overestimate vitamin A and underestimate vitamins D and K. This can be problematic, for example, in CF patients who also have CF-related liver disease, as vitamin A toxicity can affect the liver.

Vitamin A deficiency is rare except at the time of diagnosis. Vitamin A is necessary for vision, gene expression, growth, and immune function. Available forms of vitamin A include preformed vitamin A (retinol and retinoic acid) and provitamin A (alpha-carotene and beta-carotene). Vitamin A levels are monitored via serum retinol and retinol-binding protein. Vitamin A toxicity is possible in CF patients and is marked by bone mineral loss and liver abnormalities.

Vitamin D deficiency in common in CF. Vitamin D helps the body use calcium from the diet and deficiency can lead to poor improper bone mineralization. Vitamin D_3 (cholecalciferol) is contained in most supplements and is the form produced in the skin by sunlight. The CFF recommends vitamin D_3 versus vitamin D_2 (ergocalciferol) because a small study showed it achieved better target 25-hydroxyvitamin D. Levels are checked annually at the end of winter. Bone disease in CF results from decreased mineral density, which worsens with age, severe lung disease, and malnutrition. There is also an increase in fracture rates and kyphosis in young adults with CF. In addition to vitamin D deficiency, chronic corticosteroid use and reduced weight-bearing activity can contribute to bone disease.

Vitamin E is an antioxidant and its deficiency could contribute to inflammation and lung disease in CF. Vitamin E deficiency leads to delayed stretch reflexes, cerebellar ataxia, and peripheral neuropathy. Some studies have shown a correlation between vitamin E status, polyunsaturated fatty acid (PUFA) status, and inflammation in CF. Eight different forms of vitamin E exist, the most common form being alpha-tocopherol acetate. The recommended intake for CF patients is 20 times the general recommended intake. Serum vitamin E is influenced by serum lipid levels.

Vitamin K deficiency is associated with coagulation abnormalities and bone disease. Vitamin K is found in green vegetables, and vitamin K status is monitored by a serum prothrombin time. As intestinal bacteria are a source of vitamin K, supplementation should be provided during courses of antibiotic, a common occurrence in CF patients.

Essential fatty acids are long-chain PUFAs and include omega-3 and omega-6 fatty acids. Their deficiency may contribute to an inflammatory state including scaly dermatitis, alopecia, and growth failure and tends to be more common in infants. Routine supplementation is not recommended at this time. However, a systematic review showed that supplementation with omega-3 fatty acids improved several markers of lung disease.

CF patients are prone to hyponatremic dehydration under conditions of heat stress secondary to sodium losses through sweat. Sodium chloride supplementation is used especially in warm months or climates and in infants.

The CFF recommends a trial of zinc supplementation for children <2 years not growing well. Dermatitis can be a symptom of zinc deficiency.

Iron deficiency has been noted in several studies of CF patients and is monitored yearly by serum hemoglobin and hematocrit.

Oral supplements are used in CF but are often less effective because they may displace ordinary food. A systematic review showed that calorie-protein supplements are not superior to monitoring and dietary advice from a health professional and a nutritionist. Enteral nutrition is generally started via gastrostomy tube for patients with growth failure. Although there are no randomized control trials to support this, enteral nutrition is thought to improve and maintain lung function in patients with CF. For toddlers, a combination of daytime feeds, daytime meals, and nighttime continuous feeds is used. Concentrated formula delivers more calories in less volume for overnight feeds to help prevent excessive nocturnal urination.

In conclusion, CF is a disease in which nutritional status is highly important to overall disease outcomes. It is important to monitor nutritional status regularly, looking at growth and overall digestive issues including signs of malabsorption, and to screen for nutritional deficiencies. Fortunately, advances in these nutritional measures over the past several decades have resulted in improved life expectancy for this chronic disease.

Introduction

Indian curd, known as *dahi*, is a well-known fermented milk product consumed by large sections of the population throughout the Indian subcontinent, either as a part of the daily diet or as a refreshing beverage. This product finds its name in the ancient Hindu scriptures and is used in several of Ayurvedic formulations (traditional Indian medicinal system) because of its potential therapeutic properties. The beneficial aspects of *dahi* and its products have been often investigated. *Dahi* prepared from buffalo milk is white in color and possesses a firm body and slightly granular texture, whereas *dahi* prepared from cow milk is less firm and smooth in texture. *Dahi* may be consumed directly, either sweetened or salted and spiced. It is also consumed with other foods such as rice and wheat loaf. *Dahi* has assumed a special place in the daily diet of Indian populations, who prefer to take *dahi* once or twice a day in morning or evening meals. In 2010–11, the production of *dahi* was estimated at almost 8% of the total dairy production in India. Since conversion of milk into *dahi* is an important intermediate step in the manufacture of indigenous fat-rich dairy products like butter and ghee, it can be said that over 40% of the total milk production in India is converted into *dahi*. *Dahi* is also used as a vehicle to incorporate probiotics, and several varieties of *dahi* are developed for the benefit of consumers, like fruit *dahi*, sweetened *dahi*, whole-milk *dahi*, and skim-milk *dahi*. Though nowadays, *dahi* is mostly sold in polythene pouches and in set form in HDPE containers, traditional *dahi* was being sold in earthen pots. *Dahi* sold in pouches does not have the three-dimensional network structures that are typical of set *dahi*, whereas the products sold in the rigid plastic containers possess a firm body and smooth texture that appeals to consumers. Its typical flavor is the foremost quality attribute of *dahi* that determines its acceptance. The pleasant flavor of *dahi* is attributed to its diacetyl content, which is produced by citrate-fermenting lactic acid bacteria (LAB).

Definition

According to the Bureau of Indian Standards (BIS), *dahi* is a product obtained by lactic fermentation of cow or buffalo milk or mixed milk through the action of single or mixed strains of LAB. This definition does not include milk coagulated by the addition of acids and milk-coagulating enzymes. As per the Prevention of Food Adulteration Act of India (PFA, 1988), *dahi* or curd is a product obtained from pasteurized or boiled milk by souring naturally or otherwise by adding harmless lactic acid and/or other aroma-producing lactic acid bacterial cultures. *Dahi* may contain additional cane sugar. It should have the same percentage of fat and nonfat solids as the milk from which it is prepared. Where *dahi* or curd, other than skimmed-milk *dahi*, is sold or offered for sale without any indication of the class of milk, the standards prescribed for *dahi* prepared from buffalo milk should apply. This is an equivalent of yogurt made from boiled milk after inoculation through back-slopping, which consists of the leftover *dahi* from the previous lot. However, it differs from yogurt in having less acidity.

Starter Cultures Used for the Preparation of *Dahi*

In the production process of *dahi*, inoculation with small quantities of the desired fermenting microbiota, that is, through back-slopping or via the starter culture, takes place. The most important microorganisms in starter cultures are the homofermentative and heterofermentative LAB. The *dahi* starter cultures can be classified into two groups, according to the characteristics of the microorganisms: mesophilic and thermophilic cultures.

Mesophilic starter cultures are used at temperatures varying between 16 and 30 °C (Table 1). The characteristics of *dahi* starter cultures and their metabolic products are given in Table 2. The most typical representatives are the homofermentative *Lac. lactis* subsp. *lactis* and *Lac. lactis* subsp. *cremoris*. These are similar, though the former is able to produce free amino acids, which are believed to stimulate the growth of *Lac. lactis* subsp. *cremoris* strains. Another important species in the mesophilic starter category is the homofermentative *Lac. lactis* subsp. *lactis* biovar *diacetylactis*, which is able – besides lactic acid production – of fermenting citric acid into a number of other compounds such as diacetyl and carbon dioxide. However, at a pH below 5, carbon dioxide and a number of compounds similar to diacetyl, but nonaromatic, are produced. Heterofermentative aroma-producing starter cultures, like *Leu. mesenteroides* subsp. *dextranicum* and *Leu. mesenteroides* subsp. *plantarum*, are also able to ferment citric acid, that is,

Table 1 Designation of *dahi* based on types of starter cultures

Sr. no.	Designation	Cultures used	Remarks
1.	Sweet *dahi*	*Lactococcus lactis* subsp. *lactis*, single or in combination with *Lac. lactis* subsp. *cremoris*,	With or without aroma producers like *Leuconostoc mesenteroides* subsp. *dextranicum*, *Leu. mesenteroides* subsp. *plantarum*, *Lac. lactis* subsp. *lactis* biovar *diacetylactis*
2.	Sour *dahi*	*Lactobacillus delbrueckii* subsp. *bulgaricus* and *Streptococcus salivarius* subsp. *thermophilus*	Single or in combination with or without aroma producers

Table 2 Characteristics of starter cultures used in *dahi* making and their principal metabolic products

Starter organisms	Metabolic products	Lactose fermentation
Lactobacillus delbrueckii subsp. *bulgaricus*	Lactate, diacetyl, acetaldehyde	Homofermentative
Lactococcus lactis subsp. *lactis*	Lactate	Homofermentative
Str. salivarius subsp. *thermophilus*	Lactate, diacetyl, acetaldehyde	Homofermentative
Lactococcus lactis subsp. *cremoris*	Lactate	Homofermentative
Leuconostoc mesenteroides subsp. *dextranicum*	Lactate, diacetyl	Heterofermentative
Lac. lactis subsp. *lactis* biovar *diacetylactis*	Lactate, diacetyl, CO_2	Heterofermentative

into carbon dioxide, diacetyl, and some other products. Unfortunately, leuconostocs may reduce diacetyl into nonaromatic compounds again. The intensity of reduction varies between the various representatives of the strains.

Homofermentative thermophilic starter microorganisms, like *L. delbrueckii* subsp. *bulgaricus* and *Str. salivarius* subsp. *thermophilus*, are used to obtain mildly sour *dahi*. These starters play an important role in producing a good quality *dahi* having a firm and uniform consistency with a sweet aroma and acidic taste.

Classification of *Dahi*

Broadly speaking, *dahi* may be classified into two types:

- *Dahi* for churning into *desi* (indigenous) butter
- *Dahi* for direct consumption

The *dahi* for direct consumption is further classified into the following subtypes:

- (i) Whole milk *dahi* and (ii) skim-milk *dahi*
- (i) Sweet (or mildly sour) *dahi*, (ii) sour *dahi*, and (iii) sweetened *dahi*

Technology of Sweet and Sour *Dahi* Manufacture

The flow diagrams showing the steps involved in manufacture of sweet (or mildly sour) and sour *dahi* are given in Figure 1.

Preliminary Treatment of Milk

The preparation of the basic mix involves selection of milk, preheating, filtration/clarification, and standardization of the milk. The different methods for standardization indicate the possibilities that exist for either increasing or decreasing the various milk constituents, especially the fat percent. However, the choice of any particular system is primarily governed by the following factors:

(i) Cost and availability of the raw materials
(ii) Scale of production

The composition of *dahi* varies considerably. The average composition of *dahi* made from buffalo milk is delineated in Table 3. Commercial *dahi* tends to contain around 14% of milk solids.

The use of ultrafiltration to concentrate the solids in cow milk and skim milk is being considered as a feasible alternative. The importance of total solids stems from the improved consistency imparted to the *dahi* coagulum, an improvement that is carried further in the homogenization stage by employing a pressure of 2500 psi. Homogenization of milk imparts a smooth texture to the coagulum. It also reduces the chances of whey separation. Homogenization is followed by a final heat treatment of 80–90 °C for a prolonged period of 20 min. The effect of this drastic heat treatment can be summarized as follows:

- The bacterial load in the milk is reduced, and hence, the starter culture has less competition from the contaminating microorganisms.
- There is a denaturation of whey proteins (albumins and globulins) and an aggregation of the casein micelles into a three-dimensional network. The network traps the whey proteins, and the *dahi* coagulum produced subsequently is rendered more viscous.
- There is a reduction in the amount of oxygen in the milk, and as normal *dahi* cultures are microaerophilic, the lowered oxygen tension encourages their growth.
- Some limited damage to the milk proteins may occur during heating, and the breakdown products can stimulate starter activity.

Fermentation of Milk

The acidification of milk during the manufacture of *dahi* is an important biochemical process, which must be carried out under controlled conditions in special incubators and/or

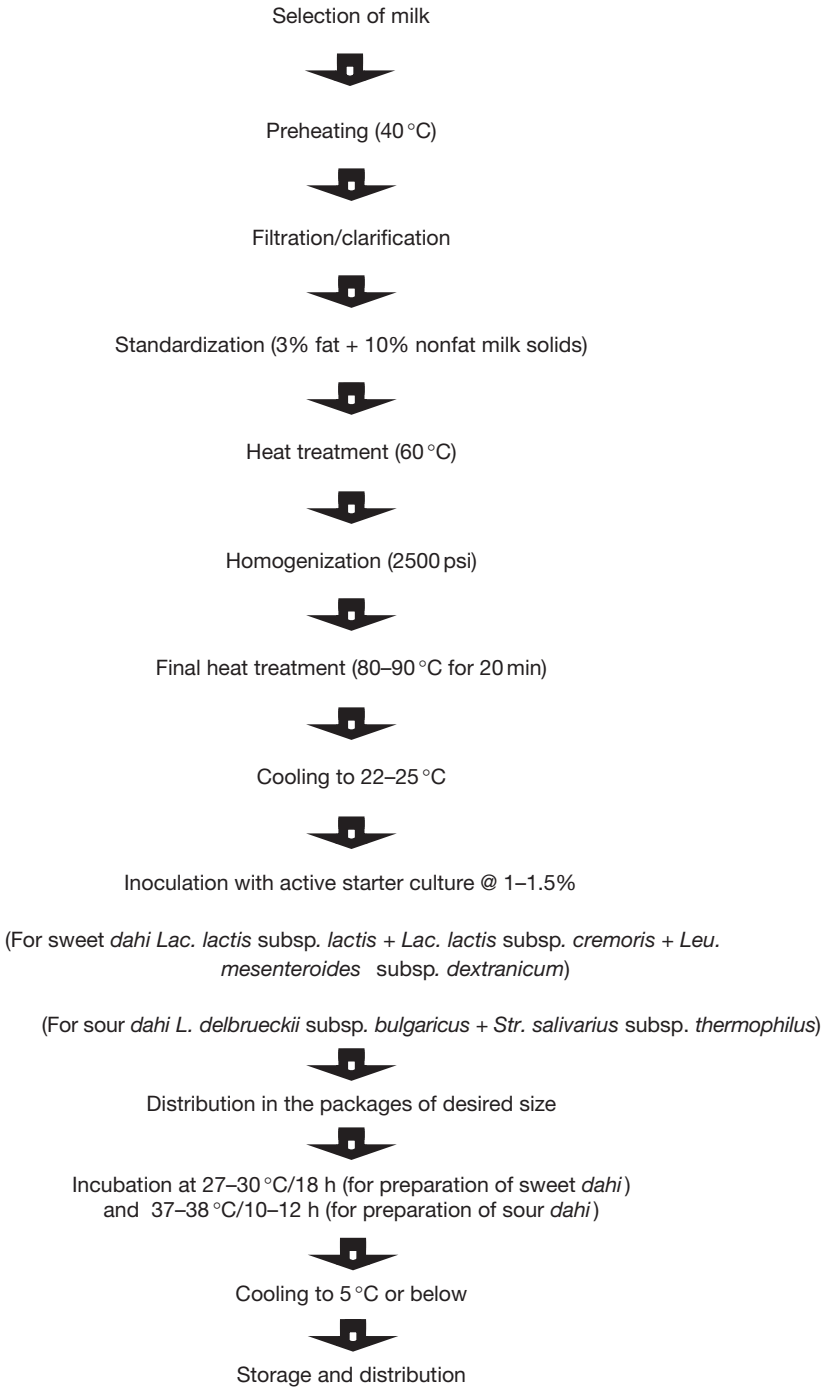

Figure 1 Flow diagram for the preparation of *dahi*.

fermentation tanks. Fermentation tanks are used as incubators only, and they are usually insulated in order to maintain appropriate temperature. The processing of the milk and the cooling of *dahi* is carried out in other equipment on the production line. Cabinets are also used for this purpose. These comprise a small insulated room, which is divided into compartments, and most incubators of this type are multipurpose chambers capable of circulating hot or cold air. Hot air is circulated during the fermentation period followed by cold air during the cooling stage. Sometimes, these cabinets are used as incubators only, and the *dahi* can be cooled in refrigerated cold storage. In the case of mildly sour *dahi* manufacture, the temperature is maintained at 27–30 °C, while for sour *dahi*, it is 37–38 °C.

Table 3 Average composition of buffalo milk *dahi*

Constituents	*%*
Moisture	85–88
Fat	5–8
Protein	3.2–3.4
Lactose	4.6–5.2
Ash	0.70–0.75
Lactic acid	0.5–1.0
Calcium	0.12–0.14
Phosphorus	0.09–0.11

Cooling of *Dahi*

After the incubation period is over, *dahi* is cooled in order to control the level of lactic acid in the product. The rate of cooling can affect the structure of the coagulum. Thus, very rapid cooling can lead to whey separation, and this is due to a too rapid concentration of protein filaments, which, in turn, affects their hydrophilic properties.

Microbiological Quality of *Dahi*

In general terms, *dahi* can be regarded as 'hygienically safe.' The reason for this confidence stems from the level of acidity present around 0.7–1.0% (lactic acid). Under this situation, potential pathogens such as *Salmonella* spp. will be largely inactive. Similarly, coliforms will be unable to survive the low pH encountered. Inhibition of some pathogens may be reinforced by the production of antimicrobial substances by the *dahi* starter organisms. Several studies have confirmed that certain LAB isolated from *dahi* can produce bacteriocins effective against several of the human Gram-positive pathogens. As far as the microbiological standards for *dahi* are concerned, the maximum acceptable number of yeasts and mold and coliforms of 100 and 10 cfu g^{-1}, respectively, is accepted by the BIS for both the sweet and sour types of *dahi*. In both types, it is mandatory that a phosphatase test should be negative.

Technology of Sweetened *Dahi* (Misti *Dahi*) Manufacture

Misti *dahi* (syn. sweetened *dahi*, red *dahi*, *payodhi*) is a traditional sweetened fermented milk product of the Eastern region of India. It is prepared on cottage scale by *halwais* (sweetmeat makers) every day to cater to local demands. Traditionally, milk added with cane sugar is continuously heated in an open pan at simmering temperature (68–70 °C) for 6–7 h to concentrate and develop an intense cooked flavor and brown color, besides increasing the viscosity and inducing other physicochemical changes. After cooling to about 40 °C, the mix is inoculated with a commercial misti *dahi* starter culture, which generally comprises a mixed lactic culture like *Lactobacillus delbrueckii* subsp. *bulgaricus*, *Streptococcus thermophilus*, and some aroma-producing organisms like *Lac. lactis* subsp. *cremoris*, as mentioned in the case of mildly sour and sour *dahi*. Wide variations in total solids content (27–43%), nonfat milk solids (11–16%), and sucrose (13–19%) in the market samples of misti *dahi* sold in Kolkata city have been reported. Many flavor defects such as overly fruity, alcoholic, highly acidic, and flat and textural defects like gassiness, weak body, wheying off, and thick crust on top surface were observed in most of the market samples. In view of the increasing nationwide demand for this product and the growing interest of the organized dairy plants for large-scale manufacture, the technology was developed to suit industrial-scale production. This technology is accepted and invariably adopted for dahi manufacture on large scale. Manufacturing technology for industrial production of misti *dahi* is given in Figure 2.

To prepare Misti *dahi*, fresh buffalo milk is standardized to 3.5% fat and 9% nonfat milk solids, and it is then heated to 65 °C in a plate heat exchanger and homogenized at a pressure of 56 kg cm^{-2} (one stage). Milk is concentrated to 1.44-fold in a vacuum evaporator. After adding cane sugar, the milk is heated at 85 °C for 10 min to generate cooked flavor. The mix is cooled to 40 °C before inoculation with a commercially available lactic culture (e.g., LF-40). In some cases, sugar, caramel, jaggery, and artificial colors are added to impart brown color. The inoculated mix is aseptically distributed into presterilized polystyrene containers of desired size and mechanically transferred to an incubation chamber at 40 °C. During the curd formation, milk must remain stationary. In all postfermentation activities, the gel should be subjected to a minimum amount of external influences. Diacetyl is the predominant flavor component, but microquantities of acetoin, acetic acid, and carbonyls are also present. Off-flavors in this product can be traced back to poor-quality raw milk, the use of contaminated cultures, high incubation temperature, and contaminated packages.

Rheological Properties

Consistency, firmness and viscosity of *dahi* are important textural parameters that govern the quality of the product. These attributes can be measured objectively by a texture analyzer or cone penetrometer. The texture analyzer works on the principle that a cylindrical steel probe penetrates into the product samples and experiences resistance during the penetration. The resistance offered by the *dahi* sample (5 °C) during the penetration of the probe up to a specified distance is recorded as firmness (newtons) of *dahi*. A cone penetrometer is a simple and useful instrument for determining the firmness or hardness of food materials. In this instrument, a conical metal probe is allowed to freely fall into the sample for a specified time, for example, 5 s. Then, its fall is arrested by an electromagnetic mechanism, and the depth of penetration is measured on a dial scale and expressed as (×0.1) mm. The higher the depth, the softer the *dahi* sample must be. Since *dahi* is generally a soft material, a metal probe would be too heavy for the purpose, so a rubber conical probe can be used.

Factors Affecting Rheological Properties of *Dahi*

Rheological parameters of *dahi* are significantly influenced by the heat treatment of the milk used for *dahi* making. It has been reported from the texture analyzer parameters that by the heat treatment of milk, the firmness of *dahi* increases from 0.039 N in no heat treatment (control) to 0.110 N in *dahi* prepared

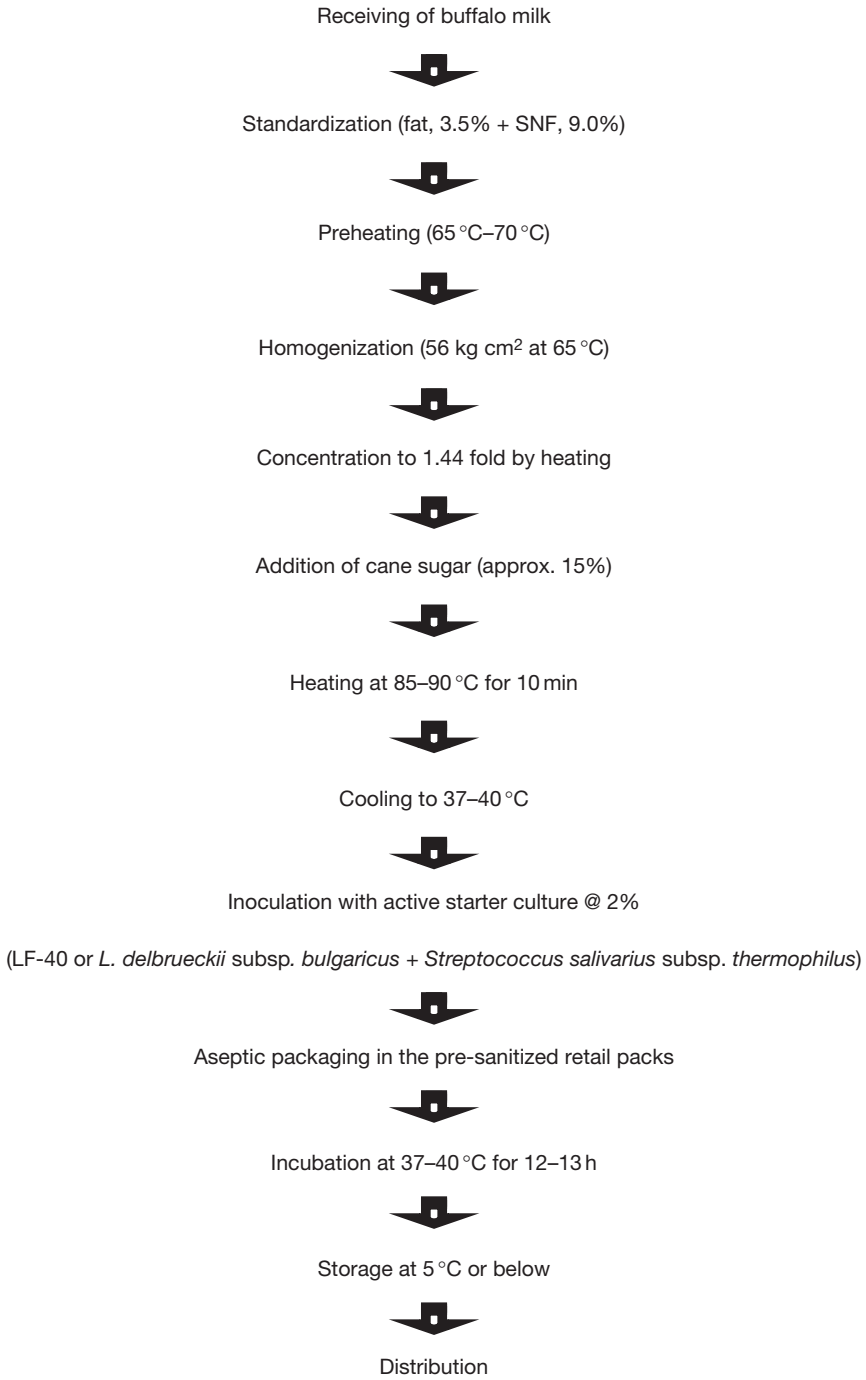

Figure 2 Flow diagram for preparation of Misti *dahi*.

from boiled milk. The low-temperature, long-time (LTLT) treated milk *dahi* has a 0.070 N firmness. Similar observations were recorded with consistency value, but the LTLT treated (0.33 N s) and boiled-milk (0.31 N s) *dahi* display almost the same consistency, yet much higher than that of the control (0.071 N s). Index of viscosity values are lower for control *dahi* (0.0012 N s), whereas those for LTLT treated milk *dahi* and boiled-milk *dahi* are 0.007 and 0.012 N s, respectively. This trend is also reflected in parameters measured by cone penetrometer.

The effect of a heat treatment of milk on the rheological parameters can be attributed mainly to the denaturation of proteins. In milk, casein exists in a colloidal state, which is sustained by calcium bridges between the casein micelles. The whey proteins exist in a soluble state and have no interaction with casein micelles. But by heat treatment of milk, the whey proteins get denatured and involved in interactions with the casein micelles without affecting the calcium bridges. As intensity of heat treatment given to milk increases, casein–whey protein interactions take place. However, during the

fermentation process, the calcium bridges between the protein particles dissolve because the calcium goes from the colloidal state to solution state, as the acidity rises and pH decreases. It also results in the slow precipitation of the casein–whey protein particles. The precipitated casein–whey protein particles arrange themselves in specific manner forming three-dimensional networks, which impart firmness to *dahi*. This network can easily be broken by subtle forces of agitation, but once broken, the network cannot be built back. However, part of the original viscosity may be recovered during storage, which is known as thixotropic character.

The sticky character acquired by the curd during fermentation is responsible for the thixotropic character and can be attributed to mucilaginous substances produced by starter bacteria. This is the reason why it is widely believed in the subcontinent that the milk should not be disturbed while setting of milk is in progress otherwise firm curd would not form. Disturbing the milk during setting means disturbing the network being formed during acid production. A firm, well-set curd is most preferred than stirred curd in India. However, most of the curd sold is stirred curd because of convenient processing steps, but manufacturers are realizing the people's preference for set curd, so set curd with a thick, firm consistency is now gaining market. In this regard, the extent of heat treatment of milk and use of starter cultures, which produce not only lactic acid and diacetyl but also texturizing compounds (heteropolysaccharides), are important. Some of the workers in this field have advocated application of inulin and texturizing substances for improving the consistency of *dahi*, whereas others used xylooligosaccharides for the purpose. The observations of these workers show that apart from heat treatment, external polysaccharides could also be employed to enhance the consistency of products like *dahi*.

Effect of Heat Treatment on the Syneresis and Acid Development in *Dahi*

Syneresis is the separation of whey from the curd. The extent of syneresis is indicative of the quality of *dahi*. Consumers prefer *dahi* with no visible whey separation. The presence of separated whey indicates excessive fermentation and stored *dahi*. During fermentation, changes take place with regard to the milk proteins, affecting water retention. Consumers tend to think that the curd showing whey separation is not fresh and hence not good. *Dahi* prepared from raw milk shows visible whey separation measured as 7.7 ml after centrifugation, whereas *dahi* prepared from milk pasteurized by LTLT shows a syneresis value of 7.2 ml, which can also be visualized. However, boiled-milk *dahi* exhibits no visible whey separation and shows firm consistency.

When well-set curd is disturbed, the whey flows through the channels in the network and finally separates out. The partially denatured proteins hold more moisture or whey, so syneresis is less in the curds prepared with high heat-treated milk (boiling). In the case of raw milk, the whey proteins are in native state so they possess low water-binding ability; hence, more syneresis is expected to take place in that curd. In LTLT treated milk, the whey protein denaturation has just begun so water binding is slightly larger than in raw milk, leading to less syneresis. In boiled milk, the proteins hold more moisture, giving low syneresis values. Thus, the firmer the curd, the lower the syneresis.

Effect of Heat Treatment on Sensory Quality and Acceptance of *Dahi*

The acceptability of *dahi* samples is generally measured on a 9-point hedonic scale. It is observed that the boiled-milk *dahi* scores highest in all the sensory attributes. Milk that does not receive any heat treatment results in *dahi* with low sensory scores that fall in the range of around 5–6, that is, 'liked slightly.' LTLT heat-treated *dahi* scores better than raw-milk *dahi* indicating that flavor, body, and texture improve by heat treatment. By heat treatment, undesirable microorganisms are killed and LAB grow with less competitive inhibition. When milk is boiled, the same happens, but because of protein–protein interaction, the body and texture improve further, which will synergistically enhance the flavor attribute. For these reasons, the overall acceptance scores are highest for the boiled-milk *dahi*.

The intensity of heat treatment given to milk influences the extent of denaturation of whey proteins. It is stated that during *dahi* manufacturing, heating of milk (90–95 °C/5 min) denatures whey proteins, which consist of α-lactalbumin and β-lactoglobulin. The denatured whey proteins interact with casein micelles by coating on their surface. The denatured whey proteins have a good water-binding ability, so they enhance the thickness of the curd. They also help in sustaining the three-dimensional structure of *dahi*. It is known that whey proteins denaturation begins at 65 °C and would almost completely be denatured (93–95%) by heat treatment of milk at 80 °C for 45 min. The water-binding ability of proteins is maximal only when they are partially denatured, that is, when the protein structure is not completely damaged. This is because of exposure of hydrophilic groups, which were otherwise remaining embedded inside the tertiary or quaternary structure. But when milk is intensely heat-treated, as in heat sterilization, that is, more than 10 psi, then whey proteins are completely denatured, their secondary structure is fully straightened out, and the hydrophilic groups are lost; as a result, the proteins lose water-binding ability. So, sterilization of milk is detrimental to the curd firmness. It is now clear that boiling the milk without holding will not lead to complete damage to the secondary structure of whey proteins, but results in only partial uncoiling leading to more number of hydrophilic groups being exposed. Thus, water-binding ability is increased.

Role of *Dahi* in Complementary Feeding

Conversion of milk into *dahi* helps to extend the shelf life of milk, thereby allowing storage and transport. In fact, the generation of lactic and short-chain fatty acids from lactose and the consequent fall in pH inhibit the growth of many pathogenic microorganisms. This technology has been widely practiced throughout India for a long time.

Dahi is nutritionally similar to unfermented milk, except that some of the lactose is broken down to glucose and galactose, which are further fermented, some vitamins are

Table 4 Mineral and vitamin content of *dahi*[a]

Sr. No.	*Constituents*	*Milk*	Dahi
1.	Mineral matter (g)	0.8	0.8
2.	Calcium (mg)	118	149
3.	Phosphorous (mg)	96	102
4.	Vitamin A (I.U.)	4.6–5.2	96.0
5.	Thiamine (μg)	55	49
6.	Riboflavin (μg)	167	157
7.	Nicotinic acid (μg)	96	86
8.	Biotin (μg)	29.0	3.2
9.	Pantothenic acid (μg)	202	183
10.	Folic acid (μg)	161	178

12.	Ascorbic acid (mg)	1.4	1.3

[a]Values given per 100 g of the product.

synthesized, and the bioavailability of Ca and P is enhanced due to increased acidity and release of some amino acids. This makes *dahi* like other fermented milks an important food in cases of lactose tolerance. In very young children, lactose intolerance is often due to an impaired activity of intestinal lactase following intestinal pathologies. Children with lactose intolerance could receive dahi and other fermented milks without showing the classical clinical signs of impaired absorption, such as intestinal bloating and gas production. In addition to that, lactase activity of live microorganisms present in *dahi* also remains after ingestion in the gastrointestinal tract, improving lactose digestion. The use of special milk formulation for lactose-intolerant subjects could not be affordable in poor regions in which the use of *dahi* can be a valid alternative. Although *dahi* is primarily regarded as a useful source of protein and minerals, vitamins from the original milk or secreted by the starter culture bacteria are usually present in detectable quantities (**Table 4**). The nutritional value of milk protein is self-evident, but it is important that the level in *dahi* is due to the concentration of milk solids, higher than in liquid milk, as is the concentration of minerals such as calcium and phosphorous. Furthermore, the low pH of *dahi* tends to make the latter more accessible for absorption through the intestinal wall.

Dahi is indeed able to enhance the absorption of some minerals, such as calcium and nonheme iron, as a result of its lower pH. The increased calcium absorption is related to both a direct effect of the acidification of intestinal lumen and the reduction of the mineral complex formation with other dietary components. If *dahi* is consumed at mealtimes, the lactic acid is likely to have a positive effect on the absorption of iron from other foods. The bioavailability of iron is more important than the total amount of iron in the diet. In contrast to breast milk, iron from unmodified cow's milk is poorly absorbed, as a result of the high content of protein and the low content of vitamin C compared with commercial infant formula. Furthermore, the early introduction of unmodified cow's milk can cause blood loss from the intestinal tract, thereby having a negative influence on iron status, especially during the first 6 months of life and also during the second half of infancy.

A number of health benefits have traditionally been attributed to *dahi* and products made from it, which have been used to prevent a wide range of diseases including atherosclerosis, allergies, and gastrointestinal disorders. Although empirical findings are yet to be supported by controlled studies, initial results from investigations into the antibacterial, immunologic, antitumor, and hypocholesterolemic effects of *dahi* consumption suggest potential benefits.

Dairy Products: Dietary and Medical Importance

F Visioli, University of Padova, Padova, Italy

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Milk is a widely disseminated beverage worldwide and is essential to the diet of several millions worldwide because it provides important macro- and micronutrients. Dairy products are also important food staples that provide protein and micronutrients in a rather concentrated form.

Milk and dairy products are perceived as nutritionally relevant foods, mostly because their calcium, protein, phosphorus, etc., content promotes skeletal, muscular, and neurological development. However, their relatively high saturated fat proportion (milk fat contains about 70% of saturated fatty acid (SFA); myristic and palmitic acids combined account for ~50%, while the rest is mostly short- and medium-chain fatty acids, including oleic acid) often raises issues in terms of adverse effects on cardiometabolism. However, the vast majority of recent epidemiological and intervention studies indicate that dairy products do not adversely affect surrogate markers of cardiovascular disease and cardiovascular prognosis. Conversely, short-chain SFA from milk and its derivatives are – apparently – benign or even beneficial with regard to inflammation. Extensive calcium intake is often frowned upon because of potentially noxious actions on coronary calcification. However, accumulated epidemiological evidence suggests that calcium does not play major roles in coronary calcification and its intake is inversely associated with blood pressure. Therefore, the hypothesized association between calcium intake and cardiovascular risk is not supported by current data and, actually, the converse might be true. In addition, some milk components such as *trans*-fatty acids, tripeptides, calcium, phosphorus, lactoferrin, and oligosaccharides might exert useful – though as yet unproven – physiological actions. Finally, milk is an efficient vehicle for fat- and lipid-soluble nutrient absorption because milk fat is highly dispersed in very small micelles; this makes milk an excellent matrix for functional foods.

In this article, the latest published evidence on milk, dairy products, and human health is summarized.

Milk, Dairy Products, and Cardiometabolism

Cardiovascular disease is the leading cause of death in the Western world and its incidence can be modulated by diet. As mentioned, milk is often perceived as a double-edged sword chiefly because of its SFA content. In addition, milk and dairy products contain cholesterol (approximately 80 mg/100 g). Therefore, several people worry that the intake of either one might theoretically have detrimental effects on their cholesterol concentrations. The net result is that cardiovascular patients or individual at risk (real or perceived) often stops using milk and its derivatives precisely to improve their prognosis. In this respect, it is noteworthy that the real contribution of dietary cholesterol to cardiovascular risk is being debated; the current consensus is that it depends on individual, inherited ability to synthesize versus absorb cholesterol. Also, the extent and the exact nature of the role of SFA in cardiovascular disease onset and development are being reexamined; moreover, genetic background is a predictor of the response to SFA intake.

The first review on the association between dairy products and circulating cholesterol concentrations has been published by St-Onge et al. In that paper, the authors mention an old study carried out in the African Maasai ethnic group. Maasais consume large amounts of milk, which, in that study, was inversely correlated with cholesterolemia. The same authors proposed milk as an inhibitor of cholesterol synthesis. Other publications expanded on the cholesterol-lowering effects of both milk and skimmed milk (which were previously suggested by Hepner et al.). In their review, St-Onge et al. hypothesized that the cholesterol-lowering effects of milk are due to the intestinal microbial fermentation of indigestible carbohydrates (see succeeding text), which would positively alter the microbiota, inhibit cholesterol synthesis, and interfere with cholesterol enterohepatic circulation, in turn lowering cholesterolemia.

A recent study performed by Høstmark et al. in 18 770 subjects examined the association between cheese consumption and circulating concentrations of high-density lipoprotein (HDL) cholesterol (which was positive) and triacylglycerols (which was negative), in different age groups. The authors attributed this effect to the fatty acid composition of cheese and its bacterial content, although this hypothesis needs confirmation.

One of the questions arising from these studies is whether various dairy products have different effects on cardiovascular risk markers. In this respect, one study equicalorically (20% of total calories, normalized for lactose and casein) compared the effects of milk, cheese, and butter, for 3 weeks. Cheese slightly increased low-density lipoprotein (LDL) cholesterol, whereas the effects of whole milk and butter were similar. These data have been replicated by Biong et al., who reported that consumption of cheese induced a lower increase of cholesterol concentrations than that of an identical amount of fat from butter. Along these lines, Nestel et al. administered 40 g day^{-1} from either cheese or butter to mildly hypercholesterolemic subjects. Total and LDL cholesterol increased significantly – after 4 weeks – in the butter group as compared with the cheese one. Some authors suggest the inclusion of modest amounts of cheese in the diets of mildly hypercholesterolemic subjects, even though current guidelines recommend otherwise. Indeed, in a study by Hjerpsted et al., 13% of total daily calories were replaced with either 143 g of cheese or 47 g of butter (with the same lipidic content), for 6 weeks, in a randomized crossover trial on healthy subjects. The result indicates that cheese does not increase LDL cholesterol compared with the run-in period; rather – as compared with butter – cheese induces a significantly lower increase in total (5.7%) cholesterol and LDL (6.9%) cholesterol.

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00214-2

Mechanistically, several hypotheses have been to explain the differential effects of cheese and butter on cholesterolemia. One such hypothesis is that calcium – whose concentrations are higher in cheese than in butter – binds to fatty acids in the intestine and forms insoluble soaps, thereby decreasing fat absorption. This hypothesis is corroborated by the higher-fat fecal excretion recorded in the cheese group with respect to the butter one. Also, the higher protein and probiotic content of cheese might theoretically contribute to its almost neutral effect on plasma cholesterol. However, it should be noted that the study by Tholstrup et al. reported a lack of difference in cholesterolemic effect of the diets containing whole milk and butter. In summary, whole milk likely raises LDL-cholesterol concentrations similar to butter, and its use by hypercholesterolemic patients or by individuals with elevated cardiovascular risk should be considered with caution. *Trans*-fatty acids are also a matter of concern in cardiometabolism, and laws are being approved to eliminate them from the diet. However, dairy *trans*-fatty acids might have different physiological actions than the industrial ones. As an example, conjugated linoleic acid is being promoted as healthful even though solid scientific evidence of its putative health effects is lacking. Yet, there are efforts to increase its concentrations in bovine milk.

Two of the most researched issues in cardiometabolism are oxidative stress and inflammation, because they play major roles in the onset and development of the metabolic syndrome (MetS).

Two large studies, that is, the Nurses' Health Study and the Multi-Ethnic Study of Atherosclerosis, reported an inverse association between a prudent diet that included low-fat dairy products and biomarkers of inflammation. In addition, Australian study reported an inverse association between MetS and type II diabetes incidence and dairy consumption in 1807 and 1824 patients, respectively. In particular, those who had the highest consumption level of dairy products witnessed a MetS risk reduction of 59%. A similar association was recorded when the incidence of diabetes was computed. These publications triggered a series of investigations aimed at clarifying mechanisms of actions and whether this association was casual or causal. Zemel et al. supplemented obese patients with skimmed milk for 28 days and recorded a significantly lower oxidative stress and inflammation. In addition, a 12-week diet administered to MetS patients that included 3.5 servings/day of milk and/or yogurt reduced oxidative stress markers after 7 days, as compared with an isocaloric diet that provided 0.5 servings/day of dairy products. After 12 weeks, decreased systemic inflammation was also recorded in the dairy group though not in the control arm.

It is noteworthy that the observed decrease in oxidative stress and inflammation markers was independent of body weight changes and became apparent shortly after the administration of dairy products. This suggests causation and an active role of milk and dairy products in reducing two hallmarks of the MetS.

A recent meta-analysis of eight randomized and controlled studies in overweight or obese subjects concluded that dairy product consumption does not negatively impact on biomarkers of inflammation. Yet, further ad hoc studies on the effects of milk and dairy products on inflammation are warranted before solid conclusions can be drawn.

Cancer

Cancer is the second cause of death in industrialized countries (and in some of them, it is actually number one). Milk and dairy products contain compounds that have suggested, in *in vitro* studies, as chemopreventive. Some epidemiological studies have been carried to ascertain whether milk and dairy product use is associated with cancer incidence. For example, Kampman et al. published an observational study in which 331 men and 350 women have been followed for 4 and 8 years, respectively, and no association between milk and fermented milk consumption and colorectal cancer was found. Other such studies yielded mixed outcomes: some of them found positive associations between dairy use and prostate and ovary cancers, whereas others found the converse when the incidence of colorectal, lung, or breast cancers was evaluated. A very large prospective study by Park et al. analyzed the diets and cancer incidence of 293 907 men and 198 903 women, with a follow-up of 7 years. In this study, calcium and dairy product use was inversely associated with gastrointestinal (GI) (especially colorectal) cancer incidence. In particular, the reduction of GI cancer risk was of 16% for men and of 23% for women. Other cancers were also inversely associated with milk and cheese consumption, namely, those of the head and neck, esophagus, stomach, colon, and bladder. As mentioned, milk contains putatively chemopreventive compounds such as calcium, vitamin D, and conjugated linoleic acid that might explain these observations. *In vitro*, calcium inhibits cell proliferation and stimulates differentiation and apoptosis in the GI tract and in the mammalian gland. As mentioned earlier, calcium also binds to fatty acids and biliary salts in the intestine, therefore lessening their potentially noxious effects on carcinogens the mucosa. Accordingly, two European studies reported an inverse association between milk use and colorectal cancer. In the first one, 45 241 subjects have been followed for 12 years, and their use of yogurt was monitored and plotted against colorectal cancer incidence, showing an inverse association that was stronger in men. A systematic review by Aune et al. took into account 19 cohort studies and reported a significantly inverse association between milk, total dairy products yet not cheese consumption, and colorectal cancer incidence. On the other hand, calcium also interacts with vitamin D and with insulin-like growth factor-1, which would increase prostate cancer risk, as shown by Park et al.

Concerning breast cancer incidence, one report by Knekt et al. found a significantly inverse association between milk use and breast cancer incidence in 4697 Finnish women. Shin et al. also published a cohort study, in which they did not find any association between dairy, calcium, or vitamin D consumption and breast cancer incidence in postmenopausal women. Conversely, in premenopausal women, a significant reduction of breast cancer risk as associated with low-fat dairy products was reported, suggesting that hormonal status might modulate the effects of milk and its derivatives on breast cancer, via unknown mechanisms. A large meta-analysis of more than

20 studies did not find any association between breast cancer incidence and dairy product use. These results have been subsequently confirmed. Conversely, Dong et al. performed a meta-analysis on 1 063 471 participants in 18 prospective cohort studies and reported an inverse association between dairy – though not milk – use and breast cancer, notably in premenopausal women and when low-fat products were separately computed. In summary, based on accumulated data, there is currently no indication that milk and dairy use favors or contrasts the incidence of breast cancer.

The association between milk use and bladder cancer incidence has also been analyzed. One meta-analysis by Mao et al. reported that high milk consumption was associated with a 16% reduction of bladder cancer risk; this inverse association was stronger in Asian subjects than in North American and was not found in Europeans. Also, the association depended upon the kind of dairy product that was analyzed. Another meta-analysis did not find any correlation among variables, after computing 14 studies on milk (4879 cases of bladder cancer) and six studies on dairy products (3087 cases), for a total of 324 241 subjects.

When other cancers, including lung, ovary, esophagus and stomach, and oropharyngeal cancers, are taken into account, no clear association between milk consumption and incidence emerges. Conversely, positive associations between dairy use and prostate cancers have been published and several mechanisms of action have been proposed to explain this hypothetical effect.

Milk as a Vehicle for Bioactive Molecules

Fat is found in milk in extremely small micelles: the average diameter of the fat globules in homogenized bovine milk is 1–3 μm; estimations indicate that 1 g of fat in milk is dispersed in 10^{10-12} micelles, that is, a very wide surface of about one square meter. Therefore, it is conceivable that lipid-soluble compounds, such as added fatty acids, liposoluble bioactive molecules, and vitamin E, are highly bioavailable when ingested with milk (Figure 1). In addition to exogenous compounds (which render some milks functional foods), milk naturally contains biologically active molecules. One example is that of oligosaccharides, which are not metabolized along human GI tract, so they reach the colon intact where they serve as specific nutrients for probiotic strains. Even though bovine milk contains only trace amounts of these potentially healthful molecules, some researchers are working toward introducing human milk oligosaccharides in that of transgenic animals. One current issue is the lack of suitable commercial standards for bovine oligosaccharides; consequently, we can only identify approximately 70 fully annotated oligosaccharides in human milk and approximately 40 in bovine milk. It is noteworthy that human milk is rich in oligosaccharides, which have been proposed as important contributors to child development, largely because they are prebiotics and help in creating a healthy microbiota. Indeed, neutral oligosaccharides – namely, the monomer *N*-acetylglucosamine and fucose – are essential to the development of the correct microbiota of breast-fed neonates, because of their immunomodulating actions. Also, acidic oligosaccharides (where the monomer is sialic acid) help in preventing the adhesion of pathogens to the intestinal mucosa. Interestingly, bovine milk also contains these oligosaccharides, which are abundant in colostrum. Fruits and vegetables also contain oligosaccharides and some of them have been synthesized; yet, those from milk are peculiar in that they exhibit a branched rather than linear structure. Moreover, they contain fucose and sialic acid, which are almost absent in other oligosaccharides. This structural difference might confirm milk oligosaccharide activities that are different than those of synthetic or vegetal origin. It must be underscored that the concentration of oligosaccharides in bovine milk decreases in a time-dependent fashion: ad hoc investigations are being carried out to stabilize oligosaccharides in milk or to formulate them as nutraceuticals or as probiotic components of functional foods.

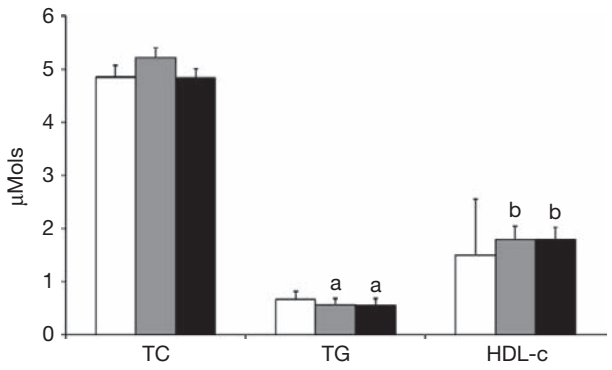

Figure 1 Milk is an efficient vehicle for omega 3 fatty acid administration. In addition to high bioavailability of added fatty acids (and, in this case, of vitamin E), this functional food improves lipid surrogate markers of cardiovascular disease. Values are the means ± SD. T_0, initial values; T_3, after 3 weeks of treatment; T_6, after 6 weeks of treatment. Values marked with letters are statistically different from those at T_0 as follows: $^{a}p < 0.05$; $^{b}p < 0.005$. Data are from Visioli et al. (2000), where full details of the study are provided.

In terms of dairy products, it is noteworthy that some kinds of cheeses, namely, those infected with *Penicillium* such as Roquefort, Stilton, and Gorgonzola, contain high amounts of andrastins A–D, which – *in vitro* – are potent inhibitors of farnesyltransferase, a key enzyme in cholesterol synthesis. Other peptides formed during ripening-induced proteolysis might further contribute healthful – albeit as yet unexplored – properties that would partially explain the paradoxically relatively low incidence of cardiovascular disease (CVD) in high-cheese-use countries.

The rapidly growing market of functional foods indicates milk as a suitable vehicle for bioactive compounds: as mentioned, milk is an excellent vehicle for fat-soluble molecules. Indeed, milk and some dairy products such as yogurt provide an excellent matrix for the administration of bioactive molecules, for example, phytosterols, and are being marketed to target population groups, pending appropriate regulatory evaluation. Nowadays, any supermarket exhibits a large number of fortified milks and dairy products, some of which do indeed contribute to well-being.

In summary, either fortified or 'natural' milk and dairy products contain several compounds – even though often present in low concentrations – that might in the future be exploited for pharmanutrition applications.

Conclusions

While milk and dairy products are often regarded as double-edged sword because of their high saturated fat content and abundance of important micro- and macronutrients, accumulated evidence suggests that their use within the frame of a balanced diet might be advantageous from a health viewpoint. It is also worth reminding that milk and dairy products account for a substantial proportion of calories and macro- and micronutrients in several populations worldwide. Therefore, their nutritional value is quantitatively relevant on a global scale.

Of course, subjects with cardiometabolic disturbances should consume dairy products in moderation and should discuss their use with their physician/nutritionist. Even though it is difficult to single out the health contribution of a particular food item, future studies might further elucidate the role of milk and dairy products in human health and disease.

Date Palm: A Wealth of Healthy Food

KM Farag, Damanhour University, Damanhour, Egypt

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Date is one of the healthiest foods in the world. It has been part of the people's life in the desert and a way of surviving arid conditions. Although about three-fourths or more of the fruit consists of sugars, there are many other nutritious components such as minerals, vitamins, antioxidants, and dietary fibers. The diversity of date palm cultivars, species, and clones adds to the wealth of this tree. The different date fruit types, whether soft, semidry, or dry, provide consumers with many choices and the ability to grow palm trees in a variety of climates. Even the edibility of the fruit varies from those that could be consumed at full coloration, as a mature fruit, called the bisr or khalal stage, to others that must be converted to the rutab stage or the ripe fruits. The mature fruit could be yellow or red (rarely orange) but not necessarily free of soluble tannins while the ripe fruit is full of phenols and tannins in a polymerized form with a consumable taste. However, the initiation of ripening means the initiation of rutab development, and the fruit becomes soft and edible. Firm texture of the rutab fruits could be maintained by applying the polyamine putrescine. The predominant sugar in dry dates is sucrose because the invertase enzymatic activity is low due to low water or high temperature stress that inhibits such activity. It was found that when a reduced rate of gain in fresh weight and volume occurs, a decrease in the rate of gain in reducing sugars and a rapid increase in accumulation of sucrose and total sugars take place. Thus, sucrose accumulation starts late in the season when the weather is usually hot, and the rate of sucrose inversion to reducing sugars at this stage varies in different date cultivars. The predominant sugars in soft dates are glucose and fructose as in Zaghloul and Barhee dates.

Description of Dates

Date palm tree is a dioecious plant where male and female flowers are born on separate palms. The tree has only one point of vegetative growth represented in the apical meristem. Date palm cultivars have specific leaf morphology whether in the distribution of leaflets (pinnae) or their angle in the three dimensions. The fruit is a berry that develops from one of three carpels found in each of the pistillate flowers. Fruit shape is usually more or less oblong or ellipsoidal. The seed is bony called the pit and about three times as long as it is wide, and it contains mainly cellulose. Female trees need artificial pollination to obtain a fair fruit set. Variations in pollen source could affect some fruit characteristics outside the embryo and the endosperm such as fruit length and size, the pulp to pit ratio, color intensity, and even the time of ripening in marginal-production areas. This has been known as the metaxenic effect of pollen grains. When pollination is prevented or when fertilization fails, all or one of the three carpels of the pistillate flowers will develop into a parthenocarpic fruit. These are called parthenocarpic single or triplets, respectively. The parthenocarpic triplets are hollow, whereas the parthenocarpic singles contain quasi-degenerated seeds. Both types of parthenocarpic fruits are found in different cultivars at various ratios, especially when failure occurs in pollination and fertilization. Data on parthenocarpic fruits showed the same pattern of growth, though at a different rate. They change their color at the same time as seed-bearing fruits but do not reach maturation, if at all, at the same time.

It was reported that the date fruit has five phases that can be distinguished. The Arabic terms for these different stages have been used in the literature. The hababouk stage of slow growth rate begins from fruit set and continues 4–5 weeks. In this time, the content of moisture in the fruit is 85–90%. This stage is followed by a rapid increase in fruit weight ranging from 6 to 10 weeks (the kimri stage), then a declining rate of growth (the depression phase of the kimri stage) until reaching to the bisr or khalal stage, which is fruit coloration. Fruit skin is relatively thin at the early stages of hababouk and kimri, which could not resist the exerted water pressure leading to cracking. Similarly, the fruit tip at the initiation of the khalal stage could crack due to the increase in water absorption while there is a reduced rate of water loss because the relative humidity is high. That is one of the factors that creates a driving force for water loss.

During the khalal stage, the fruit starts to turn from green to yellow (or red), weight gain is slow, but sucrose content increases while moisture goes down to 50–55%. In some cultivars such as Barhee and Zaghloul, tannins start to precipitate and lose their astringency. The khalal stage could be extended by applying a calcium formulation after harvest and modifying the method of packaging. During the fourth stage, namely the rutab stage, dates become half ripe and soft and turn to light brown color while the sucrose turns to invert sugars. Fruit moisture is about 35–40%, whereas the astringent taste disappear. Finally, during the tamr stage, dates become semidry or dry contain about 50% sucrose (or higher if temperature is high and water content is low). Usually the fruit moisture ranges between 20% and 25%.

Types of Cultivars

Dates can be marketed in three types, namely, soft dates, semidry, or dry. The division is based on the texture, water content, appearance, and their heat summation units. Soft dates are distinguished by their soft flesh, high moisture content (more than 30% reaching to 70%), and high sugar content, especially glucose and fructose. Examples of soft dates are Barhee, Halawy, Hayany, Zaghloul, and Samany. Semidry dates have a relatively firm flesh, fairly low moisture (20–30%), and high sugar content especially reducing and sucrose in similar amounts ranging from 35% to 37%. This

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00215-4

type includes Sewi, Al-Amry, Al-Ajlani, Dayri, and Khadrawi. Furthermore, dry dates have a hard texture, low water content (< 20%), and great sugar content, especially sucrose. Examples are Zahdi, Sayer, and Sackouttti. Moreover, soft dates could be edible at the khalal (fully colored) or at the initiation of the rutab stage depending on their soluble tannins content at this stage because they have to lose their astringent taste. It is suggested that the rate at which soluble tannins are converted to insoluble tannins varies within cultivars, making some of them edible as fresh juicy dates. Brownish color at the rutab stage is ascribed to date phenolase that works on substances such as catechin or the dactylifric acids. Furthermore, heat requirements vary among date cultivars. Soft dates require relatively lower summation of heat units as compared with semidry and dry heat. These requirements are calculated from full bloom to maturity and estimated to be 2500, above 2500–3150, and above 3150–6000 heat units for soft, semidry, and dry dates, respectively.

Production of Different Areas

In history date palm cultivation has been extending along desert areas and around the rivers. The tree favors high temperature and sunshine. Thus, date palm trees are confined to arid and semiarid regions. No wonder that date palm figures were part of ancient history and civilizations. It is reported that date palm is currently grown for fruit production used for local consumption or trade in 37 countries around the world, in addition to few other countries growing the crop on small areas. Almost all parts of the tree have been beneficial whether as an energy source or providing shade and shelter against the harsh conditions in the desert regions. Many traditional by-products have been made ranging from hand fans to furniture. According to FAO (2011), Table 1 illustrates the production areas of date palm in the leading countries.

The data in Table 1 indicated that the greatest production of dates is in United Arab Emirates even though there are much larger areas grown with date palm in other major producing countries such Saudi Arabia, Iraq, and Iran.

Date palm germplasms may exceed 5000 cultivars and clones. Most clones are less productive and susceptible to diseases than known-commercial cultivars. Many threatened clones and cultivars are subjected to extinction due to the spread of Fusarium fungi in Morocco, Tunisia, and Algeria. This is why there has been a narrow genetic diversity in these regions such as Deglet Noor in Tunisia and Algeria, although it represents over 65% of the total population, and Boufeggous-O-Moussa and Jihal in Morocco.

Table 1 Cultivated area and the total production of date palm in the leading countries

	2011 Data	
Countries	*Cultivated area (ha)*	*Total production (tons)*
Egypt	41 652	1373 570
Iran	154 274	1 016 608
Iraq	123 230	619 182
Saudi Arabia	172 297	1122 822
Oman	31 348	268 011
Morocco	70 433	117 867
Tunisia	51 000 (Feddans)	180 000
The United States	3399	30 209
United Arab Emirates	41 159	2 391 643

Source: *FAO statistics handbook* (2011). Date Palm Statistics.

The cultivated area has increased by 0.3 million hectares over the previous decade. The largest date palm areas are located in the Asian continent, which include the Middle Eastern producing countries, followed by Africa, North whereas in the Americas and Europe, the production of date palm covers only a few thousands hectares. The date crop has been also established in California, Arizona, and Mexico. The common required temperature is 35 °C necessary for an optimum development of pollen and low relative humidity for fruit setting and ripening. Date palm trees grow in nearly rainless regions at 9–39 O North latitude, which are represented by the Saharan and Southern fringe of the Near East.

The increase in relative humidity around the bunches causes some physiological disorders such as checking at the early kimri stage or black nose by reaching to initiation of maturity (the khalal stage). In both disorders, the rate of water absorption is greater than its loss from the fruit, which creates a pressure on fruit skin, resulting in surface cracking.

With regard to the distribution of date palm, this crop cultivation is spreading in both the old world (Near East, North Africa, Spain) and the new world (Australia and the American continent), where dates are grown and consumed in large quantities.

The distribution of date palm according to the latitude for both Northern and Southern Hemispheres is between 10° N (Somalia) and 39° N (Elche/Spain or Turkmenistan). Favorable areas are located between 24 and 34 (Morocco, Algeria, Tunisia, Libya, Egypt, Iraq, and Iran). In the United States, date palms are found between 33 and 35° N. Because of the climatic factors, the date palm will grow but will not fruit properly outside these defined geographical limits. Altitude is very important because it imposes the availability of water and the temperature limits that largely determine the distribution of date palm in the world. Date palm grows well from 392 m below sea level to 1500 m above with an altitude range of 1892 m.

Consumption of Dates as a Food

Dates have been the essential food in many regions around the world, especially arid zones of the old world and part of the diet all year-round. Even in the new world and Europe, date fruits have attracted the attention of the public and sport dieticians due to the high glucose and fructose content in semidry and soft dates. It was reported that one pound of dates (453 g) supplies the human body with 5.33 kJ of physiological energy.

A comparison was made to show the relative value of four types of food (cow's milk, meat, honey, and orange juice) against date fruits. The comparison showed that protein content in dates was very close to that of cow's milk, but greater than that found in honey or fresh orange juice. Meanwhile, the

date fruits were superior to all the other four types of food in potassium. Furthermore, calcium in dates was three times greater than that found in cow's meat and 15 times greater than that in honey while about half of the calcium content in the cow's milk. Moreover, phosphorus content in 100 g of dates was about two-thirds of that found in cow's milk but three times more than that found in honey. Iron, on the other hand, is much more in date fruits when compared with cow's milk, honey, or orange juice. Iodine content, as an essential element for the gland activity, in dates is equal to that found in honey or fresh orange juice. Moreover, sodium, as an important element required for water balance in the human body and that affects muscles and the nervous system, is contained in dates in smaller amounts than that found in cow's milk or meat but greater than that found in honey or fresh orange juice. Even carotenes in dates are much greater than that found in cow's milk or orange juice. These carotenes are important antioxidants for providing protection against cancer.

Dates are also an excellent source for carbohydrates, proteins, fats, dietary fibers, essential minerals, and vitamins. Edible dates have been classified into four stages termed kimri, khalal (bisr), rutab, and tamr.

These represent the astringent green, mature full-colored, soft brown, and hard raisin-like stages of development, respectively. For human consumption, in general, dates become edible at the khalal stage where the fruit color changes to a yellow or red tone, depending on the cultivar, over a period of 3–5 weeks. Fruits are rarely orange in color at the khalal stage. Few date cultivars could be consumed at the khalal stage such as Zaghloul, Samany, and Barhee because they are not astringent at this stage, and soluble tannins do not represent a problem. However, many date cultivars and clones, especially in the Arabian Peninsula need to initiate the rutab stage to get rid of the astringent taste. At the rutab stage, dates begin to soften in about a 2–4 week period due to an increased loss of moisture content and an increase in enzymatic activity of some cell wall hydrolyses such as pectinase and polygalacturonase. The conversion to the rutab stage in some cultivars is required to obtain the insoluble form of tannins. During ripening (rutab development) there is a sharp reduction in both the amount and concentration of soluble tannins indicating the possibility of ceasing their accumulation together with breakdown and/or a conversion into insoluble form during development and ripening. It was also reported that soluble tannins are polymerized when converted to the insoluble form and lose their ability to compete or bind to the binding sites of ethylene. Date fruits are also heavily consumed at the tamr stage whether semidry or dry. Dates are drier and rather firm in texture at this stage, and their color turns to a darker tone. The lower water content of dates at the tamr stage enhances their storability and shelf life. Dates, however, continue to ripen after harvest, exhibiting a characteristic respiratory rise before ripening preceded by a spike in ethylene production, which accelerates the process. The most important category of accumulated proteins involved in membrane and cell wall degradation are polygalacturonase and pectinesterases that ensure the softening of the fruit. There are also some other proteins that are responsible for the pigment degradation and color change during various stages from kimri to the tamr stages. Thus, physiological changes that occur in dates during ripening begin with the recognition of external signals, including ethylene spike that occurs before the respiratory rise.

Nutritional Value of Dates

The high content of carbohydrates in date fruit, especially sugars that reach to 88%, may lead to the impression that little is left to contribute to the nutritional value of dates. However, the fruit is full of essential nutrients such as potassium, phosphorus, sodium, zinc, manganese, magnesium, copper, iron, fluorine, and selenium. Dates are a great source of potassium that helps in the maintenance of a healthy nervous system and in balancing the body's nervous system. Phosphorus functions with calcium to help with bone strength and growth. Moreover, selenium is important for cell growth and repair. Iron is essential to production of red blood cells, which carry all the nutrients to cells throughout the body. As an example, the macro- and microelements of the two well-known cultivars, Hallawi and Zahdi, were reported (on a dry weight basis) in Table 2.

The amount of sodium in dates is low but ideal when looking at the recommended amount per day for an individual (more than 2.4–2.0 mg day^{-1}). Consuming too much sodium may increase the risk of heart disease and hypertension. Thus, dates are perfect for a healthy lifestyle because they contain reducing sugars, low sodium, no fats or cholesterol, great potassium, and calcium contents in addition to dietary fibers. The dietary fiber content of widely retailed dates was estimated at 4.4% with 3.2% insoluble and 1.2% soluble. Others reported a greater percentage of dietary fibers ranging from 6.4% to 11.5%. Variations were reported to be dependent on

the stage of ripeness. Six to seven dates, approximately 100 g, consumed daily by an adult would provide 50–100% of the recommended daily fibers uptake. Thus, dates proved to be a better snack than others containing artificial preservatives. Fluorine in dates proved to be essential to protect against tooth decay. It is even added to toothpaste, whereas selenium plays an important role in protecting against cancer and stimulating the immune system.

Dates are very rich in carbohydrates, especially sugars such as fructose, glucose, mannose, maltose, and other nonreducing sugars such as sucrose. The percentage of the reducing sugars, namely glucose and fructose, depend on the type of dates (dry, semidry, or soft) and on the cultivar. In Deglet Noor, for example, the predominant sugar was sucrose, whereas in Allig it was reduced sugars, the more abundant sugar. This trend was early reported because it was shown that rutab dates had much less sucrose than reduced sugars. This difference was ascribed to the potential presence of high invertase activity in Allig dates. A similar trend of sugars was reported for Zaghloul, Ajlany, and Sakoutti as soft, semidry, and dry dates, respectively (Table 3).

The high increase in sugars reflects on the energy produced by 1 kg of apricot, banana, orange, and dates to be 520, 970, 480, and more than 3000 calories, respectively. Meanwhile, 1 kg of cooked rice, wheat flour, or meat (without fats) produces 1800, 2295, and 2245 calories, respectively.

Dates are also rich in many vitamins such as B-carotene (vitamin A), thiamine (B_1) and riboflavin (B_2). The contents, however, vary with the cultivar and the stage of ripeness. For example, vitamin C content (ascorbic acid) in rutab dates is greater than dry dates. Ripe fruits were reported to contain a substantial amount of carotenoids including lutin and various forms of β-carotene with the total content of carotenoids decreasing toward the final ripening stages and in storage. Furthermore, dates contain a moderate amount of folic acid. Table 4 reports vitamin contents of two date cultivars on a dry weight basis, namely Hallawi and Zahdi.

With regard to phenolic compounds in dates, it was found that dates contain a number of phenolics such as phenolic acids, hydroxycinnamates and flavonoids including tannins. These compounds are beneficial for human health as antioxidants and maintaining a specific cellular homeostasis. Phenolics have also been considered a defense mechanism against pathogens.

Concerning dietary fibers in dates, it was reported that six to seven dates (about 100 g) consumed daily by an adult would provide 50–100% of the recommended daily need.

Seeds of date also contain beneficial constituents that could be utilized for animal feeding. They contain carbohydrates (62.5%), fibers (16.2%), oils (8.5%), proteins (5.2%), ash (1.1%), and moisture (6.5%). Date seeds also represent a source of sterols and alkali-soluble polysaccharide. The seeds yield a yellow green moisturizing oil rich in essential fatty acids such as lauric (8%), myristic (4%), palmitic (25%), stearic (10%), oleic (45%), and linoleic (10%) as well as traces of caprylic and capric acids, suitable for use in soap and cosmetic products.

The health benefit of dates is a relatively new important aspect of date palm. It was found that alterations induced by cerebral ischemia were significantly attenuated by 15 days of pretreatment with methanolic extract of date fruits (100 and 300 mg kg^{-1}), whereas a 30 mg kg^{-1} dose was insignificant in this regard. These results suggested the possible use of dates against bilateral common carotid artery occlusion induced oxidative stress and neuronal damage. In another recent study they investigated the role of date Palm fruit extract in protection against oxidative damage and hepatotoxicity induced by subchronic exposure to dimethoate (20 mg $kg^{-1}day^{-1}$) in rat liver. Such chemical induces an excessive production of free radicals that are responsible for several cell alterations in the organism. The study provided evidence that pretreatment with date palm extract restored the liver damage induced by dimethoate as revealed by inhibition of hepatic lipid peroxidation and prevention of oxidative stress induced hepatotoxicity. Moreover, another important beneficial health aspect of date palm extract was found with rat experiments where such extract was able to significantly reduce the frequency of defecation and decreased gastrointestinal motility. It was concluded that date palm extract may contain some pharmacologically active substances with antidiarrheal properties.

Epidemiology and Global Burden of Diarrhea

The WHO defines diarrhea as the passage of three or more loose or liquid stools per day, or more frequently than is normal for the individual. Diarrhea is the leading cause of mortality among children under 5 years of age accounting for one in ten child deaths worldwide annually. It disproportionally affects young children in low- and middle-income countries (Figure 1). In 2010, there were 1.731 billion episodes of diarrhea (36 million of which progressed to severe episodes) and in 2011, an estimated 700 000 deaths were due to diarrhea. Incidence and mortality from diarrhea and pneumonia vary by age (Figure 2) with the burden of disease mainly concentrated in the younger age groups. The epidemiology of childhood diarrhea and pneumonia overlap, likely because of shared risk factors, such as undernutrition, suboptimum breastfeeding, and zinc deficiency. Children are at the highest risk during the first 2 years of life, with 72% of deaths being secondary to diarrhea. Diarrheal mortality rates are declining by about 4% annually with disease incidence decreasing from an estimated 3.4 episodes/child-year in 1990 to 2.9 episodes/child-year in 2010. The highest burden of disease has remained consistent with respect to age in the 6–11-month-old age group having the highest incidence. The burden of mortality due to diarrhea in children less than 5 years of age in 2010 was highest in the WHO regions of Africa and Southeast Asia. It is estimated that a third of severe diarrhea episodes is preventable by vaccination (i.e., against rotavirus and cholera). Furthermore, under nutrition is a key underlying risk factor for morbidity and mortality associated with both diarrhea and pneumonia. Diarrhea disease severity in children under-five is mostly mild (~65% cases for which no care was sought/no dehydration) lasting about 4 days or moderate (~35% cases for which care was sought/any dehydration on presentation) with only 0.5% of cases being severe (cases for which care was sought, with severe dehydration on presentation) and lasting 8 days. Older children and adults have predominantly mild episodes (95%) with 4.95% being moderate and 0.05% being severe. Among individuals 16 years or older, severe episodes typically last ~3 days and cause dehydration in ~93% of cases.

Morbidity and Risk Factors for Diarrhea

Despite reduction of diarrheal mortality by use of oral rehydration therapy, persistent global burden of enteric infections results in high morbidity of up to 43% of stunted growth, affecting one-fifth of children worldwide and one-third of children in developing countries. Children suffering from diarrhea during the first 2 years of life might have on average an 8 cm growth shortfall and 10 IQ point decrement by the time they are 7–9 years old. The proposed link between enteric infections and child growth and development is a double burden of enteric infections and malnutrition, and the potential link of both of these factors to obesity later in life is an interrelated 'triple burden' (Figure 3). Important risk factors for diarrhea include lack of exclusive breastfeeding in infants younger than 6 months, undernutrition and zinc deficiency. While evidence suggests that vitamin A deficiency increases the risk of severe diarrhea, it is not an important risk factor for the incidence of diarrhea. Associations of specific water and sanitation risk factors (i.e., unwashed hands and poor water quality) with diarrhea morbidity and mortality have been shown. However, for some outcomes such as inappropriate excreta disposal, poor availability of evidence permits only rough estimates of risk. In a stratified subgroup of infants aged less than 6 months, acute lower-respiratory-tract infections are a risk factor for diarrhea. Measles is an established risk factor for diarrhea. A study from the 1980s showed that with moderate coverage of the measles vaccine (45–90%) in infants, the incidence of diarrhea could be reduced by 0.6–3.8%, and diarrhea mortality reduced by 6–26% in children younger than 5 years. Table 1 shows the effect sizes for specific confirmed biological risk factors for diarrhea.

Diarrhea Classification and Pathophysiology

Diarrhea can be classified based on duration as prolonged/acute (1–13 days) and persistent (14 days or more). Prolonged diarrhea can further be classified as prolonged/acute watery diarrhea which is loose or watery stools at least three times in a 24 h period or prolonged/acute invasive diarrhea which is gross blood (by history or inspection) in the stool of less than 14 days duration, typically accompanied by fever. Diarrhea can be secondary to one or more of the following pathophysiological processes: secretory, osmotic and inflammatory diarrhea. *Secretory diarrhea* occurs when there is a significant increase in the volume of intestinal fluid output which exceeds the reabsorptive ability of the gastrointestinal epithelium. Research initially done in patients with cholera revealed that while the secretory diarrhea in cholera does lead to significant fecal water and electrolytes loss, the gut still retains the ability to reabsorb water and electrolytes due to an intact Na-coupled solute cotransport mechanism. Chloride-mediated secretion is stimulated by second messengers in diarrheal infections secondary to *Vibrio cholerae* 01 and 139, Shigella, Salmonella, *Escherichia coli* strains and other bacterial pathogens who produce enterocyte receptor binding pathogens, causing chloride-mediated secretion stimulated by second messengers (e.g., cAMP, cGMP, and calcium). It is important to recognize that there may be a combination of osmotic and secretory diarrhea such as in the case of Rotavirus where there enterotoxin mediated secretory diarrhea along with osmotic diarrhea secondary to enterocyte

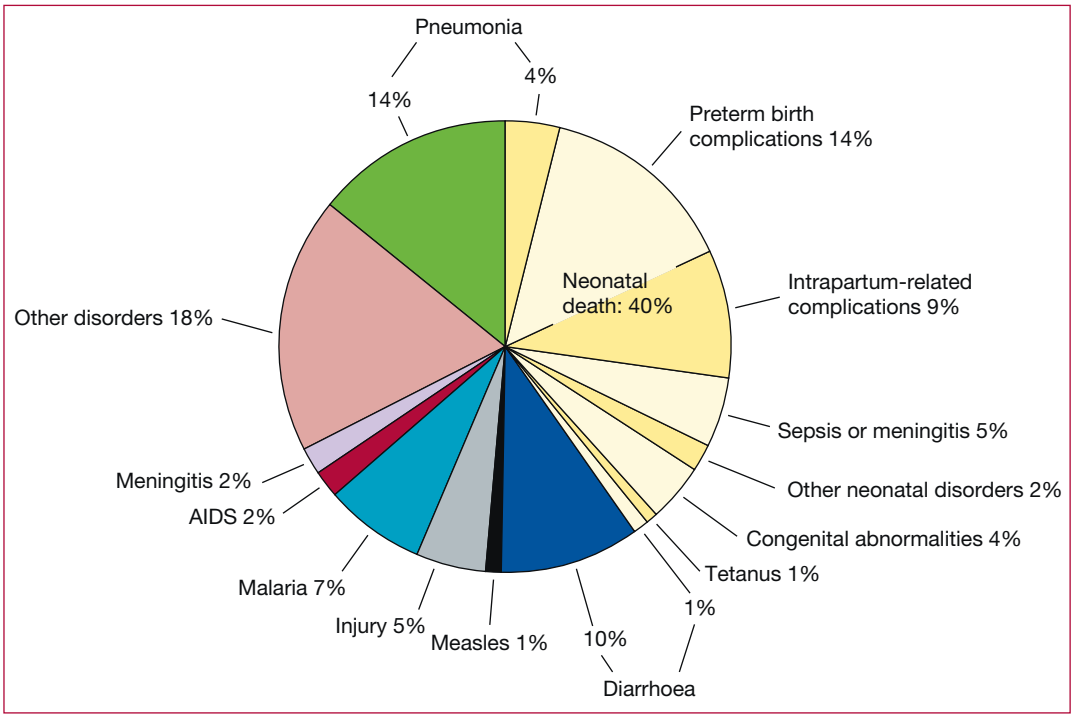

Figure 1 Global causes of childhood deaths in 2010, diarrhea kills 2195 children daily – more than malaria, measles, and AIDS combined. (Note – new figures show that neonatal component may be 44%). Reproduced from Liu, L., Johnson, H.L., Cousens, S., et al. (2012). Global, regional, and national causes of child mortality: an updated systematic analysis for 2010 with time trends since 2000. *Lancet* **379**(9832), 2151–2161.

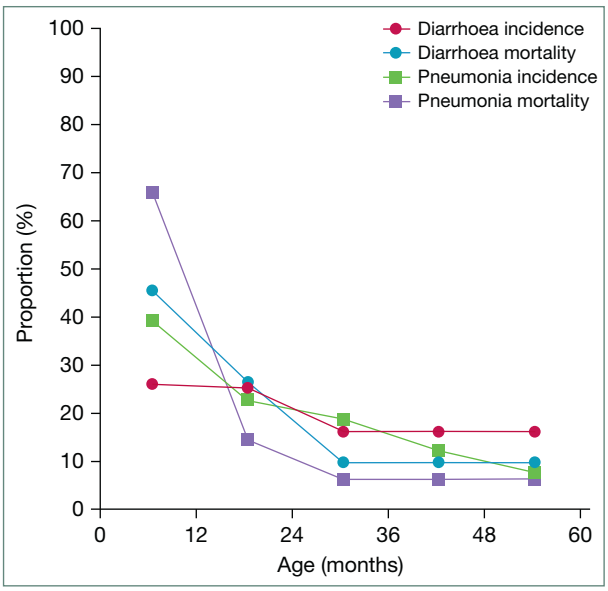

Figure 2 Distribution of cases of and deaths from diarrhea and pneumonia in children aged 0–4 years. Reproduced from Walker, C.L., Rudan, I., Liu, L., et al. (2013). Global burden of childhood pneumonia and diarrhoea. *Lancet* **381**(9875), 1405–1416.

damage. Phosphorylation-induced activation (by increase in cAMP, cGMP, or calcium) of these channels can be set off by exogenous or endogenous substances. Exogenous mediators include bacterial toxins such as cholera or shiga toxins, or parasites. Endogenous mediators can be endocrine, such as vasoactive intestinal peptide or serotonin, or released by the immune system, such as histamine, serotonin, prostaglandins, or interleukin-1. Lastly, increased intestinal permeability due to loss of cellular tight junctions can lead to increased intestinal fluid loss (Figure 4).

Poorly absorbed osmotically active substances in the gut lumen retain fluid, pull water and secondarily ions to maintain osmotic equilibrium with body fluids – this is the key underlying process behind *osmotic diarrhea*. This can occur secondary to an absorptive defect or enzyme deficiency from pancreas or intestinal wall causing maldigestion and/or malabsorption. An osmotic gradient is created that can only be neutralized by maintaining excessive amounts of water within the intestine. Examples include, malabsorption with congenital or acquired lactase deficiency, gluten-sensitive enteropathy (celiac disease) and maldigestion, as seen in pancreatic insufficiency (Figure 5).

Gastrointestinal barrier disruption by bacteria (Salmonella, *E. coli*, Campylobacter), viruses (rotaviruses, coronaviruses), and protozoa (Cryptosporium, Giardia) in addition to idiopathic inflammatory bowel diseases are common causes of *inflammatory* diarrhea. Immune cells after activation release inflammatory mediators and cytokines which stimulate secretion and activate enteric nerves. Subepithelial myofibroblasts destroy the basement membrane by metalloproteinases, damaged enterocytes are extruded, and villous atrophy develops followed by regenerative crypt hyperplasia in the small intestine and colon. These surfaces are covered with immature enterocytes that typically are deficient in the brush border enzymes and transporters necessary for absorption of nutrients and water.

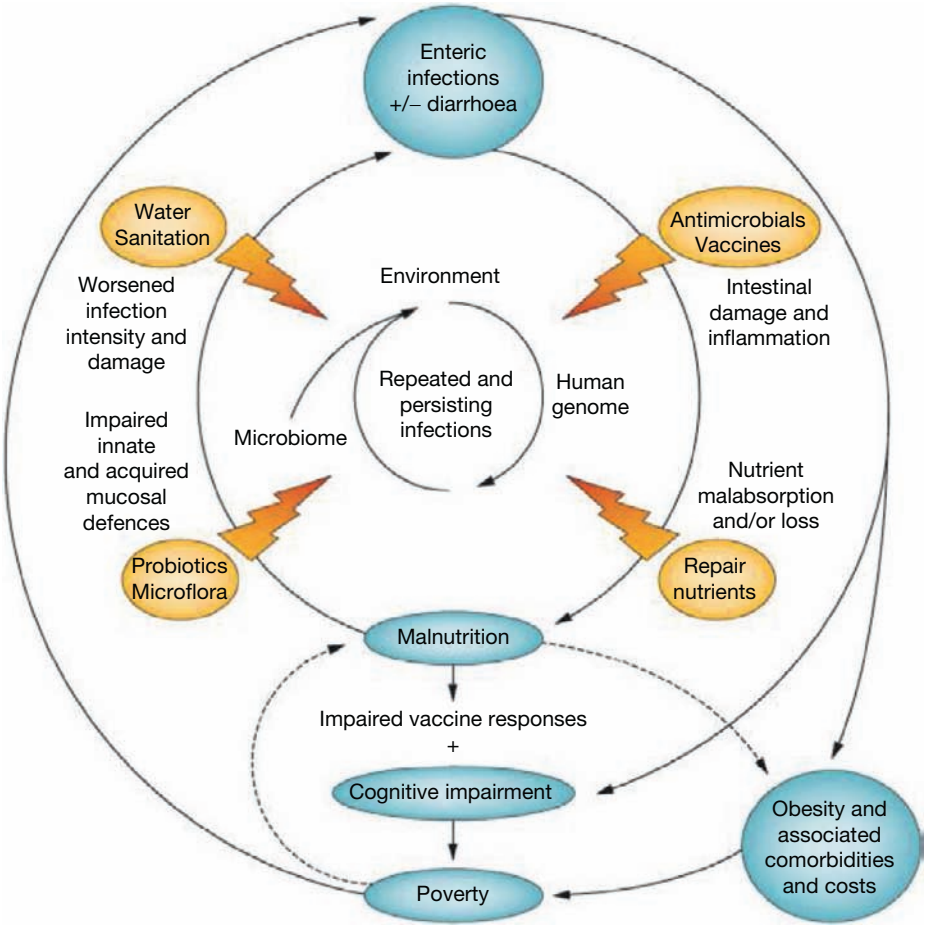

Figure 3 The vicious cycles of diseases of poverty. Enteric infections, especially in the first 2–3 years of life, with or without overt diarrhea, can predispose an individual to malnutrition and stunted growth through multiple mechanisms. Stunting by 2 years of age, in turn, is associated with impaired cognitive development that extends into later childhood and even adulthood and adult productivity. In addition, malnourished children experience both greater frequency and duration of diarrheal illnesses, and, documented in animal models, heavier infections. The latter is documented with Cryptosporidium and with enteroaggregative *E. coli*. Finally, enteric infections or stunting can predispose to obesity and its comorbidities of diabetes, hypertension, cardiovascular disease, metabolic syndrome and burgeoning healthcare expenditures, contributing to individual and societal poverty in vicious cycles. Reproduced from Guerrant, R.L., DeBoer, M.D., Moore, S.R., Scharf, R.J., and Lima, A.A. (2013). The impoverished gut – a triple burden of diarrhoea, stunting and chronic disease. *Nature Reviews Gastroenterology & Hepatology* **10**(4), 220–229.

Etiology of Diarrhea

Major etiologies for prolonged/acute and persistent diarrhea are outlined in Table 2. The most predominant cause of diarrhea in developing countries is infectious (viral, bacterial, parasitic). A systematic review of articles published between 1990 and 2011 reporting etiological agents causing diarrhea in hospitalized children less than 5 years of age showed that rotavirus, calicivirus, enteropathogenic, and enterotoxigenic *E. coli* cause more than half of all diarrheal deaths in this age group globally. A recent 3-year prospective study in four sites in Africa (the Gambia, Mali, Mozambique, Kenya) and three in Asia (India, Bangladesh, Pakistan) showed the most attributable cases of moderate to severe diarrhea in children aged 0–59 months was secondary to infection with rotavirus, Shigella, ST-ETEC, cryptosporidium, and enteropathogenic *E. coli*. Table 3 shows a comparison of viral, bacterial, and parasitic etiologic agents of diarrhea in developing countries and the United States. There is a seasonality in the transmission patterns of infectious agents in developing countries with bacterial diarrheas peaking in the hot months and viral diarrheas typically occurring throughout the year with some peaking in the cooler months. More than one pathogenic agent can exist with 11% (in community studies) and 12% (in hospital based studies) of diarrhea cases documented as having two or more enteric pathogens. Transmission of infectious agents causing diarrhea is primarily 'fecal–oral' in the setting of poor hand washing hygiene, unsanitary water and dirty food preparation. The dose of infectious agent required to cause diarrhea also matters with low infectious dose (e.g., shigella, giardia, rotavirus, cryptosporidium) can be transmitted by person-to-person contact and high infectious dose (e.g., salmonella, *E. coli*, vibrios) usually transmitted by water or food.

Table 1 Risk factors with direct biological links to diarrhea

	Morbidity	*Mortality*
Not exclusively breastfeeding (0–5 months; vs. exclusive breastfeeding)		
Partially breastfed	RR 1.7 (95% CI 1.0–2.8)[a]	RR 4.6 (95% CI 1.8–11.8)[a]
Not breastfed	RR 2.7 (95% CI 1.7–4.1)[a]	RR 10.5 (95% CI 2.8–39.6)[a]
No breastfeeding (6–23 months; vs. receives any breast milk)	RR 1.3 (95% CI 1.1–1.6)[b]	RR 2.2 (95% CI 1.1–4.2)[a]
Underweight (vs. >−2 WAZ for morbidity and >−1 WAZ for mortality)		
−2 to <−1 WAZ	–	OR 2.1 (95% CI 1.6–2.7)[c]
−3 to <−2 WAZ	RR 1.2 (95% CI 1.1–1.4)[d]	OR 3.4 (95% CI 2.7–4.4)[c]
Less than <−3 WAZ	–	OR 9.5 (95% CI 5.5–16.5)[c]
Stunting (vs. >−1 HAZ)		
−2 to <−1 HAZ	–	OR 1.2 (95% CI 0.9–1.7)[c]
−3 to <−2 HAZ	–	OR 1.6 (95% CI 1.1–2.5)[c]
<−3 HAZ	–	OR 4.6 (95% CI 2.7–8.1)[c]
Wasting[c] (vs. >−WHZ)		
−2 to <−1 WHZ	–	OR 1.2 (95% CI 0.7–1.9)[c]
−3 to <−2 WHZ	–	OR 2.9 (95% CI 1.8–4.5)[c]
<−3 WHZ	–	OR 6.3 (95% CI 2.7–14.7)[c]
Vitamin A deficiency (vs. not deficient)		RR 1.5 (95% CI 1.3–1.8)[e]
Zinc deficiency (vs. not deficient)	RR 1.2 (95% CI 1.1–1.2)[f]	RR 1.2 (95% CI 1.0–1.6)[f]

Diagnosis and Management of Acute/Prolonged and Persistent Diarrhea

Despite clinical clues, determining the causative agent of diarrhea in an individual patient on the basis of clinical grounds alone can be difficult. Both acute/prolonged and persistent diarrheas have similar initial evaluation and management. This chapter focuses on assessing the severity of illness and the need for rehydration. A brief history and directed clinical exam can help determine this and further guide the management.

History

Specific points in history include, time of onset of diarrhea, frequency, amount, consistency, and contents (blood, mucous, pus) of stool, associated signs and symptoms (fever, abdominal pain, nausea, vomiting, bloating, flatus, tenesmus), recent travel, dietary history, exposure to pets or cattle, drug history (specifically antibiotics and laxatives), pertinent past medical and surgical history, family history and day care attendance. For persistent diarrhea, the age of symptom onset and a detailed dietary history with relation between onset of symptoms and introduction to new foods is relevant.

Physical Examination

The initial physical exam focuses on signs and symptoms of dehydration (discussed below) and sepsis (fever and toxic look) which are major complications of acute and chronic diarrhea and require urgent management. Nutritional assessment is necessary and includes height, weight, vital signs, and global nutritional appearance.

Assessing Dehydration and IMCI Guidelines

Early recognition of dehydration, which is the main cause of mortality, is the most critical part of diarrhea management. Loss of water and electrolytes (sodium, chloride, potassium, and bicarbonate) via liquid stools, emesis, sweat, urine, and breathing leads to dehydration if left unreplaced. The WHO suggests assessment of dehydration on a scale of three (Figure 6).

1. Early dehydration with no signs or symptoms,
2. Moderate dehydration notable for thirst, restless, or irritable behavior, decreased skin elasticity, sunken eyes,
3. Severe dehydration when symptoms become more severe with diminished consciousness, lack of urine output, cool, moist extremities, a rapid and feeble pulse, low or undetectable blood pressure, and pale skin in the setting of clinical shock.

Lab Evaluation

For acute diarrhea, maintaining adequate intravascular volume and correcting fluid and electrolyte disturbances take priority over the identification of the causative agent. Stool cultures are usually unnecessary for immune-competent patients who present within 24 h after the onset of acute, watery diarrhea. Lab testing including

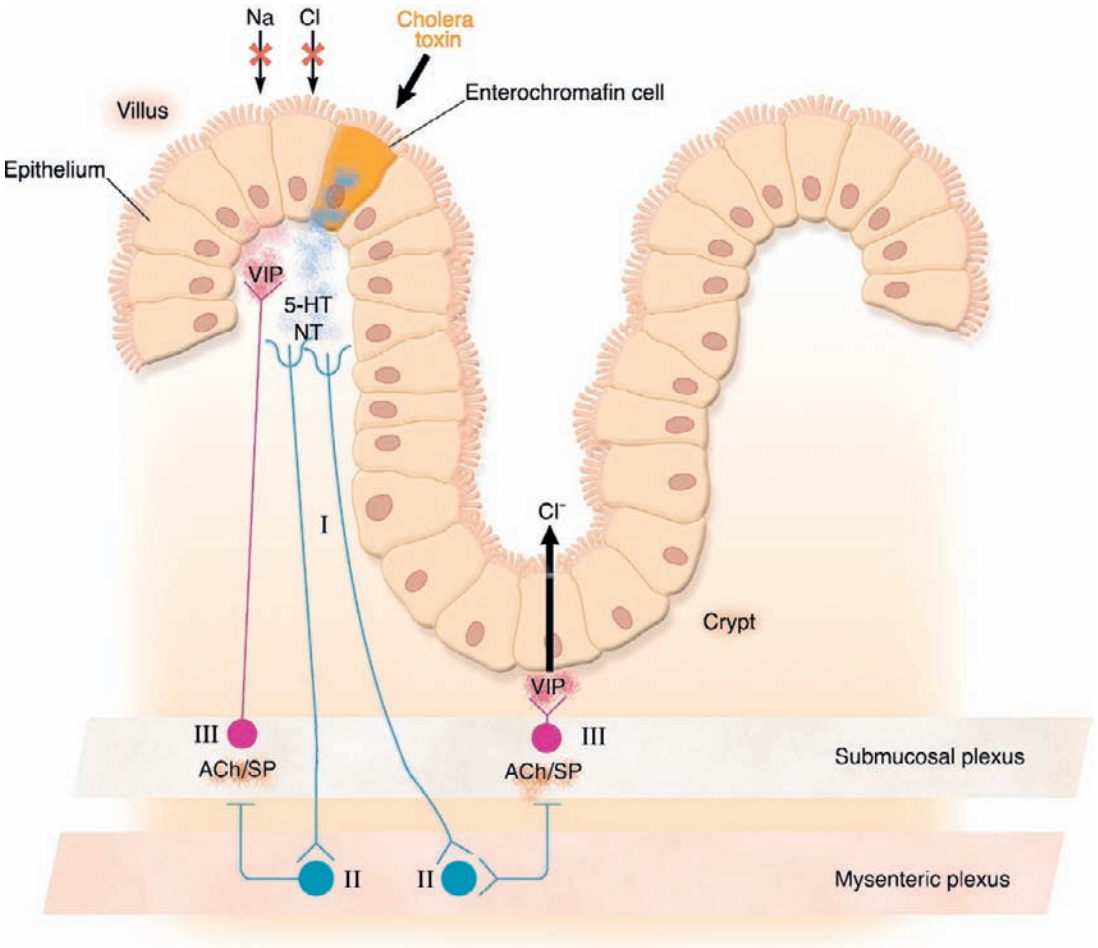

Figure 4 Pathophysiology of secretory diarrhea: diarrhea secondary to cholera toxin cholera toxin induces secretion, in part, through activation of an intramural neural reflex. Toxin attaches to enterochromaffin cells in the epithelium, causing an increase in (cAMP) there. In response to the latter, serotonin (5-HT), neurotensin (NT), and possibly additional peptides are released. These activate afferent neurons (I), whose axons course from close to the epithelium to the myenteric neural plexus, where they connect with interneurons (II) that, in turn, through release of acetylcholine (ACh) and/or substance P (SP), activate secreto-motor neurons (III) in the submucosal neural plexus. Axons from these secreto-motor neurons reach the epithelial surface, in both the villus and the crypt regions, releasing VIP and thereby stimulating secretion in crypts and inhibiting nutrient-independent salt absorption in villi. Reproduced from Field, M. (2003). Intestinal ion transport and the pathophysiology of diarrhea. *The Journal of Clinical Investigation* **111**(7), 931–943.

stool studies, blood tests, intestinal imaging, and immunologic and serologic evaluation are indicated in bloody diarrhea, high fever (>104 F), systemic illness, severe, or prolonged diarrhea, history suggestive of food poisoning, recent history of travel overseas or possibility of immune dysfunction. Supplementary laboratory studies, including serum electrolytes, to assess patients with acute diarrhea usually are unnecessary.

Treatment Approach

Fluids Resuscitation

Dehydration is the primary cause of death in patients with diarrhea and effectively addressing this is the cornerstone of diarrhea treatment. Oral rehydration solution (ORS), developed in the 1960s and 1970s by researchers in South Asia, is a simple cost-effective solution containing glucose and electrolytes that can be used to prevent and treat dehydration due to diarrhea of any cause across all ages. Development of the ORS took advantage of the glucose-coupled intestinal sodium transport mechanism discovered in the 1960s by Robert Crane. Absorption of sodium and glucose molecules across the luminal membrane is facilitated by the protein sodium glucose co-transporter 1 (SGLT1). Although nutrient-independent sodium absorption across the intestinal epithelial brush border membrane is impaired in diarrhea, cotransport of sodium and glucose is preserved. This allows absorption of sodium and thus water as provided by ORSs (Figure 7).

Once in the enterocyte, the transport of glucose into the blood is facilitated by GLUT2 (glucose transporter type 2) in the basolateral membrane with the Na+K+ATPase provides the gradient that drives the process. Key in the success of use of ORS for rehydration is the fact that these physiological processes stay intact, even in the setting of severe diarrhea.

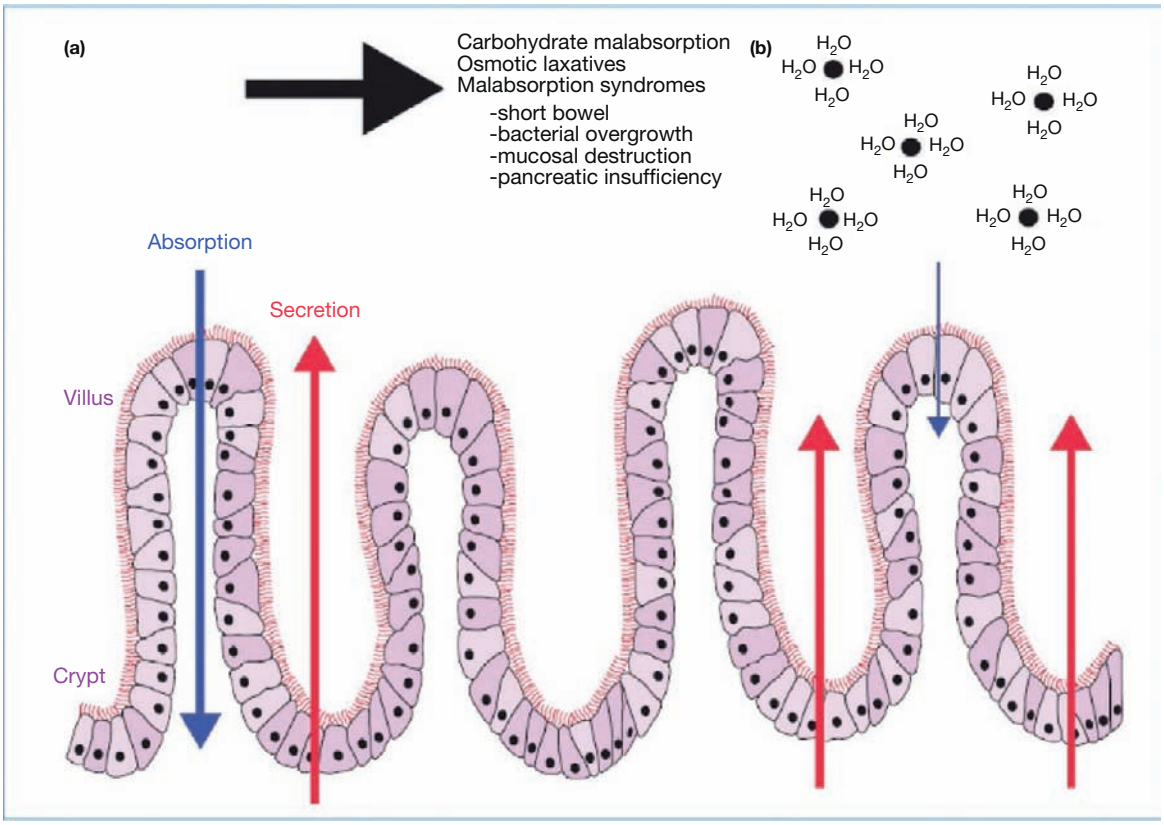

Figure 5 Pathophysiology of osmotic diarrhea. The figure demonstrates the pro-secretory effects of osmotic agents on intestinal fluid movement. (a) Represents the normal luminal environment and (b) represents the effects of osmotic agents such as non-absorbed carbohydrates. Image reproduced from the Internet http://cancerlink.ru/?page_id=1612 – free image source.

The original ORS recommended by the WHO in the 1970s had a formulation with a total osmolarity of 311 mmol l^{-1} (Table 4) but subsequent investigations lead to the current WHO recommendations from 2004 of a low osmolarity ORS (total osmolarity of 245 mmol l^{-1}, decreased concentrations of glucose and sodium). The current formulation when compared to the original formulation is associated with decrease in stool volume by about 25% when compared to the original World Health Organization/United Nations Children's Fund (WHO/UNICEF) ORS solution, reduced vomiting by almost 30%, and reduced need for unscheduled IV therapy by more than 30%. A 2010 review by Munos and colleagues assessed 205 studies and showed that universal coverage with ORS would reduce diarrhea-related deaths by 93%. There are two phases to treatment: rehydration and maintenance. In the rehydration phase, there is quick replacement of the fluid deficit over 3–4 h to achieve clinical hydration. In the maintenance phase, maintenance calories and fluids are administered with reintroductions of enteral feeding with an age-appropriate unrestricted diet, including solids. In children with mild to moderate dehydration, 50–100 ml of ORS/kg body weight during 2–4 h should be administered to replace the estimated fluid deficit, with additional ORS administered to replace ongoing losses. In the setting of severe dehydration, there is an emergent immediate need for IV rehydration. Lactated Ringer's solution, normal saline, or a similar solution should be administered (20 ml kg^{-1} body weight) until pulse, perfusion, and mental status return to normal.

Zinc Supplementation

Zinc deficiency is widespread among young children in low- and middle-income countries. It contributes to mortality and morbidity related to diarrhea, malaria, pneumonia, and restricts growth. Children with diarrhea suffer due to poor baseline dietary zinc intake with aggravated net losses of zinc during the period of illness. The WHO and UNICEF has recommended zinc for the treatment of diarrhea since 2004. Evidence suggests that zinc administration (20 mg per day until the diarrhea ceases) reduces the duration, severity and hospital admissions associated with diarrheal episodes in children in developing countries. Zinc for the treatment of diarrhea is estimated to decrease diarrhea mortality by 23% as well as significantly reducing the severity and duration of diarrheal episodes in children as well as a reduction in treatment failure or deaths in diarrheal episodes of longer duration (>14 days).

Diet

Current WHO guidelines for the management and treatment of diarrhea in children strongly recommend continued feeding alongside appropriate management. An extensive review on

Table 2 Differential diagnosis for prolonged/acute and persistent diarrhea

Prolonged/acute diarrhea (1–13d)	
Infectious	Viral (rotavirus, Norwalk, enterovirus, calcivirus); bacterial (*E. coli*, Shigella, Salmonella, Yersinia, Campylobacter, *C. difficile*, *V. cholera*, Aeromonas); Protozoa (Giardia, cryptosporidium, *E. histolytica*)
Allergy	Short exposure to allergen, challenge to known allergen
Toxic	Drug side effects, acute abdomen with diarrhea as presenting symptom, intussusception
Extra-intestinal infections	Respiratory, urinary, sepsis
Persistent diarrhea (>=14 days)	
Infantile protracted diarrhea with villous atrophy	Post infectious, food allergy, malnutrition congenital histological dysmorphism (e.g., tufting enteropathy, microvillus inclusion disease)
Infectious	Bacterial, parasitic
Inborn errors of metabolism	Familial chloride diarrhea, sodium–hydrogen exchange defect, abetalipoproteinemia and hypobetalipoproteinemia, Galactosemia, Tyrosinemia, Acrodermatitis enteropathica
Carbohydrate malabsorption	Congenital (lactase deficiency, glucose–galactose malabsorption, sucrase–isomaltase deficiency, fructose malabsorption) secondary (acquired mono and disaccharidase deficiencies)
GI organ pathology	Small intestine (celiac disease, tropical sprue, Whipple's disease, intestinal lymphangiectasia, eosinophilic gastroenteropathy, enterokinase deficiency); short bowel syndrome; ischemia; lymphoma; motility disorders (for e.g., small bowel overgrowth); pancreas (all conditions with exocrine insufficiency for e.g., cystic fibrosis); liver (all conditions leading to cholestasis, bile salt deficiency)
Immune defects	Isolated IgA deficiency, SCIDS, AIDS, autoimmune enteropathy
IBD	Crohn's disease, ulcerative colitis
Fecal impaction with overflow	Hirschsprung's disease, anorectal malfunction, functional constipation
Dietary	Overfeeding, nondigestible carbohydrates
Others	Toddler's diarrhea, Munchausen by proxy, factitious diarrhea, non-GI causes (tumors – APUDoma, ganglioneuroma, neuroblastoma)

Table 3 Comparison of viral, bacterial, and parasitic etiologic agents of diarrhea in developing countries and the United States

Etiologic agent	*Developing country*	*United States*
Viral		
Rotavirus	Important	Very important
Noroviruses	Probably important	Important
Enteric adenoviruses	Minor	Probably important
Bacteria		
Enterotoxigenic *E. coli*	Very important	Minor
Campylobacter	Important	Important
Shigella	Important	Minor
Salmonella	Variable	Important
Enterohemorrhagic *E. coli*	Minor	Important
Parasites		
Cryptosporidium	Important	Minor
Giardia	Minor	Minor
Strongyloides	Minor	Minor
Entamoeba histolytica	Minor	Minor

Source: Table modified from Lanata, C.F., Fischer-Walker, C.L., Olascoaga, A.C., Torres, C.X., Aryee, M.J., Black, R.E., and Child Health Epidemiology Reference Group of the World Health Organization and UNICEF (2013). Global causes of diarrheal disease mortality in children <5 years of age: a systematic review. *PLoS One* **8**(9), e72788.

feeding strategies and food-based interventions in children younger than 5 years with diarrhea in low- and middle-income countries showed that although illness duration was shorter and risk of treatment failure 47% lower in children with acute diarrhea who consumed lactose-free diet, there was no effect of lactose avoidance on stool output or weight gain. WHO recommends the following:

- An age-appropriate diet regardless of the fluid used for ORT (oral rehydration therapy)/maintenance
- More frequent breastfeeding or bottle feeding – special formulas or dilutions are unnecessary
- Age-appropriate fluid resuscitation
- Frequent, small meals throughout the day (six meals/day)
- Energy and micronutrient-rich foods (grains, meats, fruits, and vegetables)
- Increasing energy intake as tolerated following the diarrheal episode
- Avoid: canned fruit juices and other high-sugar food and drinks – these are hyperosmolar and can aggravate diarrhea.

Antibiotics for Cholera, Shigella, and Cryptosporidium

Antibiotics should not be used for relatively mild, self-limited infectious diarrhea to minimize development of drug resistance. When the diarrhea is hemorrhagic, seriously dehydrating, associated with serious systemic signs and symptoms, or of longer than 5 days' duration without improvement, antibiotic use is appropriate. A review by Traa and colleagues assessed the effectiveness of WHO-recommended antibiotics – ciprofloxacin, ceftriaxone, and pivmecillinam – for the treatment of dysentery, and concluded that antibiotics can be expected to

Table 4 Composition of standard and reduced-osmolarity WHO ORS

	Standard WHO (1975)	*Reduced-osmolarity WHO (2002)*
Glucose (mmol l^{-1})	111	75
Sodium (mequiv. l^{-1})	90	75
Potassium (mequiv. l^{-1})	20	20
Chloride (mequiv. l^{-1})	80	65
Citrate (mmol l^{-1})	10	10
Osmolarity (mOsml l^{-1})	311	245

Abbreviations: ORS, oral rehydration solution; WHO, World Health Organization.

decrease diarrhea mortality attributable to dysentery by more than 99%. There is evidence to recommend antibiotic use for reduction of morbidity and mortality due to cholera, Shigella spp. and cryptosporidium – Das et al. showed that in the developing country setting antibiotic management of cholera resulted in a 63% reduction in rates of clinical failure and a 75% reduction in rates of bacteriological failure. They also showed that antibiotic management of Shigella resulted in an 82% reduction in rates of clinical failure and a 96% reduction in rates of bacteriological failure. Antibiotics for treatment of cryptosporidiosis reduced mortality by 76%, rates of clinical failure by 52%, and rates of parasitological failure by 38%. The empiric antibiotic regimen should be determined by host factors, severity of illness, local resistance patterns, and history of travel to an area with increased resistance.

Probiotics

Probiotics are defined by the joint Food and Agriculture Organization/WHO Working Group as 'live microorganisms that when administered in adequate amount concern a health benefit on the host.' Recent Cochrane systematic reviews on the use of probiotics as an adjunct therapy to ORS have shown that probiotics shorten the duration of diarrhea and reduce stool frequency but the observation remains inconclusive due to few trials with small numbers of participants. Most commonly used probiotics in trials include Bifidobacterium, two genera of lactic acid bacteria (Lactobacillus and Streptococcus) and the yeast Saccharomyces. There is insufficient evidence to recommend their widespread use at this time.

Antiemetics

Vomiting associated with diarrhea causes significant additional physical discomfort and is of concern for both parents and physicians. Additionally, vomiting can limit the success of ORS and can result in increased use of intravenous (IV) rehydration, need for prolonged emergency department stays and hospitalizations. A recent systematic review evaluated seven RCTs which used ondansetron, metoclopramide, dimenhydrinate, and dexamethasone in children aged 0–12 years. They found that use of antiemetics significantly reduced the incidence of vomiting and hospitalization by 54% and reduced IV fluid requirements by 60%. A 2011 Cochrane Review on the use of antiemetics for reducing vomiting related to acute gastroenteritis in children and adolescents concluded that oral ondansetron increased the proportion of patients who had ceased vomiting and reduced the number needing IV rehydration and immediate hospital admission. IV ondansetron and metoclopramide reduced the number of episodes of vomiting and hospital admission, and dimenhydrinate as a suppository reduced the duration of vomiting. Antiemetics are effective for the management of gastroenteritis in children and have the potential to decrease morbidity and mortality burden due to diarrhea.

Breast Feeding

Breast milk provides various immunological, psychological, social, economic, and environmental benefits, and is therefore recommended as the best feeding option for newborn babies and young infants in developing countries, including HIV-infected populations. Lamberti and colleagues reviewed 18 studies from developing countries reporting the effect of breastfeeding on diarrhea morbidity and mortality. The investigators estimated that not breastfeeding was associated with a 165% increase in diarrhea incidence and mortality in 0–23-month-olds.

Vaccines for Rotavirus

Rotavirus is the most common cause of severe dehydrating diarrhea in infants worldwide. Rotavirus vaccines represent an important preventive approach to reducing the burden of diarrheal disease due to rotavirus. Since 2006 two rotavirus vaccines are currently licensed for vaccinating infants in North and South American, European, and Eastern Mediterranean countries: RotaTeq® (Merck) and Rotarix® (GlaxoSmithKline). RotaTeq®/RV5 – is a live, oral vaccine that contains five reassortant rotaviruses developed from human and bovine parent rotavirus strains and is given orally in three doses at ages 2, 4, and 6 months. Rotarix®/RV1 is a live, oral vaccine licensed in 2008 for use in the United States that contains a human rotavirus strain, this is given orally in two doses at ages 2 and 4 months. This first dose of either vaccine is most effective if it is given before a child is 15 weeks of age and children should receive all doses of rotavirus vaccine before they turn 8 months old.

In the global health setting, there is evidence suggesting that rotavirus vaccine efficacy may vary by setting due to regional differences in circulating rotavirus vaccine strains, and reduced efficacy of oral vaccines in countries with high burden of malnutrition and enteric infections. A meta-analyses by Munos et al. assessed the effectiveness of two currently marketed vaccines the pentavalent human-bovine reassortant rotavirus vaccine and monovalent attenuated human rotavirus vaccine in Phase III trials in European and Latin American sites for both vaccines, as well as the United States (including Navajo and Apache populations) and Taiwanese sites for the pentavalent vaccine. The effectiveness studies of the monovalent and pentavalent vaccines were conducted in northern Australia and Nicaragua, respectively. The authors estimated that these rotavirus vaccines could prevent

74% of rotavirus deaths and 47–57% of rotavirus hospitalizations. Data published from a randomized, placebo-controlled, multicenter trial in South Africa and Malawi evaluating the efficacy of a live, oral rotavirus vaccine in preventing severe rotavirus gastroenteritis showed that the rotavirus vaccine significantly reduced the incidence of severe rotavirus gastroenteritis among African infants during the first year of life. The ROTAVAC rotavirus vaccine study group recently published results from a Phase III clinical trial using ROTAVAC which is a new rotavirus vaccine that consists of a strain of the virus that was isolated, manufactured, and tested in India. Infants aged 6–7 weeks received three doses of oral human-bovine natural reassortant vaccine (116E) with efficacy results from the study showing the vaccine to be effective and well tolerated in Indian infants.

Vaccines for Cholera

Although case management with oral rehydration therapy has substantially improved case-fatality rates for cholera, the infection can still kill rapidly, especially in outbreak settings. Old-generation injectable cholera vaccines, abandoned since the 1970s because of their restricted effectiveness and local side effects. However, studies have shown vaccines to be effective in reducing risk of cholera infection in children younger than 5 years by 52%, increase in vibriocidal antibodies by 124% and a relative risk of one or more adverse events of 1.4. Such evidence for the effectiveness of oral cholera vaccines makes them good candidates for cholera control in endemic areas.

Improved Water Provision, Use, Sanitation, and Hygiene Promotion

Maintaining water quality (protection or treatment of water at source or point of use) is more effective than improving water supply (improved source of water or improved distribution, or both). Cairncross and colleagues estimated the effect of water, sanitation, and hygiene strategies and estimated risk reductions for diarrhea of 48% for hand washing with soap, 17% with improved water quality, and 36% with proper excreta disposal.

Community-Based Approaches

Although evidence confirms the efficacy and effectiveness of many interventions, many interventions are not accessible to people in need; hence, the focus on delivery strategies has increased. One method of community-based case management is to provide these amenities through community health workers with home visitation and community-based sessions for education and promotion of care seeking. These approaches have been assessed and concluded that that community-based interventions are associated with a 160% significant increase in the use of ORS and an 80% increase in the use of zinc in diarrhea. Furthermore, findings showed a 9% increase in care seeking for diarrhea and noted a 75% significant decline in inappropriate use of antibiotics for diarrhea.

Global Action Plan for Pneumonia and Diarrhea

The 2013 Lancet Childhood Pneumonia and Diarrhea series reviewed existing preventive and therapeutic interventions that could have a role in reducing the morbidity and mortality burden in children younger than 5 years due to diarrhea and pneumonia. The interventions with the maximum effect include breastfeeding, ORS, and community case management. The series concluded that despite a large global burden childhood diarrhea and pneumonia deaths are avoidable and 15 interventions delivered at scale can prevent most of these deaths (Figures 8 and 9). Estimates modeled with the Lives Saved Tool showed that if the interventions are scaled up by 80% in the 75 countdown countries, 95% of diarrheal, and 67% of pneumonia deaths in children younger than 5 years can be prevented by 2025. Scaling up of diarrheal and pneumonia interventions would cost US$ 6.715 billion, only $2.9 billion more than present levels of spending. Assessment is needed of the cost-effectiveness of these interventions in national health delivery frameworks. We have a clear idea of effective interventions for both diarrhea and pneumonia and with community health-worker programs increasingly being employed to reach underserved populations, real opportunities exist to scale-up community advocacy/education programs, early case detection and management strategies.

The series also included summary recommendations after a series of consultations with several hundred front line public health practitioners in target countries were held to identify key barriers to scaling up of evidence-based interventions to reduce pneumonia and diarrhea mortality. Critical barriers included: absence of national coordination within ministries and other stakeholders to deliver interventions, insufficient financial resources, inadequate training and support for health workers, poor systems for monitoring and assessment of key programmatic indicators and sporadic availability of key commodities. The final list of recommendations included: (1) Improve coordination between various groups working on preventive and treatment interventions to control pneumonia and diarrhea. (2) Substantially increase resources for child survival programs, with an emphasis on pneumonia and diarrhea control efforts. (3) Enhance efforts to attract, train, and retain a competent work force of caregivers. (4) Invest in better systems for harmonization of the collection of essential programmatic indicators, and ensure that this information is shared throughout the system. (5) Strengthen supply systems that deliver essential commodities. In summary, the cost to achieve the end of preventable deaths from pneumonia and diarrhea by 2025 is estimated to be around US$ 6.715 billion. Despite large reductions in child mortality between 2000 and 2010 (both in all-cause mortality, and specifically diarrhea and pneumonia associated), these diseases remain causes for preventable deaths. The achievement of the fourth Millennium Development Goal and the longer-term target of reduction of child mortality to 20 deaths or fewer per 1000 live births in all countries by 2035 requires significant decreases in mortality from both diarrhea and

Dietary Exposure Assessment

D Arcella, F Héraud, and M Gilsenan, European Food Safety Authority (EFSA), Parma, Italy

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Food contains, naturally, intentionally, or unintentionally, a wide range of substances that may constitute a health hazard. In this context, risk assessment provides the scientific foundation upon which the risk analysis process is built. Risk assessments are performed in a four-step process: hazard identification, hazard characterization, exposure assessment, and risk characterization. The first stage of a risk assessment, hazard identification, is primarily a question of identifying the effects that are considered as adverse, irrespective of the dose needed or the specific mechanism involved to elicit this effect. The next step, hazard characterization, is centered on the quantification of these effects, whereas dietary exposure assessment is the qualitative and/or quantitative evaluation of the likely intake of biological, chemical, or physical agents via food. Risk characterization is the final stage of risk assessment that integrates information from exposure assessment and hazard characterization into advice suitable for use in decision-making.

Dietary exposure assessments are often performed according to the fit-for-purpose principle with the consequence that there is little harmonization across disciplines with each having their own agreed international guidelines. In order to calculate reliable estimates of the amounts ingested through the diet of a specific chemical substance, three elements have to be taken into account: (1) levels and fate of the chemical in food, (2) food consumption patterns, and (3) integration of these elements to determine exposure. In all three areas, the limitations of the approaches currently used lead to uncertainties that can cause either an over- or underestimation of real intakes and thus of risk.

Presence and Levels of Chemicals in Food

A central aspect in the assessment of exposure is the concentration of the hazardous substance in food as consumed. Factors influencing the variability of the chemical concentration levels in ready-to-eat food products are of environmental origin or related to agricultural and storage practices, food processing, and cooking habits. Quantitative information on the level of a chemical in food can be obtained through analytic determination. Inaccurate measurements can lead to results differing significantly from the real concentration of the chemical in food when the amount is determined analytically. Above all, food sampling procedures for subsequent analysis can critically determine how close the measured value is to the real value. Aspects such as climate, ripeness, and soil conditions are likely to influence the absence or presence of an environmental or agricultural contaminant chemical, and this should be considered when food products are sampled for analysis and methods are chosen. For example, the presence of mycotoxin or fungicide residues in crops and derived foods is related to climatic differences and year-to-year variation. A further source of uncertainty is therefore linked to the possible effects of food processing, like washing, peeling, or cooking, on the chemical of interest, due to both industrial and household preparations.

Most of the analytic determinations of a chemical in a food that are used in dietary exposure assessments are carried out within monitoring and surveillance programs. In these cases, the concentration of a defined chemical in a food is commonly assessed by means of random stratified sampling plans or targeted sampling. The first tries to obtain a representative picture of chemical levels present in food, whereas the second is aimed at sampling those products expected to contain higher levels in a cost-effective way. Targeted data are often collected for enforcement purposes in response to specific problems. They should be used with caution in dietary exposure assessments, as they may not be representative of all foods available for sale. However, clearly representative data are often not available, and targeted data have to be used as an alternative resulting in more conservative estimates of exposure. A major limitation of using monitoring data is that often, not all commodities entering the food chain are monitored. This information might therefore not be sufficient to estimate exposure from all possible dietary sources.

After representative samples are taken, the accuracy, specificity, and sensitivity of the analytic methods used are also important. Generally, analytic methods used for screening purposes (e.g., for enforcement of maximum residue levels (MRLs) or maximum levels) tend to be less precise and are not suitable to detect residues at low levels. This is to a large extent due to the fact that the objective of analytic methods used for screening purposes is to separate the compliant from the noncompliant results. For accurate dietary exposure assessments, the limits of detection (LOD) and quantification (LOQ) should be as low as technically possible. Different recommendations exist for the handling of nondetected or nonquantified values when assessing exposure. In the substitution method, the most commonly used approach, three different scenarios are considered: the lower bound obtained by assigning a value of zero to all the samples reported as less than the LOD or LOQ, the middle bound by assigning half of the LOD or LOQ, and the upper bound by assigning the LOD or LOQ as the sample result. Other factors influencing the final result are the accuracy of the method, laboratory-to-laboratory variation, repeatability, and recovery.

A complementary tool to the monitoring and surveillance programs relies on the total diet studies (TDS), which are designed to collect representative information on the chemical occurrence in food as consumed by the population. In the framework of the TDS, both sampling frame and analytic techniques and performances are adapted in order to fit for the purpose of dietary exposure assessment.

Besides these two main sources of data, chemical concentration data can also originate from experimental trials,

legislated maximum permitted levels (MPLs), MRLs, and usage levels as reported by manufacturers. In the framework of pre-regulatory exposure assessment (e.g., pesticides), the primary sources of residue data in food are the supervised trials. These data must be submitted by the applicants in support of the registration of a pesticide. The trials are usually performed by a manufacturer and simulate a maximum registered use scenario. The trials are designed to determine the maximum residue concentration that may be present in food or feed at the earliest point at which these food commodities could enter into commerce and are used to establish legally enforceable residue limits.

When evaluating the presence and levels of chemicals in food, it is valuable to distinguish between substances intentionally added, like additives, flavorings, or enzymes, from others, such as contaminants. In the case of chemical substances intentionally added to food at various processing steps, the amounts that may be added are usually regulated by MPLs or MRLs. They are defined in the food legislation for each food category to ensure product safety. MPLs or MRLs can be used for a preliminary assessment of exposure in order to identify those substances for which acceptable or tolerable intake limits may be exceeded in a worst-case scenario. Data on the use patterns of chemical substances intentionally added to food are difficult to obtain. Information on the concentrations in brand foods is considered to be commercially sensitive and is therefore not widely available. Additives, like all other ingredients, must be included on the product label in descending order by weight at the time of manufacture. This may provide information on the simple presence and in some cases on the amounts used, but the collection of such data from labels requires major efforts.

Occurrence levels can also be obtained from the producers. These levels range from the MPL to nothing at all. Manufacturers use the chemicals, for example, an antioxidant, at the lowest effective levels in a given formulation; unnecessarily high addition is usually avoided for cost reasons and prohibited by the requirement to work according to 'good manufacturing practice.' Proposed usage levels provided by the industry are often the only available information in pre-marketing situations.

Flavoring substances do not follow the same regulation as food additives. Individual flavor components are usually not specifically indicated on the label beyond the statement that flavorings are used and maximum levels for these substances were not established. Another category of substances that are intentionally added during food processing is that of food enzymes, which are primarily used as processing aids.

Food Consumption Patterns

When assessing exposure, three different sources of information regarding food consumption can be used: food supply data, data from household consumption surveys and from individual dietary surveys, and data from duplicate diet and biomarker studies from other sources of exposure data, whereby these measures reflect both the consumption of food and the concentration of the chemical in these foods.

Disappearance data provide gross annual estimates of the national availability of food commodities. Food supply data are calculated in food balance sheets (FBSs), which are accounts, on a national level, of the annual production of food, changes in stocks, imports and exports, agricultural use, and industrial use. The result is an estimate of the average supply per head of the population, irrespective of, for instance, age or gender. Food supply data refer to food availability, which gives only a crude (usually overestimated) impression of the potential average consumption. Food losses prior to consumption, due to processing, spoilage, trimming, and waste, may not be adequately accounted for. As a result of their long history, FBSs are especially used for assessing trends over time. International FBSs are prepared and published by Eurostat and the FAO. They are compiled in the so-called GEMS/Food cluster diets, which are used by joint FAO/WHO expert meetings while performing international risk assessment.

Food available at the household level may be estimated from budget surveys and consumption surveys. The first type of survey gives information on the purchases of food in terms of expenditure and is used for economic policy. In household consumption surveys, the amounts of food and drinks brought into the household are also recorded, but not usually the meals consumed out of home. In general, household surveys do not provide information on how food is handled within the household or on actual consumption by its members. Data on the quantity of and/or expenditure on food maybe collected by record keeping, by interviews, or by both methods.

The data from dietary surveys among individuals more closely reflect actual consumption. To collect dietary intake data at an individual level, several methods can be used. The methods can be divided into two categories: recall and record methods. Recall methods reflect past consumption, varying from intake over the previous day (24 h recall) to usual food intake (dietary history or food frequency). Record methods collect information on current intake over one or more days.

The food frequency method consists of a questionnaire containing a given list of foods, for which subjects are asked to estimate the habitual frequency of consumption during a specified period of time. The 24 h dietary recall is the most common recall method used. During the interview, an individual recalls actual food intake during the preceding day. Food quantities are usually assessed by the use of household measures, food models, or picture books. The interviewer obtains information during a face-to-face interview or by telephone. In the weighed record technique, the subject is taught to weigh and record all foods and beverages immediately before eating and to weigh and describe any leftovers. The weighed method differs from the estimated record where subjects do not use a scale but estimate the portion sizes using picture books or household measures. The record is usually done over 3–7 days.

The duplicate diet method differs from the other methods in that the intake estimation does not rely on chemical data from other data sources. The concentration is measured by the chemical analysis of the duplicate diet collected.

The quality of the results of a food chemical exposure assessment will depend largely on the quality of the food consumption data used in the assessment. Collecting food consumption data in surveys and in duplicate diet samples for exposure assessment can alter the diet of study participants, resulting in a bias in intake estimate. Intake may also be altered

if participants change their diet due to fatigue or loss of interest. It is important to highlight that many dietary surveys reported energy intakes consistently lower than would be expected from the estimated basal metabolic expenditure and physical activity. This problem of underreporting of energy intakes is widespread and is one of the major biases in exposure assessments based on dietary surveys.

Another important issue is the food coding system. In dietary assessment, food products have to be identified and thereafter categorized in line with the purposes of the study. For this, national and international systems exist, but with regard to exposure assessment, unconventional categorization systems are often needed. An important limitation is that analyses of residues in cereals, fruits, and vegetables are mainly conducted in raw agricultural commodities (RACs) including peel and nonedible parts. Either processed or prepared foods are not monitored or the number of samples is very small. This is due to the fact that in the legislation, the limits of residues are mainly set for RACs, and the purpose of monitoring is usually to assess compliance, rather than exposure.

In order to estimate acute exposure, it is sufficient to record food intake for only one day, including details of the foods consumed per meal and details on the time of each eating occasion. However, food consumption data for several days per subject are required in order to assess chronic exposure. Information on food consumption for a few days may not actually represent usual intake. However, statistical techniques can be used to estimate usual intake, provided that two or more repeated and independent days are available, although consecutive days cannot be considered as independent days.

Methods Used in Dietary Exposure Assessment

Up to 15 years ago, assessment of exposure was mainly based on the estimates obtained by combining MPLs with mean food consumption data for all chemicals. However, mean consumption is not informative in relation to subjects consuming high levels of one or more food categories ('high consumers') who are more likely to ingest hazardous chemicals in excessive quantities. The methodologies now adopted to assess exposure from diet take into special consideration nonaverage individuals and in particular those who consume relatively large quantities of foods containing higher concentrations of substances that may potentially lead to a health risk. The definition of high-level consumers varies, it is normally the 90th, 95th, 97.5th, or 99th percentile of the distribution of individual intake values. A high percentile, rather than the maximum value, is usually chosen because maximum intakes are unlikely to be maintained over long periods of time and hence are not representative of high-level intakes in relation to chronic exposure. The reliability of estimates depends on the sample size available and should be considered when choosing the high percentile value to retain for the exposure assessment. It is also important to highlight that the definition of high-level consumers is a major issue since, in practice, it defines the proportion of the population that would have to exceed the 'at-risk dose' before risk mitigation measures are to be considered to reduce exposure levels. This is therefore both a scientific and a political/ethical question.

Ideally, dietary exposure to chemical substances should be assessed by combining data on the concentration in all food products with data on their consumption. Unfortunately, with the exception of duplicate diet studies, exposure assessments are not performed on the basis of consumption, occurrence, and concentration data related to the same individuals within a population. Therefore, assessments of exposure to dietary components will usually require some degree of modeling to attempt to create a representation of the real-life exposure situation. There are a number of different models for combining or integrating the consumption data with the residue/concentration data. The method chosen usually depends on a number of factors, including the purpose of the assessment (target chemical, population group, and degree of accuracy required) and the availability of data. In general, it is considered neither cost-effective nor necessary to collect detailed food consumption and chemical concentration data for every hazardous substance. A stepwise procedure is commonly used to minimize estimation costs and focus resources on the most important issues. The stepwise approach to the dietary exposure assessment of food chemicals is such that as the accuracy of dietary exposure assessments increases, the cost of collecting adequate data and resources needed to undertake the assessments also increases. The aim of the stepwise procedure is to target dietary exposure estimates to chemicals that might be of health concern for 'average consumers' or individuals belonging to certain at-risk groups. If the estimated exposure to a given pesticide residue, food additive, veterinary drug residue, and contaminant exceeds its safety limit (e.g., acceptable daily intake (ADI)), a more accurate method of dietary exposure assessment should be applied. Exposure is therefore first assessed by using methods following a deterministic approach based on conservative assumptions. Especially at this stage, the methodologies adopted to assess exposure from the diet take into special consideration 'high consumers.' However, for high consumers in particular, food consumption data are not commonly available at the individual level. Consequently, highly conservative methods are used. It is important to remind that these methods are not suitable for predicting actual exposure since they are designed to cover the worst-case scenario. Nevertheless, they are useful and inexpensive screening tools for identifying those substances for which safety limits of intake may be exceeded.

The so-called budget method is the most known screening method; it is above all used in the field of food additives. This method uses theoretical food consumption data and MPLs for additives. The budget method is based on the physiological upper limit to the amount of food and drinks that can be consumed each day and thus of food additives. For beverages, this is assumed to be 100 ml, and for solids, 25 g kg^{-1} b.w. per day. A further assumption is that only a certain proportion of the diet is likely to contain food additives. The default proportion of beverages and solid food that could contain the additive is typically assumed to be 25% but varies depending on the additive in question and the population under consideration. A model diet is, for example, used for the assessment of exposure to feed additives and veterinary drug residues. It assumes the daily consumption of 300 g of muscle (from mammals, birds, and/or fish), 100 g of liver (from mammals and/or birds), 50 or 90 g of fat (from mammals or birds, respectively), 50 or 10 g of kidney (from mammals or birds, respectively),

1500 g of milk, and 100 g of eggs. Screening methods are also used for assessing acute exposure; an example is the international estimated short-term intake, which is used in the case of pesticide residues. This method requires data on the consumption of large portions (usually the 97.5th percentile from the single-day consumption data among consumers) together with typical unit weights of the edible part of the commodities and the body weights of the population associated with the food consumption data. The baseline assumption is that a consumer may eat a large portion (high-level consumer at the top end of the distribution curve among consumers only) of a food that may contain a high residue level, as derived from supervised field trials. The acute assessment is conducted for each commodity separately as it is considered unlikely that a consumer will eat two or more different commodities with a large portion size within a short period of time and that those commodities have the highest level of the same pesticide.

When screening methods cannot rule out a safety concern, more refined methods should be applied. With access to food consumption survey information, actual mean and high percentile consumption can be used as inputs into an exposure model. Such calculations can be further refined by splitting the population into age groups and by using the average body weight within each group to estimate the mean and high percentile consumption per kg body weight. A further refinement is possible when food consumption is available at the individual level. In such cases, chemical concentrations and food consumption can be directly matched for each subject and the respective food or food category and a distribution of total exposure estimates produced, where any percentile of interest can be calculated. Dietary exposure estimates are in the majority of cases produced by considering the consumption of all foods and all subjects involved in the dietary surveys, but estimates for 'consumers only' are also calculated under specific circumstances.

The method applied in any dietary exposure assessment should be clearly stated and reproducible. Information about the model and data sources used, assumptions, limitations, and uncertainties should also be documented. When assessing the exposure, the contribution of variability (heterogeneity) and true uncertainty (lack of knowledge) should be as far as possible distinguished. Although it may be challenging to identify all the uncertainties and to distinguish them from the real variability, each scientific output should describe the types of uncertainties encountered and considered during the different risk assessment steps and indicate their relative importance and influence on the assessment outcome.

Over the past years, to get a more realistic view of exposure to hazardous substances, risk managers are becoming more interested in probabilistic modeling. In contrast, probabilistic approaches are typically more resource-intensive than deterministic approaches, but they permit the characterization of the variability and uncertainty that may exist in such exposure estimates and thus facilitate more meaningful and realistic assessments. The results, however, are only as good as the input data, algorithms, and assumptions. The critical aspects of the food consumption and chemical concentration data used to assess deterministic estimates must therefore be taken into account also when using a probabilistic approach. Moreover, the impact of the assumptions should always be tested carefully and the results should be fully documented. A modeling tool must be structured so that all algorithms and assumptions inherent to the model can be identified and validated. Sensitivity analyses should be used to set priorities for risk reduction measures and to define the main sources of uncertainty in order to plan further studies and improve the exposure estimates.

In addition, more and more concerns stand in the risk resulting from the combined exposure to multiple chemicals. One challenge is to identify which chemical mixtures the population are exposed. Developments in the research field are under way to address this challenge. Once the mixtures of interest are defined, methodologies to assess combined exposure in a risk assessment perspective do not differ greatly from the ones previously described for a single chemical. The main issue, especially when assessing acute exposure, is to address the co-occurrence of the chemicals composing the mixture in foods. Future developments in this direction mainly require adaptation of the occurrence data collection for multiple chemicals in same food samples.

Finally, there is also an increasing interest for the potential use of biomarkers for assessing exposure to food chemicals. It needs to be recognized that this approach takes account of exposure from all sources, including nondietary sources. It is thus important to understand to what extent such other sources exist and are likely to be relevant, especially if attempting to compare the results of such measurements with dietary exposure estimates assessed by means of conservative models. A number of methods for specific individual food chemicals are currently being developed, and it seems that this trend will continue.

Introduction

Anatomically, a cereal grain is a one-seeded fruit, called caryopsis, in which the fruit coat (or pericarp) is fused with the seed coat (cuticle or testa) to form what we refer to as the cereal bran. The outermost layer of the cereal kernel is thus the pericarp or the ripened ovary wall, which lacks cytoplasm and has lignified walls and is dead at harvest ripeness. The pericarp is composed of the outer epidermis, hypodermis, parenchyma, intermediate cells, cross cells, and tube cells. The seed coat (arising from the integuments) and an underneath pigment strand cover the seed completely and control water migrations between the enclosed seed and the pericarp cells. Beneath the seed coat is the aleurone layer, or the outermost layer of the endosperm tissue, which is the only endosperm tissue that will be alive at maturity. Unlike the starchy endosperm cells, the aleurone layer cells have large prominent nuclei that are not crushed during milling. The bran (Figure 1) represents these outer parts of the grains including the pericarp, the testa, and the aleurone layer. These are all fibrous layers containing cellulose, hemicellulose, lignified materials, and a wide range of bioactive compounds. Commercial bran preparations contain variable amounts of the starchy endosperm and germ depending on the variety of cereal and the milling process (Figure 2). The amount of endosperm in the commercial bran will depend on the shape of the kernel and the extraction rate with, for example, rye being more irregular in shape than wheat and, therefore, more difficult to mill to prepare 'pure' bran fractions. The relative distribution of bran, endosperm, and germ in selected cereal kernels is given in Table 1.

Composition and Properties

Brans from different cereals are different in the shape and hardness of their particles, chemical composition, color, flavor, and other sensory properties. The color of the cereal bran may vary from white, yellow, green, blue, black, and purple red depending on the variety and the type and amounts of pigments as well as the inclusion of starchy endosperm. For example, oat bran is lighter in color than rye, wheat, rice, and barley brans. Wheat bran is more yellow in color, barley bran followed by oat bran has more redness, while rye bran is greener in color. All cereal brans have a pleasant flavor with the exception of rye bran, which imparts an unpleasant feeling of grittiness, roughness, and lack of smoothness and creaminess.

Table 2 presents the major and most important constituents of cereal brans. The major chemical component in cereal brans is dietary fiber, which is defined by the American Association of Cereal Chemists as consisting of "the remnants of edible plant cells, polysaccharides, lignin and associated substances resistant to (hydrolysis) digestion by the alimentary enzymes of humans." Dietary fibers in cereal brans include water-insoluble and water-soluble types, where wheat and rye brans contain 1–5% soluble fiber, rice bran contains about 10% soluble fiber, while oats and barley contain about 30–40% soluble fibers. The insoluble dietary fiber is composed of cellulose, hemicelluloses, and small amounts of klason lignin. The hemicellulosic fraction is mainly composed of arabinoxylan (or pentosan) structured as β-(1→4)-xylopyranosyl backbone with α-L-arabinofuranosyl residues linked to the main chain as (1→2) or (1→3) side units. This hemicellulose fraction also contains side units of D-glucuronic acid or oligosaccharide side chains of galactose or xylose, and some arabinofuranosyl side units contain ferulic acid. Because of the complex structure of this fraction, it is often referred to as a heteroxylan. It is believed that the heteroxylan fraction acts as a fill in the spaces between the cellulosic microfibrils and forms a cross-linked structure with other cell wall components, via di- and triferulate bridges, that act as a cement solidifying the cell wall structure and enhancing its insolubility. Klason lignin is a complex three-dimensional hydrophobic polymeric network of aromatic p-hydroxyphenyl, guaiacyl, and syringyl units resistant to chemical and enzymatic degradation. Soluble dietary fiber is composed partly of soluble arabinoxylan, fructan, and mainly highly soluble and viscous β-glucan, which is a linear polysaccharide that consists only of β-D-glucopyranosyl units joined by either (1→3)- or (1→4)-β-D-linkages, hence the name mixed-linkage (1→3), (1→4)-β-D-glucan.

Cereal brans contain considerable amounts of minerals and vitamins and contribute considerably to the recommended daily intake (RDI) of some of these nutrients (Table 3). For example, wheat bran is a good source of the B vitamins, including niacin (19% of RDI/100 g), vitamin B_6 (18% of RDI/100 g), riboflavin and thiamine (10% of RDI/100 g), and folates (B_9) and pantothenic acid (B_5) (6% of RDI/100 g), and it provides small amounts of the lipid-soluble vitamins E and K. Wheat bran is also a rich source of eight important minerals being exceptionally high in manganese (161% of RDI/100 g), and very high in magnesium (43% of RDI/100 g), selenium (31% of RDI/100 g), and phosphorus (28% of RDI/100 g), and still a good source of iron (16% of RDI/100 g), zinc and copper (14% of RDI/100 g), and potassium (9% of RDI/100 g). Rice bran has higher values and oat bran significantly less values compared to wheat bran.

Besides fiber, cereal brans are rich sources of a wide range of bioactive secondary metabolites including phytic acid, tocopherols and tocotrienols, carotenoids, γ-aminobutyric acid, octacosanol, squalene, unsaturated fatty acids, phytosterols, and phenolic compounds. The phenolic components of cereal brans have received special interest because of their antioxidant properties. These phenolic compounds (including free aglycones, soluble conjugates, and polymeric and insoluble-bound forms) differ widely in their structures and water solubility. The free phenolic compounds are mainly present within

Physical, microscopic and chemical characterisation of industrial rye and wheat brans from the Nordic countries. *Food & Nutrition Research* 53, 1–11.

the plant cell vacuoles, the soluble esters or conjugates are esterified to sugars and other low-molecular-weight components, while the polymeric proanthocyanidins and the insoluble-bound forms are covalently bound to cell wall structural components such as cellulose, hemicellulose, lignin, pectin, and rod-shaped structural proteins. Analysis of 51 Canadian wheat cultivars revealed a variation in the contents of phenolic compounds (expressed in μg gallic acid equivalents/g of bran) with the contents of free phenolic compounds extractable with 80% ethanol ranging 850–1750 and the content of bound phenols ranging 2300–5400 with the total phenolic content ranging from 3400 to 6700 and averaging c.5200. The main phenolic compounds in nonpigmented cereal brans are the phenolic acids ferulic and p-coumaric acids, which are found mainly linked to dietary fiber. An indicative detailed high-performance liquid chromatography analysis is available for rice bran (Table 4), and it shows that pigmented brans of cereals contain much higher levels of phenolic compounds imparted by flavonoids, anthocyanins, and proanthocyanidin pigments. Consequently, brans from

pigmented cereal cultivars have higher antioxidant activities compared with brans from nonpigmented cereals.

A group of important bioactive compounds in cereal brans include sterols, steryl esters, and steryl ferulates (the steryl ferulates in rice bran are referred to as oryzanols), which are particularly interesting because of their cholesterol-lowering properties. Cereal brans are also characterized by their contents of tocotrienols and policosanol waxes (mixture of long chain alcohols) believed to have anticarcinogenic effects. Cereal brans also contain considerable amounts of phytic acid, which is not only known for its antioxidant properties but also considered an antinutritional compound as will be discussed later. Wheat and rye kernels are characterized by their contents of alkylresorcinols, which can be used as specific intake biomarkers for whole-grain and bran-rich diets including these cereals.

Health Effects

Cereal brans provide an invaluable source of soluble and insoluble dietary fiber for human nutrition. It is believed that fiber intake of 30–40 g day^{-1} is desirable and that half of it could come from cereal products and the other half from fruits and vegetables. Soluble and insoluble dietary fibers are appreciated for several health benefits including weight and diabetes management, lowering of blood cholesterol, regulation of blood glucose levels, modulation of the immune system, and anti-inflammatory effects leading to lower risk of heart disease and cancer. Insoluble dietary fibers (cellulose, some arabinoxylans, and lignins) are effective in enhancing the feeling of fullness, increasing stool size, and helping reduce constipation and hemorrhoids. Soluble fibers (some arabinoxylan and β-glucan) form a gel in the intestine and increase the water content of the stool. Cereal dietary fibers also improve microbial fermentation, promote the growth of beneficial bacteria,

and increase the production of short-chain fatty acids in the large intestine. Scientists are still in search for the putative mechanisms behind the beneficial health benefits of cereal fibers. In a metabolomic study, the intake of a high-fiber rye diet was found to increase the concentrations of the ribose metabolites ribitol and ribonic acid and the tryptophan metabolite indole acetic acid, and it was speculated that high-fiber diets increase the synthesis of serotonin and reduced hunger. A high intake of bread of whole-grain rye with added rye bran by males in the early stage of prostate cancer was found to elevate plasma betaine and dimethylglycine and 3-hydroxybutyric acid and acetone, which is explained by a shift in energy metabolism from anabolic to catabolic state. The increase in betaine explains the reduction of homocysteine and the increase of dimethylglycine and methionine.

The intake of high levels of cereal brans exposes individuals to higher intake of some antinutritional factors. The antinutrient phytic acid is known to act as a powerful chelating agent that forms insoluble complexes with divalent cations such as calcium, magnesium, zinc, and iron, thereby reducing their bioavailability. Phenolic compounds also chelate metals and reduce their bioavailability. As shown in Table 4, the content of polyphenols varies widely in wheat, rice, barley, and oat brans. Rice bran contains higher levels of phenolic compounds and oxalates followed by wheat, barley, and oat bran.

Food Applications

Brans are major side streams generated in the milling of cereal grains by the industry. Brans of wheat, oats, and rice are widely commercially available and are well characterized with respect to their composition and properties, while brans of other cereal grains are much less known. Cereal brans can be added to a number of foods to increase their fiber content and to improve their value as functional foods (the US Institute of Medicine, 2002 recommended that the intake of total dietary fiber for children and adults should be above 25 g day^{-1}). Cereal brans can be used as ingredients in a number of healthy food products including breads, cookies, crackers, snack foods, beverages, sauces, dairy products, imitation cheeses, meats and meat analogues, and many other products. One application

area for wheat bran is its incorporation in pasta manufacturing as it was shown that the addition of 25–30% of common wheat bran to a commercial pasta preparation increased its dietary fiber to a level similar to that obtained by using whole-grain durum flour and provided pasta with very good sensory quality and lower losses of dry matter and higher resistance to overcooking compared with whole-grain durum pasta. Arabinoxylans, from wheat and rye brans, may be added as thickening agents in gluten-free bread, and β-glucan may be added to contribute viscosity to, for example, yogurts and other dairy and nondairy products. The sensory and nutritional value of cereal brans may be improved by fermentation, which adds taste and flavor and removes phytic acid and some of the antinutritional factors. An important product from rice bran is rice bran oil, which is high in γ-oryzanols and tocotrienols and well known for its cholesterol-lowering properties.

In this article, the main characteristics and properties of cereal brans have been discussed. Cereal brans can be exploited as ingredients in a number of functional foods aiming for control of energy intake and health benefits against diabetes, coronary heart disease, and some cancers. The possibilities for applications in food products are wide and unlimited and offer the industry new opportunities for the production of innovative and healthy food products having high contents of fiber and associated bioactive compounds.

Introduction

This article presents a brief overview and comparison of commonly utilized methods for quantifying dietary fiber in food. There are, fundamentally, only two types of methods. Both rely on the removal of nonfiber components by a combination of physical, chemical, and enzymatic procedures prior to measurement of dietary fiber. The gravimetric methods measure dietary fiber by weighing the residue, and the gas–liquid chromatographic (GLC) methods measure dietary fiber by hydrolyzing a treated sample with acid to sugar monomers prior to quantification by GLC. Although, on the surface, both types of methods appear similar, there are fundamental practical differences that have come about because of variations in the individual method steps and differences in the choice of reagents and enzymes. These practical differences have significant consequences since they determine the final composition of dietary fiber as measured by each method.

Procedures have been described for isolating and analyzing dietary fiber in specific foods as well as analyzing carbohydrate polymers that are not digested in the small intestine and are not identified as dietary fiber by the current Association of Official Analytical Chemists (AOAC) methods. This article, however, will focus on practical methods that are applicable to the routine analysis of a wide range of foods. Most total dietary fiber (TDF) methods also allow for the quantification of different fiber fractions such as soluble fiber, insoluble fiber, hemicelluloses, cellulose, and lignin. In this article, only the methods that measure TDF are reviewed. This is partly because of space limitations and partly because the individual fiber components have not yet been positively associated with human physiological effects. For example, soluble and insoluble fiber can be readily measured, but these designations have little physiological meaning since the digestive properties and physiological benefits associated with some soluble fiber can be found in some insoluble fibers and the physiological benefits associated with insoluble fibers are also found with some soluble fibers. In addition, some processing techniques can also partly depolymerize insoluble fiber that may then be found in the soluble fiber fraction.

The early work of Van Soest focussed on measuring ruminant fiber (mainly hemicellulose, cellulose, and lignin), but these procedures could not be used to measure TDF because they would have underestimated the TDF content of human foods by missing a significant proportion of the soluble dietary fiber. All the modern methods incorporate steps to measure soluble fiber. This is important since it can represent a significant proportion of the TDF of a food. The chemical complexity and physical variability of the dietary fiber fraction in various foodstuffs as well as the various food-processing techniques have contributed to the difficulties encountered in devising adequate dietary fiber methods. Many of the present-day TDF procedures are based on the pioneering work of Southgate.

Ideal reference standards do not exist for dietary fiber analysis. Purified fiber components and unpurified standardized 'reference samples' are both used as standards of analysis, but the former group rarely represents the complex dietary fiber matrix found in foods and the latter group remains variable in composition, structure, and properties.

Historical Perspectives on Dietary Fiber Values

Several different measures of dietary fiber and dietary fiber fractions have been reported for foods over the last 150 years. It is important to put these values into some sort of context to understand the differences between these measurements and the implications for human dietary fiber research.

The crude fiber method was standardized in the late nineteenth century in Germany. It was initially developed to analyze ruminant feeds and silage. It is a highly empirical method that uses sequential extractions with hot dilute acid and alkali. The crude fiber residue contains no soluble fiber and retains only about 15% of the total hemicelluloses, 50–100% cellulose, and 10–50% lignin. The variability in the method and the variable losses of various dietary fiber fractions mean that crude fiber values are of little value in human nutrition.

Acid detergent fiber (ADF) represented the first method that reproducibly maintained specific dietary fiber fractions. ADF is obtained by refluxing in 1 N mol l^{-1} sulfuric acid containing cetylmethylammonium bromide detergent followed by filtering and washing. This fraction contains mostly cellulose and lignin.

Neutral detergent fiber (NDF) represents the insoluble fraction of TDF. It is obtained by refluxing in a solution of sodium lauryl sulfate followed by filtration and washing. NDF includes most of the cell wall material but excludes the soluble β-glucans and soluble hemicelluloses. It includes the ADF fraction as well as the insoluble hemicelluloses. It thus underestimates TDF because it does not measure soluble dietary fiber.

In some older tables, TDF values are reported as the sum of NDF and pectin (estimated TDF) but, as shown in Figure 1, this value is not always accurate. Figure 1 also presents the relationship between insoluble dietary fiber (essentially NDF but using porcine pancreatic α-amylase to remove starch; see succeeding text) and TDF (as determined by the rapid health protection branch (HPB) method; see succeeding text) determined for the same foods. The insoluble dietary fiber underestimates the TDF value by ~40%, but this is not constant. The differences between TDF and insoluble dietary fiber represent actual differences measured on the same food sample, but the differences between the estimated TDF and the actual TDF

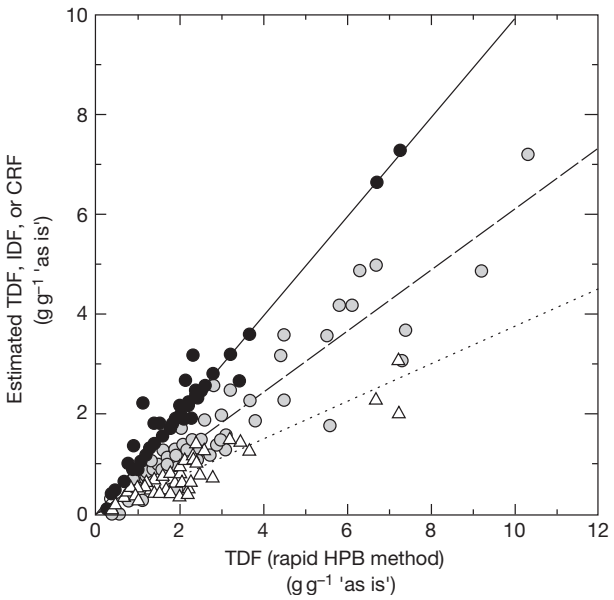

Figure 1 Relationship between crude fiber (CRF; white triangles), insoluble fiber (IDF; gray circles), estimated total dietary fiber (TDF, total of pectin + neutral detergent fiber (NDF); black circles), and TDF values for different types of foods. The TDF and CRF values are from the Canadian Nutrient File (Health Canada 1997; Mongeau et al., 1989). TDF and IDF values were determined by the rapid HPB method (AOAC 992.16, see text). The solid line represents a 1:1 correspondence. The dashed line (IDF) and the dotted line (CRF) are regression lines with the intercept fixed at the origin. Insoluble dietary fiber is essentially NDF but includes a treatment with porcine pancreatic α-amylase. The NDF + pectin values are ultimately from the USDA Nutrient Database (1999).

values were performed at different times with different procedures using different food samples so that procedural variations may account for some of the differences. For example, it is known that some previously determined NDF values were measured after incubation at lower (suboptimal) temperatures that may have given higher and more variable values due to incomplete starch digestion.

In addition to the relationships described earlier, Figure 1 shows the relationship between crude fiber (CRF) and TDF (as determined by the rapid HPB method) for foods from the Canadian Nutrient File. Like the insoluble dietary fiber values, the CRF values significantly underestimate the TDF values; however, in this case, the variability is largely due to the CRF method. Figure 1 shows no consistent relationship between TDF and CRF or insoluble dietary fiber (and thus NDF). Thus, it is not possible to predict TDF values from either CRF or insoluble dietary fiber: a complete TDF measure is required.

Gravimetric Methods

Gravimetric methods use enzyme and/or chemical treatments to remove material that is digestible in the small intestine. Ideally, these treatments should mimic the digestive processes to arrive at a sample that is representative of the material entering the large intestine of humans. Because dietary fiber represents the structural components of plant cell wall material, the weight of the residue is corrected for the presence of noncombustible materials (such as minerals) and corrections may also be applied for components that are incompletely digested by the procedure (such as protein). The remaining weight is considered to be dietary fiber. In order to measure the remaining material gravimetrically, it must be filtered through glass crucibles of defined porosities. It is, therefore, important when preparing the sample to ensure that it is not too finely ground. The use of a Wiley mill avoids these problems and minimizes particle loss during filtration. Many different gravimetric methods have been published with many variations in reagents, temperatures, and incubation times. However, relatively few of these methods have been approved by the AOAC after rigorous testing and interlaboratory verification. Three AOAC-approved methods will be discussed in detail in this section: the rapid HPB method, the Prosky method, and the Lee method. Before presenting these methods, we will first discuss the detergent system.

The Detergent System

When introduced in 1963, the detergent system represented a great improvement over the CRF method, and it is still in use today for measuring insoluble dietary fiber. It has been widely used to measure silage and ruminant feed fiber. The system includes the NDF and the ADF procedures, which use hot detergent to remove digestible material and soluble fiber. The detergent system discriminates among the insoluble fibers – hemicelluloses, cellulose, and lignin. A chelating agent in the neutral detergent solution permits the solubilization of insoluble pectin. When NDF and ADF procedures are performed sequentially, the difference in weight between the NDF and the ADF extracts is an estimation of the insoluble hemicellulose fraction. The ADF residue contains lignin, cellulose, and (if present) cutin. Lignin can be measured by gently oxidizing the ADF residue with potassium permanganate. A 72% sulfuric acid treatment hydrolyzes cellulose leaving cutin, phlobaphenes, and the Maillard products.

NDF and Porcine α-Amylase

Since water-insoluble dietary fibers represent a major fraction of TDF, the NDF procedure represents a simple method that can form part of an overall procedure for measuring TDF in human foods. Nonfiber materials such as starch, most protein, and any fiber-like artifacts remaining in the NDF residue can be efficiently removed by rapid treatment with α-amylase from porcine pancreas (A-3176, Sigma Chemical Co., St Louis, MO); the rapid treatment consists of 5 and 60 min incubations at 55 °C and is at least as effective as the 18 h treatment at 37 °C originally proposed by Schaller. The source of the enzyme is specified since pancreatin and other preparations of porcine pancreas α-amylase are much less efficient. Unpurified porcine α-amylase has unique amylolytic and proteolytic activities when applied after the neutral detergent extraction step, making it an ideal enzyme to use for measuring insoluble dietary fiber.

The heat-stable α-amylase from *Bacillus subtilis* has also been used to digest starch after the neutral detergent extraction

step, but several potential problems arise with this enzyme. It may contain fiber-digesting enzymes that could lead to an underestimation of the cellulose and hemicellulose fractions. On the other hand, it does not completely remove the nonfiber material (such as starch), which will lead to an overestimation of the lignin and possibly the hemicellulose fractions. The final value, therefore, represents a compromise between these two competing factors. Table 1 shows that, for shredded wheat, the NDF residue obtained after treatment with *B. subtilis* α-amylase contained 30% more material than that obtained after treatment with porcine pancreas α-amylase. This residue apparently contained three times more lignin and four times more protein. Both the NDF residue and the apparent lignin content were also higher in samples of bran flakes. Other problems are apparent with the *B. subtilis* α-amylase. For example, toasting whole wheat bread increased the *B. subtilis* α-amylase-measured NDF and lignin values by two- and fivefold, respectively (Table 1), but no such differences were noted with the porcine pancreas α-amylase. The efficacy of the porcine pancreas α-amylase treatment has been verified in various foods and food products and confirmed by other researchers.

In addition to its demonstrated capabilities in avoiding artifactual increases in the estimation of various dietary fiber fractions, porcine pancreas α-amylase enzyme also facilitates rapid filtration in subsequent steps (starch and protein tend to clog the crucibles). The neutral detergent–α-amylase combination is advantageous for research analyses since the neutral detergent solution discriminates well between plant and bacterial cell walls. This is important because bacterial cell walls interfere with the fiber analysis of fecal samples.

Other modifications from the original Van Soest NDF method include the deletion of decalin, 2-ethoxyethanol, and sulfite (to maximize the recovery of lignin).

Rapid HPB Method

The rapid HPB method described here is the AOAC No. 992.16 method. In order to obtain a measure of the TDF in a sample, one needs only to combine the insoluble dietary fiber from the NDF + porcine pancreas α-amylase treatment with a specifically tailored method for measuring soluble fiber. In the rapid HPB method, the soluble fiber procedure was devised to maximize the recovery of soluble fiber while excluding protein and other precipitable, nonfiber materials. This latter characteristic is important if one wishes to avoid time-consuming protein determinations that are part of other procedures. The soluble fiber procedure includes a gelatinization step in acetate buffer at pH 4.5 (121 °C) followed by a treatment with heat-stable α-amylase (100 °C) to remove any starch. Starch gelatinization is important to ensure complete starch hydrolysis. The soluble material is separated from insoluble fiber by filtration and is treated at 60 °C with amyloglucosidase (to finish starch digestion by hydrolyzing branched residues) and then with protease (to hydrolyze the peptide bonds of protein). The soluble fiber is then precipitated in 80% ethanol at room temperature; the sugar and amino acid residues remain soluble in ethanol.

Acetate buffer at pH 4.5 favors the exclusion of protein and appears to prevent the degradation of fiber components that may occur at high temperatures. This does not occur as readily at the relatively higher pH values used by other TDF procedures (e.g., phosphate buffer at pH 7). The heat-processed reference standards extracted from apple and carrot, and used in some collaborative studies, may show lower TDF values due to the loss of pectin during analysis. The differences are less apparent when expressed on a 'per gram fresh weight' basis. Without a method for accurately measuring all cell wall components, it is difficult to provide an absolute compositional measure of the constituents of dietary fiber as measured by different methods. However, the use of differential procedures to obtain fiber fractions (ADF and NDF), coupled with sulfuric acid digestion, permanganate oxidation, and total nitrogen analysis, allows an estimate of the relative contribution of several plant components to the final TDF value.

Figure 2 shows a comparison between several methods for measuring dietary fiber and the relative amounts of the components retained by each method. The rapid HPB method retains lignin (a structural polyphenol), the cell wall-associated protein, and a small amount of starch. The significant amount of starch retained by the Prosky method (see succeeding text) is readily apparent when TDF values are measured in legumes. Table 2 shows a comparison of four different methods for measuring TDF in green peas. The starch in the residue was estimated by subtracting the values from the total nonstarch polysaccharides (NSPs) + lignin measured by the Englyst procedure. The table also shows the effect of adding porcine pancreas α-amylase.

The method is considered 'rapid' when compared to other fiber methods, particularly when the Fibertec E (for soluble fiber) and the Fibertec I (for insoluble fiber) are used. For example, the maximum number of duplicate determinations using the Prosky TDF method is 20 per week, while 44 duplicate TDF determinations per week are possible using the rapid HPB method. This evaluation takes into account the time required for preparing the reagents and performing the

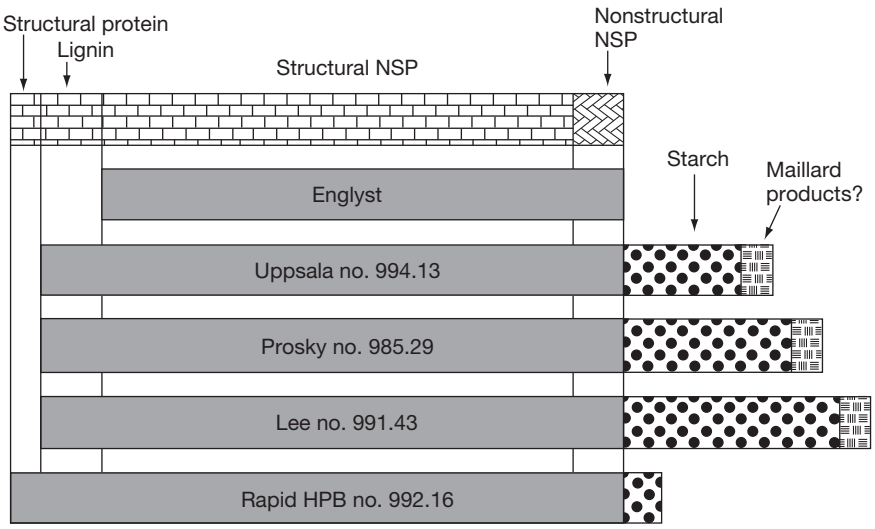

Figure 2 Material measured as dietary fiber by unmodified methods for all food categories. The surface area of the box is proportional to its total dietary fiber (TDF) value. It shows whether the method includes lignin and structural fiber protein or if it excludes starch and the Maillard products. The cell wall material corresponds to the structural nonstarch polysaccharides (NSP), lignin, and structural protein. The larger amounts of starch retained by the Theander, Prosky, and Lee methods are most evident when measuring TDF in legumes. AOAC numbers for each procedure are indicated. Adapted from Mongeau, R. (1995). HPB, Health Protection Branch, Health Canada.

Table 2 Total dietary fiber (TDF) in boiled dried green peas as measured by four different methods with or without added porcine pancreas α-amylase

Method	*TDF on a 'per g dry weight basis' (%)*	*Estimated starch content (%)*
Rapid HPB method, separate	9.9 ± 0.1	2.7
Prosky TDF method	19.0 ± 0.2	11.8
Prosky TDF method + porcine pancreas α-amylase	12.3 ± 0.3	5.1
Lee TDF method	18.8 ± 0.3	11.6
Lee TDF method + porcine pancreas α-amylase	12.3 ± 0.3	5.1
Englyst method (NSPs + lignin)	7.2 ± 0.2	
Englyst method (omit DMSO)	10.4 ± 0.1	3.2

NSPs, nonstarch polysaccharides; DMSO, dimethyl sulfoxide.
Starch content estimated by subtracting the NSP + lignin value from the TDF estimate.

analysis, but not the time required for preparing the samples (freeze-drying and grinding).

Both separate and sequential rapid HPB methods are available and Table 3 presents a comparison between them. In the sequential method, the insoluble residue generated during the soluble fiber determination is treated with neutral detergent and porcine α-amylase yielding the insoluble fiber residue. Thus, a single sample generates both insoluble and soluble fiber measurements to give the TDF value. The separate method requires two samples for analysis. Using a single sample to measure TDF gives a more accurate and reliable measurement because it eliminates potential cross contamination that could give rise to falsely high TDF readings. For example, if the insoluble fiber fraction contains some small amount of soluble fiber, it will be counted twice in the final value (once in the insoluble fraction and once in the soluble fraction). The far right column of Table 3 shows that the TDF values are comparable when measured by either procedure and demonstrates the variability in the procedure.

In a comparison of 28 foods from various categories, the rapid sequential HPB method agreed well with the Prosky TDF method (slope = 0.99, intercept = −0.11, $r^2 = 0.985$) and with the Englyst GLC method (slope = 1.03, intercept = 0.15, $r^2 = 0.989$). For comparison with the Englyst method, it was necessary to measure lignin in each food and add its weight to the total NSP (obtained from the Englyst analysis). This gave a TDF value that was comparable to that measured gravimetrically. The regression parameters indicate that the rapid HPB method and the Prosky TDF method retain similar material in the final fraction (Figure 2). However, the negative intercept shows that the Prosky TDF method gives a higher value than the rapid HPB method when measuring foods containing low amounts of fiber.

The Prosky, Lee, and Asp Methods

The Prosky TDF method has also been referred to as the AOAC method since 1985. The Prosky, Lee, and Asp methods are similar but differ in the sources and types of enzymes as well as in the type and pH value of the buffers. The TDF values from all three methods are comparable (see Table 2 for a comparison between the Prosky and the Lee methods for green peas). In the Prosky and Lee TDF methods, duplicate samples are treated with α-amylase, protease, and amyloglucosidase to remove digestible material. Four volumes of 95% ethanol are

Table 3 Comparison of total dietary fiber (TDF) values by gas–liquid chromatography (GLC: nonstarch polysaccharides (NSPs) + lignin) or gravimetric methods (on a g 100 g^{-1} dry weight basis)

				Gravimetric TDF values[c]		
Food	*NSP*[a]	*NSP*[b]	*Permanganate lignin*	*Prosky*	*Rapid separate*[d]	*Rapid sequential*
Apple	9.9–14.7	13.4	0.8	14.6	14.1	14.6
Beans, green	27.8–32.2	30.6	2.1	33.7	31.3	29.1

then added and the precipitate filtered through Celite C-211 (Thermo Fisher Scientific, Mississauga, Ontario, Canada). The residue contains a substantial amount of nitrogen requiring a total nitrogen analysis (N) and subsequent back-calculation to correct for protein content (N content × 6.25). One of the duplicates is also analyzed for ash as in other gravimetric analyses, and this, too, is subtracted from the residue weight. It is proposed that the use of this protein conversion factor leads to overestimation of dietary fiber (Table 4). The additional protein determination step prevents this method from being considered rapid. As pointed out earlier and in Tables 3 and 4, the final insoluble dietary fiber residue can retain significant amounts of starch. In a simplified version of the Prosky method, the protease step is skipped since protein is measured in the final residue. This means that a larger amount of protein is subtracted as compared with the original Prosky procedure and this may contribute to some variability. The nature of the Celite used in different laboratories has also been considered as a source of variability. Other modifications have also been proposed to improve the precision of the Prosky method. The method comparisons in Tables 2 and 3 were confined to the results obtained with the original version of the Prosky method.

Table 4 Polysaccharide and unidentified material in the Prosky total dietary fiber (TDF) method for selected food groups

	Prosky TDF method residue (g 100 g^{-1} dry matter)		
Food	*Starch*	*Total polysaccharides*	*Unidentified material*
Bread	1.0	5.1	0.8
Other cereals	0.3	3.8	1.0
Green vegetables	1.5	25.6	4.6
Other vegetables	1.8	10.2	7.5
Canned vegetables	2.3	12.9	4.0
Fresh fruit	0.2	8.6	3.5
Fruit products	0.1	2.5	1.5
Nuts	0.4	6.7	2.5

Values represent TDF measurements after correction for ash and 'protein' (N × 6.25). Part of the unidentified material represents lignin but the values are too large to be accounted for as lignin only.

Complete Polysaccharidic Components (GLC Methods)

Southgate published the original TDF method that required the hydrolysis of fiber into its individual polysaccharidic components. In Southgate's method, TDF represented NSPs plus lignin, but the method also provided values for hemicellulose and cellulose content. The method used 85% (v/v) alcohol to precipitate soluble starch residues followed by gelatinization and starch digestion with an appropriate enzyme. The original enzyme used by Southgate (takadiastase) had both amylolytic and proteolytic activities. However, in the 1970s, this enzyme became unavailable and other enzymes were used as replacements. It is apparent that some of these replacement enzymes are often less effective (Tables 2 and 3) but the α-amylase from porcine pancreas appears to be adequate. The original Southgate method measured the NSPs colorimetrically, but now, more specific methods are available such as GLC.

The more modern chemical methods use a combination of enzyme and/or chemical treatments to remove digestible material. The residue is then hydrolyzed by acid prior to the measurement of the sugar content. The acid treatment needs to be severe enough to assure complete hydrolysis but mild enough to prevent monomer degradation. The neutral fiber polysaccharidic constituents are measured chemically, usually by GLC after derivatization to a measurable form (e.g., by forming alditol acetates). Chemical derivatization is not required when high-performance liquid chromatography is used to measure the residue concentration. Acidic sugars (uronic acids) are measured colorimetrically. The total NSP content is obtained by appropriate calculations and TDF is calculated as the sum of

NSPs + lignin. The main GLC methods have been published by Anderson, Englyst, and Theander and their coworkers. Marlett used a modified Uppsala method. The GLC methods are different in several aspects, including the starch gelatinization step, enzyme treatments, and conditions of acid hydrolysis. This explains why the methods may be in agreement for some foods, but not for others.

The Englyst Method

Like all GLC methods, the Englyst method measures NSPs (neutral sugars + uronic acids). However, unlike other methods, the Englyst method is completely applicable to processed foods because it makes use of dimethyl sulfoxide (DMSO) during the gelatinization step to disperse the starch completely. This is followed by treatment with a heat-stable α-amylase and by a mixture of pullulanase–pancreatin in acetate buffer at pH 5.2. This treatment completely removes all the starch, leaving only the nonstarch polypeptides (Figure 2). The total insoluble and soluble NSPs are then precipitated in 80% ethanol and collected by centrifugation prior to hydrolysis with sulfuric acid. Neutral sugar residues are measured by GLC as alditol acetates and uronic acids are measured colorimetrically. According to Englyst and Cummings, the method can be performed in approximately the same amount of time as the Prosky TDF method. However, the GLC instrument must be equipped with an autosampler for the comparison to be valid. A rapid version of the Englyst method also exists with the sugar components measured colorimetrically, but this does not represent a substantial reduction in assay time when compared to the GLC method with an autosampler.

The Englyst method is the only dietary fiber method that does not include lignin. The role of noncarbohydrate components (which include lignin) in *in vivo* fiber digestion may be significant. There is some debate over whether some of the starch and structural protein should be considered as dietary fiber. These components would have to be measured by other methods if they were included in the TDF value.

The Uppsala Method

In the Uppsala method, there is a provision for an initial extraction in 80% ethanol if the sample contains very large amounts of mono-, di-, and oligosaccharides. This extraction appears important in reducing any coprecipitation of nonpolymeric sugars and fiber. Starch is digested in acetate buffer at pH 5.0 by incubating with a thermostable α-amylase and then with amyloglucosidase. DMSO is not used and starch may be less efficiently dispersed and, therefore, less efficiently removed (Figure 2). After reprecipitating in ethanol and centrifuging, the residue is hydrolyzed with sulfuric acid. As in the Englyst method, neutral polysaccharides are analyzed as alditol acetates by GLC and uronic acids by decarboxylation with special equipment or by colorimetry.

Unlike the Englyst method, the Klason lignin is measured gravimetrically. Potential errors can arise when lignin is measured independently and added back to NSPs. For example, the lignin fraction may include other nondigested fiber materials (such as cellulose), which would then overestimate insoluble fiber. This was apparently the reason behind an apparent lignin value of 0.9–3.5% (dry weight basis) measured in apples, peas, or a food composite. This value is suspect because low permanganate lignin values (obtained after the treatment of the insoluble fiber residue with porcine pancreas α-amylase and subsequent workup to obtain an ADF residue) were obtained, which were independent of any food-processing method (similar to the values in Table 1). Marlett had discussed the necessity of measuring lignin and the problems related to its measurement.

The Anderson Method

As in the Englyst method, the Anderson GLC method uses DMSO to disperse starch prior to hydrolysis. The starch is then digested with porcine pancreas α-amylase in acetate buffer at pH 5.2. After precipitation with four volumes of ethanol, the residue is extracted with water at 100 °C to obtain soluble and insoluble fiber fractions. Following centrifugation, the soluble fiber from the supernatant and the insoluble fiber from the pellet are hydrolyzed with sulfuric acid. The Klason lignin is measured as the loss in weight of the nonhydrolyzed insoluble residue after ashing.

Comparison of GLC and Gravimetric Methods for Measuring TDF

As already indicated, there is general agreement between the rapid HPB method and the Prosky and Englyst methods. The regression coefficients were 0.985 and 0.989 for the Prosky and Englyst methods, respectively. Other comparisons have also shown good agreement between values. For example, in a comparison of 25 different foods, TDF values as measured by the rapid HPB method agreed with those reported by Anderson and Bridges (modified Englyst method) and with those reported by Marlett (modified Uppsala method). However, more direct comparisons are needed to determine the potential problems with each method.

Table 3 presents a comparison of the TDF values expressed on a 'per gram dry weight' basis to magnify differences that may be partly hidden when the values are expressed on a 'per gram fresh weight' basis. In order to compare TDF values, the permanganate lignin values need to be added to the NSP values. Three different levels of variability are apparent from the data shown in Table 3. The range of NSP values obtained from three different laboratories (using three slightly different methods and different food samples) illustrates, in part, the intermethod variability. In addition, there is some interlaboratory variability, as shown by a comparison of four laboratories as well as an inherent variability in the samples (including stage of maturation of the product). Direct comparisons are only possible for the results in the five right-hand columns. These samples were composites based on winter and summer collections of up to 20 individual foods over 30 months in different locations. The results show that, when lignin is included in the final TDF value, there is good agreement between GLC and gravimetric methods for the indicated foods.

Nutritional Labeling and Analysis

It is difficult to decide on a single method for measuring the dietary fiber content of all foods. The challenge is to find a

single method that works adequately for all food groups and is independent of sample processing. Several candidates are possible, but to a large extent, the final decision will reflect the definition of dietary fiber. The dietary fiber definition must not be driven by available methodologies but must be arrived at independently of methodological considerations. As shown in Figure 2, it is possible to make a case for including structural protein, lignin, structural, and nonstructural NSPs, as well as some starch. Each method includes variable amounts of all these components. In addition to these complications, it is also possible to separate TDF into insoluble and soluble components. Once again, each method uses different procedures to measure these fractions so that the measured content of insoluble and soluble fiber will differ from laboratory to laboratory. Consumption of these different fiber fractions has not yet been related to definite physiological effects, although there appears to be a role for viscous soluble dietary fiber in reducing the risk factors for cardiovascular disease. The role of starch and other nonstarch polymers not traditionally associated with dietary fiber has yet to be determined as well. Therefore, the following discussion deals only with practical considerations in choosing a TDF method for food labeling.

Equipment

A method requiring simple, inexpensive equipment would be the most widely applicable because it would be more acceptable to nations unwilling or unable to spend considerable sums of money to monitor labeling. In general, the gravimetric methods require simpler equipment and the rapid HPB method is less costly than other gravimetric procedures because it does not require elemental nitrogen analysis. The Englyst colorimetric method can be completed with a simple spectrophotometer, although this method is less robust than the GLC method. Except for the Englyst method, all methods require a muffle furnace for ashing the samples. Although the gravimetric systems require simpler equipment, a hot-water supply is needed and analyses are greatly aided by purchasing semiautomated filtering/refluxing equipment that would increase the cost. However, these pieces of equipment are usually less expensive to maintain than GLCs.

Operator Time

Because it does not include a protein determination, the rapid HPB method requires the least amount of operator time per duplicate determination. Methods that require sugar derivatization and analysis by GLC tend to be longer than the gravimetric methods, especially when lignin measurement is included. The time required for these methods is greatly reduced if the GLC system includes an autosampler. Semiautomatic equipment is available for the gravimetric determinations, but filtering time can be slow, especially for samples that contain a considerable amount of starch.

Lignin

The Englyst method is the only one that does not include lignin in the final TDF value. Most researchers consider lignin to be an important dietary fiber constituent, and, consequently, most methods include a measure of the lignin content. In the GLC methods, the adoption of the Klason method (residue after sulfuric acid digestion) for measuring lignin means that other nonfiber materials such as the Maillard products may be included in the lignin fraction. This could lead to overestimation of the lignin content and, consequently, overestimation of the insoluble dietary fiber and TDF values. Lignin may be more accurately measured by a combination of NDF + porcine pancreas α-amylase and ADF treatments prior to permanganate oxidation. This would, however, increase the time required for analysis as well as increase the amount of sample needed per assay.

Independence from Food Processing

Different methods include different amounts of starch in the final TDF estimate (Figure 2). The only method that does not include any starch is the Englyst method because it completely solubilizes the starch with DMSO prior to enzymatic hydrolysis. There are several different types of starch, some of which arise from food preparation such as retrograde starch, and so the inclusion of starch in a method could be problematic. An example of the potential for problems comes from measuring the TDF values in cooked and uncooked rice and potatoes (high-starch foods) using the Prosky method. The Prosky method gave higher TDF values in the cooked foods. Problems were also noted with roasted peanuts where nonfiber material was included with TDF as well as toasted whole wheat bread (Table 1). Lower cooking temperatures (i.e., 95 °C compared to 100–120 °C) artificially increased the TDF content of white navy beans when the Prosky and Lee methods were used. Some of the problems may have been related to the choice of enzyme used to degrade starch, as was observed for toasted whole wheat bread (Table 1).

In general, the Englyst method is independent of the effects of food processing because it uses DMSO to aid in removing starch and nonpolymeric sugars. This helps exclude food preparation artifacts, such as retrograde starch, as well as the Maillard products, from the final analysis, but it also means that lignin is not included. It also means that lignin is excluded from the final analysis. Other methods that rely on GLC identification of NSPs include the Klason lignin, but this analysis has other problems (see preceding text). Of the gravimetric methods, the rapid HPB method appears to be independent from food processing and, at the same time, includes lignin in the final value.

Precision

Method variability pooled over all foods has been measured in a US Department of Agriculture study using 25 duplicate food samples. Different laboratories were asked to measure TDF in the samples without knowing their composition or source. The coefficient of variation for a single observation was 3.0% with the rapid HPB method, 4.7% with the Prosky TDF method, and 8.4% for the Uppsala method. This represents an estimation of the intralaboratory precision for selected unprocessed and processed foods. More interlaboratory work comparing precision of several methods is needed.

Remaining Problems

The general agreement between the different methods for measuring fiber is encouraging because it opens the door to universal acceptance of a dietary fiber method. However, many problems remain. First, an alcohol precipitation step is used to separate fiber material from nonfiber material. This step usually follows starch digestion and is designed to precipitate sugar polymers. It is possible that some of the fiber components are not completely precipitated and that some sugars released by starch digestion are coprecipitated. This may vary with the method and may be the source of some of the intermethod variability. In addition, the selectivity of this step in separating sugar polymers from nonpolymeric compounds has been questioned. In particular, polymers such as oligofructose (actually a mixture of oligomers and polymers) do not precipitate during the subsequent centrifugation. The 'dietary fiber' nature of these polymers is currently being debated.

Second, structural fiber protein may represent up to 10% of dietary fiber in immature plant tissues. It is impossible, at the present time, to quantify this protein (although the rapid HPB gravimetric method presumably includes it). Except for the rapid HPB method, this fraction is excluded from the reported TDF values.

Third, the colorimetric method for the determination of uronic acid values (included in most GLC methods) needs to be reexamined. This is because the uronic acid content of vegetables was shown to be higher when measured by a decarboxylation method.

Fourthly, there are a small number of foods where significant method disagreement occurs. For example, for soya bean fiber isolate, the NSP value using the Englyst GLC method is lower than the TDF value measured gravimetrically. The reasons for these discrepancies need to be examined in order to determine the exact TDF composition measured by each method. These comparisons will greatly improve fiber methodology.

Finally, although both acetone and ether have been used to remove fat from the samples prior to analysis, their efficacy is questionable and only the defatting procedure of Bligh and Dyer is efficient enough to defat all food samples completely. Caution is warranted when substituting defatting procedures since TDF methods have been validated with their respective defatting methods and substitutions may produce unexpected results. For example, the degree of lignin removal with the Bligh and Dyer procedure is unknown. There is some question as to the necessity for complete defatting since the methods were validated with a wide variety of food samples, all with different fat contents. It may be necessary to reexamine the importance of fat removal prior to analysis in samples containing high amounts of fat.

Conclusion

Comparable TDF values can be obtained for many foods using any of the methodologies discussed earlier. Some foods are more problematic and require a careful choice of methodology. Significant causes of error have been identified, including the potential precipitation of incompletely digested starch and the measurement of the Klason lignin, particularly in processed foods. The inclusion of the Maillard products in the Klason lignin may significantly increase the final TDF value. The following treatment is recommended: NDF, porcine pancreas α-amylase, ADF, and permanganate treatment. This procedure gives permanganate lignin values that are independent of food processing and, when added to NSPs determined by GLC, provides a detailed and known measurement of dietary fiber. The rapid HPB method, including the neutral detergent and porcine α-amylase treatments, has several advantages and would serve as a good method for food labeling.

Caloric Value in Human Nutrition

All food contains energy, which is needed by the body to fuel metabolic processes. This energy is obtained through the oxidation of macronutrients (carbohydrate, fat, and protein) and is partly captured as chemical energy in compounds such as adenosine triphosphate (ATP). These 'high-energy' compounds are used to drive many processes, including the biosynthesis of cellular components, the maintenance of ion concentrations across membranes, the initial phases of catabolic pathways, cell replication, mechanical function, etc. The large amount of energy released by the hydrolysis of ATP ($\sim$7 kcal mol^{-1} under cellular conditions) is captured by coupling its hydrolysis to other chemical reactions to drive them to completion.

The energy captured as ATP equivalents is one end of a long chain of digestive and metabolic processes that starts as the gross energy of the macronutrients in ingested food (Figure 1). Significant losses in energy occur during the digestive process. These can be identified and quantified as losses due to incomplete digestion and absorption (loss in fecal energy to give apparent digestible energy; DE_{app}), losses to fermentation gases and urinary nitrogen energy (to give apparent metabolizable energy), and losses associated with the digestive process itself and with the absorption and storage of food (to give net energy). Calculating the metabolizable energy from a food requires the collection of all excreta (including methane and hydrogen gases). For substances that are fermented, extra information is also required as discussed later in this article. Net energy values are more difficult to estimate and require some assumptions about digestive processes (see section on factorial models of fermentation, eqn [19]).

Metabolizable energy values are the commonly reported food energy values found on product labels. These were initially determined in the 1900s by a German scientist who was a pioneer in this area. To honor his name, these factors are commonly referred to as 'Atwater factors.' Both general and specific Atwater factors exist. The specific values were measured in individual foods. The general values (4 for carbohydrate, 9 for fat, 4 for protein, and 7 for alcohol) were calculated from the specific Atwater factors using average intakes of mixed diets. The more modern food energy values, as contained in tables such as the US Department of Agriculture Handbook #8, represent specific Atwater factors as modified by Merrill and Watt. Although we refer to these factors as metabolizable energy values for macronutrients, the values for carbohydrate and fat are, in reality, DE_{app} values. This is because urinary and gaseous energy losses were considered as insignificant for these macronutrients. In the case of the protein Atwater factors, urinary energy losses were taken into account, but gaseous energy losses were, again, assumed to be negligible. The Atwater factors for fat, protein, and carbohydrate represent the total energy available for metabolism, and this heat should be equivalent to the energy measured with a whole-body calorimeter.

Digestible sugars, fats, and proteins are readily absorbed in the small intestine by physiological and biochemical processes that capture the maximum energy from these food components. These macronutrients are virtually completely absorbed by the small intestine with little energy finding its way into the large intestine. In fact, with diets high in digestible sugars, fats, and proteins, most of the energy entering the large intestine comes from small intestine secretions and from the sloughing off of dead intestinal cells. It is the relative simplicity of the digestive process coupled with the high degree of absorption that allows the comparatively easy metabolic energy calculation for these macronutrients.

Not all food components are readily digested and absorbed in the small intestine. Nonstarch long-chain polysaccharides such as those associated with plant cell walls are not digested by human enzymatic secretions. Many other carbohydrates are not well absorbed by the small intestine. These pass into the large intestine where they are anaerobically fermented by the bacterial population that resides there. For the sake of clarity, the terms 'undigested' and 'resistant' will be used here to refer to the degradation processes occurring in the upper gastrointestinal tract (mostly by host digestive enzymes), and the term 'fermentation' and related words will be used to refer to the bacterial degradation processes occurring in the lower gastrointestinal tract. The energy losses associated with fermentation are not as readily measured, and so calculation of the metabolizable energy for fermentable food components is not as straightforward as it is for sugars, fats, and proteins. The present chapter outlines different methods for obtaining the metabolizable energy of food components not digested and absorbed in the small intestine.

A short note about the methods used to determine macronutrient content of foods is in order. In some countries like the United States and Canada, the carbohydrate content is determined by subtracting the fat, protein, water, and ash content of the food from the total weight (difference method). This measurement includes both 'available carbohydrate' (i.e., carbohydrate that can be digested in the small intestine) and dietary fiber. Other countries, such as Great Britain and Australia, measure 'available carbohydrate' directly using chromatographic methods. The carbohydrate values from this latter method do not include dietary fiber. Specific Atwater factors used in the United States and Canada take into account some (but not all) of the energy losses associated with dietary fiber because they rely on the apparent digestibility of carbohydrate to calculate food energy. This approach overestimates energy availability from mixed diets. In Europe, the general Atwater factor for carbohydrate (4 kcal g^{-1}, 16.7 kJ) is used to calculate

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00782-0

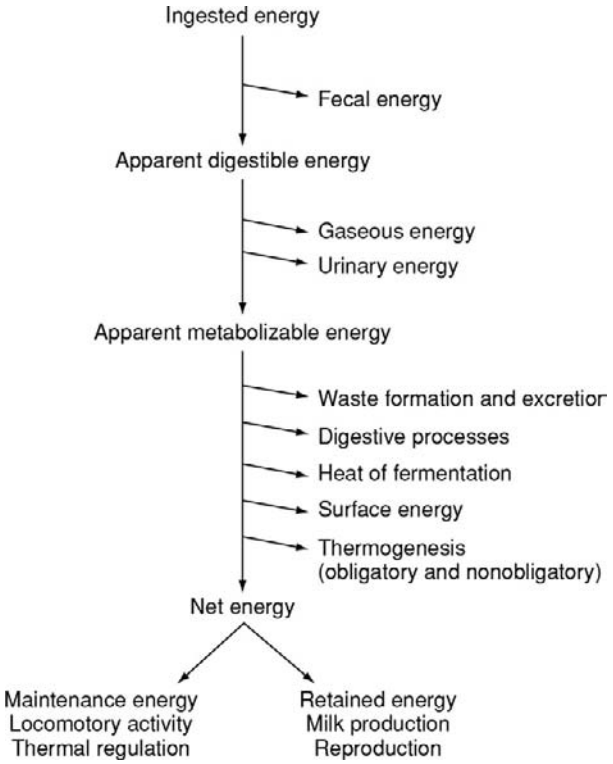

Figure 1 Diagrammatic representation of the energy losses associated with various stages of digestion and the resulting determined energy values.

carbohydrate energy after subtracting the dietary fiber content. This method underestimates the energy of mixed diets. When 'available carbohydrate' is measured directly, one must also measure dietary fiber and use a dietary fiber-specific energy value to calculate the energy contribution from dietary fiber.

Digestible Energy and Metabolizable Energy: Calculations

Digestible Energy

As noted earlier, the digestible energy of a substance is the difference between the ingested energy and the energy excreted in the feces. This is, in principle, a simple definition but gives rise to two different digestible energy values depending on how the measurement is made: the apparent digestible energy and the partial digestible energy. We begin by defining IM_s as the ingested mass of a measured substance FM_s as the amount of the substance of interest. This substance can represent any dietary material, but for the purposes of this article, we will assume that it escapes digestion in the small intestine and reaches the large intestine where it may (or may not) be fermented. If we further define recovered in the feces, the apparent digestibility (D_{app}) can be calculated as

$$D_{app} = (IM_s - FM_s)/IM_s \quad [1]$$

The apparent digestible energy value (DE_{app}) is simply the apparent digestibility multiplied by the heat of combustion (ΔH_c) of the material:

$$DE_{app} = D_{app} \times \Delta H_c \quad [2]$$

The DE_{app} takes into account only the energy loss associated with incomplete digestion of a single food component and not any potential interaction of the component with macronutrients. If the food component is fermented, part of its energy value will be captured and utilized by the host, part of the remaining energy will appear in the feces, and part will be lost to other processes (discussed in the succeeding text). Thus, the DE_{app} overestimates the true digestible energy.

Partial digestible energy values (DE_{part}) describe the influence of a dietary substance on the energy digestibility of the whole diet. As such, they represent a more complete picture of the energy intake and excretion associated with ingestion of a particular food component. Calculating DE_{part} values requires measurement of overall energy balance. The first step is to define the energy digestibility (D_{energy}) of the overall diet as

$$D_{energy} = (IE_T - FE)/IE_T \quad [3]$$

where IE_T is the total ingested energy and FE is the fecal energy. Partial digestible energy values are determined by adding a varying amount of a food component (as a supplement) to an unchanging basal diet. The energy digestibilities of the unsupplemented and supplemented diets are then determined (eqn [3]) and are plotted as a function of the fraction of ingested energy that is derived from the supplement (IE_S/IE_T). If the supplement has a lower digestibility than that of the overall diet, the graph should be a straight line with a negative slope – the energy digestibility of the overall diet will decrease with increasing amounts of the supplement. The partial indigestibility of the supplement (S_D) is given by

$$S_D = \Delta D_{energy}/\Delta(IE_S/IE_T) + (1 - D_{energy,0}) \quad [4]$$

where $D_{energy,0}$ is the energy digestibility of the basal (unsupplemented) diet. The DE_{part} is obtained by multiplying the partial digestibility (1 – the partial indigestibility) of the supplement by its heat of combustion:

$$DE_{part} = \Delta H_c \times (1 - S_D) \quad [5]$$

Partial and apparent digestibilities can differ by a considerable amount. In general, $DE_{part} < DE_{app}$ because DE_{part} includes energy losses that are not accounted for by DE_{app} measurements. This is illustrated by an experiment that compared the DE_{app} and DE_{part} values for the fiber component of hard red wheat bran (bran is ~40% fiber). Measurement of the diet and fecal fiber content and the diet and fecal energy content gave a $DE_{app} = 1.82 \pm 0.17$ kcal g^{-1} (7.6 kJ g^{-1}) and a $DE_{part} = 0.45 \pm 0.10$ kcal g^{-1} (1.9 kJ g^{-1}). The DE_{app} value shows that, for every gram of wheat bran fiber ingested, $4.15 - 1.82 = 2.33$ kcal (9.7 kJ) of energy was lost to feces in the form of fiber. The DE_{part} value shows that $1.82 - 0.45 = 1.37$ kcal (5.8 kJ) of extra energy was lost to the feces in addition to that lost from fecal fiber excretion. Thus, only $0.45/1.82 \times 100\% = 25\%$ of the energy of the fermented wheat fiber was potentially retained by the rats (see later in text for other calculations on the metabolizable energy value of wheat fiber). These calculations show the importance of determining the total energy losses in a digestion experiment involving fermentable substances.

Metabolizable Energy

Like digestible energy values, it is possible to define two different metabolizable energy values. Livesey (1993) called the Atwater metabolizable energy values 'apparent metabolizable energy' values (ME_{app}) because they do not take into account all the energy losses normally associated with metabolizable energy measurements:

$$ME = IE - (FE + UE + GE) \quad [6]$$

where UE is the urinary energy and GE is the gaseous energy. If a strict parallel between digestible energy and metabolizable energy is to be made, one could also define ME_{app} as $DE_{app} - (UE + GE)$. In essence, this is the definition used by Atwater with some assumptions. For fat and carbohydrate, it was assumed that GE and UE were negligible. For protein, it was assumed that GE was negligible but UE was not.

Partial metabolizable energy values (ME_{part}) can also be calculated in a fashion analogous to DE_{part} values. In this case, we define the total energy loss as

$$\sum E_{losses} = FE + GE + UE \quad [7]$$

Once again, we define the energy metabolizability of the total diet as

$$M_{energy} = \left(IE_T - \sum E_{losses}\right)/IE_T \quad [8]$$

and use this value to define a partial energy 'nonmetabolizability' (S_M):

$$S_M = \Delta M_{energy}/\Delta(IE_S/IE_T) + \left(1 - M_{energy,0}\right) \quad [9]$$

where $M_{energy,0}$ is the energy metabolizability of the basal (unsupplemented) diet. The ME_{part} is then given by

$$ME_{part} = \Delta H_c \times (1 - S_M) \quad [10]$$

Equations that minimize the error structure for experimentally determining DE_{part} and ME_{part} are also available.

Like DE_{part} values, ME_{part} values describe the influence of a part of the diet on the energy metabolizability of the whole diet. For protein and fat, it is thought that $ME_{part} > ME_{app}$ because fecal excretion of bacterial nitrogen and fat will decrease the ME_{app} value. Note that energy losses to bacterial fat and nitrogen are not simply due to the loss of macronutrient mass. Energy is required for the *de novo* bacterial synthesis of fat- and protein-containing macromolecular structures, which are then excreted in the feces. This energy is also lost. For carbohydrates, it is thought that ME_{part} and ME_{app} are equivalent since bacteria do not contain appreciable amounts of carbohydrate. For carbohydrates that escape digestion in the small intestine and are partially or completely fermented, like those in dietary fiber, $ME_{app} > ME_{part}$ because of the extra energy losses that occur during fermentation. This energy loss is the subject of this article.

Metabolizable or Net Energy?

The discrepancies between ME_{app} and ME_{part} energy values mean that a more accurate system for measuring food metabolizable energy must be employed for diets containing appreciable amounts of undigested and fermented carbohydrates as the greatest differences occur with these food components. Many methods can be used to obtain the ME values of food components that are not digested by the small intestine. Whole-body calorimetric measurements (in a chamber where an individual can be placed for experimentation) can be used to determine the energy value directly, estimates of the metabolizability can be obtained from mixed diets, body energy measurements can be made in laboratory animals and related back to the metabolizable energy of the food, and theoretical calculations can provide a general model for estimating metabolizable energy.

Large differences exist between the energy losses associated with the digestion of macronutrients (fat, carbohydrate, and protein) and undigested and fermented carbohydrates. Figure 2 shows an example of the various processes that occur in the gastrointestinal tract during the consumption of a partially digested and partially fermented food. Because the final energy value is net of all major losses of energy, many researchers have called it a net metabolizable energy (NME). This should not be confused with the net energy values used for livestock, which represent different energy measurements. Also, it is not the net energy of Figure 1, which incorporates many more energy losses. The NME is a more practical measure of food energy for undigested and fermented substrates because it takes into account energy losses that do not occur for fat, carbohydrate, and protein. Use of this value would allow comparisons between the energy values of different food components.

Mathematical Models for Undigested and Fermented Compounds: Sugar Alcohols

It is technically difficult and expensive to measure all stages of the fermentation process and determine the energy losses

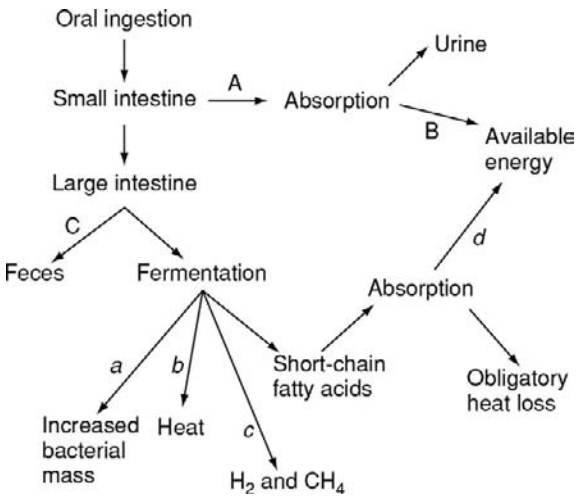

Figure 2 Scheme showing various stages of digestion of a macronutrient that is partially digested in the small intestine and partially fermented in the large intestine. The letters represent fractions of the initial amount that proceed down various pathways (see text).

associated with each step. This is true of human whole-body calorimetric measurements since analysis requires a complete energy balance profile for each subject (see succeeding text). A more simplistic approach involves the construction of a mathematical model of the digestive events in the large intestine. This approach has most commonly been applied to the energy value of sugar alcohols but can also be extended to other partially or completely fermentable carbohydrates.

Common dietary sugars (such as glucose, galactose, and fructose) have a ketone or aldehyde group that allows cyclization to a hexose or pentose ring structure. Reduction of this carbonyl group to an alcohol produces a sugar alcohol that cannot cyclize. The resulting sugar alcohols are not well absorbed in the small intestine so that a significant percentage can pass intact into the large intestine. Isomalt (Palatinit®), an equimolar mixture of two disaccharide alcohols (α-D-glucopyranosyl-1,1-D-mannitol and α-D-glucopyranosyl-1,6-D-sorbitol), is an example of a sugar alcohol that is virtually unabsorbed in the small intestine. It passes intact into the large intestine, where it is rapidly and completely fermented by the bacterial population that resides there. As such, it represents a model for a theoretical dietary fiber that is completely fermented in the large intestine and can be used as a basis for constructing a mathematical model.

A good mathematical model seeks to define all losses that occur during fermentation of ingested material and assign reasonable factors to these losses. Figure 2 presents the scheme for such a model. Fermentable substances provide carbon units for bacterial growth and reproduction and serve as metabolizable substrates to meet the colonic bacterial population's energy requirements for maintenance and growth. Four major products result from anaerobic colonic fermentation: increased bacterial mass (factor *a*, Figure 2), heat energy loss due to fermentation (factor *b*, Figure 2), methane and hydrogen gas (factor *c*, Figure 2), and short-chain fatty acids (SCFAs). Humans can only use SCFAs as an energy source. Thus, the metabolic energy yield of the sugar alcohol has been reduced by the losses to bacterial mass, as well as the heat and gas produced during fermentation. It has also been reported that SCFAs may produce significantly less ATP per gram of absorbed SCFA than glucose, so an additional energy loss to this difference in metabolic efficiency should also be included (factor *d*, Figure 2).

The fermentation model of Figure 2 can be expressed as an equation that incorporates the four major processes by which energy is lost during fermentation. The equation describing the scheme of Figure 2, as it applies to sugar alcohols, was first developed for the Nutrition Council of Holland and has been recognized by several authors as an alternative method for calculating the energy value of sugar alcohols. For partly fermentable substances, it can be written as

$$\mathrm{NME} = \Delta H_c \times [(A \times B) + \alpha \times (1 - A - C) - \beta] \qquad [11]$$

where ΔH_c is the heat of combustion of the substance in question, A represents the fraction of the ingested substance absorbed in the small intestine, B represents the fraction of absorbed substance that is metabolized, and C represents the fraction of the ingested substance that is excreted intact in feces (Figure 2). The factor α represents the proportion of energy derived from fermentation of the substance. It can be calculated from eqn [12]:

$$\alpha = (1 - a - b - c) \times d \qquad [12]$$

The factor β was not present in the original equation and represents the extra energy lost due to the presence of the fermentable carbohydrate. This can come about through binding to macronutrients, changes in osmotic balance, alterations in transit time, changes in intestinal viscosity, inhibition of digestive enzymes, inhibition of macronutrient uptake, or increased sloughing of intestinal cells. As discussed earlier (see section on DE_{part} and ME_{part}), measuring the appearance of an undigested food component in the feces is not sufficient to account for all of the energy losses that can occur when a diet is supplemented with a fermentable carbohydrate. In a practical sense, it is impossible to differentiate between any 'extra' energy lost to the feces (β) and the energy lost due to increased bacterial mass that results from fermentation (factor *a*). The solution is to set $\beta = 0$ in eqn [11] and measure total fecal output.

Using the mathematical model of eqns [11] and [12] requires a knowledge of factors *A*, *B*, and *C*, which are obtained from experimental evidence. For sugar alcohols, values for factor *A* have been obtained from ileostomy patients or by direct sampling using multiple lumen tubes. Factor *B* (the amount of sugar alcohol metabolized) has been estimated indirectly by measuring urinary sugar alcohol content (the amount of sugar alcohol not metabolized).

In the original factorial model paper, the Nutrition Council of Holland held α to be constant for all sugar alcohols and estimated it at 0.5. This value included fermentation energy losses resulting from increased microbial mass excreted in the feces ($a \approx 0.2$), loss of H_2 and CH_4 ($c = 0.03$–0.08), heat produced by microbes ($b = 0.02$–0.05), and higher heat loss during utilization of SCFAs as compared with glucose ($d = 0.80$–0.85). Summing these factors gives a value of 0.40–0.53. The value of 0.5 was adopted because the Nutrition Council of Holland did not want to suggest that the value was known with high precision (they could have used 0.46–0.47 as the average) and because they wanted to include some energy lost to increased cell proliferation in the large intestine caused by increased fermentation. Thus, the slightly higher value of 0.5 was chosen as an estimate of the total losses during fermentation. In a later review of the value of α, it was determined that the individual factors that contribute to α should give a value closer to 0.6. However, in the same review, the author noted that the factorial procedure overestimates energy values to the extent that it takes no account of osmotic effects of the sugar alcohol. Thus, the results of energy values calculated by the Dutch method are probably fairly accurate. Many researchers agree that the value of 0.5 represents a reasonable estimate of the fermentation process.

For completely fermentable substrates that are not absorbed by the small intestine, like sugar alcohols, the MNE value is $0.5 \times \Delta H_c$ because $A = 0$ and $C = 0$. As indicated earlier, the value of β is set to 0, and any 'extra' energy lost due to ingestion is incorporated into the factor α, which has been estimated at 0.5. Thus, for the sugar alcohol isomalt (which is completely fermented and not absorbed by the small intestine), the energy value is ~ 1.9 kcal g^{-1} (8 kJ g^{-1}, approximately half the heat of combustion). For completely fermentable dietary fibers, the $0.5 \times \Delta H_c$ rule of thumb

represents an upper limit of the NME since dietary fiber is known to bind fats and cholesterol as well as inhibit carbohydrate absorption. Thus, dietary fiber may interact with other macronutrients to decrease their metabolizable energy values. This will give a lower NME value for dietary fiber since there will be a higher excretion of fecal energy.

When all the energy losses are included, the energy value of dietary fiber can be small compared with the ingested value. For example, measurements with hard red spring wheat fiber give NME values of ~ 0.3 kcal g^{-1}, even though the total ingested energy is ~ 4 kcal g^{-1}. In the case of hard red spring wheat bran, much of the energy is lost to excretion; wheat bran dietary fiber is incompletely fermented so that $\sim 60\%$ is lost directly to the feces. In addition, a significant loss of energy comes from dietary fiber interactions with macronutrients plus other losses due to the presence of wheat bran fiber (β). Finally, energy is lost during the fermentation process itself. The energy value of hard red spring wheat fiber is not typical of other dietary fibers, as shall be shown in the following sections (Table 1).

Whole-body Calorimetric Measurements: Lactitol as a Model

Indirect calorimetry (a type of whole-body calorimetry where all gas consumption and gas exhalation are continuously monitored) can be used to determine energy expenditure through the use of equations relating total O_2 consumption, CO_2 expiration, and urinary nitrogen excretion to energy utilization. One such equation is

$$\text{Heat production} = 16.175\,O_2 + 5.021\,CO_2 - 5.987\,\text{urea N} - 4.5\,H_2 \quad [13]$$

In addition to total energy production, indirect calorimetry provides information on macronutrient utilization through the nonprotein respiratory quotient (RQ). The RQ is the ratio of CO_2 expired to O_2 consumed during a defined period. The theoretical RQ values are known for fat, carbohydrate, and protein oxidation, making it possible to determine total fat, carbohydrate, and protein oxidation. When protein oxidation is estimated from nitrogen excretion, fat and carbohydrate oxidation can be calculated as follows:

$$\text{Nonprotein RQ} = 1.00 \times \text{carbohydrate oxidation} + 0.707 \times \text{fat oxidation} \quad [14]$$

However, caution is needed when estimating fuel oxidation from nonprotein RQ values, since the RQ itself can vary considerably depending on the fat and protein mixture being oxidized. In addition to the problem of obtaining an accurate picture of fat and carbohydrate oxidation from nonprotein RQ values, it is also not possible to distinguish between the oxidation of carbohydrate + fat and the oxidation of SCFAs produced by carbohydrate fermentation. When measuring the apparent metabolizable energy value of a macronutrient that represents a small proportion of the total diet, there is a high potential for error when macronutrient oxidation profiles are measured. However, theoretical calculations show that there is much less error associated with measuring energy loss.

An example of the use of indirect calorimetry for measuring the metabolic energy of completely fermentable substances is the determination of the net energy value for lactitol, a disaccharide sugar alcohol (4-*O*-(β-D-galactopyranosyl)-D-sorbitol). The total energy balance was measured during the experimental period in the calorimeter. The retained energy of each subject was then calculated as

$$\text{RE(retained energy)} = \text{IE}_\text{T} - (\text{fecal E} + \text{urine E} + \text{gaseous E} + \text{expended E}) \quad [15]$$

The energy needed to maintain energy balance (metabolizable energy for maintenance; ME_m) could then be determined as

$$\text{ME}_\text{m} = \text{metabolizable energy intake} + \text{negative RE} - 1.11 \times \text{positive RE} \quad [16]$$

The factor 1.11 represents the cost of depositing body energy and was measured in an earlier experiment. The difference in ME_m on a diet supplemented with sucrose versus one supplemented with lactitol is a measure of the energy lost from lactitol and can be expressed as the change in ME_m adjusted for the metabolic weight of the individuals (weight$^{0.75}$):

Table 1 Potential error associated with oxidation of 50 g of a carbohydrate versus fermentation and oxidation of the released short-chain fatty acids[a]

Substrate	*RQ*	*Oxidation substrates (mol)*[b]	*O_2 consumed (mol)*	*H^{eq}*[c]	*kcal per 50 g*
50 g of sucrose	1.00	0.146 CHO	1.753	5.012	250.6
50 g of lactitol	0.943	0.409 (CHO) + 0.099 (fat)	1.113 (CHO) + 0.269 (fat)	4.981 (CHO) + 4.682 (fat)	153.1
50 g of lactitol	0.943	0.508 SCFA	1.382	4.663	144.5

[a]The table illustrates the potential error involved in measuring the apparent metabolic energy value of a completely fermentable supplement (lactitol) by indirect calorimetry. This was done by calculating the apparent metabolic energy value using two different methods. It was assumed that lactitol was fermented to a mixture of SCFAs followed by complete oxidation to CO_2 and water plus fermentation gases. In an indirect calorimeter, oxidation of SCFAs can be mistaken as oxidation of fat and carbohydrate in a 0.195:0.808 ratio. Oxidation of these substrates would give 153.1 kcal per 50 g. Oxidation of the SCFA directly would give 144.5 kcal per 50 g of original lactitol. Thus, an error of $\sim 6\%$ can occur when indirect calorimetry is used to measure the metabolic energy value of lactitol. The yield of SCFAs from lactitol and the proportion of acetate, propionate, and butyrate (115.1:35.38:24.5 per 100 mol of glucose) represent weighted averages of literature values for ruminants. As such, these calculations approximate the actual error associated with indirect calorimetry, which varies from individual to individual.

[b]Equivalent mol of sucrose or SCFAs obtained from 50 g of substrate.

[c]H^{eq} values from Livesey, G. and Elia, M. (1988). Estimation of energy expenditure, net carbohydrate utilization, and net oxidation and synthesis by indirect calorimetry: evaluation of errors with special reference to the detailed composition of fuels. *American Journal of Clinical Nutrition* 47: 608–628. The H^{eq} value for glucose was used for carbohydrate and the H^{eq} value for the fat mixture of an omnivore diet was used for fat. The H^{eq} value for SCFAs represents a weighted average.

$$\Delta ME_m = (ME_m/weight^{0.75})_{lactitol} - (ME_m/weight^{0.75})_{sucrose} \quad [17]$$

and the NME can then be calculated as

$$NME = ME_{part} - \Delta ME_m/(IS/weight^{0.75})_{lactitol} \quad [18]$$

where ME_{part} is obtained from eqn [10] and IS is the ingested mass of the supplement (lactitol). The ME_m values are divided by the metabolic weight to account for differences in metabolic mass. Using this procedure, a value of 2.4 kcal g^{-1} (10 kJ g^{-1}) for lactitol was obtained. Note that some measure of the energy expenditure is required in this experiment (eqn [15]). The authors relied on diaries and ankle actometers and corrected to equal actometer counts. They acknowledged that this was not very satisfactory; there is a potential 15% error in the final net energy value for lactitol.

Metabolizable Energy Value of Dietary Fiber in Mixed Diets

Up to this point, this article has focussed on undigested and fermented food components as a general group of substances. This section will deal specifically with dietary fiber, a partly fermented food component that passes through the small intestine unacted upon by human digestive enzymes. Dietary fiber is a mixture of nonstarch polysaccharides and lignin that are structural components of plant cell walls.

As indicated earlier, it is not appropriate to use metabolizable energy values for dietary fiber since many more energy losses are associated with fiber digestion as compared with the digestion of fat, carbohydrate, and protein. Equations have been developed to take account of these extra losses and provide a method to calculate the NME value of a fermentable dietary component when the fecal energy losses are known. These equations show that approximately one-half of the potential energy is available to the host when undigested carbohydrates are completely fermented. This value is widely accepted.

Knowledge of the energy yield from the fermented portion of dietary fiber is not sufficient in and of itself to allow the calculation of dietary fiber NME since a significant proportion of the 'fermentable' dietary components are not fermented but appear in the feces. In addition, some 'extra' energy (factor β, eqn [13]) may be lost during digestion because of the intimate physical interaction between dietary fiber and the food matrix. The aim of these studies is to determine a general NME value for dietary fiber that can be used to calculate the metabolizable energy of mixed human diets. To overcome these problems, two solutions have been employed. The first solution involved determining individual digestibility factors for specific foods and using these to calculate metabolizable energy intake. This method has the advantage that macronutrient digestibility is measured directly for specific foods and multiplied by the specific heats of combustion when available. In this method, the calculated digestible energies of the diets are close to the measured values for mixed diets since the final value reflects the sum of the individual components. This method has some problems. In the system of Merrill and Watt, the digestibility of carbohydrates was determined by difference, so accurate values for carbohydrate digestibility are lacking. This also means that a digestibility value for the fermentable food component portion of the carbohydrate fraction (as determined by difference) is lacking. It is, therefore, not possible to calculate the metabolic energy of a food of known composition since values for undigested and fermented components are not available. This limits the usefulness of this system to foods that have been measured. In addition to this problem, the NME value is appropriate for undigested and fermented food components, whereas the digestible energy value is not. Thus, this system does not allow any correction for energy lost when food components are resistant to digestion but fermented in the lower gut.

The second solution is to use an average digestibility value determined by examining typical mixed diets. This can be calculated by two separate methods: using a factorial approach and using an empirical model. Factorial models relate total protein, fat, carbohydrate, and dietary fiber intake to digestible energy through an equation of the type:

$$\begin{aligned} ME(kca) = {} & 4.0 \times protein(g) + 9.0 \times fat(g) + 3.75 \\ & \times carbohydrate(g) + NME_{DF} \\ & \times dietary\ fiber(g) \end{aligned} \quad [19]$$

In the development of eqn [19], carbohydrate was determined directly (not determined by difference) and is expressed as monomeric units. Dietary fiber must also be measured directly through an approved, reproducible method that is not affected by food processing. The factors 4 (protein) and 9 (fat) are the general Atwater factors derived from mixed diets. The value of 3.75 for carbohydrate is slightly lower than the general Atwater factor of 4. This reflects the fact that the carbohydrate is expressed as the total monomeric weight.

The value of NME_{DF} (the NME for dietary fiber) comes from an analysis of the dietary fiber digestibility of mixed diets and the loss of energy to feces in mixed Western diets. This value is determined as follows. Firstly, the DE_{part} value for dietary fiber is obtained by comparing the digestible energies of mixed diets to the metabolizable energy calculated by eqn [19]. The apparent digestible and metabolizable energies for carbohydrate and fat are identical since the macronutrient digestibilities were accounted for, and urine and gaseous losses of these components were negligible. Protein losses are corrected for urine nitrogen and protein digestibilities. The digestible energy for dietary fiber (DE dietary fiber) was estimated by

$$\begin{aligned} DE\ dietary\ fiber &= \Delta H_c \times D_{app} \times (1 - a) \\ &= 4.1\ kcal\ g^{-1} \times 0.7 \times 0.7 \\ &= 2.0\ kcal\ g^{-1} (8.4\ kJ\ g^{-1}) \end{aligned} \quad [20]$$

The apparent digestibility of dietary fiber is around 0.7. The value of factor a in eqn [20] needs to be defined for dietary fiber. For sugar alcohols, the value is ~0.2 (see preceding text). A value of 0.3 has been adopted for dietary fibers in humans. This value reflects the fact that the majority of energy loss estimates lie between 0.2 and 0.4 kcal $kcal^{-1}$ of fermented energy. As already mentioned, a value of 0.2 was obtained when measuring lactitol energy utilization in human subjects. It has also been suggested that between 20% and 30% of the energy in undigested and fermented carbohydrates is mikuutilized by bacteria in humans. A value of 0.2 kcal $kcal^{-1}$ of fermented material has been measured in rats fed with an α-amylase-resistant pea starch, and a value of 0.4 kcal $kcal^{-1}$ of fermented material has been measured in rats fed with guar gum. In human diets with high intakes of dietary fiber, an increased fecal energy output of 0.3

and 0.39 kcal kcal^{-1} of energy fermented, respectively, has been measured. Overall, these data suggest that about 0.3 kcal of energy is lost to the feces per kcal of energy fermented. Thus, $1.0 - 0.3 = 0.7$ kcal kcal^{-1} is retained.

As indicated earlier, the digestible energy value does not give an accurate picture of the energy losses that occur during fermentation of undigested food components. Correction factors must be included for energy losses to the heat of fermentation (factor *b*), losses to fermentation gases (factor *c*), and the relative efficiency of utilization of SCFAs (factor *d*). Correcting the digestible energy for these values gives

$$\begin{aligned} \text{NME}_{\text{DF}} &= \Delta H_c \times D_{\text{app}} \times 0.54 \\ &= 4.1 \text{ kcal g}^{-1} \times 0.7 \times 0.54 = 1.5 \text{ kcal g}^{-1} \end{aligned} \quad [21]$$

Equation [21] shows that the NME value for dietary fiber is approximately 1.5 kcal g^{-1}. Equation [21] applies strictly to dietary fiber because the ΔH_c value and digestibilities were determined for dietary fiber. It is useful for calculating the metabolic energy values of mixed diets because the digestibilities were determined for mixed diets. It is comparable, therefore, with the general Atwater factors of 4, 9, and 4 for carbohydrate, fat, and protein.

Empirical models represent another method for determining total energy intake. Empirical models are, in general, superior to the factorial models for a number of reasons, the most important being that the empirical models are much more robust to errors in carbohydrate, fat, and protein determinations as well as to the use of general Atwater factors. An example of an empirical equation is as follows:

$$\begin{aligned} \text{ME} = 0.96 &\times \text{total energy(kcal)} - 2.5 \text{ kcal g}^{-1} \\ &\times \text{dietary fiber(g)} - 12 \text{ kcal g}^{-1} \\ &\times \text{ingested nitrogen(g)} \end{aligned} \quad [22]$$

Equation [22] relates the metabolizable energy to total energy, protein, and dietary fiber only. The factor 0.96 represents the metabolizability of mixed diets in the absence of dietary fiber. The value of 2.5 kcal g^{-1} represents the NME energy loss associated with ingestion of dietary fiber. This value is therefore the difference between the heat of combustion of dietary fiber and its NME_{DF} value (determined in the preceding):

$$\begin{aligned} 2.5 \text{ kcal g}^{-1} &= \Delta H_c - \text{NME}_{\text{DF}} \\ &= 4.0 \text{ kcal g}^{-1} - 1.5 \text{ kcal g}^{-1} \end{aligned} \quad [23]$$

A version of eqn [22] was tested for bias and accuracy of prediction by comparison with 43 human diets containing varied intakes and sources of dietary fiber. The equation showed no bias over a wide range of dietary fiber intake (2–93 g daily). By necessity, this test was performed by comparing DE_{part} values because ME_{part} values cannot be measured directly for fermentable food components. This analysis provides further evidence for a general NME for dietary fiber of 1.5 kcal g^{-1}.

Overall Conclusion

Eating food components that are not digestible but that are fermentable lowers the amount of metabolizable and digestible energy available from food. This occurs because of two different processes. Fermentable food components, like dietary fiber, are not 100% fermentable, and so the NME for these components is lower than that of protein, carbohydrate, and fat. In addition, fermentation itself is associated with many different energy losses, including losses to increased bacterial mass, the heat of fermentation, fermentation gases, and a lower efficiency of host utilization of SCFAs. Because the digestion of fermentable food components is so different from that of macronutrients, special equations are needed to determine the NME yield.

It is possible to utilize data from several sources to obtain an estimate of the relative losses that occur during fermentative digestion and back-correct to obtain an unbiased estimate of the energy value of dietary fiber. Taking into account all these energy losses, an NME value for dietary fiber of 1.5 kcal g^{-1} (6.3 kJ g^{-1}) has been calculated. This appears to accurately predict energy losses associated with mixed Western diets when analyzed using either factorial or empirical models. Thus, the NME of 1.5 kcal g^{-1} (6.3 kJ g^{-1}) can be used in a fashion similar to the general Atwater factors of 4, 9, and 4 for protein, fat, and carbohydrate to predict the metabolizable energy of mixed Western diets. Individually measured NME values for fiber in whole foods may differ from this value since dietary fiber is fermented to different extents and is intimately associated with the food matrix, which may limit macronutrient digestibility. Thus, individual measurements are needed for direct comparison and may be required for specific types of foods.

Introduction

The term 'crude fiber' dates from the nineteenth century, when it was used to describe the material that remained after rigorous nonenzymatic hydrolysis of animal feedstuffs. The importance of similar undigestible residues in human foods was recognized in the early 1970s by the physician and epidemiologist Hugh Trowell, but he also argued that the crude fiber figures then available for foods had little physiological significance and were of no value in the context of human diets. He therefore coined the term 'dietary fiber' for what he and others came to define as "The sum of lignin and the plant polysaccharides that are not digested by the endogenous secretions of the mammalian digestive tract." In practice, these residues contain resistant starch molecules, but for many years, a narrower definition, which included only 'nonstarch polysaccharides' (NSP), found favor, particularly in the United Kingdom. However, the most recent CODEX definition (2009) states that "Dietary fiber means carbohydrate polymers with 10 or more monomeric units, which are not hydrolyzed by the endogenous enzymes in the small intestine of humans." This definition, which has been widely adopted internationally, includes both resistant starch molecules and cell wall polysaccharides, together with lignin and a few other minor components. Certain isolated or synthetic polysaccharides can also be included in the definition, so long as they have been shown to exert beneficial physiological effects. Dietary fiber thus includes a large and complex mixture of polysaccharides that share few properties other than resistance to digestive enzymes. The presence of undigested cell wall fragments and dispersed polysaccharides in the intestinal lumen can alter physiological processes throughout the gut, but the effects of different fiber components depend upon their varied physical and chemical properties during digestion and their varying susceptibilities to degradation by bacterial enzymes in the colon. It is important to realize that a single analytic value for the fiber content of a food is a poor guide to its physiological effects. This article will review the main mechanisms of action of resistant polysaccharides in the alimentary tract and their implications for human health.

Fiber in the Alimentary Tract

Food is conveyed through the alimentary tract by the rhythmic muscular activity of peristalsis. Digestive enzymes are released into the lumen at intervals to facilitate the breakdown of macromolecules into fragments that can then be absorbed and utilized by the body. The earliest stages of digestion begin in the mouth, where food particles are reduced in size and lubricated with saliva, which also contains the digestive enzyme salivary amylase. In the stomach, any large particles that remain are broken down by rigorous muscular activity in the presence of hydrochloric acid and proteolytic enzymes. The need to disrupt and disperse intractable food particles and cell walls delays gastric emptying, and since cell wall polysaccharides help to determine the texture of many plant foods, and hard foods tend to be chewed more thoroughly than soft foods, the presence of dietary fiber in unrefined foods may begin to regulate digestion at a very early stage. Apples, for example, tend to be consumed more slowly than apple juice, and the absorption of sugar from apples is also slower. Similarly, the rate at which the products of starch digestion are absorbed from cubes of cooked potato has been shown to be much slower when they are swallowed whole than when they are chewed normally. The nutritional significance of such effects is not entirely clear, but they may limit the rate at which glucose from some foods enters the circulation.

Small Intestine

The small intestine is the largest of the digestive organs, with the greatest surface area, as befits its role as the main site of nutrient absorption. The semiliquid products of gastric digestion are released at intervals into the small intestine and propelled away from the gastroduodenal junction by peristaltic movements at about 1 cm min^{-1}. The hydrolysis of proteins, triglycerides, and starch continues within the duodenum and upper jejunum, under the influence of pancreatic enzymes. The final stages of digestion occur at the mucosal surface, where the products are absorbed into the circulation, along with water and electrolytes, via the specialized epithelial cells of the intestinal villi. Muscular activity in the small intestinal wall, together with rhythmic contractions of the villi, ensures that the partially digested chyme is well stirred. In adults, the first fermentable residues from a meal containing complex carbohydrates enter the colon ~4.5 h after ingestion. When a solution containing indigestible sugar is swallowed without food, it reaches the colon about 1.5 h earlier than when the same material is added to a solid meal containing dietary fiber. The effects of dietary fiber on transit through the small intestine are complex and difficult to study. Experiments with human subjects suggest that though coarse bran added to experimental meals delays gastric emptying, it may accelerate small intestinal transit. However, there is also some evidence that phase separation occurs, so that bran may accumulate in the distal ileum without any delay in transit of the liquid phase to the colon. Viscous polysaccharides such as guar gum appear to have little effect on small intestinal transit in humans.

Carbohydrate Metabolism

In his early work, Trowell proposed that dietary fiber was a major factor in the prevention of type 2 diabetes. Indeed, he

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00783-2

argued that this condition was largely unknown in Western Europe prior to the introduction of mechanized flour milling because until then, the consumption of unrefined carbohydrate foods had favored slow absorption of glucose, which placed less strain upon the ability of the pancreas to maintain glucose homeostasis. Whatever its merits, this hypothesis stimulated a great deal of research on the effects of cell wall polysaccharides on the digestion and absorption of carbohydrates, and this has undoubtedly shed light on the role of dietary fiber in the management of diabetes. The 'glycemic index' (GI) quantifies the appearance of glucose in the bloodstream after ingestion of a carbohydrate-rich food. To determine the GI for a specific food, fasted subjects are given a test meal containing a standardized quantity of carbohydrate. The area under the blood-glucose curve in response to the test meal, divided by that produced by an equal quantity of a reference carbohydrate such as glucose, gives a ratio that, expressed as a percentage, is the GI. When glucose is used as the standard, unrefined foods containing dietary fiber often have a GI substantially lower than 100%.

The resistance of plant cell walls to digestion during passage through the gut varies considerably from one food to another, and any cell walls that remain intact in the small intestine will impede the access of pancreatic amylase to starch. Even when enzymes and their substrates do come into contact, the presence of cell wall polysaccharides may slow the diffusion of hydrolytic products through the partially digested matrix in the gut lumen. Pulses tend to give particularly low GI values, probably because legume seeds have relatively thick cell walls that resist destruction during processing and cooking. This particular effect of fiber on GI cannot be predicted from simple analytic values for total fiber because it reflects the structure, as opposed to the absolute quantity, of cell wall polysaccharides within the food.

Many studies on postprandial glycemia have been conducted using isolated fiber supplements added to glucose test meals or to low-fiber sources of starch. They demonstrate that, contrary to Trowell's original hypothesis, wheat bran and other insoluble cell wall materials have little effect on glucose metabolism. However, certain polysaccharides, such as guar gum, pectin, and oat beta-glucan, which form viscous solutions in the stomach and small intestine, do reduce the GI of foods to which they are added. Highly viscous food components may delay gastric emptying but the primary mechanism of action appears to be suppression of convective stirring in the fluid layer adjacent to the mucosal surface. The rapid uptake of monosaccharides by the epithelial cells tends to reduce the concentration of glucose in this boundary layer, so that absorption from the gut lumen becomes rate-limited by the relatively slow process of diffusion. The overall effect is to delay the assimilation of glucose and hence suppress the glycemic response to glucose or starchy foods. A similar mechanism probably inhibits the reabsorption of cholesterol and bile salts in the distal ileum, and this may account for another important physiological effect of viscous polysaccharides such as oat beta-glucan, which is to reduce plasma cholesterol levels in humans.

Mineral Metabolism

Polysaccharides and phenolic components of cell walls often contain polar groups that can interact with ionized solutes in the gastrointestinal contents. Such molecular binding effects do occur *in vitro* and might, in principle, restrict the availability of nutrients and other substances for absorption in the small intestine. Iron, zinc, and calcium are absorbed relatively poorly from the human diet, and there have been some concerns that high intakes of dietary fiber might exert an adverse effect on human mineral nutrition. However, studies with subjects who, for clinical reasons, have had the colon removed and the small bowel brought to the abdominal surface (ileostomists) suggest that neutral polysaccharides do not bind minerals to any significant extent. Charged polysaccharides such as pectin can bind mineral cations, but fermentation of cell walls in the colon probably releases iron and calcium into the lumen, whence they may be salvaged by colonic absorption. There is little objective evidence that dietary fiber per se has an adverse effect on mineral metabolism. Furthermore, consumption of highly fermentable oligosaccharides such as inulin has been shown to improve calcium absorption in humans and animal models, apparently because the production of short-chain fatty acids stimulates active mineral transport in the colon.

The effect of phytate (myoinositol hexaphosphate) is generally considered to be more significant than that of fiber. Phytate is often present in close association with cell wall polysaccharides in unprocessed legume seeds, oats, and other cereals. Phytate does exert a potent binding effect on minerals and has been shown to reduce the availability of magnesium, zinc, and calcium for absorption in trials with human volunteers. Phytate levels in foods can be reduced by the activity of endogenous phytase, by hydrolysis with exogenous enzymes, or by fermentation. Dephytinized products may be of benefit to individuals at risk of suboptimal mineral status.

Large Intestine

The large intestine, which is located distal to the small bowel, salvages energy from food residues and from endogenous proteins and carbohydrates that have escaped digestion and absorption. Its other main role is to form and store feces. Fecal microorganisms degrade undigested starch and many of the polysaccharides that comprise dietary fiber, to yield the volatile fatty acids butyrate, propionate, and acetate. Whereas the foregut of ruminants is adapted to provide a watery, nutrient-rich environment for bacterial fermentation, it is the colon that provides the main site of permanent bacterial colonization in the human alimentary tract. The development of rapid and inexpensive gene sequencing technology has revolutionized the study of this gastrointestinal microbiota in recent years, and the gut microbiome, as it is now known, derives much of its nutrition from dietary fiber. The metabolic activities of the gut bacteria are now thought to exert a major influence on human metabolic health, and the effects of diet on the composition of the microbiome are a major focus of interest.

Absorption and metabolism of short-chain fatty acids derived from carbohydrate fermentation provides an important route for the recovery of energy from undigested polysaccharides. Butyrate functions as a major fuel for the colonic mucosal cells, whereas propionate and acetate are absorbed and metabolized systemically. The other major breakdown products of carbohydrate fermentation are hydrogen, methane, and carbon dioxide, which together comprise flatus gas.

Excess gas production is said to cause distention and pain in some individuals, especially those attempting to increase their fiber consumption, but this is probably caused more by fermentation of oligosaccharides such as stachyose and verbascose, found, for example, in legume seeds, rather than the cell wall polysaccharides themselves. The proximal colon contains about 200 g of dilute fecal material, portions of which are transferred at regular intervals from the right colon into the transverse and distal segments for partial dehydration and storage. The pattern of motility in the large intestine is similar in principle to that of the rest of the alimentary tract, but the rate of transit is slower. In healthy individuals, stools are passed with a frequency varying from once or twice a day to once every 2–3 days.

Fecal Bulk and Composition

The ability of dietary fiber to prevent cancer and various degenerative diseases of the alimentary tract was proposed by Denis Burkitt, who based his hypothesis largely on the concept of fecal bulk. His field observations in Africa, where cancer and other chronic bowel diseases were rare, suggested that populations consuming traditional rural diets rich in vegetables and cereal foods produced bulkier, more frequent stools than persons living in the industrialized West. Burkitt argued that consumption of highly processed cereals in industrialized societies led to chronic constipation and that this caused prolonged high pressures both within the colonic lumen and also within the lower abdomen as a result of straining to pass hard stools. This in turn was thought to increase the risk of various diseases of muscular degeneration including varicose veins, hemorrhoids, hiatus hernia, and colonic diverticula. Furthermore, infrequent defecation was thought to cause prolonged exposure of the colonic epithelial cells to mutagenic chemicals that could initiate cancer. Although Burkitt's overall hypothesis for the beneficial effects of fecal bulk is undoubtedly an oversimplification, it has never been comprehensively refuted. There is relatively strong epidemiological evidence for a protective effect of dietary fiber against colorectal cancer, and although there is no conclusive evidence from randomized controlled trials, this association provides one of the main reasons for recommendations to maintain relatively high levels of fiber consumption in the United Kingdom (30 g day^{-1} in adults) and elsewhere.

It is certainly true that the consumption of dietary fiber is a major determinant of both fecal bulk and bowel habit, but the magnitude of the effect depends upon the type of fiber consumed. Soluble cell wall polysaccharides such as pectin are readily fermented by the microflora, whereas lignified tissues such as wheat bran tend to remain partially intact in the feces. Both classes of dietary fiber can contribute to fecal bulk but by different mechanisms. The increment in stool mass caused by wheat bran depends to some extent on particle size, but in healthy Western populations, it has been shown that for every 1 g of wheat bran consumed per day, the output of stool is increased by between 3 and 5 g. Other sources of dietary fiber also favor water retention. For example, ispaghula, which is a mucilaginous material derived from *Psyllium*, is used pharmaceutically as a bulk laxative. Soluble polysaccharides such as guar and oat β-glucan are readily fermented by anaerobic bacteria, but solubility is no guarantee of fermentability, as is illustrated by modified cellulose gums such as methylcellulose, which is highly resistant to degradation in the human gut. Fermentation reduces the mass and water-holding capacity of soluble polysaccharides considerably, but the bacterial cells derived from them do make some contribution to total fecal output. Thus, although all forms of dietary fiber exert some fecal bulking effects, their magnitude cannot be deduced from a single analytic measurement of total fiber content.

Apart from increasing the availability of energy from dietary fiber, the major effect of bacterial fermentation is to regulate the physical and chemical properties of the intraluminal environment. The production of metabolites by the fecal microbiome is strongly influenced by both the level and type of dietary fiber consumed by the host, and it is conjectured that a high consumption of fiber favors a less carcinogenic chemical environment in the fecal stream. Most colorectal carcinomas develop progressively from precancerous lesions called adenomatous polyps. The gradual transition from a normal crypt via a precancerous lesion to a malignant tumor is associated with a progressive loss of differentiation, deregulation of cell growth, and an accumulation of mutations in genes associated with the control of cell proliferation and death. These somatic mutations are assumed to be caused primarily by mutagenic chemicals in the feces that have been shown to be carcinogenic in animals. These include heterocyclic aromatic amines created during the cooking of meat at high temperatures and *N*-nitrosamines derived by bacterial metabolism from dietary proteins. It has not been established conclusively that these substances cause colorectal carcinogenesis in humans, but there is strong circumstantial evidence that they do and it is prudent to adopt nutritional strategies to reduce their concentration in the colon.

The realization that colorectal carcinogenesis is a prolonged multistage process involving changes to a complex array of genes raises new questions about interactions between the colonic epithelial cells, dietary fiber, and other constituents of the fecal stream. Bile acids, which are produced by the liver and secreted into the gut lumen, where they facilitate the digestion and absorption of fat, are known to increase the rate at which colonic mucosal cells divide. This is particularly true of secondary bile acids (e.g., deoxycholic acid and lithocholic acid) produced by bacterial metabolism of primary bile acids in the colon. It has been proposed that bile salts act as tumor promoters in the human colon, accelerating the carcinogenic process initiated by fecal mutagens. High-fat diets tend to stimulate the release of bile acids and increase their concentration in the feces, and this may partially explain the adverse effects of Western diets on the risk of bowel cancer in human populations. However, increased fecal bulk will tend to dilute the concentration of bile salts and reduce their residence time. Furthermore, recent studies suggest that fermentation of dietary fiber shifts the composition and metabolic activities of the fecal microbiome so as to inhibit the production of secondary bile acids. The nonfermentable particulate components of plant cell walls may also provide a finely dispersed solid phase on to which bile acids can bind, so that their concentration in the aqueous phase of the feces is reduced still further.

Cellular Physiology

Fermentation of carbohydrates lowers the pH of the feces and increases the concentration of short-chain fatty acids in contact with the mucosal cells. There is evidence that these changes modify the intraluminal environment in such a way as to regulate the birth and death of the mucosal cells. Programmed cell death (apoptosis) is a mechanism whereby damaged cells are removed selectively from a tissue in an orderly manner that does not cause inflammation or general tissue destruction. This may well provide a defense against the survival of cells carrying tumorigenic mutations. Apart from the role of butyrate as an essential source of energy for the colonic mucosa, it also suppresses proliferation, increases differentiation, and induces apoptosis in many types of tumor cell grown *in vitro*. Tumor cell lines established from adenomatous polyps and carcinomas from human colon undergo increased apoptosis in the presence of butyrate, at concentrations close to those that occur *in vivo*. Unabsorbed starch and fermentable components of cereal fiber may provide a source of increased butyrate, which helps to suppress the proliferation of tumor cells and increase the likelihood of their deletion from the tissue by apoptosis. If so, much may depend on the rate of fermentation. Sugars and small oligosaccharides probably disappear too rapidly after entering the colon to provide a supply of butyrate to the distal colorectum, whereas lignified plant cell walls and some types of resistant starch that are slowly fermented may deliver butyrate efficiently to more distal regions of the colonic mucosa.

Adverse Physiological Effects

There are few well-authenticated adverse effects of dietary fiber. Some cases of pediatric malnutrition caused by very high fiber intakes have been reported, but this problem appears to be confined to grossly unbalanced diets. Similarly, the few cases of gastrointestinal obstruction in the literature appear to stem from very abnormal intakes of wheat bran or from swallowing nonhydrated supplements of viscous polysaccharides intended for consumption as a drink. There is some evidence that patients with a history of gastrointestinal surgery are at increased risk of obstruction due to abnormally high intakes of cereal bran.

Sources of Fiber

As should now be obvious, although all plant foods provide some form of dietary fiber, not all components of fiber have the same physiological effects. In the United Kingdom, about 47% of total fiber intake is obtained from bread of various types and from breakfast cereals. The level of fiber in bread depends upon the extraction rate, which is the proportion of the original grain used to make flour. White flour has an extraction rate of about 70% and contains about 3% NSP, whereas 'wholemeal' (100% extraction) flour contains about 10% NSP. Wheat bran, which contains about 40% NSP, can be added to the diet as a supplement, but it usually requires processing to increase its palatability. One of the lasting effects of the dietary fiber hypothesis has been to increase the variety of high extraction cereal products in the market place. Such products tend to contain primarily insoluble, poorly fermentable polysaccharides, and they provide an effective way of increasing fiber intake to increase stool bulk. Oats, rye, and barley contain higher quantities of soluble fiber than wheat. Oat bran in particular is an important source of β-glucan, which has been shown to reduce plasma low-density lipoprotein cholesterol levels in humans. A further 45% of total fiber intake in the United Kingdom comes from fruits and vegetables. Typically, the levels of NSP in fruits and vegetables are between 1% and 5% of fresh weight, and the polysaccharides are mostly soluble pectins and arabinogalactans, which are readily fermentable in the large bowel. For reasons described earlier, soluble fiber from vegetables and fruit does not have the bulk laxative effect of cereal bran, but it does provide fermentable carbohydrate for fermentation in the colon.

Background

Although dietary fiber has been known for more than 2000 years under various terms (e.g., bran and roughage), the term 'dietary fiber' first appeared in 1953 and referred to hemicellulose, cellulose, and lignin. The term 'fiber' is somewhat misleading since only a fraction (cellulose) of dietary fiber is fibrillar in nature. To correct this misnomer, other terms (e.g., plantix) have been proposed, but despite these efforts, the term 'dietary fiber' has survived.

This section deals with several different aspects of dietary fiber, including its determination and many of its physiological effects. Most of this information is relatively new and is the result of progress in research brought about in the last 30 years. The first part of this article will focus on the nature and composition of dietary fiber, its properties, and examples of sources of dietary fiber. This is followed by a definition of dietary fiber. Although this should be a relatively straightforward description, there are many different viewpoints concerning the nature and physiological effects that dietary fiber should have. These will be discussed in relationship to the physiological effects of dietary fiber.

Chemical Structure

The composition and structure of dietary fiber differ from plant to plant. It is also a function of the portion of the plant that is edible and the stage of maturation and is largely composed of the cell wall (structural) components that give the plant physical stability. As such, it is made of highly interlinked sugar-based and phenolic-based polymers (hemicelluloses, pectic substances, phenolics, glycoproteins, and proteoglycans) in a matrix of amorphous structure with some enmeshed cellulose microfibrils. The cell wall components are intimately linked together through various linkages including protein–sugar bonds.
