Mutagens

TJ Schrader, Health Canada, Ottawa, ON, Canada

Background

Mutagens are chemical compounds or forms of radiation (such as ultraviolet (UV) light or x-rays) that cause irreversible and heritable changes (mutations) in the cellular genetic material, deoxyribonucleic acid (DNA). Mutagenic lesions persist when they escape detection by protective cellular DNA repair mechanisms, when mistakes occur in the repair process, or when repair mechanisms are overwhelmed by extensive damage. Upon subsequent cellular replication, these mutations become permanent (*fixed*) in the genome and are inherited by all daughter cells. In this way, mutagenesis becomes a cumulative process, stretching over the lifetime of an organism.

The biological consequences of a mutation depend upon many critical factors such as the target loci, size of the mutation, timing during the cell cycle, and compounding effects of preexisting mutations. Thus, a mutagenic event occurring in a nonfunctional area of DNA will have no effect (*silent mutation*), whereas a similar change in an actively transcribed region may profoundly affect gene expression and phenotype or even lead to cell death (*lethal mutation*). The influence of mutations in human health is underscored by several human disease states caused by mutations that disrupt regulatory regions or gene coding sequences, resulting in altered gene expression and protein function. For example, mutations in genes that promote or inhibit growth and cellular replication (*proto-oncogenes* and *tumor suppressor genes*, respectively) or code for components of DNA repair pathways are important contributors to the multistage development of cancer. In addition, the accumulation of mutations over time, leading to gradually less efficient cellular repair capabilities, has been linked to the aging process and associated degenerative diseases. While the health of a particular individual can be affected by mutations in somatic cells, mutagenic events in germ cells (*germ line mutations*) lead to the transmission of genetic diseases to subsequent generations. Genetic predispositions to certain breast and colon cancers, cystic fibrosis, and Huntington's disease are included among many examples of such inheritable diseases.

Although many dietary and environmental agents have been classified as mutagens, cells are constantly subjected to a barrage of spontaneous DNA damage. The spontaneous hydrolysis of DNA bases from the sugar–phosphate backbone, constant exposure of cellular DNA to oxygen-derived free radicals, and low rates of miscopying during DNA replication all contribute towards the mutational burden. In addition to these sources, significant exposure to mutagenic compounds can occur through food and water and through environmental and occupational sources. Many natural constituents of food are mutagenic and are produced by plants as defense agents. However, additional foodborne mutagens can be present as residues of compounds used during food production or leached from packaging materials. Mutagenic compounds can also be produced during food cooking and preparation. Foods also contain many compounds that can modulate the activity of mutagens. In order to minimize exposure to mutagens, the majority of developed countries have instituted regulatory protocols governing the introduction of new foods and food-associated chemicals before they are accepted into the marketplace. With advances in the understanding of mutagenic processes, existing foods and food contact items may also be reassessed for acceptability.

Molecular Mechanisms of Mutagenesis

DNA Damage

DNA is a double helical structure composed of paired heterocyclic nitrogenous purine and pyrimidine bases attached to a backbone of deoxyribose and phosphoric acid. The purine bases (guanine and adenine) and pyrimidine bases (cytosine and thymine) form specific base pairs (guanine/cytosine and adenine/thymine) stabilized by hydrogen bonding. The specificity of base pairing and sequence of bases along the DNA double helix forms the foundation of the genetic code, and any change can give rise to mutations, expressed as alterations in gene expression or in protein structure and function.

Spontaneous damage

Instability of various parts of the DNA molecule in aqueous solution leads to spontaneous DNA damage and mutations. In addition to base deamination, the bonds between purines or pyrimidines and deoxyribose can spontaneously hydrolyze, creating apurinic/apyrimidinic (AP) sites, leaving the sugar–phosphate backbone susceptible to strand breakage. Also, the bases can exist in a number of slightly different (*tautomeric*) forms, several of which lead to mispairing because of altered hydrogen bonding characteristics.

Chemical adducts

DNA also comes under assault from a number of dietary and environmental factors that interact with several relatively reactive sites within the structure of DNA, leading to mutagenic events. Many chemical mutagens are electrophiles that are reactive, electron-deficient species able to form covalent adducts with nucleophilic sites within DNA. Binding of chemical adducts to the purine/pyrimidine bases can stabilize alternative tautomeric structures or otherwise alter their structural and hydrogen bonding characteristics. These modifications not only alter the base pair coding properties and cause mistakes to be made during replication and transcription but also lead to increased base hydrolysis and AP site formation. In addition, some chemical agents produce inter- and intrastrand cross-linking of DNA, which prevents strand separation and causes particular difficulties for replication, transcription, and repair processes.

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00476-1

Oxidative damage

Other mutagens can act through the induction of oxidative stress and cause oxygen or nitrogen radical formation. Radicals are highly reactive compounds that contain unpaired electrons and include hydroperoxide, hydroxyl, and superoxide radicals. Transition metal ions such as iron and copper can catalyze the formation of free radicals (*Fenton reaction*). The interaction of free radicals with DNA results in single- and double-strand breaks, hydroxylated derivatives of bases, and several other lesions.

DNA intercalation

Finally, some mutagens do not actually react with DNA but modify its structure by intercalating between the complementary strands of DNA, disrupting hydrogen bonding between base pairs. The presence of such compounds causes misreading during replication and transcription, leading to the generation of mutations.

Metabolic Activation

Some mutagenic compounds (*direct-acting* mutagens) are able to interact with DNA without any further modifications; however, many other compounds (*indirect-acting* mutagens) become mutagenic as unwanted by-products of transformations carried out by cellular detoxification pathways. Several hydroxylation (*phase I*) and conjugation (*phase II*) pathways are available for detoxification to increase the water solubility of chemical compounds and aid in their excretion. Although the enzyme systems are generally most highly expressed in the liver, other tissue types maintain these capabilities to varying degrees. The phase I reactions are carried out by the cytochrome P450 enzyme system, which consists of a large family of related enzymes in which each isozyme shows specificity for particular chemical structures. During phase II reactions, more polar groups can be added by glutathione *S*-transferase, glucuronide transferase, microsomal epoxide hydrase, or acetyltransferase. Generally, phase II reactions inactivate mutagens, but instances of the opposite outcome have been found. Several other enzymes, including flavin monooxygenase and prostaglandin H synthetase, are also known to activate mutagens.

Mutagens as Genotoxic versus Nongenotoxic Carcinogens

Chemicals or other treatments found to induce cancer (*carcinogens*) are further characterized as either *genotoxic* or *nongenotoxic*, according to their mechanisms of action. In general, genotoxic treatments result in alterations to the structure of DNA, while nongenotoxic carcinogens operate through receptor-based or indirect oxidative stress mechanisms, such as inflammation. Since mutagens result in heritable alterations to DNA, they are generally regarded as a subset of genotoxic carcinogens. However, conditions set in motion by nongenotoxic carcinogens, such as the release of oxidative species during an inflammatory response, may activate mutagens and thus produce a secondary genotoxic response.

DNA Repair

Several mechanisms have evolved to remove lesions in DNA and to restore the structural and coding properties of the base sequence in the damaged region.

Direct reversal

Direct reversal of damage is perhaps the simplest process, whereby a single gene product can repair a particular form of damage. In mammalian cells, mutagenic O^6-methylguanine residues are removed by a damage reversal mechanism in which the O^6-alkyl group is removed by an O^6-methylguanine transferase in a 'suicide reaction,' resulting in inactivation of the enzyme. A second form of damage reversal is observed in the repair of simple strand breaks, which can be repaired by ligation in a process catalyzed by DNA ligase. Finally, a DNA purine insertase activity has been described by which apurinic sites in DNA are repaired by the direct insertion of purines.

Excision repair

The major and most versatile mechanism used by mammalian cells to remove altered bases or nucleotides within DNA is known as *excision repair*. Excision repair proceeds in several successive steps in a multiple enzyme process. Three major excision repair pathways using different sets of enzymes have been described: base excision repair, nucleotide excision repair, and mismatch repair.

Base excision repair removes misincorporated bases such as uracil and most methylated base damage. The majority of base damage is repaired by the replacement of a single damaged nucleotide with its normal counterpart, but base excision repair can also result in the synthesis of 2–10 nucleotide 'repair patches.' Initially, the damaged base is recognized and removed by a damage-specific glycosylase leaving an AP site in the DNA. For single-nucleotide repair, the deoxyribose phosphate residue in the DNA backbone is removed and a replacement nucleotide inserted by activities associated with DNA polymerase β. Longer patches result when either polymerase β or another repair DNA polymerase synthesizes a stretch of DNA. In this process, a flap region of single-stranded DNA is displaced and is then degraded by a deoxyribonuclease activity. Both types of base excision repair are completed when DNA ligase seals the final nick remaining in the DNA backbone.

The *nucleotide excision repair* pathway involves 20–30 gene products and is responsible for removing damage caused by agents that introduce bulky adducts into DNA. The initial recognition of DNA damage by a recognition complex recruits the entire multicomponent repair enzyme complex (*excinuclease*) to the lesion. The excinuclease nicks the damaged strand on either side of the damage site, releasing an oligonucleotide of approximately 30 base pairs in length. After the gap is filled in by a DNA polymerase using the opposite strand as a template, the nick at the end of the repair patch is sealed by ligase. Nucleotide excision repair has also been shown to be closely linked with transcription (*transcription-coupled repair*) by which actively transcribed genes are preferentially repaired compared with silent regions of the genome. A component of the nucleotide excision repair complex (TFIID) is shared with

the complex involved in gene transcription and mediates the recruitment of DNA repair machinery to the damage site when RNA polymerase stalls at a lesion.

Mismatch repair is a form of excision repair that corrects mismatched base pairs resulting from replication errors and heteroduplexes formed during recombination. The interaction of various components involved in mismatch repair is less understood but results in repair patches of 100–1000 nucleotides. Mutations in mismatch repair genes have been linked to an increased risk for inherited forms of colon cancer.

Classes of mutations

Mutations can range in size from single base pair changes to the loss or duplication of entire chromosomes. Many factors, such as the mutagenic agent, particular region of DNA affected, preexisting damage, and timing during the cell cycle, can influence the magnitude of a mutation. Mutations can be classified into four broad groups: extragenic, gene, chromosomal, and genomic mutations.

Extragenic mutations

Extragenic mutations occur outside of the gene coding sequence and are usually silent. However, if the mutation occurs in an important regulatory sequence, gene expression can be affected.

Gene mutations

Gene mutations occur within the coding sequence of a gene. *Point mutations* involve the substitution of bases, causing either transitions (the substitution of a purine for purine or pyrimidine for pyrimidine) or transversions (the substitution of a purine for a pyrimidine or vice versa). If such a mutation occurs in the wobble position of a codon, the chance of a change occurring in the translated protein structure or function will be much reduced. However, a single base pair change elsewhere in the sequence can result in proteins with decreased or modified functions and can also affect protein synthesis and degradation. *Frameshift mutations* occur when bases are either lost or inserted, thus resulting in a shift of the reading frame by the transcriptional machinery. Frameshift mutations can result in the production of modified or inactive proteins and may be lethal to the cell. *Block mutations* occur when large sections of a gene are deleted, inverted, or duplicated and can lead to defective proteins being produced.

Chromosomal mutations

Compared with gene mutations, chromosomal mutations represent a class of mutations that affect larger regions of DNA within chromosomes and may involve the deletion, translocation, duplication, or further amplification of whole genes. Chromosomal mutations may lead to either increased or decreased gene expression and can also result in the abnormal expression of normally silent parts of the genome.

Genomic mutations

Genomic mutations involve the duplication or loss of entire chromosomes. Such mutations can have far-reaching effects on gene expression and survival. Typically, the progression of a cancer is marked by cells that have developed progressively altered complements of chromosomes.

Mutagenicity Assays

Unlike the typical genotyping of a human or other organism in which inherited mutations are generally common to all, or most, tissues and cells within the body, exposure to a mutagen, either environmentally or in a laboratory setting, will create a more-or-less random collection of mutations differing from cell to cell, making detection akin to finding a needle in a haystack. Thus, when testing for mutagens, the detection of a rare mutational event requires some form of selection procedure to amplify or isolate a particular mutated target before more exacting characterization of mutated sequences can take place.

Despite these limitations, many assay systems have been developed to examine mutagenicity and induction of DNA damage. In many instances, mutagenicity assays are used as shorter-term, more economical surrogates for the 2-year rat carcinogenesis bioassay. Although a high correlation exists between mutagenicity and carcinogenicity, neither this correlation nor that between results obtained with different mutagenicity tests is perfect. Therefore, test chemicals are generally subjected to a battery of three tests or more to gain a more balanced assessment. Widely used mutagenicity assays include both short-term bacterial, fungal, and mammalian cell-based (*in vitro*) and animal-based (*in vivo*) assay systems. Mutations within a target gene are detected as a loss of function (*forward mutations*) or as a reversal of the effect of a previous mutation (*reverse mutations*). To help meet regulatory needs, several mutagenicity assays have been validated and accepted internationally through the Organisation for Economic Co-operation and Development (OECD) and are available as *OECD Test Guidelines*. The test guidelines represent protocols and performance standards agreed upon by international panels of experts and provide standardized methods for industry, academia, and government testing laboratories, which are recognized by the majority of regulatory bodies.

These assays generally rely upon a change in phenotype as an end point and therefore may miss some silent mutations. *In vitro* systems are generally conducted in the presence and absence of a source of metabolic activation, which can include rat liver homogenate (S9 microsomes) or liver cells. The application of molecular biology and biotechnology to many of these systems has led to further refinement and increased molecular characterization of the mutations induced.

The Ames *Salmonella* test and the *E. coli* tryptophan assay are bacterial systems that measure reversions induced at genes responsible for the synthesis of histidine and tryptophan, respectively. Growth of the bacteria on minimal plates requires back mutations at the indicated loci, and therefore, test chemical mutagenicity is assessed according to colony formation. The Ames *Salmonella* test has been widely accepted and validated as a bacterial assay with different strains available that respond to base pair and frameshift mutagens and oxidative damage. Various refinements to the Ames *Salmonella* test have been developed, including a series of bacterial strains that are reverted at specific base pairs, allowing the spectrum of induced mutations to be assessed, as well as bacteria that

express various mammalian phase I and phase II genes to examine the effects of particular types of activation. Several selectable targets can be examined for the induction of forward mutations in mammalian cells, including gene loci encoding thymidine kinase in L51278Y mouse lymphoma cells, hypoxanthine-guanine phosphoribosyltransferase (*HGPRT*) in Chinese hamster ovaries or V79 cells, and Na^+/K^+-ATPase in V79 cells. Mutagenesis at the HGPRT locus has also been examined in human lymphocytes and fibroblasts. Plasmid shuttle vectors have also been developed, which can be exposed to the test chemical, introduced into mammalian cells for repair, and then recovered and reintroduced into an indicator strain of *E. coli* for scoring of mutations. If needed, the plasmids can be recovered again and sequenced.

More recently, faster (*higher-throughput*), fluorescence-based assays have been developed that use instrumental analysis (flow cytometry) to replace the time-consuming step of resistant colony formation. These assays are particularly useful for mammalian or human cell-based assays, which are slower than bacterial assays but better reflect the human situation. For instance, cell lines have been created, which contain the gene encoding the jellyfish green fluorescent protein (GFP) under transcriptional control of a promoter requiring the mutation or reversion of other gene sequences for expression. Thus, the fluorescence signal of GFP is used as a *transcriptional reporter* reflective of mutational events elsewhere in the genome. *In vivo* mutagen exposures can be evaluated by determining the loss of cell surface proteins requiring glycosylphosphatidylinositol (GPI) for attachment. Reduced fluorescence of peripheral blood cells stained with fluorescence-labeled antibodies specific for GPI cell surface proteins is indicative of mutations to the PIGA gene, the product of which is necessary for GPI synthesis.

Germ line mutations may be assessed in rodents using the specific locus test, dominant lethal assay, and heritable translocation test. Transgenic mice incorporating λ phage *lacI* or *lacZ* gene sequences have also been developed, which provide shorter-term, *in vivo* mutagenicity assays. DNA isolated from these animals is incorporated into λ phage, which is used to infect the proper *E. coli* host, forming either clear or colored plaques in the bacterial lawn. The transgenic assays allow mutations to be examined in all somatic tissues and germ line tissues and provide a well-characterized target for sequence analysis.

Chromosomal aberrations can be examined both *in vitro* using cell lines and *in vivo* using animal tissues, generally bone marrow. Stained metaphase chromosome spreads are examined microscopically for structural chromosomal aberrations. A newer variation of this technique, fluorescence *in situ* hybridization, uses fluorescent-labeled DNA probes specific for particular chromosomal sequences to test for aberrations. Another chromosomal aberration assay is the micronucleus test using bone marrow and peripheral blood erythrocytes or lymphocytes. Micronuclei are small particles containing acentric fragments of chromosomes or entire chromosomes that are left behind in the cytoplasm after mutagen treatment. Micronuclei formation may be enumerated by microscopy or flow cytometry.

Sister chromatid exchange uses differential labeling techniques to measure the crossing over between each half of a replicated chromosome. The biological significance of sister chromatid exchange is not known, as the phenomenon does not appear to be related to the mechanisms involved in chromosomal aberration formation and is not directly related to mutagenesis. However, most alkylating agents and compounds that create adducts and single-strand breakage increase sister chromatid exchange. Therefore, the assay tends to be used as a complement to mutagenesis and chromosomal aberration assays.

Quantitative Structure–Activity Relationship Modeling

Although high-throughput assays hold much promise, the sheer number of new and legacy chemicals requiring characterization places huge demands on time and laboratory resources. These challenges have led to a computer-aided informatics approach known as *quantitative structure–activity relationship* (*QSAR*) modeling. QSAR approaches have led to the development of a number of computer (*in silico*) models that scan the chemical structure for *structural alerts* indicative of mutagenic or other toxic potentials. Data from benchtop experimentation continue to strengthen these models such that structural features may, in the future, be sufficient to negate the need for *in vivo* testing and limit requirements to a minimum of *in vitro* confirmatory assays.

Food-Associated Mutagens

The investigation of mutagens in food is an important component of food safety research. Mutagens found in food can be divided into three groups: naturally occurring compounds, those formed by heating or processing, and additives and contaminants, including pesticides.

Naturally Occurring Mutagens

The natural components of food account for over 99% of the carcinogenic and toxic chemicals to which humans are exposed. Most of these natural mutagens are produced by plants as natural pesticides. Many of these intrinsic chemicals are almost impossible to regulate or remove, although guidelines for acceptable exposure limits of some natural contaminants such as mycotoxins are enforced.

Flavonoids form a major group of natural plant compounds, and in a survey of mutagenesis using the Ames *Salmonella* test, 33 out of 70 natural and synthetic flavonoids proved to be mutagenic, producing both base pair and frameshift mutations. Studies indicate that only the flavonol (3-hydroxyflavone) members of this group are mutagenic. Myricetin and quercetin are direct-acting mutagenic flavonoids, whereas kaempferol is indirect-acting. Norwogonin and sexangularetin are two other indirect-acting flavonoids. The *pyrrolizidine alkaloids* represent another large group of widespread mutagenic plant compounds found in some herbal teas and medicines and include compounds such as monocrotaline, dehydro monocrotaline, retrorsine, and isatidine. Pyrrolizidine alkaloids are indirect-acting mutagens, with some compounds inducing DNA strand breakage, whereas others form DNA and DNA–protein cross-links. Another class of mutagenic compounds is the *glucosinolates*, which are found in cruciferous vegetables. Glucosinolates are broken down into isothiocyanates or nitriles, including the mutagenic allyl isothiocyanate glucoside (sinigrin). The mutagen aquilide A

(ptaquiloside) from bracken fern (fiddleheads) is a related *glycoside* and can also be passed through cows' milk. *Catechol-type phenolics*, such as tannins and caffeic acid and its esters (chlorogenic and neochlorogenic acids), are more widespread than other natural pesticides and can induce chromosomal damage. Caffeic acid conjugates can be present in higher plants, with coffee, apple, and lettuce as major sources in the human diet. A class of chemicals known as *linear furanocoumarins*, found in parsley and celery, has several mutagenic members, including psoralen, 5-methoxypsoralen (bergapten), and 8-methoxypsoralen (xanthotoxin). Linear furanocoumarins intercalate into DNA and form mono- and diadducts in the presence of long-wave UV light. A number of mutagenic *hydrazine* compounds such as hydrazinobenzoate are found in 30 species of mushrooms. Estragole and safrole are mutagenic *alkenylbenzenes* that are found in a number of spices such as black pepper, basil, fennel, and nutmeg. Other food-related mutagens include ethyl acrylate from pineapples, sesamol from sesame seeds, and benzyl acetate from basil, jasmine tea, and honey.

Mycotoxins are an important source of mutagenic contamination resulting from mold growth in foodstuffs. Human exposure can occur through grain crops, meat products, milk and eggs, nuts and peanuts, fruits, and juice. *Aspergillus* spp. produce a family of aflatoxin mycotoxins (aflatoxins B1, B2, G1, and G2), of which aflatoxin B1 is the most potent. Food products produced from livestock fed with aflatoxin-contaminated feeds can also serve as a potential source of human exposure. Other mutagenic mycotoxins include fusarin C produced by *Fusarium* sp., luteoskyrin (*Penicillium* sp.), sterigmatocystin (*Aspergillus* sp.), ochratoxin A, and patulin (*Aspergillus* and *Penicillium* spp.). *Alternaria* spp., of which *A. alternata* is primarily responsible for black spots on tomatoes and blackheads on grain, produce a number of mutagenic toxins such as altertoxins I, II, and III and stemphyltoxin III (Figure 1).

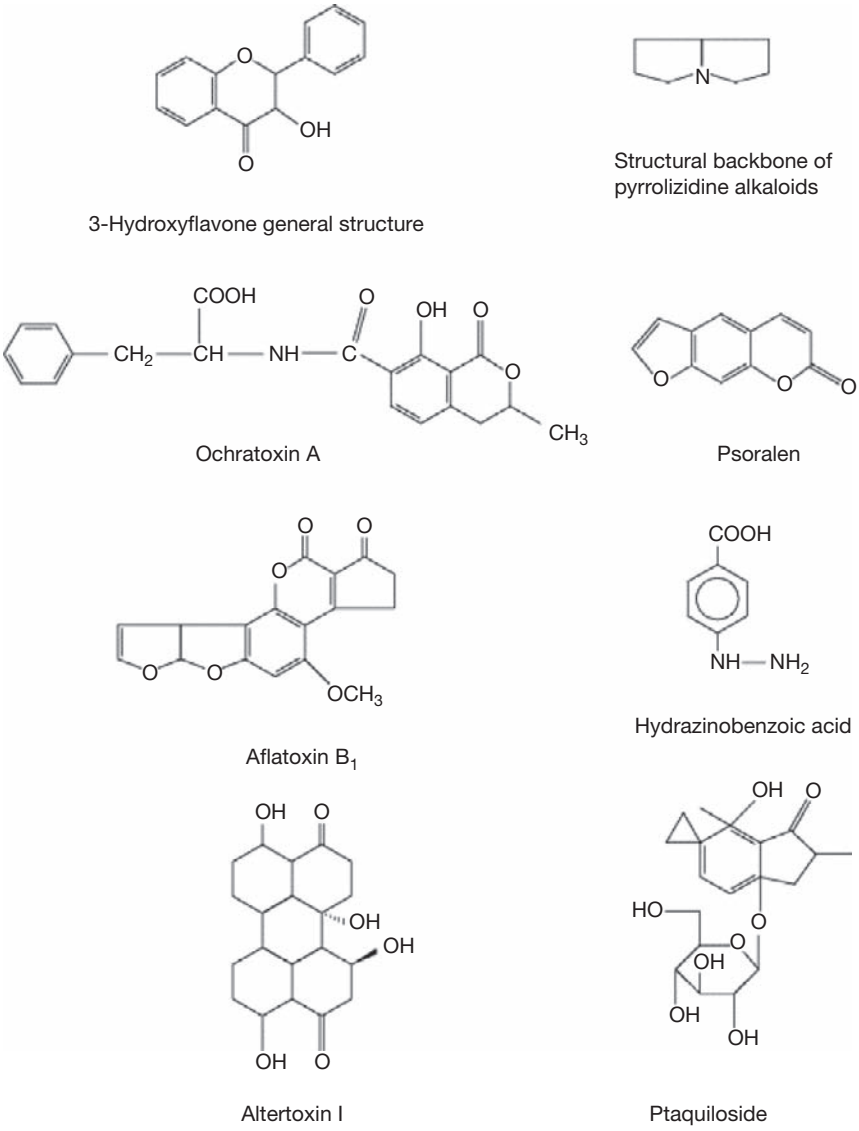

Figure 1 Structures of selected naturally occurring mutagens.

Mutagens Formed during Processing, Preparation, or Storage

Many very significant mutagens are formed during the processing and preparation of food. Mutagens that are formed as a result of heating and preparation are extremely difficult to avoid or regulate.

Grilling or charring of protein-rich foods has been shown to produce some of the most potent mutagens described to date. *Polycyclic heterocyclic amines* are indirect mutagens formed during frying or grilling of meat and fish. This group includes several related amino-imidazo-azaarene structures belonging to three major families: (1) imidazoquinolines (4-MeIQ), (2) imidazoquinoxalines (8-MeIQx and 4,8-DiMeIQx), and (3) imidazopyridines (PhIP). Grilling also produces a number of amino acid pyrolysis products (Trp-P-1, Trp-P-2, Lys-P-1, Phe-P-1, and IQx) and oxygen-containing heterocycles. Generally, PhIP is the predominant heterocyclic amine found and can be transferred to infants through breast milk.

Heterocyclic amines appear to be formed by a Maillard reaction between creatine or creatinine, an amino acid, and a sugar such as glucose or fructose. The Maillard reaction is responsible for browning, which provides the improved appearance, flavoring, and aroma of heated foods. The reaction starts as a condensation between reducing sugars and the amino groups of amino acids, peptides, or proteins. The initial products may proceed through a very complex series of transformations resulting in the formation of thousands of compounds, including both mutagens and nonmutagens. Two contaminants produced during heating are acrylamide and furan, which can be metabolized to the mutagens glycidamide and *cis*-2-butene-1,4-dial, respectively.

Polycyclic aromatic hydrocarbons are a second class of mutagenic compounds formed during the grilling or smoking of meat and fish. Polycyclic aromatic hydrocarbons are common pyrolysis products of most organic materials and include benzo[a]pyrene, 1-nitropyrene, and 1,6-dinitropyrene. The *furfurals*, another class of compounds, are produced during the heating of sugars. Hydroxymethylfurfural is a heat-induced decomposition product of hexoses, which becomes mutagenic after sulfate conjugation.

Other processes can give rise to mutagens. *Urethane* (ethyl carbamate) is found in fermented foods and in beverages treated with the fungicide pyrocarbonate. The use of acid hydrolysis during soy sauce production can produce chloropropanediols and their related fatty acid esters, of which 3-monochloropropanediol can be metabolized to the mutagen *glycidol*, an epoxide. *N-Nitrosodimethylamine* is a naturally occurring mutagen present in cheese, soybean oil, canned fruit, meat products, and alcoholic beverages but is also formed from the use of elastic rubber nettings in cured pork products. Most nitrosamines cross the placental barrier or pass into the mother's milk, thereby leading to possible *in utero* and infant exposure. Lipid peroxidation occurs with the storage of fats and oils, owing to the reaction of oxygen with sites of unsaturated bonds. The resulting lipid hydroperoxides, peroxy radicals, and hydroxyl radicals cause rancidity and are potential DNA-damaging agents. A variety of epoxides and aldehydes are also formed, including malondialdehyde, a potential mutagen (Figure 2).

Food Additives and Contaminants

Food additives and contaminants (including pesticide residues) are compounds that are added to food at some point during its production. Exposure to these substances can be controlled, and the introduction of new chemicals used in food manufacture falls under government regulation. Older additives or chemical contaminants are also reviewed periodically for exposure and health effects.

The use of nitrite, butylated hydroxyanisole (BHA), and butylated hydroxytoluene (BHT) as food preservatives has been controversial. *Nitrite* enters the diet both through its use as a common food preservative and through gut microbe-mediated reduction of nitrate from ingested vegetables. Nitrite cycles from the gut to the saliva and can react at acidic pH with amines, amino acids, phenols, and mercaptans, frequently resulting in the formation of mutagenic (nitroso) compounds. Mutagens can also be found in the smoke of nitrite-treated meat during frying. The formation of 2-chloro-4-methylthiobutanoic acid, a mutagen in salted, pickled fish, has also been linked to nitrite use. BHA and BHT have been added to foods and packaging as synthetic antioxidants. Previous concerns over BHA's carcinogenic risk to humans appear unwarranted and related to the large doses used in rodent feeding studies. BHT increases the proliferation of pretumor liver cells in rodent models but has little effect on normal cells.

The artificial sweeteners saccharin and cyclamate have also been shown to have mutagenic properties, although saccharin-induced bladder carcinogenesis in rodents also appears to result from the large doses used. Also, the mutagenicity of some colors has led to their use being banned, although low levels of extractable mutagenic contaminants have been detected in others. Mutagenic heterocyclic amino acids have been found in some flavors.

Contaminants may occur in food as residues of pesticides and fungicides, solvents, or compounds, such as styrene leaching from packaging material. The persistent organochlorine pesticide toxaphene has been found in rural foods consumed by indigenous peoples in the Arctic region, having been carried and deposited through airborne transport from sites in the south.

Mutagens in Water

Drinking water provides another potential source of mutagenic compounds. Water disinfection by chlorination can produce many types of mutagenic chlorinated organic compounds, of which 3-chloro-4-(dichloromethyl)-5-hydroxy-2-(5H)-furanone (MX) is the most potent. Other mutagenic chlorinated butenoic acids, including EMX (the reduced form of MX), brominated trihalomethanes, and dichloroacetonitrile, are also produced. Dichloroacetonitrile is a direct-acting mutagen and induces DNA strand breaks in cultured human lymphoblastic cells. Other less potent mutagenic disinfection by-products include dichloroacetic acid, trichloroacetic acid, and chloral hydrate. Radioactive contamination can also contribute mutagenic activity in areas where water is contaminated with ^{40}K or uranium and thorium decay products (such as radon).

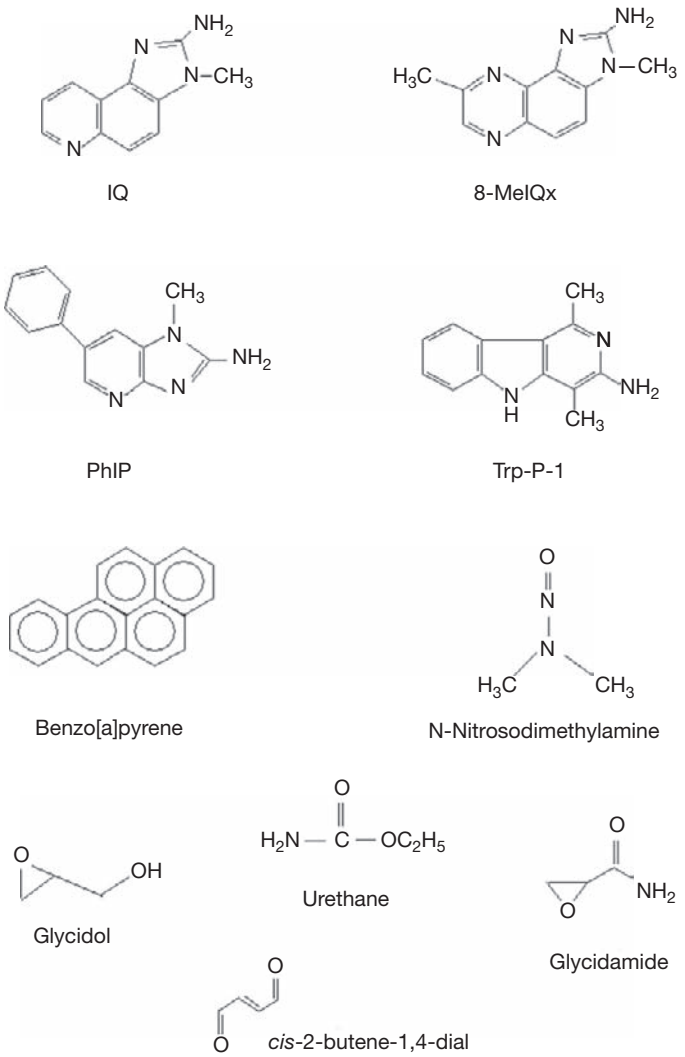

Figure 2 Structures of selected mutagens formed during grilling and processing.

Mutagens in Feces

Human feces have been found to contain a class of mutagenic compounds known as fecapentaenes, the major forms of which are fecapentaene-12 and fecapentaene-14. These compounds appear to be synthesized by intestinal bacteria and are lipid-soluble, direct-acting base pair and frameshift mutagens. Fecapentaene-12 also causes increased sister chromatid exchanges, *HGPRT* mutagenesis, and oxidative damage. Bile salts have been shown to augment the ability of fecapentaenes-12 and -14 to induce DNA repair in bacteria, underscoring their possible role in colon carcinogenesis associated with high-fat, low-fiber diets.

Prevention and Modification of Mutagen Formation

A well-balanced diet also provides many compounds that can decrease exposure to mutagens. Studies consistently show that a greater consumption of fruits and vegetables is associated with a lowering of cancer incidence. These compounds can act at all levels of mutagenesis by (1) preventing mutagen formation and acting as antioxidants, (2) deactivating mutagenic compounds, and (3) inducing detoxifying enzymes or inhibiting monooxygenase activity.

Several natural antioxidants, such as ascorbic acid, β-carotene, α-tocopherol, polyphenolic acids, flavonoids, and other plant phenolics, have a direct mutagen-scavenging activity. For example, in addition to neutralizing oxygen radicals, many of these compounds inhibit the formation of nitrosamines by competing with the amine group. Mutagenic agents may be inactivated through the formation of complexes with calcium, casein, chlorophyll, and carbonyl compounds. Some evidence suggests that calcium can inhibit familial colon carcinogenesis through inhibition of lipid peroxidation. Both iron deficiency and excess have been associated with oxidative DNA damage, and zinc deficiency causes chromosome breaks. The activity of glutathione-dependent detoxification systems is increased by selenium and diallyl disulfide, from garlic, cysteamine,

cysteine, and a variety of phenolic compounds. Monooxygenase activity and the formation of reactive compounds can be inhibited by phenolic acids, free fatty acids, flavonoids, and other polyphenols, methylxanthines, vitamins, and biogenic amines. Conjugated dienoic isomers of linoleic acid are antimutagenic compounds in extracts of fried ground beef and dairy products, which appear to act through signal transduction pathways and prostaglandin synthesis. Tannins or polyphenols in green tea have been found to be antimutagenic in some assays, but the effects appear to depend upon the dose and timing of exposure. Several other compounds have shown antimutagenic activity, including β-diketones, catechins, lignans, and isoflavones. Finally, dietary fiber can complex with mutagenic compounds and limit their uptake.

Mutagenic effects resulting from altered DNA metabolism can also be influenced by diet. Adequate intake of essential nutrients such as folate, vitamin B_{12}, and vitamin B_6 aids nucleotide synthesis and prevents DNA strand breakage. Niacin, methylxanthines, and some phenols have been attributed to the promotion of DNA damage repair (Figure 3).

Further Considerations

Much work remains to completely characterize the role of food-associated mutagens and antimutagens in human carcinogenesis. Despite the magnitude and frequency of exposure to these compounds, they remain underrepresented in mutagenicity studies relative to synthetic chemicals. Additional characterization is needed of the human consequences of exposure to many antioxidants that appear to inhibit mutagenesis at low concentrations but have the opposite effect at high concentrations. In addition, more emphasis should be placed on the effects of chemical mixtures to study the effects of combinations of compounds encountered in the diet.

Assay systems can be improved. Cell culture-based assays promise higher throughput and minimization of animal use, but many cell types have lost or possess unstable metabolic activities, limiting confidence in results. The effects of metabolic activation may be better studied by introducing expression vectors representing the genes of interest into cultured cells. Such an approach will also help to address cell-type specific mechanisms of mutagenesis and aid in developing increasingly realistic models. Although genomic, proteomic, and metabolomic analyses of perturbations in biochemical pathways hold much promise in delineating toxicological effects, much more characterization is needed to correlate these end points to mutagenesis per se. The influence of gut flora on mutagen availability, activation, and possible protective effects is an emerging field. In addition, the identification of the active mutagenic species, probably short-lived reactive intermediates identifiable by specialized spin trapping

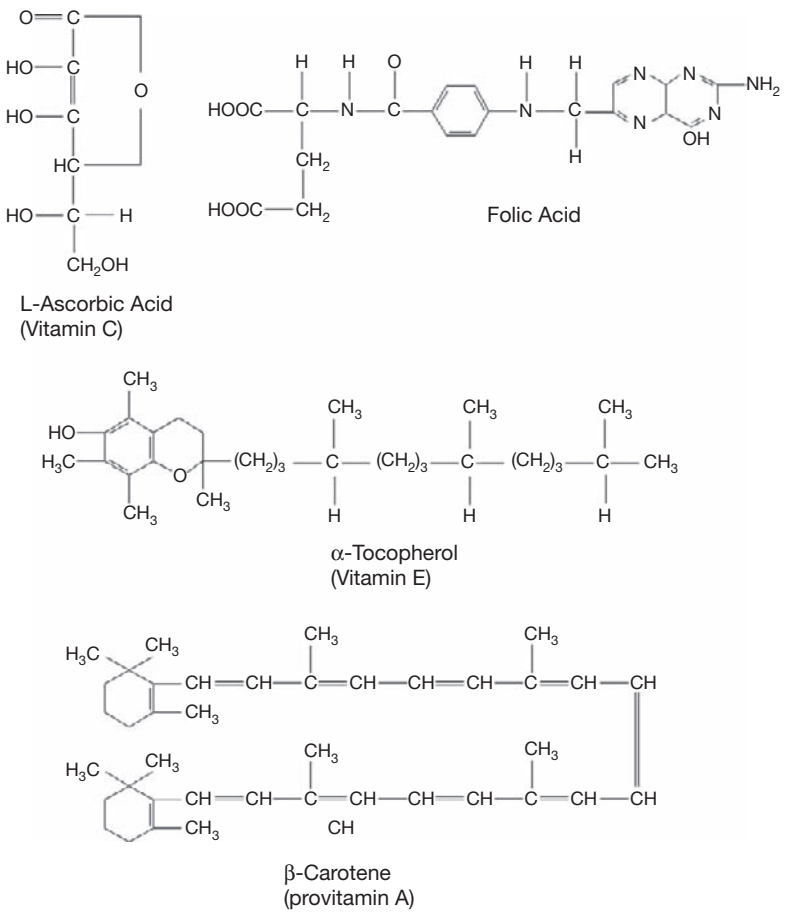

Figure 3 Structures of common dietary antioxidant antimutagens.

techniques, will greatly assist in mechanistic understanding and QSAR development.

Finally, the nature of the dose response exhibited by mutagens and the use of such data in human health risk assessments continue to evolve. Regulatory bodies have routinely applied an extra level of safety in considering the activity of mutagens, which has been thought to display a linear response with concentration, regardless of dose. However, assays usually present a *point of departure* from linearity at lower concentrations, which may be indicative of assay detection limits but, particularly *in vivo*, may also reflect the interplay of a number of factors, including absorption, excretion, bioactivation/detoxification, and inter-/intracellular transport. A better understanding of mutagenic activity in dose–response relationships will strengthen health risk assessments and the regulatory process.

Mycotoxins: Classification

M Mostrom, North Dakota State University, Fargo, ND, USA

Introduction

Mycotoxins are natural, secondary fungal metabolites produced by molds, invading a wide variety of foods and feeds. The recognition of moldy grains was described in the Old Testament of the Bible and the potential adverse effects from moldy infected grains (ergots) were observed centuries ago in several human epidemics and termed 'holy fires' and 'Saint Anthony's Fire' associated with humans experiencing burning pain from gangrenous effects of ergot alkaloids. A majority of the fungi contaminating foods and feeds are *Aspergillus* sp., *Fusarium* sp., *Penicillium* sp., and *Claviceps purpurea* associated with ergot production. The growth of molds and subsequent mycotoxin production can occur at several points: (1) on crops in the field, (2) during grain storage, (3) transportation of feeds from the farm to destinations of use, and (4) in food processing (such as malting and fermentation). The knowledge of toxic effect of moldy feeds in humans and animals was slow to be gained, with human epidemics of ergot poisoning documented since the Middle Ages. In the latter part of the twentieth century, moldy feed and adverse conditions in humans and animals were associated with chemical compounds produced by molds or mycotoxins. Mycotoxins are chemical compounds that, at sufficiently high concentrations, can cause adverse effects in humans and animals. Both adequate food availability and scientific awareness that mycotoxins in sufficiently high concentrations can limit food use need to be evaluated for the continuing health of human populations, particularly in developing countries. Several recent surveys of thousands of feed and feed raw materials worldwide indicate that over 70% of grains and feeds are contaminated with mycotoxins, although the mycotoxin concentrations are often below regulatory guidelines. The surveys also detected multiple mycotoxins contaminating feeds. Increasing mycotoxin surveillance programs in feeds, using adequate sampling protocols to sample suspected feeds and detect the 'hot spots' of mold growth, using appropriate testing of samples, and utilization and enforcement of regulatory guidelines aids in control and limiting the use of highly contaminated feeds in human and animal populations and safeguards health. A description of the toxicities of the more commonly detected mycotoxins in foods is discussed elsewhere in this encyclopedia. Hundreds of mycotoxins have been identified, but only a relatively few mycotoxins are well characterized and recognized in foods or feeds. This article describes the more commonly detected mycotoxins found in foods and the conditions of mold growth in feeds and foods.

Aflatoxins

Aflatoxins are an important group of structurally related difuranocoumarin compounds produced primarily by *A. flavus*, *A. parasiticus*, and *A. nomius*. These mycotoxins are found worldwide, but more commonly are produced in warm, subtropical, and tropical climates. Aflatoxins can occur preharvest on starchy cereal crops, cottonseeds, and peanuts or postharvest on stored commodities (Table 1). Strains of *A. flavus* typically invade insect- or drought-damaged or senescent plant tissue and mainly produce aflatoxin B_1. Aflatoxin B_1 is generally found in the highest concentration and considered the most toxic and carcinogenic of the aflatoxins. Strains of *A. parasiticus* can produce aflatoxins B_1 (AB1) and B_2, and G_1 and G_2 that fluoresce blue or green, respectively, under ultraviolet light. Aflatoxins M_1 and M_2 are 4-hydroxylated metabolites of aflatoxin B_1 and B_2, respectively, and can occur in aflatoxin-contaminated feed and more importantly in tissues, milk, and dairy products. In heavily infected grains, a yellowish-green pigmented mass of *Aspergillus* growth can be visible on the corn kernels (Figure 1). Invaded kernels can contain extremely high concentrations of aflatoxin (up to 400 $\mu g\ g^{-1}$), which illustrates the importance of adequate sampling of suspected commodities for testing. High concentrations of aflatoxins can occur in field crops with insect or bird damage and hot weather. Sweet corn is considered potentially more vulnerable for aflatoxin accumulation than is field corn because of the higher sugar content. Grain commodities stored on the farm outside on the ground or in inadequate structures that allow access to moisture and oxygen can undergo extensive mold invasion and aflatoxin production during the storage period. During an investigation of possible mycotoxin contamination of feedstuffs, a concern is that the grain or food consumed by the susceptible population prior to the investigation may be entirely consumed and none may be available for chemical testing and mycotoxin determination.

Mold growth and aflatoxin production in a field crop occurs during drought, but aflatoxins could potentially be reduced by the use of pesticides to diminish insect invasion and by using a crop variety that is more tolerant to high temperatures. To prevent aflatoxin production postharvest, storage moisture of $<12\%$ is recommended for cereals grains and <8–9% moisture for oilseeds over a wide range of temperatures. Storing grains and oil seeds in clean, weatherproof structures and cleaning grains to remove light weight or broken grains can reduce mycotoxins. Changing the grain source or avoiding incorporation of the contaminated commodity in the diet will prevent adverse effects, but in poor populations that depend on local grain sources for survival these may not be options. Several measures, including mold inhibitors, physical separation of damaged grain, fermentation, thermal treatment (roasting), irradiation, ammoniation, ozonation, and the use of 'mycotoxin adsorbents,' have been taken to reduce aflatoxin contamination of feeds. No method is without drawbacks, including cost, large-scale application, and only partial success. Numerous products are marketed to sequester or 'bind' mycotoxins and reduce absorption from an animal's gastrointestinal tract; in the United States, these agents are typically sold as anti-caking or free-flow agents. Agents tested include sodium calcium aluminosilicates, activated charcoal, bentonite and

Table 1 Summary table of fungal species and their mycotoxins and commodities affected

Fungal species	*Mycotoxin classification*	*Chemical structure*	*Mycotoxins identification*	*Commodity*
A. flavus, *A. parasiticus*	Aflatoxins	Difuranocoumarins	B1, B2, G1, G2 M1, M2	Corn/maize, peanuts, tree nuts, cottonseed, rice, copra, heat, spices, cocoa (chocolate products) Milk products
Fusarium sp. (*F. graminearum*, *F. poae*, *F. acuminatum*, *F. sporotrichiodes*, *F. equiseti*)	Trichothecenes	Sesquiterpenoids with a C12-13epoxy group	DON (deoxynivalenol) or vomitoxin, nivalenol, 3- and 15-acetylDON, T-2 toxin, HT-2 toxin, T-2 tetral, DAS (diacetoxyscirpenol), neosolaniol	Wheat, maize, hay
F. graminearum, *F. culmorum*, *F. equiseti*	Zearalenone	Macrocyclic lactone	Zearalenone	Wheat, maize/corn, hay
F. verticillioides (syn. *F. moniliforme*), *F. proliferatum*	Fumonisins	Aliphatic hydrocarbons	FB1, FB2, FB3	Corn Corn based foods
Claviceps sp. *C. purpurea* (*C. fusiformis*, *C. paspali*)	Ergot alkaloids	Indoles	Ergopeptine alkaloids: ergotamine, Ergocristine, ergosine, ergocryptine, ergovaline, Ergoline alkaloids: Lysergic acid, Lyergol, lysergic acid amide, ergonovine, Clavines	Rye, wheat, Cereals Grasses
A. alutaceus var. *alutaceus* (formerly *A. ochraceus*), *A. westerdijkiae* and *A. Steynii* and *Penicillium verrucosum* (formerly *P. viridicatum*)	Ochratoxins	Isocoumarin	Ochratoxin A	Cereal grains (wheat, barley, oats, corn), Dry beans, peanuts, grapes, raisins, cheese, Apple juice Swine tissue
Penicillium expansum, *Aspergillus* sp., *Byssochlamys fulva*, *B. nivea*.	Patulin	Cyclic γ-lactone	Patulin	Rotten Fruits, Apple juice, Applesauce

various clays, yeast cultures, esterified glucomannan, and others. Several of these compounds show potential in partially binding aflatoxin B_1 and reducing aflatoxin M_1 contamination in milk. Positive responses in reducing aflatoxin M_1 in milk are not consistent for all these binders. The US Food and Drug Administration (FDA) has not licensed any product for use as a 'mycotoxin binder' in animal feeds.

Fumonisins

Fumonisins are a group of heat-stable, water-soluble mycotoxins primarily produced in white and yellow corn in the field by *Fuarsium verticillioides* (syn. *F. moniliforme*) and *F. proliferatum*. Fumonisin contamination of other commodities is very limited, although fumonisins can be concentrated

in coproducts of corn ethanol production in the distiller's grains. A period of drought during the growing season followed by wet, warm conditions during pollination of corn favors development of fumonisins. Insect or bird damage to corn provides a portal for mold invasion of the kernels, and often fumonisins are found in very high concentrations in corn screenings containing damaged kernels. Frequently, fumonisins are found to co-occur with other mycotoxins, particularly aflatoxin and tricothecenes, specifically deoxynivalenol (DON). Toxicity is associated with fumonisins B_1 and B_2, with fumonisin B_2 usually occurring at about 30% of fumonisin B_1 concentration. Fumonisins FB_3, FB_4, FA_1, and FA_2 occur at low concentrations and do not appear to be important toxicants at this time. Fumonisins are chemically characterized as an aliphatic hydrocarbon with a terminal amine group and tricarboxylic acid side chains and are structurally similar to sphingolipids in cellular membranes. Horses (and rabbits) are the sensitive species. Fumonisins inhibit ceramide synthase enzyme involved with the conversion of sphinganine to sphingosine, which can increase sphinganine tissue concentrations and interfere with cellular growth, differentiation, and cell communication resulting in toxicity and carcinogenicity. Liver toxicity is often involved across species. Tissue and milk residues are not considered to be a problem.

Ergot Alkaloids

Historically, ergot has been associated with gangrene (peripheral vascular constriction in extremities), central nervous system (hallucinations and giddiness) and gastrointestinal disturbances, and reproductive effects of abortion in humans and agalactia (poor milk production) in animals. Ergot bodies are *C. purpurea* mycelia and hardened exudates of 'honeydew' with fungal conidia that replace a grass or cereal grain ovary with a hardened, dark sclerotium. The sclerotium is harvested with the grain, and if not physically screened out of the grain, it can end up in feeds and foods (such as flour). Rye, triticale, wheat, barley, oats, and various grasses can be infected by *C. purpurea*. The US Standards for grain define ergoty wheat and barley at >0.05% and >0.3% ergot sclerotia, respectively. Ergot alkaloids can also be found within plant tissues, especially tall fescue grasses, produced by endophytic fungi. Due to the pharmacological actions of several ergot alkaloids, these compounds have been used therapeutically for vasoconstrictive action and several of the ergot alkaloids are biosynthesized for medical uses. The pharmacological effects are the result of the ergotalkaloids' effects of partial agonism or antagonism at adrenergic, dopaminergic, and serotonergic receptors. To complicate the pharmacological effect, the species, physiological and endocrinological state influence response to the ergot alkaloid effects.

Climatic condition in the spring involving cool damp weather delays crop pollination and allows *C. purpurea* germination and development in the field. No-till farming, shallow cultivation, and failure to rotate crops increase the potential for ergot germination. Sporadic cases of cutaneous and gangrenous ergotism occur when livestock are made to pasture grasses with infected seed heads. Ergot alkaloids are composed of primary toxicants or ergopeptine alkaloids (ergotamine, ergocristine, ergosine, ergocryptine, ergocornine, and ergovaline) and ergoline alkaloids (ergonovine, lysergic acid, lysergol, and lysergic acid amide).

Ochratoxins

Ochratoxins are phenylalanine–dihydroisocoumarin compounds produced primarily by *A. alutaceus* var. *alutaceus* (formerly *A. ochraceus*), *A. westerdijkiae*, and *A. steynii* and *P. verrucosum* (formerly *P. viridicatum*); *A. alutaceus* is a common fungi in the warmer, temperate or tropical climates and *P. verrucosum* is considered a postharvest contamination of grain in colder climates (<30 °C). *A. carbonarius* and *A. niger* have been recently recognized as ochratoxin producers, although *A. niger* is a very uncommon producer of ochratoxins. *A. alutaceus* and ochratoxins have been reported in dried and stored foods, including dried meats and fish, beans, nuts, cereals and cereal products, coffee beans, grapes, figs, and spices. A majority of the exposure to ochratoxins is from *Penicillium* infection of wheat and barley in Europe and to a lesser extent in Canada (Figure 2). Consumption of ochratoxin-contaminated grain by swine can lead to accumulation of ochratoxins in body tissues and residues in swine kidneys. The European Union has regulatory guidelines for ochratoxin in foods for human consumption and for feedstuffs for animals; the US FDA currently does not have guidelines for ochratoxin.

Trichothecenes and DON

Trichothecenes are produced by several genera of fungi, including *Fusarium*, *Stachybotrys*, *Myrothecium*, *Trichothecium*, *Trichoderma*, *Cephalosporium*, *Cylindrocarpon*, *Verticimonosporium*, and *Phomopsis*. Trichothecene mycotoxins have also been isolated from Brazilian plants, *Baccharis* sp.; however, all medically and economically important sources to date have been fungal, especially *Fusarium*. *Fusarium* is a major agricultural plant pathogen in temperate growing regions where it causes *Fusarium*

Figure 2 *Penicillium* and *Fusarium* spp. mold growing on grain stored in metal grain bins. (Photo courtesy of Dr. Barry Jacobsen, Plant Pathologist, Montana State University.)

head blight in wheat, barley, triticale, and other grains. *F. graminearum* has an optimum temperature range for growth of 26–28 °C at a water activity (a_W) >0.88. *F. culmorum* grows optimally at 21 °C when a_W > 0.87. While increased rainfall will increase *Fusarium* head blight, the incidence of blight is primarily affected by moisture at anthesis (flowering) when the temperature is in the optimum range.

Fusarium species vary in toxigenic potential by strain, which in turn varies with geographic location. Mycotoxin production by *Fusarium* fungi is heavily dependent on oxygen, environmental pH, osmotic tension, and sometimes temperature. For example, the trichothecene DON is produced under conditions of low oxygen tension, whereas production of the mycoestrogen zearalenone by the same *Fusarium* fungus requires oxygen saturation. Unusually cool weather conditions in late summer and early fall, coupled with heavy rainfall in the upper Mid-west of the United States, can result in widespread, severe *Fusarium* infestation and mycotoxin production in corn. Toxigenic *Fusarium*, such as *F. sporotrichioides*, *F. poae*, and *F. graminearum* can produce several trichothecenes under these conditions (DON, T-2 toxin, HT-2 toxin, diacetoxyscirpenol (DAS), neosolaniol, and T-2 tetraol) and zearalenone. *Fusarium* molds are the most economically important source of trichothecene mycotoxins.

Trichothecenes are sesquiterpenoid compounds with an epoxy group at C12–13 that is considered essential for toxicity. While over a hundred trichothecene mycotoxins have been identified, typically a relative few are considered important in foods. Trichothecenes are stable compounds and can remain present at toxic concentrations in feed for years. Trichothecenes are chemically classified into four types based upon substitutions at five positions of the trichothecene skeleton. Type A trichothecenes include toxic trichothecenes, T-2 toxin, its deacetylated metabolite HT-2 toxin, and DAS or anguidine. These are most commonly produced by *F. sporotrichioides* and *F. poae*. Both of these *Fusarium* spp. produce toxic metabolites in light or darkness and at low temperatures (<−2 °C); however, sharp fluctuations in temperature increases the toxicity of extracts. Optimal production of T-2 toxin by *F. sporotrichioides* in grains occurs at 6–12 °C as compared with zearalenone production at an optimal 19–20 °C. The production of T-2 toxin by *F. sporotrichiodes* has been proposed as the causative agent of alimentary toxic aleukia in humans consuming wet, moldy grains in the former USSR. Type B trichothecenes are common field contaminants of grains and include DON or vomitoxin and acetylated mycotoxins 15- and 3-acetyl DON, nivalenol, and fusarenone-X (4-acetylnivalenol) produced by *F. culmorum* and *F. graminearum*, and other, closely related fungi. In North America, *F. graminearum* characteristically produces DON and 15-ADON; during cooler, wet conditions, production of 3-ADON and nivalenol can be detected in cereals. *F. graminearum* most commonly occurs in southern China, North America, and Eastern Europe, and *F. culmorum* more commonly occurs in Western Europe. Other strains of *F. graminearum*, mostly of Japanese origin, produce nivalenol and fusarenone X, zearalenone, and butenolide. *F. culmorum* strains from the Netherlands produced predominately DON and 3-ADON, while strains of *F. crookwellense*, collected from four continents, produced 4,15-diacetylnivalenol regardless of the source. The Type B trichothecenes are characterized by a keto group at C-8 and hydroxyl group at C-7; these are less toxic than Type A trichothecenes and the macrocyclic trichothecenes produced by *Stachybotrys*. Although not a trichothecene, the estrogenic mycotoxin zeralenone is often found together with DON in North America. More serious toxic effects could be underestimated in moldy corn if only DON and not acetylated DON or additional trichothecenes are assayed.

The Type C trichothecenes, such as crotocin (or Antibiotic T), have a second epoxide ring at C-7,8 and are not produced by *Fusarium* nor are these compounds associated with toxic effects. The Type D trichothecenes are potent, cytotoxic compounds with a macrocyclic ring linking C-4 and C-15 on the trichothecene skeleton. The genus *Myrothecium* can produce verrucarins and roridins that are diesters of the trichothecene verrucarol and are acutely toxic to mammalian cell lines *in vitro* and a wide range of animals with *in vivo* exposure. Naturally occurring toxicoses have rarely been attributed to the *Myrothecium* toxins. Although *Fusarium* does not produce type D trichothecenes, the fungus *S. alternans* Bonorden (synonyms *S. atra* Corda and *S. chartarum* (Ehrenberg ex Link) Hughes), which grows worldwide on cellulosic vegetation and mildewed wet straw and dry wall in wet areas of a building (i.e., bathrooms), produces macrocyclic trichothecene mycotoxins. These mycotoxins, including satratoxins G and H, verrucarin J, and roridin E, are stable and highly toxic. While horses are the most sensitive species to these compounds, stachybotryotoxicosis has been described in numerous animals in many countries of Europe, South Africa, and India.

In North America, the trichothecenes produced by *Fusarium* are the major contaminates in cereal crops. *Fusarium* contamination increases with delayed harvests under wet conditions on a variety of crops. *Fusarium* mycotoxins not only occur in the grain, but also in the vegetative part of the plant. Straw and hay contamination with DON may be as high as 100–150 mg DON per kg (dry weight basis) in wet periods. *Fusarium* infection of immature corn generally results in higher trichothecene and zearalenone concentrations in the cob, as compared with the mycotoxin concentrations in the kernels (**Figure 3**). Usually grain stored at moisture concentrations <0.70a_W or <14.5% moisture by weight is not susceptible to fungal growth or mycotoxin production. Both the European Union and the US FDA have regulatory guidelines for DON.

Zearalenone

Zearalenone, previously known as F-2, is a nonsteroidal estrogenic mycotoxin produced by *F. graminearum* (teleomorph *Gibberella zeae*). Additional *Fusarium* fungi capable of producing zearalenone include *F. culmorum*, *verticillioides* (*moniliforme*), *sporotrichioides*, *semitectum*, *equiseti*, and *oxysporum*. Zearalenone is chemically described as 6-(10-hydroxy-6-oxo-*trans*-1-undecenyl)-β-resorcyclic acid lactone. At least seven derivatives of zearalenone have been reported in natural occurrence in corn. Zearalenone and uterotrophic active derivatives were classified as estrogens in that they have an affinity for the estrogen reception and produce estrus or cornification of the

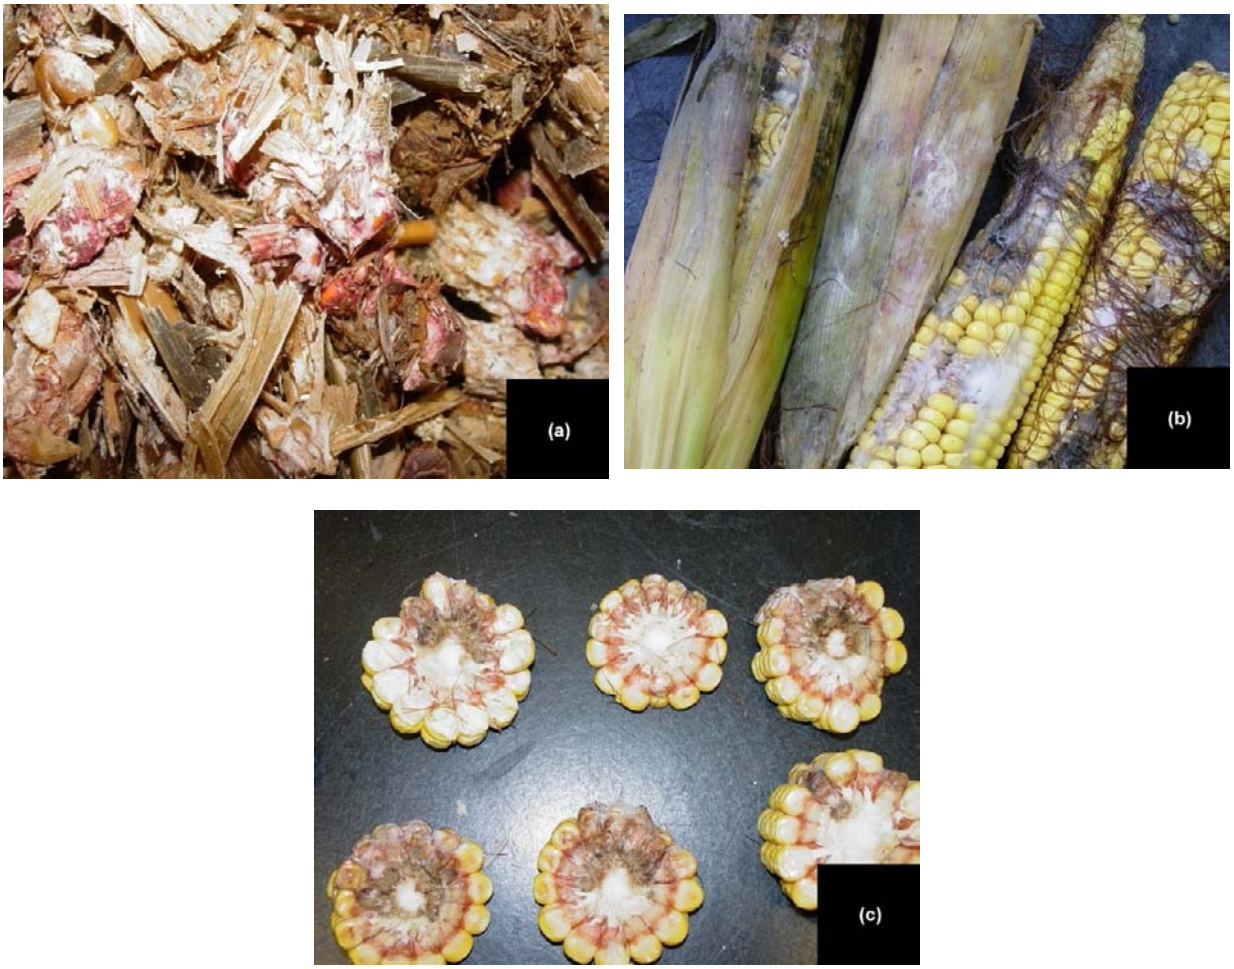

Figure 3 *Fusarium* sp. growing on corn silage with DON contamination (a), field corn with *Fusarium* sp. growth and T-2 toxin contamination (b), and Fusarium sp. invading corn kernels and cobs (c). (Photos: Dr. M. Mostrom, NDSU.)

vagina of adult mice. Zearalenone can be produced on numerous substrates, including wheat, barley, corn, corn silage, rice, sorghum, and occasionally in forages. Production in soybeans is uncommon. Moisture content and the presence of oxygen are critical factors for zearalenone production. In laboratory cultures, *Fusarium* growth occurs during a 3-week period at moisture levels over 20% and between 20 and 25 °C. If the fungus is stressed by cool temperatures of 8–15 °C for several weeks, zearalenone can be produced. Production of zearalenone in the field is similar to that in the laboratory, with alternating moderate and low temperature weather capable of stimulating zearalenone production. Very high concentrations of zearalenone, which can occur naturally in some field samples, generally result from improper storage at high moisture rather than production in the field. In addition to the co-occurrence of other estrogenic metabolites, such as α- and β-zearalenol, zearalenone is commonly detected in grains with another *Fusarium* mycotoxin DON. Zearalenone is heat stable, but can be partially destroyed during extrusion cooking of cereals.

Contamination of cereal grains by zearalenone has been reported worldwide, primarily in temperate climates. Typically, zearalenone concentrations are low in grain contaminated in the field, but increase under storage conditions with moisture > 30–40%. Zearalenone has major effects on reproduction that can lead to hyperestrogenism.

Mycotoxin Conjugates

The relatively recent finding of conjugated mycotoxins, including the 'masked mycotoxins' for soluble conjugates or 'bound mycotoxins' for insoluble conjugates, has complicated interpretation of mycotoxin concentrations and importance of these findings for toxic effects. Current thinking is that conjugated mycotoxins can originate from fungi, plants, food processing, and animals. Some of the fungal conjugated mycotoxins include 3-acetyl DON (3ADON) and 15-acetyl DON (15ADON) that are often detected in *Fusarium*-contaminated grains along with DON. These mycotoxins are unique compounds that appear to be produced under different conditions. Typically in North America, when higher DON concentrations (over 3–5 mg kg^{-1}) are detected, 15-ADON can be often found; usually *F. graminearum* is the contaminating fungus on grain. Not as frequently detected in North America is 3ADON, which is found with higher concentrations of DON

and can be associated with wetter climatic conditions. Zearalenone 4-sulfate is another conjugated mycotoxin produced as a natural *Fusarium* metabolite, and can be detected in fungal cultures and in maize.

Plants appear to have protective mechanisms to convert toxic compounds (such as mycotoxins) into more polar metabolites. The conjugated mycotoxin, DON 3-β-D-gluopyranoside (D3G) was initially found in maize cell suspension cultures and then in naturally contaminated maize, wheat, and barley. D3G has been reported in significant concentrations (1000 $\mu g\,kg^{-1}$) and can be detected at 70% or the DON concentration. The question of whether the glucosides are less toxic storage mycotoxins that are formed for plant self-protection and whether the release of toxic aglycones from the glucosides by herbivore ingestion can cause toxicity is yet to be determined. Food processing, such as heating and fermentation, can alter mycotoxin concentrations and mycotoxin structure. Higher concentrations of D3G have been detected in malt as compared to the DON plus D3G concentrations in the original grain used. It has been hypothesized that bound mycotoxins in the cell wall polymer of grains could be released enzymatically during malting. Excessive heating, such as baking, can alter the chemical structure of mycotoxins.

Mycotoxins can undergo metabolism in the mammalian liver and other organs and be excreted in urine and feces. Mycotoxins undergo conjugation with glucuronide (i.e., DON and zearalenone), and sulfates or react with proteins, glutathione, and cysteine (i.e., ochration A and patulin) with subsequent excretion. These conjugated mycotoxins could be used as biomarkers of exposure but are not likely to be found in food or feedstuffs and play a role in masked mycotoxins.

Mycotoxins: Occurrence and Determination

Y Picó, University of Valencia, Valencia, Spain

Introduction

The term mycotoxin comes from the Greek words 'mykes' for fungus and 'toxicon' for poison. Mycotoxins are toxic secondary metabolites produced by a large number of fungal species potentially infesting food at all stages of production, processing, and storage. The main genera of mycotoxin-producing fungi are *Aspergillus*, *Fusarium*, and *Penicillium*. Although secondary metabolites are commonly formed by simple biosynthetic reactions from small molecules (acetates, pyruvates, etc.), mycotoxins are chemically and structurally diverse (Figure 1). More than 300 mycotoxins are known today, but only aflatoxins (aflatoxins B1, B2, G1, G2, and M1), fusarium toxins (deoxynivalenol, zearalenone, fumonisins B1 and B2, and T-2 and HT-2 toxins), patulin, and ochratoxin A are regulated by European Union (EU) legislation for different foods. Raw materials and products that are frequently contaminated include corn, sorghum, wheat, barley, rice, oats, and livestock such as milk and cheese by-products.

Mycotoxins are a potential threat to human and animal health through the intake of contaminated food. These compounds produce a wide range of adverse and toxic effects in animals: (i) aflatoxins are carcinogenic and cause acute hepatitis, and also reduce the immune response; (ii) citrinin has a nephrotoxic effect; (iii) T2 toxin produces a loss of weight and causes beak lesions in birds; (iv) fumonisins are carcinogenic, hepatotoxic agents, and in horses cause leukoencephalomalacia; (v) ochratoxins are also carcinogenic, nephrotoxic, teratogenic, and hepatotoxic; (vi) trichothecenes have activity as immunodepressants and cause gastrointestinal bleeding; and (vii) zearalenone has estrogenic activity. To give an idea of the interest in these compounds, in the last 3 years, the European Food Safety Authority (EFSA) has launched three calls for data on mycotoxins' occurrence to support the scientific opinions about their importance within the food and feed safety. Currently, the new scientific opinions issued in 2011 and 2012 cover a large number of traditional and emerging mycotoxins.

Methods for the analysis of mycotoxins in food number in the thousands. Conventional methods of analysis for mycotoxins have included enzyme-linked immunosorbent assay (ELISA), thin-layer chromatography (TLC), high-resolution liquid chromatography with fluorescence (HPLC-FL), high-resolution liquid chromatography with diode array (HPLC-DAD), high-resolution liquid chromatography coupled to mass spectrometry (HPLC-MS), and gas chromatography coupled to mass spectrometry (GC-MS). Most of these methods employ a cleanup step by solid phase extraction (SPE) or by immunoaffinity techniques to eliminate interference and improve the mycotoxins' determination. With these newer and higher throughput analytical tools, researchers are now able to get results more efficiently and cost effectively in a matter of hours to days. The purpose of this chapter is to briefly evaluate the extent of mycotoxins' contamination and their co-occurrence in food, and to discuss the current procedures to analyze them. For this, the importance of sampling and sample preparation is discussed, and the most-often-used methods to identify and quantify mycotoxins are described. Particular emphasis is given to recent developments and new techniques that have been used in the analysis and detection of mycotoxins.

Occurrence in Food

The Food and Agriculture Organization (FAO) estimates that 25% of the world's food crops are affected by mycotoxins. Contamination of mycotoxins can occur when food is a growing crop or during storage, processing, or handling, and after the finished food products have been prepared for sale or consumption. Thus, economical losses occur at all levels. Environmental stress conditions such as insect infestation, drought, cultivar susceptibility, mechanical damage, nutritional deficiencies, and unseasonable temperature, rainfall, or humidity can promote mycotoxin production in growing crops. Most mycotoxins are chemically stable during storage and processing, even at high temperatures. Consequently, mycotoxins may also be found in beer and wine resulting from the use of contaminated barley, other cereals, and grapes in their production. They can also enter the human food chain via meat or other animal products such as eggs, milk, and cheese as the result of livestock eating contaminated feed.

Mycotoxins can occur both in temperate and tropical regions of the world, depending on the species of fungi. For example, *Aspergillus* species find optimal conditions in tropical and subtropical areas, whereas *Fusarium* and *Penicillium* species are also adapted to Europe and US climates. However, globalization of the food and feed trade results in a worldwide distribution of mycotoxins. As an illustrative example, the Biomin Mycotoxin Survey Program deserves mention. In the more than 4000 samples analyzed, aflatoxins were present in 25%; zearalenone, 46%; deoxynivalenol, 64%; fumonisins, 56%; and ochratoxin A, 31% (Figure 2). The ability of mold species to produce several kinds of mycotoxins originates multiple contaminations in a food. Several types of mycotoxins may also be in the same food because they came from different contaminated ingredients or raw materials.

Mycotoxins comprise a wide variety of chemical compounds (more than 300, as mentioned), with very different molecular structures as a result of the numerous species of fungi responsible for their production. Major and minor classes of mycotoxins can be differentiated. Aflatoxins, ochratoxins, trichothecenes, fumonisins, patulin, zearalenone, and ergot alkaloids are the major classes, and also raise the most important concern for human and animal health.

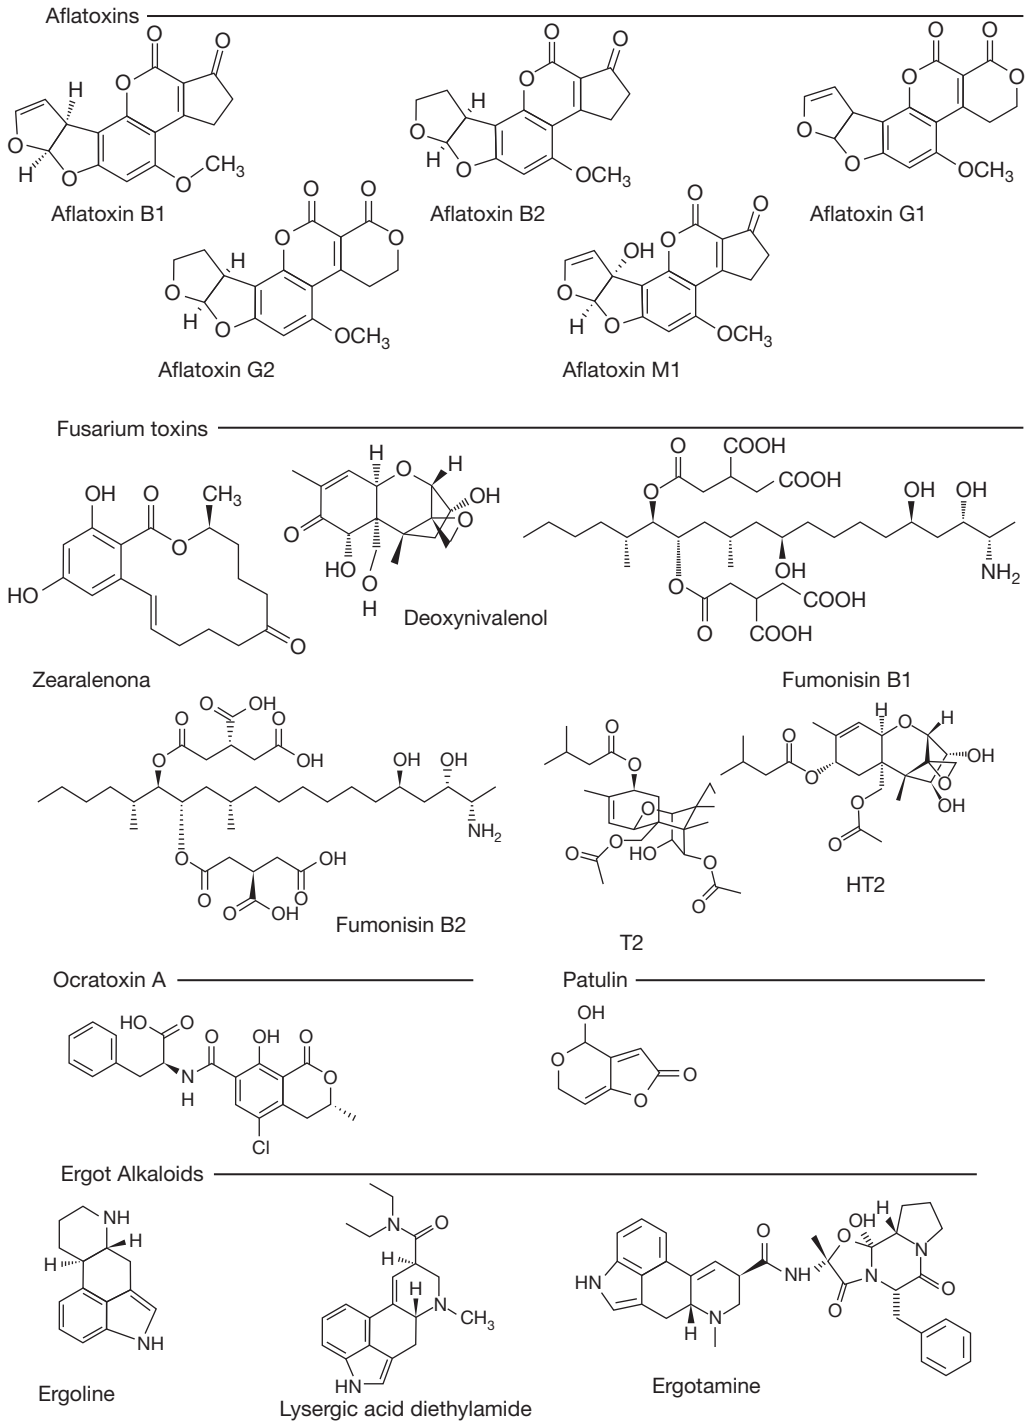

Figure 1 Examples of common mycotoxins, illustrating the structural diversity of these compounds.

Aflatoxins, produced primarily by *Aspergillus flavus* and *A. parasiticus*, are mycotoxins of major concern because they are carcinogenic. There are at least 14 different types of aflatoxins produced by these molds, but the four major aflatoxins are B1, B2, G1, and G2, plus two additional metabolic products, M1 and M2, that are of significance as direct contaminants of foods and feeds. The aflatoxins M1 and M2 were first isolated from the milk of lactating animals fed with aflatoxin-contaminated feed, hence the M designation. The B designation of aflatoxins B1 and B2 resulted from the exhibition of blue fluorescence under ultraviolet (UV) light, while the G designation refers to the yellow-green fluorescence under UV light. Aflatoxins are substances that are chemically related to difuranocoumarin and classified in two groups according to their chemical structure (Figure 1): the difurocoumarocyclopentenone series (including aflatoxins B1 and B2 and characterized by a

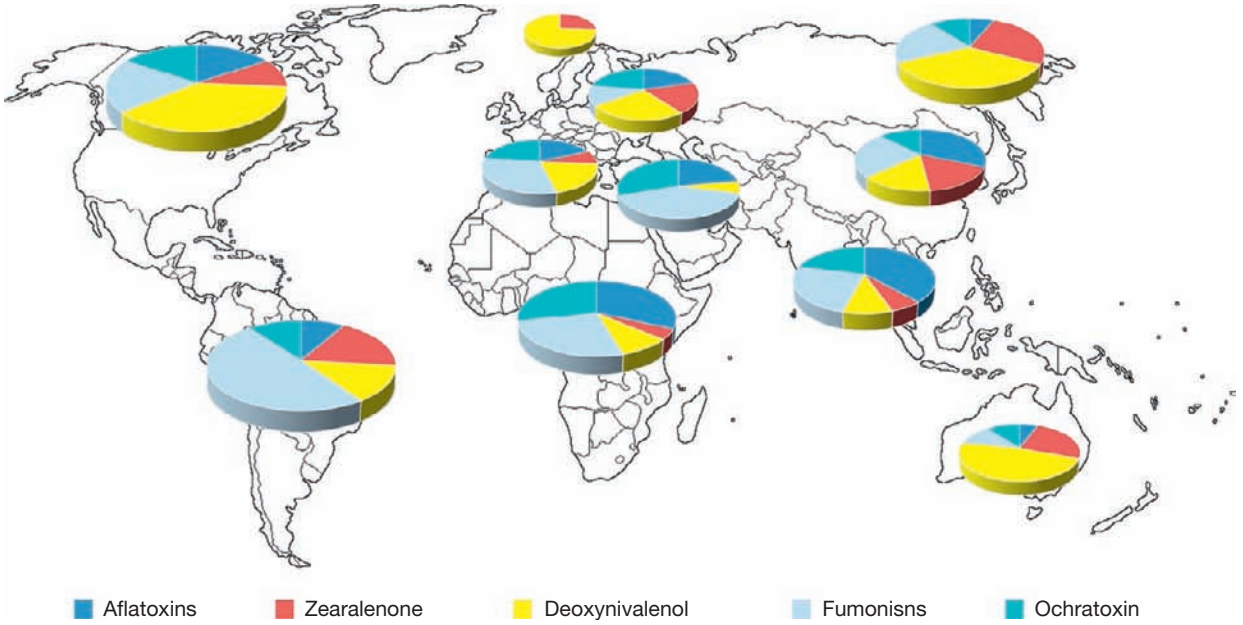

Figure 2 An overview of mycotoxin contamination worldwide (from data reported by BIOMIN Holding GmbH, 2012).

cyclopentenone ring) and the difurocoumarolactone series (including aflatoxins G1 and G2 that contain a D lactone ring). Aflatoxins have been detected in milk, cheese, corn, peanuts, cottonseed, nuts, almonds, figs, spices, and a variety of other foods and feeds. Milk, eggs, and meat products can be contaminated because of the animal consumption of aflatoxin-contaminated feed. However, the commodities with the highest risk of aflatoxin contamination are corn, peanuts, and cottonseed.

Trichothecenes are a group of about 150 mycotoxins produced by several fungi Fusarium — particularly *Fusarium graminearum* and *F. sporotrichioides* — *Trichoderma*, *Trichothecium*, and others. The most important structural features causing the biological activities of trichothecenes are 12, 13-epoxy ring, the presence of hydroxyl or acetyl groups, and the structure and position of the side chains (Figure 1). They can be distinguished into two groups: macrocyclic and nonmacrocyclic. The latter group is also subdivided into the Type A and Type B trichothecenes. Type A trichothecenes include T-2, HT-2, neosolaniol, and diacetoxyscirpenol, and Type B consists of deoxynivalenol, nivalenol, and 3-acetyldeoxynivalenol. Type A are of special interest because they are more toxic than the other foodborne mycotoxins. However, deoxynivalenol (Type B) is of concern, as it is the most prevalent trichothecene in Europe. The thricothecenes have been frequently detected in cereals, infant foods, fruits, vegetables, and even products of animal origin.

Fumonisins are a group of mycotoxins produced primarily by *F. verticillioides* and *F. proliferatum*, although a few other Fusarium species may also produce them. There are at least 28 different forms of fumonisins, most designated as A-series, B-series, C-series, and P-series. Fumonisin B1 is the most abundant, followed by B2. Chemically, fumonisin B1 is a diester of propane-1,2,3-tricarboxylic acid and 2-amino-12,16-dimethyl-3,5,10,14,15-pentahydroxyeicosane (Figure 1). Fumonisin B2 is a deoxy-analog of the fumonisin B1. Fumonisin B1 typically accounts for 70–80% of the total fumonisins produced, while fumonisin B2 usually makes up 15–25%. Fumonisins are soluble in polar solvents because of the four free carboxyl groups, the hydroxyl groups, and the amino group. Their insolubility in many organic solvents such as chloroform and hexane commonly used in mycotoxin analysis partly explains the difficulty in their original identification. The natural occurrence of fumonisins in cereals, particularly maize and maize-based products, has been reported worldwide.

Zearalenone is a nonsteroidal, phenolic resorcyclic acid lactone estrogenic toxin produced mainly by *F. graminearum*, *F. culmorum*, and *F. sacchari*. It is commonly found in maize but can be found also in other crops such as wheat, barley, sorghum, and rye. Zearalenone is a white crystalline compound that exhibits blue-green fluorescence when excited by long wavelength UV light (360 nm) and a more intense green fluorescence when excited with short wavelength UV light (260 nm). Soluble in water and in aqueous alkali, it is slightly soluble in hexane and progressively more soluble in benzene, acetonitrile, methylene chloride, methanol, ethanol, and acetone.

Ochratoxin A, produced primarily by *Penicillium viridicatum*, but also by certain Aspergillus molds (e.g., *A. ochraceous*), is a compound with phenylalanine-containing dihydroisocoumarin and also a chlorine on the aromatic ring, which accounts for its toxicity. It is a colorless crystalline compound, exhibiting blue fluorescence under UV light. Its sodium salt is soluble in water; as an acid, it is moderately soluble in polar organic solvents such as chloroform and methanol and dissolves in dilute aqueous sodium bicarbonate. On acid hydrolysis, ochratoxin A yields phenylalanine and an optically active lactone acid, ochratoxin α. Reaction in methanol and chloridric acid yields the ochratoxin methyl ester, which can be used as a confirmatory. Ochratoxin A has been detected in various types of food, including cereal products, coffee, spices, beer, grape and its derivatives, and products of animal origin.

Patulin is a lactone produced by a variety of molds, in particular, *Aspergillus* and *Penicillium* and *Byssochlamys*. Most commonly found in rotting apples, in general the amount of patulin in apple products is viewed as a measure of the quality of the apples used in production. In addition, patulin has been found in other foods such as grains, fruits, and vegetables. Patulin is destroyed by alcoholic fermentation and thus is not found in either alcoholic fruit beverages or vinegars produced from fruit juices. Thermal processing causes only moderate reductions in patulin levels, thus patulin present in apple juice will survive the pasteurization processes. Patulin can be isolated as colorless to white crystals from ethereal extracts that have no optical activity. It melts at about 110 °C. It is soluble in water, methanol, ethanol, acetone, and ethyl or amyl acetate and less soluble in diethyl ether and benzene.

Ergot alkaloids are mycotoxins produced by several species of fungi in the genus Claviceps. In AD 944–945, in the Aquitane region of France, the symptoms of the disease called St. Anthony's fire – burning skin, insects crawling under the skin, and the loss of hands and feet – suggested ergot poisoning. Ergot poisoning in humans and domestic animals is known as ergotism. This disease may cause strange hallucinations, the feeling of itchy and burning skin, gangrene, loss of hands and feet, and even death. Ergotism is one of the oldest known human diseases caused by mycotoxins. The ergot alkaloids are indole compounds that are biosynthetically derived from L-tryptophan and represent the largest group of nitrogenous fungal metabolites found in nature. There are four main groups of ergot alkaloids: the clavines (agroclavine, elymoclavine, lysergol), the lysergic acids, the lysergic acid amides (ergine, ergonovine), and the ergopeptides (ergotamine, ergovaline, α-ergosine). More than 80 different ergot alkaloids have been isolated, mainly from various Claviceps species (more than 70 alkaloids), but also from other fungi and from higher plants. In addition to the naturally occurring ergonovine (used as an oxytocic) and ergotamine (an analgesic used to control migraines), synthetic derivatives of continuing importance today are the oxytocic methergine, the antimigraine drugs dihydroergotamine and methysergide, the antisenility nootropic (smart drug) Hydergine™, and bromocriptine, used for numerous purposes including treatment of Parkinson's disease. Selected members of these groups of compounds are involved in either nervous or gangrenous syndromes in humans and animals that consume grains or grain products contaminated with the sclerotia of the fungus.

In addition to this major class of mycotoxins, the minor class (citrinin, cyclopiazonic acid, sterigmatocystin, moniliformin, gliotoxin, citreoviridin, tremorgenic mycotoxins, penicillic acid, roquefortine, 3-nitropropionic acid, and fusaproliferin) is also noteworthy.

Determination of Mycotoxins

The classification of the analytical methods to determine mycotoxins can be performed according to different criteria. The more useful one is done according to the type of chemical/biological/physical principle used and to the time of analysis:

- Rapid methods (ELISA, lateral flow devices (LFD), dipsticks, biosensors, fluorescence polarization immunoassay (FPIA))
- Chromatographic methods (HPLC, GC, TLC, LC-MS/MS)

In addition to that, an appropriate sampling plan is mandatory in order to provide accurate and representative results, and proper sample extraction and cleanup is also required.

Sampling

Sampling is always an important step for any method aiming to quantify food contaminants due to the overall complexity of food matrices, but particularly in the case of mycotoxins, sampling is by far the largest contribution to the total error. In addition, the associated variability is largely dependent on the level of the toxin. Then, taking a representative sample from the lot under investigation presents almost unique characteristics because only a few units (0.1% approx. for a wide variety of agricultural commodities) are likely to be highly contaminated, resulting in an overall significant contamination of the lot. Appropriate sampling procedures are a prerequisite for obtaining reliable results because of the heterogeneous distribution of mycotoxins in grains and other food products. To reduce the variability of analytical results, the European Union has established a common sampling procedure according to Community Regulation No. 401/2006 for the official control of mycotoxin levels in foodstuffs (cereals and derived products, dried fruits, groundnuts, nuts, spices, milk and derived products, coffee and derived products, fruit juice, and solid apple products). The basic principle underlying the sampling plan is the sampling of an usually high number of incremental samples evenly distributed in the lot, the gathering of the collected incremental samples in a number of aggregate (generally one) samples, the grinding or slurring of the aggregate(s) samples, and the deriving of the laboratory samples from the aggregate sample(s). The number and weight of the incremental samples and of the aggregate sample(s) are dependent on the matrix and the size of the lot under consideration.

Sample Preparation

Although solid liquid extraction using solvents is the oldest sample preparation technique, it is still one of the most frequently used for mycotoxin extraction. A wide variety of solvents have been used, depending on the analyte to be extracted. Most mycotoxins are soluble in polar and slightly polar solvents, and insoluble in apolar solvents. Thus, mixtures of organic solvents, such as acetone, acetonitrile, chloroform, dichloromethane, ethyl acetate, or methanol, with small amounts of diluted acids or water are frequently used. The addition of water or acidified water solutions (i.e., with formic acid, acetic acid, and citric acid) usually improves the efficiency of extraction, because water increases penetration of the solvent into the material and an acid solution can help the extraction by breaking interactions between the toxins and other sample constituents like proteins or sugars. Sometimes, nonpolar solvents such as hexane and cyclohexane are used before or following the solvent procedure to remove lipophilic components. In addition to the type of solvent, sample/extractive solvent ratio, temperature, and time of extraction are other important parameters that should be carefully controlled to achieve accurate quantification. Following the solvent

extraction, a centrifugation or filtration of the extract is normally required before concentration and/or cleanup steps.

The development of multi-mycotoxin methods with one common sample preparation and a single final determination is highly desirable. In this regard, the most critical step is the development of an extraction that attains good recoveries for all mycotoxins under investigation in the food matrix. For multi-mycotoxin extraction, the mixtures of acetonitrile and water are the most common. In fact, these binary mixtures provide good yields for most of the analytes, with the exception of fumonisin, which needs acidification to obtain good recoveries. At a low pH, the four carboxylic groups of fumonisin are protonated (i.e., neutral), leading to less interaction and binding to the sample matrix.

Recently, the quick, easy, cheap, effective, rugged, and safe (QuEChERS) extraction procedure has been frequently employed as a sample preparation methodology for multiresidue mycotoxin analysis. The original QuEChERS method developed for pesticide residues consists of extraction with acetonitrile by salting out after the addition of adequately mixed salts (anhydrous magnesium sulfate and sodium chloride), after which the extract is subjected to dispersive solid-phase cleanup (d-SPE) with primary secondary amine and anhydrous magnesium sulfate. However, many modifications have been introduced, such as buffering the extraction medium with an acetate or citrate buffer, or changes in the dispersive sorbents.

The solid–liquid extraction required an energy input as mechanical shaking or ultrasounds to favor the extraction. Nonconventional extraction uses other types of energy inputs and includes pressurized liquid extraction, also known as accelerated solvent extraction; supercritical fluid extraction; and microwave-assisted extraction. They have the advantage of requiring smaller volumes of solvent, and they usually provide better extraction efficiencies (in terms of extraction yield and/or recovery) when compared with conventional solid liquid extraction.

Other miniaturized extraction techniques, such as matrix solid phase dispersion, solid-phase microextraction, and dispersive liquid–liquid microextraction, have been less employed to achieve extraction and cleanup during the determination of multiresidue and multiclass compounds in different matrices requiring less organic solvent, and in general yield satisfactory results.

Cleanup Methods

The most used cleanup procedures are liquid/liquid partition, SPE, and multifunctional solid phase extraction (Mycosep® SPE). SPE is currently applied for the extraction of mycotoxins from liquid samples or, in the case of solid matrices, as cleanup and/or concentration step after a previous extraction. In the simpler procedures, the sample is passed through a cartridge or a disc filled with a solid sorbent where the mycotoxins are absorbed and then eluted with an organic solvent. There is a wide range of column packings commercially available with different sorbents, so the choice depends on the food matrix, the analytes, and the interferences that could be present, and also when SPE is used as the cleanup step on the solvent in which the analytes were extracted. Silica gel cartridges, Florisil®, and cyano find widespread application in the determination of thricothecenes, while strong anion-exchange was used to isolate anionic compounds such as fumonisins.

Mycosep® and Multisep® columns are other well-established, non-specific SPE cleanup methods. These columns are filled by adsorbents such as charcoal, celite, ion-exchange resins, polymers, and other materials, packed into a plastic tube between two filter discs. In this process, interfering substances such as proteins, fats, and pigments are adsorbed in the solid phase, while the purified extract passes through the column. Many types of Mycosep® and Multisep® columns are available (Mycosep® and Multisep® 113, 216, 225, 226, 227, 229, etc.) with different adsorbent composition, the choice of which depends on the matrix and the mycotoxins. This cleanup procedure is very simple and quick, because there is no need for column preconditioning or rinsing. However, the columns are single-use only and do not allow any sample concentration, and purification of extracts is not always effective, depending on the matrix. Moreover, they are designed per analyte or a group of similar compounds.

SPE extraction is a safe, efficient, and reproducible technique. However, the procedure also presents some limitations, such as the impossibility of using a single cartridge for all mycotoxins, and the fact that method performance can be affected by several conditions, such as pH, type of solvent, and ionic strength of the sample.

Highly selective sorbents are also important tools that have gained popularity in recent years within the cleanup of mycotoxins. The most popular are based on antibodies (immunoaffinity columns, IAC) or molecularly imprinted polymers (MIPs), with IAC being the most used in mycotoxin analysis.

IAC consists of an activated solid-phase support, binded to specific antibodies for a given mycotoxin that binds it when the extract passes through the column, while impurities are removed by a rising step. Then, the mycotoxins are eluted with a miscible solvent or by antibody denaturation. If the sample is very complex, the combination of IAC with another extraction procedure, such as liquid–liquid extraction and SPE, could be necessary. The major advantage of IAC is the specific interaction between the antibody and the target analyte, as well as its rapidity. However, the procedure has some weaknesses, such as antibodies' denaturation in the presence of even low concentrations of organic solvents. The extract must be an aqueous solution containing little or no organic solvent. As with all antibody-based methods, there is also the possibility of nonspecific interactions due to cross-reactivities with other mycotoxins. Furthermore, immunoaffinity materials are expensive, and the columns only enable a single application. There are commercially available columns for thricothecenes, ocratoxins, aflatoxins, fumonisins, and others. Multifunctional columns for the simultaneous determination of different groups of mycotoxins are also available. Although there are some publications using IAC multi-mycotoxins, the use of IAC for multi-mycotoxin determination requires changes in development and format before its application to a large number of mycotoxins.

MIPs are prepared by polymerization of selected monomers around the template molecule, which is usually a structural analog of the compound of interest. The retention of the

analyte results from a shape recognition in artificial binding sites that recognize the target molecule. It is very promising and provides several advantages, such as high selectivity and great stability to heating and pH shifts. However, some mycotoxins are too toxic or too expensive to be used in MIPs preparation and they can pose some problems, such as inconsistent molecular recognition, polymer swelling in unfavorable solvents, slow binding kinetics, and potential sample contamination by template bleeding. Then, this cleanup method is less used.

Qualitative and Quantitative Analysis

Screening methods

Screening assays are very important tools for monitoring mycotoxins in food and feed. Most of the methods correspond to mere qualitative tests able to demonstrate the presence or absence of the toxin in question, although there are also a variety of rapid tests providing semi-quantitative or quantitative results.

Among the screening methods, immunochemical methods – which include ELISA, LFD, dipstick tests, FPIAs as well as, more recently, biosensors and noninvasive methods based on infrared and acoustic techniques – have shown great potential for mycotoxin analysis.

The ELISA method for determining mycotoxins has been available for more than 15 years. The technology is based on the ability of a specific antibody to distinguish the three-dimensional structure of a given mycotoxin. The direct competitive ELISA is used commonly in mycotoxin analysis. A microtiter ELISA plate consists of the balance of the antigen–antibody complex reaction. The majority of test kits available commercially to determine mycotoxins by ELISA are currently working on the base of the kinetics of antigen–antibody union before this union reaches the equilibrium, which reduces the incubation time from hours ($\sim$2 h) to minutes ($\sim$10 min). Although the reduction in the time of incubation may lead to some loss of sensitivity of the assay, the technique can provide accurate and reproducible results.

In addition, various immunostrips or immunodipsticks, also named lateral flow devices, have been developed for mycotoxin testing in the field, using either membranes with immobilized antibodies or dry reagents on the test strip, where the sample flows by capillary forces. The results provided by these tests are mostly based on a visual evaluation, giving a yes/no answer, or on portable photometric strip readers, providing quantitative or semi-quantitative results. Nevertheless, problems with reproducibility, reliability with different matrices, and sensitivity may sometimes limit their application, together with the lack of reliable method validation.

Several FPIA formats are available for mycotoxins. The sensitivity of FPIA was similar to ELISA; however, it is the least labor-intensive and requires the least amount of time to be performed. The FPIAs required less than 90 min to be performed, and no coating of plates was required.

Immunoassay methods, whatever type they are, were developed for detection of mycotoxins belonging to the same group. However, there is a trend in the more recent assays to detect simultaneously several mycotoxins from different groups.

Biosensors are composed of one biological component (nucleic acids, enzymes, antibodies, cells) that reacts selectively with the mycotoxin of interest, and by a transducing element responsible for converting the change of the physical variable produced by the interaction between the target molecule and the biological component into a measurable signal. The advantages of this technology may include more rapid assays, reusable and long-life sensor elements, the capacity for continuous monitoring, and industrially low-cost devices. The use of biosensors for the detection of mycotoxins is rapidly increasing, including disposable DNA electrochemical biosensors, handled immunoaffinity fluorimetric biosensors, and biosensors based on lipid films and liposomes. The most-used biosensors for the analysis of mycotoxin are those based on the interaction of a specific antibody, or an antibody fragment, and the mycotoxin. The transducing elements can be optical, piezoelectric, or electrochemical. Optical detectors can be based on surface plasmon resonance, fluorescence (fluorescence-based array biosensors, also called NRL-array biosensors), optical waveguide light mode spectroscopy, or total internal reflection ellipsometry, while electrochemical detectors are based on potentiometry with a carbon working electrode, differential pulse voltammetry, conductometry, and so on. Some of these sensors are designed for a single mycotoxin detection, while others are capable of multi-mycotoxin sensing.

Chromatographic methods

Nowadays, mycotoxins are typically determined using chromatographic methods, usually gas chromatography–mass spectrometry (GC-MS) and liquid chromatography-mass spectrometry (LC-MS). Mycotoxins are mostly polar compounds. Then, LC-MS is clearly preferred over GC-MS. GC analysis commonly requires a previous derivatization step, with silylation and acylation reactions being the most common approaches for mycotoxin analysis.

TLC-based methods have decreased steadily over the past few years, but, especially in developing countries, this analytical technique is still routinely used. TLC methods allow for a precise determination at levels not lower than 2 ng g^{-1}. Their disadvantages, however, include the use of solvents that are considered to be an ecological hazard. A large number of TLC-based methods were accepted by the AOAC as official methods, including the methods for the determination of deoxynivalenol in barley and wheat, for aflatoxins in peanuts and corn, for aflatoxin M1 in milk and cheeses, for ochratoxin A in barley and in green coffee, and for zearalenone in corn. A recent TLC improvement is the use of a microcomputer interfaced with a fluorodensitometer to simplify data handling.

Traditionally, mycotoxins have also been determined by HPLC-DAD, and those that are also fluorescent as fumonisins by HPLC-FLD. However, over the last few years, liquid chromatography–tandem mass spectrometry (LC-MS/MS) has become the most extensively used analytical method for mycotoxins belonging to different chemical families, enabling their efficient quantitative determination in several food commodities. HPLC separation exclusively relies on reversed-phase materials (RP-18) with acetonitrile/methanol/water, methanol/water, and acetonitrile/water mixtures as mobile phases, isocratic or in gradient. Acetic acid and ammonium acetate are predominantly applied as additives either to improve chromatographic separation or to force adduct formation for improved MS. APCI and ESI have been effectively applied in

positive and negative ionization mode for the analysis of mycotoxins. Multistage MS applications with triple quadrupole and/or linear ion trap instrumentation have been performed either to achieve accurate quantification down to the low ppb range working in multiple selected reaction monitoring mode, or for structural elucidation by enhanced precursor and product ion scans. Combining HPLC with tandem MS results in a powerful tool for characterization and identification, especially for detection of so-called conjugated mycotoxin, in which the toxin is usually bound to a more polar substance like glucose or other sugars. These conjugated mycotoxins are referred to as masked mycotoxins, as these substances escape routine detection methods but can release their toxic precursors after hydrolysis. Also with LC-MS, there is currently a strong trend toward multi-mycotoxin methods for simultaneous determination, particularly for mycotoxins belonging to different chemical families. This approach has the advantage of enabling the reduction or possibly the omission of sample cleanup. In addition to the multi-analyte requirement, multi-substrate methods are even more demanding. This approach, nevertheless, has the advantages of speed and ease of application with one method for multiple mycotoxin–matrix combinations over a broad range of mycotoxin classes, which is of special interest for high-throughput routine analysis. However, the latest trends in mycotoxin analysis have been to take advantage of ultra-high resolution mass spectrometry, which simultaneously

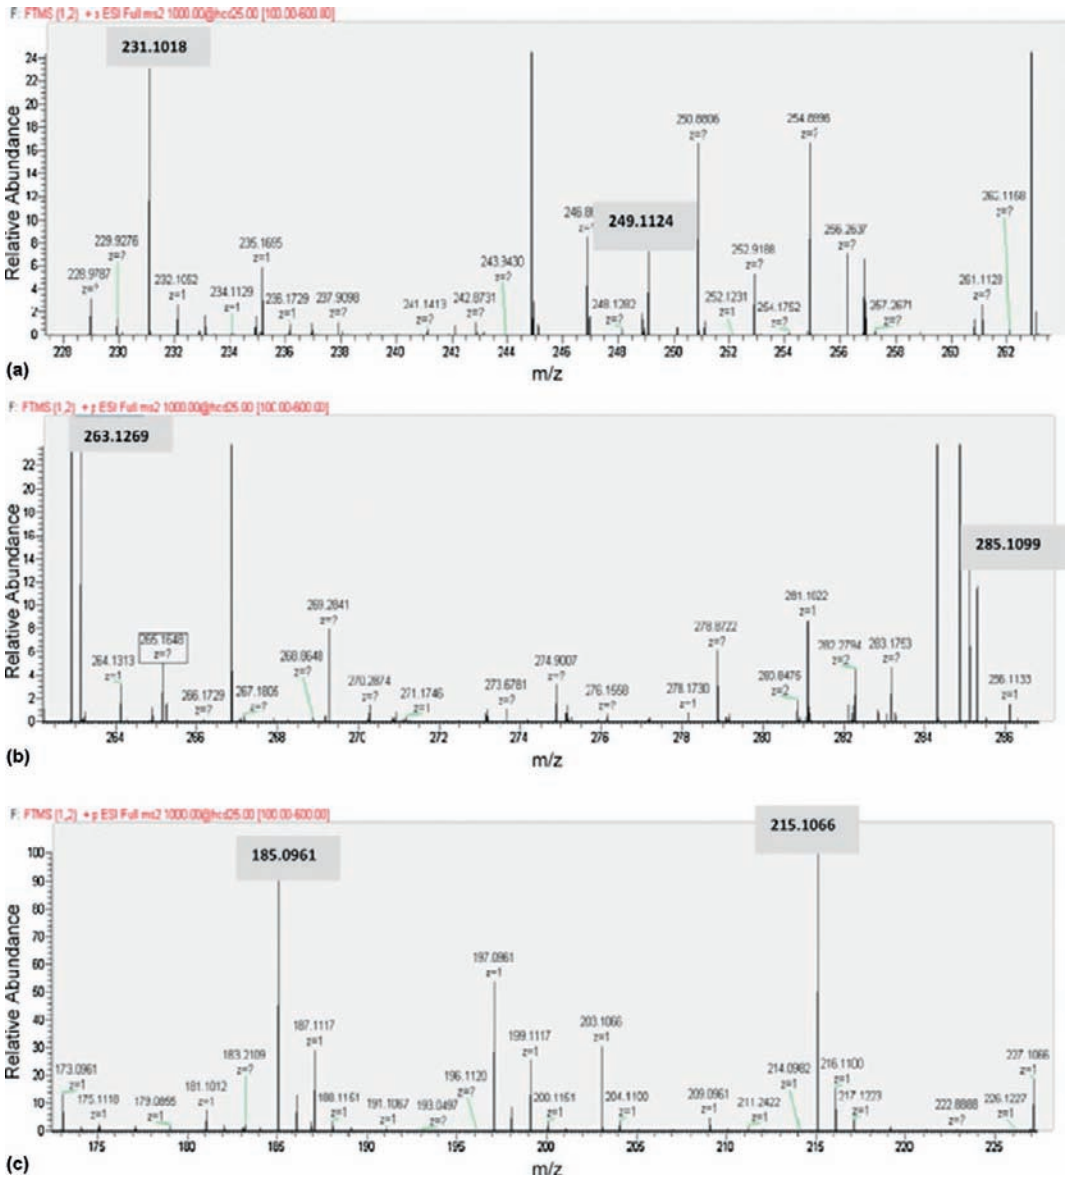

Figure 3 Examples of HCD-MS spectra of deoxynivalenol (a), HT-2 (b), and T-2 (c) obtained by analyzing a bread sample spiked with the three mycotoxins at 412.5 ng g^{-1}. Reproduced from Monaci, L., De Angelis, E. and Visconti, A. (2011). Determination of deoxynivalenol, T-2 and HT-2 toxins in a bread model food by liquid chromatography–high resolution-Orbitrap-mass spectrometry equipped with a high-energy collision dissociation cell. *Journal of Chromatography A* **1218**(48), 8646–8654, with permission from Elsevier.

achieves qualitative and quantitative analysis for target, nontarget, and unknown compounds. High-resolution mass spectrometry has been applied to mycotoxin analysis using orbitrap or quadrupole time-of-flight, and has been recently applied to detect mycotoxins in beer and human milk. An example of typical accurate spectra obtained for each mycotoxin by its fragmentation is depicted in Figure 3.

GC-based methods have a narrower scope, but they have been applied to determine thricothecenes to confirm patulin and to determine some mycotoxins. In particular, the analytical techniques employing GC and capillary columns are useful for the simultaneous determination of different trichothecenes. For the detection step, heptafluorobutyryl, trimethylsilyl, and trifluoroacetyl derivatives are frequently used, coupled with electron capture detection. However, MS is strongly recommended for peak confirmation. In the multistage tandem mass spectrometric analysis, triple quadrupole is used for accurate quantification and ion trap is selected for the fragmentation behavior studies acquiring information about the product ions, while GC-TOF is used as a novel technique for accurate mass measurements based on the extract masses. Limitations such as the need to derivatize the samples before analysis have led to a prevalence of LC-MS over GC-MS approaches.

In recent years, substantial developments have been made in the field of mass spectrometry, enabling introduction of novel ambient desorption ionization techniques such as direct analysis in real time, desorption electrospray ionization, surface desorption atmospheric-pressure chemical ionization, and atmospheric-pressure solid analysis probe. These ion sources achieve high-throughput of analyses, which can be carried out under ambient conditions without (chromatographic) separation of sample components prior to desorption/ionization or need for complicated and time-demanding sample pretreatment procedures. These interfaces have already shown proper prospects to be applied in the mycotoxin analysis.

Conclusions

Although there is a large range of methods for screening and quantification of mycotoxins in food, not all of them cover a broad range of mycotoxins. The current trend has been increasing through the development of multi-mycotoxin methods. One of the latest developments, based on the QuEChERS procedure and its variants, increased the scope of mycotoxins to be analyzed simultaneously when coupled to GC-MS or LC-MS/MS instruments. The application of MS in conjunction with other tools for decreasing limits of detection has been of increased interest in recent times. Future trends would focus on rapid assays and tools that would measure multiple toxins from a single matrix.

Introduction

Mycotoxins or fungal metabolites are found in many of the staple foods worldwide. These natural chemical compounds can be produced by molds on crops in the field, during storage and transportation, and in food processing. If consumed in adequate quantities, mycotoxins can cause a variety of adverse effects in humans and animals termed mycotoxicosis. Often, the better-quality grains are used for export markets, which have more stringent regulatory guidelines and safe usage for grains and foods than use of contaminated grains within the country. This strategy results in the use of higher mycotoxin-contaminated foods in poorer, more vulnerable human populations, particularly in developing nations with little regulatory oversight of raw products.

Cereal grains are at their highest quality and have little risk of mold during storage when they are fully mature at harvest, are free of field mold damage, and have little mechanical damage to the outer seed coat and when harvest is not delayed by climate factors. Climatic events, particularly wetter weather during plant flowering and higher temperatures during field maturation and storage, increase the ability of molds to infect food supplies. The conditions for mold growth, including adequate growth matrices, source of oxygen, moisture level in grain or the water activity (a_w), and temperature, are critical to the success of mold invasion in grains and food. Subsequent conditions and mold stress can cause the mold to produce mycotoxins, which can be generated very rapidly in stressful conditions. A wide variety of molds can grow on field crops; these molds may or may not be mycotoxin producers. Successive mold populations can occur during storage by increasing temperature and moisture in the local environment of grains ('hot spots') and favor the growth of additional molds. Mold spores can deteriorate, but mycotoxins can remain remarkably stable for years in foods and survive many processing procedures.

Over the years, thousands of mycotoxins have been identified, but only a few mycotoxins are well recognized and documented in contaminated foods and feeds. Historically, the knowledge that certain foods can be associated with adverse effects has been observed in populations. Even prior to the Middle Ages, clinical symptoms of ergotism, including marked central nervous system (hallucinations) and gangrenous (peripheral vascular constriction of extremities) effects in humans, were noted in wetter years. The poorer populations consuming coarser grains, such as rye flour, were more prone to adverse effects. In the early to mid-1900s, human epidemics characterized by fever, hemorrhages, and immune suppression were reported in the former USSR. The syndrome was termed alimentary toxic aleukia and was linked with consumption of overwintered grains contaminated with mold, which was later associated with *Fusarium* and T-2 toxin. In animal populations, the use of corn screenings from drought years was often associated with blindness, ataxia, and death in horses, and the use of mold-contaminated corn in wet years was associated with estrogenic signs (swollen vulvae and enlarged mammary glands) in pigs, although no toxic compounds were identified in these syndromes until the latter half of the twentieth century. In the early 1960s, 'Turkey X disease' was identified in England and associated with mold-contaminated peanuts in poultry feed and death of turkeys. Aflatoxins were identified as the cause of marked liver or hepatic damage in the turkeys. Subsequently, a number of mycotoxins were identified in grains and food. Mycotoxins can cause a variety of acute and chronic effects in humans and animals. Some of these conditions are well characterized, and some are possible associations of cause–effect. This article will discuss the more common mycotoxins in food and adverse effects attributed to these toxins.

Aflatoxins

Aflatoxins are potent liver toxins, immunosuppressants, carcinogens, and mutagens and can cause important public health problems. Clinical symptoms of aflatoxicosis include vomiting and abdominal pain, liver necrosis with elevated hepatic enzymes and bilirubin, prolonged clotting times, decreased production of milk and eggs in animals, growth impairment in the young, and reduced immune competence (i.e., vaccine failure or poor antibiotic response in animals and lower populations of immune cells in human subjects). Several large outbreaks of acute aflatoxicosis involving homegrown maize causing liver necrosis and deaths have been reported in India and Kenya. Numerous governments regulate the allowable concentrations of aflatoxins in human foods, fluid milk, and animal feeds. Table 1 summarizes the fungi and associated mycotoxins found in various commodities and the clinical diseases observed in humans and animals.

Aflatoxin B_1 has been associated with hepatocellular carcinoma in humans and is included in group 1 as a human carcinogen by the International Agency for Research on Cancer (IARC). Aflatoxin M_1, a metabolite of aflatoxin B_1, has lower toxicity and carcinogenic activity than AB1. Sterigmatocystin, a mycotoxin produced by *Aspergillus versicolor* and other molds, is a precursor in the synthesis of aflatoxins, a hepatotoxin and carcinogen, and capable of toxicosis similar to, but less toxic than, aflatoxins.

Aflatoxins are low-molecular-weight, lipophilic compounds that are passively absorbed from the gastrointestinal tract. Aflatoxins are absorbed from the intestinal tract into the hepatic portal system. Young animals absorb aflatoxins more efficiently than older animals – therefore, the concern for exposure to aflatoxins in milk and baby foods. Aflatoxin B_1 can bind reversibly to albumin, with unbound aflatoxin B_1 passing from the circulation into tissues. Aflatoxins do not

Table 1 Summary table of fungi, associated mycotoxins, and clinical disease

Fungal species	*Mycotoxin classification*	*Mycotoxins identification*	*Commodity*	*Clinical signs/symptoms*
Aspergillus flavus, *Aspergillus parasiticus*	Aflatoxins	B1, B2, G1, G2 M1, M2	Corn/maize, peanuts, tree nuts, cottonseed, rice, copra, heat, spices, cocoa (chocolate products) Milk products and tissues	Liver toxicity, poor weight gains, immunosuppression, hemorrhages, cancer, death
Fusarium sp. *(F. graminearum, F. Poae, F. acuminatum, F. sporotrichiodes, F. equiseti)*	Trichothecenes	DON (deoxynivalenol) or vomitoxin, nivalenol, 3- and 15-acetylDON, T-2 toxin, HT-2 toxin, T-2 tetral, DAS (diacetoxyscirpenol), neosolaniol	Wheat, maize, hay, straw Overwintered grains	Gastroenteritis, vomiting, diarrhea, immunosuppression, poor growth
Fusarium graminearum, F. culmorum, F. equiseti	Zearalenone	Zearalenone	Wheat, maize/corn, hay	Hyperestrogenism, infertility
Fusarium verticillioides (syn. *F. moniliforme*), *F. proliferatum*	Fumonisins	FB1, FB2, FB3	Corn Corn-based foods	Mild liver toxicity, mild kidney lesions, leukoencephalomalacia (horses), pulmonary edema (swine), possible carcinogen in humans
Claviceps sp. *C. purpurea [C. fusiformis, C. paspali] [Neotyphodium coenophialum in tall fescue grasses]*	Ergot alkaloids	Ergopeptine alkaloids: ergotamine, ergocristine, ergosine, ergocryptine, ergovaline, ergoline alkaloids: lysergic acid, lyergol, lysergic acid amide, ergonovine, clavines	Rye, wheat, cereals, grasses	Vasoconstriction with loss of extremities (ears, feet, tails in livestock), agalactia (reduced milk production in animals), abortions (humans), gastroenteritis, hallucinations (humans)
Aspergillus alutaceus var. alutaceus (formerly *A.ochraceus*), *A. westerdijkiae* and *A. Steynii* and *Penicillium verrucosum* (formerly *P. viridicatum)*	Ochratoxins	Ochratoxin A	Cereal grains (wheat, barley, oats, corn), dry beans, peanuts, grapes, raisins, cheese, apple juice Swine tissue	Liver and kidney toxic, immunosuppressive
Penicillium expansum, *Aspergillus* sp., *Byssochlamys fulva*, *B. nivea*	Patulin	Patulin	Rotten fruits, apple juice, applesauce	Immunotoxicity, liver, spleen, and kidney damage

readily accumulate in tissues, but can be detected in the liver and milk. Repeated exposures can generate toxic effects in tissues. Aflatoxins may cross the placenta and damage fetal tissue; however, little work has focused on reproductive effects. Aflatoxin elimination is through the bile, feces, and urine and into the milk and eggs. Most species eliminate the toxin within 24 h after exposure.

Aflatoxin B_1 is biotransformed by the liver and to a lesser extent the kidney, intestinal tract, and other organs into several products, with the most important toxic product being aflatoxin B_1-8,9-epoxide. The covalent binding of aflatoxin 8,9-epoxide to DNA, RNA, and proteins results in tissue adducts and reduced synthesis of these products and disruption of cellular processes and organ function. The outcome results in cellular necrosis, immunosuppression (both humoral and cell-mediated immunities), mutagenesis, and neoplasms. Additional biotransformation products (e.g., AFM_1, AFM_2, AFQ_1, and aflatoxicol) are less toxic; conjugation of these products with glucuronide and sulfate is detoxification reactions. The metabolite aflatoxicol, which is a carcinogen to animals and possibly a carcinogen to human, can be oxidized back to aflatoxin B_1 and serve as a source for AFB_1 in the body. Aflatoxicol has been detected in milk, eggs, fermented dairy products, and tissues. Pasteurization and ultrapasteurization of milk with various level of fat content did not destroy aflatoxicol. Aflatoxin M_1 is the major excretion product in urine and milk and can be monitored for exposure; aflatoxin M_1 appears quickly in milk and is regulated with allowable concentrations in milk. The European Union maximum allowable concentration in milk is 50 ng l^{-1} (0.05 ppb) aflatoxin M_1, and the US Food and Drug Administration action (FDA) limit is 500 or 0.5 μg l^{-1} (0.5 ppb) in milk. The US FDA action limit for human food products (except milk) is 20 μg kg^{-1} (ppb); the European

Union regulations are stricter for aflatoxin contamination of human food.

All animals are susceptible to aflatoxins, but the sensitivity varies between species with young animals and monogastrics being more at risk for toxicosis. Numerous studies including case-control studies, cross-sectional surveys, and prospective cohort investigations in high-risk human populations have examined the relationship between aflatoxin exposure and human hepatocellular carcinoma, with epidemiological studies supporting animal experimental studies that aflatoxin dietary levels are correlated with human hepatocellular carcinoma. Exposure to aflatoxin and hepatitis B virus greatly increases the risk of liver carcinoma, a particular problem in developing countries. Many mammals and fish are susceptible to the toxic effects of aflatoxin; dogs are quite susceptible to lower aflatoxin concentration in pet foods, while sheep are considered the most resistant domesticated species to toxic effects of aflatoxins.

A diagnosis of aflatoxicosis is based on typical clinical signs and lesions, demonstrating toxic (not trace) concentrations in the ration. Positive fluorescence of grain under a 'black light' (blue-green color at 365 nm) suggests *Aspergillus* metabolites, but not specifically aflatoxins. Various analytic methods can be utilized to determine aflatoxins in feedstuffs; the most important aspect of analysis is to acquire a representative sample of the suspect feed or feeds. When sampling for aflatoxins in feed, the more random and larger the sampling, the better chances will be to detect aflatoxins. In a small sample, even one contaminated kernel can dramatically alter analytic results. Uneven distribution of mold and mycotoxins in a storage facility requires multiple samples at both the perimeter and center of the storage area. A more representative sample is obtained by periodic sampling from a flowing or moving stream of suspect feed to generate a large sample volume (5–10 kg), mixing the sample, and subsampling for analysis. No specific treatment is available for aflatoxicosis beyond quickly removing the contaminated ration and replacing with an uncontaminated food sources. Providing optimum dietary protein, vitamins, and trace elements may aid recovery.

Fumonisins

Fumonisins are produced by *Fusarium* molds primarily on corn and absorbed from the gastrointestinal tract and appear to be rapidly excreted unmetabolized from the gut. Several studies have linked fumonisin contamination of maize with esophageal cancer in humans in South Africa and China; however, a definitive link of fumonisin B1 to human cancer has not been determined. Fumonisin B1 is classified as possibly carcinogenic to humans (IARC group 2B) with inadequate evidence of carcinogenicity in humans but sufficient evidence for carcinogenicity in rodent livers. Fumonisin exposure and possible neural tube defects have been reported in animal studies and suggested to occur in human babies when mothers in early pregnancy consume fumonisin-contaminated maize.

Fumonisins are somewhat unique in that markedly different clinical signs occur in different species with toxicity, although liver damage appears to be common across species. Horses are very sensitive to fumonisins and develop liver toxicity and neurological signs of blindness, ataxia, and aimless circling that progresses to death; the lesion is leukoencephalomalacia or liquefactive necrosis of the white matter in cerebral hemispheres. At toxic levels of fumonisins, pigs develop open mouth breathing, cyanosis of the skin and mucous membrane, high respiratory rate, inactivity, and death that is related to pulmonary edema. Poultry and adult cattle are relatively resistant to fumonisins and may develop liver damage and reduced feed intake at quite high concentrations of fumonisins in feed. Both the US FDA and European Union have recommended guidance levels of fumonisins in animal feeds.

Trichothecenes

Of the trichothecenes, deoxynivalenol (DON) is probably the most commonly detected in cereal grains throughout the world. This mycotoxin is resistant to milling and processing and readily enters the animal feed and human food chains. Foodborne trichothecene contamination, in particular DON, has been linked to acute human adverse effects (gastroenteritis) or mycotoxicoses in China, India, and Japan, but little information is available regarding potential health effects from chronic exposure.

Field reports of trichothecene toxicity in livestock in North America typically involve DON contamination. Most trichothecene exposures are of a chronic to subchronic nature with low dietary DON concentrations associated with nutritional impairment, reduced production, and possible diminished immune responses. Swine and monogastrics are more sensitive to trichothecenes. DON is not associated with fatal disease.

Trichothecenes have multiple toxic effects on eukaryotic cells, including inhibition of protein, RNA, and DNA syntheses, alteration of membrane structure and mitochondrial function, stimulation of lipid peroxidation, induction of programmed cell death or apoptosis, and activation of cytokines and chemokines. Diarrhea is fairly common following trichothecene ingestion. Altered intestinal absorption of compounds and impaired permeability are caused by morphological and functional damage to intestinal mucosa. Significant metabolism of trichothecenes can occur prior to absorption. The hallmark clinical sign of trichothecene toxicosis in animals is feed refusal. Free DON and conjugated DON have been detected in cow's milk at low levels ($<4\ \text{ng ml}^{-1}$) with an estimated 0.0001% of administered dose excreted in milk.

Clinical signs of the more toxic trichothecenes (type A) in animals and humans include vomiting or emesis; feed refusal and weight loss; diarrhea; immunomodulation; coagulopathy and hemorrhage; cellular necrosis of mitotically active tissues such as intestinal mucosa, skin, bone marrow, spleen, testis, and ovary; and death. T-2 toxin can also cross the placenta and potentially affect a developing fetus. Poultry are sensitive to the type A trichothecenes and can develop yellow, caseous plaques on the beak and in the oral cavity along with a dramatic drop in egg production and weight at low concentrations of T-2 toxin. These very toxic trichothecenes are cytotoxic mycotoxins with clinical signs resembling radiation poisoning. T-2 and HT-2 toxin, often found together in plants, are some of the most toxic trichothecenes detected in feeds. Dramatic weather patterns have created wet, cooler conditions in central and

southern United States leading to *Fusarium* growth on wet pasture grasses and production of T-2 toxin, HT-2 toxin, and other mycotoxins in feedstuffs that normally would not be considered to be susceptible to these molds.

Due to the vague nature of toxic effects attributed to low concentrations of trichothecenes, a solid link between low-level exposure and a specific trichothecene(s) is difficult to establish. Mycotoxins may play a role in subtle adverse effects, but diagnostic consideration needs to move beyond just 'test the feed for toxins' and evaluate nutrition and coexisting diseases. Storage of grains at less than 13–14% moisture (<0.70 α_w) and that of hay/straw at less than 20% moisture are important in preventing trichothecene production. After the contaminated feed is removed from the diet and exposure stopped, animals generally have a good prognosis for recovery from type B trichothecenes, but a graver prognosis for recovery from type A trichothecene toxicosis. Table 1 provides a summary of the toxic effects of trichothecenes in animals.

Deoxynivalenol or Vomitoxin

The fungus usually involved in scabby grain blights was identified as *Gibberella zeae* (Schwabe) or *Fusarium graminearum*, its asexual or conidial phase. DON or vomitoxin, also known as Rd toxin, 4-DON, was demonstrated to be the *Fusarium* toxin responsible for feed refusal and emesis (vomiting) in monogastric animals fed with contaminated corn.

Of the trichothecenes, DON is regarded as the most commonly detected trichothecene in cereal grains throughout the world. This mycotoxin is resistant to milling and most processing and readily enters the human food and animal feed chains. Foodborne trichothecene contamination, in particular DON, has been linked to acute human toxicoses in China, India, and Japan, but little information is available regarding potential health effects from chronic exposure. The primary complaint was gastroenteritis.

After oral exposure, DON is rapidly and nearly completely absorbed in the stomach and upper gastrointestinal tract. Pigs dosed with DON had quick absorption of greater than 50% of the DON administered that was highly distributed, with an apparent volume of distribution (V_d) higher than total body water and serum elimination half-lives of 6.3 and 5.3 h in the chronic and acute DON-fed pigs, respectively. A majority of DON ingested from dietary exposure is eliminated in the urine and feces, with the urine being the main excretory route of DON in an unmetabolized form. Minor elimination of DON is in the bile.

In contrast with the poor metabolism of DON by swine, the rumen of cattle is capable of extensive metabolism of DON and other trichothecenes. The major metabolite of oral DON in ruminants is 3α,7α,15-trihyroxytrichothec-9,12-diene-8-one (deepoxydeoxynivalenol or DOM-1). Deepoxidation of DON to DOM-1 is considered a deactivation step resulting in a noncytotoxic compound; thus, ruminal metabolism serves a protective function. Because biotransformation occurs in the rumen, little parent compound is available for absorption.

Trichothecenes bind to ribosomes in eukaryotic cells, in particular to the 60S ribosomal subunits, and interfere with peptidyl transferase activity. Inhibition of protein synthesis requires an intact 9,10 double bond and the C-12,13 epoxide. Trichothecenes can be divided into two groups based on their site of action on protein synthesis, either preferential inhibition of initiation or inhibition of elongation or termination. The cytotoxicity of DON, a trichothecene with a keto group at C-8 and a hydroxyl group at C-7, results from protein synthesis inhibition at the ribosomal level during the elongation and termination step in mammalian cells. The US FDA and European Union have issues recommended levels of DON in human foods and animal feeds.

Zearalenone

Estrogenism in swine was reported in the mid 1920s in the Midwest. Much later in the century, the discovery of the *Fusarium* mycotoxin zearalenone was linked to hyperestrogenism. Typical clinical signs of hyperestrogenism in animals are swelling of the vulva, increase in uterine size and secretions, mammary gland hyperplasia and secretion, prolonged estrus, anestrus, increased incidence of pseudopregnancy, infertility, and decreased libido, and secondary complications are rectal and vaginal prolapses, stillbirths, and small litters. Prepubertal swine are the most sensitive species.

Following ingestion, zearalenone undergoes reduction of the 6′ ketone to a secondary alcohol, which leads to two diastereoisomeric zearalenols (α and β) that are naturally occurring fungal metabolites. The α-zearalenol metabolite is about three times more estrogenic than zeraralenone.

Zearalenone and metabolites can interact directly with the cytoplasmic receptor that binds 17β-estradiol and translocate receptor sites to the nucleus. In the nucleus, stimulation of RNA leads to protein synthesis and clinical signs of estrogenism. Within the resorcylic acids, α-zearalenol exhibited the greatest binding affinity for cytosolic estrogen receptors, while zearalenone and β-zearalenol displayed much lower binding affinities. The hydroxylation of zearalenone to α-zearalenol apparently is an activation process, whereas the production of β-zearalenol would be a deactivation process. Interspecies variations in sensitivity to zearalenone in the feed could be related to different metabolites produced and the relative binding affinities of zearalenone and metabolites formed.

While zearalenone primarily affects reproduction, it may have additional effects. Zearalenone can also act on the hypothalamic–hypophysial axis. Zearalenone acted as a ligand for human pregnane X receptor, which can activate a transcription factor regulating the expression of numerous hepatic drug-metabolizing enzymes, including expression of cytochrome P450 enzymes. This suggests a potential for zearalenone to induce metabolism of drugs. At natural contamination levels in food and feeds, zearalenone does not appear to impact the immune response.

Zearalenone is fairly, rapidly, and extensively absorbed with oral exposure. Following zearalenone administration, zearalenone can be localized in reproductive tissues (ovary and uterus), adipose tissue, and interstitial cells of the testes. The reported biological half-life of total plasma zearalenone radioactivity following the oral dosage in pigs is 86 h. Species differences in zearalenone susceptibility might be related to

hepatic biotransformation, with the highest amount of α-zearalenol produced by pig hepatic microsomes, whereas chicken microsomes produced the highest amounts of β-zearalenol.

Zearalenone can undergo rumen metabolism, with reduction to mostly α-zearalenol (increased estrogenic activity compared to zearalenone) and to a lower amount of β-zearalenol. Zearalenone undergoes extensive enterohepatic circulation and biliary excretion in most species. The major route of excretion for most species is through the feces, although rabbits primarily excrete zearalenone in the urine. No major retention of radio-labeled activity was found in edible muscle tissue, but lipophilic metabolite(s) was reported in egg yolk (at about 2 mg kg^{-1} concentration) 72 h postdosing.

Concern has focused on potential residue of zearalenone and its metabolites in milk, eggs, and foods and precocious development of sexual characteristics in young female girls, although no definitive link has been made. Zearalenone and α- and β-zearalenols can be transmitted into the milk of sheep, cows, and pigs administered high doses of zearalenone. Hyperestrogenism has been reported in lambs and pigs nursing dams dosed with zearalenone. This research indicated that minimal transmission of zearalenone occurs into milk and only for a short period of time after exposure to high concentrations of zearalenone. Zearalenone residues in edible tissue are considered minimal.

Zearalenone has low acute toxicity in most species. In most natural conditions, the concentrations of zearalenone are less than 20 mg kg^{-1} (ppm) and generally less than 5 mg zearalenone/kg feed. Abortions have been associated in field cases with natural *Fusarium* mold exposure, but have not been reproduced with experimental studies. The European Union has regulatory guidelines for zearalenone in animal feeds, whereas the US FDA has not issued any guidelines for zearalenone.

Ochratoxin

Ochratoxins are produced by the fungi *A. alutaceus* var. *alutaceus* (formerly *A. ochraceus*), *A. westerdijkiae*, and *A. steynii* and *Penicillium verrucosum* (formerly *P. viridicatum*). Ochratoxin contamination occurs in a wide variety of foods, including grapes, raisins, coffee, wheat, and other cereal crops. The most toxic of the ochratoxins is ochratoxin A (OTA). OTA is absorbed in the gastrointestinal tract and bound to plasma proteins and is the major compound found in blood. Metabolism can occur through cytochrome P450 enzymes and by cyclooxygenase, lipoxygenase, and epoxygenase enzymes to numerous metabolites, including ochratoxin α, which is considered nontoxic and excreted in urine. Ochratoxins are potent kidney toxicants, immunosuppressants, and possible human carcinogens. The role of OTA in potential carcinogenicity has been hypothesized to be from formation of DNA adducts, oxygen radical formation, and alteration in gene expression involved in cellular proliferation and cell death. OTA is predominately distributed to the kidneys and to a lesser extent to the liver, muscle, and fat. Lesions have been reported in the liver, heart, and gastrointestinal tract of various species exposed to OTA. They inhibit phenylalanine–tRNA ligase causing inhibition of protein, RNA, and DNA syntheses and deplete humoral factors, especially immunoglobulins, and decrease natural killer cell activity.

Descriptive reports associating OTA with cancer usually focused on the incidence of Balkan endemic nephropathy in humans and urinary tract tumors in Balkan countries. However, recent studies indicate that dietary exposure to aristolochic acid from plants is a significant risk factor for chronic kidney failure and the cause of Balkan endemic nephropathy. Aristolochic acid exposure was associated with DNA adducts in kidney tissues and mutations of A:T pairs of the p53 gene. There is evidence that OTA is carcinogenic in experimental animals, but the evidence is not adequate for an increased risk of cancer in humans. OTA is classified in IARC group 2B, possibly carcinogenic to humans

Ruminants are more resistant to ochratoxin, as compared to monogastrics, because rumen protozoal metabolism quickly converts OTA to the less toxic ochratoxin α. The elimination half-life in ruminants is short, about 17.3 h as compared to 100 h in pigs. Regulatory concerns for OTA are focused on potential residues in the kidneys of pigs and in ruminants for accumulation in tissues and milk residues. Another nephrotoxic mycotoxin often found with ochratoxins is citrinin. Citrinin is produced by *Penicillium* molds under similar conditions of ochratoxins, with optimal production at 30 °C. OTA and citrinin target the renal proximal tubule, causing dehydration, hypothermia, and death in animals. Histological lesions in the kidney were hyaline casts, dilated tubules, and fibrosis in the kidneys and fatty changes in the liver.

Ergot Alkaloids

Ergot can refer to the disease caused by *Claviceps* sp. invading the developing ovary of certain grasses and to the visible sclerotium or ergot body of *Claviceps purpurea* growing on rye, wheat, and other cereals and grasses.

Following ingestion of the ergopeptine alkaloids, the compounds are rapidly cleared from the blood by the liver and undergo primarily biliary excretion; ergot alkaloids are not thought to be excreted in milk. Ergopeptine alkaloids cause vasoconstriction through inhibition of the D_1 dopaminergic receptor and partial agonism of the α_1-adrenergic and serotonin receptors. Constriction of small arteries can lead to ischemia and necrosis of the distal portions of the limbs and ears and tails of animals; the burning sensation from vasoconstriction leads to the term used with ergot toxicity or 'holy fire.' Uterine contractions in late pregnancy are associated with stimulation of α_1-adrenergic receptors, but evidence for abortion is vague in animals, but described more frequently in human conditions. Decreased prolactin secretion by lactotropes in the anterior pituitary is associated with ergopeptine alkaloid stimulation of D2-dopamine receptors, which leads to clinical signs of poor milk production in animals. Table 1 summarizes the fungi, ergot alkaloids, and clinical disease associated with ergotism.

Susceptibility of livestock to ergotism appears to vary with species, breed, age, gender, and physiological state. Ruminants are considered susceptible because of the types of diets (both grains and grasses) and ruminal pH that can favor fermentation and enhanced extraction of ergot alkaloids from sclerotia. Numerous risk factors influence the development of clinical

signs, including extremes in environmental temperatures (too cold or hot), physiological state, and ergot alkaloid dose. The concentration of ergot alkaloids in *C. purpurea* sclerotia is highly variable, between 0 and almost 10 000 mg kg^{-1}, and the relative concentrations of individual ergopeptine alkaloids vary. The threshold concentrations of total ergot alkaloids or ergopeptine alkaloids capable of causing ergotism in animals have not been established; however, the threshold ergovaline concentrations that produce clinical fescue toxicosis related to ergot alkaloids are approximately 200–800 μg kg^{-1} in a total ration and likely approximate the threshold concentrations of ergopeptine alkaloids that produce ergotism in livestock. Dietary concentrations of 0.3–1% sclerotia have been associated with clinical signs of ergotism in cattle. Initial clinical signs of ergotism can appear as pain and lameness (e.g., stamping the feet) with affected areas feeling cool to the touch. With disease progression, a sharp line of demarcation appears between healthy and nonviable tissue, which can be followed by necrosis and sloughing of tissue. Additional clinical signs may affect the gastrointestinal tract (e.g., constipation, diarrhea, or internal bleeding). During hot, humid weather, clinical signs of ergotism may include hyperthermia and lower milk production and feed intake in animals. Hyperthermia is related to poor heat dissipation from the body surface, and reduced milk production is associated with hypoprolactinemia. To avoid adverse effects of ergot on livestock performance, the total dietary concentrations of ergot alkaloids should be less than 100–200 μg kg^{-1}.

Patulin

Patulin is a cyclic γ-lactone mycotoxin found in fruits, particularly moldy apples and apple juice. Several molds produce patulin including, *P. expansum*, *Aspergillus* sp., and *Byssochlamys fulva* and *B. nivea*. Patulin is a small, water-soluble polar compound that is absorbed quickly, metabolized, and excreted in urine. Characterized as an electrophilic molecule, patulin can cause adverse effects through covalent bonds to the thiol groups of proteins and glutathione. Acute symptoms of patulin exposure include immune toxicity, particularly inhibition of macrophage functions, neurotoxicity, and possible damage to the liver, spleen, and kidney.

Introduction

The considerable potential of nanotechnology for improving food safety, quality, and healthfulness is increasingly being recognized, as demonstrated by the major increase in the number of publications and patents on this topic. Some of the most important potential applications of nanotechnology in food are summarized in the succeeding text:

- *Encapsulation systems* for the protection, controlled release, and targeted delivery of bioactive, flavor, color, or antimicrobial molecules
- *Texture building structures* for improving food quality and novelty
- *Biosensors* for rapid detection of microbial or trace element contamination
- *Active packaging* strategies to improve food quality and safety

Food nanotechnology focuses on those structures that have at least one dimension smaller than around 1000 nm but larger than a single molecule and include nanoparticles, nanofibers, and nanofilms. All of these structures already find widespread application in food processing or storage. Their small dimensions result in unique, novel, and very attractive functionalities.

Nanoparticles can be produced by two different fabrication principles, that is, top-down and bottom-up techniques. In the top-down process, a large clump of material is broken down into nanosized particles by an external force (e.g., physical, chemical, or mechanical forces). In the bottom-up process, atoms, molecules, or small particles assemble into nanostructures. Bottom-up processes are preferable in terms of controllability, engineering, cost, and energy requirement and will therefore be the focus of this article. There are numerous examples of bottom-up nanostructure formation processes found in nature. Spontaneous self-assembly is one of the driving forces for bottom-up processes, which is mediated through relatively weak intermolecular interactions, such as van der Waals, hydrogen bonding, electrostatic, hydrophobic, and/or steric exclusion interactions. In this manuscript, covalent bonds will also be considered as these are often useful in the food industry to further stabilize the formed nanostructures by strengthening the bonds between the self-assembled molecules. Self-assembly processes usually take place under relatively mild conditions (i.e., temperature, pressure, and pH), and upscaling of these methods is typically relatively straightforward. Nanostructures to be used in the food production chain are mainly produced in a liquid phase to ensure the mobility, stability, and the interaction/reaction of the various components involved.

In this article, different nanostructure types will be described and the molecular self-assembly process will be discussed. The application of the different nanostructures in food products will also be highlighted, before concluding with some future perspectives and consumer perception toward nanotechnology.

Nanostructure Types

Different nanostructure types (Figure 1) can be produced from food-grade ingredients that have different compositions, structures, properties, and applications. The materials used to build these different structures for food applications should typically be natural, biocompatible, biodegradable, and food-grade. Biomolecules that already have found widespread use are polysaccharides (e.g., alginate, carrageenan, chitosan, dextran, pectin, and xanthan), proteins (e.g., casein, gliadin, soy protein, whey protein, and zein), lipids (e.g., long- and medium-chain triglycerides and flavor oils), and phospholipids (e.g., dairy, soy, or egg lecithin).

Nanoparticles

Different types of nanoparticles can be distinguished based on their composition and structure, for example, capsules, hydrogel

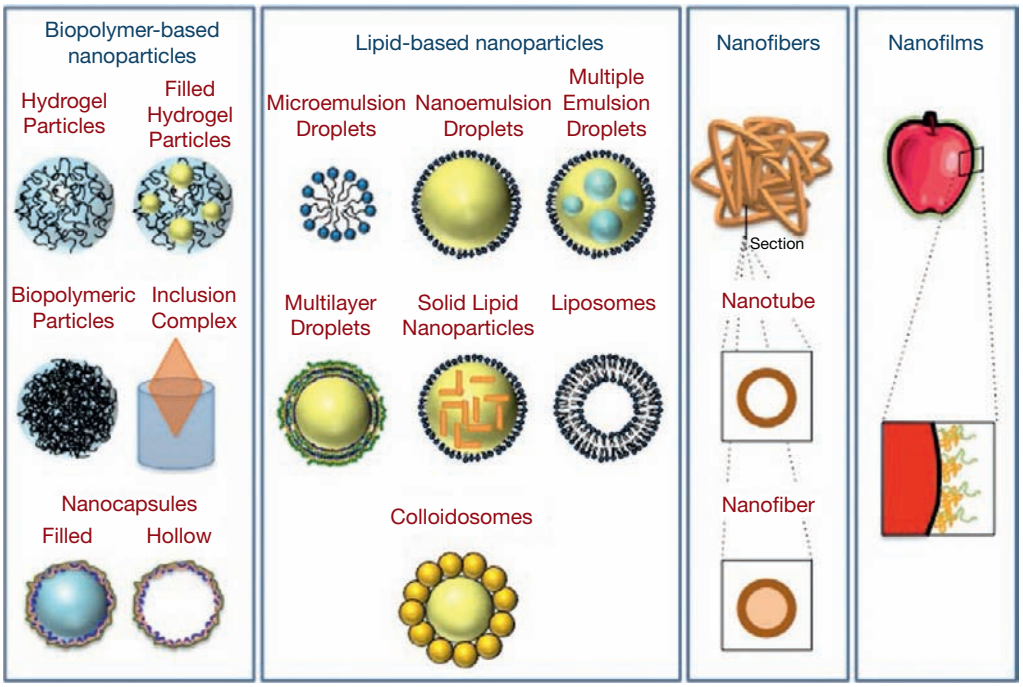

Figure 1 Examples of nanostructures that can be used in food processing (structures are not drawn to scale).

particles, biopolymeric particles, liposomes, nanoemulsions, molecular inclusion complexes, and solid lipid nanoparticles. Some of the most suitable nanoparticles for food applications will be briefly discussed in this article. For clarity, the particles are divided into two sections based on their main building material, that is, biopolymers and lipids. However, the boundary between these two groups is not always clear as lipid-based systems are often stabilized and coated by biopolymers, while biopolymeric nanoparticles can also contain lipid inclusions.

Biopolymer-based nanoparticles

Biopolymers, that is, polysaccharides and proteins, are excellent building molecules for nanoparticles. They cover a wide range of properties and functionalities due to the versatility of their basic units (monosaccharides or amino acids), arranged in a specific macromolecular structure. Different chemical, physical, or enzymatic methods can be used to modify their structures and therefore give rise to different macromolecular properties and functionalities. Some of the most important molecular properties of biopolymers that influence their ability to form nanoparticles with specific functional properties are their molecular weight, electrical charge characteristics, polarity, and chemical reactivity.

Nanosized hydrogels are composed of a cross-linked polymeric matrix that fills the entire volume of the particle and holds high amounts of water. Gelation can be induced by cross-linking agents (e.g., multivalent salts) or enzymes and pH or temperature changes (e.g., heating or cooling). Techniques that can be used to produce nanosized hydrogel particles are emulsion templating and gelation in nanosized molds. The hydrogel particles can also enclose smaller substructures such as lipid droplets. These more complex structures are denoted as filled hydrogel particles.

Biopolymeric nanoparticles are also fabricated from biopolymers but typically have a much denser internal core (lower water content) than hydrogel particles. These particles can be made by liquid antisolvent precipitation, thermal denaturation of globular proteins (e.g., soy, egg, or whey proteins), or self-assembly of flexible proteins (e.g., casein).

Inclusion complexes entrap a guest molecule in a host molecule by physicochemical forces. These resulting molecular complexes may increase the water dispersibility of the guest molecule, protect it from chemical degradation, and help mask undesirable flavor attributes (such as bitterness). The list of host molecules suitable for food systems is currently rather limited, with cyclodextrins, starch, and whey proteins being the most widely used in a food context.

Nanoparticles typically have a homogeneous structure throughout, whereas *nanocapsules* have an external shell that surrounds an internal core, which may be gaseous, liquid, or solid. Bioactive components are typically encapsulated within the core, while the shell is designed to protect them or to control their release. The shell may be constructed from a single layer or from multiple layers. Based on the application and the substance that makes up the core, the nanocapsules can be classified as filled (or loaded) or hollow (or unloaded).

Lipid-based nanoparticles

Lipids are typically immiscible with water, which leads to phase separation and the creation of an oil–water interface. The interfacial area for lipid-based nanoparticles is typically large and needs to be stabilized by amphiphilic surfactants, biopolymers, or particles.

Microemulsions are thermodynamically stable colloidal dispersions with particle diameters well below 100 nm. Oil-in-water (O/W) microemulsions are usually fabricated from

predominantly hydrophilic surfactants. The surfactant molecules arrange themselves so that the nonpolar tails form a hydrophobic core and the polar heads form a hydrophilic shell that is in contact with water. Conversely, water-in-oil (W/O) microemulsions are typically formed from hydrophobic surfactants. In this case, polar head groups form a hydrophilic core, while the nonpolar tails form a hydrophobic shell in contact with the surrounding oil. Microemulsions form spontaneously when certain combinations of surfactant, oil, and water are mixed together under appropriate environmental conditions (e.g., temperature).

Nanoemulsions are colloidal dispersions typically formed from emulsifiers, oil, and water. Like conventional emulsions, nanoemulsions are thermodynamically unstable systems; however, they have smaller droplet sizes (i.e., radius <100 nm). As a result, they have different physicochemical properties, such as higher optical clarity, higher stability to aggregation and creaming, and higher bioavailability. Two basic nanoemulsion types can be distinguished, that is, O/W and W/O nanoemulsions. O/W nanoemulsions consist of oil droplets dispersed into a continuous aqueous phase, while W/O nanoemulsions consist of water droplets dispersed into a continuous oil phase. Nanoemulsion production techniques can be categorized as low- or high-energy methods. Low-energy methods can be considered to be bottom-up methods and are based on the spontaneous formation of nanosized oil droplets when the composition and temperature of surfactant–oil–water systems are changed. These, hence, do not require high-energy input. Nanoemulsions can also be fabricated by high-energy methods that are a top-down approach that utilizes intense disruptive forces to break down larger droplets into smaller ones. Typical production methods involve high-pressure homogenization or sonication.

The simple emulsions discussed in the preceding text can be used to build more complex structured emulsions using nanotechnology principles. *Multiple emulsions* (such as W/O/W and O/W/O) are formed by homogenizing an emulsion with a liquid that has an opposite polarity to its continuous phase (e.g., a W/O emulsion with water). *Multilayer emulsions* are composed of lipid droplets coated by multiple layers of biopolymers or other materials. The formation of multiple layers can improve the physical or chemical stability of emulsions or be used to design controlled or targeted delivery systems. The multiple layers are typically formed by layerwise electrostatic deposition of oppositely charged biopolymers. *Solid lipid nanoparticles* are O/W nanoemulsions in which the lipid phase is either fully or partially solidified. These systems are usually prepared by preparing an O/W nanoemulsion at a temperature that is higher than the melting point of the lipid phase and then cooling down to initiate crystallization of the lipid phase.

Nanoliposomes are formed from phospholipids that tend to self-assemble into vesicle structures in aqueous media upon energy input. They may have single or multiple bilayers and may have diameters of as small as tens of nanometers. Their physicochemical and functional properties depend on the composition, preparation method, and environmental conditions.

Colloidosomes or *pickering emulsions* are emulsions stabilized by the adsorption of other particles to the oil–water interface. Once the particles are adsorbed at the interface, they prevent the aggregation and coalescence of the emulsion droplets. In foods, the stabilizing particles may be fat crystals or biopolymer biopolymer-based nanoparticles.

Nanofibers and Nanotubes

Nanofibers and nanotubes are being developed as potential structure building or encapsulation ingredients in foods. Nanofibers composed of biopolymers can be produced by electrospinning. Typically, the biopolymers are dissolved in an appropriate solvent and then forced through a nozzle using a high-voltage electrical field and collected on a grounded plate. In principle, nearly every soluble polymer with a high enough molecular weight can be electrospun. However, research to date has mainly focussed on proteins and it has often proved difficult to spin proteins under food-grade conditions. Furthermore, the complex three-dimensional structure and strong inter- and intramolecular interactions of proteins often need to be overcome by additives. Inclusion of gelatin or zein as carriers for other proteins during electrospinning has also been successfully explored. Nanofibers have the advantages that they are easily recoverable but still have a very large surface-to-volume ratio. Nanotubes that typically have a hollow core may be useful for delivery applications as they can be fairly easily loaded with large quantities of bioactive molecules.

Nanofilms

Nanofilms can be described as a thin layer of polymers attached to a food product or food packaging material. Nanofilms are very fragile due to their extremely thin nature; therefore, they are more likely to be used as coatings that are attached to food surfaces, rather than as self-standing films. Nanofilms are usually created using layer-by-layer deposition techniques. These structures have potential applications in the active food packaging field and for nanofiltration.

Intermolecular Interactions and Self-Assembly

All atoms, molecules, and particles experience forces between them, which will determine their tendency to self-assemble into specific structures (Figure 2). These interactions can be characterized by their sign (attractive or repulsive), strength (weak to strong), and range (short to long) (Table 1). Atoms, molecules, and particles typically experience a combination of forces. Several theories have been developed to model the total interaction energy between molecules and particles. One of the most popular theories to predict the interaction between charged particles is the DLVO theory. In this theory, the total interaction between molecules and nanostructures is calculated as the sum of the van der Waals attraction and electrostatic repulsion. The DLVO theory has proved useful for predicting the stability of particles against aggregation in various food systems. However, there are many limitations to the practical application of this theory due to its underlying assumptions: it ignores many important interactions (e.g., steric, hydrophobic, and depletion), it assumes the particles

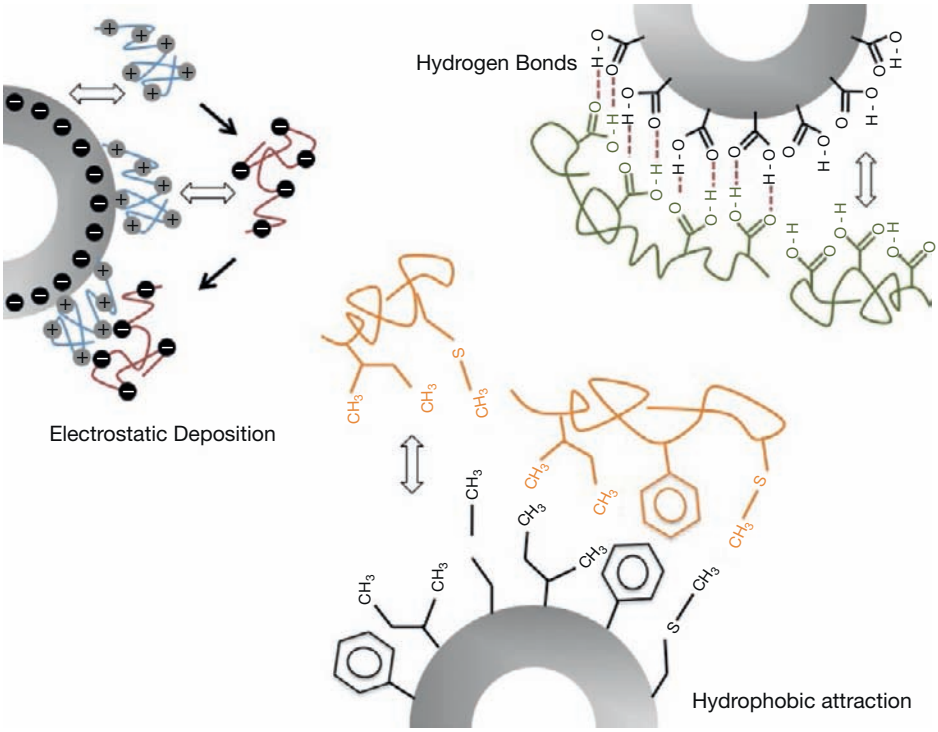

Figure 2 Schematic representation of the interaction between molecules and particle surface for electrostatic attraction, hydrogen bond formation, and hydrophobic attraction.

Table 1 Overview of the different intra- and intermolecular interactions and their characteristics

Interaction type	*Description*	*Attractive or repulsive*	*Other characteristics*
Electrostatic or Coulomb interaction	Interaction between charged entities	Attractive or repulsive	Inversely related to the square of the distance between the charge centers. Not direction-specific and quite strong interaction
Hydrogen bond	Interaction between a hydrogen atom in a molecule and an electronegative group (typically oxygen or nitrogen)	Attractive	Relatively short-lived, moderately strong, direction-specific
Hydrophobic interaction	Attraction between aliphatic chains and aromatic groups	Attractive	Relatively short-ranged, not direction-specific, moderately strong, but their magnitude increases with increasing temperature
van der Waals interaction	Interaction between (induced) dipoles	Attractive	Ubiquitous, relatively weak, very short-ranged (inversely related to the sixth power of the distance between the dipoles), additive
Covalent bond	Electrons are shared between the orbitals of more than one atom	Attractive	Direction-specific, atom-specific, short-ranged

are homogeneous spheres, and it assumes only two particles are involved in the interaction.

Spontaneous self-assembly is the organization of molecules into larger structures solely based on their intermolecular interactions and thermal energy effects, without the interference of external agents. This kind of self-assembly occurs during the formation of surfactant micelles. Directed self-assembly relies on the tendency for the molecules to spontaneously associate with each other, but the type of structures formed is controlled by manipulating external conditions. This kind of self-assembly occurs during multilayer formation. Both spontaneous and directed self-assembly of biopolymers and lipid-like molecules occur in nature during the creation of biological nanostructures, such as protein complexes, cell walls, or phospholipid membranes. Food scientists can use the knowledge of the molecular interactions between different molecules to assemble different structures in foods.

Electrostatic Attraction

Electrostatic attraction between oppositely charged groups is one of the most important interactions utilized to assemble specific structures and is widely used to form nanoparticles and to modify nanoscale surface properties.

Ionic gelation: Charged biopolymers are often made to gel by adding oppositely charged substances, such as mineral ions. For example, anionic polysaccharides (such as alginate, carrageenan, and pectin) can be gelled by adding cationic mineral ions (such as calcium). Ionic gelation is commonly used as a step in the formation of hydrogel particles, such as calcium alginate or pectin beads.

Coacervation: Coacervates are hydrogel particles that are typically formed when oppositely charged biopolymers associate with each other through electrostatic attraction. These particles are widely used in the food industry for encapsulation and release purposes.

Hydrogen Bonds

Hydrogen bonds are important in the formation and stabilization of biopolymer complexes and may play an important role in the formation of hydrogel particles, for example, gelatin beads. They have also been employed as the driving force to create and stabilize layer-by-layer films intended for food packaging. Hydrogen bonds typically weaken as the temperature is increased, which may lead to dissociation of gel-like structures. This phenomenon can be used for controlled release applications.

Hydrophobic Interactions

Hydrophobic interactions play an important role in the formation of many heat-induced gels. For example, the heating of a globular protein solution triggers the unfolding of the protein and the exposure of hydrophobic groups that are normally buried inside the protein interior. Interaction between the exposed hydrophobic patches on the protein surfaces results in the formation of an irreversible gel structure. Hydrophobic interactions also play an important role in the *liquid antisolvent process*, one of the techniques used to produce biopolymeric nanoparticles. By decreasing the solvent power of the solution in which a biopolymer/protein has been dissolved, the three-dimensional structure of the protein changes, and the protein partially denatures or unfolds by the exposure to the less favorable environmental conditions. As a result, the biopolymers prefer to associate with each other over the interaction with the 'low-quality' solvent. As several structures on the biopolymer are now exposed, which are usually buried inside the native biopolymer structure (e.g., hydrophobic patches in proteins), new interaction possibilities between the biopolymers are created. Although hydrogen bonds and electrostatic interactions will probably also play a role, the irreversible hydrophobic interactions are believed to be a significant driving force behind the formation of protein particles using this method. Hydrophobic attraction is also the driving force to create *inclusion complexes*. The center of the host molecules (such as cyclodextrins and amylose coils) is usually highly hydrophobic. In aqueous media, hydrophobic guest molecules will be attracted to the center of these structures, replacing part of the water inside. These complexes are therefore more thermodynamically stable.

Covalent Interactions

Covalent bonds are often used to stabilize the nanostructures in foods against changes in pH, temperature, and ionic strength. The formation of covalent bonds can be induced by heating a mixture of polysaccharides and proteins to induce Maillard reactions, by adding cross-linking chemical agents or enzymes (e.g., transglutaminase or laccase), or by UV light treatment.

Combined Interactions

In reality, the interaction between the different building blocks used to fabricate nanoparticles often involves more than one type of interaction, and therefore, these all have to be carefully controlled to obtain the desired structure and performance.

Surface Engineering

The surface properties of particles determine their behavior in the food matrix and in the gastrointestinal tract (GIT). The properties of nanostructures can be manipulated by controlling their surface properties, for example, by coating them with one or more layers of biopolymer or lipid. The attachment of biopolymers to the nanostructure surface is generally driven by electrostatic attraction. The interfacial layers can also be further stabilized, and their permeability can be reduced by (enzymatic) cross-linking. The electrostatic layer-by-layer deposition technique has been widely used to create multilayered particles or film surfaces using biopolymers. Every new coating layer reverses the charge on the particles, which ensures that only single layers of the molecules are deposited during each coating cycle, and that this method can be repeated for different cycles and can give rise to the formation of particles with multiple layers. Polyelectrolytes are generally preferred over small molecules as these ensure a good adhesion of a layer to a surface by having a certain number of ionic bonds. Salt can be used to smoothen the conformational structure of the multiple layers as they can break ionic bonds between the different layers, which, after removal of the salt, can reassemble in a more equilibrated conformation. Next to electrostatic interactions, hydrophobic attraction, hydrogen bonding, and/or specific molecular interaction can also be used to trigger the deposition of a new layer of molecules on a surface.

Furthermore, edible or nonedible nanofilms can also be engineered in such a way as to display a specific functionality, such as antimicrobial or chelating properties. The attachment of the bioactive molecules to the surface can be based on electrostatic or covalent interactions. As mentioned in section 'Covalent Interactions,' covalent bonds can be created by UV light irradiation or by the use of cross-linking agents. In the case of nonedible films, a wider selection of cross-linking agents can be used since they do not necessarily have to be food-grade because they are not directly applied on the food product. A common and promising practice in the food industry is the modification of a surface to make it more suitable for the attachment of bioactive compounds. Surface modification can be performed through a wide variety of techniques: wet chemical technique, silane monolayers, ionized gas treatment, and UV light irradiation.

Utilization in Food

In this section, we highlight a number of promising and emerging nanotechnology applications in the food industry.

Delivery Systems

Nanostructures are promising carriers for biological and functional compounds with regard to their protection, controlled release, and targeted delivery during food processing, storage, and/or after food ingestion. These systems can also be utilized to mask off-flavors, to stabilize the color of food products, to increase the shelf life of products by controlled release of antimicrobial agents, to increase the solubility of bioactives, or to decrease unwanted chemical reactions. Next to increasing the stability of the enclosed component by shielding it from environmental influences, sometimes, targeted delivery of the enclosed component in the GIT is envisaged. Size reduction often goes hand in hand with improved bioadhesive properties of nanosized particles, which leads to a prolonged residence time and, often, higher absorption in the GIT. Combined with a large surface area per volume, this leads to a higher bioavailability of the enclosed bioactive components. Next to size, the interaction of nanoparticles with the GIT is determined by nanoparticle morphology, charge, surface characteristics, and hydrophilicity. A decision scheme has been developed to predict the potential uptake of nanoparticles in the GIT. To study the behavior and suitability of a nanosystem for the delivery of bioactives in the human body, standardized laboratory protocols have been developed to mimic the conditions in the GIT. However, these methods have predominantly been applied to lipid-based nanoparticles. Only very few *in vitro* studies can be found that focus on the bioavailability of components enclosed in biopolymer-based nanoparticles.

Stabilizers of Food Texture

Nanostructures are promising materials to alter, improve, or mimic the structure and texture of food products. The quest for healthier food products often involves the reduction of one food ingredient (e.g., fat) or product (e.g., meat) in our diet. However, the reduction or removal of a food ingredient often has drastic effects on the overall food matrix properties. Although reducing the fat content will decrease the caloric content of the food product and can provide a solution for obesity, this often also leads to a decrease in the palatability of the food product. Therefore, the development and marketing of these products still prove challenging. The role of fat in food products is very diverse since it affects texture, appearance, flavor, etc., and so, the mere replacement of fat droplets by another component without losing fat functionality is not straightforward. A possible strategy that recently came into focus is controlled flocculation of fat droplets, which leads to increases in viscous or elastic properties. In this way, highly viscous and even gel-like textures typical for high-fat products can be created while using significantly lower fat contents. Flocculation can be induced by changing the system pH, by heating, or the addition of multivalent cations, dependent on the emulsifier used.

Nonmeat products have been developed that nevertheless have an appealing meat-like structure. One of the explored strategies comprises the use of protein nanofibers, produced by electrospinning. After spinning, the fibers also need to be aligned in order to mimic the meat structure.

Nanobiosensors

Nanobiosensors are built to recognize several target groups/molecules to detect pathogens or hazardous chemicals in a fast and reliable way. The overall goal is to produce nanobiosensors that are user-friendly and reduce the reagent volumes and detection time without compromising the test sensitivity. The incorporation of nanotechnology in the development of biosensors has drastically reduced the detection limits of the devices. The sensitivity of these sensors can even go as low as one pathogen cell. The improved sensitivity of the sensors relies on the size of the nanoparticles that control various electronic and optical features for detection and quantification.

Hydrogel nanoparticles can also be used to build nanobiosensors, since these structures can improve the retention of analytes and can be tailored to create specific responses to mechanical, optical, thermal, magnetic, and electrical stimulation. The signals that the nanobiosensors use to detect the analytes can be microgravimetrically, electrochemically, magnetically, and/or optically detected. Microfluidics are an important tool for designing and manufacturing these kinds of sensors to reduce sample volume and to make devices more portable and autonomous. Nanobiosensors can be used along the whole production chain from the field to the supermarket. They can be used to detect pathogens, harmful substances, and adulteration.

Food Packaging

Prolonging and ensuring the shelf life of a food product is a constant challenge for food scientists and technologists. The use of nanostructured or nanomodified materials is a promising way to achieve this goal. Edible food coatings can be applied directly on the product, while nonedible coatings often work as a protective container without being part of or being directly applied to the food product.

Edible nanofilms can be engineered as single or multilayer structures that function as a barrier for agents that are detrimental to stability or safety, such as oxygen, moisture, and/or microorganisms. Edible nanofilms can also work as delivery systems for antioxidant or antimicrobial agents like essential oils, which ideally should be released over time. Probiotic bacteria have also been introduced to edible films to create functional food products. The advantage of using edible films is that the probiotic can be added to minimally processed foods like fruits or vegetables or food products that have already been processed to ensure the viability of the enclosed probiotic.

The surfaces of nonedible films, such as plastics for food packaging, can also be engineered to serve as active packaging materials. This strategy often focuses on oxidation prevention or minimizing microbial spoilage of the contained food. Surface engineering can also be applied to surfaces that are in contact with foods during processing to avoid fouling, the formation of biofilms, or the loss of process efficiency.

Societal Perception and Future Trends

The application of nanostructures in the food industry raises questions on food safety and security. All materials, to some

extent, pose some threat to human health and environment, but, as described in the preceding text, the small dimensions of these structures further increase the reactivity and interaction with the GIT. Nanotoxicology evaluates the toxicity effects of nanoscale materials on the health of organisms. This research field will need to keep pace with the developments made in the food nanotechnology field. Next to assessing the risk, the public perception also needs to be taken into consideration. Thinking and talking about food nanotechnology in all openness with all partners involved is essential to the future and success of the application of nanotechnology in a food context.

One of the obvious short-term trends in the food nanotechnology field is pushing the limits of what is possible by combining materials, fabrication strategies, and intermolecular force manipulation. To date, however, nanostructures to be used in the food science field are often developed in an empirical way. This has led to the development of a lot of different systems but is simultaneously very time-consuming and expensive. A reverse engineering approach, which starts from the functionality that the particles must display to select appropriate ingredients and production methodologies, would tremendously speed up the fabrication of particles with tailor-made functionality. However, the absence of in-depth knowledge on the underlying intermolecular interactions determining the particle formation and stability is slowing down the applicability of the reverse engineering approach. Furthermore, the complexity and biological variability and, hence, unpredictable behavior of the majority of the ingredients used to produce these nanoparticles further hamper this approach. A thorough characterization and more reliable, constant supply of certain macromolecules with well-defined properties and specifications would greatly enhance a more evidence-based approach to the production of tailor-made particles to be used in the food context.

Introduction

Natamycin is a naturally occurring antimicrobial compound that is generally produced by the bacterium *Streptomyces natalensis*. Given a generally recognized as safe (GRAS) status, it is considered as a natural preservative by the European Union (EEC No. 235). Natamycin is usually applied at concentrations between 1 and 10 mg l^{-1}. It was discovered in the 1950s where it was described for the first time by Struyk as "a new crystalline antibiotic, pimaricin, has been isolated from the fermentation broth of culture of *Streptomyces* species, isolated from soil sample obtained near Pietermaritzburg, State of Natal, Union of South Africa. The organism which makes it has been named *Streptomyces natalensis*."

Natamycin also known as pimaricin or tennectin is a polyene macrolide antimycotic produced by submerged fermentation of strains of *Actinomycetes* such as *Streptomyces natalensis*, *Streptomyces chattanogenesis*, and other closely related species. Due to its inherent property of being safe to humans, it is widely used against yeast and molds. In a study, it was found to be effective in controlling the growth of *Aspergillus carbonarius* strains and the production of its mycotoxin under different environmental conditions. Diverse works have shown its activity against *Aspergillus flavus*, *Aspergillus carbonarius*, *Aspergillus niger*, *Aspergillus versicolor*, *Penicillium chrysogenum*, *P. glabrum*, *P. commune*, *P. verrucosum*, *Byssochlamys*, and other species of molds. Because of this selective action, major applications of natamycin as a biopreservative have been seen in bacterial fermented foods since it exhibits no antibacterial activity. Thus, it can be used on the surface of cheese and fermented meats or in yogurt, fermented creams, and similar products. It is effective at low concentrations, possesses broad-spectrum activity, lacks resistance development, has no negative effect on the quality of food products, and has prolonged working time. The amphoteric character of natamycin is responsible for its low solubility in most solvents.

At extreme pH values (high or low), natamycin is completely soluble, which can be used to optimize/control the availability of active natamycin. Under these conditions, natamycin possesses strong antimycotic activity but is also rapidly decomposed. Therefore, such solutions might be beneficial in the case of extreme contamination, but under normal hygienic conditions, there is no added value in this approach.

Commercial Preparations of Natamycin

Commercial preparations available are Natamax® (Danisco, Denmark), Delvocid® (DSM, Holland), Natacyn® (US and Canadian brand names), Miconacina (Mexican brand name), and Silver Elephant Natamycin (Zhejiang Silver Elephant Bioengineering Co., Ltd., China). Most of the preparations comprise 50% natamycin with the incipient being lactose, glucose, or salt. Preparations are also available that contain food-grade polymers that aid the adherence of natamycin for surface treatments of foods.

Chemical, Physical, and Biological Properties

Natamycin belongs to the group of polyene macrolide antimycotics characterized by its macrocyclic lactone ring with a number of conjugated carbon–carbon double bonds (Figure 1). Chemically, it is (1*R*,3*S*,5*R*,7*R*,12*R*,22*R*,24*S*,25*R*,26*S*)-22-{[(3*S*,4*S*,5*S*,6*R*)-4-amino-3,5-dihydroxy-6-methyloxan-2-yl] oxy}-1,3,26-trihydroxy-12-methyl-10-oxo-6,11,28-trioxatricyclo [22.3.1.$0^{5,7}$]octacosa-8,14,16,18,20-pentaene-25-carboxylic acid, used for a variety of fungal infections, mainly topically.

The structure of natamycin could be determined using proton and ^{13}C NMR (nuclear magnetic resonance) spectroscopy and 3-D structure by the latter. The molecular weight of natamycin is 665.75 with an empirical formula $C_{33}H_{47}NO_{13}$. Its CAS registry number is 7681-93-8. The isoelectric point of natamycin is 6.5. It is a white or creamy-white powder with almost no odor or taste. Solid natamycin and natamycin suspensions are quite stable to heat. Even heating for several hours at 100 °C causes only a slight decrease of its activity. Natamycin is soluble in polar organic solvents, like glacial acetic acid and dimethylformamide, slightly soluble in methanol, and practically insoluble in fatty and mineral oils and water.

Solubility of Natamycin

In aqueous solutions, its solubility is approximately 40 ppm. A suspension containing 0.5% natamycin at pH 6.5 hardly loses any activity at room temperature in the dark, which proves that neutral aqueous suspensions of natamycin are also very stable. Natamycin has low solubility in water (~40 μg ml^{-1}), but this low solubility is an advantage in the surface treatments of foods because it ensures that the preservative remains on the surface of the food where needed, rather than migrating into the foods. Increased solubility occurs with the range of solvents.

Degradation Products of Natamycin

Under the influence of ultraviolet light, gamma irradiations, or acid conditions, natamycin decomposes resulting in the loss of the tetraene structure yielding among others mycosamine, aponatamycin, and dinatamycinolidediol for degradation products. The acute toxicity of these products was investigated and is at an even higher dose (based on LD50 values) than natamycin itself. Natamycin is inactivated by chlorine, peroxides,

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00482-7

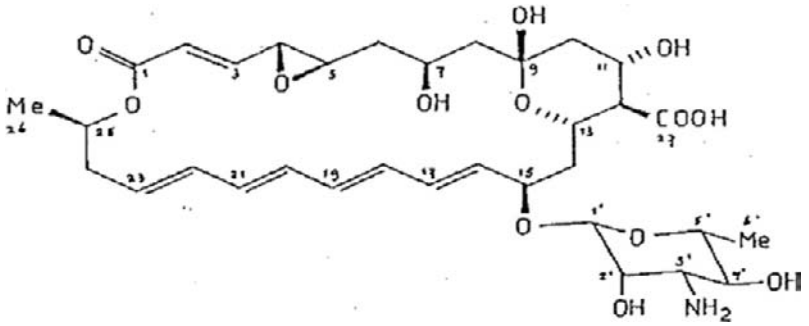

Figure 1 Structure of natamycin.

antioxidants, sulfites, and sodium formaldehyde sulfoxylate, which might be used as cleaning agents.

Anhydrous Form of Natamycin

It can be prepared by drying the trihydrate in vacuum at room temperature over phosphorus pentoxide. The anhydrate is unstable; it loses 15% of its activity when stored for 48 h under optimal conditions. However, when stored under nitrogen or at low temperatures, it is more stable.

Stability of Natamycin

The barium and calcium salts of natamycin and a new crystalline form, also a trihydrate, have also been studied. The stability of the new trihydrate is less than the stability of the regular type. The salts in their solid form are stable but, once in contact with water, they dissolve rapidly and are converted into the more stable regular trihydrate. In principle, this phenomenon could be used to obtain a highly active preparation of dissolved natamycin for a short period of time.

Production of Natamycin

Natamycin is produced by inoculating a pure culture of *Streptomyces natalensis* into a medium containing a carbon source (starch and molasses), nitrogen source (corn steep liquor, casein, and soybean meal), and antifoaming agents with continuous aeration and mechanical agitation, which aids the process with a temperature and pH range of 26–30 °C and 6–8, respectively (Figure 2). After completion of fermentation, insoluble natamycin is subjected to centrifugation where its crystals are separated from most of the residual mycelium and are isolated as a suspension. The suspension is further recrystallized, filtered, and washed, which is again resuspended and filtered. Finally, natamycin crystals are dried and milled to the final powder form and packed. The dry powder is in trihydrate form, which is sufficiently stable to be stored for years with few percent loss of activity. It has been established that the nitrogen source (inorganic and organic) exhibited a significant effect on the natamycin production.

The addition of short-chain fatty acids (viz., acetic, propionic, and butyric) not only increased the antibiotic yield but also decreased the production time from 96 h to only 84 h in shake flask cultures. The maximum volumetric production of 3.98 g l^{-1} was achieved after 84 h in carboxylic acid-supplemented culture (acetate and propionate in a ratio of 7:1). Under optimal cultivation conditions, high concentrations of natamycin can be obtained (3.94 g l^{-1}) with *Streptomyces gilvosporeus* LK-196 in pilot plants that could be further enhanced by chromosomal integration of the *Vitreoscilla* hemoglobin gene (vgb) responsible to reduce oxygen limitation, which is a critical factor in its production. Improved natamycin production by the engineering of phosphopantetheinyl transferases in *Streptomyces chattanoogensis* L10 has been observed. Also, the engineered *Streptomyces chattanoogensis* Dl, generated by inserting an extra copy of scnRII into the chromosome of strain L10, increased its natamycin production by 3.3-fold in a YSG medium and 4.6-fold in a YEME medium without sucrose.

Method of Assay

The methods used for the determination of natamycin are agar diffusion bioassay, high performance liquid chromatography (HPLC), ultraviolet spectrophotometry, and the enzyme immunoassay.

Regulatory Status for Use in Foods

Natamycin is allowed for use in many countries as a food additive and a natural preservative in a variety of foods including dairy foods to control the growth of fungi and yeast (Table 1). On 1 April 2014, the Food Standards Australia New Zealand (FSANZ) published Notification Circular 06-14, which includes Application A1095 to extend the use of natamycin as a preservative in fermented milk products. The primary food uses are in the surface treatment of cheeses and sausages. Several codex standards for cheese permit the presence of natamycin on the cheese surface/rind at a level of 2 mg dm^{-2} to a maximum depth of 5 mm (e.g., mold-ripened cheese like Brie, Camembert, Munster, and Port Salut). The Joint FAO/WHO Expert Committee on Food Additives (JECFA) reviewed the safety of natamycin in 1968, 1979, and 2001 and assigned an acceptable daily intake value of 0.3 mg kg^{-1} body weight per day.

Elsewhere, the permitted uses differ from country to country. In most non-European countries, natamycin is allowed for the surface treatment of cheeses and/or sausages or other meat products. Since regulations may change, the regulation in a country must be checked before applying natamycin in food products.

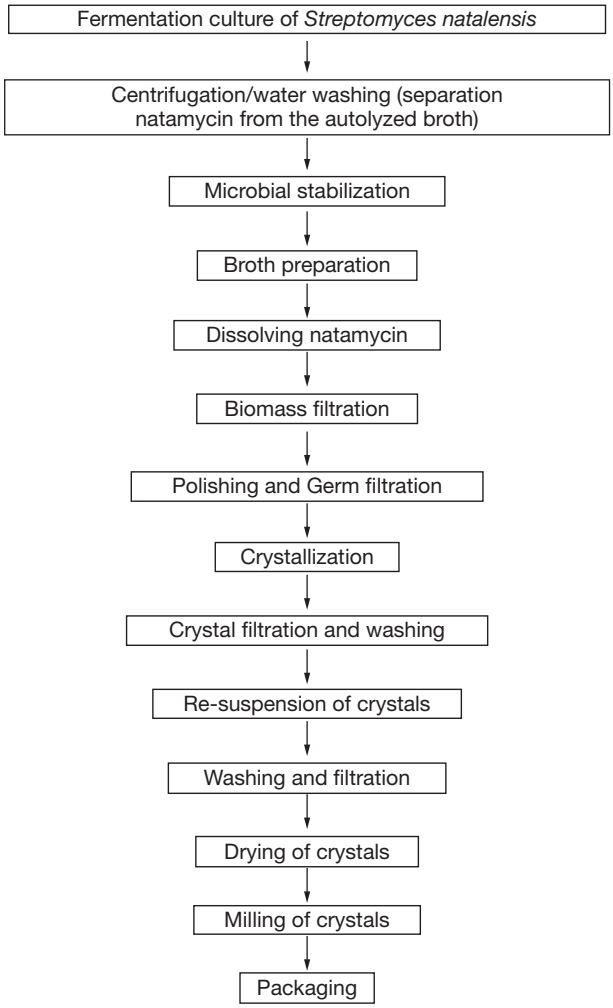

Figure 2 A flow chart of the natamycin production.

Table 1 Permitted levels of natamycin in different countries

Country	*Permitted level*	*Application*
The European Union	1 mg dm^{-2} surface Depth – >5 mm	Surface treatment of hard, semihard, and semisoft cheeses and dried and cured sausages
The United States	Not to exceed 20 g kg^{-1}	Applied on cheese
Canada	Up to 20 ppm	Cheeses
Canada	Up to 10 ppm	Shredded/grated cheese
Australia	15 mg kg^{-1}	Cheese and cheese products

Mode of Action of Natamycin

Natamycin appears to have an all-or-none effect, which destroys the cell membrane without noticeable prior damage. The eukaryotic cell membrane has lipids, phospholipids, proteins, and sterols (ergosterol) where sterols play an important role in the selective action of polyene antimycotics. Natamycin has a high affinity for ergosterol and binds irreversibly to the ergosterol in the fungal cell membrane. This results in the formation of the polyene–sterol complex, which leads to the rapid leakage of essential ions and small peptides by altering the permeability of the membrane (**Figure 3**). Although the activity against fungi is dose-related, natamycin is predominantly fungicidal. Natamycin is not effective *in vitro* against Gram-positive or Gram-negative bacteria.

Yeast sterol biosynthetic mutants revealed the importance of the double bonds in the B ring of ergosterol for the natamycin–ergosterol interaction and the consecutive block of fungal growth by not affecting the permeability of the yeast plasma membrane. As recently demonstrated, natamycin inhibits the growth of yeast and fungi via the immediate inhibition of amino acid and glucose transport across the plasma membrane. This is attributable to ergosterol-specific and reversible inhibition of membrane transport proteins. Vesicles of *Acholeplasma laidlawii* were prepared with either ergosterol or cholesterol as the membrane sterol. Studies showed that natamycin induced leakage of potassium ions in the vesicles of *Acholeplasma laidlawii* containing membrane sterol (ergosterol) equivalent to that of fungal cell membrane but caused no

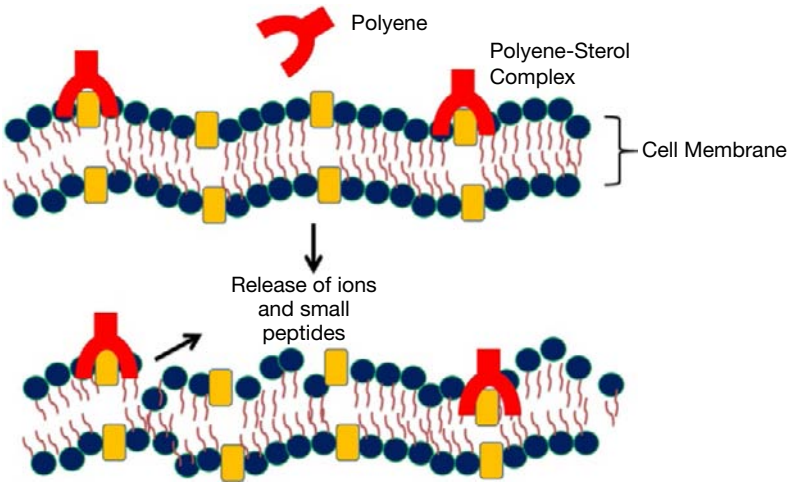

Figure 3 Mode of action of natamycin – a polyene.

damage when cholesterol was present in the vesicles. Also, natamycin inhibited the priming stage of vacuole fusion, which is known to be ergosterol-dependent. This led to the conclusion that ergosterol is the molecular target for natamycin on the fungal cell membrane.

The detailed mechanism of action of natamycin resembles that of another polyene antimycotic, amphotericin B, which forms chiral aggregates at the bilayer–water interface. In the absence of ergosterol, the aggregates remained at the surface of the bilayer, whereas in its presence, the aggregates get embedded in the phospholipid bilayers, which are the precursors of pore formation. Also, as the fungal culture ages, natamycin becomes less effective in its fungicidal action. The cell wall prevents direct interaction of natamycin with the older tissue in the lower part of the hyphae; therefore, natamycin stops the growth of the fungal mycelium only at the tip of the growing hypha. The older cells are not killed directly but are also unlikely to survive as natamycin inhibits the germination of fungal spores by an unknown mechanism. It was suggested that natamycin prevents fungal spoilage by the inhibition of early endocytosis in fungal cells.

Table 2 Sensitivity to natamycin of fungi isolated in Dutch cheese factories and warehouses

Microorganism	*MIC (ppm)*
Aspergillus flavus and *Aspergillus parasiticus*	10–20
Aspergillus fumigatus, *Aspergillus penicillioides*, and *Aspergillus versicolor*	<10
Cladosporium candidum	1–15
Debaryomyces hansenii	1–15
Eurotium herbariorum	1–15
Geotrichum candidum	1–15
Mucor racemosus	1–15
Penicillium brevicompactum, *P. camemberti*, *P. commune*, *P. corylophilum*, *P. glabrum*, *P. nalgiovense*, *P. roqueforti*, and *P. solitum*	1–15

Sensitivity of Molds and Yeast to Natamycin

Natamycin is active against most fungi and yeast at low concentrations. The minimum inhibitory concentration (MIC) for natamycin against all foodborne fungi and yeast is less than 20 ppm, while the solubility of natamycin in aqueous food systems is around 40 ppm. It has been demonstrated in practice that under acceptable hygienic conditions, this concentration of dissolved natamycin is sufficient to prevent fungal and yeast growth. The majority of yeast and molds were inhibited at concentrations of 1–15 ppm of natamycin in various dairy foods and beverages except a few listed in Tables 2–4.

All isolates of fungal flora obtained from ten farm-level cheese production plants in Spain had MICs of 10 ppm or less except for a *Geotrichum* species that had an MIC of 12.5 ppm. Similarly, in a survey of 16 Dutch factories producing dry sausages to isolate less sensitive yeast and molds, growth was observed on very few plates containing 2 ppm natamycin. In a German study, the sensitivity of 83 yeast to natamycin was examined where none of the yeast isolated from food products were able to grow at a concentration of 3 ppm of natamycin.

Resistance to Natamycin

After decades of continuous use, no resistant molds and yeast were reported against natamycin, which is quite remarkable as compared with other preservatives. In general, yeast are less resistant (MICs below 5 ppm) than molds (MICs above 10 ppm). The EFSA Panel on Food Additives and Nutrient Sources Added to Food has revised its use, concluding that natamycin is very poorly absorbed and therefore does not possess a toxic risk.

Table 3 Sensitivity to natamycin of fungi and yeast occurring on sausages

Microorganism	*MIC (ppm)*	*Source of microorganism*
Molds		
Alternaria alternata	10–20	Blood
Aspergillus flavus	<5	Air
Aspergillus niger	<5	Fruit
Aspergillus versicolor	<5	Soil
Cladosporium cladosporioides	<5	Meat stamp
Eurotium appendiculatum	<5	Smoked sausage
Eurotium herbariorum	<5	Board
Geotrichum candidum	5–10	Soil
Mucor racemosus	<5	Sausage
Penicillium chrysogenum	<5	Meat
Penicillium glabrum	5–10	Soil
Penicillium nalgiovense	<5	Sausage
Penicillium verrucosum	<5	Meat
Rhizopus stolonifer	5–10	Bread

Yeast		
Candida zeylanoides	<5	Sausage
Cryptococcus laurentii	<5	Air
Debaryomyces hansenii	<5	Sausage
Rhodotorula mucilaginosa	<5	Air
Trichosporon pullulans	<5	Frozen beef

Source: Stark, J. (2003). Natamycin: an effective fungicide for food and beverages. In Roller, S. (eds.) *Natural antimicrobials for the minimal processing of foods*, pp. 82–97. Cambridge: Woodhead Publishing Ltd.

The lack of increased resistance among fungi was due to the lethal activity of the compound. The possibility might arise in low-ergosterol or ergosterol-free mutants, but they are unlikely to survive in nature. Attempts to induce natamycin tolerance in molds were not a success story. To date, the maximum tolerance to natamycin is seen in *P. discolor*. Although it was proved that natamycin has no toxic effects even at high levels of ingestion, its application as food additive is restricted, because of the possible danger of resistance formation.

Applications of Natamycin

In Dairy Foods

Natamycin is used in the food industry as a hurdle to fungal outgrowth in dairy products, meats, and other foods where it remains on the surface of the product and hardly penetrates the product, which differentiates it from other preservatives. For the surface treatment of cheese, natamycin is usually applied as a coating and as a dipping or spraying agent or could be added to the brine as an alternative treatment. Successful application of natamycin is on almost every type of cheese. It was found effective in preserving soft cheeses with no harmful effects on ripening. Galotyri cheese (Greek traditional cheese), when treated with natamycin and nisin, not only inhibited the growth of molds and yeast but also enhanced the shelf life and product characteristics (>28 days) as compared with the control sample (14–15 days).

A study on the inactivation of *Saccharomyces cerevisiae* treated with different levels of natamycin and inoculum sizes in liquid cheese whey revealed that an apparent reduction of the yeast population occurred at concentrations of 12.5 mg l^{-1} and during storage. The surface treatment of blue cheese with natamycin was also responsible for alleviating the growth of spoilage organisms and enhanced the flavor of the cheese without affecting the development of blue mold in the punch holes. Similar effects were being observed in various sausages when applied in a concentration ranging from 500 to 2000 ppm. Moreover, 10–100 ppm of natamycin was responsible for enhancing the shelf life of berries. It was observed that the presence of natamycin in the dairy product labneh (Greek yogurt) prevented fungal and yeast spoilage, although it was not legally permitted. A study confirmed that there is no harm

Table 4 Sensitivity to natamycin of yeast isolated from beverages and fruit products

Microorganisms	*MIC (ppm)*	*Source of microorganisms*
Saccharomyces cerevisiae	1.5	Grape juice

to health in the use of natamycin as a biopreservative in a doogh (Iranian yogurt drink) in spite of the national regulatory agencies not permitting the preservative use. The additions of natamycin at a concentration of 8 ppm in yogurt resulted in maximum inhibition of yeast counts and did not affect quality parameters before or after fermentation of the milk base as the bacteria involved in the fermentation are insensitive toward it. Preservation studies in yogurt showed the efficacy of natamycin at doses of 5–20 ppm, which prevented the growth of most relevant food spoilage molds.

In Fermented Foods

Natamycin could also help to control the spoilage of fresh packed or cured seasoned table olives caused by yeast. Studies showed that natamycin at low concentrations can efficiently inhibit the growth of three yeast species widely found in table olives in the presence of low and high concentrations of citric acid and sodium chloride, respectively. Similar observations were observed in black olives. Natamycin (160 mg l^{-1}) inhibited the growth of *Aspergillus flavus* on whole olives for 21 days at 15 °C and for 7 days in olive paste. Also, the addition of natamycin could retard the spoilage of acidified foods by *Saccharomyces cerevisiae* when combined with mild heat treatments.

In Antimicrobial Packaging

Packages with antimicrobial activity based on preservative releasing offer a promising form of active packaging systems applicable in food processing. In this context, polymer packaging films releasing nisin and natamycin inhibited the growth of indicator microorganisms (*Penicillium expansum*, *Fusarium culmorum*, *Lactobacillus helveticus*, and *Listeria ivanovii*) when applied on surface-ripened cheese, thus proving a potent antimicrobial agent. Edible films produced from whey protein isolate (WPI) and glycerol, including the incorporation of lactic acid and propionic acid (PRO), chitooligosaccharides (COS) with a nominal MW of 3 kDa, and natamycin as antimicrobial agents exhibited different degrees of effectiveness against several target microorganisms. Organic acids showed highest activity against Gram-positive microorganisms, COS against Gram-negative microorganisms, and natamycin against yeast. Based on this, the formulation for an active edible film (10%(w/w) WPI with 5%(w/w) glycerol (as base matrix), incorporated with 6 g l^{-1} lactic acid (LA) and 0.25 g l^{-1} natamycin (NA)) could be applied in dairy products, namely, cheese wrapping due to their good synergistic performance against microorganisms commonly found on cheese surfaces, that is, bacteria and yeast, without significantly compromising the tensile, barrier, and optical properties of the resulting WPI films.

The matrix films of whey proteins containing antimicrobial agents, namely, malic acid, nisin, and natamycin, were shown to be active against *Penicillium aeruginosa*, *Y. lipolytica*, *L. monocytogenes*, *Penicillium commune*, and *Penicillium chrysogenum*. Chitosan films containing natamycin showed antimicrobial activity against various emergent foodborne pathogens, proving to be a feasible and attractive method for food biopreservation. The physicochemical properties of alginate/chitosan composite films containing natamycin as an antimicrobial agent concluded that composite films added with natamycin exhibit suitable functional attributes and show good perspectives for acting as antimicrobial films intended for food applications. Low-density polyethylene films coated by commercially available polyvinyl chloride lacquer with the addition of nisin preparation Nisaplin® (5% w/w) and/or natamycin preparation Delvocid™ (10% w/w) significantly retarded the growth of harmful microorganisms causing hindrances in the storage of cheese and raw chicken meat.

A study showed that the incorporation of low concentrations of natamycin in a tapioca starch–glycerol matrix acted as an effective antimycotic against *Saccharomyces cerevisiae*, as high concentration of it affects the mechanical properties and color of the starch edible films. Natamycin was also incorporated into alginate films to produce antimicrobial packaging using three different approaches (conventional loading method, immersion procedure, and supercritical solvent impregnation (SSI) method) where the SSI (CO_2 + EtOH) process produced visually attractive and translucent films with antimicrobial packaging.

Other Food Commodities

Apart from a potent application as a food preservative, the potential of using natamycin as a biocontrol agent for plant fungal pathogens, such as *F. oxysporum*, *B. cinerea*, and *M. laxa*, has been suggested. Natamycin has been quite effective in controlling crop pests and was found to have no adverse effects on nontarget organisms or on the environment. The combined treatment of button mushrooms with natamycin and pure oxygen has the potential to improve the quality of button mushrooms and extend the shelf life. Even natamycin finds its use as a drug of choice in mouth dissolving tablets, a noninvasive drug delivery system, emerged as an alternative to conventional capsules and tablets mainly for the pediatric and geriatric patients finding difficulty in swallowing. Besides, it has been applied in medical therapy to handle various ocular problems like conjunctivitis and fungal keratitis, which is a major cause of blindness in developing countries of the world.

Conclusion

Economic losses due to spoilage and health risks associated with the growth of pathogenic or mycotoxin-producing molds are the important issues. Natamycin has a GRAS status and long history of safe use in preventing fungal growth on the surface of various foods and beverages. It is a potent antimycotic agent used to overcome the problem of fungal spoilage, which decreases the shelf life of foods. Therefore, it can offer a tremendous opportunity for advancing the field of food preservation and safety. In addition to this, it has found wide applications in medical therapies.

History

Niacin also known as vitamin B_3, the third water-soluble vitamin discovered, plays a vital role in the overall development of the body, deficiency of which could result into problems associated with the skin (pellagra), digestion, and brain functions. Pellagra was first described in Spain by Casal in 1735 after the introduction of maize into Europe from the America. The history of pellagra, its recognition, and causation are listed in Table 1. In the 1920s, Goldberger in the United States reported that pellagra and black tongue in dogs responded to treatment with animal protein and also to boiled protein-free extracts of yeast. Niacin was first described by chemist Hugo Weidel in 1873 and extracted by Casimir Funk, but he thought it to be thiamine. Afterward, Conrad Elvehjem a biochemist from Wisconsin in 1937 extracted an active ingredient from livers that was referred as 'pellagra-preventing factor' and the 'anti-black tongue factor' called niacin. In general, it has been termed as 'vitamin PP,' 'vitamin P-P,' and 'PP factor.' As a memory jogger, one can recall that 'low B_3 = the 3 Ds of pellagra,' that is, dermatitis, diarrhea, and dementia. The name niacin comes from *nic*otinic *ac*id + vitam*in*, to distance itself from the word nicotine, which the public knows as a toxic chemical found in tobacco. Nicotinic acid and nicotinamide had been isolated from the coenzymes now known as nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP) by 1934–35; hence, knowledge of their biochemical roles in electron-transfer reactions preceded the discovery of their nutritional significance. By 1946, the metabolism of dietary tryptophan to an active form of the vitamin had been demonstrated.

Chemistry

The term niacin is accepted as a broad descriptor of vitamers, nicotinic acid, nicotinamide, and a variety of pyridine nucleotide structures. By definition, niacin refers to nicotinic acid (pyridine-3-carboxylic acid), nicotinamide (pyridine-3-carboxamide), and derivatives that exhibit the biological activity of nicotinamide. Nicotinic acid and nicotinamide are not directly convertible to each other; however, both the compounds are precursors of coenzymes NAD and NADP stored in the cytoplasm, bound to protein. NAD converts to NADP by phosphorylation in the presence of the enzyme NAD^+ kinase. The structure of NAD can be envisaged as the adenosine diphosphate-ribose (ADP-ribose) moiety attached covalently to nicotinamide through a β-*N*-glycosidic linkage (Figure 1). This linkage constitutes a high-energy bond, the energy of which supplies the driving force for various ADP-ribosylation reactions catalyzed by NAD glycohydrolases. NAD is actively involved not only in the catabolism of fat, carbohydrate, protein, and alcohol but also in the cell signaling as well as DNA repair, whereas NADP is mostly involved in anabolism reactions such as fatty acid and cholesterol synthesis.

Physical and Chemical Properties of Niacin Vitamers

Niacin vitamers are categorized under water-soluble vitamin B complex where nicotinamide is more water-soluble than nicotinic acid. The molecular weight of nicotinic acid and nicotinamide is 123.11 and 122.12 g $mol^{-1,}$ respectively, with an empirical formula of $C_6H_5NO_2$ and $C_6H_6N_2O$. Nicotinic acid and nicotinamide have CAS registry numbers, namely, 59-67-6 and 98-92-0. Nicotinic acid is a white crystalline odorless powder with stability under ordinary conditions but should be protected from light at room temperature. Niacin vitamers are resistant to heat, oxidation, and alkalies, which makes niacin the most stable vitamin. Niacin is well absorbed when taken orally. Nicotinic acid sublimes at boiling point, 236 to −239 °C, and its melting point is 128–131 °C. It is slightly soluble in boiling water and boiling alcohol and does not dissolve in propanediol, chloroform, alkali solution, and lipid-soluble ether solvent with pH of 2.7. It has specific gravity of 1.473 and vapor density of 4.25. The acute toxicity of nicotinic acid is based on LD50 values when supplemented orally in rats (7000 mg kg^{-1}). It is generally recognized as safe substance, but washing with water is preferred immediately when it comes in contact with skin or eyes. Nicotinamide is a solid white crystalline powder. It sublimes at boiling point 224 °C and its melting point is 127–131 °C. It has density of 1.4 and vapor pressure of 31.4 hPa. Its solubility in water is high and is used to enrich various foods, drinks, and feeds.

Deficiency Indicators and Outcomes

Niacin deficiency is sometimes seen in developed countries, and it is usually apparent in conditions of poverty, malnutrition, chronic alcoholism, psychosis, and some types of slow-growing tumors called carcinoid tumors. Studies revealed that in patients with alcoholic pellagra, niacin deficiency may be an important factor influencing both the onset and the severity of this condition. Patients with alcoholism typically experience increased intestinal permeability, leading to negative health outcomes. High-energy requirements (the brain) or high-turnover-rate organs (the gut and skin) are usually most susceptible to deficiency of niacin, which is usually found in the people with high intake of maize or millet in their diet, because the excess of leucine interferes in the conversion of tryptophan to niacin. Hartnup's disease is a hereditary metabolic disorder, affecting the absorption of tryptophan culminating to deficiency of niacin in the intestines and kidneys. The lack of

Table 1 History of pellagra and recognition of its causes in human populations

1	A poorly understood disease (dermatitis, gastrointestinal, and mental signs/symptoms) appeared in Europe in the eighteenth and nineteenth centuries and then in the southern United States in the first decade of the twentieth century and was named 'pellagra' (meaning raw/rough skin)
2	Favored causal hypotheses included infection, moldy grain, and insects
3	In 1914–16, Joseph Goldberger disproved the infection hypothesis: by self-experimentation and then producing pellagra in prisoners fed with mainly corn diets
4	In 1920s, Joseph Goldberger developed the 'black tongue' model of pellagra in dogs fed with corn diets
5	In 1930s, nicotinic acid was isolated as a pure water-soluble compound (vitamin) of known structure, from yeast and liver extracts, able to cure pellagra and black tongue
6	In the mid-twentieth century, unavailable niacin is bound in the complex niacytin in corn. Heating in an alkaline environment (as in Mexican tortillas) can release it
7	Niacin can be produced from tryptophan in the body. Pellagragenic diets are low in tryptophan as well as in niacin. The concept of 'niacin equivalents' (milligram niacin plus 160th of milligram tryptophan) in food developed. Human requirements estimated
8	The Indian cereal 'jowar' is shown to be pellagragenic. Some, but not all, studies have implicated its high leucine content
9	Niacin and riboflavin deficiencies often coexist; the signs and symptoms of pellagra-like disease are often attributable to multiple nutrient deficiencies
10	Certain inborn errors of metabolism (genetic defects), or iatrogenic effects of drugs, can mimic the signs, symptoms, and metabolic defects of pellagra

Table 2 Signs and symptoms of niacin deficiency in humans and animals

Human deficiency
Loss of appetite and weight
Dermatosis (hyperpigmentation, hyperkeratosis, and desquamation of the epidermis, especially where frequently exposed to strong sunlight)
Anorexia
Achlorhydria
Angular stomatitis, cheilosis, magenta tongue
Diarrhea
Anemia
Neuropathy (headache, dizziness, tremor, neurosis, and apathy)
Death in severe and prolonged cases
Black tongue in dogs and cats
Pustules in mouth and excessive salivation, darkening, and necrosis of the tongue
Diarrhea
Pigs
Neurological lesions affecting ganglion cells; histopathology of nerves
Degeneration of intestinal mucosa and diarrhea
Anemia
Rats
Reduced growth rate
Alopecia (roughened skin)
Damage to peripheral nerves (cells and axons)
Birds (*e.g., chickens and ducks*)
Inflammation of the upper gastrointestinal tract
Dermatitis
Diarrhea

Source: Bates, C. J. (2013). *Niacin and pellagra. Encyclopedia of human nutrition* (3rd ed.), pp. 182–188. Oxford: Elsevier.

niacin may also be observed in pandemic deficiency disease, which is caused by a lack of five crucial vitamins (niacin, vitamin C, thiamine, vitamin D, and vitamin A).

Niacin deficiency can result in mild and severe effects (Table 2). Mild niacin deficiency has been shown to slow metabolism, causing decreased tolerance to cold. Severe deficiency results in pellagra, a chronic wasting (three Ds) disease, which consists of dermatitis (hyperpigmentation, hyperkeratosis, and desquamation – especially when exposed to the sun), diarrhea, and dementia (mental depression) as well as 'Casal's necklace' lesions on the lower neck. The dermatitis is symmetrical, bilateral, hyperpigmented, and photosensitive and begins with erythema resembling sunburned areas. It appears mostly on skin exposed to sun such as hands, legs, face, and neck. Gradually, these areas become reddish brown, rough,

scaly, and keratotic. Gastrointestinal disorders and mucosal abnormalities are also observed. Cerebral manifestations including headache, irritability, confusion, fatigue, apathy, and insomnia precede encephalopathy (inflammation of the brain). Mental changes consist of depression, irritability, and delirium. Other symptoms are nausea, loss of appetite, tiredness, weight loss, coated tongue and sores in the mouth, forgetfulness, anemia, and death if left untreated.

Dietary Sources

Niacin is not a true vitamin as it can be produced by the metabolism of essential amino acid tryptophan. Because of the contribution of tryptophan, foods containing balanced protein are important contributors to the total niacin equivalent intake. The term 'niacin equivalent' (NE) is used to describe the contribution to dietary intake of all forms of niacin that are available to the body and refers to preformed niacin (provides ~50% of the niacin supply in the diet) in addition to niacin formed from the conversion of tryptophan where 60 mg of tryptophan is equal to one milligram of niacin. Niacin is found in both plant and animal foods. Lean red meat, poultry, and liver contain high levels of both niacin and tryptophan and, together with legumes, are important sources of the vitamin. Peanut butter is an excellent source of niacin. Cheese and eggs are relatively poor sources of preformed niacin, but these high-protein foods contain ample amounts of tryptophan and therefore have a high niacin equivalent. Fruits and vegetables provide useful amounts, depending upon the dietary intake. Other useful sources are whole grain cereals, bread, tea, and coffee. Predominantly in maize and other cereals, vitamin occurs in an unabsorbable form called niacytin. The milling of cereals removes most of the niacin since it is concentrated in the aleurone and germ layers. Therefore, in the United Kingdom, it is compulsory by law to add niacin to white flour (mostly 70% extraction rate) at 16 mg kg^{-1}, and all flours other than whole meal (100% extraction) must be enriched. From Table 3, it can be seen that different foods differ considerably, not only in their contribution to NE but also in the ratio of the contribution from preformed niacin and from tryptophan.

Bioavailability

The majority of the bound nicotinic acid in mature cereal grains is biologically unavailable after conventional cooking. About 10% of the total niacin was released as free nicotinic acid after extraction of sorghum meal with 0.1 N HCl. This suggests that a small proportion of bound nicotinic acid can be hydrolyzed by gastric juice and made available. Pellagra, the disease caused by a deficiency of both niacin and tryptophan, has commonly been found in population groups having maize as their staple food. In 1951, it was found that niacin in maize is biologically unavailable and could only be released in very alkaline lime water of pH 11; this process is known as nixtamalization. Mexican and Central American peasants and Hopi Indians in Arizona rely upon maize as a staple food and yet do not experience pellagra. The explanation for this paradox lies in the way in which these people prepare the maize for bread making. In the traditional preparation of Mexican tortillas, the maize is soaked at alkaline pH in lime water before baking, and this process releases the nicotinic acid from its bound forms. In the making of piki bread, the Hopi Indians use wood ash, which is alkaline and also results in the liberation of nicotinic acid.

Recommended Daily Allowance

Requirement varies with the protein content of diet. The requirement for niacin increases in increased calorie intake or expenditure, in acute illness, after severe infection, during injury, etc. The recommended daily allowance (RDA) for niacin, revised in 1998, is based on the prevention of deficiency and given by the Food and Nutrition Board (FNB) of the US

Table 3 Niacin equivalents in mg/100 g of selected foodstuffs

Food	*Niacin equivalents from preformed niacin (mg/100 g)*	*Niacin equivalents from tryptophan (mg/100 g)*	*Total niacin equivalents (mg/100 g)/(mg MJ^{-1})*
Milk	0.2	0.6	0.8/2.9
Raw beef	5.0	4.7	9.7/18
Raw white fish	2.4	3.4	5.8/17
Raw eggs	0.1	3.7	3.8/6.1
Raw potatoes	0.6	0.5	1.1/3.4
Raw peas	2.5	1.1	3.6/10.5
Raw peanuts	13.8	2.9	19.3/8.2
White bread	1.6	2.0	3.6/2.5
Rice, uncooked	4.2	1.6	5.8/3.6
Maize (sweet corn)	2.0	0.5	2.5/5.3
Cornflakes (fortified)	15.0	0.9	15.9/10.0
Coffee	24.8	2.9	27.7/87

Note: Coffee is a good source of niacin, because it is released from the bound form, trigonelline, by roasting. Much of the niacin in maize and part of that in other cereals, including unfortified bread, are unavailable for use by the body, being bound in large molecular complexes. On average, 60 mg tryptophan yields 1 mg NE.

Table 4 Recommended dietary allowance (RDA) for niacin

Life stage	*Age*	*Males (mg NE[a]/day)*	*Females (mg NE/day)*
Infants	0–6 months	2 (AI)	2 (AI)
Infants	7–12 months	4 (AI)	4 (AI)
Children	1–3 years	6	6
Children	4–8 years	8	8
Children	9–13 years	12	12
Adolescents	14–18 years	16	14
Adults	19 years and older	16	14
Pregnancy	All ages	–	18
Breast-feeding	All ages	–	17

[a]NE, niacin equivalent: 1 mg NE = 60 mg of tryptophan = 1 mg niacin; AI, adequate intake.

Source: DRI report. (1998). Niacin. In: Food and Nutrition Board, Institute of Medicine (ed.) *Dietary references intakes for thiamine, riboflavin, niacin, vitamin B6, folate, vitamin B12, pantothenic acid, biotin and choline*. Washington, DC: National Academy Press; chapter 6, pp. 123–149.

Institute of Medicine. Excretion metabolites of niacin were used as an indicator of niacin nutritional status rather than symptoms of pellagra. The RDA of niacin for different age groups is given in Table 4. The recommended therapeutic dose could be up to 300 mg daily for considerable time. For treating osteoarthritis and type 1 diabetes, the recommended doses of nicotinamide are 3 g and 25 mg day^{-1}, respectively. To prevent heart disease in the people with high cholesterol, recommended dose of niacin is 2–6 g daily.

Absorption and Metabolism

Niacin vitamers are rapidly absorbed in the small intestine. For intact nucleotides, pyrophosphatase activity in the upper small intestine metabolizes NAD(P) to yield nicotinamide mononucleotide (NMN), which is then quickly hydrolyzed to form nicotinamide riboside and eventually free nicotinamide. Absorption of both nicotinic acid and nicotinamide at low concentrations appears to be via sodium-dependent facilitated diffusion or by carrier-mediated transport making use of proton cotransporters and anion antiporter. Higher concentrations of both forms appear to be absorbed by passive diffusion. Once absorbed from the lumen into the enterocyte, nicotinamide may be converted to NAD or released into the portal circulation. The bulk of nicotinic acid taken up by the enterocyte is converted via the Preiss–Handler pathway to NAD, whereas some of nicotinic acid moves into the blood in its native form. As required, NAD glycohydrolases in the enterocytes release nicotinamide from NAD into the plasma as the principal circulating form of niacin.

Possible pathway involved in the degradation of NAD (or NADP) to nicotinamide is depicted in Figure 2. The enzyme present in intestinal secretion, NAD pyrophosphate (EC 3.6.1.22), breaks the phosphodiester bond of NAD to form NMN and adenosine monophosphate (AMP). NMN is rapidly hydrolyzed to nicotinamide riboside and inorganic phosphate followed by the reaction of the riboside with inorganic phosphate to form nicotinamide and ribose 1-phosphate. These reactions happen in the presence of intestinal cells, showing that enzyme responsible for catalyzing the reactions is intracellular or membrane-bound. Upon entry into the cells, the nicotinamide was immediately metabolized to NAD.

Synthesis of NAD from the dietary tryptophan is carried out via the kynurenine pathway (Figure 3). The first and rate-limiting enzyme, tryptophan dioxygenase, is sensitive to induction by both glucocorticoid hormones and glucagon. This is true induction of new mRNA and protein synthesis. The first step is catalyzed by the extrahepatic enzyme indoleamine 2, 3-dioxygenase (IDO), which is responsible for the oxidative cleavage of tryptophan. The chronic stimulation of tryptophan oxidation, mediated by an increased activity of IDO and/or inadequate niacin levels, is observed in a number of diseases, including human immunodeficiency virus infection. However, the synthesis of niacin from tryptophan is a fairly inefficient pathway that depends on enzymes requiring vitamin B_6 and riboflavin, as well as an enzyme containing heme (iron). A variety of nutrient deficiencies, toxins, genetic and metabolic abnormalities, etc., all influence the niacin status and requirements. Because the electron-transport functions of NAD frequently involve flavin coenzymes, and because both flavin coenzymes and vitamin B_6 coenzymes are involved in the conversion of tryptophan to niacin *in vivo*, there are important metabolic interactions between these B vitamins. Their clinical deficiency signs also converge, sometimes making it difficult to distinguish between deficiencies of different B vitamins.

Postabsorptive Metabolism

Rapid absorption of niacin occurs into the human upper ileum, peak levels appearing in blood plasma within 5–10 min. Absorption also occurs in the large intestine, making niacin from gut bacteria available to the intestinal cells. The liver is a major site of conversion of niacin to its functional products, that is, nicotinamide–nucleotide coenzymes. Nicotinamide can pass readily between the cerebrospinal fluid and the plasma, thus ensuring a sufficient supply to the brain and the spinal cord. The liver contains greater niacin coenzyme concentrations than most other tissues, but all metabolically active tissues contain these essential coenzymes. There is a continuous turnover of these nucleotides in the body and very little storage; the excess of niacin is converted to methylated derivatives in the liver, which are excreted into the urine.

Biochemical Functions

Coenzyme Role in Oxidation–Reduction Reactions

Niacin is a component of two coenzymes: NAD and NADP where their oxidized forms, that is, NAD^+ and $NADP^+$, play an essential role in many biochemical reactions, especially redox reactions in which oxidoreductase enzymes transfer hydrogen. Examples of typical reactions are listed in Table 5. The oxidation of a substrate catalyzed by an NAD^+- or $NADP^+$-dependent dehydrogenase is shown in (Figure 4). Two hydrogen atoms (comprising a total of two protons and two electrons) are removed from the substrate to be oxidized (AH2). The pyridine ring of the oxidized form of coenzyme accepts a hydride anion (H^-), consisting of the two electrons and one of the protons; the remaining proton is released to the medium. Reduction of the coenzyme is stereospecific with regard to the hydrogen on the carbon-4 of the pyridine ring. Some enzymes have stereospecificity for the A side, while others for the B side.

The nicotinamide coenzymes are not tightly bound to their apoenzymes and are not, therefore, prosthetic groups with an important exception of glyceraldehyde-3-phosphate dehydrogenase in mammalian muscle containing a binding site for NAD^+ in each of its four subunits.

Although NAD and NADP undergo similar reversible reduction at the molecular level, their metabolic functions are entirely different. The NADH produced during the tricarboxylic acid cycle is reoxidized by transferring its electrons to the electron-transport chain, thereby providing ATP by the coupled process of oxidative phosphorylation. NADH required for gluconeogenesis is generated via the oxidation of fatty acids and deamination of amino acids. NADP, on the other hand, participates in the pentose phosphate pathway, which is not primarily a provider of energy.

The resulting NADPH is used as a reducing agent to synthesize, among other materials, fatty acids, glutamate, cholesterol (precursor of steroid hormones), and deoxyribonucleotides (precursors of DNA).

Role in Nonredox Reactions

NAD functions in ADP-ribosylation, a reversible post-translational modification of proteins in which the ADP-ribose

ADP-ribose-nicotinamide + protein ⟶ ADP- ribose-protein + nicotinamide + H^+

Figure 5 In mono-ADP-ribosylation, a single unit of ADP-ribose is transferred to the target protein with the concomitant release of nicotinamide and a proton.

moiety of NAD is transferred to acceptor proteins, thereby altering their function. ADP-ribosylation reactions are classified into two major groups: mono-ADP-ribosylation and poly-ADP-ribosylation.

Mono-ADP-Ribosylation

The transfer of ADP-ribose to the acceptor protein is catalyzed by ADP-ribosyltransferase enzymes, which were first discovered in certain bacteria, where they mediate the action of toxins, such as cholera, diphtheria, and pertussis toxin as well as heat-labile enterotoxin. In mammalian cells, these enzymes transfer an ADP-ribose residue from NAD to a specific amino acid of a target protein, with the creation of an ADP-ribosylated protein and the release of nicotinamide (Figure 5). Since much information is present regarding ADP-ribosylation in bacterial toxins, therefore, they will be further discussed.

The cholera toxin and heat-labile enterotoxin are an oligomeric complex also denoted as AB_5. Subunit B binds while subunit A activates the G protein, which activates adenylate cyclase. Subunit A has two important segments. The A1 portion of the chain (CTA1) is a globular enzyme payload that ADP-ribosylates G protein, while the A2 chain (CTA2) forms an extended alpha helix, which sits snugly in the central pore of subunit B ring. The CTA1 fragment catalyzes ADP-ribosylation of the Gs alpha-subunit ($G_\alpha s$) proteins using NAD, which causes the $G_\alpha s$ subunit to lose its catalytic activity in hydrolyzing GTP to GDP + Pi, so it remains activated longer than normal. Increased $G_\alpha s$ activation leads to increased adenylate cyclase activity, which increases the intracellular concentration of cAMP to more than 100-fold over normal and overactivates cytosolic protein kinase A (PKA). These active PKAs then phosphorylate the cystic fibrosis transmembrane conductance regulator (CFTR) chloride channel proteins, which leads to ATP-mediated efflux of chloride ions and leads to the secretion of H_2O, Na^+, K^+, and HCO_3^- into the intestinal lumen. In addition, the entry of Na^+ and consequently the entry of water into enterocytes are diminished. The combined effects result in rapid fluid loss from the intestine.

Pertussis toxin ADP-ribosylates alpha-subunit of the inhibitory G protein (Gi). The modified G protein uncouples from the receptor, thereby maintaining the protein as its inactive heterotrimer. Because this inhibitory G protein is inactivated, inhibition of adenylyl cyclase is removed and the result is increased cyclase activity.

Two bacterial exotoxins, diphtheria toxin and *Pseudomonas aeruginosa* exotoxin A, catalyze the transfer of NAD^+ to a

diphthamide residue in eukaryotic elongation factor-2, inactivating this protein. It does so by ADP-ribosylating the unusual amino acid diphthamide. In this way, it acts as a RNA translational inhibitor and the uncontrolled action of these exotoxins results in the death of the host cells. The catalyzed reaction is as follows:

$$\mathrm{NAD^{+}peptide\ dipthamide} \leftrightarrow \mathrm{nicotinamide+}$$
$$\mathrm{peptide} - N - (\mathrm{ADP} - \mathrm{D} - \mathrm{ribosyl})\mathrm{dipthamide}$$

Poly-ADP-Ribosylation

Multiple groups of ADP-ribose moieties can also be transferred to proteins to form long branched chains, in a reaction called poly-ADP-ribosylation carried out by the poly(ADP-ribose) polymerases (PARPs), which are found in most eukaryotes, but not prokaryotes or yeast. The poly(ADP-ribose) structure is involved in the regulation of several cellular processes.

Role of NAD in Repairing DNA Nicks

The role of nicotinamide in DNA repair and maintenance of genomic stability is tightly related to its functions as a precursor and a substrate for PARP-1. PARP-1 is a nuclear enzyme, which detects DNA damage, binds to DNA single- or double-strand breaks, and then uses NAD^{+} as a substrate to form nicotinamide and ADP-ribose. Subsequent enzymatic reactions lead to the formation of branched ADP-ribose polymers on a nuclear acceptor protein. Poly-ADP-ribosylation of the acceptor protein has been hypothesized to function in DNA repair by modifying structural proteins proximal to DNA strand breaks, facilitating the opening of the condensed chromatin structure, which is required for the recruitment of DNA repair complexes. Poly(ADP-ribose) glycohydrolase is the main enzyme involved in the catabolism of poly(ADP-ribose), reversing the automodified state of poly(ADP-ribose) polymerase; this reactivates the polymerase and restores DNA binding.

PARP-1 itself is also known to be part of chromatin structure and involved in maintaining a compact chromatin structure, preventing inadvertent transcription from occurring. Unfolding of the compact chromatin structure allows DNA regulatory and repair processes access to the damaged sites as well as to replication and transcription initiation sites. PARP-1 has been reported to play a key role in the nucleotide excision repair (NER) pathway used to remove bulky DNA adducts and in the base excision repair (BER) pathway by interacting with BER protein XRCC1 (x-ray repair cross complementing 1). PARP-1 is involved in maintaining chromosomal integrity by protecting broken DNA from inappropriate homologous recombination during DNA repair and replication. PARP knockout mice exhibited dramatically increased sensitivity to ionizing radiation and alkylating agents and showed a two- to threefold increase in spontaneous sister chromatid exchange (SCE) and amplified SCE and micronuclei (MN) formation induced by carcinogens. PARP-null mice also showed extreme sensitivity to nitrosamine-induced carcinogenesis and had shorter telomeres and increased end-to-end chromosomal fusions, aneuploid cells, and chromosome fragments. Thus, nicotinamide is involved in the maintenance of genomic stability by providing a substrate for PARP-1, preserving a cellular energy reserve for ATP-dependent DNA repair, and enabling preservation of PARP-1 integrity.

Role of Niacin in Diseases

Pharmacological levels of niacin (2–6 g day^{-1}), which are in excess of the RDA, have been used in attempts to treat Hartnup's disease, carcinoid syndrome, poor glucose tolerance, atherosclerosis, hyperlipidemia, schizophrenia, insulin-dependent diabetes mellitus, and a variety of skin disorders.

Historically, nicotinic acid has been administered to patients with a variety of disorders, often more for the dramatic skin reaction than proved curative powers. Its most successful use is for the treatment of hyperlipidemia.

Nicotinamide does not share these effects of nicotinic acid on lipid metabolism or its associated toxicity. However, it has been shown to act as an inhibitor of poly(ADP-ribose) synthetase in pancreatic β cells in animal studies, thereby protecting them from chemically induced diabetes, albeit sometimes complicated by β-cell tumor formation. Studies on human diabetes have so far yielded inconsistent results. One preliminary study suggested that nicotinamide may improve arthritis symptoms, including increased joint mobility and reduced amount of nonsteroidal anti-inflammatory drugs needed. Moreover, researches are going on for studying topical forms of nicotinic acid to treat rosacea, aging, attention-deficit hyperactivity disorder, migraines, dizziness, depression, motion sickness, and alcohol dependence and prevent skin cancer. Nicotinamide is applied to the skin for treating a skin condition called inflammatory acne vulgaris. One among every four men in the United Kingdom reportedly suffers erectile dysfunction at some point in their lives. Niacin plays a crucial role in nourishing the scalp and hair cells. Niacin and other B vitamins help body to produce energy from the foods. Getting too little niacin may drain your energy, making it difficult to burn more calories than one eat, an essential component of successful weight loss. Furthermore, many niacin-rich foods help with weight loss because they provide other nutrients, such as protein and fiber, that aid in healthy weight management.

Mechanism of Action in Cardiovascular Disease

Pharmacological doses of nicotinic acid (but not nicotinamide) are used as a cholesterol-lowering drug. Nicotinic acid has been found to result in markedly increased HDL-cholesterol levels, as well as decreased serum Lp(a) lipoprotein concentrations, and a shift from small dense low-density lipoprotein (LDL) particles to large, buoyant LDL particles, all of which are considered cardioprotective changes in blood lipid profiles. The mechanisms of action of high-dose nicotinic acid are unrelated to the formation of NAD(P) and unrelated to the actions of nicotinamide. The main effect is a decrease in lipolysis in adipose tissue due to an inhibition of adenylate cyclase activity. The resulting drop in cAMP levels leads to the decreased mobilization of fatty acids, which is at least partially responsible for a drop in very low-density lipoprotein (VLDL) formation by the liver and a subsequent drop in LDL levels, although there may also be direct effects on liver lipid metabolism. In addition to the blood lipid effects, high-dose nicotinic acid causes a dramatic skin flush of the face and upper

trunk. All of these blood lipid effects appear to be due to the binding of nicotinic acid to a high-affinity receptor, which is in turn linked to an inhibitory G protein, leading to decreased cAMP levels and inhibition of hormone-sensitive lipase. This receptor is known as the niacin receptor or HM74A. It is termed as an orphan receptor, as nicotinic acid is not thought to be its natural ligand, given the unphysiologically high doses required to activate it. The skin flush, which is mediated by prostaglandin formation, also appears to be caused by the binding of nicotinic acid to HM74A, in this case, on the surface of macrophages.

Interactions of Niacin with Drugs

Niacin interacts with some of the drugs resulting into various side effects. Allopurinol (zyloprim), probenecid, and sulfinpyrazone (anturane) are used to treat gout. Taking large doses of niacin along with these drugs might worsen gout and decreases their effectiveness. Clonidine and niacin both lower blood pressure, and ingestion of niacin in high amount with clonidine might cause blood pressure to become too low. Long-term use of nicotinic acid and nicotinamide might increase blood sugar and thereby might decrease the effectiveness of diabetes medications. Niacin can adversely affect the muscles; it was observed that taking niacin with statins can increase the risk of muscle problems. Taking nicotinic acid and/or nicotinamide and using a nicotine patch can increase the possibility of becoming flushed and dizzy.

Toxicity

Niacin from foods is not known to cause adverse effects. However, sometimes administration of chronic high oral doses ($>$1200 mg day^{-1}) of nicotinic acid used to lower the LDL cholesterol and triglyceride levels and massive consumption of foods fortified with high levels of niacin can lead to hepatotoxicity as well as dermatologic manifestations. In high doses, nicotinic acid competes with uric acid for excretion, culminating to increase in the incidence of gouty arthritis. Extremely high doses of niacin can also cause niacin maculopathy, a thickening of the macula and retina, which leads to blurred vision and blindness, whereas the complication was observed to be reversible after decreasing the niacin intake. The common side effects of niacin include flushing, itching, and gastrointestinal disturbances, such as dyspepsia, nausea, and vomiting. Hepatotoxicity (liver cell damage), including elevated liver enzymes and jaundice, has been observed at intakes as low as 750 mg of niacin per day for less than 3 months. In contradiction, nicotinamide is generally better tolerated than nicotinic acid, and generally, it does not cause flushing; however, nausea, vomiting, and signs of liver toxicity have been observed at very high doses (3 g day^{-1}). High dose of niacin can result into more complications in the prevalence of certain diseases like allergy, irregular heartbeat, diabetes, gout, gall bladder disease, liver and kidney disease, and stomach or intestinal ulcers. The US Food and Nutrition Board proposed an upper limit (UL) of 35 mg day^{-1} for niacin. This value was also set for pregnant and lactating adult women. The UL was adjusted for children and adolescents on the basis of relative body weight, and it is applicable to individuals who are being treated with a nutrient under medical supervision, such as for lowering of cholesterol levels. The tolerable upper intake levels (UL) of niacin for various age groups adopted by the US Food and Nutrition Board are given in Table 6.

Table 6 Tolerable upper intake levels (UL) of niacin for various age groups

Age groups	*Niacin equivalents (mg day^{-1})*
Infants, 0–12 months	Not possible to establish
Children	
1–3 years	10
4–8 years	15
9–13 years	20
Adolescents, 14–18 years	30
Men, 19 years and older	35
Women, 19 years and older	35
Pregnant women	35
Lactating women	35

Assessment of Niacin

Since the development of blood-based status analysis for niacin has lagged behind that of the other components of the vitamin B complex, therefore, some studies suggested that the erythrocyte concentration of the niacin-derived coenzyme NAD may provide useful information about the niacin status of human subjects, that a reduction in the ratio of NAD to NADP to below 1.0 in red cells may provide an evidence of niacin deficiency, and that a decline in plasma tryptophan levels may indicate a more severe deficiency than a decline in red cell NAD levels. The niacin coenzymes can be quantitated either by enzyme-linked reactions or by making use of their natural fluorescence in alkaline solution. At present, niacin status is most commonly assessed by the assay of some of the breakdown products of niacin coenzymes in the urine. Among these, N1-methylnicotinamide (NMN) is the easiest to measure, because of a convenient *in vitro* conversion to a fluorescent product, which can then be quantitated. However, more definitive and reliable information can be obtained by the measurement of urinary NMN in conjunction with one or more of the urinary pyridone turnover products (N1-methyl-2-pyridone-5-carboxamide and N1-methyl-4-pyridone-3-carboxamide), which can be detected and quantitated by UV absorption following high-pressure liquid chromatography (Figure 6).

Conclusion

Niacin a water-soluble vitamin plays a vital role in human body, deficiency of which results into 3 Ds of pellagra, that is, dermatitis, diarrhea, and dementia. It is available in different forms, out of which nicotinic acid has cholesterol-lowering

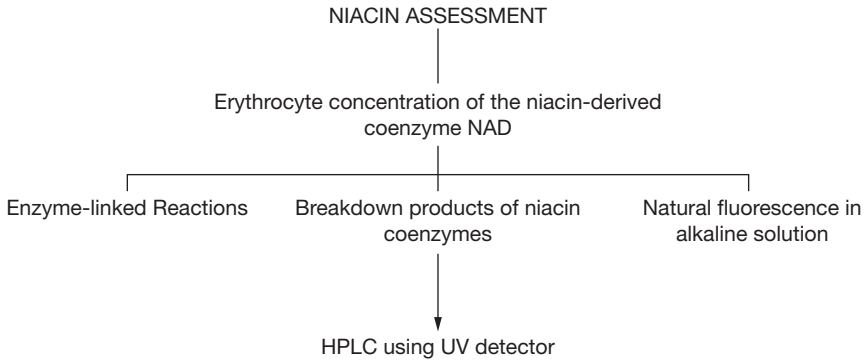

Figure 6 Methods for niacin assessment.

property. However, niacin overdose can also worsen the situation and might culminate to various health complications. Recent research has indicated that nicotinamide riboside uniquely supports neuronal NAD synthesis, thereby deserving future therapeutic studies. Niacin and some related compounds have many wide-ranging metabolic effects, and their medical significance has attracted renewed interest in recent years.

Nitrites and Nitrates

Sources and Production

All life requires nitrogen compounds. Nitrogen is the most abundant element in the atmosphere, making up 78% of the air we breathe. N_2 is chemically inert and must be converted to biologically active 'fixed' nitrogen. Through the atmospheric nitrogen cycle, elemental nitrogen (N_2) is fixed into usable forms for plants such as ammonia, nitrite, and nitrate by both lightning strikes and nitrifying bacteria. These nitrogen oxides participate in complex biological processes essential for agriculture and human biology. Any plants or vegetables grown in soil will accumulate nitrite and nitrate. As a result, when humans or other animals consume plants or vegetables, we are exposed to nitrite and nitrate. There are four primary sources of exposure to nitrite and nitrate: (1) endogenous production of nitric oxide (NO), (2) dietary exposure to nitrite and nitrates in food, (3) drinking water, and (4) swallowing saliva. The majority of exposure to nitrite and nitrate in most people is through dietary consumption of vegetables. Cured and processed meats contribute very little to the overall burden of exposure. Individual levels of exposure are dependent upon where and how one lives and works, what types of food one eats, endothelial function, and lifestyle habits. Adequate exposure to nitrite and nitrate from these sources poses little risk with known benefits.

Endogenous Production

Nitrite and nitrate are formed from the oxidation of endogenously produced NO. NO is produced by the enzyme nitric oxide synthase (eNOS) in the endothelial cells that line all blood vessels and lymphatic vessels throughout the body. NO is also produced within the nervous system (nNOS) and immune system (iNOS). NO is a potent vasodilator, inhibitor of platelet aggregation, and the active species of nitroglycerin. NO is synthesized by mammalian cells from L-arginine through a complex oxidation reaction catalyzed by the NOS enzymes. NOS catalyzes the NADPH- and oxygen-dependent oxidation of L-arginine to NO plus L-citrulline in a reaction that requires several cofactors in the presence of oxygen, including NADPH, FAD, FMN, tetrahydrobiopterin, heme, reduced glutathione, and calmodulin. The endogenous production of NO by NOS has been established as playing an important role in vascular homeostasis, neurotransmission, and host defense mechanisms. In fact, NO is one of the most important molecules produced within the human body. The major metabolism of NO is the stepwise oxidation to nitrite and nitrate. In plasma, NO is oxidized almost completely to nitrite, in which form it will remain stable for several hours. In contrast, NO and nitrite are rapidly oxidized to nitrate in whole blood. NO can also be enzymatically oxidized to nitrite by ceruloplasmin or other metal-containing proteins. The half-life of NO is about 1 s, whereas the half-life of nitrite in human blood is about 110 s when produced within the vascular compartment. Nitrite, when consumed orally, can have a half-life of greater than 1h. Nitrate, by contrast, has a circulating half-life of 5–8 h. During fasting conditions with a low previous intake of nitrite-/nitrate-rich foods, enzymatic NO formation accounts for the majority of nitrite and nitrate in the human body. It is now estimated that our body (average 70 kg) produces 1.68 mmole NO per day (based on 1μmole per kg h^{-1} NO production) in a healthy individual. The majority of this NO produced will end up as nitrite and nitrate. In the plasma, steady-state concentrations of nitrite are conserved across various mammalian species, including humans, in the range of 150–600 nM. It has been shown that up to 50–70% of plasma nitrite is derived from eNOS activity in fasted humans and other mammals. As much as 50% of NO activity/availability can be derived from eating nitrite- and nitrate-rich foods. This becomes extremely important when one realizes that you can combat conditions of low vascular NO production through consuming nitrite- and nitrate-rich foods.

Diet

Diet is considered the largest source of nitrite and nitrate exposure. Nitrite and nitrate have been used for centuries in curing and preserving meats and fish and in manufacturing certain cheeses. These two anions are also found naturally in certain foods, primarily green leafy vegetables. When added to foods, specifically meats for curing, nitrite has at least three functions. Firstly, it contributes to the flavor due to the inhibition of the development of rancidity. Secondly, it reacts with myoglobin to give mononitrosylhemochrome, which give the characteristic pink color of cured meat. Thirdly, it inhibits the growth of food spoilage bacteria, most importantly, *Clostridium botulinum*. *C. botulinum* thrives under anaerobic conditions and produces a neurotoxin, which is one of the most lethal natural products known. In this regard, nitrite is critical to the food and meat industries. Vegetables contribute over 85% of the daily dietary intake of nitrate and nitrite. We and others have estimated that approximately 80% of dietary nitrate and nitrite are derived from vegetable consumption. Therefore, the primary source of exposure to nitrate by humans is through eating vegetables. Most people would not argue that a diet rich in vegetables is healthy. Recent reports have shown that less than 5% of the ingested nitrite and nitrate are derived from cured meat sources with the remainder 10–15% coming from drinking water and our own saliva.

Historically, much of the quantified exposure of nitrite and nitrate has been based on the focus of dietary ingestion and endogenous formation of nitrosamines as a cause of human cancers. What is often not understood is that nitrite and nitrate are essential for growth and reproduction of all plant and animal life. Nitrogen is a basic constituent of proteins. The form of nitrogen within plants when consumed by animals,

including humans, has important effects on growth and reproduction. Several different groups of nitrogen-containing compounds may be found in plants. The amount of each form depends on plant species, maturity, and environmental conditions during growth, amount of sunlight, and time of harvest. These nitrogen compounds may be broadly classified as either protein or nonprotein compounds. Under normal growing conditions, plants use nitrogen to form plant proteins. When normal growth is affected, protein formation may be slowed, and the nitrogen content in the plant may then become nonprotein nitrogen. Nitrate, nitrite, amides, free amino acids, and small peptides make up most of the nonprotein nitrogen fraction. Nitrate is a natural material in soils. Adequate supply of nitrate is necessary for good plant growth. More than 90% of the nitrogen absorbed by plants is in the form of nitrate. Soils can be supplemented with nitrogen often in the form of ammonium nitrogen (NH_4^+), which is rapidly converted to nitrate (NO_3^-) in the soil by nitrifying bacteria. Chemical fertilizers may be composed of ammonium nitrate, ammonium phosphates, ammonium sulfate, alkaline metal nitrate salts, urea, and other organic forms of nitrogen. Microorganisms must change organic nitrogen to ammonium or nitrate ions before plants can use it. Usual release of available nitrogen from soil organic matter is 1–4% annually, depending on soil texture and weather conditions. Animal manure is an excellent source of nitrogen and can contribute significantly to soil improvement. Animal manure contains about 10 lb of nitrogen per ton, poultry manure 20 lb per ton, and legume residues 20–80 lb per ton. About half of this organic nitrogen may be converted to nitrate nitrogen and become available for plant use the year it is added to the soil. However, if it is low in phosphorus content; excessive manure applications can result in toxic levels of nitrate in forage crops the same as excessive use of chemical nitrogen fertilizer. Adding phosphate fertilizer to manure can reduce the nitrate content in the crop produced.

Nitrate content of plants is determined by their inherited metabolic pattern (genetics) and the available nitrate in the soil. Applying fertilizer in amounts beyond the ability of the vegetable crop to use them may result in an accumulation of nitrate, particularly if some other essential nutrient is not adequate, such as phosphorus. Leafy green vegetables and some root crops naturally contain nitrates, and there are wide variations between species and even variations between geographic regions in which they are grown. There are also seasonal differences. Nitrate content in spinach can be almost twice as high in autumn–winter harvest as in spring harvest. Disruption of normal plant growth increases the probability for nitrate accumulation in leaves, stems, and stalks. Factors favoring accumulation of nitrate in plants include drought, high temperatures (rapid transpiration of water), shading and cloudiness (reduced protein synthesis), deficiency of other plant growth nutrients (phosphorus, potassium, and calcium), excessive soil nitrogen (manures, legume, residues, effluents and solid wastes, and nitrogen fertilizer), damage from insects and certain weed control chemicals, and immaturity at harvest. As a result of all of these factors, nitrate content of vegetables is highly variable but still represents the main dietary source of nitrate. A survey of several vegetables from five different US cities reveals that the nitrite and nitrate content can vary by as much as 500-fold in the same vegetable purchase at retail in different cities. This creates a real problem when trying to get an average of nitrite and nitrate content for estimation of exposure across the United States.

Breast milk is nature's most perfect food and is the primary nutrient source for infants. Previously published studies in our lab reveal the presence of high concentrations of nitrite and nitrate in human breast milk. Early-postpartum breast milk from certain mothers contained the highest nitrite concentration of any food or beverage product tested (near 20 μM). This becomes extremely interesting in terms of levels of nitrite exposure determined from ingestion and based on body weight of an infant (near 1 mg kg^{-1}). Nitrite and nitrate not only are important for adult nutrition and diet but also are very important for infants. In fact, formula-fed babies do not receive any nitrite and nitrate from the formula and may be a possible mechanism for the health disparities between breast-fed and formula-fed babies.

Drinking Water

Even though drinking water usually contains very low levels of nitrate and nitrite, when large volumes are consumed, this can be a significant source for ingestion. The US Environmental Protection Agency regulates nitrate and nitrite contamination levels in approximately 160 000 different water supplies across the United States and does periodic monitoring. The regulatory maximum contaminant level (MCL) for nitrate is 10 mg l^{-1} nitrogen from nitrate, which equates to 44 mg nitrate ion per l. For nitrite, the MCL is 1 mg l^{-1} nitrogen or 3.3 mg l^{-1} nitrite ion. Using these maximum values as an estimate for intake may provide a crude estimate of an upper limit for the drinking water contribution to ingestion of nitrite and nitrate in the United States. Recommended dietary consumption of water and beverages is listed at 2.7 l per day for adult males and 2.2 l per day for females. Thus, as much as 60–119 mg per day nitrate ingestion from drinking water may occur in drinking water meeting legal standards. Likewise, as much as 4.6 to 8.9 mg per day of nitrite may also be ingested from drinking water.

The natural background levels of nitrate and nitrite are very low in water, generally < 10 mg l^{-1} for the former and rarely over 3 mg l^{-1} for the latter. The increased use of nitrogen fertilizers in agriculture during the second half of the twentieth century contributed to potential contamination of water supplies by nitrate-containing runoff from farms to watersheds that ultimately became sources of drinking water. Levels of nitrate can be significantly higher in shallow wells that are connected to agricultural runoff. Much less is known about private wells, which in the United States are usually required to be tested only when the well is constructed or when the property is sold.

Saliva

Similar to the environmental nitrogen cycle, there is now a recognized human nitrogen cycle (Figure 1), whereby nitrate is reduced to nitrite and to NO. Nitrate, after its absorption in the upper gastrointestinal tract, reaches the salivary glands via the blood circulation where it is secreted into the oral cavity and partially reduced to nitrite by the oral microflora. There is a

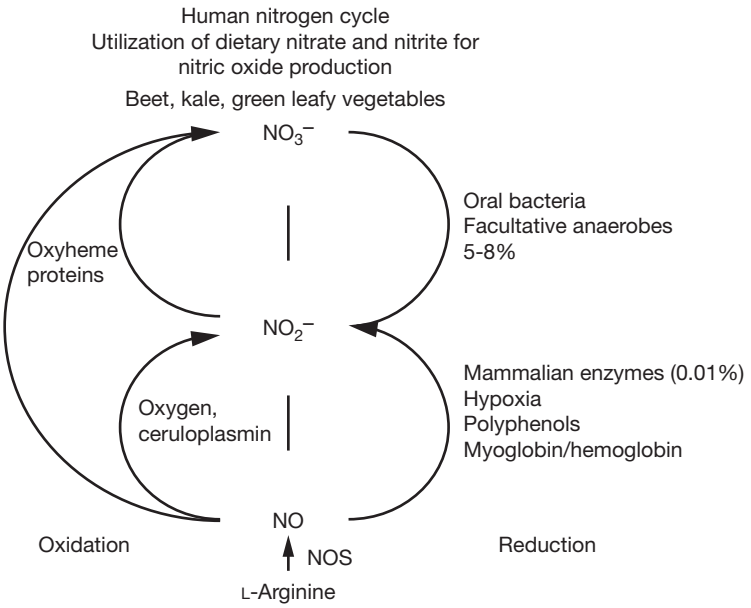

Figure 1 Nitrate: nitrite: nitric oxide recycling pathway.

linear relationship between the amounts of nitrate ingested and amounts of nitrate and nitrite found in saliva. The ability of the oral microflora to reduce nitrate to nitrite depends on the individual community of oral commensal bacteria. Age may also be a factor. Mean salivary nitrite was found to increase from well below 1 ppm in infants of up to 6 months to about 7 ppm or higher in adults, but levels over 500 mg l^{-1} have been reported to occur subsequent to consumption of nitrate-rich foods. Early work by Tannenbaum et al. reported that nitrite in saliva of healthy individuals is 6–10 mg l^{-1} and higher levels in the hundreds of mg l^{-1} could form under conditions of very high nitrate intake and active bacterial reduction in saliva. Recently, it was reported that salivary nitrite levels in fasting individuals were 1.9 mg l^{-1}, which were increased to near 100 mg l^{-1} after a standardized nitrate load of 4.6 mg kg^{-1} body weight was administered. It is extremely difficult to accurately quantify the contribution of saliva to nitrate and nitrite ingestion and exposure, but it must be considered to be a major source. The current consensus is that as much as 25% of dietary, water-solubilized, and endogenously generated nitrate is recycled in the body via the enterosalivary route and that up to 20% of that nitrate pool is reduced in the saliva by commensal bacteria. Based on an average 2.0 mg l^{-1} concentration of nitrite in saliva and secretion of 1.5 l per day, saliva can commonly be a source of as much 15 mg ingested nitrite per day, but under conditions of sustained nitrate intake from vegetables, this could go even higher.

Although it is not widely realized, potassium nitrate is used in many toothpaste formulations to reduce sensitivity. Potassium nitrate is the active antisensitivity ingredient that penetrates the exposed tubules (tiny holes) of the teeth to relieve the pain from sensitive nerves inside teeth. Additionally, it is one of the ADA-approved ingredients to treat tooth hypersensitivity. Toothpaste designed for sensitive teeth is formulated with up to 5% (5000 ppm) potassium nitrate, which is higher than the concentration found in vegetables. Since toothpaste is not commonly swallowed, the net contribution to nitrate and nitrite exposure cannot be accurately estimated. However, nitrate and nitrite as water-soluble ions are likely to be extracted from the toothpaste and mixed with saliva. The total exposure could therefore be equivalent to or greater than that contributed by water or cured processed meats.

Patterns of Consumption

The National Research Council report The Health Effects of Nitrate, Nitrite, and N-Nitroso Compounds (NRC 1981) reported estimates of nitrite and nitrate intake based on food consumption tables. They report that the average total nitrite and nitrate intakes in the United States were 0.77 and 76 mg, respectively, per day. The mean intake estimates for nitrate and nitrite in the United States and Europe vary by investigator but are consistent and comparable. International estimates of nitrate intakes from food are 31–185 mg per day in Europe and in the United States about 40–100 mg per day. The bioavailability of dietary nitrate is 100%. Nitrate intakes from sources other than vegetables, including drinking water and cured meats, have been estimated to average 35–44 mg per person per day for a 60 kg human. Nitrite intakes vary from 0 to 20 mg per day or up to 0.25 mg kg^{-1} body weight. Based upon a conservative recommendation to consume 400 g of different fruits and vegetables per day at median nitrate concentrations, dietary concentration of nitrate would be ~157 mg per day. In the EU population, where fruit consumption (nitrate concentration averaging <10 mg kg^{-1} FW) constitutes over half the 400 g intake recommendation, actual nitrate intakes would approximate 81–106 mg per day before additional nitrate losses are taken into consideration based on washing, peeling, and/or cooking. The Dietary Approaches to Stop Hypertension (DASH) studies found that diets rich in

vegetables (i.e., 8–10 servings) and low-fat dairy products can lower blood pressure to an extent similar to that achieved with single hypertensive medications. We have previously demonstrated that persons consuming the DASH (Dietary Approaches to Stop Hypertension) diet could consume upward of 1000 mg of nitrate per day or roughly 12.5 mg kg^{-1} per day and may explain the mechanism of action for the antihypertensive effects of the DASH diet.

The Mediterranean diet, which is known to be cardioprotective and confer anticancer properties, is inherently high in nitrate. Green leafy vegetables and cured meat are staples of the dietary patterns of the people in the Mediterranean regions. Multiple studies now reveal that the health benefits of the Mediterranean diet may be partly due to the nitrite and nitrate content of their diet. Similar studies have been reported for the Japanese diet. Dietary nitrate in Japanese traditional foods lowers diastolic blood pressure in healthy volunteers. Since the majority of nitrite and nitrate are derived from green leafy vegetables, any diet rich in vegetables will increase the daily exposure to nitrite and nitrate, particularly vegetarians. Most if not all of the epidemiological data to date reveal that a diet rich in green leafy vegetables is extremely healthy and can prevent many diseases. We may now have a mechanism that explains some or most of the health benefits from certain diets and dietary patterns through their nitrite and nitrate content.

Availability, Absorption, and Metabolism

Nitrate ingested from the diet is rapidly absorbed in the small intestine, mixes with the endogenous nitrate from oxidation of NO, and is readily distributed throughout the body. About 25% of an oral nitrate load is concentrated and excreted by salivary glands, so that salivary nitrate concentration is approximately 10 times higher than plasma nitrate. Approximately 20% of salivary nitrate is reduced to nitrite in the mouth by facultative anaerobic bacteria, which are found on the surface of the tongue, resulting in about a 5% reduction of total ingested nitrate to nitrite. Swallowed nitrite in the saliva then disproportionates with the formation of NO (nitrite $pK_a \sim 3.4$) after entering the acidic environment of the stomach, helping to reduce gastrointestinal tract infection and increase mucous barrier thickness and gastric blood flow. As a result, nitrate ingestion is the main source of nitrite exposure in humans through the bacteria reduction of nitrate to nitrite. This biochemistry has been demonstrated stoichiometrically in mice fed twenty times higher nitrate than nitrite. Humans, unlike prokaryotes, are thought to lack the enzymatic machinery to reduce nitrate back to nitrite, so this pathway is largely dependent upon oral commensal bacteria to reduce nitrate to its active form nitrite. Nitrate when consumed orally reaches a peak plasma concentration in about 1 h. Since nitrate is a relatively small anion and is not protein-bound, its pharmacokinetics and half-life suggest that it is reabsorbed in the renal tubules. Nitrate is excreted in the urine directly or after conversion to urea. Clearance of nitrate from the blood to urine approximates 20 ml min^{-1} in adults indicating considerable renal tubular reabsorption of the ion. It is estimated that 96% of the filtered nitrite and nitrate are reabsorbed in the renal tubules. Other studies in dogs suggest that approximately 80% of filtered nitrate is reabsorbed. The high concentration of nitrate and nitrite in saliva, continuous production from NO in the vascular compartment, and then reabsorption from renal tubules strongly suggest that nitrate and nitrite have a definite role in normal human physiology. They serve as important substrates for NO production.

Nitrite and nitrate have many functions in the skin, including the mediation of inflammation and antimicrobial defense, wound healing, regulation of keratinocyte homeostasis, and regulation of apoptosis following ultraviolet (UV) radiation via their metabolism to NO. Nitrate, nitrite, or nitrosothiols present on the skin are stable until cleaved by UV to release NO. This may explain in part the health benefits of moderate sunlight exposure. Nitrate and nitrite found in sweat are very important in the production of NO. The concentration of nitrite and nitrate in and on our body is controlled by dietary intake of these anions and endogenous production from the oxidation of NO and the presence of denitrifying bacteria.

Health Effects

The number of basic science reports and even clinical reports on the use of nitrite and nitrate has risen dramatically over the past decade. According to clinicaltrials.gov, there are now over 45 clinical trials using sodium nitrite and over 50 studies using sodium or potassium nitrate for specific human diseases. Some of the earliest studies on the cardioprotective and hepatoprotective effects of nitrite were conducted in mice. Nitrite has been shown to clearly protect the heart from injury from heart attack, suppress microvascular inflammation, prevent renal injury from hypertension, and reverse vascular endothelial dysfunction and large elastic artery stiffness with aging. A study administering a sodium nitrite capsule to diabetics found that a single administration of 80 mg sodium nitrite was well tolerated. The single dose caused a significant drop in systolic blood pressure with no effect on the diastolic pressure. Plasma nitrite levels rose between 3 and 4 μM. The dose used in that study is far greater than what could be consumed through a diet. Studies using a patented formulation (US patents 8 303 995, 8 298 589, and 8 435 570) using 15–20 mg of sodium nitrite in the form of an orally disintegrating tablet found that it could modify cardiovascular risk factors in patients over the age of 40, significantly reduce triglycerides, and reduce blood pressure. This same lozenge was used in a pediatric patient with argininosuccinic aciduria (ASA) and significantly reduced his blood pressure when prescription medications were ineffective. A more recent clinical trial using the nitrite lozenge reveals that a single lozenge can significantly reduce blood pressure, dilate blood vessels, and improve endothelial function and arterial compliance in hypertensive patients. Furthermore, in a study of prehypertensive patients (BP $>120/80<139/89$), administration of one lozenge twice daily leads to a significant reduction in blood pressure (12 mmHg systolic and 6 mmHg diastolic) after 30 days. These studies clearly demonstrate the safety and efficacy of low doses of nitrite in humans, either consumed as a therapy or consumed through the diet.

Nitrate itself is inactive and without effect. Nitrate must first be reduced by oral commensal bacteria to nitrite, and then,

nitrite has biological activity. As described in the preceding text, only about 5% of the total nitrate is reduced to nitrite. All biological effects of nitrate are abolished by antiseptic mouthwash that kills oral bacteria. There are now many studies showing health benefits in humans of dietary nitrate including blood pressure regulation and sports performance. Nitrate administered in the drinking water of mice deficient in the enzyme that makes NO can reverse features of metabolic syndrome. Nitrate studies have now been translated to humans. For the majority of studies in humans, beetroot juice has been the dietary nitrate source of choice. However, to obtain sufficient nitrate levels for improved performance, a minimum of 500 ml of beetroot juice needs to be provided at least 2.5 h prior to exercise in order to allow sufficient time for enterosalivary circulation and reduction to nitrite. Research indicates that raising the nitrate and nitrite levels in the body prior to exercise by consumption of dietary nitrate can increase NO production and lead to an increased oxygen efficiency and exercise performance. Consumption of 500 ml of beetroot juice, which is high in dietary nitrate (527 mg), 2.5 h before exercise improved the power output and performance of 9 club-level competitive male cyclists during a 4 km and 16.1 km cycling time trial compared to placebo. Additionally, in another study in older adults, dietary supplementation with beetroot juice, containing approximately 400 mg nitrate per dose twice per day (816 mg total), increased plasma nitrite concentration, reduced blood pressure, and positively influenced physiological responses to exercise. Nitrate supplementation at a dose of 6.62 mg kg^{-1} can also enhance exercise performance in patients with peripheral artery disease. Improvements in exercise performance following beetroot juice consumption have typically been found to range between 2% and 16% and demonstrated in such exercise modalities as running, cycling, rowing, and resistance exercise.

There are also several studies showing blood pressure-lowering effects of nitrate when consumed through beetroot juice. Investigators have administered 0.5 l of 15 mM (638 mg) nitrate to healthy adults and found that it lowered blood pressure 6 h later. Others have administered potassium nitrate capsules containing 700 mg or 1488 mg of nitrate or had patients drink beetroot juice that contained 468 mg of nitrate and found that all forms of nitrate led to a dose-dependent decrease in blood pressure beginning after 90 min and lasting for several hours. Consumption of 0.1 mmol kg^{-1} body weight nitrate (595 mg for a 70 kg adult) for 3 days can significantly reduce diastolic blood pressure. The diastolic blood pressure was on average 3.7 mmHg lower after nitrate supplementation than after placebo supplementation, and the mean arterial pressure was 3.2 mmHg lower. These authors state that this is the equivalent of nitrate found in 150–250 g of green leafy vegetables or beets. Similarly, other investigators demonstrate that drinking (0.5 l per day; 5.2 mmol of NO_3 per day) of beetroot juice (442 mg per day) acutely reduces blood pressure and the oxygen cost of submaximal exercise and that these effects are maintained for at least 15 days if supplementation is continued. Interestingly, in another study, supplementation of the diet with 7.5 mmol (638 mg) of nitrate per day for 2 weeks caused an increase in plasma nitrite and nitrate concentration, but did not lower blood pressure, improve endothelial function, or improve insulin sensitivity in individuals with type II diabetes. There appear to be patient populations that do not respond to nitrate. Administration of 9.3 mg kg^{-1} sodium nitrate for 4 weeks to older patients with increased cardiovascular risk profiles can reverse vascular dysfunction. There is a relatively large range of nitrite and nitrate dosing that has been studied in humans and mice that provide clear therapeutic benefit without any signs of toxicity.

Summary

As science advances and new discoveries and understanding are made apparent, it is important to be able to incorporate these new findings into meaningful guidelines that can enhance health, lengthen life, and reduce illness and disability. It is known that it takes approximately 17 years for new basic science discoveries to become standard of care or be fully implemented into public health. As Paracelsus exclaimed, "the dose makes the poison." There are clear and delineated doses of both nitrite and nitrate that provide indisputable evidence of promoting health and even treating serious medical conditions. Fortunately, these doses fall well below toxic and fatal doses. This provides a sufficient range that can safely be achieved from diet alone. At a time when the globe is faced with epidemics of heart disease, obesity, and metabolic syndrome, we can no longer ignore fundamental nutritional, biochemical, and physiological benefits of nutrients found in the most healthy and nutritious foods, nitrite and nitrate, especially since the etiology of the aforementioned diseases is based on poor diet and nutrition. As with any nutrient, it is time to consider the risk–benefit analysis of nitrite and nitrate. It is known that lowering blood pressure by just 5 mmHg reduces the risk of stroke by 35% and the risk of ischemic heart disease by 21%, the top two killers of people worldwide. There are now clear, indisputable blood pressure-lowering effects of dietary nitrite and nitrate by at least 5 mmHg. By recognizing these relatively new findings and implanting nutritional and dietary interventions with sufficient nitrite and nitrate, perhaps, 35% or roughly 6 million deaths could be prevented each year. I have referred to nitrite as a vitamin previously and even proclaimed it 'vitamin N,' but perhaps, it may fit the characteristics of a dietary mineral. A mineral is by definition a solid inorganic substance of natural occurrence. After all, sulfates and phosphates are recognized minerals, and nitrite and nitrate are similar in structure and composition except replacing the sulfur and phosphorus with nitrogen, respectively, with different oxidation states. How we classify nitrite and nitrate may not be important at this stage other than to finally recognize them for nutrients that they are. The underlying chemistry of these two anions must be controlled for to maximize the benefits while preventing any unwanted nitrosation chemistry causing *N*-nitrosamine formation. Nutritionists, physiologists, physicians, toxicologists, meat scientists, and dieticians from both academia and industry need to converge to recognize and establish nutrient guidelines for nitrite and nitrate similar to other well-recognized nutrients. The data and facts are now available for such an initiative. It is time to change the dialogue from one of avoiding nitrite and nitrate in the diet to one of including sufficient amounts to achieve the well-documented health benefits from them.

Novel Foods

S Hendrich, Iowa State University, Ames, IA, USA

© 2016 Elsevier Ltd. All rights reserved.

The term 'novel foods' is a food regulatory construct currently enacted in some form in the European Union, the United States, Canada, China, South Korea, Japan, Singapore, Australia, and New Zealand and other countries. In the United States, regulations related to novel foods fall under the category of 'new dietary ingredients' (NDIs), a part of the Dietary Supplement Health and Education Act (DSHEA). Novel foods include foods or food ingredients that have not been used to any significant extent in the particular country prior to the date of the regulation. Such regulations have been in place since the late 1990s and pertain to a number of different types of foods/ingredients (Table 1). The safety of novel foods is the driving concern for such regulations. The novel food must be shown to not cause harm when ingested. Harm may be due to toxicants present in the novel food. As an example, the introduction into soybeans of a gene coding for a known allergenic protein from Brazil nut created allergic responses in skin prick tests of individuals with a Brazil nut allergy. This finding halted further development of that variety of genetically modified (GM) soybeans for use as a food for humans and has remained an obvious, crucial cautionary example in the realms of GM technology and novel foods. But harm might also occur if the novel food is intended to be used to substitute for a conventional food, yet the novel food is lacking key nutrients present in the conventional food. For example, an orange-colored and orange-flavored drink that mimicked orange juice but did not contain substantially equivalent amounts of vitamin C and folic acid would be of concern for consumer safety by this criterion. Providing appropriate information to consumers through labeling of novel ingredients or ingredients that may pose ethical concerns for some consumers has also been a driving force for novel food regulations, especially in the European Union. Labeling of novel foods remains controversial, mostly in relation to GM foods. Such labeling is not mandated in the United States, but a number of states have attempted to enact 'right to know' labeling for GM foods, with Vermont recently passing such a law. A petition to US Food and Drug Administration (FDA) to require GM food labeling was submitted in 2011 by the Center for Food Safety, a nongovernmental organization with headquarters in Washington DC, but the petition has yet to be acted upon. US federal legislation has been introduced to block state 'right to know' laws, but this also remains to be acted upon.

Novel Food Categories and Examples

Most novel foods appearing in the novel food catalog of the European Union are in the category of plant species or products derived from plant species with no significant history of use in European countries. Novel foods generally fall into one or more of four subcategories:

- Plant species or components (e.g., leaf, bark, and root) used as alternative food ingredient sources
- Fruits and vegetables not native or unfamiliar to the country
- Plant species or components with medicinal uses but unfamiliar to the country
- New pure food ingredients derived from plant species

Many of the plant species listed by the EU as novel foods are sources of food ingredients. The extraction or other preparation of such ingredients may serve as alternatives to traditional ingredient sources. Examples include *Abies alba* (European silver fir) from which an essential oil for flavoring may be derived; *Agave sisalana*, a source of fructose syrup; and *Acacia nilotica* (prickly acacia or wattle) as a source of gum Arabic.

Tropical fruits and unusual vegetables are also included as novel foods. Breadfruit (*Artocarpus altilis*) and kiwi fruit (*Actinidia deliciosa*) are examples. Examples of novel vegetables include sea aster (*Aster tripolium*), a salt-tolerant plant that grows in marshes that may be eaten as a young plant, and *Atriplex hortensis*, orache, or mountain spinach. The acidic green or red leaves may be used in salads.

Examples of medicinal plants or plant components in the novel food catalog include root extract of *Astragalus membranaceus*, which is thought to benefit heart disease and suppress inflammatory responses, based on *in vitro* and animal model studies. *Angelica sinensis* or dong quai, a perennial in the carrot family, is a botanical listed among novel foods that may be marketed as relieving hot flushes during menopause, but very limited clinical trial data do not support that use.

New pure food ingredient examples include agmatine ((4-aminobutyl) guanidine sulfate), which had protective effects against Alzheimer's disease in a rat model, but no human trials have yet been published on this compound. Agmatine is found in plant foods, fish, and meat and is produced by bacteria. Fermented cabbage, soy, meats, and cheeses contain a few mg agmatine per kg versus much lower to nondetectable amounts in nonfermented similar foods, as reviewed by Galgano et al. Arabinogalactan is another novel ingredient, derived from larch wood and classified as 'generally recognized as safe' for use as a food gum.

NDIs: Novel Foods in the United States

In the United States, examples of NDIs from the inception of DSHEA through 2004 were well described in a review of this aspect of DSHEA by McGuffin and Young. The American Herbal Products Association (AHPA) maintains a NDI database that includes nearly 700 items to date. This database is accessible only by subscription. The regulation of NDIs is intended to keep drugs separate from foods. For example, FDA ruled that acamprosate (acetyl homotaurine, a synthetic amino acid used to help maintain sobriety in individuals who have abused ethanol) and idebenone (a synthetic analog of coenzyme Q_{10} that is being investigated for efficacy in treating

Table 1 Novel foods and food ingredients: categories and examples

Category	*Description and notes*	*Examples*[a]
Pure chemical	New food additives. Regulated under food additive laws	Carnosine, antioxidant found naturally in meats Lycopene, antioxidant found in tomatoes
Genetically modified plant, animal, or microorganism with a history of use as a food source or source of food ingredient	Organism modified by insertion of a new gene or genes, from either the same species or a different species (transgenic). Standard of 'substantial equivalence' may permit use, that is, that the genetic modification does not substantially change the food product composition (<10% difference in amount of food chemical component such as protein, starch, and vitamin)	Foods or food ingredients derived from genetically modified maize line NK 603 Foods or food ingredients derived from Roundup Ready maize line GA21
Genetically modified plant, animal or microorganism with *no* history of use as a food source or source of food ingredient	Organism modified by insertion of a new gene or genes, from either the same species or a different species (transgenic)	None approved to date
Complex novel food, not genetically modified	New food or food with novel ingredients from nongenetically modified sources	Dragon fruit (in countries outside Southeast Asia) Chia seed Margarine-type spread containing phytostanols
Food processed by a novel technology	New processing methods that have the potential to change nutritional composition of a food or introduce toxic substances into the food	High-pressure pasteurized fruit products (juices and pastes)
Cloned animals	Animals derived from cloning	None approved to date, proposed EU regulations to ban cloned animals as food sources were tabled in 2013

[a]Examples from the European Union Novel Food Catalogue (http://ec.europa.eu/food/food/biotechnology/novelfood/novel_food_catalogue_en.htm) or list of authorizations (http://ec.europa.eu/food/food/biotechnology/novelfood/authorisations_en.htm).

several neurological diseases) were not to be considered NDIs. Purified trans-resveratrol, while a component of grapes and some other plants, was also deemed by FDA not to qualify as a NDI. Such purified plant constituents, as opposed to plant extracts containing trans-resveratrol, would require investigational new drug applications to be approved by FDA for their further development for use by humans. The reason for this is that even if the constituent is to be used in amounts similar to that in a food, humans have not been exposed to the pure compound, which might act differently when completed and separated from its food matrix. Effective doses of purified food constituents for disease prevention or treatment may be many-fold greater than what would be possible to obtain from the food. For example, a trial of resveratrol in mice with diet-induced obesity showed that 22 mg resveratrol per kg body weight increase longevity and significantly suppressed adverse metabolic effects of obesity while not reducing body weight. This dose, on a surface area-equivalent basis, would be about 100 mg resveratrol per person. Resveratrol concentration in a type of red wine was about 2 mg l^{-1}. Needless to say, 50 l of wine per day would not be a feasible, effective resveratrol source. Thus, resveratrol in the context of preventing adverse effects of obesity would seemingly be needed in pharmacological rather than dietary amounts.

Investigational new drug (IND) applications must include animal pharmacology and toxicology studies across doses and time periods of intended use of the new drug; detailed information about the manufacturing, composition, and stability of the new drug; and information about the clinical trial protocols including investigator qualifications and risk assessment so that FDA can assure safety of the trial participants before the new drug is investigated. IND applications require considerable financial resources.

It is not uncommon for dietary constituents to have the ability to prevent, mitigate, or treat diseases and to help in the maintenance of health, either in general or for specific organs or functions of the body. Further, in the interest of separating drugs from foods, food labeling regulations require FDA approval for a 'health claim' to be made about a food or food ingredient/component. A 'health claim' is basically that a food or food ingredient acts similarly to a drug (prevents, mitigates, or treats a disease). For what is referred to as an 'unqualified' health claim to be permitted on a food label, vast amounts of human clinical trial data and other safety and efficacy data must be submitted by the petitioner, and an expert panel must agree that the preponderance of evidence supports the claim (Table 2). Lesser amounts of data may be submitted for varying levels of 'qualified' health claims (Table 2). Premarket notifications of an NDI for which a 'health claim' is not sought, but for which there is some reason to think a health benefit exists that does *not* involve prevention, mitigation, or treatment of a specific disease, are a way for food and food ingredient companies to introduce novel foods/ingredients that may benefit consumers' health, without meeting rigorous evidence standards or conditions required for marketing of disease-specific therapies, but permitting assurance of safety of the novel food/ingredient. Labels of products containing NDIs would not be permitted to bear health claims unless a

Table 2 Examples of food ingredients with varying levels of US FDA approved health claims

Food ingredient	*Health claim*	*Level of claim*
Whole oat-soluble fiber	Diets low in saturated fat and cholesterol that include soluble fiber from whole oats may reduce the risk of heart disease	Unqualified
Soy protein	Diets low in saturated fat and cholesterol that include 25 g of soy protein a day may reduce the risk of heart disease. One serving of (name of food) provides 6.25 g of soy protein	Unqualified
Plant sterol esters	Plant sterols: foods containing at least 0.65 g per serving of plant sterols, eating twice a day with meals for a daily total intake of at least 1.3 g as part of a diet low in saturated fat and cholesterol, may reduce the risk of heart disease. A serving of (name of food) supplies ( ) grams of vegetable oil sterol esters	Unqualified
Omega-3 fatty acids	Supportive but not conclusive research shows that consumption of EPA and DHA omega-3 fatty acids may reduce the risk of coronary heart disease. One serving of (name of the food) provides ( ) gram of EPA and DHA omega-3 fatty acids (see nutrition information for total fat, saturated fat, and cholesterol content)	Qualified – moderate level of scientific support
Monounsaturated fats from olive oil	Limited and not conclusive scientific evidence suggests that eating about two tablespoons (23 g) of olive oil daily may reduce the risk of coronary heart disease due to the monounsaturated fat in olive oil. To achieve this possible benefit, olive oil is to replace a similar amount of saturated fat and not increase the total number of calories you eat in a day. One serving of this product contains (x) grams of olive oil	Qualified – limited level of scientific support
Corn oil and corn oil-containing products	Very limited and preliminary scientific evidence suggests that eating about one tablespoon (16 g) of corn oil daily may reduce the risk of heart disease due to the unsaturated fat content in corn oil. FDA concludes that there is little scientific evidence supporting this claim. To achieve this possible benefit, corn oil is to replace a similar amount of saturated fat and not increase the total number of calories you eat in a day. One serving of this product contains (x) grams of corn oil	Qualified – lowest level of scientific support

separate health claim petition was approved. Products containing NDI may bear substantiated 'structure–function' claims that strictly avoid mention of efficacy against diseases, such as 'improves mental function,' 'improves bone health,' or 'helps with healthy aging.' FDA should be notified of, but does not approve, such claims. What constitutes substantiation of structure/function claims ranges from a history of use for certain functions to experimental evidence, but not necessarily involving human clinical trials.

From the review of the legal history of NDIs by McGuffin and Young, some patterns emerge. NDIs are almost entirely of botanical origins. They may take the form of a dietary ingredient, an extract, a source of a raw material, or a component of a dietary supplement. FDA may affirm, acknowledge, or reject premarket notifications of NDIs. For example, FDA affirmed that a dietary supplement containing 250 mg of the yeast *Phaffia rhodozyma* as a source of the carotenoid astaxanthin would reasonably be expected to be safe. FDA also affirmed conjugated linoleic acid as an NDI. FDA acknowledged an astaxanthin-containing extract of *Haematococcus pluvialis* with language indicating that the safety rationale presented was not inadequate, as it also did for a brand of krill oil. FDA rejected more than 25 NDI notices between 1994 and 2004. Examples include *Kalanchoe pinnata* leaf and *Sutherlandia frutescens* and *Hordeum vulgare* extract and *Echium plantagineum* as a seed oil source. *Kalanchoe pinnata* leaf may have been rejected because it contains cardiotoxic bufadienolides. Although *Sutherlandia frutescens* did not show toxicity in a limited number of animals and short-term human phase I trials, it contains ~2 mg canavanine per g leaf, a nonprotein amino acid shown to exert toxicity in animal studies. *Hordeum vulgare* (barley straw) extract was shown to have mutagenic activity, which presumably would have raised concern with FDA. *E. plantagineum* (also known as purple viper's bugloss) contains a mixture of fatty acids including stearidonic acid that may suppress inflammatory responses in patients with asthma, but this plant is also a good source of pyrrolizidine alkaloids that are hepatotoxic to humans and livestock, causing severe illness in some cases. These compounds are soluble in ethanol and would not be expected to carry over in high concentrations into oil extracted from the plant material, but this seems not to have been studied to date. Thus, FDA may have acted out of caution for potential toxicity to reject an NDI notification for this oil source. Recent examples of NDIs filed by the FDA are noted in Table 3; most are new sources or derivatives of essential nutrients.

Table 3 Recent examples of new dietary ingredient notifications filed by US Food and Drug Administration

Ingredient name	*Year*
Almega PL omega-3 oil from microalgae *Nannochloropsis oculata*	2014
PureQQ pyrroloquinoline quinone	2013
Quatrefolic®, (6S)-5-methyltetrahydrofolic acid glucosamine salt	2010
AlgaeCal, calcium carbonate, and magnesium carbonate derived from marine algae	2009
Diosmin, inulin, and inulin-type fructans	2008
Capsiate Natura and capsiate (capsinoid) supplement	2007

Safety Assessment: Best Practices for Novel Foods and NDIs

Safety of novel foods may well be assessed according to principles published in 2003 laid out by an expert group from

International Life Sciences Institute (ILSI) Europe (http://ilsi.org/Publications/14_ILSI-safetyNovelFood.pdf). Before toxicology testing, consideration of the chemical structure of the pure ingredient or key constituents of the novel food may predict the likelihood of uptake and bioavailability of the substance and toxicity. Large (molecular weight >500), nondigestible, and water-soluble substances would be much less likely to be absorbable or take up into body tissues. Mutagenicity, for example, is well characterized chemically, and predictive computer programs are available that may assist in ruling out this possibility for the new ingredient or novel food.

Assessing the intended and likely intake of novel foods or NDIs, including consideration of the intake by specific subpopulations intended to be marketed to, is a key step in evaluating safety, as the likely intake sets the boundaries for intake of any potential toxicants in the novel food. If the novel food is intended to take the place nutritionally of a conventional food, the nutritional compositional equivalence of the new food to its conventional counterpart is a crucial consideration and would almost certainly require fairly detailed analytic chemistry of nutrients in the novel food.

For nutritional analysis, for assessment of 'substantial equivalence,' or for adequate characterization of a novel food with no clear traditional equivalent, analytic chemistry will generally be a crucial challenge. Foods are complex mixtures. The forms of bioactive constituents of lower molecular weight (m.w. < 500) in foods are very often glucosides. Rarely are standards available for these glucosides or their aglucons. Often, an aglucon may have multiple glucosidic forms with additional substituents present, as for soybean isoflavones. Considerable effort will be needed to identify and purify key novel food constituents; advanced analytic chemistry expertise and instrumentation will be required, including NMR and mass spectrometry. Stability analysis of standards will also be needed. Some commercial analytic laboratories exist that may assist with this aspect of developing a novel food. Collaboration with university faculty and staff, especially with food analysis expertise, would be another likely route of assistance in adequately characterizing a novel food.

For GM foods or ingredients derived from GM species, assuring that the GM species has similar agronomic or production characteristics to the traditional version of the species is a key general approach that helps to avoid unintended effects of the GM process. Assurance of compositional equivalence (proximate analysis of lipid, protein, moisture, and ash and analysis of amino acids, vitamins, minerals, key toxicants, and antinutrients) of the GM food compared to the conventional version of the food should be done. Because GM foods contain modified genes, which code for specific proteins, allergenicity (which is due to reaction to specific proteins) is a major toxicological consideration. Avoiding the introduction of a gene for a major allergenic protein to a GM food is an obvious caution, as mentioned in the preceding text with the example of Brazil nut protein introduced into a GM soybean variety. Comparing the amino acid sequence of the protein expressed by the genetic modification with known allergenic proteins would be a key need in GM food safety evaluation.

In most cases of toxicological testing of novel foods or NDIs, the crucial tests would compare the new food/ingredient to a conventional counterpart that the new food is intended to replace. The key question is whether the new food is as safe as its traditional counterpart. Probably at a minimum, rodent subchronic (90-day) and short-term human trials would be important for such comparisons. Testing of whole foods is much more complex than testing of pure ingredients; well-controlled dietary formulations are crucial, but controlling for differences in multiple ingredients as would be highly likely with a whole food test is very challenging. The finding of a serious adverse effect from such a test would need to lead to additional tests to pinpoint the cause and to determine approaches for remediation and mitigation. FDA and its counterpart agencies in many countries specify types of testing required for new food additives, which are quite extensive. Based on analytic information on the novel food obtained before testing, at least some of the same types of tests used for assessing safety of newly proposed food additives would be recommended for novel foods. Specific standards for safety testing for novel foods would be very difficult to create, given the broad range of types of such foods. Postmarket assessment, including monitoring of adverse events, is important once a novel food or NDI is introduced.

From recent reports of the American Association of Poison Control Centers, in the general area of dietary supplements, major adverse events are quite rare (Figure 1). Deaths from vitamins, minerals, and botanical dietary supplements reported to US Poison Control Centers range from 0 to 4 per year in total in each of these three categories from 2003 to 2012 (http://www.aapcc.org/annual-reports/). Such data suggest that current regulatory frameworks for dietary supplements and NDIs may be adequate to protect public health. But as seen in Figure 1, the decline in adverse events from botanical dietary supplements after 2005 shows that hundreds of people suffered adverse effects before FDA was able to obtain a final ruling to ban ephedra and related substances. DSHEA permits FDA to ban a dietary supplement only after it can prove harm from the dietary supplement. The recent data trend (Figure 1) suggests that the US dietary supplement industry has taken the ephedra example as a caution. Hopefully, such cases may be avoided by voluntary action of this industry, the appropriate use of NDI notifications, and adequate pretesting of NDIs.

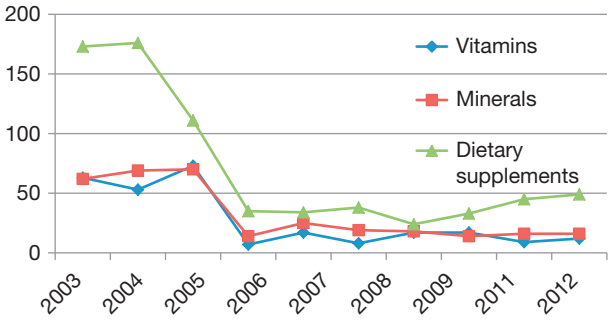

Figure 1 Major adverse events (requiring hospitalization) reported to US Poison Controls Centers from 2003 to 2012. Data were extracted from American Association of Poison Control Centers annual reports (http://www.aapcc.org/annual-reports/).

Conclusion

Although recent trends in the US suggest that dietary supplements including NDIs are rarely harmful, increasing trends for consumers to want 'natural' products, nondrug remedies, and foods that do not contain manufactured chemical additives indicate that consumers will need to be increasingly vigilant about novel foods and NDIs because their regulation is less stringent than for conventional food additives. Past examples illustrate that 'natural' sources of food or dietary supplement ingredients are not necessarily safer. For example, lead was present in the majority of 'natural' calcium supplement products tested and to lesser extent in refined calcium supplement products. The mineral dolomite as a calcium supplement tended to be more heavily lead-contaminated than other sources. Plant or phytotoxins are widely distributed in nature and vary greatly in chemical structure, and a history of use may not suffice as evidence of lack of adverse effects of a particular novel food source. Interactions between plant constituents and pharmaceuticals are common. Users of dietary supplements should disclose such use to their health care providers. Use of standardized dietary supplement products will help to limit variability in effects. Using products for which scientific data are available, especially human clinical placebo-controlled trial data on safety and efficacy under the conditions of intended use, would help to assure novel food safety for consumers. Maintaining skepticism when a novel food product is recommended by someone who stands to gain financially from the product sale is also a wise course of action. Novel food product information from government or university sources generally will be nonbiased and provide reliable help for safety assurance for consumers.

Introduction

The nucleic acids, vital constituents of all living cells, were discovered by Miescher in 1868, isolated from the nuclei of pus cells and spermatozoa of Rhine salmon. Some of the earliest observations of macromolecules within living cells were of nucleic acids in the form of chromosomes. Nucleic acids were named partly based on their chemical properties and partly on the observation that they represent a major constituent of the cell nucleus. The fact that they form the chemical basis for the transmission of genetic traits was not realized until 1941. When the fine thread-like nucleic acids were isolated from cells and analyzed biochemically, they were found to be composed of three relatively simple components: sugar, phosphate, and a base. For many years, this chemical composition, which is relatively simple compared to that of proteins, led to nucleic acids being overlooked as genetic macromolecules. There are two main types of nucleic acids: deoxyribonucleic acid (DNA) and ribonucleic acid (RNA). DNA is found largely in the nucleus of the cell, but certain organelles also contain DNA, including mitochondria and plastids. RNA is also found in the nucleus, but it is also present in the cytoplasm in large amounts. DNA and RNA are responsible for storing and implementing the genetic information in the cell. DNA is a long polymer made from repeating units called nucleotides (adenine, guanine, thymine, and cytosine). As first discovered by James D. Watson and Francis Crick, the structure of the DNA of all species comprises two helical chains each coiled around the same axis, and each with a pitch of 34 Å (3.4 nm) and a radius of 10 Å (1.0 nm).

Physiology

Chemical Structure of Nucleic Acids

DNA is a polymeric molecule, which is composed of repeating nucleotide subunits. The order of nucleotide subunits contained in the linear sequence or primary structure of these polymers represents all of the genetic information carried by a cell. Each nucleotide is composed of a phosphate group; a pentose (5 carbons) sugar and a cyclic nitrogen-containing compound called a base. In DNA, the sugar moiety is 2-deoxyribose. Eukaryotic DNA is composed of four different bases: adenine, guanine, thymine, and cytosine. The bases are attached as side chains to the sugars; they differ from one 'letter' to the other. These bases are classified based on their chemical structure into two groups:

Adenine and guanine are double-ring structures termed purines, and thymine and cytosine are single-ring structures termed pyrimidines. The overall composition of DNA shows that the concentration of thymine is always equal to the concentration of adenine, and the concentration of cytosine is always equal to guanine. Thus, the total concentration of pyrimidines always equals the total concentration of purines. These monomeric units are linked together into the polymeric structure by 3′,5′-phosphodiester bonds (Figure 1). Natural DNAs display large size variations, depending on the source, with the relative molecular weight ranging from 1.6×10^6 Da for bacteriophage DNA to 1×10^{11} Da for a human chromosome.

The RNA molecule is chemically single-stranded, but double helical regions arise when stretches of complementary sequences allow hairpin loops to form. In addition, the base uracil (U) is found in RNA instead of thymine, and the pentose is ribose. Ribosomes are very large molecular systems, which translate genomic information from messenger RNAs (mRNAs) into proteins. Special attention has recently been given to certain small RNA strands that form specific 3D structures with catalytic activity: the ribozymes. Interest in these molecules is twofold: they may provide new perspectives on the question of what came first, proteins or DNA, and they may allow the construction of new types of enzymes.

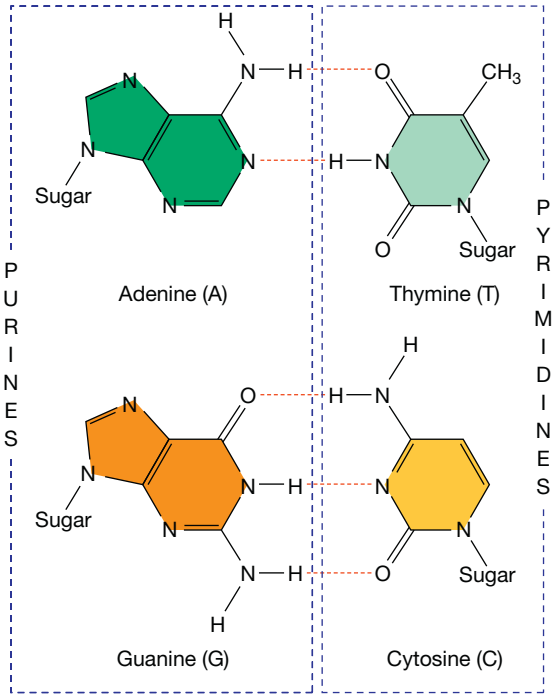

Figure 1 Chemical structure of purine and pyrimidine deoxyribonucleosides and their pairing pattern.

Nucleic Acids and Genetic Information

Genetic information is stored in the sequence of bases along a nucleic acid chain. The bases have an additional special property: they form specific pairs with one another that are stabilized by hydrogen bonds. The base pairing results in the formation of a double helix, a helical structure consisting of two strands. These base pairs provide a mechanism for copying the genetic information in an existing nucleic acid chain to form a new chain. Although RNA probably functioned as the genetic material very early in evolutionary history, the genes of all modern cells and many viruses are made of DNA. DNA is replicated by the action of DNA polymerase enzymes. These exquisitely specific enzymes copy sequences from nucleic acid templates with an error rate of less than 1 in 100 million nucleotides.

Genes specify the kinds of proteins that are made by cells, but DNA is not the direct template for protein synthesis. Rather, the templates for protein synthesis are RNA molecules. In particular, a class of RNA molecules called mRNA are the information-carrying intermediates in protein synthesis. Other RNA molecules, such as transfer RNA (tRNA) and ribosomal RNA (rRNA), are part of the protein-synthesizing machinery. All forms of cellular RNA are synthesized by RNA polymerases that take instructions from DNA templates. This process of transcription is followed by translation, which is the synthesis of proteins according to instructions given by mRNA templates. Thus, the flow of genetic information, or gene expression, in normal cells is as follows:

$$\text{DNA} \xrightarrow{\text{transcription}} \text{RNA} \xrightarrow{\text{translation}} \text{Protein}$$

This flow of information is dependent on the genetic code, which defines the relation between the sequence of bases in DNA (or its mRNA transcript) and the sequence of amino acids in a protein. The code is nearly the same in all organisms: a sequence of three bases, called a codon, specifies an amino acid. Codons in mRNA are read sequentially by tRNA molecules, which serve as adaptors in protein synthesis. Protein synthesis takes place on ribosomes, which are complex assemblies of rRNAs and more than 50 kinds of proteins.

The hereditary material in the nucleus of human cells is packed into 23 chromosomes, and additional DNA is found in the mitochondria. The human genome is known to contain $\sim 3 \times 10^4$ coding sequences, or genes, and a substantial proportion of DNA has a regulatory role in the transcription of the genes. The sequence of the four bases and the capacity of DNA to be copied into two complementary strands underlie the genetic information of all living organisms. Interactions between DNA and the transcription factors determine the time and place in the body where genes are transcribed, causing development and metabolism to occur.

RNA molecules are synthesized initially on a DNA template by a DNA-dependent RNA polymerase in a process called transcription, in which ribonucleotides complementary to the bases of one strand of DNA are joined by 30–50 phosphodiester bonds. Cells contain three types of RNA, each of which is chemically modified after transcription from the DNA template. The three kinds of RNA together are important in the translation of the genetic message to synthesize proteins in the cell. Most RNA is in the cytoplasm, principally in the form of rRNA (80% of the total), which performs structural and catalytic roles in ribosomes, the site of the growing polypeptide chain in protein synthesis, whereas mRNA (5%) provides the template for protein synthesis. The amino acids are brought to the assembly site covalently bonded to tRNA (15%), with their order in the growing protein being specified by the order of the bases in mRNA.

Biosynthesis of Nucleic Acids in Humans

Formation of Deoxyribonucleotides

The first step in the synthesis of DNA and RNA in humans (and probably for all living beings) involves the formation of the purine and pyrimidine ribonucleotides. Two routes derive them endogenously: the energy-intensive multistep *de novo* route, using small molecules such as carbon dioxide, amino acids, and ribose sugars as precursors; and the energetically less expensive 'salvage' pathway (Figure 2).

The typical cell contains five to ten times as much RNA (mRNAs, rRNAs, and tRNAs) as DNA. Therefore, the majority of nucleotide biosynthesis has as its purpose the production of rNTPs. However, because proliferating cells need to replicate their genomes, the production of dNTPs is also necessary. This process begins with the reduction of rNDPs, followed by phosphorylation to yield the dNTPs. The phosphorylation of dNDPs to dNTPs is catalyzed by the same nucleoside diphosphate kinases (NDKs) that phosphorylate rNDPs to rNTPs, using ATP as the phosphate donor (Figure 3).

Given that the goal of nucleotide synthesis is to create eight distinct types of nucleotide, each containing three modular parts (sugar, base, and phosphate(s)), the process is fairly complex. As with any biochemical pathway, a metabolic map is helpful for conceptualizing the overall framework. Figure 3 depicts the assembly of each type of nucleotide at the general level. The total intracellular concentration of a given type of nucleotide (e.g., AMP + ADP + ATP) is tightly regulated and stays relatively constant, although there may be major changes in the individual concentrations, depending on the energy state of the cell (e.g., ATP increases while AMP decreases). The pathways for the *de novo* synthesis of purines and pyrimidines are primarily regulated by the concentrations of their own products, which inhibit further production. This form of

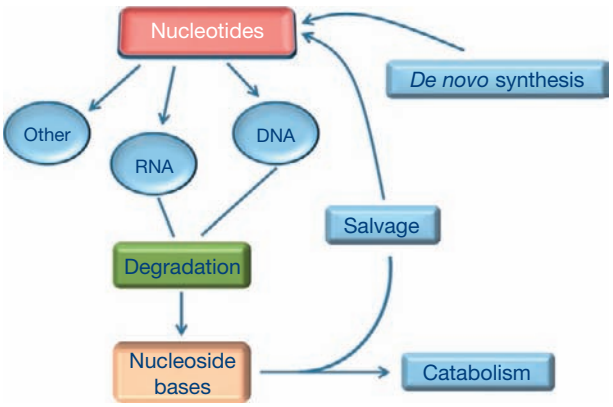

Figure 2 Overview of nucleotide metabolism.

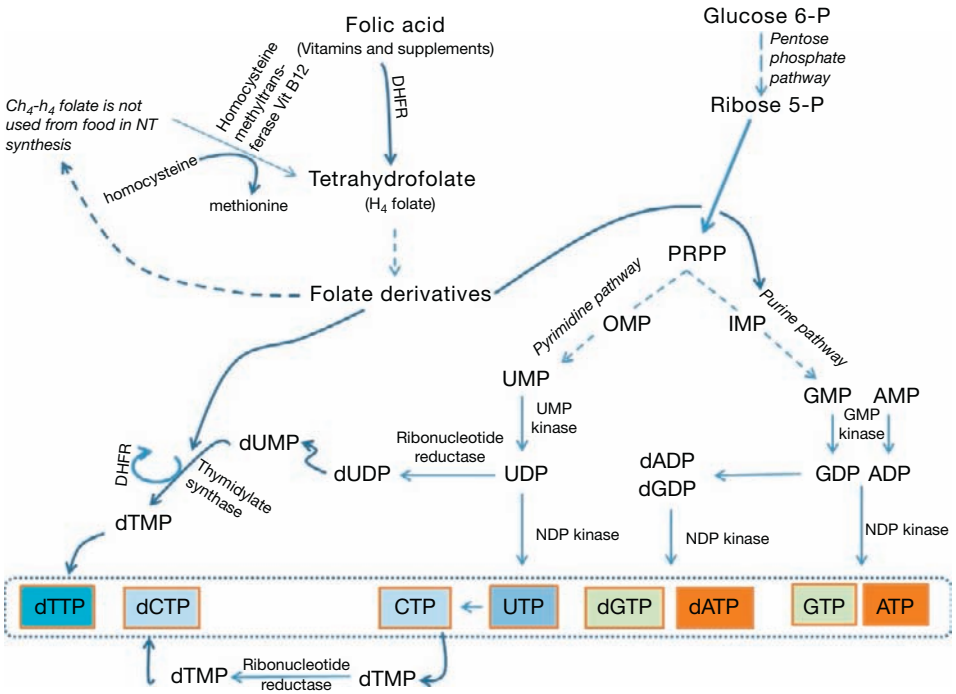

Figure 3 General plan of nucleotide synthesis.

regulation ensures an adequate supply of nucleotides while preventing their overproduction. The synthesis of the 5-carbon sugar ribose pathway gives a clear view about regulatory pathways in nucleotide synthesis.

The pentose phosphate pathway

Synthesis of nucleotides requires a source of ribose 5-phosphate. This compound is produced from glucose 6-phosphate via the pentose phosphate pathway (also called the hexose monophosphate shunt). In addition to producing ribose 5-phosphate, the pathway is a major source of NADPH, a coenzyme required for anabolism and the repair of oxidative damage. The pentose phosphate pathway occurs in the cytosol of cells. The pathway has oxidative and nonoxidative parts, which can operate more or less independently. The oxidative part of the pathway converts glucose 6-phosphate to ribose 5-phosphate and produces two NADPH (Figure 4).

Most of the steps in this part of the pathway are thermodynamically irreversible, thus ensuring that the cell maintains a high NADPH-to-NADP ratio, which is particularly important in cells that carry out NADPH-dependent processes such as fatty-acid biosynthesis (liver, mammary glands (lactating), and adipose), steroid-hormone synthesis (testes, ovaries, and adrenal cortex), and the reduction of glutathione (erythrocytes; a key reaction in protection from oxidative damage). Further utilization of ribulose 5-phosphate occurs via reversible nonoxidative reactions. In cells that have large needs for nucleotides, most of the ribulose 5-phosphate is converted to ribose 5-phosphate and used for nucleotide biosynthesis. In cells that need more NADPH than nucleotides, the excess ribulose 5-phosphate is converted to compounds that enter glycolysis in a series of reversible reactions.

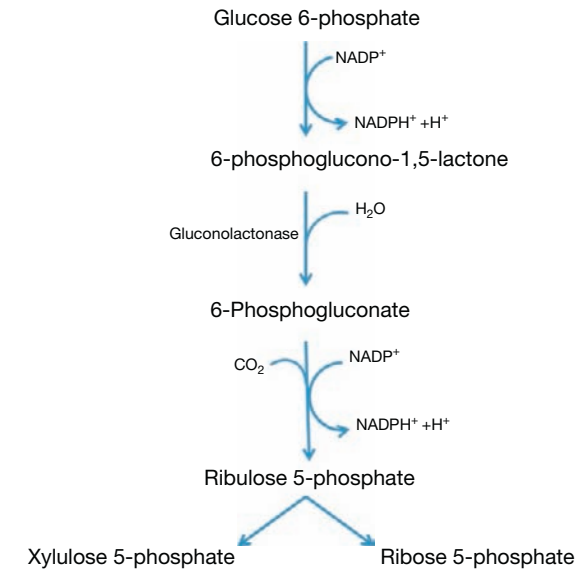

Figure 4 Pentose-phosphate synthesis pathway.

Glucose 6-Phosphate Dehydrogenase Deficiency

Interestingly, the key disorder associated with defects in the pentose phosphate pathway does not arise from a failure to synthesize nucleotides, but rather deficient NADPH production. The first NADPH-producing reaction of the pentose phosphate pathway is catalyzed by glucose 6-phosphate dehydrogenase (G6PD), an enzyme produced from a gene on the X chromosome. Unlike other cells, erythrocytes lack mitochondrial pathways that produce NADPH, and they rely solely on the pentose phosphate pathway for NADPH production.

Mutations that reduce G6PD activity result in a decreased ability to produce NADPH, which impairs the normal red blood cell response to oxidative damage. G6PD-deficient individuals are typically asymptomatic unless exposed to conditions that increase production of reactive oxidants (e.g., hydrogen peroxide) that damage hemoglobin, membrane lipids, and other cellular components. Such oxidative damage can lead to hemolytic anemia. Conditions that can precipitate hemolytic anemia in the setting of G6PD deficiency include infection, the use of certain drugs (including sulfa drugs and antimalarial drugs), and consumption of fava beans.

Role of NADPH in G6PD deficiency

Normally, hydrogen peroxide is eliminated by glutathione. Glutathione is a tripeptide made up of glutamate, cysteine, and glycine. Its sulfur-containing side chain can reduce hydrogen peroxide to water, and it is oxidized in the process (Figure 5). Glutathione reductase restores glutathione to its reduced form using NADPH as the source of reducing power. Ribonucleotide reductase (RR) is a multifunctional enzyme that contains redox-active thiol groups for the transfer of electrons during the reduction reactions. In the process of reducing the rNDP to a dNDP, RR becomes oxidized. RR is reduced, in turn, by either thioredoxin or glutaredoxin. The ultimate source of the electrons is NADPH. The electrons are shuttled through a complex series of steps involving the enzyme, thioredoxin reductase, that regenerates the reduced form of thioredoxin. Glutaredoxin gives up its electrons to glutathione, which is then reduced by glutathione reductase.

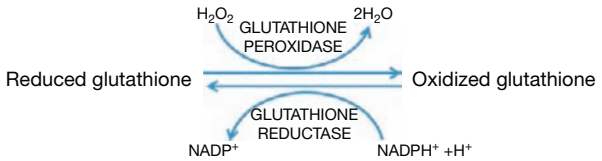

Figure 5 Restoring glutathione using NADPH.

Thus, mutations that decrease G6PD activity impair the red cell's ability to detoxify hydrogen peroxide. G6PD deficiency is very common; about 400 million people worldwide are affected. Frequencies are highest in tropical Africa, parts of the Middle East, and Southeast Asia (Figure 6). On the other hand, in the process of nucleic-acid synthesis, the folic acid obtained from vitamins and other food supplements coverts into tetrahydrofolate (THF), folate derivatives, which further enter into the purine pathway, as well as the dUMP-to-dTMP pathway (Figure 3). Thus, THF plays an important relevance in physiological processes for nucleic acid synthesis.

THF – Clinical Relevance

THF is regenerated from the dihydrofolate (DHF) product of the thymidylate synthase reaction by the action of dihydrofolate reductase (DHFR), an enzyme that requires NADPH (Figure 3). Cells that are unable to regenerate THF suffer defective DNA synthesis and eventually result in cell death. For this reason, as well as the fact that dTTP is utilized only in DNA, it is therapeutically possible to target rapidly proliferating cells over nonproliferating cells through the inhibition of thymidylate synthase. Many anticancer drugs act directly to inhibit thymidylate synthase, or indirectly, by inhibiting DHFR.

The class of molecules used to inhibit thymidylate synthase is called the suicide substrates because they irreversibly inhibit the enzyme. Molecules of this class include 5-fluorouracil and 5-fluorodeoxyuridine. Both are converted within cells to 5-fluorodeoxyuridylate, FdUMP. Many DHFR inhibitors have been synthesized, including methotrexate, aminopterin, and trimethoprim, which are an analog of folic acid.

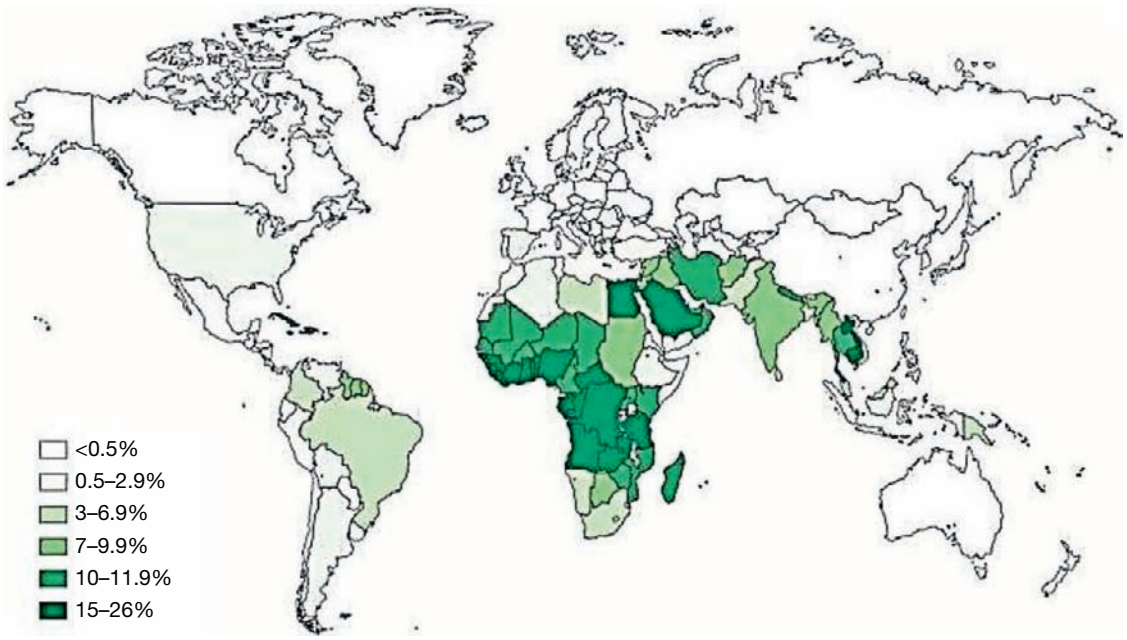

Figure 6 Global scenario of G6PD deficiency.

De novo *ribonucleotide synthesis*

Purine and pyrimidine nucleoside 5′-monophosphates can be synthesized *de novo* from 5-phosphoribosyl-1-pyrophosphate (PRPP) and various carbon and nitrogen donors. The raw materials for both types of nucleotide have a common origin. However, the pathways by which they are formed are separate and distinct in organization. In the pyrimidine pathway, the ring structure of the base is assembled first and then attached to the pentose sugar PRPP. In contrast, the purine pathway starts with the pentose sugar and builds the ring structure of the base upon it. Nucleoside 5′-monophosphates are phosphorylated to form the corresponding diphosphates by one of several nucleoside monophosphate (NMP) kinases, each of which is specific for the base component of the nucleotide (Figure 3). Nucleoside diphosphates (NDPs) can be converted to triphosphates by a nonspecific NDK. ATP is the phosphate donor in all of these phosphorylation reactions.

General Overview of Nucleotide Catabolism and Salvage

Nucleic acid turnover occurs continuously in most cells. mRNA, in particular, is actively synthesized and degraded. These degradative processes can lead to the release of free purines in the form of adenine, guanine, and hypoxanthine (the base in inosine 5′-monophosphate (IMP)). Ther breakdown of DNA and RNA releases nucleoside 5′-monophosphates, which can be hydrolyzed by 5′-nucleotidases to yield nucleosides. These substances represent a metabolic investment by cells. So-called salvage pathways exist to recover them in useful form. Salvage reactions involve the resynthesis of nucleotides from bases via phosphoribosyltransferases. Although both purine and pyrimidine nucleosides can be degraded to waste products that are excreted, the catabolic pathways have branch points in most cells at which the components of nucleotides can be salvaged (Figure 7).

Interconversion of the Nucleotides

During the catabolism of nucleic acids, nucleoside mono- and diphosphates are released. The nucleosides do not accumulate to any significant degree, owing to the action of nucleoside kinases. These include both NMP kinases and NDP kinases. The NMP kinases catalyze ATP-dependent reactions of the type

$$\text{dNMP} + \text{ATP} \leftrightarrow (\text{d})\text{NDP} + \text{ADP}$$

There are four classes of NMP kinases that catalyze, respectively, the phosphorylation of

(i) AMP and dAMP; this kinase is known as adenylate kinase
(ii) GMP and dGMP
(iii) CMP, UMP, and dCMP
(iv) dTMP

The enzyme adenylate kinase is important for ensuring adequate levels of energy in cells such as liver and muscle. The predominant reaction catalyzed by adenylate kinase is

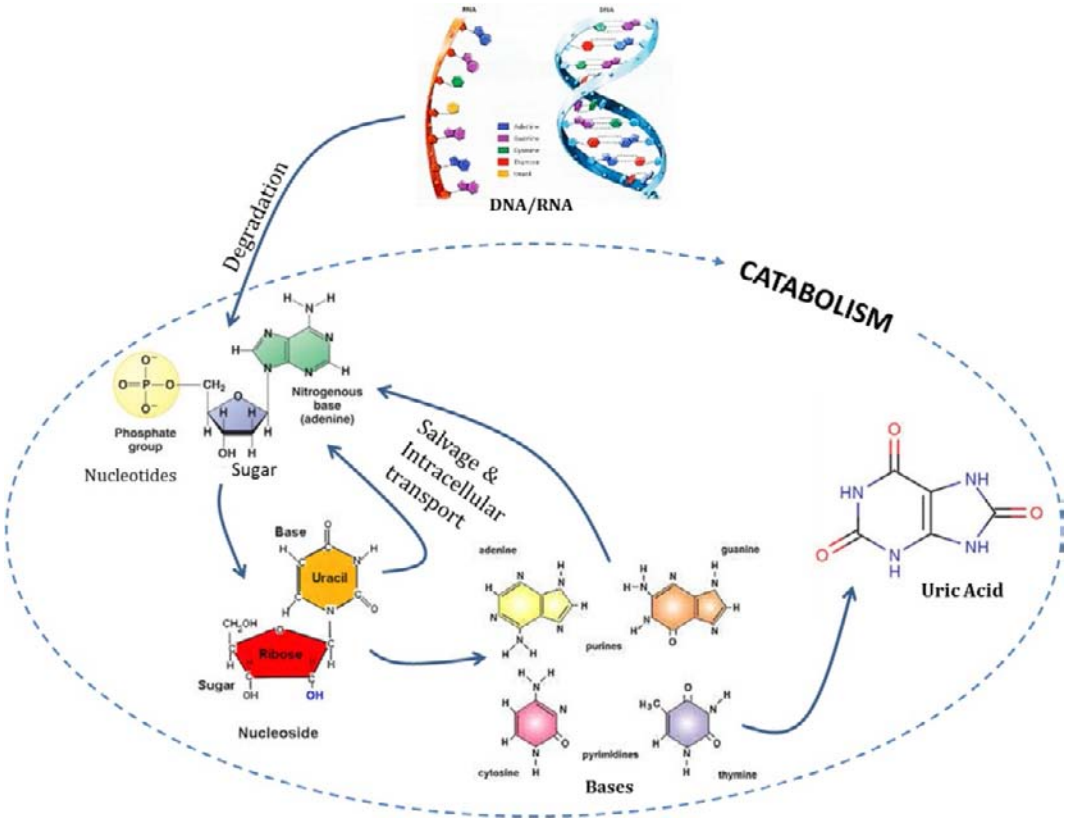

Figure 7 Overview of nucleotide salvage.

$$2ADP \leftrightarrow AMP + ATP$$

The NDP kinases catalyze a reaction of the type

$$N_1TP + N_2DP \leftrightarrow N_1DP + N_2TP$$

N_1 can represent a purine ribo- or deoxyribonucleotide, and N_2 can represent a pyrimidine ribo- or deoxyribonucleotide. The activity of the NDP kinases can range from 10 to 100 times higher than that of the NMP kinases. This difference in activity maintains a relatively high intracellular level of (d)NTPs relative to that of (d)NDPs. Unlike the substrate specificity seen for the NMP kinases, the NDP kinases recognize a wide spectrum of (d)NDPs and (d)NTPs.

The shared catabolism and salvage pathways saves metabolic energy on one hand while prevent nucleotide pools from reaching toxic levels on other side. Unless the flow of nucleotides into the shared salvage–catabolism pathway is greater than usual, normally more components are salvaged than are catabolized (intestinal epithelial cells are exceptions to this rule; they completely catabolize the components of dietary nucleotides rather than salvage them). This makes sense because, although nucleotide synthesis is energy-intensive, the complete breakdown yields very little energy. As with many metabolites, the liver is a 'way station' for nucleotides. The liver is a major site for both *de novo* nucleotide synthesis and degradation. Excess nucleosides and bases are supplied by hepatocytes to other tissues, such as the brain and muscle, which utilize salvage pathways to generate needed nucleotides. Importantly, nucleosides and bases cross membranes but nucleotides do not. The salvage pathways also make it possible for nucleotides and their components released by cells undergoing apoptosis to be reused. Many cell types contain 5′-nucleotidases on the outer surface of the plasma membrane and can therefore convert extracellular nucleotides to nucleosides, which can be taken up using Na^+/nucleoside symporters. Pyrimidine catabolism and salvage pathways are rarely associated with disease. Derangements of purine salvage–catabolism are more common. Purine salvage pathways are also important clinically for metabolism of certain drugs.

Clinical Considerations

A few important drugs inhibit key steps in *de novo* purine nucleotide synthesis and, as a result, kill rapidly dividing cells. Mercaptopurine and azathioprine (a prodrug that is converted in the body to mercaptopurine), both inhibitors of several steps in *de novo* purine synthesis, are cancer chemotherapeutic drugs that are also used as immune suppressants in the treatment of many diseases, including rheumatoid arthritis, lupus, and inflammatory bowel disease (IBD).

IMP dehydrogenase, an enzyme that carries out one of the steps in synthesis of GMP from IMP, is inhibited by the immunosuppressant drug mycophenolate mofetil, which is widely used to prevent solid organ transplant rejection. Lymphocytes are unique in being unable to utilize salvage pathways to generate GMP. Their dependence on *de novo* synthesis for GMP means the proliferation of these cells is selectively inhibited by this drug. Note the role of formyl-H_4folate, a form of reduced folate carrying a formyl group, in providing a 1-carbon unit for the synthesis of the inosine base.

Moreover, clinically important carbamoyl phosphate is an intermediate in another key metabolic pathway, and it is utilized as a substrate in the urea cycle by the enzyme ornithine transcarbamoylase. Inherited deficiency of this enzyme (the most common urea-cycle defect) is associated with hyperammonemia and associated problems, but it is also marked by elevated blood and urinary orotate, because excess carbamoyl phosphate shunts into pyrimidine nucleotide metabolism. Another inherited defect in pyrimidine nucleotide synthesis, orotic aciduria, arises from deficiency of enzymes that convert orotate to orotidine monophosphate (OMP) and uridine monophosphate (UMP). In addition to urinary excretion of orotate, this disease is associated with poor growth and megaloblastic anemia. Also importantly, a step in the synthesis of UMP from orotic acid is inhibited by the antirheumatic drug leflunomide.

Dietary Nucleic Acid Metabolism in Humans

The normal human diet is rich in both DNA and RNA because food is derived from once-living organisms. The metabolism of these exogenous nucleic acids follows a pattern similar to the intracellular process described previously, but the bacterial flora of the intestine are the first point of attack. This digestion is rapid. Some studies demonstrated that up to 50% of radiolabeled dietary purine was degraded and lost as carbon dioxide gas within 30 min, with the remaining 43% being recovered in the urine and 5% in the feces. It has been shown that dietary pyrimidine nucleotides, but not purines, are incorporated into RNA.

Humans thus have no apparent requirement for purines from the diet, and the intestinal mucosa provides an effective barrier to their uptake through a battery of enzymes that rapidly degrade purine nucleotides, nucleosides, and bases to the metabolic waste product, uric acid. This phenomenon may represent an important evolutionary development to protect the integrity of the cellular DNA or to ensure that levels of ATP do not fluctuate in concert with the dietary intake of purines. The potential toxicity of dietary nucleic acids to humans usually arises not from the nucleic acids but from their metabolic end-products (principally uric acid). Many investigators have shown that the fate of the dietary purine moiety depends on whether it is administered in the form of DNA, RNA, mononucleotides, nucleosides, or bases, with some being catabolized more readily than others. When normal subjects are fed RNA, the increase in the excretion of uric acid is dramatic alongside a modest increase in plasma-urate concentrations. The effect of RNA is also twice that of DNA when the increase in purines in the plasma is measured. On the other hand, pyrimidine mononucleotides and uridine, but not the base uracil, are absorbed readily from the intestine and utilized for nucleic-acid synthesis. This has been demonstrated by studies of humans with hereditary orotic aciduria, a rare defect in *de novo* pyrimidine synthesis at the fourth step involving the conversion of orotic acid to UMP. Such patients have a severe megaloblastic anemia that does not respond to the usual forms of treatment. They have been sustained for more than 40 years on oral uridine, indicating that the dietary pyrimidine is

absorbed intact and can compensate totally for lack of *de novo* synthesis in humans. Studies using radiolabeled purines and pyrimidines in mice have provided further evidence for the incorporation of dietary pyrimidine nucleosides, but not purine nucleosides, into hepatic RNA.

Gout: An Excess of Uric Acid

Gout is the clinical term describing the physiological consequences resulting from the derangement of uric-acid metabolism accompanying excessive uric-acid accumulation in body fluids. Uric acid and urate salts are rather insoluble in water and tend to precipitate from solution if produced in excess. Uric acid is the end product of purine metabolism in humans. At physiological pH, uric acid is 98% ionized and is present mainly as urate ions. In extracellular fluids, uric acid exists as a solution of monosodium urate, which has very low solubility and can precipitate very easily. The most common symptom of gout is arthritic pain in the joints as a result of urate deposition in cartilaginous tissue. The joint of the big toe is particularly susceptible.

Normal Uric-Acid Metabolism

Purine nucleotides are components of nucleic acids; they are also intimately involved in energy transformation and phosphorylation reactions and act as second messengers.

There are three sources of purines in humans:

(i) The diet
(ii) Degradation of endogenous nucleotides
(iii) *De novo* synthesis

The kidney and the intestine excrete urate. In the intestine, urate is metabolized to carbon dioxide and ammonia by bacterial action ('uricolysis').

Urate-handling by the kidney is complex (Figure 8). It is filtered by the glomeruli and then almost completely reabsorbed in the proximal tubules; in the distal tubules, both reabsorption and secretion occurs. Net urate clearance is only 10% of the filtered load. If the filtered load is increased in normal subjects, excretion is increased. In patients with renal failure, however, urate excretion decreases with a decrease in glomerular filtration rate, and the serum level rises. Dietary purines account only for 30% of excreted urates.

The metabolic pathways leading to endogenous uric-acid synthesis are mediated by several enzymes in a complex fashion. There is *de novo* synthesis from ribose-1-phosphate to inosine, as well as a secondary salvage pathway that leads to the production of uric acid by converting guanine and adenine bases into inosine, which is in the main pathway of xanthine production (Figure 9). Xanthine is oxidized by xanthine oxidase to uric acid. Uric acid is the last stage in purine degradation in humans, because all primates lack the enzyme (uricase) to convert uric acid into allantoin.

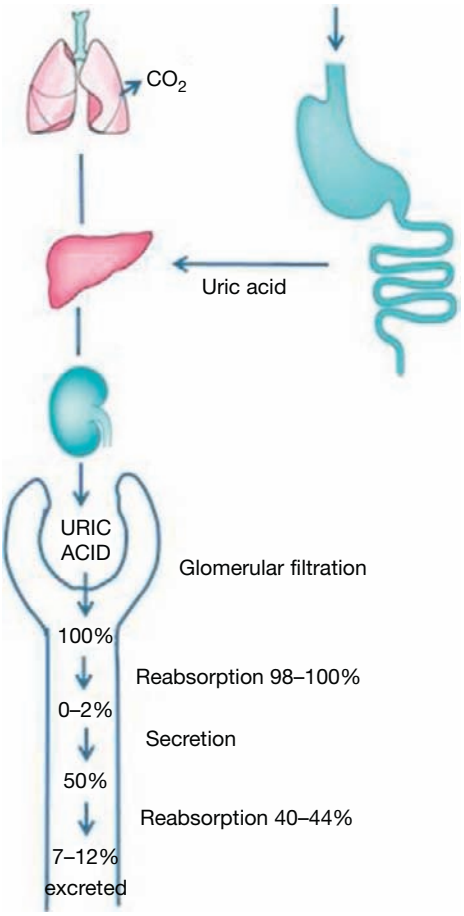

Figure 8 Uric-acid filtration mechanism.

Uric Acid in Serum

Serum concentrations of uric acid are higher in men than in women (gout is much more common in men), tend to rise with age, and tend to be higher in individuals of higher economic classes and in obese people. There is considerable variation in serum-urate concentrations between different ethnic groups.

Although the mechanism of gout has not been completely elucidated, the likelihood of gout increases with increased serum urate levels. However, only a small proportion of individuals with elevated uric acid levels develop gout (in the Western Hemisphere, it is estimated that 10% of the population has high uric acid levels, but only 0.5% develop gout). The solubility of urate decreases with decreasing temperature, explaining the increased incidence of gout in peripheral joints (which are cooler). Hyperuricemia can be caused by increased formation of uric acid, by reduced excretion by the kidneys, or by a combination of both mechanisms.

Increased formation of uric acid occurs with:

- High dietary intake
- Increased purine synthesis
  - Idiopathic
  - Inherited (several genetic mechanisms have been described)

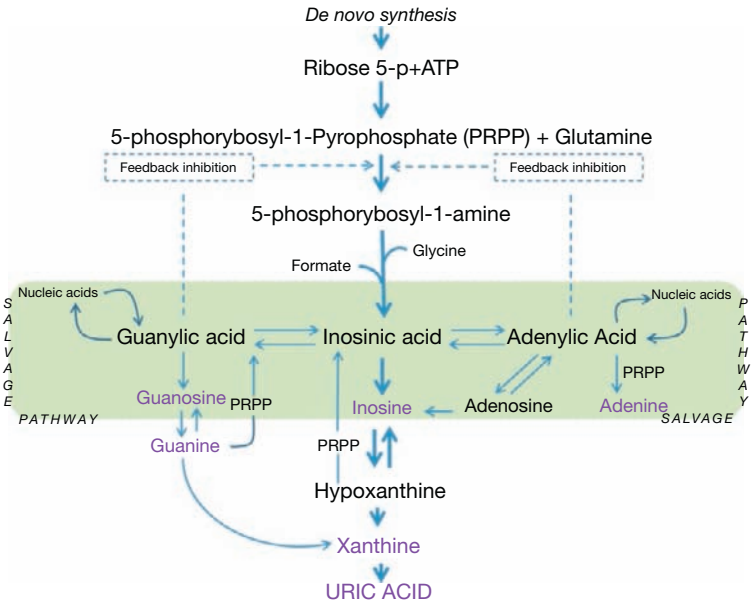

Figure 9 Endogenous uric-acid synthesis.

- Increased nucleic acid turnover
  - Myeloproliferative disorders (e.g., leukemias)
  - Psoriasis
  - Secondary polycythemia
  - Carcinomatosis
  - Chronic hemolytic anemias
  - Cytotoxic drugs

Reduced excretion of uric acid by the kidneys occurs with:

- Chronic renal disease
- Drugs (thiazides, salicylates)
- Poisons (lead)
- Increased organic-acid concentration in blood (lactic acid, acetoacetic acid, beta-hydroxybutyrate)
- Hyperparathyroidism

Dietary Sources of Nucleic Acids

Nucleic Acid–Rich Foods

Animal origin

- Wild or farmed game meats: venison, pheasant, rabbit, hare, deer, and pork
- Seafoods: sardines, sprats, herring, bloaters, anchovies, fish roe, caviar, taramasalata, trout or salmon, lobster, crab, and prawns

Plant origin

- Vegetables: asparagus, avocado pears, peas, spinach, mushrooms, broad beans, cauliflower, and eggplant
- Pulses and grains: legumes, pulses, and soya products such as bean curd, tofu, and Quorn
- Cereals: all bran, oat, rye, or wheat cereals and products; whole meal, rye, and brown breads
- Other: beer and yeast extracts/tablets; meat or vegetable extracts

Foods That Are Moderate or Low Sources of Purine

Animal origin

- Beef, lamb, pork (steak or chops), bacon, ham, sausages, some poultry, and tongue (all should be eaten in moderation)
- Fish: bass, bream, cod, crab, eel, kippers, lobster, lemon sole, plaice, and trout

Plant origin

- Carrots, parsnip, potatoes, lettuce, leeks, cabbage, sprouts, marrow, courgettes, peanuts, cashew nuts, white bread or flour, cakes, scones, biscuits, and cereals

Purine-Free Food Sources

Animal origin

- Milk, cheese, eggs, butter, margarine, cream, and ice cream

Plant origin

- Sugar, jam, marmalade, honey, sweets, cucumber, tomato, onions, pumpkin, fruits (fresh, cooked, or tinned), nuts, puddings, custards, yogurt, fruit juices, and soft drinks

Nutrition and Health Claims for Food: Regulatory Controls, Consumer Perception, and Nutrition Labeling

MJ Ruffell, Nutrition and Health Claims, Leatherhead, UK

© 2016 Elsevier Ltd. All rights reserved.

Introduction

The WHO Global Action Plan for the Prevention and Control of NCDs (2013) highlights the importance of the diet and calls upon the private sector to improve the provision of affordable and accessible healthy options, which may be the result of reformulation or fortification and which meet a high standard of nutrition labeling. Together with other population lifestyle changes, WHO aims to achieve a 25% relative reduction in premature mortality from cardiovascular diseases, cancer, diabetes, and chronic respiratory conditions by 2025. There are three key voluntary targets for foods: to reduce the mean population salt intake by 30%, to lower blood pressure by 25%, and to halt the rise in obesity and diabetes.

The links between diet and health are well documented, including those highlighted in the preceding chapters of this book. The body of evidence continues to grow, from not only ongoing research in well-established areas of nutrition but also emerging science suggesting benefits from new research areas or innovative foods and ingredients. Whether they are called 'functional foods,' 'nutraceuticals,' 'bioactives,' or similar, they are all foods with health benefits, resulting from either naturally occurring food components or those that are added or removed during manufacturing. When referring to the promotion or advertising of foods, nutrition claims can highlight a nutritional property of the food, while health claims are used to describe a particular beneficial relationship between food and health.

The use of valid health messages and clear nutrition labeling are a crucial part of assisting consumers to make informed choices about their diet. When consumed in the recommended quantities, as part of a healthy diet and lifestyle, foods can offer a range of benefits, from cholesterol reduction to the maintenance of normal bone structure in adults; and normal visual development in young babies or normal cognitive development in children. Such messages have been the mainstay of public health nutrition campaigns and healthcare professionals in the past, but food manufacturers now also use them as a marketing tool to help increase the appeal of a product or brand range. Although nutrition and health claims are by no means a requirement to sell foods with health benefits, if companies do choose to use them, they will most likely need to comply with regulations to promote fair trade and protect consumers from misleading or stretched claims.

As to meaningfulness to the consumer and the effect of claims on purchasing choice and longer-term health outcomes, the jury is still out. Further research is needed to help inform industry, health practitioners, and policy makers. It has been found that health claims can influence expectations about both the sensory and health benefits of the product, but not always accurately. Furthermore, consumer understanding can be affected by a number of variables, which, together with the nature of controls around the world, will be covered further in this article.

Regulatory Control of Nutrition and Health Claims

A number of countries around the world have adopted, or are in the process of adopting, some form of regulation for the responsible use of nutrition and health claims. Although there are some key differences, these systems are grounded in similar principles that aim to provide a level playing field and help ensure that robust science is behind the claims to protect consumers. Some of the key differences relate to pre-market approval versus notification, legislation versus self-regulation, whether 'therapeutic' foods are included or covered by other legislation, or the ability to use alternative wording of authorized claims. Some countries such as the United States and Japan also allow for lower levels of substantiation to enable the use of 'qualified health claims', that is, claims with a disclaimer to inform the consumer that they are not based on consensus opinion. It has been argued that to support the global marketplace, from both the consumer perspective and industry perspective, greater harmonization is required on the substantiation and regulation of claims.

Some countries use the term 'nutrition claim' while others refer to 'nutrient content claims.' There is no global definition of 'health claim'; however, they are usually subcategorized along the lines of either 'health maintenance' (or structure/function) claims or 'disease risk reduction' claims. Product-specific claims are permitted in a few countries, while generic claims relating to food components tend to be more widely accepted. Each regulatory system can be highly detailed, and comprehensive reviews and comparisons of various countries have been published elsewhere.

To provide a flavor of the regulatory systems governing health messages used in a commercial context, an overview of the European Regulation on Nutrition and Health Claims (EC 1924/2006) follows as an example.

Regulation EC 1924/2006 ('the EC Regulation' hereafter) applies to all information in commercial communication relating to packaged or unpackaged food (including labels and all forms of promotion and advertising, such as TV, web, and social media) that could state, suggest, or imply a relationship with health such as messages about the general diet, natural foods, manufactured foods, ready meals, nutrients, dietary supplements, beverages, and any other food-related elements within wider health plans such as fitness and well-being programs or weight loss regimes.

As defined by the EC Regulation, a 'nutrition claim' infers that a food "has a particular beneficial nutritional property due to the presence or absence of energy or nutrients" (e.g., 'low in salt,' 'reduced energy,' and 'high in fiber'), whereas 'health claim' means "any claim that states, suggests or implies that a relationship exists between a food category, a food or one of its constituents and health" (e.g., "Biotin contributes to normal functioning of the nervous system"). The EC Regulation also

provides a specific definition for 'reduction of disease risk claim,' that is, "any health claim that states, suggests or implies that the consumption of a food category, a food or one of its constituents significantly reduces a risk factor in the development of a human disease" (e.g., "Supplemental folic acid intake increases maternal folate status. Low maternal folate status is a risk factor in the development of neural tube defects in the developing foetus").

In the EU only those claims that have been authorized by the European Commission are available for use with complying foods (as opposed to a notification system employed by some other countries). As of January 2015, there were some 256 authorized health claims; however, 222 of these were published as one list in 2012, nearly 2 years later than expected, highlighting the complexity of developing an EU-wide list of permitted claims.

Each authorized claim carries specific conditions for use for that claim, such as product compositional criteria and additional labeling requirements for that claim. Manufacturers must also meet all other general conditions set out in the regulation, such as providing full nutrition labeling, ensuring that claims are not ambiguous or misleading, ensuring that claims do not encourage or condone excess consumption of a food, and ensuring that they do not imply that a balanced diet cannot provide necessary nutrients. To this end, the European Commission and some individual EU member states have prepared guidance on the implementation of the regulation to help companies apply the claims appropriately.

The EC Regulation states that claims must "be well understood by the average consumer." The preamble to the regulation describes this to be someone who is "reasonably well-informed and reasonably observant and circumspect, taking into account social, cultural and linguistic factors" and goes on to say that the regulation "makes provision to prevent the exploitation of consumers whose characteristics make them particularly vulnerable to misleading claims."

Alternative wording of claims is permitted; however, this must not mislead or confuse consumers and must retain the meaning of the authorized wording. Ideally, claims with associated periphery text and imagery in their final context should be tested with consumers to ensure legal and scientific acceptability. In a bid to assist companies and enforcement in the application of this principle, the UK Department of Health has published specific guidance developed in partnership with other EU member states.

The European Food Safety Authority (EFSA) is the scientific body that assesses the evidence, submitted by individuals or organizations, and provides an opinion on whether or not a 'cause and effect' relationship has been established on which to base a claim. Following a positive opinion, the claim is adopted into EU law, unless there is a legal reason not to do so (two positive opinions, in relation to fats and sodium, were rejected on the basis that they "would convey a conflicting and confusing message to consumers, because it would encourage consumption of those nutrients for which, on the basis of generally accepted scientific advice, European, national and international authorities inform the consumer that their intake should be reduced" and it was considered that these two claims would breach the EC Regulation in terms of being ambiguous or misleading in light of wider dietary recommendations (Commission Regulation (EU) No. 432/2012)).

The regulation also allows for new claims to be added to the list, including product-specific claims. Applicants may also request 'proprietary data status', granted for 5 years, if it can be demonstrated that the claim could not be authorized otherwise.

The submission procedure requires that companies prepare a dossier of evidence, which must adhere to the scientific criteria and format set out in EFSA guidelines. This includes characterization of the food or food component and a systematic review, based on the totality of available pertinent data, to demonstrate that a specific beneficial physiological effect has been achieved in a study group that is representative of the target population for which the claim is intended.

The process of scientific assessment and legal authorization takes a minimum of 9–12 months; however, there is minimal opportunity to communicate with EFSA prior to or during the submission process when questions arise. EFSA agrees that dedicated submitter support would be beneficial to all concerned; however, at the time of writing, funding has not been sufficient to provide additional resources for this purpose.

In addition to the stringent authorization process, there are extra rules that limit certain types of claims or their application.

Blanket prohibitions exist for messages that could state or imply:

- that health could be affected by not consuming the food;
- the treatment, prevention, or cure of disease(s) as a result of eating, or not eating, certain foods;
- a specific rate or amount of weight loss;
- that an individual doctor or healthcare professional has endorsed the food or that they are made reference to within a claim;
- nutrition or health benefits of alcohol.

Vague, non-specific suggestions such as 'good for you' are permitted by the regulation, but only when anchored by a relevant, authorized claim to validate their use. The EC has published specific guidance on this topic, provided for under Article 10 of the EC Regulation (European Commission 2013/63/EU).

Mandatory statements are required with all health claims, as follows:

- A statement indicating the importance of a varied and balanced diet and a healthy lifestyle.
- The quantity of the food and pattern of consumption required to obtain the claimed beneficial effects.
- Where appropriate, a statement addressed to persons who should avoid using the food.
- An appropriate warning for products that are likely to present a health risk if consumed to excess.

Regarding the balanced diet and lifestyle statement, although the regulation does not stipulate where this information should appear in relation to the claim, research suggests it should be at least in the same field of vision so to reflect the importance of the overall diet and not to mislead consumers as to the potency of the product in isolation.

In terms of which foods can carry nutrition or health claims, the EC Regulation includes an article on 'nutrient profiles,' included to restrict the use of nutrition and health

claims to foods with an overall 'favorable' nutrient composition, with "the aim to avoid a situation where nutrition or health claims mask the overall nutritional status of a food product, which could mislead consumers when trying to make healthy choices in the context of a balanced diet."

In theory, 'less healthy' foods can fail one of the nutrient profile criteria and still make a nutrition claim, as long as the failing nutrient is stated clearly, for example, 'low in fat, high in salt.' However, no health claims will be permitted if the food fails any of the criteria.

EFSA has provided a scientific opinion on the setting of nutrition profiles (2008); however, due to the complex and political nature of agreeing thresholds to suit all interested parties, a system has not yet been agreed. Once in place, companies will have 2 years to comply by removing claims or reformulating their products to meet the nutrient thresholds.

In addition to the overarching EC Regulation and associated community and national guidance, some European member states are subject to further local rules. There is an argument that this is creating an inconsistency in local implementation of the regulation and does support a harmonized approach across Europe. For example, in the United Kingdom, companies must also comply with the self-regulatory codes on broadcast and non-broadcast advertising (also covering the Internet). Complaints about misleading claims are investigated and judged by the Advertising Standards Authority, and some consider that its approach is grounded in an overly stringent interpretation of the rules.

At the time of writing, there are a number of 'on-hold' health claims, which relate mostly to botanical ingredients. This is due to an overlap between the EC claims Regulation (foreseen to include botanical food products) and the existing legal framework for traditional herbal medicinal products, under Directive 2004/24/EC. Here a pharmacological effect is considered plausible based on traditional use only, as defined by the Directive. Given that medicinal claims are forbidden in relation to foods, differences in legal requirements between health claims and traditional herbal products could mean that the same substance is treated differently, depending on whether it is present in a food or in a medicine, which possibly leads to consumer confusion. Until such time as a decision is reached, national legislation will continue to apply. It is not currently known when a decision will be reached on these claims, but when they are, it is likely that companies will have 6 months to remove unauthorized claims.

The Consumer Perspective

Research into consumer attitudes to foods with health benefits and understanding of claims is important on a number of levels. In the first instance, testing can demonstrate that a company's claims are well understood by the average consumer and not misleading – a general principle under most jurisdictions. Research can also help predict whether claims are appealing to consumers and will encourage purchases and brand loyalty, which in turn helps to drive innovation. In the longer term, and from a public health perspective, research should help determine whether claims actually result in ongoing and wider good food choices and, ultimately, whether these food choices improve major health outcomes. However, the research into consumer attitudes and preferences is mixed.

The previously strong global growth in 'health and well-being' foods has declined in recent years, largely due to the economic recession influencing consumer food purchases and new regulations imposing stricter control of the use of nutrition and health claims. However, some claim areas are thought to be reinvigorating the market, such as those in relation to energy, mood enhancement, digestion, and heart benefits. Given that the use of nutrition and health claims is primarily a marketing choice and not a prerequisite for the sale of 'healthier' foods, it can be expected that claims will come and go over time, selected by food companies based on reported consumer trends. This variation may add to the challenge of mapping and understanding consumer acceptance of claims, given that food purchases (and consumption) are already governed by a complex set of dynamic interactions in addition to differences due to cultures, food types, and eating occasions.

The global aging population phenomenon has led to the UN predicting that by 2047, the number of older people in the world will, for the first time in history, exceed the number of young people. The associated increasing prevalence of non-communicable diseases means that studies relating to consumer preferences and understanding of nutrition and health claims in older subjects will be particularly useful. This was highlighted by a Canadian study, where the mean age was 70.8 years, which found that subjects were motivated to increase their understanding of foods with health benefits and that labels were the preferred source of information. Subjects reported that more information could be provided to assist them in their understanding of the health benefits, adding that this was likely to mean they would consume more of these products.

Yet an international study in the general population, related to salt reduction, where the mean age was 39.7 years, found that TV advertising, social network sites (e.g., blogs), and newspapers were the preferred means of communication rather than food labels and packaging. Thus, it is important that research captures the differences within and between age groups.

For claims to have any chance at success, attention must first be paid to getting the product fundamentals right, such as taste, price, and the general appeal of the product and packaging. It has also been found that for claims to be well received by consumers, they must already have a positive attitude towards healthy foods in general and, ideally, be familiar with the subject of the claim for it to be perceived as useful.

Claims can be helpful in facilitating choice and educating consumers about lesser known foods or ingredients and their beneficial effects as well as reinforcing the widespread public health messages and big campaigns. However, it has been noted in relation to the EU health claims system that there is some misalignment between authorized claims and some general dietary recommendations. Examples include a lack of claims for the benefits of fruit and vegetables or wholegrains, since the Regulation requires specific nutrients to be clearly defined (or 'characterized') rather than a food group being the subject of the claim. This could ultimately confuse some consumers and place an additional burden on healthcare professionals in order to explain the differences.

In some instances, claims have been authorized but have had low uptake by the industry in response to some research

findings, which could also help explain the previous point. For example, in Europe, 'health by stealth' and incremental reductions through reformulation have been highly successful approaches to reducing population salt intakes. Evidence suggests that nutrition or health claims announcing 'low' or 'reduced salt' may be off-putting to consumers who make assumptions that foods with less salt will not meet their taste expectations. Yet other researchers have reported that for some consumers, the impression of healthiness is linked to positive connotations such as increased 'freshness' and 'quality' and associated foods are therefore expected to taste better too. Further research is needed to build understanding on how certain nutrients or health messages are likely to be received by consumers.

Due to the number of variables and need for large-scale research, the European Community has provided funding under its Seventh Framework Programme and has begun work on 'CLYMBOL,' a project running from 2012 to 2016. The work aims to gain a better understanding of the effects of health claims and symbols on food labels and how this affects purchase and consumption behavior. Interim results in 2013 relating to five EU countries found that there was a low proportion of health claims in the market generally compared with nutrition claims, with only 10% prepacked foods carrying health claims and 20% bearing nutrition claims.

Future insights gained from research such as CLYMBOL will help both food companies and policy makers to understand how to optimize the use health messages as claims and, where appropriate, how best to align with public health messages delivered by healthcare professionals or through public health campaigns.

Other Types of Food Legislation and Nutrition Labeling

Food legislation is designed to protect consumers from foods that could be injurious to their health (laws on food safety) and from misleading information (laws on food labeling, advertising, and fair commercial practices). Food manufacturers must also adhere to any specific legislation concerning their particular category (e.g., 'natural spring waters,' 'novel foods,' and 'dietetic foods') and their marketing choices, such as nutrition and health claims. Compositional criteria may be stipulated (e.g., for foods marketed as 'meal replacements' and milk products) as well as specific advertising rules and mandatory statements (e.g., in relation to infant formulas, allergen labeling, and country of origin labeling). In addition to legislation, there may also be local rules, guidelines, and codes of practice to help interpret and implement the laws in a uniform manner.

Globally, food law is vast in its breadth and depth, and detailed requirements should be considered by experts in the field to ensure completeness and accuracy of application for the local market. In an attempt to promote consistency of all food standards work undertaken by international governmental and nongovernmental bodies, the Codex Alimentarius Commission was set up in 1963 by FAO and WHO to "develop harmonised international food standards, guidelines and codes of practice to protect the health of the consumers and ensure fair practices in the food trade." Its work includes, to name a few, a long and varied list of topics such as 'Guidelines for the Production, Processing, Labelling and Marketing of Organically Produced Foods'; 'Principles for the Risk Analysis of Foods Derived from Modern Biotechnology'; 'Guidelines on Substances used as Processing Aids'; 'Guidelines for Vitamin and Mineral Food Supplements'; 'Guidelines for the Use of Nutrition and Health Claims and Nutrition Labelling'; 'Standard for Fermented Milks'; 'Standard for Fat Spreads and Blended Spreads'; and 'Recommended Methods of Analysis and Sampling.'

Within its 'Guidelines on Nutrition Labelling,' the Codex Alimentarius Commission defines nutrition labeling as "a description intended to inform the consumer of nutritional properties of a food, which has two components: a nutrient declaration and supplementary nutrition information. Nutrient declaration means a standardized statement or listing of the nutrient content of a food and supplementary nutrition information. The content of supplementary nutrition information will vary from one country to another and within any country from one target population group to another according to the educational policy of the country and the needs of the target groups."

Nutrition labeling is most commonly found on the back of prepacked foods but can also be found on the front of pack (repeating some but not all of the details on the back in the form of icons, symbols, numbers, or text); on websites and in leaflets; in menus or on menu boards at eating establishments; and in relation to non-prepacked foods.

In many jurisdictions, the standard practice has been to provide this information in a numerical and tabular format; however, research found that this is not always understood well by consumers. Recent studies suggest that labels would be more effective if they were less numerically complicated and if they provided more interpretive elements about the nature of the product (such as color, symbols, and text) to aid consumer understanding of the information and to motivate healthier choices.

Each year, the European Food Information Council (EUFIC) and its partner food information organizations publish the 'Global Update on Nutrition Labelling,' providing a snapshot in research developments and approaches to nutrition labeling. The latest update (2015) highlights that although many countries now have some form of nutrition labeling in place, there is still disagreement about which format most effectively influences consumer behavior (14 countries have a voluntary scheme and around 50 countries operate mandatory labeling). More research is required to determine which labeling scheme is preferred by consumers and offers the best guidance to influence purchasing decisions and overall diets.

The World Cancer Research Fund (WCRF) has developed the NOURISHING framework, which aims to help identify the effectiveness of nutrition labeling and claims in relation to population health outcomes. This framework has been designed to help policy makers around the world to promote healthy diets and reduce obesity by identifying and monitoring areas for improvement, including tailoring actions to different populations. A key policy area within the framework is 'Nutrition label standards & regulations on the use of claims and implied claims on foods,' which is based on evidence that

nutrition labeling and claims can be a valuable tool to both consumers and food manufacturers. The WCRF publishes an updated list of international 'key action' examples with the aim of sharing knowledge and encouraging the use of clear nutrition information as appropriate around the globe.

Summary

The focus of this article has been limited to nutrition and health claims for food and the regulatory controls governing their use in the commercial context, together with a brief mention of nutrition labeling and other food-related laws. Given the relative newness of the subject, evidence is still building about whether the various systems around the world will achieve their aims to help protect and inform consumers; facilitate choice and encourage innovation, investment, and fair trade. Ongoing research is required in a number of areas including the influence of factors such as age, education, culture, and socioeconomic groups on food choice and consumer perception of claims. Research is also required to determine the relative differences of specific nutrients and their value as nutrition or health claims in different food applications.

For nutrition and health claims to be accepted and relevant to target populations, the research net must be cast far and wide to gain insight into the perceptions of consumers from all walks of life and all countries where claims are permitted. The findings and building a picture of key themes will have relevance to policy makers, health professionals and marketeers alike.

Introduction

Nutrition is a fundamental aspect of life, and it is linked to multiple components, systems, and processes, including those occurring during diseases, such as infection. In this context, nutrition has a close relationship with infection. For example, malnutrition is considered to be an important cause of immunodeficiency worldwide, predisposing the malnourished to multiple infections. All forms of immunodeficiency predispose to malnutrition, particularly those opportunistic, related to those altered states of immunity. Malnutrition is a condition that, by itself, increases the host's susceptibility to infectious diseases, and these infections, in turn, have negative repercussions on the metabolism of the host, worsening the nutritional state. In other words, malnutrition alters the host's response to infections, and infections increase malnutrition. This malnutrition–infection complex is associated with significant morbidity and mortality worldwide, particularly in developing countries, where food insecurity and undernutrition primarily affect children. Accordingly, children constitute one of the most vulnerable populations, and infectious diseases cause over half of the total deaths in children under 5 years of age. As stated, the relationship between malnutrition and infection is bidirectional, because infectious diseases can be associated with malnutrition (e.g., giardiasis can compromise intestinal absorption). In regard to parasitoses, many epidemiological studies have found significant connections between helminthic diseases (e.g., ascariasis, trichuriasis, hookworm, and strongyloidiasis, etc.) and protozoan infections (e.g., giardiasis, amebiasis, etc.).

Micronutrient deficiencies and infections are intricately linked, with deficiencies being related to poor growth, impaired intellectual performance, and predisposition to infections (mainly bacterial, viral, and parasitic). In fact, poor nutrition may drive the enormous worldwide impact of parasitic infections. Foodborne infection, in particular, represents a major burden on public health and even the political and economic development of many countries and regions, and this phenomenon should be the subject of ever more focused investigation.

This article describes the relationship between nutrition and infection, with a focus on how malnutrition affects susceptibility to infection and the burden that infections, especially foodborne infections, place on public health.

Food and Infections

Foodborne diseases are considered to be a major public health problem, being an important cause of morbidity and mortality worldwide, with the highest rates in low- and middle-income countries. Foodborne infections are related to unsafe food, and their global burden and economic costs are considered to be a threat to public health and development. According to the U.S. Centers of Disease Control and Prevention (CDC), around 76 million cases of foodborne illnesses occur in each year in the United States, leading to 325 000 hospitalizations and 5000 deaths. The resulting economic burden is estimated to be $10–83 billion USD per year. Australia and New Zealand have estimated costs up to $86 million per year, and across Europe, the annual cost has been estimated to be $71 million. However, there are no comprehensive global assessments of foodborne disease, and, as a result, the real total burden remains unclear, especially in the tropical, developing countries where these infections are most prevalent.

A foodborne disease occurs as the result of the ingestion of contaminated food products, and it includes a huge number of illnesses caused by different pathogens (e.g., bacteria, fungus, viruses, parasite, and even prions). Chemicals in foods can also produce illness, but this type of illness is not infectious in nature, and it will not be considered here. The World Health Organization (WHO), United Nations Food and Agriculture Organization (FAO), and CDC, as well as other international health organization, have identified risk factors crucial to foodborne outbreaks, including the use of unsafe water sources, inadequate cooking processes, contaminated equipment, and poor personal hygiene, especially as it applies to the food handler. Recently, the FAO and WHO investigated the ten foodborne parasites with the greatest global impact, developing a joint report, 'Multicriteria-based ranking for risk management of food-borne parasites,' based on the parasites' burden on human health and other factors, including the geographical ranges of the organisms. According to the report, the top ten parasites are as follows:

1. *Taenia solium* (pork tapeworm): in pork
2. *Echinococcus granulosus* (hydatid worm or dog tapeworm): in fresh produce
3. *Echinococcus multilocularis* (a type of tapeworm): in fresh produce
4. *Toxoplasma gondii* (protozoa): in meat from small ruminants, pork, beef, game meat (red meat and organs)
5. *Cryptosporidium* spp.(protozoa): in fresh produce, fruit juice, milk
6. *Entamoeba histolytica* (protozoa): in fresh produce
7. *Trichinella spiralis* (pork worm): in pork
8. *Opisthorchiidae* (family of flatworms): in freshwater fish
9. *Ascaris* spp. (small intestinal roundworms): in fresh produce
10. *Trypanosoma cruzi* (protozoa): in fruit juices

Although the report looked at the problem of parasites on a global scale, individual parasites can have greater relevance to

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00491-8

different countries and regions. For instance, *T. cruzi* is commonly encountered in rural Brazil, where *Opisthorchiidae* is unknown, while the latter is prevalent in Southeast Asia, which has no presence of the former.

The different pathogens can be transmitted to food by many ways. *T. cruzi*, which causes Chagas disease, is most commonly associated with household insect vectors (bed bugs), but it can also be orally transmitted. However, hand hygiene plays the most important role as a vehicle for transfering pathogens to food. That is why the food handlers, defined as the persons who manipulate the food in process, are considered to be crucial as vectors of foodborne infections. All of these factors remain of utmost importance, leading to the necessity for strict hygiene practices among food handlers, in order to prevent foodborne illness. Fecal–oral transmission tends to be to most common cause of food contamination, and it involves the fecally contaminated hands of food workers. Bacterial, viral, and parasitic infections have been connected to this way of transmission, including *Salmonella* spp., hepatitis A viris, *Giardia intestinalis*, and *Yersinia* spp., among many others. The only effective strategy for preventing of fecal–oral transmission is strict personal hygiene. Another important point to consider is that the presence of infected skin lesions in the food handler has been closely related with staphylococcal and streptococcal infections. Regarding the different types of food implicated in foodborne diseases, there appears to be a relationship between hand contact time during the preparation of the food and the transmission of pathogens, with sandwiches, salads, and cooked meals being the most important vehicles of transmission.

In addition to hands, nasopharyngeal secretions can cause the transmission of a pathogen into the food supply. Foodborne illness via staphylococcal and streptococcal infections has also been related to nasopharyngeal secretions, as shown by the development of streptococcal pharyngitis and its connection to the presence of the bacteria in the pharynx of the food handler.

Aerosolization, fomites (infectious media adhering to solid objects), and insects are also different ways for pathogens to be transmitted, outside of the contamination of food. Aerosolization transmits the norovirus. Fomites can also spread the norovirus, as well as hepatitis A. Finally, insects, such as flies, cockroaches, and triatomine bugs, are the vectors for assorted bacteria and protozoans.

Incidence and Trends

The Foodborne Diseases Active Surveillance Network (FoodNet) has been describing the incidence and trends of foodborne disease in the United States since 1996, and the 2012 FoodNet report shows that there was a total of 19 531 infections, leading to 4563 hospitalizations and 68 deaths (for a overall case fatality rate of 3.4‰). Another two recent reports from FoodNet show that *Salmonella*, *Campylobacter*, *Shigella*, *Cryptosporidium*, and Shiga toxin *Escherichia coli* (STEC) remain the main causes of laboratory-confirmed foodborne diseases in the United States.

Age is an important factor in foodborne illnes, with most cases in children under 5 years of age. In people older than 65 years, there has also been a high incidence, including hospitalizations and fatalities. Comparing in these populations for the period 2006–08 with the year 2012, infection rates increased for *Campylobacter* (by 14%) and *Vibrio* (by 43%). *Vibrio* infection was also related to a high percentage of mortality in persons over 65 years.

For different infections, the incidence rates, per 100 000 people, were as follows: *Salmonella*: 7800; *Campylobacter*: 6793; *Shigella*: 2138; *Cryptosporidium*: 1234; non-Shiga toxin-producing *E. coli* (nSTEC): 551; STEC: 531; *Vibrio*: 193; *Yersinia*: 155; *Listeria*: 121; and *Cyclospora*: 15. In children under 5 years of age, there was a high incidence of *Cryptosporidium*, and in adults over 65 years, there were more cases of *Listeria* and *Vibrio* infection.

Malnutrition and the Infection Cycle

The complex interaction between infection and malnutrition creates a hostile environment that perpetuates a vicious circle that leads to the two entities benefiting from each other. Some of the phenomenon involved during different parts of the cycle include decreases in the activity of macrophages, diminishment of the inflammatory response, and a reduction in the capacity to create specific antibodies. However, there are two effects that can occur in the presence of both malnutrition and infection. The first one is the synergistic effect, and it happens when an infection worsens the malnutrition or when the malnutrition contributes to decreasing the immune response to infection. The second effect is an antagonist mechanism, which occurs less frequently than the synergistic effect. The antagonistic mechanism happens when malnutrition decreases the multiplication of the agent.

Malnutrition can make a person more susceptible to infection, and infection contributes to malnutrition, which causes a vicious cycle (Figure 1).

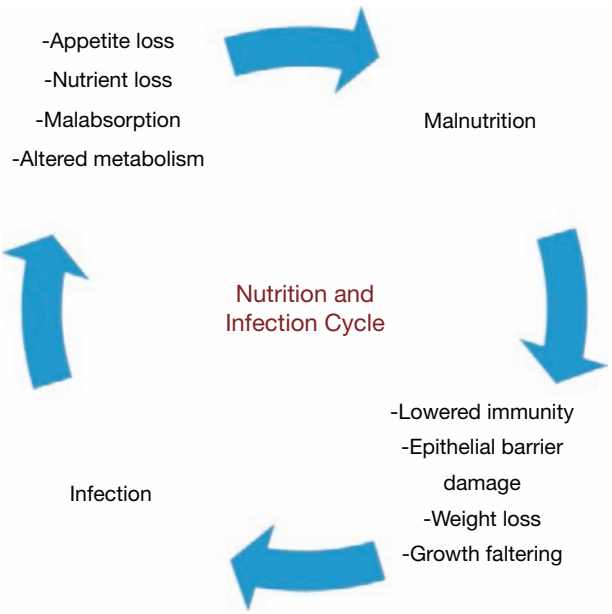

Figure 1 Nutrition and infection cycle.

Worldwide, severe malnutrition is the most prevalent cause of immunodeficiency, affecting as much as 50% of the population in some impoverished communities. Severe protein energy malnutrition (PEM) in children is clinically defined as a weight-to-height ratio below 70% and/or the appearance of pitting edema on both feet, and it is categorized as either marasmus, a chronic wasting condition, or kwashiorkor, which is characterized by edema and anemia. PEM causes susceptibility to the infections described in the following section.

During childhood, severe malnutrition affects thymic development, which, in turn, compromises immunity in children through a long-term reduction of peripheral lymphocyte counts, causing susceptibility to infections and nutritionally acquired immunodeficiency syndrome. Thymus atrophy has been observed in children with malnutrition, and the patent atrophic condition appears to result from a decrease in T-cell proliferation and increased depletion by apoptosis, affecting mainly immature T CD4+ and T CD8+ cells. This has been, at least partially, attributed to lower leptin levels during starvation or malnutrition.

Malnutrition clearly affects hematopoiesis, determining anemia, leucopenia, and severe reduction in bone marrow. The production of IL-6 and TNF-α by bone marrow cells is also significantly lower in malnourished animals. The capacity of malnourished hematopoietic stroma to support the growth of hematopoietic stem cells (CD34+) in vitro is also decreased. This finding relates to disease formation, because CD34+ cells are able to generate multiple lymphohematopoietic lineages, including myeloid, erythroid, and lymphoid (B and T) types.

In malnourished children, both acquired and innate immunity is affected, making them more susceptible to opportunistic pathogens such as *Pneumocystis jirovecii*. In addition, PEM impairs the linear growth of children; it has been suggested that acute-phase response and proinflammatory cytokines directly affect the bone remodeling required for longitudinal growth.

Specific Immunological Alterations in Undernutrition

A series of specific immune responses and their alteration during undernutrition have been described and characterized.

Cell-mediated immune response alterations

As previously mentioned, severe malnutrition in newborns and small children causes atrophy of the thymus, with reduced cell numbers and, subsequently, ill-developed peripheral lymphoid organs (e.g., lymph nodes and spleen). This leads to long-lasting immune defects characterized by leucopenia, depressed serum complement activity, decreased CD4 to CD8 ratio, and increased numbers of CD4/CD8 double-negative T cells, contributing to the appearance of immature T cells in the periphery. The biological function of different cell types (macrophages and Kupffer cells) is clearly decreased during nutritional deficiencies. There is also impaired activation of T cells, which has been clearly associated with deficits of cytokine production, which are the main molecular mediators of immunity. This was evident from a study of malnourished children who showed reduced production of type 1 cytokines (IL-2 and IFN-γ).

Epithelial barrier alterations

Immune defense at the epithelial barrier of the undernourished host is compromised because of the altered architecture of the gut mucosa, with structural effects including the flattening of the hypotrophic microvilli, reductions in lymphocyte counts in Peyer's patches, and reductions in immunoglobulin A (IgA) secretion, all of which are characteristics of environmental enteric dysfunction.

Complement alterations

The availability of complement components and phagocyte function are compromised during malnutrition, directly affecting pathogen elimination. This happens because the complement system by itself can destroy bacteria or viruses or because complement receptors present on the phagocyte surface mediate the capture of pathogens. Significantly lower levels of complement, especially C3, which is the main opsonic component, were described by Sakamoto and coworkers. In addition, the ability of phagocytes to ingest and kill pathogens was also reduced. The restriction of complement components affects the capacity of professional phagocytes to engulf and eliminate pathogens.

Antibody alterations

In regard to antibody production, malnourished children are deficient in IgE antibodies that protect against *Ascaris lumbricoides*, even though they have high concentrations of total IgE; the IgE antibodies that these children do have are neither worm-specific nor protective, and their memory T cells do not recognize helminthes antigens.

Malnutrition Increases Risk of Infection

Malnourished children suffer more frequently from respiratory infections, infectious diarrhea, measles, and malaria, with each condition characterized by a protracted course and exacerbated disease. Tuberculosis is an infection that is particularly influenced by undernutrition, and it is a major cause of morbidity and mortality in developing countries. Approximately one-third of the world's population is infected with *Mycobacterium tuberculosis*, generally in a subclinical form. Similarly, undernutrition may also affect the clinical outcome of tuberculosis. A recent meta-analysis suggested that low serum vitamin D levels are associated with higher risk of tuberculosis activation. It has also been suggested that malnutrition may contribute to the appearance of *M. tuberculosis* strains that are multiply resistant to antituberculosis medications.

Another disease that is associated with malnutrition is measles; even though effective vaccines for measles exist, it continues to cause severe disease and death in children worldwide. Among other factors, malnutrition and vitamin A deficiency increase complication rates. There is experimental evidence that vitamin A supplementation in children is associated with an average reduction of 23% in mortality risk, as well as an attenuation in disease severity. For this reason, the WHO recommends the administration of two oral doses of 200 000 IU of vitamin A to children with measles who live in vitamin A deficiency areas.

Malnutrition and intestinal parasitism share a similar geographic distributions, with the same individuals experiencing

both diseases simultaneously. The coexistence of undernutrition and nematode infection involves two causal pathways: (1) malnutrition augments susceptibility to infection, and (2) the infection itself leads to a more accentuated undernutrition. Parasites that clearly affect the nutritional status are soil-transmitted helminths, *G. intestinalis*, *E. histolytica*, coccidian protozoans, and *Schistosoma* spp.

Noma is an opportunistic infection promoted by extreme poverty, which evolves rapidly from a gingival inflammation to mutilating orofacial gangrene. Even though it can be observed worldwide, noma is much more common in sub-Saharan Africa. It results from very complex interactions between malnutrition, infection, and compromised immunity, and it is very frequently preceded by malaria, measles, and severe necrotizing ulcerative gingivitis.

As mentioned previously, undernourished hosts are more susceptible to infections and to developing a severe course of infection due to impaired immune function. However, current works suggest that nutritional status can also increase the pathogenicity of the infecting agent or even change an avirulent virus into a virulent one. Animal models, particularly mice models, have provided the foundation of this theory. In a mouse model with selenium and vitamin E deficiency, a benign strain of Coxsackie virus B3 became virulent and caused myocarditis, as the result of a mutation in the viral genome caused by a decrease in dietary nutritional antioxidants; in other words, nutritional deficiencies changed an avirulent virus into a virulent one. Additionally, deficiencies of lycopene, vitamin E, and the B group vitamins have been serologically related to both CVB4 and CVA9, which were responsible for an epidemic of optic and peripheral neuropathy in Cuba in the early 1990s. These studies suggest that host nutritional status has influence beyond the host itself, altering the genome of viruses present in the host community.

Micronutrients in the Prevention of Infections

Ensuring adequate micronutrient status is important for the prevention of certain infections. Several micronutrients, such as vitamin A, beta-carotene, folic acid, vitamin B12, vitamin C, riboflavin, iron, zinc, and selenium, have immunomodulating functions and thus influence susceptibility to infections, as well as the course and outcome of the illness. The effects of micronutrient deficiency have been evaluated by several experimental models (Table 1).

Vitamin A has been termed the 'anti-infective nutrient,' although there is little evidence that it prevents the incidence of new infections. The one area in which the administration of this vitamin has actually been effective is in the prevention of neonatal infections. It has also been demonstrated that children with infectious diseases such as pneumonia and rheumatic fever tend to have low levels of vitamin A. In addition, adequate vitamin A stores are related to faster growth and better appetite.

Similarly, although iron supports components of the host-defense system, such as phagocytosis, there is no evidence that iron itself prevents infections. In fact, rich stores of iron and the high-dose administration of the nutrient have been associated with increased susceptibility to or morbidity from certain intracellular pathogens such as the plasmodium of malaria and the protozoa *E. histolytica*, among others.

By contrast, zinc is emerging as a nutrient that can reduce the risk of infections and reinfection through supplementation. Recent trials of zinc supplementation have shown substantial benefits to children at risk of deficiency. Zinc supplementation also appears to reduce the duration and severity of acute diarrhea in India, as well as to improve outcomes in subsets of patients with persistent diarrhea in Peru. Zinc supplementation may not be safe and advantageous for everyone, however. In children with severe PEM, a three-armed trial in Bangladesh comparing a placebo to two doses of zinc supplementation found a higher mortality rate among those receiving a very high zinc dose. Finally, vitamin D has recently emerged as a nutrient of interest with promise for prophylactic application in epidemic viral diseases such as influenza and diverse microbial infections.

Obesity and Infection

Obesity is an increasing problem in public health, clearly associated with a high risk of multiple pathological conditions,

Table 1 Effects of malnutrition on the immune system in some experimental models

Experimental model	*Diet restriction*	*Effect*
Human reconstituted SCID mice	Total vitamin A restriction; 7-day gestation period	Impaired antibody production after tetanus toxoid immunization
SD rats	Total Zn restriction; 34 weeks	Thymus atrophy, oligospermia, testicular atrophy, and loss of sperm cells and spermatocytes
BALB/c mice	Total vitamin A restriction; 2–5 weeks	Increased Th2 and T regulatory cells, decreased Th1
C57BL/6 mice	Total dietary restriction (70%); 52 weeks	Decreased humoral response to hepatitis B virus

including cardiovascular and metabolic diseases. Likewise, obesity affects different organs and systems, generating an environment susceptible to an increased risk of infection, and there is evidence of immune system impairment, indicated by alteration in cell differentiation, cytokine production, and thus chemotaxis during the immune response. In terms of cardiorespiratory function, overweight states produce mechanical ventilation disorders, causing pulmonary restriction and affecting the immune response at this level; this is analogous to infections at the skin level, because of altered tissue perfusion.

There has been developing research interest on the relationship between obesity and infection, with a focus on the bidirectional interaction between the two: obesity has been linked to increased risk of infection with different pathogens, and some pathogens have been associated with an increased risk for developing obesity. For example, *Taenia* infection has been associated with decreased levels of leptin, a hormone associated with signaling satiety after food intake. Also, an association has been found between seropositivity for *T. gondii* and obesity, although the causal mechanism of this interaction has not been identified. As a matter of speculation, it may be mediated by complex mechanisms through which *T. gondii* influences different neurological centers involved in motivation and survival.

Finally, it has been shown that obesity is an independent risk factor for the development of *Clostridium difficile* infection, but the mechanisms underlying this relationship are still unknown. Given this evidence, future research should be directed toward clarifying the mechanisms involved in the relationship between obesity and the risk of infection, as well as the clinical significance of this interaction, in order to define the relevance and potential benefit of early therapeutic interventions for patients predisposed to acquiring potentially dangerous pathogens.

From Infection to Malnutrition

Multiple mechanisms have been associated with nutritional impairment during infection, including factors related to the decreased intake of nutrients and increased nutrient loss. Although initially representing a host-defense strategy, some of these mechanisms can ultimately have a negative impact on nutritional status.

Many infectious diseases that compromise the nutritional status directly affect the gastrointestinal tract. Hyporexia, poor appetite, or frank anorexia is frequent when the food intake is associated with vomiting or diarrhea. The symptomatic manifestations can evolve from a variety of associated mechanisms, however; these include the decreased intake of solids due to xerostomia (dry mouth) secondary to diarrheal dehydration; changes in the absorption surface of the gastrointestinal lumen, with destruction of the intestinal villi, induced by bacterial toxins; and nutrient loss through hypersecretion across the mucosa. These mechanisms directly affect the absorption or retention capacity of a nutrient. Not only the nutrients acquired through diet are lost, though. Endogenous nutrients that are generated during the normal cell turnover of the gastrointestinal epithelium can also be lost, when, under normal conditions, they would be largely reabsorbed.

Similarly, respiratory diseases can affect undernutrition. Delay in growth has been documented in children with recurrent lower respiratory infections, as compared to unaffected children. Although the mechanisms behind this relationship have not been clearly elucidated, it has been suggested that fever and hyporexia are the main associated factors.

There are also chronic infectious diseases whose characteristics of chronicity lead to a state of cachexia, as occurs with tuberculosis and HIV infection. In fact, in children with HIV, alterations in nutritional status can often represent the first clinical sign of the condition, and wasting syndrome is considered to be a feature of AIDS. In HIV patients with more severely disrupted nutritional status, the CD4 lymphocyte count is general substantially reduced, emphasizing the important role of immunological alterations in the pathogenesis of malnutrition.

Conclusions

The activation and maintenance of the immune response requires adequate energy consumption. PEM is a critical – but underestimated – factor contributing to susceptibility to infection, causing impaired immune function, as well as alterations in the normal development of children. Once the infection is established, it, in turn, contributes to further malnutrition, therefore perpetuating a vicious cycle. An adequate micronutrient status is important for the prevention of certain infections; therefore, in impoverished countries where malnutrition represents a great burden, mainly in children, strategies must be implemented in order to reduce the morbidity and mortality caused by malnutrition and, more particularly, chronic undernourishment.

Nutritional Epidemiology

Nutritional epidemiology is the application of epidemiological methods to the study of how diet is related to health and disease in humans at the population level. Nutritional exposures have been studied in relation to a wide variety of health outcomes, such as infectious diseases, chronic diseases, cancer, and congenital malformations. Epidemiologists investigate how nutrition affects the occurrence of disease by collecting data on and comparing large groups of people. Statistical methods are employed to estimate the extent to which a factor influences risk of disease in a population. This estimate is often expressed as a measure of association. Epidemiological methods are also used to estimate the nutritional status of populations.

In epidemiological research, diet can be studied at different levels comprising intake of nutrients, foods, food groups, and/or patterns. These exposures can be measured by directly ascertaining what people eat (e.g., through the administration of questionnaires), by measuring markers of intake in biological specimens, or by estimating body size and the relative size of body compartments.

The exposure measure of interest in nutritional epidemiology is usually long-term diet, since the effects of intake on most health outcomes, especially those related to noncommunicable diseases, are likely to occur over extended periods.

Findings from epidemiological studies can contribute to the development of policies on diet and health, ranging from governmental dietary guidelines to food fortification and banning of substances from food. Randomized controlled trials provide the strongest evidence of a causal relationship between an exposure and health outcome. However, randomized trials of dietary interventions have several limitations and are often unfeasible for ethical or practical reasons. Thus, nutritional policy decisions are often guided by findings from a combination of sources, including observational epidemiological studies in which participants have been followed prospectively.

Methods of Measuring Diet

A major challenge faced in nutritional epidemiology is the limited availability of methods to accurately measure diet at the population level. Studying diet as a cause of disease can be difficult for several reasons. First, diet is not a single exposure, but instead comprises a group of exposures (e.g., nutrients, foods, or food groups) that are often highly correlated. Second, in many cases, nearly everyone in a population is exposed to the same dietary factors; thus, dietary exposures are continuous variables often with a limited range of variation. Third, people generally do not make sudden changes to their diet at easily identifiable time points. Rather, eating patterns change gradually over several years. Finally, recalling what one eats on a given day can be difficult, and most individuals do not know the exact contents of the food they eat. Despite these challenges, several methods are currently available to assess diet at the population level.

Report of Food Intake

Diet Record

Diet records are used to assess short-term intake. Individuals prospectively record their food and beverage intake over a period of 3–7 days, providing detailed descriptions of the foods, preparation methods, and quantities consumed. Quantities are assessed by actual weighing of food and volumetric measurements or estimated with the use of photographs. Diet records provide quantitatively accurate information and often serve as the 'gold standard' to validate other dietary assessment methods. Individuals do not have to rely on memory to record their diet and, therefore, are less likely to omit foods. Diet records require significant training of participants, who need to be literate and highly motivated. The burdensome nature of diet recording can lead to participant fatigue, reduced cooperation over time, and alteration of typical eating habits to simplify recording. Diet records are costly and consequently are most commonly used in clinical or research settings to monitor compliance to dietary interventions or to validate other instruments.

Twenty-Four-Hour Recall

Twenty-four-hour recalls are also used to assess short-term intake. The method consists of asking study participants to recall and report their food and beverage intake in the preceding 24 h. Interviewers use standard questions to obtain detailed information from participants through an interview conducted in person or by telephone. This method is easily implemented through a quick, inexpensive interview and often has a high response rate. Participants are not required to have high literacy to complete 24 h recalls. Although long-term memory is not needed, accurate recall of the previous day's intake and quantities of food may still be difficult. Detailed, sensitive probing by well-trained interviewers in a relaxed, unhurried setting can reduce erroneous recall of foods. Interviewers may relate a participant's activities to food consumption and refer to a list of commonly forgotten foods to support recall. Food models and photographs can be used to aid recall of portion sizes. Subjects may also be trained prior to the interview in estimating portion sizes and providing adequate descriptive detail to improve accuracy in recall. Twenty-four-hour recalls can provide detailed information without altering eating behaviors; however, the dietary information supplied by this method does not represent an individual's usual diet and does not account for day-to-day variation. This method is often used to describe the average diet of a group or population.

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00494-3

A 24 h recall allows researchers to assess mean absolute nutrient intake and compare mean intake over time.

Food Frequency Questionnaire

Food frequency questionnaires (FFQs) are used to measure long-term dietary intake. In general, one's usual average intake over an extended period is easier to recall than specific intake over a short time. Thus, dietary information supplied by an FFQ over a long period, although crude, is often more helpful than precise information obtained over a short period. FFQs do not quantify absolute intake, but instead rank individuals within a population with respect to intake. FFQs are composed of a food list accompanied by a question, typically close-ended, on the frequency of consumption for each item, usually over the previous year. Several factors are involved in selecting foods to include in an FFQ. They should be eaten reasonably often in a population, but their consumption must still vary between subjects. Included foods should have substantial nutrient content and not be highly correlated with another food on the list. Frequency categories must be mutually exclusive and have adequately narrow time intervals to capture variability of consumption between subjects. To allow estimation of absolute intake, portion sizes may be included by providing specific size options for each food, from which the participant can choose. However, portion sizes in FFQs are often poorly estimated. Moreover, portion size is correlated with frequency since the variability of intake in a population is largely driven by the frequency of intake rather than absolute amount consumed. Thus, including portion size does not appreciably contribute to ranking a population's intake, and it is often omitted from FFQs. In this case, an average or typical serving size, as provided in food composition tables, is used to compute nutrient intakes. FFQs can be self-administered or completed in an interview. They are inexpensive and relatively easy for participants to complete. FFQs may misclassify individuals with unusual diets, and they must be adapted for different populations. Used and validated in many settings, FFQs are region-specific and may require nutrient databases similarly specific to a region.

The reliability, or reproducibility, of an FFQ may be evaluated by computing the correlation of responses from repeated administrations of the questionnaire to the same subjects in a population. The validity, or accuracy, of an FFQ can be determined by comparing the instrument to another method considered superior to the FFQ, such as the diet record.

In all of these methods, food composition tables are used to compute nutrient intake from the reported consumed foods. Food composition tables and nutrient databases have been constructed for diets in several countries. A key assumption in using these tables is that the nutrient content of a food is constant. Databases can differ in the estimation of the nutrient content of the same food, which can be a source of systematic error in epidemiological studies.

Biomarkers

A biochemical indicator, or biomarker, is the concentration of a nutrient or a substance affected by intake of a nutrient or food in blood or tissue. Biomarkers are used in epidemiological studies as a measure of nutrient intake. Biomarkers may be used to complement the methods based on reported food intake described earlier. Studies that rely on participants to remember what they consumed may be subject to bias; for example, participants who have the disease under study may unintentionally recall food intake differently than participants who did not have the disease. Biomarkers, therefore, can be useful surrogates of intake in studies in which recall bias and participant compliance in reporting food consumption may be concerns. Biomarkers are also used as a measure nutrient intake when food composition tables are inaccurate or unavailable.

Epidemiologists also use biomarkers to measure nutrient status. Nutrient status is determined by nutrient intake in addition to many other factors. Nutrient concentrations are influenced by physiological processes including absorption, metabolism, transport, and excretion. Genetic and lifestyle factors can further modify these processes. Some nutrients, such as vitamin D, are both consumed and synthesized endogenously. Biomarkers for these nutrients, therefore, may better reflect the dose to which tissues are exposed than dietary intake alone.

To be an indicator of nutrient intake, a biomarker concentration should correlate well with nutrient intake. A biomarker of nutrient intake should not be regulated so tightly by homeostatic mechanisms that its concentration is constant over the entire range of normal consumption and cannot be used to discriminate between different levels of intake. Given long-term nutrient exposures are generally most relevant in epidemiological studies, an ideal biomarker concentration reflects dietary intake over time and is insensitive to short-term fluctuations in intake. Time integration is partially a function of the tissue specimen from which the biomarker is sampled. For example, fatty acids are stored in adipose tissue, which has a long half-life compared to plasma. The concentrations of many fatty acids measured in adipose tissue correlate higher with dietary intake than samples from other compartments.

Biomarkers are also employed in epidemiological studies as gold standards to validate against other methods of dietary assessment. The biomarker concentration must reflect intake for this use. To have an accurate estimation of validity, the measurement error of the gold standard must be uncorrelated with the measurement error of the test under evaluation (e.g., report of intake). Biomarkers are particularly useful in validation studies because errors in the measurement of a biomarker, such as technical measurement errors or random physiological variation, are uncorrelated with the typical errors that occur with other dietary assessment methods, including recall of diet.

Anthropometry

Anthropometric measurements, due to the ease of their assessment in the field, are frequently used as a measure of nutritional status in epidemiological studies. As measures of dietary intake, anthropometric measurements generally represent energy balance (e.g., body mass index and size of body compartments) or diet and environmental influences during childhood (e.g., height).

Self-reported height and weight are useful proxy measures in large epidemiological studies in which it is not possible to

obtain measurements on all study participants. A tendency for underestimation of weight and overestimation of height by participants can introduce systematic bias into studies using self-reported data. The prevalence of obesity may be underestimated as a result of this bias. Nonetheless, high correlations between measured and reported weight, including recall of weight several years earlier, have been observed in validity studies.

Sources of Variation in Diet

Long-term dietary exposures, as opposed to short-term intake, are usually of primary interest to epidemiologists studying a particular disease outcome. Although diet can be extremely variable from day-to-day, one important assumption in nutritional epidemiology is that this day-to-day variation is superimposed on an underlying, consistent pattern in intake over time. Due to the variability in intake from one day to the next, measuring an individual's diet for a single day provides a poor assessment of one's long-term intake. A person's true long-term nutrient intake is better estimated by the mean intake for multiple days. Therefore, the population distribution of intake is better represented when several days are measured.

The extent to which nutrient intake varies from day-to-day depends on the nutrient. Total energy intake is physiologically tightly regulated and, therefore, has a low day-to-day variation. Since macronutrients contribute substantially to total energy intake, macronutrient intake also has low day-to-day variation. By contrast, there is greater variability in micronutrient intake. Micronutrients are present in specific foods, of which consumption can vary widely on a day-to-day basis.

Variation in dietary intake can be large in developing countries where food intake is often directly related to income. Socioeconomic inequities among people in low- and middle-income countries result in large between-person variation in dietary intake. Day-to-day variation can be large if people are able to afford particular foods sporadically. Furthermore, the effects of seasonal variation on availability of foods can be greater in developing countries compared to industrialized countries.

Most studies indicate that the majority of day-to-day variability in intake occurs at random; that is, there are not clearly identifiable sources to explain it. This random 'within-person variation' accounts for most of the variability in intake at the population level. The second component consists of true differences in intake between persons in the population, and it is the variability component of interest in epidemiological research. When measures of intake rely on assessing only one day per person, within-person day-to-day variation results in an overestimation of extreme intakes. This affects estimations of the proportion of people in the population with intake above or below a given nutrient value and tends to attenuate measures of association between nutrient intake and health outcomes.

The effects of random within-person day-to-day variation on estimates of prevalence or association can be ameliorated in a number of ways. First, in nutrition surveys aimed at determining the proportion of the population with absolute intake above or below a given nutrient value, collecting more than one day of intake in a subgroup allows one to identify the contribution of within-person variation to the total variance and to adjust the prevalence estimates. Available methods accommodate for uneven number of measures per person and deviations of the nutrient distributions from normality. Second, in epidemiological studies in which short-term intake measures are used as the exposure or the outcome, replicate measures within-person can be averaged, and this average can be used to represent each participant's data point for analysis. Finally, the assessment of long-term diet with the use of the FFQ tends to average out within-person variation and should be the method of choice in studies of diet and disease.

Total Energy Intake

At a population level, the primary determinants of variability in energy, or caloric, intake between people include body size, physical activity, metabolic efficiency, and weight change. The relative contributions of these factors to energy intake depend on the population under study.

Total energy intake is important in nutritional epidemiology for several reasons. First, individual differences in energy intake may lead to extraneous between-person variation in intake of other nutrients because the consumption of all nutrients is correlated to some extent with total energy intake. This correlation occurs because larger, more active people tend to eat more than smaller, less active people. Second, energy intake may be an independent primary cause of disease, and it may be relevant to measure its effect. Third, when caloric intake is an independent predictor of disease, the effects of specific nutrients may be confounded, or distorted, by total energy intake.

Adjustment for total energy intake should be conducted in most epidemiological studies assessing diet composition. Adjusted analyses allow us to remove the extraneous variation described earlier from estimates of association, as well as account for potential confounding by total energy intake. Some nutrients, such as macronutrients, are metabolized or consumed in proportion to total caloric intake; therefore, interpreting associations with these nutrients relative to energy intake is appropriate.

There are several analytic methods to adjust for energy intake. Some of the most widely used include the nutrient-residual method and the multivariable density model. In the nutrient-residual method, residuals are computed from a regression model in which nutrient intake is regressed on total caloric intake. Since the residuals do not have a reasonable interpretation on their own, they are often scaled by adding a constant value, such as the expected nutrient intake at the mean caloric intake. The nutrient residual, a measure of nutrient intake uncorrelated with total caloric intake, is then used as an independent variable in a regression model predicting a disease outcome. Models including the nutrient residual are isocaloric or adjusted for total caloric intake. However, if energy intake is associated with the disease, the model should include total caloric intake as a predictor in addition to the nutrient residual. This inclusion decreases random error of the residual and allows estimation of the independent effect of total energy intake.

The multivariable density model also controls for total energy intake. In this model, a disease outcome is regressed on two predictor variables, a nutrient density and total caloric intake. A nutrient density is equal to the nutrient intake value divided by total caloric intake. An advantage of the multivariable density model is that it allows public health recommendations to be provided relative to total energy intake. Long-term total caloric intake on the average is relatively constant. Consequently, people are more effectively able to reduce intake of a given macronutrient, such as saturated fat, by substituting calories they consumed from foods containing that macronutrient with other foods rather than reducing their total food intake.

In very few instances, absolute intake of a nutrient, regardless of total energy intake, may be of primary interest. This is the case of determining the specific requirements for an organ or biological function, such as iron requirements to prevent or treat anemia.

Measurement Error

All epidemiological data are subject to errors. Thus, any measurement of a dietary exposure, whether it is from a questionnaire on dietary intake, biochemical assay, or assessment of body composition, may contain some form of error. The implications of an error in the measurement of an exposure on measures of association with disease depend on the type of error. Error can be random or systematic, and in epidemiology, both kinds of error can occur within individuals or between people.

The day-to-day variation in a person's dietary intake is an example of random within-person error. Additionally, random within-person error arises from errors in measuring dietary intake on a given day. Systematic within-person error occurs when a person consistently over- or underreports a food item on repeated questionnaires. Systematic within-person error may also happen if a food item frequently consumed by a study participant is not included in a questionnaire.

Systematic within-person error can be distributed randomly in a population. For example, random between-person error occurs when consistent underreporting of a food item by some people is canceled out by overreporting of that item by others. As a result, the observed mean for the study group is the true mean, but the standard deviation of the distribution is larger than the true value.

Systematic between-person error occurs when systematic within-person error is not distributed randomly among study participants. When an item frequently consumed in a population is not included in a questionnaire, the item is underreported for those who consume the food. This omission affects everyone systematically in the same direction but not necessarily equally since it is likely that some people consume more of the food than others.

Random error, whether within- or between-person, usually attenuates correlations and biases measures of association toward the null value. When systematic errors affect all subjects equally, measures of association are not affected; however, this is probably rare in practice.

Measures of association, including correlation coefficients, regression coefficients, and relative risks, can be corrected for measurement error when an exposure has been assessed with an imperfect method, such as an FFQ, and additional information is available from reliability or validation studies. Correction for random within-person error requires a single replicate measure. One can correct for systematic within-person error by conducting a calibration study using a gold standard method, such as a diet record.

Systematic errors can also occur between groups being compared in an epidemiological study, such as participants with and without disease. These errors are usually the result of biases, either in selecting study participants or in measuring exposures. Systematic between-group error should be avoided through careful study design since it is difficult to correct for it analytically.

Nuts: Brazil Nuts

AM Kluczkovski and M Martins, Federal University of Amazonas, R. Comendador Alexandre Amorim, Manaus, Brazil

Sources and Production

Brazil nut (*Bertholletia excelsa* HBK), a plant in the family of *Lecythidaceae*, is native to the Amazon rain forest, is exploited commercially, and is geographically distributed in adjacent areas in Brazil, Bolivia, and Peru. It is an extractive product, collected directly from the native forest, with high ecological, social, economic, and nutritional values. Brazil nut is considered a good nutritional source for functional food and an alternative source of protein and energy for some consumer groups. It is a significant product of the Amazon rain forest and in production chains of various foods, with worldwide production of 78 000 tons, with Brazil accounted for ~40% of this value in 2008. The Brazil nut production chain starts in the forest communities, sometimes indigenous, with the harvesting of its fruit, known as 'pods,' which falls freely from the trees to the ground during the rainy season and from which the seeds are removed and transported for industrial treatment in processing plants. In the processing plants, there are several different steps to remove the visually stained or moldy nuts and to reduce moisture content. In-shell or shelled Brazil nuts (Figure 1) are then packaged for sale. A brown skin rich in protein, lipids, and selenium is obtained as a waste product resulting from processing. It can be used in the dietary supplement industry due to its antioxidant potential and also in the area of biotechnology to obtain enzymes with industrial potential. The kernels that do not meet the size standards (small, medium, and large) or have undesirable sensory characteristics (color, shape, or stains) according to industry standards can be otherwise used in pieces and/or as ingredients for the production of other products, such as cereal bars and cookies. The Brazilian production has two different purposes in terms of trade: domestic consumption (70–75%) and export (25–30%). Other importing countries of Brazil nut are Bolivia, the United States, Australia, Hong Kong, and some European countries. Other products can be obtained from the industrial processing of whole nuts or pieces of nuts, for example, oil and cake (partially or fully defatted), which are obtained by mechanical press and/or by extracting the fatty material using solvents or CO_2. The Brazil nut flour is another product that showed high energy value (431.48 kcal), protein content of 45.92 g%, and fiber of 17.14%. Brazil nut oil can be used in cosmetics, foods, and pharmaceuticals. The brown residue of the oil extraction by pressing the nut, generally called cake, has aroused great interest among researchers given its high protein content. An aqueous extract, popularly known as 'milk,' is obtained by dehulling previously dehydrated fresh nuts, which are then shredded producing thick white 'milk' that is subsequently diluted in water. This product is similar to coconut milk; it is rich in protein and is used as an ingredient in foods. In addition to the aqueous extract, a dry extract, a high-protein product, can be obtained by freeze-drying; it is an alternative product to cow's milk and soy milk. Therefore, Brazil nut products are an important alternative for specific groups of consumers, such as those who have high energy and protein requirements or lactose intolerant individuals.

Patterns of Consumption

Adequate intake of selenium (Se) is essential for normal activity of numerous enzymes involved in the protection against oxidative stress, immune system, and regulation of the thyroid. It was demonstrated that 100 μg day^{-1} of selenium (equivalent to two units of Brazil nuts) for 3 months was effective in increasing plasma selenium concentrations and glutathione peroxidase in healthy individuals. According to previous work, the ingestion of a single serving of Brazil nut (5 g) a day for 3 months seems to be effective in increasing the concentration of selenium and glutathione peroxidase activity in patients with selenium deficiency improving the antioxidant capacity of this mineral. Therefore, according to many scientific studies, the daily consumption of Brazil nut has beneficial effects on human body metabolism. In addition to Se, other minerals such as barium (Ba) and radium (Ra) can also be found in Brazil nuts; it is noteworthy that the radioactive dose–effect relationship associated with their consumption does not pose risks to consumers.

Availability, Absorption, and Metabolism

Table 1 shows the nutritional composition of Brazil nut according to several authors. Among the bioavailable nutrients are the vegetable proteins with high digestibility and sulfur amino acids, methionine and cysteine (Table 2). The high content of lipids (over 60%) can also be observed, and the ratio of saturated, monounsaturated, and polyunsaturated fatty acids is 25:41:34. This indicates that the content of unsaturated fat in the Brazil nut is higher than that of any other nut, and due to its high lipid content, its intake should be moderate. Brazil nut is a great source of vitamin E, bioactive compounds, and other micronutrients, such as phytosterols, tocopherols, squalene, and phenolic compounds. Beta- and gamma-tocopherols are the most abundant tocopherol isomers present in Brazil nuts. Brazil nut also contains numerous minerals such as calcium, magnesium, phosphorus, and potassium. With regard to its influence on human metabolism, the consumption of Brazil nut daily improves both the selenium status and the lipid profile, especially high-density lipoprotein and cholesterol levels, thus reducing cardiovascular risks in obese people.

Valine	6.3
Methionine	2.4
Cysteine	1.0
Isoleucine	4.0
Leucine	7.9
Phenylalanine	3.8
Lysine	2.5

Health Effects

Brazil nut has significant nutritional properties that can help in the prevention of certain chronic diseases such as heart diseases. The nutrient composition of Brazil nut can produce beneficial effects due to its antioxidant and antiproliferative activities that are associated with a lower risk of developing atherosclerosis and cancer. The consumption of three to five nuts a day for 16 weeks improved the lipid profile and microvascular function in obese adolescents, possibly due to the high content of unsaturated fatty acids and bioactive substances. A long-term decrease in inflammatory markers after a single intake of Brazil nuts in healthy individuals had been reported. Despite its recognized nutritional properties, its protein level can be associated with allergic reactions to the 2*S* albumin content in sensitive individuals. When considering the protein content of the Brazil nut as potentially high (13–19 g%), food allergy related to its protein fractions deserves special attention in order to keep customers informed about the protein content of either in-shell or shelled Brazil nuts, mainly on the product labeling. Another important factor when acquiring this product is information from the supplier to avoid the consumption of nuts contaminated by aflatoxin, a metabolite carcinogenic to humans produced by fungi present in the production chain. In conclusion, it is important to emphasize that the Brazil nut has commercial importance as an export product of some countries and cultural importance to the people of the rain forest in addition to consuming it, using the collection of Brazil nuts as income. Several studies have been conducted focusing on the prevention of contamination ensuring the safety of this product from forest to production and consumption. The research is necessary in order to improve the quality of this important Amazon nutritional source for functional food.

Introduction

Extensive research on nuts and health outcomes has been conducted in the last two decades since the results of the prospective Adventist Health Study relating frequent nut consumption to a lower risk of coronary heart disease (CHD) were published in the early 1990s. Together with cereal grains and legumes, nuts are high energy, nutrient-dense seeds, rich in nutrients, minerals, vitamins, and bioactive phytochemicals destined to protect the plant's DNA and sustain the growth of the future seedling. Nut constituents are bioavailable after consumption by humans and synergize in the body to beneficially affect metabolic and vascular physiology pathways leading to protection from cardiometabolic disorders.

The scientific evidence supporting the definition of nuts as heart-healthy foods stems from observations from both epidemiological studies and randomized clinical trials. Large observational studies have shown that the frequency of nut consumption relates inversely to incident CHD and diabetes, while many feeding trials comparing diets enriched with various nuts to control diets have demonstrated a consistent cholesterol-lowering effect associated with a beneficial impact on other intermediate markers of cardiovascular risk. The accumulating evidence on the cardiovascular benefit of frequent nut consumption has prompted the inclusion of this food group in many guidelines on lifestyle and health. In the summer of 2003, the US Food and Drug Administration issued a health claim for nuts in general and walnuts in particular based on the link between nut consumption and a reduced risk of CHD. Nuts have also been included in the American Heart Association (AHA) report setting goals for health promotion and disease reduction for 2020 and the newest AHA/American College of Cardiology guideline on lifestyle management to reduce cardiovascular risk; furthermore, nuts are an important component and part of the definition of one of the healthiest dietary patterns, the Mediterranean diet. In this article, current knowledge on the expanding topic of nut consumption and health will be summarized.

Nutrient Content of Nuts

Nuts are one of the natural plant foods richest in fat after vegetable oils, with a total fat content that ranges from 46% in cashews and pistachios to 76% in macadamia nuts (Table 1). Importantly, the saturated fatty acid content of nuts is low (range, 4–16%), while most fat is made up of unsaturated fatty acids, predominantly monounsaturated fatty acids, although polyunsaturated fatty acids, mainly linoleic acid, abound in walnuts, pine nuts, and Brazil nuts. Walnuts also contain sizable proportions of α-linolenic acid, the vegetable omega-3 fatty acid. The beneficial lipid profile of nuts is believed to contribute to the salutary effects of its frequent consumption.

Nuts also contain other bioactive macronutrients with potential health benefits. Thus, approximately 25% of the energy provided by nuts is made up of protein with a high content of the amino acid L-arginine, the substrate for endothelium-derived nitric oxide synthesis, a main regulator of vascular tone and blood pressure. This might explain the beneficial effects of nut consumption on vascular reactivity, as discussed below. Nuts also are a good source of dietary fiber, which ranges from 4 to 11 g per 100 g (Table 1). Among nut constituents, there are relevant amounts of essential micronutrients that are associated with an improved health status when consumed at doses beyond those necessary to prevent deficiency states. They include the B-vitamin folate and antioxidant vitamins (e.g., tocopherols) and polyphenols. Most antioxidants in nuts are located in the pellicle or outer soft shell, which means that significant quantities are lost when nuts are peeled or roasted. These facts should be considered when giving advice on nut consumption for health promotion.

Like all plant-based foods, nuts are cholesterol-free, but they contain sizeable amounts of phytosterols, compounds structurally related to cholesterol that have bulkier and more hydrophobic molecules, which confer them a higher affinity for intestinal micelles than has cholesterol. Thus, when phytosterols are present in the intestinal lumen, cholesterol is displaced from micelles and the amount available for absorption is limited, the end result being a reduction of circulating cholesterol. The richness of nuts in these compounds probably contributes to their cholesterol-lowering effect, as discussed below. Also, like most vegetables, nuts have very low sodium content but contain a high proportion of beneficial minerals, such as calcium, magnesium, and potassium (Table 1). A low sodium intake together with a high intake of calcium, magnesium and potassium is associated with protection against hypertension, insulin resistance, and overall cardiovascular risk, besides bone demineralization.

In summary, the nutrient and phytochemical components of nuts have all been documented to contribute to a reduced risk of CHD and related metabolic alterations. This might explain why nut consumption is associated with beneficial health effects in both observational studies and clinical trials.

Nuts and Cardiovascular Health

There has been much research on nut consumption as the exposure of interest in observational studies of diet and heart health and on nut-enriched diets as intervention in randomized clinical trials with outcomes on intermediate biomarkers of cardiovascular risk. Clinical cardiovascular endpoints (CHD, stroke, type-2 diabetes, hypertension, and metabolic syndrome) have been investigated in several prospective studies, while clinical trials have mainly explored the effects of nut diets on the lipid profile, but also on adiposity, blood pressure, insulin

Table 1 Average composition of nuts in macro and micronutrients and selected phytochemicals (per 100 g)

Nuts	Energy (kJ)	Protein (g)	Fiber (g)	Fat (g)	SFA (g)	MUFA (g)	PUFA (g)	LA (g)	ALA (g)	PS (mg)	Sodium (mg)	Potassium (mg)	Calcium (mg)	Total polyphenols (mg)

resistance, endothelial function, oxidation, and inflammation. The PREDIMED (PREvención con DIeta MEDiterránea) randomized clinical trial of primary cardiovascular prevention has been an important exception because it included nut supplementation in one study arm and had cardiovascular events as the main outcome. The scientific evidence collected in these studies is summarized here.

Epidemiological Studies

Coronary heart disease

Six large prospective studies, five of them conducted in the United States and one in Spain, investigated the associations of dietary factors with health outcomes and described a protective effect of nut consumption on fatal and nonfatal CHD after follow-up ranging from 6 to 30 years. Based on recent meta-analyses of these studies, the consumption of nuts was inversely associated with fatal CHD in six studies including 6749 events, with a risk ratio (RR) per four weekly servings of nuts (one serving equals 28.4 g) of 0.76 (95% CI, 0.69–0.84) and with nonfatal CHD in four studies comprising 2101 events, with an RR of 0.78 (95% CI, 0.67–0.92). When expressing the results for each serving per day of nut consumption, the pooled RR for CHD (fatal and nonfatal) was 0.72 (95% CI, 0.64–0.81). A dose–response relationship between nut consumption and reduced CHD mortality was observed in all studies (Figure 1). The consistency of findings in all prospective cohort studies strongly suggests a causal association between nut consumption and reduced CHD rates.

Stroke

The findings of prospective studies are less consistent regarding nut consumption and the risk of stroke. Meta-analytical evidence from four studies indicates that there was no association between the consumption of each one serving of nuts per day and risk of stroke (RR: 0.90; 95% CI, 0.71–1.14) or for the comparison of extreme quantiles of nut intake and incident stroke (RR: 0.91; 95% CI, 0.81–1.02). The findings of the PREDIMED trial, however, indicate that nut consumption within the context of the Mediterranean diet reduces the risk of stroke, as discussed below.

Type-2 diabetes

The association between nut consumption and diabetes risk has been investigated in six epidemiological studies. Findings from the large prospective Nurses' Health Study cohort suggested that nut and peanut butter consumption was associated with a reduced incidence of diabetes in women, but this relationship was not observed in post-menopausal women from the Iowa Women's Health Study, another large U.S. observational cohort. In a prospective Chinese study of nearly 64 000 women it was also shown that nut consumption protected from diabetes risk. These findings, however, were not confirmed in male participants in another large prospective U.S. cohort, the Physicians Health Study. A further report from the Nurses' Health Study with extended follow-up for 10 years showed that consumption of walnuts, but not other nuts, was associated with reduced diabetes rates. The more recent study was a cross-sectional assessment of the PREDIMED cohort of older persons at high-cardiovascular risk and it showed a reduced prevalence of diabetes with increasing nut consumption. A meta-analysis of these six studies totalling 13 308 events showed an RR of diabetes per four weekly servings of nuts of 0.87 (95% CI, 0.81–0.94). Another meta-analysis showed that the RR of type-2 diabetes for each incremental serving per day of nuts was 0.80 (95% CI, 0.69–0.94) without adjustment for body mass index (BMI); with adjustment, the association was attenuated, with an RR of 1.03 (95% CI, 0.91–1.16). Clearly, the epidemiological evidence of a protective effect of nut consumption on diabetes risk is weaker than for CHD.

Metabolic syndrome

The association of nut consumption with metabolic syndrome, a high-cardiovascular risk cluster of at least three risk factors

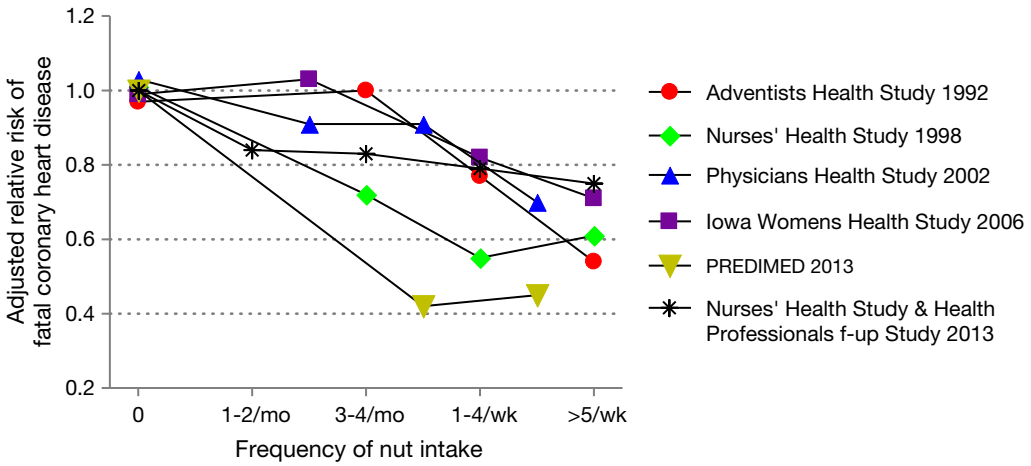

Figure 1 Incidence of fatal coronary heart disease (CHD) by frequency of nut intake. The results of six large prospective studies in which nut consumption was the exposure of interest and the outcome was death from CHD are shown.

related to insulin resistance (abdominal obesity, high blood pressure, impaired fasting glucose, high triglycerides, and low HDL-cholesterol), has been assessed in three epidemiologic studies. Frequent nut eaters had a lower prevalence of metabolic syndrome in a preliminary report of the PREDIMED study and higher reversion rates in a report of the full cohort, and the main driver was decreased visceral adiposity. A lower prevalence of the metabolic syndrome in frequent nut consumers was also described in a large cross-sectional report from the U.S. National Health and Nutrition Examination Survey (NHANES) for 2001–04. Finally, lower incident metabolic syndrome was reported for frequent nut eaters in the prospective Seguimiento Universidad de Navarra (SUN) cohort of Spanish university graduates. These findings further support nuts as heart-healthy foods.

Hypertension

Four prospective studies, three conducted in the United States and one in Spain, have examined the frequency of nut consumption in relation to incident hypertension. In the Coronary Artery Risk Development in Young Adults (CARDIA) study with 15 years of follow-up, participants in the upper category of nut consumption had a 15% decreased risk of hypertension compared those eating nuts infrequently. In the large men cohort of the Physicians Health Study, the risk of hypertension was reduced by 18% in those who consumed nuts daily compared with non consumers and were lean at baseline, but not when they were overweight or obese. A prospective study of university graduates in Spain reported a non significant 23% lower risk of incident hypertension for the highest versus lowest nut-consumption category after 4.3 years of follow-up. Another prospective U.S. study of middle-aged adults showed a 13% lower risk of incident hypertension in the top quintile of nut consumption compared with the bottom quintile after a 9-year follow-up. The cross-sectional NHANES 2001–04 study also reported a lower prevalence of hypertension in nut consumers compared with non consumers. These studies have been recently meta-analyzed with the conclusion that the consumption of each one serving of nuts per day was significantly associated with lower incident hypertension rates with an RR of 0.66 (95% CI, 0.44–1.00; $P=0.049$).

Inflammation

Chronic low-grade inflammation, which can be conventionally estimated from levels of circulating biomarkers, is believed to be a key process in atherogenesis and the occurrence of ischemic events. Three cross-sectional studies have investigated circulating inflammatory biomarkers in relation to nut consumption. In the Multi-Ethnic Study of Atherosclerosis, an analysis of data from nearly 6000 participants showed that the frequency of nut consumption related inversely associated to levels of inflammatory markers, C-reactive protein (CRP), interleukin-6 (IL-6), and fibrinogen. Another study of close to 1000 diabetic women from the NHS cohort showed an association between nut consumption and increased circulating adiponectin, an anti-inflammatory cytokine secreted by adipose tissue. In a cross-sectional assessment of the PREDIMED study cohort involving 772 older individuals at high-cardiovascular risk, increasing nut consumption related to decreasing serum levels of intercellular adhesion molecule-1 (ICAM-1), but not those of CRP or IL-6. Thus, lessening the inflammatory status might be one mechanism by which nut consumption decreases CHD risk.

In summary, the results of several prospective studies strongly suggest that regular consumption of nuts is beneficial for CHD risk. The risk of stroke in relation to nut consumption has been less investigated than CHD risk and epidemiologic data do not consistently support a protective effect; confirmation of a protective role in stroke must await further studies. Diabetes is another high-cardiovascular risk condition that has been favorably affected by nut consumption in prospective studies. Epidemiologic evidence also points to a protective effect of nut consumption on the metabolic syndrome, as well as in hypertension, one of the components of the syndrome. Finally, there is also suggestive epidemiologic evidence that frequent nut consumers display reduced circulating markers of systemic inflammation.

Randomized Clinical Trials

After publication of the results of the first observational studies suggested that nut consumption protected from CHD, clinical trials began to explore the underlying mechanisms by investigating the effects of diets supplemented with nuts on intermediate biomarkers of cardiovascular risk. Most randomized clinical trials have compared nut-enriched diets with control diets for outcomes on blood lipid changes in individuals with normal or moderately elevated blood cholesterol levels. Some studies have also evaluated nut effects on glycemic control in patients with type-2 diabetes. Other studies have examined whether unrestricted consumption of high-energy nuts has any effect on body weight and other adiposity measures. Additional clinical trial have evaluated the effects of nut-enriched diets on intermediate markers of cardiovascular risk, such as blood pressure, insulin sensitivity, endothelial function, and inflammatory status. Almonds and walnuts have been the nuts most studied. The long-term PREDIMED trial targeted the effects of nut consumption on both intermediate cardiometabolic markers and clinical outcomes, such as the metabolic syndrome, diabetes, and cardiovascular diseases. Given the relevance of PREDIMED for the topic of nuts and cardiovascular health, its results will be detailed in a separate section.

Blood lipids

The first controlled clinical trial with nuts, published in 1993, investigated the lipid effects of a walnut diet versus a control diet in healthy volunteers and showed that it was associated with a reduction in blood cholesterol levels. Since then the effects of the consumption of different nuts on blood lipids and lipoproteins have been examined in many clinical studies. A pooled analysis of 25 studies assessed the lipid effects of diets enriched with different nuts versus control diets during periods of 3–8 weeks. The results demonstrated that nuts had a consistent cholesterol-lowering effect that was related to both dose and baseline cholesterol level, similar by gender and across all age groups, and independent of the type of nut tested. Specifically, consumption of 67 g (2.4 oz) of nuts per day was associated with mean reductions of 0.28 mmol l^{-1} (5.1%) in total cholesterol, 0.26 mmol l^{-1} (7.4%) in LDL-cholesterol, and 0.22 (8.3%) in LDL:HDL ratios ($P<0.001$, all). Nuts had no effect on HDL-cholesterol or triglycerides, except in participants with serum triglycerides >1.68 mmol l^{-1}, in whom a significant mean 0.11 mmol l^{-1} reduction was observed. A separate meta-analysis of 13 studies examined the effect of walnuts on the lipid profile and showed that, compared to control diets, diets enriched with walnuts in amounts ranging from 30 to 108 g day^{-1} (10–24% of energy) were associated with weighted mean reductions of total cholesterol and LDL-cholesterol of 0.27 and 0.248 mmol l^{-1} ($P<0.001$, both), respectively. Thus, the lipid effects of walnuts were similar to those described in the pooled analysis for different nut types. Clinical trials examining nut diets for lipid effects have usually been short term, but a few studies have shown that efficacy is maintained in the long term. For instance, adding walnuts (12% of energy) to the usual diet of free-living individuals to whom no dietary advice was given during a 6-month period reduced total cholesterol by 0.13 mmol l^{-1} ($P=0.02$) and triglycerides by 0.09 mmol l^{-1} ($P=0.03$), with a nearly significant decrease of 0.09 mmol l^{-1} in LDL-cholesterol ($P=0.06$). Likewise, a walnut diet compared to a control diet for 1 year in obese patients with type-2 diabetes showed maintained, albeit small, LDL-cholesterol reductions and HDL-cholesterol increases.

Glycemic control

Acute feeding studies using test meals with a high glycemic index with or without added nuts have shown reduced postprandial glucose responses following nut meals, suggesting that nuts might be useful in diabetic control. Feeding nut-enriched diets to patients with type-2 diabetes fed diets for up to 12 weeks has also been associated with improved glycemic control. It may seem counterintuitive to recommend energy-dense nuts to diabetic patients for the fear of gaining weight. However, as discussed below, there is no evidence that frequent nut consumption promotes weight gain, thus they can safely be recommended to patients with type-2 diabetes, who are usually overweight.

Other markers of cardiometabolic risk

The unique composition of nuts in bioactive nutrients and phytochemicals also underlies the effects of their consumption on cardiometabolic markers other than the lipid profile and glycemic control. A few studies have shown beneficial effects of nuts on vascular reactivity, oxidative stress, and inflammation. Small clinical trials, mostly testing walnuts, have demonstrated beneficial effects on both fasting and postprandial endothelial function, as ascertained by flow-mediated dilatation studies in the brachial artery, reduced circulating levels of endothelial activation molecules or inhibition of proinflammatory cytokine production by blood mononuclear cells. An effect of nut diets on resting blood pressure has been difficult to uncover in clinical studies, but testing hemodynamic responses to stress has detected beneficial effects on blood pressure and total peripheral resistance. Improved vascular reactivity in studies with walnuts may be attributed to their richness in polyunsaturated fatty acids, particularly α-linolenic acid, L-arginine (the precursor of nitrous oxide) and potent polyphenols.

The consumption of antioxidant-rich nuts has also been associated with an improved oxidative status. This has been reported for monounsaturated fatty acid-rich nuts, such as almonds, pistachios and hazelnuts, but not for polyunsaturated fatty acid-rich walnuts, albeit no deleterious effects on oxidation have been described. Nut feeding studies have documented reduced circulating concentrations of inflammatory cytokines but no consistent changes of CRP. A novel mechanism by which walnut consumption may reduce cardiovascular risk has recently been reported: increased cholesterol efflux from cholesterol-laden macrophages exposed to human serum collected after a walnut meal, suggesting improved functionality of HDL, the main lipoprotein particles involved in reverse cholesterol transport. In summary, the emerging picture is that nut consumption has beneficial effects on cardiovascular risk factors beyond well known lipid lowering without incurring undue increases in adiposity.

Cardiovascular effects of nuts in the PREDIMED trial

The PREDIMED study is a large, parallel group, multi center, 5-year field trial of nutrition intervention conducted in Spain.

Eligible participants were men, 55–80 years of age, and women, 60–80 years of age at high risk of cardiovascular disease but who had not suffered any ischemic event at enrolment. Participants were randomized into three groups, two high-fat, high-unsaturated fat Mediterranean diets, which were supplemented with either extra-virgin olive oil or mixed nuts, or a control diet (advice to reduce all types of dietary diet). They received quarterly individual and group educational sessions and, depending on group assignment, free provision of extra-virgin olive oil (1 l/week), mixed Mediterranean nuts (30 g day^{-1}, 15 g walnuts, 7.5 g almonds, and 7.5 g hazelnuts), or small non-food gifts. The recommended diets were non energy restricted and increased physical activity was not promoted, thus the full effect of dietary intervention alone could be ascertained. The primary end point was an aggregate of major cardiovascular events (myocardial infarction, stroke, and cardiovascular death).

Since its inception in October 2003, the trial's results have provided significant evidence on the beneficial health effects of Mediterranean diets enriched with both supplemental foods. The efficacy of the PREDIMED nutritional intervention has generally been similar for both the extra-virgin olive oil and nut-supplemented Mediterranean diets in comparison with the control diet. The main results concerning the nut-supplemented Mediterranean diet are summarized below.

A study involving nearly 750 participants completing intervention for 3 months showed that, compared to the control diet, the two supplemented Mediterranean diets were associated with significant reductions of both systolic and diastolic blood pressure and total and LDL-cholesterol; increased HDL-cholesterol; decreased fasting glucose in diabetic participants and increased insulin sensitivity in those without diabetes; and reduction in circulating levels of inflammatory cytokines. The nut-enriched diet also reduced fasting triglycerides and both intervention diets resulted in reduced oxidized LDL levels. While results on lipids, glycemic control, oxidation, and inflammation were essentially confirmatory, the blood pressure-lowering effect of the nut-enriched diet was novel. Noticeably, reduced blood pressure by both PREDIMED Mediterranean diets after treatment for 1 year was confirmed in a sub study using 24-h ambulatory blood pressure monitoring, the gold standard to ascertain the effects of interventions on blood pressure.

Another PREDIMED sub study showed both reduction in circulating inflammatory biomarkers and reduced expression of ligands for inflammatory molecules in circulating monocytes after 3-month intervention with the two Mediterranean diets, thus beginning to unravel the molecular bases for their anti-inflammatory effects. The PREDIMED Mediterranean diet supplemented with nuts has also demonstrated an anti atherosclerotic effect, namely delayed progression of carotid intima-media thickness and plaque after intervention for 2 years.

The effects of the interventions on metabolic syndrome status and incident diabetes were secondary end points of the PREDIMED trial. In the first 1224 trial participants completing intervention for 1 year, the nut-rich Mediterranean diet was associated with a 14% reduction in the prevalence of metabolic syndrome and in the full cohort, a 28% increase in reversion rates was documented; in both studies, the beneficial effect of the nut-enriched diet on metabolic syndrome was mainly due to reduced visceral adiposity. Because there were no weight changes, this suggests fat redistribution away from the abdominal compartment. In one of the PREDIMED recruiting centers, yearly oral glucose tolerance tests were performed in non-diabetic participants to detect incident diabetes. Results in 418 subjects followed for a mean of 4 years showed that both Mediterranean diets were protective of diabetes, and the reduction of incidence in the nuts arm was 52% compared with the control diet. Again, this beneficial effect took place in the absence of weight loss or increased energy expenditure in physical activity. However, the results for the full PREDIMED cohort showed only a non significant 18% reduction of incident diabetes for the Mediterranean diet enriched with nuts.

The results of the PREDIMED randomized trial on the primary end point have shown for the first time a reduction of incident cardiovascular diseases after long-term consumption of the two Mediterranean diets. After a median follow-up of 4.8 years in 7447 participants, those assigned the two Mediterranean diets showed a 30% reduction in cardiovascular disease events (myocardial infarction, stroke or cardiovascular death) compared to the control diet. As seen in Figure 2, the curves of the two Mediterranean diet groups and the control group diverged soon after the beginning of the study. Such an early and sustained reduction in cardiovascular events fits with the improvement of intermediate cardiovascular risk markers observed after follow-up for only 3 months. The nut-supplemented diet also resulted in a significant 49% reduction in stroke risk, which differs from the generally null findings of epidemiologic studies on nut consumption and incident stroke. The two PREDIMED Mediterranean diets were associated with non significant reductions in myocardial infarction and no effect could be discerned on total mortality, although the trial was not powered for these outcomes. It must be underlined that the Mediterranean diet interventions were conceived to improve the overall dietary pattern, but the principal between-group differences in food consumption were for the supplemental items. Thus, nuts probably accounted for most of the observed benefit in the corresponding Mediterranean diet group. A protective effect of both Mediterranean diets on peripheral arterial disease, another cardiovascular outcome, was also reported. However, as opposed to the olive oil-enriched diet, no beneficial effect of the nut-supplemented diet on atrial fibrillation, an additional PREDIMED outcome, could be discerned.

The beneficial effects shown in the PREDIMED trial for the nut-enriched Mediterranean diet on intermediate cardiovascular risk biomarkers include blood pressure, the lipid profile, insulin resistance, lipoprotein oxidation, and systemic inflammation. This diet was also associated with reduction in visceral adiposity, metabolic syndrome and diabetes, as well as delayed atherosclerosis progression. Such multiple beneficial effects provide a mechanistic explanation for the observed protection of long-term consumption of a Mediterranean diet supplemented with nuts against cardiovascular diseases. Because PREDIMED was a controlled, randomized clinical trial, its results provide first class evidence on the potential of nuts and other healthy foods such as extra-virgin olive oil to improve cardiovascular health.

Mortality

Besides reporting on nut consumption and fatal CHD, several prospective studies have provided data on all-cause mortality.

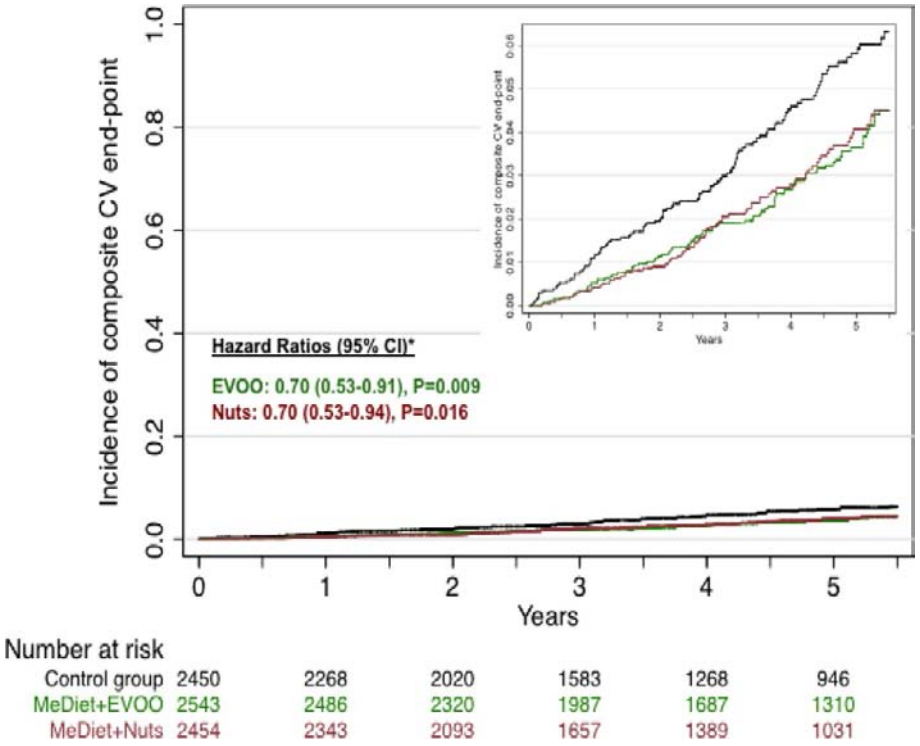

Figure 2 Incidence of cardiovascular disease by intervention group in the PREDIMED study. Med Diet, mediterranean diet; EVOO, extra-virgin olive oil. Reprinted from Estruch, R., Ros, E., Salas-Salvadó, J., et al. (2013). Primary prevention of cardiovascular disease with a Mediterranean diet. *The New England Journal of Medicine* 368, 1279–1290, with permission by Massachusetts Medical Society, Copyright © (2013).

Among them stand two large cohorts of women from the Nurses' Health Study ($n = 76\,464$) and men from the Health Professionals Follow-up Study ($n = 42\,498$) with 27 429 overall deaths after follow-up of 30 and 24 years, respectively. A meta-analysis of prospective cohort studies with high-quality scores, large sample sizes, and long-term follow-up that reported on nut consumption and total mortality showed a pooled RR (95% CIs) for each serving per day of 0.83 (0.76–0.91) for all-cause mortality and a pooled RR for the comparison of extreme quantiles of 0.85 (0.79–0.91). There are no clinical trials reporting on nut consumption and mortality because the size and duration of follow-up of a study with this outcome would make it unfeasible. Nevertheless, the epidemiological evidence strongly suggests that frequent nut consumption has a beneficial impact on chronic conditions that shorten life span well beyond cardiovascular diseases.

Cancer

The fact that, among edible plant foods, nuts are among those richest in phytochemicals with significant antioxidant and immunomodulatory properties suggests that their customary consumption might have a chemopreventive potential by either blocking tumor initiation or preventing the progression of cancer. Indeed some *in vitro* and animal studies have shown that nut phytochemicals promote apoptosis in cancerous cells and stop cancer cell growth. Other nut components, such as folic acid, are important in the process of repair of cancer-inducing DNA damage, while some polyphenols abundant in nuts have shown an antitumor cell invasion effect, thereby limiting metastasis. Studies in animal models of cancer fed whole nuts have also shown reduced cancer growth, particularly with walnuts and mammary tumors.

However, the epidemiological evidence of a protective effect of nuts on cancer incidence is weak and inconclusive; this is partly due to difficulties in the interpretation of epidemiological data, since most of the studies often associated nuts with legumes and seeds in a single food group. There is some evidence suggesting that nuts may be anticarcinogenic, especially on colorectal cancer in women and prostate cancer, but data are insufficient to draw any conclusion on the potential protective effects of nuts on cancer development or progression.

Remarkably, besides a reduction in fatal CHD rates and all-cause mortality, nut consumption was associated with decreased cancer deaths in two large prospective studies. In the pooled cohort of women from the Nurses' Health Study and men from the Health Professionals Follow-up Study, the multivariate-adjusted hazard ratio for cancer death ($n = 10\,293$) among study participants who consumed nuts two or more times per week versus those who never consumed nuts was 0.91 (95% CI, 0.85–0.97). In the PREDIMED study considered as an observational cohort, the adjusted hazard ratio for cancer death was 0.60 (0.37–0.98) for consumers of more than three servings of nuts per week compared to those who never consumed nuts, and walnuts were more protective than other nuts. Given that

incident cancer was a pre specified outcome of the PREDIMED trial, its extended follow-up may shed light on the potential anticarcinogenic effect of nuts.

Neurodegenerative Diseases

The nutrient density of nuts, particularly their high polyphenol content, and their beneficial effects on vascular risk factors and function, which are well known to affect cognition, also suggest that their increased consumption might promote brain health and thereby relate to improved cognition and/or decreased rates of dementia. *In vitro* studies have shown that polyphenolic compounds found in nuts reduce the oxidant and inflammatory load on brain cells, improve inter neuronal signaling, and increase neurogenesis. Data from experimental animal models fed whole nuts, especially walnuts, indicate improved performance in cognitive and motor tasks involving working memory compared to control diets. Animal studies have also shown that nut diets enhance clearance of toxic protein aggregates from the brain.

Few prospective studies have focussed on the relation of nut intake to cognition. A study from a Dutch cohort with 2613 participants reported that total nut intake was associated with better cognitive function at initial assessment, but not with decline after follow-up for 5 years. Similar results were reported from a sub cohort of 15 467 older women from the Nurses' Health Study followed for 6 years. Preliminary data from subsets of the PREDIMED study indicate that the Mediterranean diet with nuts is associated with lower rates of depression (a surrogate of impaired brain health), improved concentrations of plasma brain-derived neurotrophic factor, and better overall cognition. Again, incidence of neurodegenerative diseases, including Alzheimer's disease, vascular dementia, and Parkinson disease, was a pre specified outcome of the PREDIMED study and results are eagerly awaited.

Nuts and Body Weight

There is a widespread perception that all fatty foods provide excess energy and promote obesity, which has had a negative effect on the image of nuts. However, there is no epidemiologic or clinical trial evidence that frequent nut consumption promotes weight gain; rather, data from large prospective studies suggest inverse associations between the frequency of nut consumption and BMI or weight gain over time after adjustment for confounders. Similar findings regarding BMI together with reduced waist circumference have been shown for increasing nut consumption in cross-sectional studies and in the PREDIMED cohort considered as a longitudinal study. A meta-analysis of clinical trials that tested nut diets versus control diets showed small non significant associations of nut intake with reduced adiposity measures. The mechanism for the lack of weight gain after consuming nuts lies in their prominent satiating effect, which results in food compensation accounting for up to 75% of the energy they provide. An additional factor that curtails energy acquisition after eating nuts is fat malabsorption, documented as increased fecal fat excretion, which is attributable to incomplete digestion of their matrices because the fat of nuts is enclosed within cell membranes, which are not readily available to digestive enzymes. In conclusion, there is a substantial body of evidence to alleviate the fear of undue weight gain when eating high-fat nuts.

Conclusion

Nuts are seeds, energy-dense foods with an optimal composition in macronutrients, micronutrients and bioactive phytochemicals and this is likely to be of utmost importance for their wide range of health effects. As summarized in Table 2, there is consistent evidence from epidemiologic studies and clinical trials of the beneficial effects of nuts on risk for cardiovascular diseases, diabetes, and intermediate risk factors. Increasing evidence indicates that including nuts in a healthy

[c]Evidence collected only in the PREDIMED trial.

diet provides protection against cardiometabolic disorders beyond that attributable to the other components of a healthy diet. Data on critical outcomes such as cancer and neurodegenerative diseases is still emerging, but there are reasons to believe that nut consumption will also protect against these devastating conditions. Nut-rich diets have also been related to reduced all-cause, cardiovascular and cancer mortality. Contrary to popular belief due to the high energy content of nuts, their consumption does not induce undue weight gain, which is attributable in part to increased satiation and lesser intake of other high-energy foods in subsequent meals. Nut components such as unsaturated fatty acids, L-arginine, non-sodium minerals, and polyphenols target multiple cardiovascular risk factors and metabolic pathways, providing a mechanistic explanation for cardiovascular risk reduction. The results of the PREDIMED trial have provided first class evidence that long-term compliance with a healthy diet enriched with one daily serving of nuts reduces the incidence of type-2 diabetes and cardiovascular diseases, particularly stroke. Ongoing research in the context of this landmark trial will eventually show whether the salutary effects of nuts reach to the prevention of other epidemic chronic diseases, including cancer and neurodegenerative disorders.

Production, Trade, and Consumption

Oat is a cereal grain that is widely grown for use as animal feed and for human consumption. In 2013, 10.45 million hectares of land was planted with oats worldwide (Figure 1). The European Union (EU-27) produces approximately one-third of the world's oat supply, mainly in Poland, Finland, Spain, Sweden, and Germany. In 2011, production in the EU-27 increased by 1.7% over the previous year to 11.6 MT. Russia, the largest producer, grows about 20% of the world's oats. Canada is the largest exporter of oats (1.6 million tons in 2012), whereas the United States is the largest importer (1.6 million tons in 2012).

Although oats are grown in many countries, the total production is only about 1% of the world's grain production. It currently ranks sixth in the world's production behind corn (40%), wheat (29%), rice (20%), barley (6%), and sorghum (3%). Of the oats grown, the majority are used for animal feed. Only about 25% of the crop is milled for human consumption. Human consumption is highest in the European Union (1.8 million tons per year) followed by Russia (1.5 million tons per year), the United States (1.1 million tons per year), and Canada (0.75 million tons per year).

It is believed that oats, *Avena sativa*, have been cultivated in Europe and Asia for 4000–5000 years. Another species, *A. byzantina*, was domesticated in northwest Africa and performs better in tropical latitudes. Much of the breeding activity in recent years has targeted adapting oats for particular regions. To this end, varieties are being produced that are drought-tolerant, winter-hardy, resistant to lodging caused by wind or rain, and resistant to diseases and pests found in different areas. Breeding programs also aim to increase yield and improve milling quality. Varieties of naked oats have been developed for Canada and China. The advantage of naked oats is reduced shipping costs because the hull need not be shipped and dehulling is not required during processing. However, without the protective hull, the pericarp is more susceptible to damage, which can lead to a decrease in quality due to breakage and off-flavors. Breeding programs are also attempting to produce oats with higher content of mixed-linkage β-glucan (hereafter referred to as β-glucan), the cell wall component that is mostly responsible for the oat's reputation as a health food. The content of β-glucan in commercially available varieties ranges from 2 to 8 g per 100 g and breeding programs for high β-glucan varieties with good agronomic traits continue.

Nutrition

Oats are higher in oil and protein and lower in starch than wheat (Table 1). The oil is high in phospholipids and glycolipids that have high emulsifying capacity, and oat protein has a better amino acid balance and thus superior protein quality (protein efficiency ratio = 1.8) than wheat protein (protein efficiency ratio = 0.8). Because the amino acid sequence is sufficiently different from gluten, hordein, and secalin, the avidin protein in oats does not contain the epitopes that elicit reactions in persons with celiac disease. Therefore, it can be consumed by celiac patients provided that it is not contaminated with wheat, barley, or rye. Oats tend to be higher in calcium, iron, magnesium, phosphorus, zinc, and folate than wheat, barley, and rye, but lower in niacin.

Health Benefits of Oats

Beyond providing good basic nutrition, oats also provide additional health benefits. There is solid evidence that the soluble fiber in oats, β-glucan, reduces serum LDL cholesterol in people with mildly elevated cholesterol levels and attenuates postprandial blood glucose concentrations. In addition, a group of polyphenols found in oats, known as avenanthramides, are potent antioxidants that have been shown to reduce inflammatory responses. β-Glucans may also have anti-inflammatory capabilities. There is also growing evidence that oats extend the sense of satiety after a meal and thus reduce calorie intake at a subsequent meal.

Cholesterol Reduction and Heart Health

The soluble fiber β-glucan has been identified as the bioactive component of oats that facilitates the reduction of serum cholesterol levels in persons with mildly elevated cholesterol levels. The ability of oats to reduce total and LDL cholesterol has been associated with β-glucan's capacity to form very viscous solutions at low concentrations. Two mechanisms of action appear to be involved. In the upper intestine, the viscosity of the meal bolus hinders the emulsification of fat into small droplets and reduces absorption of cholesterol. Thus, an increased amount of ingested cholesterol is excreted. At the same time, bile acids are secreted by the gall bladder to aid

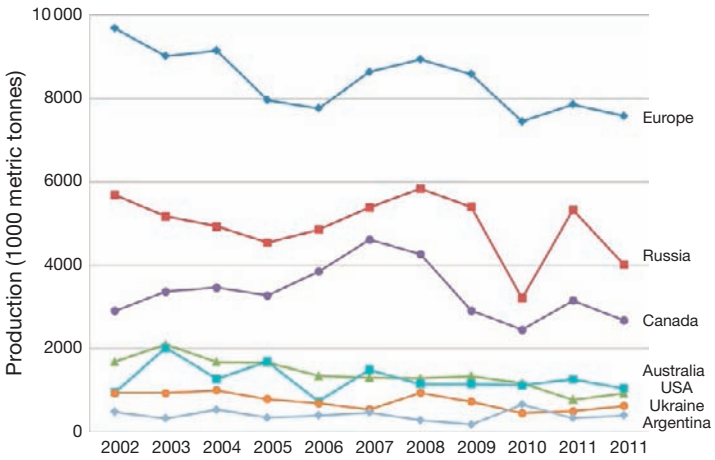

Figure 1 Historical production trends for the seven largest oat producers in the world. Data from USDA.

emulsification and digestion of fat. The reabsorption of the bile acids is also inhibited by the increased viscosity and the rate of excretion increases. In preparation for digestion of the next meal, new bile acids are synthesized from cholesterol stores in the liver. The consumption of 3 g of oat or barley β-glucan daily is recommended to lower cholesterol levels.

Blood Sugar Control and Type 2 Diabetes

The increased viscosity associated with β-glucan also influences the digestion and absorption of carbohydrates. Oat foods have been shown to reduce the concentration of glucose in the bloodstream in the 2 h following a meal. The postprandial

blood glucose levels are significantly lower than a control meal in a dose-responsive manner. The glycemic index (GI), a ranking of carbohydrate foods on a scale from 0 to 100 according to the extent to which they raise blood sugar levels after eating, is frequently used to assess oat foods and many oat foods are considered to have low GI (<55).

It is believed that the mechanism of action involves a number of elements. The increased viscosity of the meal bolus slows gastric emptying rate and impedes the mixing of digestive enzymes with the food, slowing the release of glucose from starch. It also slows the rate at which glucose is transported to the gut wall and absorbed. Reduction in the rate of glucose absorption means that the pancreas is able to respond with insulin to remove glucose from the bloodstream more effectively, thus blunting postprandial spikes in blood glucose levels. The attenuation of blood glucose and insulin levels has been associated with a reduction in the risk of the development of type 2 diabetes.

Satiety and Obesity

The extension of satiety is desirable to prevent hunger between meals and reduce calorie intake at the following meal. In addition to extending the time required for blood glucose concentrations to return to baseline and attenuating insulin levels, oats appear to influence other gut hormones. Both protein and increased viscosity have been associated with extended satiety and may contribute to this effect.

Antioxidants and Anti-inflammatory Potential

Avenanthramides are a class of phenolic compounds found uniquely in oats. They are phenolic acids conjugated with amides that have been shown to be potent antioxidants. They are found as both free and bound forms in the groat. Anti-inflammatory and antiatherogenic activities have been demonstrated by avenanthramides at parts per million levels, suggesting that they may reduce the risk of cardiovascular disease. Avenanthramides decrease the expression of endothelial proinflammatory cytokines at least in part through the inhibition of nuclear factor-κB activation and proteasome activity suppression.

Oat Ingredients and Foods

Oats are consumed in a wide variety of food products. Whole groats can be boiled and eaten as a rice substitute. Frequently, oats are milled and flaked to produce oatmeal used to make porridge or baked goods. Oat flours are used for breads, breakfast cereals, and baked goods. Oat bran is made by removing part of the endosperm to enrich the nutrients found in the subaleurone and aleurone layers.

Oat Milling and Processing

When harvested oats arrive at the mill, they are subjected to a series of procedures before they can be used in food products. Although they may have received some preliminary cleaning prior to transportation, the first step at the mill is a cleaning process to remove unwanted materials (e.g., seeds from other crops, weed seeds, stones and dust, and metal fragments). Various devices are used to accomplish this, including screens, gravity tables, aspirators, and magnets. At the end of this process, the clean milling oats, or green oats, are graded into up to four size fractions based on density and weight, which optimizes the efficiency of the next step: dehulling. The most common method of hull removal uses impact dehullers, in which oats are fed onto a rotating disk that propels them onto the cylindrical housing of the dehuller, where the impact separates the hulls from the groats. The lighter hulls are removed by aspiration, and undehulled oats are separated from groats by a density table system and returned to the dehulling stream. A set of scouring brushes may be used to further clean the groats and remove trichomes before kilning. During the kilning process, steam is used to inactivate enzymes in the raw groats, which are then roasted to develop a desirable toasted flavor, and the moisture content is reduced sufficiently for product storage. Kilned groats can be flaked whole, to produce large flake oats, or cut to produce steel-cut groats, which can be used as is or flaked further to produce quick-cooking oats. The oats (whole or steel-cut) are first steamed or tempered to toughen the groat and minimize the production of fines, before flattening between two large rollers. Further processing to either oat flour (used mostly for baby foods and ready-to-eat cereals) or oat bran can start with either stabilized whole groats or flakes. Whole oat flour or a combination of low bran oat flour and oat bran can be produced. Hammer mills are most commonly used to grind the product, although rollers can also be used.

Oat Products

Oat porridge is probably the oldest and best known oat food. It is made by boiling oatmeal in water and/or milk until the starch is gelatinized. Oatmeal is available in a range of flake sizes from large flake, which results in a coarse, chewy texture, to instant oatmeal, which has a smooth, creamy texture. Steel-cut oats are cut rather than flaked. They require a longer cooking time than oatmeal and result in a coarser texture. Oat bran is also used to make porridge with higher fiber content.

Oatmeal, oat bran, and oat flour are used in a wide range of products, from breakfast cereals to bakery products. Oat flour and bran, alone or in combination with other flours, are extruded to make ready-to-eat breakfast cereals. The heat and pressure of the extrusion process gelatinize the starch and increase the solubility of β-glucan. Extruded whole oat and oat bran cereals have been shown to reduce cholesterol in people with mildly elevated cholesterol levels when they consume at least 3 g of β-glucan daily. Oat bran cereal containing at least 4 g β-glucan per serving has low GI, whereas whole oat cereal has high GI. Oat bran cereal has also been demonstrated to extend satiety and influence gut hormones associated with hunger.

A wide range of bakery products containing oats and oat fractions are now available. Breads can be found on supermarket shelves containing both whole oats and oat bran. The long proofing time required for the yeast fermentation has been shown to result in partial depolymerization of β-glucan in breads containing wheat flour in addition to oat ingredients.

The depolymerization appears to be caused by endogenous β-glucanase enzymes in wheat. Despite the partial degradation of β-glucan, several studies have found that oat bran bread significantly reduced LDL cholesterol levels in people with mildly elevated cholesterol, although some studies failed to demonstrate significant reductions. Other bakery products incorporating oatmeal, oat bran, and oat flour include muffins, granola bars, cookies, and crackers. Unlike yeast breads, chemically leavened products have a shorter preparation time and tend not to exhibit depolymerization of β-glucan. Oat bran muffins with at least 4 g of β-glucan per serving significantly reduced postprandial blood glucose response. Whole oat muffins and muffin mixes have low to medium GI. Oat bran, which is composed of the outer layers of the groat (the pericarp, aleurone, and subaleurone layers), has been shown to contain the highest levels of β-glucan, as well as avenanthramides, the bioavailability of which has been demonstrated in oat bran muffins.

Increasingly, oats are being used in less conventional applications. Oat pasta is still a novelty in North America and Europe, but it is common in some areas of China. A host of novel food products incorporating oats or oat fractions have been developed in Scandinavia, such as yogurt-like fermented products and high β-glucan drinks. Oat milk is also available. The soluble components are extracted from oats in a process similar to the manufacture of soy milk. There is preliminary evidence that oat milk reduces cholesterol when consumed on a regular basis.

Microstructure

Raw Groat

The oat groat is packaged much like most of the cereals (Figure 2), with a protective pericarp surrounding the kernel, inside of which is the aleurone layer, made up of a single layer of thick-walled, cuboidal cells. This layer contains the bulk of the minerals and vitamins of the oat, as well as significant amounts of protein and lipid. These outer layers, as well as a small part of the endosperm (typically just one or two layers of thick-walled subaleurone cells), make up the bran fraction in milling. At the proximal end of the kernel is the embryo, or germ, which contains the scutellum and the embryonic axis. The germ is also high in lipid and protein and, in the scutellum, some minerals as well. The remainder of the kernel is composed of the starchy endosperm, which is the main storage tissue of the kernel.

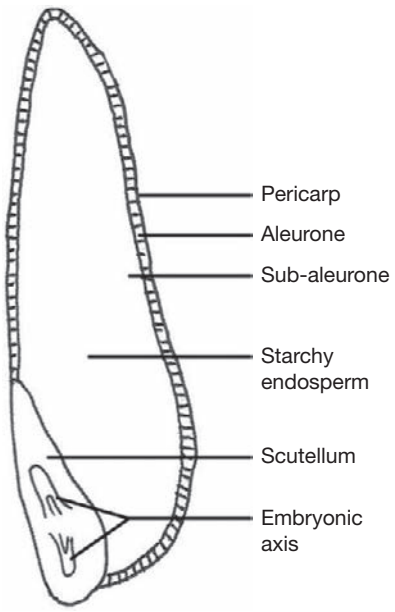

Figure 2 Diagram showing the different tissues of the oat groat.

Like most other cereals, the starchy endosperm contains starch granules embedded in a protein matrix. Figure 3(a) shows a cross section of oat groat stained to demonstrate starch (purple) and protein (green). Starch is present mainly in compound grains, which are composed of multiple smaller granules, although some larger single granules are also present. Individual protein bodies can be distinguished in the protein matrix, particularly in the subaleurone region, where there is less starch. Unlike most cereals, the endosperm also contains significant amounts of lipid distributed as small lipid bodies throughout the protein matrix, although in much lower concentrations than the protein and starch. The cell walls of the starchy endosperm are also rich in β-glucans (up to 85% of the wall), particularly in the subaleurone region, where the walls are typically thicker than in the central endosperm. Figure 3(c) shows a section of oat in the subaleurone region, stained with calcofluor white to demonstrate β-glucans. The walls are thickest immediately adjacent to the aleurone layer (at the top of the micrograph) and become progressively thinner into the endosperm.

Cooked Groat

Although the majority of oats for food use are cut and flaked before packaging or incorporation into other products, there is a growing trend for the consumption of whole cooked groats as a rice alternative. In the whole cooked groat, the nutritional components remain mostly in place, although the starch granules within the larger compound grains swell and often fuse in varying stages of gelatinization. In some areas, amylose can leach from some granules and aggregates on the outside of the granules, visible as a darker purple outline in the upper left corner of Figure 3(b). There is also some disruption of the cell walls and leaching of β-glucans (Figure 3(d)). The β-glucans released from the wall would be more available for physiological action in the gut.

Oat Products

Figure 4 presents cryosections of some common oat cereals. Although a proportion of whole, large groats are flaked after kilning to make large flake, or 'old fashioned' oatmeal, most groats enter the production line as steel-cut oats. Despite being kilned, the microstructure of the raw steel-cut oat differs very little from a raw groat (Figure 4(a)). The starch granules are very slightly swollen, but little gelatinization has occurred. However, after cooking in water to make porridge, the starch granules are swollen and fused, and the cell walls are swollen as well (Figure 4(b)). The level of gelatinization of starch

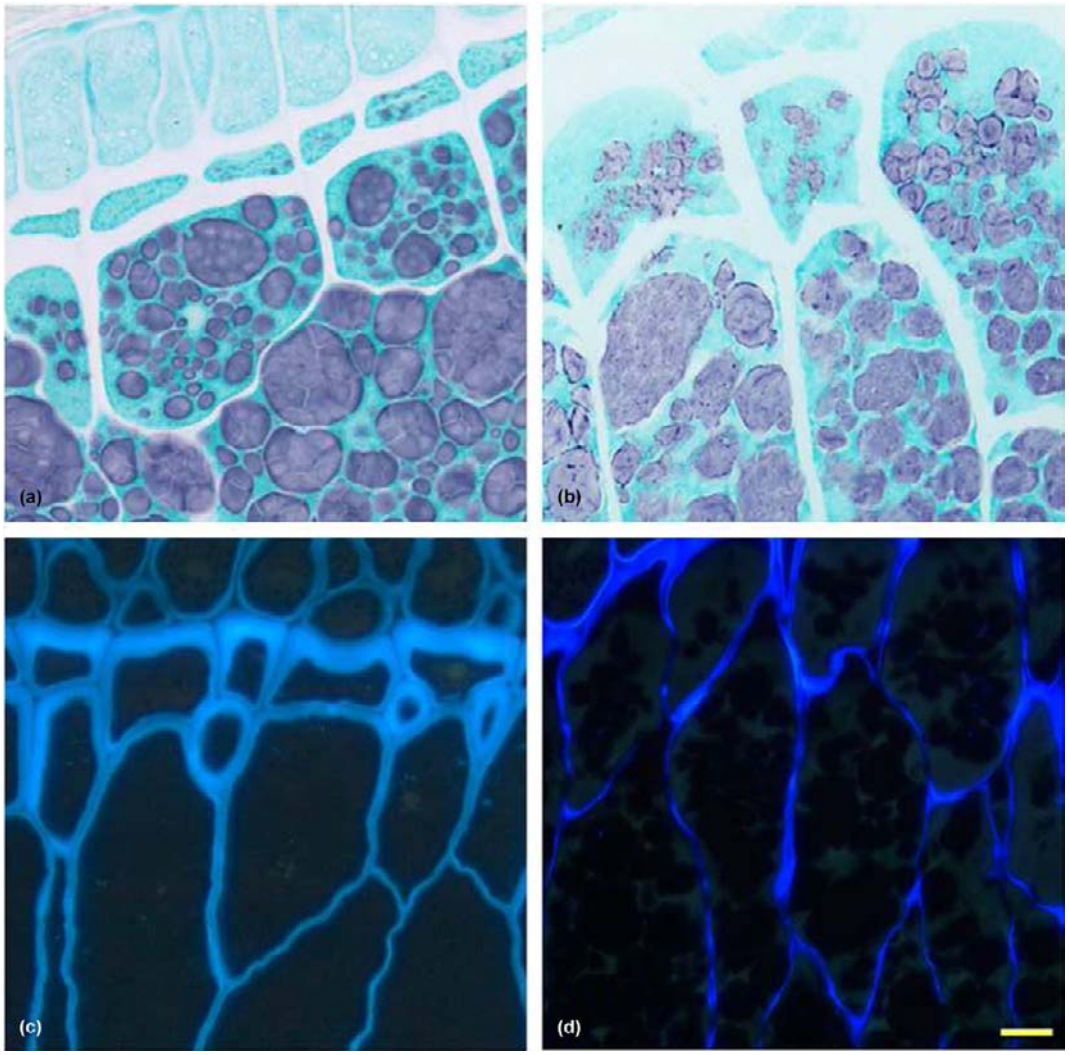

Figure 3 Raw (a, c) and cooked (b, d) oat groats. (a, b) Resin-embedded sections stained with light green to demonstrate protein and iodine/potassium iodide (IKI) to demonstrate starch. (c, d) Stained with calcofluor white to demonstrate mixed-linkage β-glucan. Bar = 20 μm.

granules varies depending on how close to the cut surface they are. Starch, protein, and cell wall material released from the cut surfaces of the oats form a matrix of sorts for the cut oat pieces in the steel-cut oat porridge (see bottom of Figure 4(c)).

Steaming and flaking of whole groats to make large flake oats cause many ruptures in the endosperm, and some gelatinization of starch granules is evident, even before cooking. Although there is some cell wall fragmentation due to tissue disruption, the β-glucans in the wall are essentially intact (not shown). Oat flakes in this form are often incorporated into muesli, granola mixes, and granola bars, with little change in microstructure or nutrient distribution. When the large flake oats are cooked in water to make porridge, the starch granules swell and fuse, ultimately becoming completely gelatinized (Figure 4(d)). In areas of the endosperm with intact cells, the cell walls are swollen but intact.

When the pieces of steel-cut oats are steamed and flaked, quick-cooking oatmeal is produced. Raw flakes of quick-cooking oatmeal show more extensive tissue disruption and swelling and gelatinization of starch granules (Figure 4(e)). Like the large flakes, quick oats can be used in muesli, granola mix, or granola bars as is. Cooking as porridge continues the gelatinization of starch, with granule swelling, fusion, and gelatinization, accompanied by leaching and aggregation of amylose from the starch granules (Figure 4(f)). Where there are intact cells, the walls are disrupted, and β-glucans are leached from the walls. This is particularly evident in the thick subaleurone walls (Figure 5(a)). Leaching of β-glucan from cell walls was observed in all cooked oat cereals.

Cooking of the various porridges renders the starch and proteins more easily digestible and also partially solubilizes the β-glucans. The viscosity increase caused by the increase in soluble β-glucan blunts glycemic response, while the heat and moisture increase the fraction of starch that is rapidly broken down to glucose.

Raw oat flakes are often further milled into flour and/or oat bran to make infant cereals or extruded ready-to-eat cereals. Even in a formulated extruded cereal, fragments of oat kernel

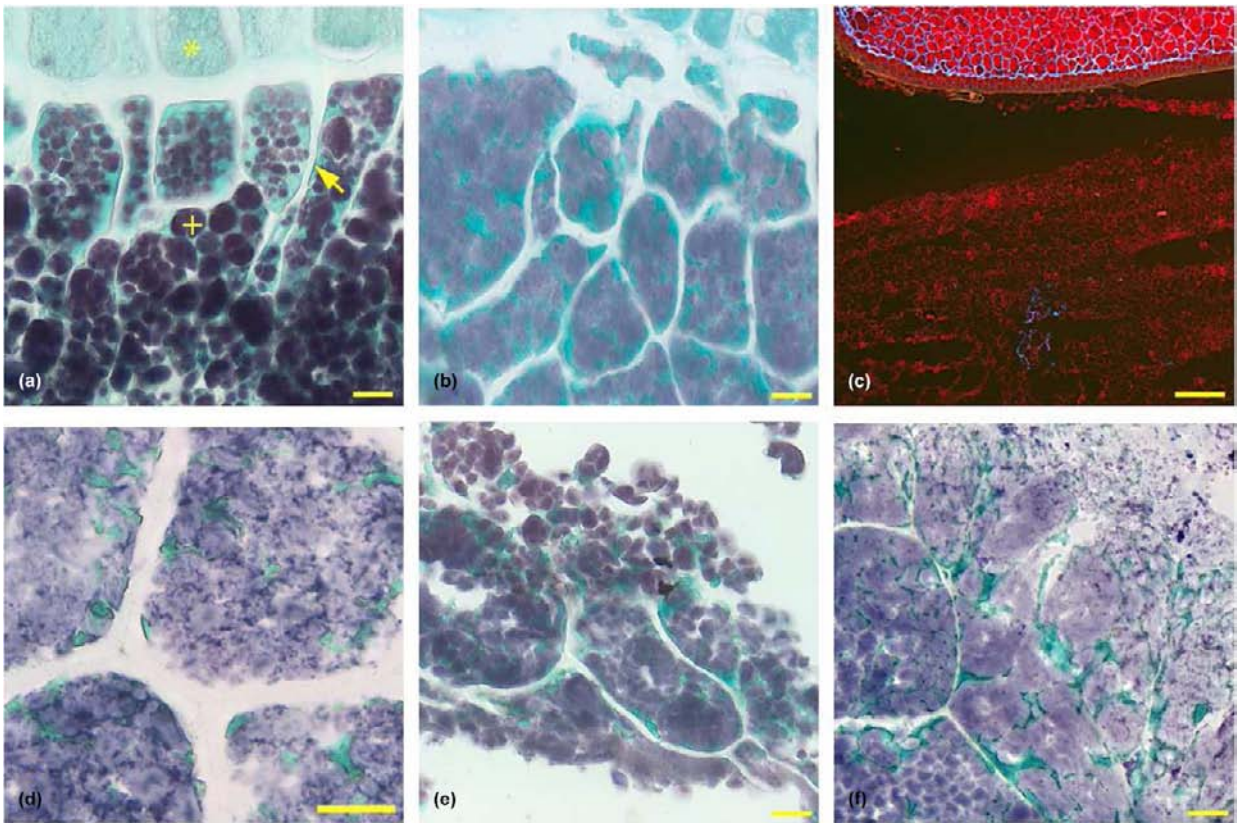

Figure 4 Raw and cooked oat cereals. (a–c) Steel-cut oats. (a) Raw, stained with IKI; *, aleurone cell; +, starch granule; arrow, subaleurone cell wall. Bar = 20 μm. (b) Cooked, IKI, bar = 20 μm. Figure 5 Oat products: (a) Quick oat flakes, cooked, CF & FG, bar = 50 μm. (b) Ready-to-eat cereal, CF & FG, bar = 50 μm. (c) Oat bran muffin, CF, bar = 100 μm. (d) Oat bran bread, IKI, bar = 20 μm. (e) Oat bran bread, CF & FG, bar = 50 μm. (f) Oat bran pasta – cooked, CF, bar = 100 μm. IKI, iodine/potassium iodide reagent; FG, fast green; CF, calcofluor white. Cryosections.

are recognizable (Figure 5(b)), although gelatinization of starch granules is extensive. Large pieces of oat bran can be seen, in which the β-glucans are clearly visible in the intact subaleurone walls. Smaller fragments of the cell wall (blue flecks) are also visible in the starch matrix. Disruption of the cell walls may affect physiological function.

Some products that are primarily wheat-based, such as quick breads, yeast breads, and pasta, can be enriched with oat bran, thus combining the processing functionality of wheat with the physiological benefits of oats. The physiological efficacy of β-glucan in quick breads such as muffins is affected by storage conditions. Figure 5(c) shows a section of a fresh oat bran muffin. Many fragments of aleurone can be distinguished; however, the subaleurone cell walls are not distinct. Instead, the β-glucan has been solubilized and is present as an amorphous matrix throughout the muffin. Yeast breads have a spongelike microstructure, with air cells surrounded by 'walls' with starch granules embedded in a fibrillar gluten (protein) matrix (Figure 5(d)). At the junctions where the air cells are connected, thicker areas of protein matrix can be found. Figure 5(e) shows one of these junction areas in bread enriched with oat bran. During the long fermentation process required for the dough to proof and rise before baking, the β-glucan in the dough is partially depolymerized by enzymes in the wheat (Figure 5(e)), which may compromise the physiological effectiveness of the product. Pasta is another wheat-based product that can be enriched with oat bran for putative health benefits. Figure 5(f) shows a cross section of a cooked noodle enriched with oat bran. When the cooked pasta is stained to demonstrate β-glucan, fragments of oat cell wall can be seen throughout the protein–starch matrix. In addition, there is a layer of solubilized β-glucan that has migrated to the surface of the noodle during cooking (bottom), which would tend to make the β-glucan more available.

Summary

Oats are a globally produced crop, although they account for only 1% of world's cereal production. They provide excellent nutrition from both macro (protein, starch, lipid, and fiber) and micro (vitamins, minerals, and antioxidants) components. Whole oats and a variety of oat products and fractions are available for use as is or the incorporation into oat-enriched foods. Consumption of oats and oat products has been shown to be beneficial for both lipid metabolism and carbohydrate metabolism in humans. Much of this benefit is attributed to the content of mixed-linkage β-glucan, as well as antioxidants such as avenanthramides. The relative availability (and therefore physiological functionality) of these and other nutritional components are impacted by both industrial processing and home preparation practices, which are reflected in microstructural changes.

Obesity Management

LJ Cheskin, RA Frutchey, L Bunyard, and S Glascoe, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, USA

© 2016 Elsevier Ltd. All rights reserved.

Introduction

The prevalence of obesity has nearly doubled in the past generation, with two-thirds of American adults now overweight or obese. If current trends continue, it has been projected that essentially all Americans will be overweight by 2030. The recent increase in prevalence is even more dramatic among children and the extremely obese.

What is causing this epidemic? Despite recent discoveries in the molecular genetics of obesity, genetic influences are not a likely explanation for the rapid recent changes in the prevalence of obesity. Obesity is a result of a complex interplay between genetic, behavioral, and environmental factors that include diet and exercise.

In the United States, although the percent of energy intake derived from fat is decreasing (from a high of 40% to about 32% today), total daily caloric intake is increasing, and refined carbohydrate intake is increasing. Meanwhile, growing numbers of adults and children engage in virtually no physical activity. The built environment is a large contributor to this inactivity and, thus, plays a significant role in the US obesity epidemic.

Obesity is close second to cigarette smoking as the most important modifiable cause of death. It is a risk factor for diseases of virtually every organ system, including certain cancers, and the most important risk factor in the development of diabetes and multiple other health complications. The risk of comorbid medical conditions increases with the degree of obesity, although for some complications – notably dyslipidemias, which are associated with cardiovascular risk factors, type 2 diabetes, and hypertension – the risk correlates best with the regional distribution of fat.

Obesity also increases overall mortality and shortens life expectancy by at least several years in individuals who are $>25\ \mathrm{kg\,m^{-2}}$; this reduction can be dramatic for those who have a BMI of $>35\ \mathrm{kg\,km^{-2}}$. In addition to the medical risks, often more motivating for many people seeking to lose weight are the untoward psychosocial consequences of obesity.

This article aims to provide an overview of the assessment and treatment of obesity, with the primary focus on dietary, exercise, and behavioral interventions. Pharmacological and surgical therapies are a second-line option in the treatment of obesity and are reviewed in less depth.

Evaluating Obesity

Obesity is defined as an excess of body fat (>25% of body weight for men and >30% for women) rather than an excess of body weight per se. However, the measurement of percent body fat is more difficult to obtain and not as intuitive as body weight. Measuring weight adjusted for height, or BMI, defined as weight in kilograms divided by the square of the height in meters, is usually the first step in assessing obesity. While BMI is the standard measure of relative weight, it may overstate the actual degree of adiposity in very muscular people (e.g., certain types of athletes and laborers) and may understate adiposity in very sedentary individuals with little muscle mass. A BMI of 25–30 $\mathrm{kg\,m^{-2}}$ is defined as overweight, 30–40 $\mathrm{kg\,m^{-2}}$ as obese, and 40 or more $\mathrm{kg\,m^{-2}}$ as severely/morbidly/grade III obese.

Waist circumference is the second step in the assessment of obesity. In women, a waist circumference of greater than 35 in. and, in men, greater than 40 in. constitutes abdominal/visceral obesity and is associated with an increased risk of health complications. Waist circumference can be easily measured with a tape measure around the widest point above the hips. Note that visceral obesity can exist even in the absence of overall obesity (i.e., at BMIs below the cutoff points for obesity or overweight). With visceral obesity, even with a normal BMI, it is probably best to encourage weight loss for medical reasons.

Dietary Assessment

A formal dietary assessment, best conducted by a registered dietitian with training and expertise in weight management, can identify problem areas in diet requiring modification for weight loss to occur. It may consist of a 24 h recall of food intake, a food frequency assessment to determine adequacy and composition of the diet, anthropometric assessment, and an interview assessing meal patterns, beverage consumption, food/taste preferences, portion sizes, grocery shopping/cooking pattern, restaurant dining, and any religious or cultural customs that may affect the patient's diet.

The results should be interpreted cautiously, because both underreporting and restrained eating while under observation (either intentional or unintentional) are common. Despite these shortcomings, the information gathered can be quite valuable. For example, if an individual reports drinking almost 1000 calories per day in juice and soda, simply switching to noncaloric beverages would promote a significant weight loss (assuming dietary compensation does not occur).

Metabolic Testing

Assessment of the patient's resting metabolic rate (RMR) via a metabolic cart (indirect calorimetry) is recommended if the necessary equipment and staffing are available. RMR (also called resting energy expenditure (REE)), obtained by either metabolic cart or estimation formulas, is then used to determine daily caloric needs by multiplying RMR by an activity factor ranging from 1.3 (for very sedentary) to 2.0 or more (for very physically active individuals). This estimate of total daily energy expenditure is used by the dietitian to determine the patient's initial caloric requirements and an estimated rate of weight loss, given a specific reduction in energy intake in the diet.

Nutrition

Nutritional Management of Mild to Moderate Obesity

Nutritional management of obesity entails an individualized approach, based on the dietary assessment, within a multidisciplinary setting whenever possible. For patients with mild to moderate obesity, a moderate caloric deficit of at most 500–1000 calories per day is recommended to promote a 0.4–0.85 kg weight loss per week. A low-calorie, individualized food-based diet that is either balanced-deficit (reducing the total number of calories while keeping proportions from carbohydrate, fat, and protein basically the same as before) or fat-deficient diet, with most of the caloric reduction resulting from restriction of fat, can be prescribed. The latter approach is preferable for Americans, whose typical diet is too high in fat. Also, a greater volume of food can be eaten on a diet that emphasizes complex carbohydrates and reduces fat intake to 20–25% of calories consumed.

The diet must be realistic – that is, based on dietary modification and practical changes in eating habits. Nutritional recommendations should be determined by the patient's current eating habits, preferences, lifestyle, ethnicity and culture, other coexisting medical conditions, and potential nutrient–drug interactions. The patient should be advised to drink at least 1.5–2.0 l of water daily, unless contraindicated (e.g., by congestive heart failure, edema, or renal insufficiency). Patients should also be encouraged to self-monitor their food intake, which may include measuring portion sizes and recording and calculating calories, fat grams, and/or carbohydrate grams. If energy intake is prescribed below 1200 calories per day, taking a daily multivitamin and mineral supplement is helpful to ensure adequate intake.

Nutritional Management of Severe Obesity

A medically supervised very low calorie diet (VLCD) (fewer than 800 calories per day) weight management approach is appropriate for individuals who are severely overweight (generally BMI $\geq$ 35) and/or those with serious medical conditions related to their obesity. Obese patients who have failed multiple weight reduction attempts through traditional programs may also be considered for aggressive strategies. A VLCD may consist of food, commercially available liquid supplements, or a combination of the two. It is recommended that patients being considered for VLCDs undergo a comprehensive medical examination and an ECG. Absolute contraindications include the presence of untreated or severe cardiac, hepatic, renal, or thromboembolic disease; type 1 diabetes; cancer; and severe eating disorders. Weekly medical supervision is recommended while on the VLCD. With full adherence, weight loss averages 1.1–1.8 kg per week, depending on body mass and physical activity level. A high protein content consumed during a VLCD may minimize muscle wasting as the rapid weight loss occurs. The diet period is followed by progressive refeeding. Throughout the course of dieting, education on nutrition, exercise, and behavior modification will help the patient maintain his or her weight loss during and beyond the refeeding phase. For this reason, multidisciplinary treatment is strongly recommended in combination with the VLCD. Without this education and support, weight gain will likely occur almost as rapidly as weight loss.

Exercise

Exercise/Fitness Assessment

The exercise/fitness assessment should be performed by a trained exercise physiologist and should explore the patient's usual degree of physical activity, any limiting factors such as joint disease or injuries, preferred types of activity, and measurement of the patient's current level of fitness. A fitness test consisting of a Harvard step test, test of flexibility, and bioelectric impedance testing may be used to assess body composition. A formal stress test is not required unless active cardiovascular disease is suspected. The exercise physiologist may also explore lifestyle factors such as usual work hours, social support, and nearby facilities or other resources that could promote increased activity level.

Exercise Treatment

Although regular, moderate physical activity alone results in limited weight loss over the long term, it is an essential component of any weight management program. Research has shown that patients who diet and exercise regularly are much more likely to maintain weight loss than those treated with diet alone. When performed in conjunction with caloric restriction, regular, moderate physical activity achieves the following effects: increases 24 h energy expenditure, maintains (or minimizes loss of) lean body mass, reduces cardiovascular risk by producing beneficial changes in the lipid profile, has positive psychological effects, improves insulin sensitivity, and may provide other health benefits independent of weight loss.

In determining an appropriate, individualized exercise program, the exercise physiologist and the patient together should consider a plan that (1) fits into the patient's schedule and lifestyle, (2) is liked or disliked by the patient, (3) makes use of the patient's resources, and (4) is based on the patient's current level of fitness. The exercise physiologist should ensure that, before beginning a fitness program, all patients can recognize and deal with abnormal physical responses to physical activity.

When beginning an exercise program, it is worthwhile to start with small goals and increase the level and intensity of exercise gradually. Eventually, the exercise goal of any weight management program should be 30–60 min of continuous, moderate-intensity physical activity five to seven times per week. Until a patient can tolerate 30 min of continuous activity, several 10 min periods of physical activity throughout the day can help build the patient's endurance while still burning calories. Additionally, short exercise and rest intervals can be alternated. The intensity, duration, and frequency of activity should be progressively increased, according to the patient's increasing ability. Patients should be encouraged to self-monitor their daily physical activities, including type of activity, time performed, and duration, so that progress can be appreciated and the goal reset a bit higher from time to time.

Resistance Training

Resistance (strength) training can be added to an aerobic exercise regimen and has been shown to help preserve muscle mass. Studies have shown that resistance training along with

aerobic exercise in addition to calorie-restricted diet results in weight loss along with muscle strength preservation and improvements in physical functioning. While resistance training may not correlate with body weight changes during the weight loss phase and/or may result in weight gain since muscle mass (which is denser than fat) increases with resistance training, it is important for weight maintenance. One study reported that those who incorporated resistance training during the weight maintenance phase were likely to regain fat mass at a slower pace or were less likely to regain fat mass at all, compared to those who did not, in spite of overall body weight regain. Additionally, resistance training is associated with lower levels of visceral fat, which corresponds to a lower risk of cardiovascular disease. While a lot of emphasis has been placed on aerobic training to lose body weight/fat, combining resistance training with calorie-restricted regimen for weight loss can indirectly aid in both weight loss and maintenance by improving muscle mass, strength, and endurance.

Behavior Therapy

Psychological and Behavioral Assessment

A psychosocial and behavioral assessment is an important component of multidisciplinary treatment that can provide considerable information about the patient's readiness for lifestyle change, emotional health, and triggers for inappropriate eating. The assessment explores the patient's history of weight gain and loss, history of previous diet attempts, patterns of weight maintenance or relapse, and motivation for weight loss. Current eating behaviors are assessed, and antecedents or 'triggers' that cause the patient to eat when not hungry or to overeat are examined. Triggers might be environmental (e.g., seeing or smelling tempting food), mental (e.g., thoughts about food), emotional (e.g., eating for comfort and eating for reward), social (e.g., dining out with friends and alcohol consumption), habitual (e.g., eating at a certain time), or physiological (e.g., poor sleep and hormones). The stages of change model for behavior change intervention may be useful in assessing the readiness state of the patient to make behavior changes, while motivational interviewing techniques can be used to identify reasons for wanting to change behavior, as well as barriers that have a negative impact on motivation.

A licensed clinician should conduct a thorough psychological evaluation and screen for mental health conditions, past or present. Both mood disorders and eating disorders are prevalent in this population. Obese persons with significant mood-related symptoms should be provided appropriate treatment (cognitive behavior therapy and/or pharmacotherapy) prior to or concomitant with weight reduction efforts. Individual or group psychotherapy may also be beneficial to address other issues related to obesity, such as low self-esteem, body image, and relationship problems. Binge eating or other eating disorders often coexist with obesity and may require separate treatment by a specialist.

Behavioral Treatment

Behavioral treatment of obesity aims to identify triggers for excess caloric intake/inadequate physical activity and to develop approaches to address these behaviors. Studies show that behavior therapy as an adjunct to exercise and diet therapy for weight loss produces significantly better results than exercise and diet alone. Typically, a psychologist or mental health professional on the team suggests or implements behavioral techniques, although these tools may be useful in all components of treatment. The principles used in behavior modification typically include goal setting, self-monitoring, stimulus control, contingency management, self-care (including stress management and sleep hygiene), cognitive restructuring, social support, and relapse prevention.

Goal Setting

Whether the goal is a target weight loss, daily calorie, or exercise goal, goal setting is a common component in behavioral weight loss treatment. Research clearly demonstrates that goals can favorably enhance performance, including weight loss outcomes. Larger goals can often be broken down into smaller more manageable goals that are easier to implement and monitor.

Self-Monitoring

Self-monitoring for weight management generally involves recording dietary intake and physical activity to increase the patient's awareness of his or her own behavior and to promote positive behavior change. Research has consistently demonstrated that self-monitoring is associated with improved treatment outcomes, and patients often report that it is one of the most helpful obesity management tools. Patients may be encouraged to record the time of eating episodes, type and amount of food eaten, feelings of hunger and satiety, place, context, and/or comments in order to better understand behavioral patterns and triggers. Self-weighing allows participants to assess the effectiveness of their current weight loss strategies and to make corrective action if necessary. Regular self-weighing is associated with lower BMI and greater weight loss.

Stimulus Control

Evidence for the impact of the food and physical activity environment on eating and sedentary behaviors is well documented. Eating cues in the environment are numerous, ever-present, and often outside of an individual's conscious awareness. Stimulus control strategies might include recommendations such as only eating at the kitchen table and not in front of the television, keeping tempting, high-calorie foods out of the house (or, at least, out of sight), and laying out exercise clothes the night before as a reminder to exercise in the morning.

Problem Solving

Motivational interviewing techniques can be used to help patients identify and overcome barriers to behavior change (i.e., no safe place to exercise outside the home and dislike of vegetables).

Contingency Management

Contingency management involves rewarding desired changes in behavior, such as increasing frequency of exercise or reducing intake of fast foods. The rewards can be granted by the patient, the patient's family, and/or the weight management center; however, rewards must be of value and reinforcing to the patient in order to be effective. One contingency management technique used to enhance motivation is incentives (usually money).

Cognitive Techniques

Behavioral-based therapies have evolved over time to emphasize cognitive elements. For example, participants may be taught to stop dichotomous thinking (e.g., I blew my diet; I'm off the program), to ban perfectionist attitudes and imperatives (e.g., I will *never* eat more than 1200 calories a day), and to be aware of attitude traps (e.g., my life will be perfect when I lose weight; I can't wait for the program to end so I can get back to normal eating). Mindfulness-based (e.g., acceptance) and control-based (e.g., distraction and delay) techniques may be taught as a means of helping participants manage cravings or thoughts about food. In addition, problem-solving techniques are often taught to patients to help them to break down more difficult or larger barriers to successful behavioral change.

Self-Care

Behavioral intervention targeting self-care focuses on improving sleep hygiene, time management, and stress management. Sleep and stress are closely and reciprocally linked. In addition, both sleep deprivation and high levels of stress appear to have a detrimental effect on weight management. One recent study, involving a 6-month behavioral weight loss intervention, found that lower baseline stress levels and longer sleep duration predicted greater weight loss over the course of the intervention.

Social Support

Social support, usually from the patient's family or a support group, is used to maintain motivation and provide reinforcement for appropriate behavior changes. Facilitated support groups are often an integral part of comprehensive weight loss treatment for these reasons, and they further serve to 'normalize' the ups and downs of the treatment process. Studies show that group treatment can produce significantly greater weight loss (~13%) than individual sessions (>11%) and are more likely to help maintain weight loss.

Relapse Prevention

Given the high rates of dietary relapse following weight loss, researchers have attempted to provide relapse prevention training to improve long-term weight loss maintenance. Based on models such as Marlatt and Gordon's relapse prevention model, weight loss researchers have attempted to help participants identify situations with high risk for a dietary lapse and to teach coping skills to successfully cope with the relapse crisis.

In summary, comprehensive psychological and behavioral therapy is crucial in the treatment of obesity. The aforementioned strategies, employed throughout treatment, help patients to better understand and modify problematic thoughts, moods, and behaviors. The resulting lifestyle changes can effectively bring about modest, yet clinically significant weight loss.

Pharmacological Treatment for Weight Loss

Lifestyle modifications discussed earlier form the cornerstone and first stage of any weight loss plan. Adjunctive anorectic medications may be useful, if this approach (lifestyle modifications including diet, exercise, and behavior therapy) alone does not result in weight loss. Pharmacotherapy may be helpful at the point where compliance to lifestyle modification begins to waver or physical hunger becomes an issue during dieting. There is little doubt that such medications significantly increase weight loss during the period in which they are used and may help with maintaining weight loss (though there tends to be regain even with continued use). However, pharmacological treatments are best suited for those who are severely obese ($>40\ \mathrm{kg\ m^{-2}}$) or who have significant medical comorbidities. The agents available are growing in number in very recent years and include appetite suppressants and fat-absorption blockers.

Surgical Treatment of Obesity

While lifestyle modifications that include combinations of diet, exercise, behavior therapy, and pharmacological agents for the severely obese can produce changes in body weight, these changes may prove to be inadequate, leaving weight loss surgery as a second-stage approach. The NIH consensus conference on gastrointestinal surgery for severe obesity concluded that weight loss surgery may be an appropriate option for those who are severely obese ($\mathrm{BMI} \geq 40\ \mathrm{kg\ m^{-2}}$) or those who have a BMI of $>35\ \mathrm{kg\ m^{-2}}$ with two or more obesity-related comorbidities.

Before an obese individual decides upon surgery to lose weight or their physician decides to recommend surgery as an option, it is important to thoroughly evaluate the patient using a multidisciplinary approach. This should ideally involve not only the surgeon and referring physician but also dietitians, psychologists, nurses, and an anesthesiologist. The patient's medical and nutritional history must be evaluated, as well as psychological assessment to better understand any underlying issues before a decision should be reached regarding suitability for surgery. Contraindications include issues that can hinder adherence to the recommended postoperative care needed to achieve expected outcomes. These issues include psychological disturbances, medical problems that may worsen or contraindicate major surgery, and a nonsupportive environment.

In summary, surgical treatments are the most efficacious option for individuals who have severe obesity and show

weight loss superior to other approaches. However, the rate of success following bariatric surgery is highly variable, and risks of postoperative complications are present. Therefore, a multidisciplinary approach needs to be adopted so that proper evaluation and selection of the patients occurs preoperatively and long-term postoperative care and monitoring is ensured.

Conclusions

Maintenance

Maintaining weight loss seems to be inherently more difficult than losing weight. Unfortunately, the long-term success rate for all weight loss methods (excluding surgery), defined as losing weight and keeping the majority of it off for at least 5 years, is low – perhaps 5–15%. Even after the most state-of-the-art, medically monitored comprehensive treatment, it is likely that patients will gradually return to their baseline weight within 3–5 years after treatment termination. Only the continuous-care model of management, which views obesity as a chronic disease requiring continuous support or contact after the end of formal treatment, has been found to produce significant maintenance of weight loss.

There are many factors that contribute to this relapse, including low motivation and support from the provider diminishing or ending. While weight regain is very difficult to prevent entirely, continuation of some form of exercise may slow and diminish its degree. Those who exercised regained ~7 lbs less in body weight compared to those who did not exercise. Other studies show that physical activity alone may not help in maintaining weight loss, though. Dietary restraint along with physical activity may prove to be more successful in maintaining weight loss and slowing/preventing weight regain than physical activity alone. Restricting calories from fat along with high physical activity may prove to be the most effective strategy to maintain weight loss on a long-term basis.

One study showed that teaching individuals to take responsibility for weight maintenance by developing problem-solving skills to overcome setbacks improves weight loss maintenance. These techniques and skills include providing incentives for motivation, learning how to preplan weekly low-calorie meals, how to control portions, providing additional support from peers, increasing provider and patient contact, and encouraging self-monitoring. Social support, along with these techniques, improves weight maintenance after initial weight loss. Thus, several studies suggest that behavior therapy beyond the initial weight loss phase is important in maintaining the weight loss.

While several diets have been reported superior for achieving weight loss, the choice of a specific dietary approach needs to be individualized based on an individual's goals, medical needs, and preferences. No one dietary approach appears to be substantially better or worse than the others. Many people are motivated to lose weight faster during the initial phases of weight control, which can help guide the choice of dietary approach toward a more aggressive level of energy restriction, if medically appropriate. It is probable that some form of continuous or punctuated long-term care will be necessary for many (if not all) obese patients to maintain the dietary and lifestyle changes that produced their weight loss. With ongoing support from a physician or other health care providers, patients will be better able to maintain their changes in eating and activity behavior and the resultant weight loss.

Regrettably, optimal strategies for weight maintenance are in a state of evolution and represent the key limitation of our current treatment of this highly prevalent, medically hazardous, and chronic condition. Research has identified continued program contact (e.g., monthly), regular physical activity, nutritional sophistication, and self-monitoring as four predictors of weight maintenance. It not surprising that the strategies helpful in promoting weight loss, such as self-monitoring, physical activity, regular weigh-ins, and attendance at a multidisciplinary program, will be the same strategies necessary for long-term maintenance of weight loss.

Summary

Obesity management is perhaps the greatest challenge faced by health care professionals today. With the rise in obesity rates come a plethora of medical complications. Almost all adults who become obese will do so not because of a specific medical or metabolic condition, but because of lifestyle behaviors leading to increased food consumption and/or decreased energy expenditure. Further research is needed in understanding the basis of certain behaviors adopted by obese individuals and ways to modify them more effectively to achieve long-term weight management.

To prevent obesity or slow its progression, efforts should be devoted to improving environmental factors and personal behavior. While the obesity treatment modalities discussed in this article can be successfully applied to obese individuals, changing/improving our environment is the key to preventing and reversing this public health epidemic.

Why We Care about Obesity

Obesity is one of the most challenging health issues facing society today. Almost every country around the world has seen increasing rates of this problem. Obesity affects people of all ages, ethnicities, and sociodemographic backgrounds. In the last 30 years, rates have doubled throughout the world. Contrary to popular perception, 65% of the world's population lives in countries where more people die from overweight than from underweight. Although obesity was once considered a disease of affluence, levels are increasing in low- and middle-income countries (LMICs), particularly in urban settings.

Overweight and obesity are defined as an abnormal or excessive accumulation of fat that may impair health. Body mass index (BMI) is a standardized, population-based measure used to categorize individuals as overweight or obese. An individual with a BMI of 25 or more is considered overweight, and someone with a BMI of 30 or more is considered obese. Obesity is classified further based on grades of severity: obese class I (BMI 30–34.9), obese class II (BMI 35.5–39.9), and obese class III (BMI 40 or greater). The higher a person's BMI, the greater the health risks. Among children, weight status is determined using age- and sex-specific percentiles for BMI. Overweight is defined as a BMI above the 85th percentile and obesity as a BMI above the 95th percentile for children of the same age and sex.

The obesity epidemic has immense consequences for both individuals and society. Obesity has negative effects on an individual's health, well-being, and quality of life because of resulting chronic conditions, which lead to increased disability and premature death. Obesity is the fifth leading mortality risk factor worldwide, and ~3.4 million adults die each year as a result of being overweight or obese. Obesity is associated with higher risks of developing hypertension, high cholesterol, osteoarthritis, respiratory disorders, and fertility problems. Furthermore, obesity increases the risk of type 2 diabetes, cardiovascular disease, and some cancers. Obesity also adversely affects an individual's mental and psychological well-being.

Obesity-related costs continue to increase globally, which compromises the economies and health-care systems of all nations. Annual US health-care costs attributed to obesity are estimated at approximately $190 billion. Health-care costs for obese patients are 40% higher than for those with normal body weight, and it is estimated that if obesity trends in the United States continue at the current rate, by 2030, obesity-related medical costs could increase $48–$66 billion per year. The increase in prevalence of type 2 diabetes, which costs the US economy an estimated $180 billion per year, has paralleled the increase in obesity. A large proportion of these costs are borne by overburdened public health-care systems, whose resources could be better utilized for nonpreventable conditions. In addition to direct health-care and disability costs, obesity is linked to increased costs in the workplace due to loss of productivity and excessive absenteeism and higher costs of adapting to an increasingly obese population. The environmental costs of obesity are also escalating as a result of greater food production, fuel use, and greenhouse gas emissions. A greater dependency on technologies that limit physical activity such as manufacture of cars and labor-saving machinery, production of processed foods, and adaptation of the infrastructure to support heavier individuals contributes to cumulative negative environmental effects. Annual greenhouse gas emissions from food production and car travel associated with increased adiposity in a population of 1 billion people are estimated at ~0.4–1 additional gigatons of carbon dioxide equivalents.

The global burden of obesity will continue to grow unless action is taken to reverse current trends. The future health, social, economic, and environmental costs could be overwhelming and will affect everyone adversely, from individuals, families, and schools to small businesses, governments, and large corporations. The difficulties of treating obesity and the slow progress made to date in reversing the trend emphasize the need to prioritize obesity prevention and management worldwide. Warranting particular attention is the fact that many LMICs now face the multiple burdens of infectious diseases and undernutrition coupled with growing rates of obesity. Developing countries, particularly in urban settings, have undergone a 'nutrition transition' whereby traditional diets have been replaced with diets high in refined, energy-dense, yet nutrient-poor foods. The public health capacity of LMICs is significantly strained to accommodate this additional burden.

Causes

Whereas the underlying mechanism of obesity at the individual level is an imbalance of calorie intake and expenditure, social, cultural, and environmental influences on individual calorie intake and expenditure greatly affect the incidence of the condition. These influencing factors include the importance of individual and household food preferences, availability of fast food in the neighborhood, and cultural expectations regarding food and physical activity. Increases in obesity prevalence follow an established pattern: in LMICs, as gross domestic product (GDP) increases, high-income groups in urban areas are the first to have high obesity prevalence, followed by low-income groups and those in rural areas. This

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00500-6

phenomenon, known as the 'nutrition transition,' occurs when individuals move from eating local staple foods to having access to calorie-dense, nutrient-poor foods and concurrently become less active. As GDP increases, mean BMI increases linearly up to \$5000 year^{-1} per person GDP; above that level, the relationship is flat.

Economic success facilitates obesity but is not always required; obesity prevalence is high in some low-income countries and areas such as the Pacific Islands nations. A unique challenge for developing countries in the nutrition transition is that mothers are often undernourished, and this is known to influence an infant's birth weight and genetic ability to metabolize glucose effectively. Evidence supports this *thrifty phenotype* hypothesis, in which poorly nourished infants become 'thrifty' and are unable to compensate later in life when nutrient intake increases in an environment in which high-calorie food is widely available.

The drivers of the obesity epidemic in the food system, including the increased supply of cheap, high-calorie foods, greater access to foods, and persuasive food marketing, are complex and interconnected. In the framework developed by Swinburn and colleagues, energy imbalance is affected by largely individual behavior patterns, including high energy intake and low physical activity; these behaviors are influenced by important environmental and system drivers, including the food supply. These drivers, in turn, are moderated by environmental characteristics such as culture, activity, and transportation. At the highest level, systemic drivers, including policy and economic systems, impact the environment (Figure 1).

Prevalence

According to the World Health Organization, obesity rates have nearly doubled since 1980. In 2008, an estimated 1.5 billion adults over the age of 20 years (35%) were overweight, and 500 million (11%) were obese. In the United States, which has one of the highest rates of overweight and obesity in the world, ~35% of adults and 17% of children (almost one in every five) are obese (Figure 2).

Halting the global increase in obesity is one of the targets of the Global Monitoring Framework for noncommunicable diseases (NCDs), an international framework that was formally adopted in 2013 following the adoption of the Political Declaration on NCDs by the United Nations General Assembly in 2011. The framework comprises a list of 25 key indicators, including prevalence rates of adult and child obesity, that member countries are encouraged to track systematically to assess progress in preventing and controlling major NCDs.

In the United States, data from the National Health and Nutrition Examination Survey between 2011 and 2012 showed the first evidence that obesity rates have started to level off during the 2000s. During the same period, more than two-thirds of adults and one-third of children were overweight. There was a significant increase in the prevalence of obesity among women 60 years and older (Figure 3). Non-Hispanic black and middle-aged women had significantly higher obesity levels than did other population subgroups (Figure 4).

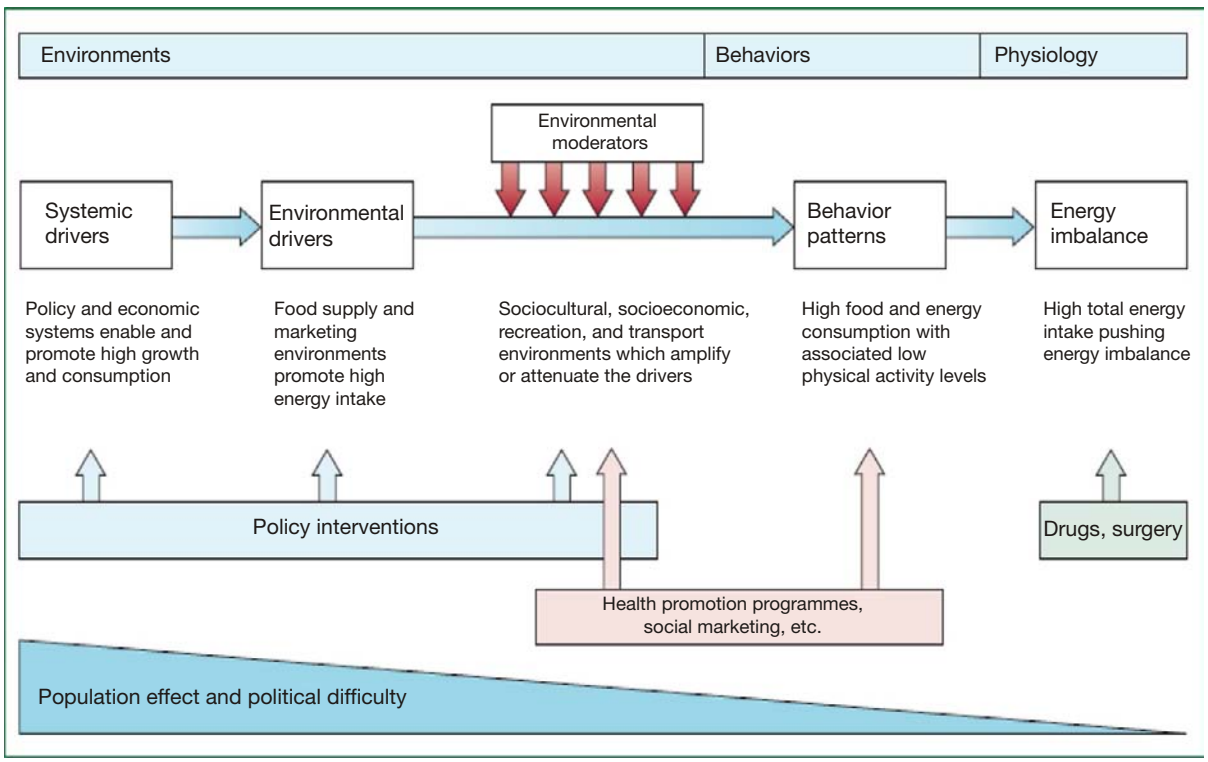

Figure 1 Framework for categorizing determinants of and solutions for obesity. Reproduced from Swinburn, B. A., Sacks, G. A., Hall, K. D., et al. (2011). The global obesity pandemic: shaped by global drivers and local environments. *Lancet* **378**, 804–814.

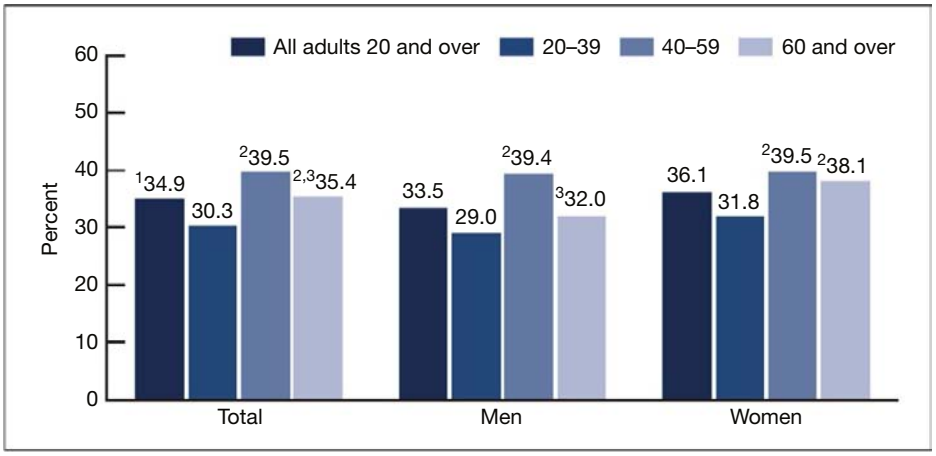
Global, regional and national prevalence of overweight and obesity in children and adults during 1980–2013: a systematic analysis for the Global Burden of Disease Study 2013. *Lancet* **384**(9945), 766–781.

The overall prevalence of obesity in youth remained unchanged from rates between 2009 and 2010, and there has been no significant change since 2003–04; the same trend was observed among adults. Analyses show that the flat growth trend among children was primarily due to a decrease in obesity prevalence among those aged 2–5 years, from 14% to 8% between 2003–04 and 2011–12. No significant differences were observed between boys and girls; however, Hispanic youth showed significantly higher rates of obesity than did non-Hispanic Asians (22.4% vs. 8.6%). The overall declining prevalence of obesity among toddlers observed in the National Health and Nutrition Examination Survey is consistent with other reported data from the US Virgin Islands and Massachusetts and with recent declines in extreme obesity among US preschoolers in low-income families. Data for middle and high school students appear to be more mixed. Recent studies from Europe have also shown a leveling off of obesity prevalence, including a decline among German children and a slowing of the rate of increase in adult obesity in England.

Previous studies of the US population have shown an association between obesity rates and socioeconomic status as measured by education levels and income; however, a recent



[1]Crude estimate 35.1%.

Figure 4 Age-adjusted prevalence of obesity, by sex and race, among adults 20 and over: the United States, 2011–12. Reproduced from Ogden, C. L., Carroll, M. D., Kit, B. K., and Flegal, K. M. (2013). Prevalence of obesity among adults: United States, 2011–2012. NCHS Data Brief No. 131. http://www.cdc.gov/nchs/data/databriefs/db131.pdf.

study that investigated the association by poverty income ratio (PIR) found that only 20% of obese US adults have low incomes (below 130% of the federal poverty level). There were striking differences in prevalence rates by race/ethnicity and gender. Among men, obesity levels were generally similar across all income groups, although they were slightly higher at higher income levels. Among non-Hispanic black and Mexican-American men, obesity levels decreased as income level decreased. In contrast, among women, obesity prevalence increased as income decreased: for example, 29% of women who are obese live in households with PIRs of at least 350%, whereas 42% of obese women live in households with PIRs smaller than 130%. This trend was only significant among non-Hispanic white women. Similar gender differences were

observed regarding educational attainment. There was no significant association between education and obesity prevalence among men; however, obesity prevalence among women increased as education level decreased.

Although rates of obesity are leveling off in some developed nations, they continue to rise in developing countries. The prevalence of childhood overweight and obesity in the developing world increased from 8.1% of boys and 8.4% of girls in 1980 to 12.9% and 13.4%, respectively, in 2013. Distinct geographic patterns are evident, with higher rates in the Middle East, North Africa, and some Pacific Islands and Caribbean nations. In Latin America, the highest rates of childhood obesity among boys were observed in Chile (11.9%) and Mexico (10.5%), and the highest rates among girls were seen in Uruguay (18.1%) and Costa Rica (12.4%). It was estimated that in 2013, obesity rates among adults exceeded 50% of men in Tonga and of women in Kuwait, Samoa, Qatar, Libya, Tonga, Kiribati, and the Federated States of Micronesia. In China and India, although obesity prevalence has increased over time, rates remain relatively low, with 3.8% of men and 5% of women classified as obese in China and 3.7% and 4.2%, respectively, in India in 2013.

Projections

Despite evidence of stabilizing obesity levels in some populations, the existing high rates have far-reaching consequences for population health and the economies of nations. Because the aging populations of most countries are increasing, the projected health and economic burdens of obesity are of great concern and add urgency to the need to implement effective and sustainable individual- and population-based interventions. For example, it has been estimated that rising obesity levels accounted for 27% of US health-care expenditures between 1987 and 2001. A systematic review of the worldwide costs of obesity by Withrow and colleagues concluded that direct medical costs of treating obesity accounted for between 0.7% and 2.6% of a country's total national health-care expenditures. A study by Wang and colleagues suggested that there would be an additional 65 million obese adults in the United States by 2030, which would accrue 6–8 million excess cases of diabetes, 5–6.8 million cases of coronary heart disease and stroke, and ~500 000 additional cases of cancer. The projected health-care costs of treating obesity-related disorders in by 2030 are in the region of $66 billion, increasing the 2009 level of US health-care spending ($2.5 trillion) by an additional 2.6%. For the United Kingdom, Wang and colleagues projected an increase of 11 million more obese adults, which would result in an excess of 544 000–668 000 cases of diabetes, 331 000–461 000 cases of coronary heart disease and stroke, and 87 000–130 000 cases of cancer. This increased disease burden in 2030 would represent ~2% of total annual health-care spending in 2009 (approximately £110 billion).

Impact

Health Consequences

Overweight and obesity are the leading causes of death worldwide, with an estimated 3.4 million adult deaths each year attributed to being overweight or obese. Approximately 44% of diabetes, 23% of ischemic heart disease, and between 7% and 41% of cancers are due to overweight and obesity. Overweight and obesity are related to more deaths than is underweight. High BMI is an independent risk factor for chronic diseases, including cardiovascular disease, diabetes, musculoskeletal disorders, and some cancers. Obesity increases the risk of depression by 55%. Childhood obesity is associated with adult obesity and related risks. Obese children are also at risk of hypertension, early cardiovascular disease markers, insulin resistance, breathing difficulties, and bone fractures. Obese adolescents have more mental health problems, including anxiety, depression, and reported suicide attempts.

Stigma and Discrimination

Obese individuals are stigmatized and discriminated against. Over the past decade, weight discrimination has increased 66%. Negative stereotypes include those of overweight and obese individuals as lazy, sloppy, and less competent than are normal-weight individuals. Weight stigmatization has been observed in employment, health care, and education. Overweight and obese employees are discriminated against in the workplace in terms of hiring, wages, promotions, and termination. One study found that 25% of overweight and obese women report job discrimination because of weight; 54% report stigmatization by coworkers; and 43% report stigmatization by employers or supervisors. A nationally representative study found that overweight adults were 12 times more likely to face employment discrimination than were normal-weight adults; obese adults were 37 times more likely, and severely obese responders were 100 times more likely. Studies have found that overweight negatively affects wages. One study of more than 12 000 workers found a wage penalty for obese employees, ranging from 0.7% to 3.4% for men and from 2.3% to 6.1% for women. A study of more than 25 000 workers found that a weight increase of 64 lb was associated with a 9% wage decrease for white women. This is equivalent to 1.5 years of education or 3 years of work experience.

Physicians have negative attitudes towards obese individuals, with beliefs aligning with current stereotypes. A study found that more than half of physicians viewed obese patients as awkward, unattractive, ugly, and noncompliant. One-third viewed obese patients as weak willed, sloppy, and lazy. Studies in France, Australia, Britain, and Israel have found similar negative attitudes of physicians towards obese patients. Nurses, medical students, fitness professionals, and dieticians have also been observed to harbor negative bias towards obese patients. Overweight and obese students face stigma in educational settings from teachers, peers, and parents. Obesity has been associated with lower educational attainment in Sweden, England, and the United States.

Economic Impact

Obesity costs are increasing worldwide. In 2010, annual costs were calculated to be $4879 for obese women and $2646 for obese men. This includes direct medical costs, reduced wages, short-term disability, disability pension insurance, absenteeism, presenteeism, gasoline, and life insurance. Direct per-

person medical costs of overweight and obesity in 2008 were estimated to be $266 and $1.723, respectively. Direct costs of overweight and obesity to the National Health Service in England have increased from approximately £479 million in 1998 to roughly £4 billion in 2007. Estimates of indirect costs have increased from £2.6 billion in 1998 to £15.8 billion in 2007 and are projected to increase to £27 billion in 2015. Obesity costs, including medical care and absenteeism, for a company with 1000 employees are estimated to be $\$277\,000\ year^{-1}$. Even the military is affected by obesity: ~25% of young adults are too heavy to be eligible for military service. The military spends more than $1 billion per year treating weight-related diseases in the military forces.

Addressing Obesity

A great deal of research has been devoted to interventions to address obesity among both children and adults. The World Obesity Federation highlights the SPOTLIGHT project, which has undertaken a survey throughout Europe on obesity interventions to improve diet and physical activity. In the United States, The Community Guide has reviewed interventions in community settings to prevent and control obesity. These include behavioral interventions to reduce screen time among children, school-based programs, worksite programs, and technology-based interventions.

The contexts in which people live, work, learn, play, and pray impact eating and physical activity behaviors. Family exposure and behaviors affect calorie intake and obesity risk for children, as parents or adult caregivers prepare meals for children and set taste preferences, often for life. Adults spend nearly one-quarter of their lives at work, which offers the potential for long-term intervention through well-designed, comprehensive health promotion programs. Schools offer a great opportunity for obesity prevention by improving food options and including physical activity. In the United States, nutrition standards for school meals were changed through the Healthy, Hunger-Free Kids Act of 2010. Organizations such as the GENYOUth Foundation work to improve nutrition and increase activity in schools. GENYOUth, in partnership with the National Dairy Council and the National Football League, offers Fuel Up to Play 60, a program encouraging a nutrient-rich diet and 60 min of activity daily, to 70 000 US schools, impacting 36.6 million students.

The EPODE International Network, an approach for communities to implement effective and sustainable strategies to prevent childhood obesity, has 25 programs involving 150 million people in 15 countries. EPODE helps communities change social norms, behaviors, and environment to encourage healthy lifestyles. In France, obesity and overweight were reduced by 10% between 2005 and 2009; in Belgium, implementation of the community-based program Viasano resulted in a 20% reduction of overweight in the population between 2007 and 2010.

The costs and resources required to deliver effective in-person behavioral therapy have led increasingly to technology-supported programs for weight management. Mobile devices and the Internet show promise as effective platforms. Participant engagement in, and adherence to, many technology-based weight management programs is strengthened by the incorporation of self-monitoring tools, assistance with goal setting, real-time feedback, and support from fellow participants or coaches. Further benefits are evident from the low implementation costs and widespread availability of such programs, particularly in developing countries where the uptake of mobile phone technology has increased rapidly. The long-term effect sizes of these technology-assisted programs compared with those of intensive lifestyle modification, however, remain unclear.

Modeling has been used to assess cost-effectiveness of interventions in addition to effectiveness. The review by Swinburn and colleagues indicated that policy-level interventions (such as taxes and regulations) showed greater cost-effectiveness than did clinical interventions. This finding is consistent with a 2014 study that estimates that a national $0.01 per ounce sugar-sweetened excise tax in the United States is a better tactic to reduce childhood obesity than are after-school physical activity programs and advertising bans on unhealthy foods. A study of health effects and cost-effectiveness of efforts in LMICs concluded that population-based strategies (health information and communication), fiscal measures (price increases for unhealthy foods), and regulation (e.g., restricting food marketing directed towards children) would be most cost-effective in reducing unhealthy diets and increasing physical activity.

Clearly, interventions alone are not enough to address obesity; rather, a comprehensive strategy is needed that includes multisectoral action. Gortmaker and colleagues highlighted a systems approach to addressing obesity that comprises action by governments, international agencies, the private sector, civil society, health professionals, and individuals. Governments can introduce and implement policies to prevent obesity in the health and other sectors such as agriculture, transportation, and urban planning. Government leadership is needed to accelerate obesity prevention. Local policies have had more success in moving from proposal to action than have federal or even state-level policies. For example, the nation's first soda tax was passed in 2014 in Berkley, California. Other cities have proposed similar actions to tax soda or limit beverage sizes, although none have yet passed, and similar policies are not politically feasible at the federal level. Tax policies to address obesity have been introduced in other countries, such as Mexico, where soda is now taxed at 1 peso per liter and high-calorie foods at 8% of cost. The food industry has taken action to address obesity on several fronts, including reformulating products to reduce sugar, salt, and fat; developing more healthy products; and reducing marketing directed towards children. The International Food & Beverage Alliance comprises food and beverage companies committed to addressing health and wellness in support of the World Health Organization's Global Strategy on Diet, Physical Activity and Health.

Conclusion

Obesity is a continuing challenge because of its increasing prevalence, its health and economic impact, and the lack of sustainable solutions. Comprehensive approaches that address environmental, economic, social, and individual factors affecting obesity will need to be taken. Addressing the complex issue

of obesity will require a solution that includes interventions and policies from multiple sectors. Although there is evidence showing that policies and interventions can improve diet and increase physical activity, other factors, such as cost, feasibility, and sustainability, must be considered. Further research is needed to develop successful interventions to prevent obesity as well as to support sustained weight loss for currently obese individuals.

Introduction

Epidemiological studies conducted over the last decades have clearly documented the widespread occurrence and consequences of obesity in the United States and worldwide. These studies have allowed us to gain insights into the causes of obesity and the causes of the epidemic of obesity. The epidemic and universal nature of the problem of obesity is now clear. Moreover, the serious and numerous complications associated with obesity place an excessive burden at both the individual/clinical level and the population/health system level. Over the same period, definitions and measurement methods have evolved in an attempt to improve the characterization of the burden of the disease and the consequences. While body mass index (BMI) has been widely used because of its simplicity, the cutoffs have been somewhat controversial in particular in individuals of Asian or African origin. Major concerns of the epidemiology of obesity are the inequalities seen throughout the world showing a dual pattern, with obesity generally affecting more economically developed nations and, at the same time, economically disadvantaged populations within these countries. Major advances in the control of infectious diseases and the aging of the population have helped to increase the number of susceptible individuals. In addition, major changes in the food systems, availability, and affordability of healthy foods and changes in patterns of physical activity have played a major role in the development of the epidemic. Most of the work related to strategies for the prevention and treatment of obesity has had a focus at the individual level, with more recent push on macrosocial and upstream level of prevention and control.

Definition and Measurement of Obesity

The World Health Organization defines obesity as abnormal or excessive body fat accumulation (adiposity) that may impair health.

The exact definition of 'excessive' or the threshold for labeling abnormal accumulation of body fat is ill-defined. Adiposity, as other human traits such as blood pressure and blood glucose, is a continuous trait, and therefore, the sorting of individuals into disease categories is not straightforward. In spite of that, there has been an emphasis on defining cut points, and these cut points and their resulting diagnoses are fundamental in clinical care and practice as they result in treatment, prognosis, and administrative justification of health-care resource use.

Tools to measure body composition including body fat more directly (e.g., densitometry, bioelectrical impedance, dual-energy x-ray absorptiometry, and dilution techniques) are not widely available and are costly and laborious, and therefore, their use is limited to small clinical or laboratory settings. For practical reasons, most epidemiological studies rely on simpler anthropometric measurements, in particular the measurement of weight, skinfold thickness, and circumference of the trunk and limbs. Most of the studies define obesity using a measure of body weight adjusted by height. The most common one is the BMI (or Quetelet's index), calculated as follows: weight in kilograms divided by height in meters squared. Studies have shown that there is a high correlation between BMI and body fat percent. However, the main limitations of BMI are the lack of distinction between fat mass and fat-free mass and differences in muscle and adipose tissue distribution by age, sex, race/ethnicity, and other factors. As it will be discussed in the succeeding text, these differences have led to conclude that different cutoffs by race/ethnicity are needed to more accurately characterize obesity and to classify risk in certain subgroups.

Studies of individuals using very sophisticated methods such as magnetic resonance imaging have demonstrated that at any given BMI, the degree of fatness may be very different. Therefore, certain populations (like aging populations) may have a trend for increased adiposity accompanied by a stable (or even decreasing) BMI trends.

The other important threat to the accuracy of BMI is the use of self-report information weight and height information. Large epidemiological studies in many countries are often limited to the use of self-report data, and it is important to be aware of biases in the reporting, with more important misclassification at the extremes.

Notwithstanding its limitations, several studies have shown the prognostic value of elevated BMI for identifying individuals or populations at risk of health consequences, and BMI remains the most important and widely used indicator in surveillance systems for measuring the burden of the disease, for tracking trends over time, and for evaluating the effects of interventions.

Among adults, two other complementary and widely used measures of excess adiposity include waist circumference and waist-to-hip ratio. Both highlight the relevance of abdominal fat mass (also referred to as abdominal or visceral obesity). On the basis of the large body of evidence demonstrating an increased risk of health complications with increased waist circumference or waist-to-hip ratio, the WHO and other organizations have recommended their use. A very important issue for the use and interpretation of both waist circumference and waist-to-hip ratio is the protocol used in the assessment. Critical elements of the protocol include the anatomic placement of the measuring tape, the tightness, the type of tape, the subject's position, phase of respiration, abdominal tension, and clothing. It is of paramount importance to follow standardized protocols for their measurement and in the report of the findings, to explicitly provide information of the placement of the tape.

The WHO proposed and established the classification of body weight based on BMI in 1993 and 1997, respectively

(Table 1). While that classification has been considered universal, there have been controversies around the cutoffs as they have been considered inappropriate in certain populations, in particular for those of Asian descent. The 2 main motivations for suggesting to move the cutoffs are (1) the increased evidence of an association between BMI and increased risk of outcomes at a lower BMI and (2) the increased evidence of different association of BMI, percentage of body fat, and body fat distribution across the populations.

In light of these facts, in Japan, obesity is defined as BMI ≥ 25 kg m^{-2}, and in China, it is defined as BMI ≥ 28 kg m^{-2}. Medical organizations are also starting to modify guidelines, the American Diabetes Association 'Standards of Medical Care in Diabetes – 2015' made a specific change in 2015 and lowered the BMI cut point to 23 kg m^{-2} (vs. 23 kg m^{-2}) for screening for diabetes among Asian Americans.

Based on the waist circumference and waist-to-hip ratio, the WHO has also provided cut points to define abdominal obesity (Table 1).

Table 1 World Health Organization classification of body weight based on body mass index and cutoff points based on waist circumference, waist-to-hip ratio, and risk of metabolic complications

Indicator	*Cutoff points*	*Classification*
Body mass index (kg m^{-2})	<18.5	Underweight
	18.5–4.9	Normal weight
	25.0–29.9	Overweight
	30.0–34.9	Class I obesity
	35.0–39.9	Class II obesity
	≥40	Class III obesity
Waist circumference (cm)	>94 (M); >80 (W)	Risk of metabolic complications increased
	>102 (M); >88 (W)	Risk of metabolic complications substantially increased
Waist-to-hip ratio (cm)	≥0.90 (M); ≥0.85 (W)	

Magnitude of the Problem

Epidemiological studies are the foundation for disease control and prevention, and national surveys of weight, height, and other anthropometric indicators have been a constant resource of data at the national level. Although most of these studies were first undertaken to document problems related to the opposite problem of obesity, namely, undernutrition, these sources then were well positioned to measure the magnitude of the problem of obesity and for the identification of trends over time.

Using data from these national surveys, the epidemic of obesity was first appreciated in the United States and started between 1970s and 1980s when the prevalence of obesity started to increase at an alarming rate (Figure 1). Large increases in average BMI were observed between surveys conducted in the late 1970s and the mid-1980s and have continued to increase thereafter (Figure 2). Shortly after, other developed countries also started to see a steep increase in the prevalence of obesity (Figure 1). At the same time, developing countries faced two opposing problems: the problem of undernutrition and that of obesity (nutritional transition). By 2000, the number of adults with excessive weight surpassed the number of those underweight. Consequently, it has been estimated that the prevalence of obesity in the world nearly doubled between 1980 and 2008 (from 6.4% to 12%) with the largest increase between 2000 and 2008.

Although obesity is considered a global epidemic, there are substantial variations in the prevalence across countries, ranging from ~1% in Bangladesh, the Democratic Republic of Congo, and Ethiopia to ~75% in some countries in Oceania (Tonga, Nauru, and the Cook Islands) (Figure 3). Overall, economically developed nations exhibit higher prevalences of obesity compared to emerging or developing countries.

A second pattern emerges when looking at obesity prevalence within developed countries, where an inverse gradient between obesity and socioeconomic position is apparent.

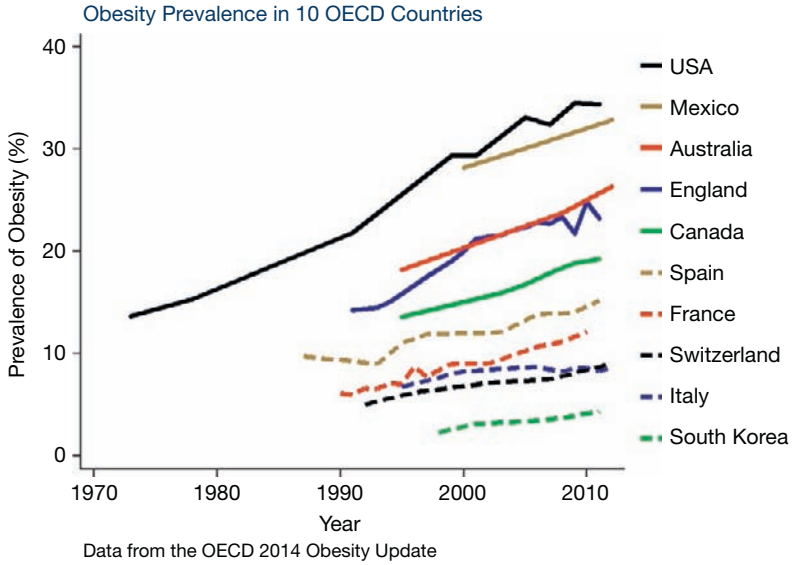

Figure 1 Obesity trends over time.

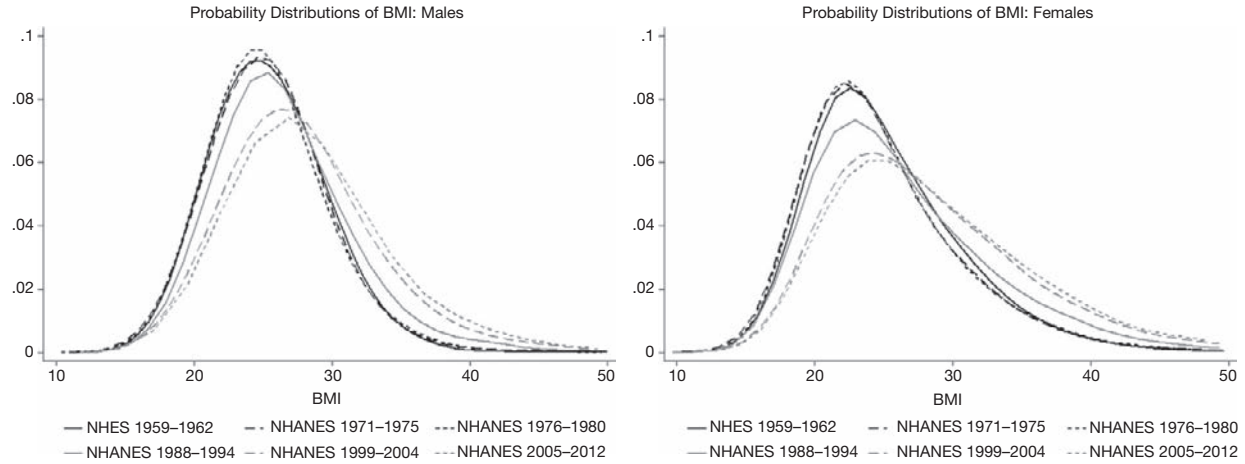

Figure 2 Temporal changes in body mass index distribution in the United States by sex.

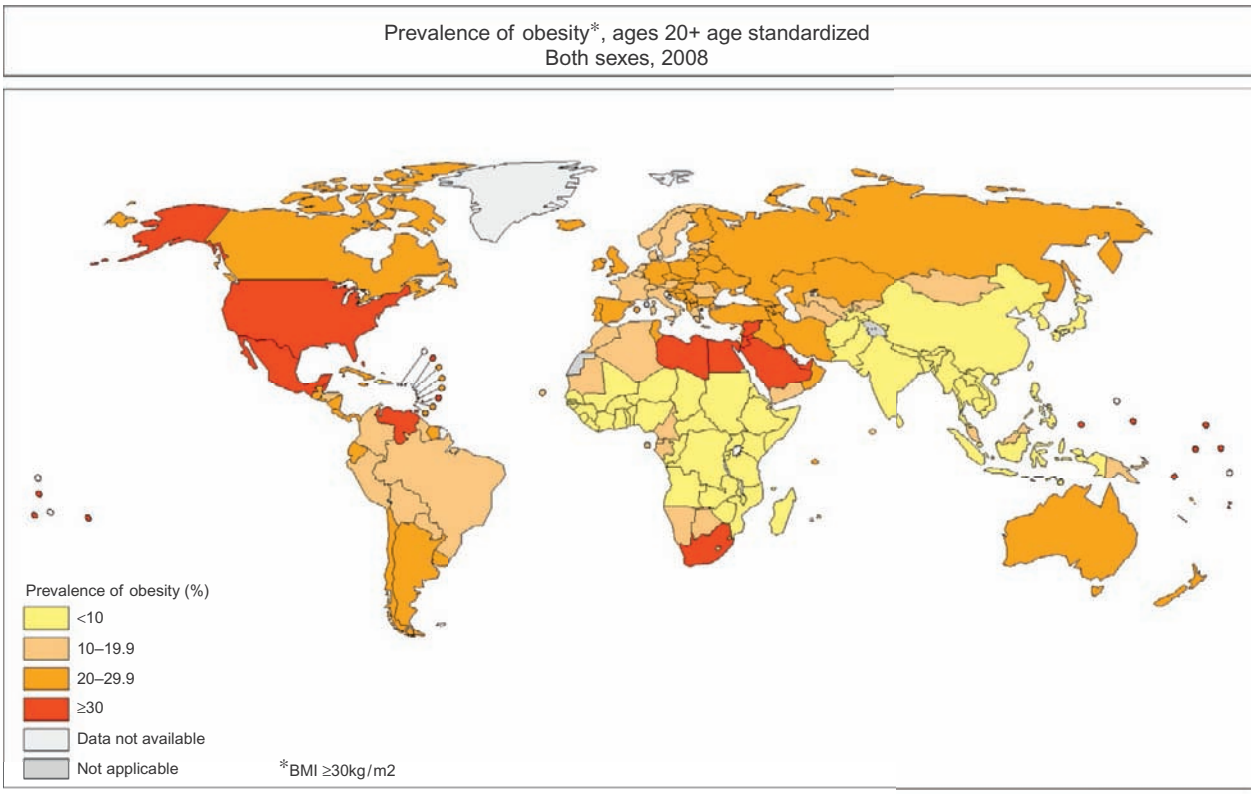

The boundaries and names shown and the designations used on this map do not imply the expression of any opinion whatsoever on the part of the World Health Organization concerning the legal status of any country, territory, city or area or of its authorities, or concerning the delimitation of its frontiers or boundaries. Dotted lines on the maps represent approximate border lines for which there may not yet be full agreement.

Figure 3 Worldwide prevalence of obesity.

Population groups with low socioeconomic status (education, income, or occupational class) show increased rates of obesity, likely contributing to the mortality differentials that exist in most developed nations.

The causes of these international and national disparities are diverse and complex. In the next section, we elaborate on a general framework to study these causes and list potential determinants of obesity.

Causes of Obesity

As stated by Geoffrey Rose in his article 'Sick individuals and sick populations,' when studying the origins of a disease, it is important to differentiate two types of causes: the causes of cases and the determinants of incidence. In this case, the first relates to why some individuals become obese (as compared to individuals who do not), while the second looks at the causes

in the variation of obesity rates in different populations or the same population over time (e.g., the epidemic of obesity). These two types of causes need not be the same. Therefore, the causes that are relevant in the clinic may not be relevant in departments of health (and vice versa).

Causes of Obesity among Individuals

Among individuals, causes of obesity can be divided into two categories: medical and nonmedical causes. Medical causes are those derived from medical conditions that directly or indirectly increase adiposity. Table 2 lists potential medical causes for obesity. Most of these causes are rare in most populations and therefore are not major contributors to the epidemic of obesity.

Nonmedical causes are those not derived from medically recognized conditions. In simple terms, obesity is usually the result of an energy imbalance gap between calorie intake and calorie output, that is, an imbalance between diet (too many calories consumed) and physical activity (too few calories burned).

While it has been of great interest to determine whether specific dietary components (e.g., fat, refined carbohydrates, and high-fructose corn syrup) or dietary patterns have different effects on obesity, results of controlled clinical trials have resulted in conflicting results. Most clinical guidelines for the management of obesity currently recommend comprehensive lifestyle interventions with moderately reduced caloric intake and increased physical activity.

A second aspect of these nonmedical causes is genetic predispositions to obesity. Several candidate genes have been studied, including the FTO, MC4R, and LEPR genes. These genes have been shown to have significant (but weak) associations with an increased risk of obesity. In general, it is considered that genetic predisposition of obesity is the result of a polygenic expression not attributable to a single gene.

Causes of the Epidemic of Obesity

The study of the differences in obesity rates between populations or within the same population over time requires the identification of mass influences that affect entire populations and put people at risk for disease. In the case of obesity, if we want to understand why (a) most developed countries have seen an increase in obesity in the last four decades; (b) most developing countries have also seen an increase, delayed by a few decades; and (c) there are spatial within- and across-country differences, we need to look at the mass influences that have changed over time or that are different within/across countries.

Mass influences of obesity include (see Cutler's recommended reading) the following:

- On the energy intake (consumption) side
  - Increased availability of ultraprocessed foods that are able to have increased shelf life but lose nutritional value and are energy-dense
  - Shift from a food pattern based on the classic core (whole carbohydrate), pulse (legume), and fringe (spice, flavor, and meat) to one based on refined carbohydrates and animal protein and fat
  - Increased availability of cheap sweeteners (like high-fructose corn syrup)
  - Globalization of food consumption and production, which reduces reliance on seasons or agricultural capability of countries
- On the energy expenditure side
  - Increased reliance on motorized transport
  - Reduced demand for labor-intensive work
  - Increased demand for sedentary leisure activities (like TV watching)
- Other/miscellaneous
  - Increased work hours (which lead to decreased time availability for proper meal preparation and leisure time physical activity)

Although it is clear that there have been major changes in factors influencing the energy intake and energy expenditure at the population level, the contribution of each and their preponderance in the epidemic of obesity has been less clear and subject of heated debate. A number of studies have now documented the gradual increases of energy intake in the last four or five decades with relatively little change in the physical activity and therefore suggest that energy intake has been the major driver. Therefore, while not discouraging physical activity, as it has many health benefits (even in the absence of weight loss), the major efforts to address the obesity epidemic need to target energy/food supply. Additionally, while a number of clinical studies have been conducted to test the effects of different diet compositions or patterns among individuals, fewer studies have addressed this question at the population level. These studies will be key for formulating prevention policies.

More recently, with the realization of the complex nature of obesity and the epidemic of obesity, studies focused on examining the role of single factors on obesity have been subject to criticism. This epidemic involves a complex interplay between many of its biological, behavioral, social, economic, political, and cultural determinants. In an attempt to overcome that limitation, it has been proposed that complex systems methods may be more appropriate for addressing the problem of obesity. In complex system methods, determinants are

Table 2 Medical causes of obesity

Drug-induced

Hypothalamic obesity
Cushing's syndrome
Hypothyroidism
Polycystic ovary syndrome
Growth hormone deficiency
Genetic
Leptin deficiency

connected through feedback loops and exhibit nonlinear behaviors and emergence (patterns that cannot be predicted by looking at individual components of the system). For example, increased work hours that lead to decreased time availability may lead to increased demand of ultraprocessed ready-to-eat foods that shift food patterns to refined carbohydrates and meat. These increased demands for refined carbohydrates may lead to regulations and subsidies that emphasize their consumption even more, causing an amplification of these effects.

Complications of Obesity

Obesity has been shown to be associated with many health outcomes either directly (low back pain and arthritis) or indirectly (through a number of metabolic disorders) (Table 3). Particularly relevant are the strong and robust associations between obesity and type 2 diabetes, high blood pressure, and dyslipidemia, as they represent the major causes of cardiovascular disease, and cardiovascular disease is the leading cause of death in both developed and developing countries.

An area that has generated controversy is the effect of obesity among people with already established chronic diseases. Studies looking at the association between obesity and mortality in this subpopulation have been paradoxical. While in the general population, there is a benefit (or no harm) of being normal weight (BMI of 18.5–25) compared to overweight or obese, this association is not easily reproduced in observational studies of people with chronic conditions, where the most protective weight can be found in the overweight or mildly obese categories. This phenomenon has been termed the 'obesity paradox' and it has been found in populations with diabetes, chronic kidney disease, or heart disease. Some of the potential explanations for this phenomenon include the following:

- Mechanistic/physiological: postulates that the presence of fat in people with chronic diseases is due to its hormonal effects and it leads to protection against frailty.
- Residual confounding: highlights that the role of lack of adjustment or imperfect adjustment for important factors correlated with the level of adiposity and mortality (e.g., smoking).
- Reverse causality: as many chronic illnesses lead to unintended weight loss. Therefore, if not properly accounted for, a preexisting illness may cause weight loss and lead to increase risk of death.
- Selection bias/collider stratification bias: the most novel explanation. If an individual has diabetes and is nonobese, this individual may be more likely to have a third factor causing diabetes (and mortality). Therefore, a spurious (not causal) association between normal weight and higher mortality is created.

In summary, better designed observational and interventional studies are needed to understand the complex nature of this phenomenon and to better guide policy and clinical interventions in obese people with already established chronic diseases.

Table 3 Complications of obesity

Endocrinological
Type 2 diabetes
Infertility
PCOS
Rheumatologic/orthopedic
Osteoarthritis
Gout
Low back pain
Limited mobility
Ulcers
Gastroenterological
Gallbladder disease
Fatty liver disease
Gastroesophageal reflux
Respiratory
Obstructive sleep apnea
Urological and nephrological
Erectile dysfunction
Urinary incontinence
Chronic kidney disease
Hypogonadism
Cardiovascular system
High blood pressure
High cholesterol
Ischemic heart disease
Peripheral arterial disease
Heart failure
DVT/PE
Neurological/psychiatric
Depression
Others
Certain cancers
Quality of life
Stigma

Concluding Remarks

The medical paradigm has largely focused on sick or high-risk individuals. This thinking has shaped most of the research questions, planning of health expenditures, and provision of care. For example, we have continuously focused on answering the following question: Why did this individual develop obesity? As stated before, it is important, however, to distinguish that factors that explain the incidence of disease within a population and the risk factors for disease within an individual are not necessarily the same. We then need to ask ourselves, why does this population have this rate of obesity compared to another population? Or why has obesity increased in this population in the last decades? By answering that question, public health practitioners will then be able to effectively prevent or reduce the burden of obesity in our populations.

Obesity: The Role of Diet

LE Matarese, East Carolina University, Greenville, NC, USA

© 2016 Elsevier Ltd. All rights reserved.

Introduction

The incidence of overweight and obesity has grown to alarming rates worldwide. They are risk factors for serious chronic diseases and for several of the leading causes of preventable death, including cardiovascular disease, diabetes mellitus, and many types of cancer. The causes of obesity are multifactorial and not well understood. There have been numerous presumed contributors including the increased availability of inexpensive; highly refined, high-density foods; sedentary lifestyle; sleep apnea; endocrine function; smoking cessation; pharmaceutical iatrogenesis, adipose cellularity, increasing maternal age, and intrauterine and intergeneration effects. These factors are not only numerous but also interrelated and dynamic. Lifestyle changes including diet intervention, exercise, and behavior modification have been considered the cornerstone of therapy. These are achievable, modifiable behaviors that can reduce the incidence of preventable diseases. Although each of these cornerstone therapies is important in the care of these patients, this article will focus on diet modification for the treatment of obesity.

Metabolic Factors Affecting Weight Loss

To consider weight loss as merely a function of producing a caloric deficit regardless of dietary macronutrient composition or variances in biological systems is an oversimplification. The principles regarding regulation of heat, temperature, energy, and work are defined by the laws of thermodynamics. These laws are often applied to the induction and maintenance of weight loss such that when energy consumption is less than expenditure, there is mobilization of adipose tissue resulting in a reduction of body weight. However, when applied to living organisms, the equation becomes far more complex. The second law of thermodynamics dictates that there is an inevitable metabolic inefficiency in all biological and biochemical process. Therefore, it is impossible to convert a specific amount of energy into an equivalent amount of work. Energy is derived from chemical reactions in the body from the diet. But calories are not converted to energy on a one-to-one basis because of the inefficiency defined by the second law of thermodynamics. There is a larger loss of energy when one has to metabolize protein instead of merely oxidizing carbohydrate as an energy substrate.

Beyond the concept of thermodynamics, the biochemical, physiological, psychological, emotional, economic, and social factors surrounding mechanisms of weight loss are multifaceted, interrelated, and dynamic. Each of these factors has the potential to exert a significant biological and metabolic influence. For example, an increase in physical activity may influence metabolic rate that in turn affects insulin sensitivity and insulin resistance. There are other metabolic factors and changes that contribute to obesity. Alterations in endocrine function (e.g., decreases in leptin and increases in ghrelin) affect appetite and satiety level. There may be changes in neuroendocrine signaling (e.g., decreased satiety signaling) and changes in the responsiveness to food intake. With advancing age, there is a naturally occurring reduction in lean body mass, metabolic rate, energy expenditure, and physical activity, all of which will result in increased weight gain if the same level of calories is consumed throughout the life span. This along with many other factors affects the gut microbiota, which in turn influences the storage and release of energy. When oral intake is restricted to attempt to reduce body weight, there may be increased metabolic efficiency, making weight loss more difficult. There are also societal and economic factors that are intimately related to the biological and physiological factors. Our food supply has become more refined and highly processed often resulting in foods that are lower in nutrient concentration. This in turn affects satiety value due to the high concentration of refined sugars and the relatively low concentration of complex carbohydrates and dietary fiber. When there are financial limitations, people will purchase readily available low-cost foods, which may be low in nutrients but high in fat and refined carbohydrates. These are just some of the reasons why affecting a significant and sustained weight loss has been so difficult. Obesity is a very complex disorder with multiple factors, which are interrelated and dynamic such that a change in one factor will produce a change in another factor.

The Role of Diet

Although there are numerous factors affecting weight management, clearly, the role of diet is central in achieving and maintaining a healthy body weight. A plethora of weight loss diets have been proposed over the years. Many of these diets eliminate one or more of the essential food groups or recommend consumption of one type of food at the expense of other foods with little to no supporting evidence. These are commonly referred to as fad diets and are generally popularized in the lay literature. However, there are diets that are based on sound physiological and metabolic principles and studied under rigorous controlled conditions. Most of the modifications in diet have centered on altering the macronutrient composition (i.e., carbohydrate, protein, and fat) of the diet. These macronutrients cannot be considered in isolation. When the percentage of one component is changed, there will be a corresponding increase or decrease in the other components. Additionally, it is not simply a matter of increasing or decreasing the percentages of the three basic macronutrients, but it is also a matter of defining each of these macronutrients. A carbohydrate is not a uniform organic compound. For example, carbohydrates may be defined as simple or complex, by glycemic index (GI) and glycemic load, or by the fiber content (viscous vs. fermentable). Protein may be derived from animal, plant, or marine

sources, all with varying amino acid profiles. Fat encompasses monosaturated, polyunsaturated, saturated, and *trans* fats. They may include omega-3, omega-6, and omega-9 fatty acids or a combination. Along with altering the macronutrient content of the diet, attention must be given to the micronutrient portion to ensure adequate intake of vitamins, minerals, and trace elements.

Low-Fat and Very Low-Fat Diets

For many years, the traditional approach to weight loss had been with the use of the low-fat and very low-fat diet. Since fat is most calorically dense of the macronutrients (9 kcal g^{-1}), it was logical to assume that restricting its intake would result in weight loss. The exact composition of the low-fat diet varies but generally contains between 20% and 30% of calories from fat, and the very low-fat diet contains less than 19% of calories coming from fat. This means that the carbohydrate and in some instances the protein content of the diet will be higher. These diets tended to be lower in calories when properly initiated and resulted in weight loss when done correctly. Unfortunately, many individuals believed that a low-fat diet meant they could eat as many calories as desired as long as these foods were low in fat. The use of the low-fat diet without calorie restriction will not result in weight loss.

Since high-fat diets have been linked to inflammatory states, coronary artery disease, and various cancers, there was interest in determining if these diets could prevent or reverse disease in addition to reducing body weight. One of the most studied dietary interventions is the Ornish diet, which integrates a vegetarian diet with a fat intake of 10% of total calories. The program also integrates exercise, meditation, and smoking cessation. In an early pilot trial, Ornish was able to demonstrate positive effects in patients with ischemic heart disease including reductions in total cholesterol and a trend toward improved cardiac ejection fraction. However, high-density lipoprotein (HDL) levels decreased by 20%. To test the long-term effectiveness of this plan, they embarked on a 5-year randomized controlled trial of 48 patients with coronary heart disease. Subjects lost an average of 5.8 kg compared with no change in the control group, and the diet lowered low-density lipoprotein (LDL) levels by approximately 20%. Triglyceride and HDL levels were unchanged. Study participants following the Ornish diet had a 91% decrease in angina symptoms at 1 year and a 72% decrease at 5 years. The control group had a 186% increase in angina symptoms at 1 year and a 36% decrease at 5 years. The reduction at 5 years in the control group was attributed to greater rates of bypass surgery and angioplasty but not a function of the diet.

However, results from the low-fat arm of the Women's Health Initiative in which 20% of the calories came from fat with emphasis on fruits, vegetables, and grains failed to demonstrate any difference in cancer rates or incidence in cardiovascular disease, and overall, there was poor weight loss. Unfortunately, it was difficult for the participants to adhere to the diet and most of the subjects only achieved 24% fat consumption and, after 8 years, drifted up to 29% fat intake. The diet did not limit the calorie level nor did it define the type of fat to be consumed. Thus, individuals may have been following a lower level of fat, but the fat could have included harmful fats such as *trans* fats. The failure of the low-fat diet to induce weight loss and reverse or prevent disease in this long-term study reflects one of the major problems with low-fat diet. People often assumed that they could eat any level calories, as long as it was low fat. According to the CDC, energy intake increased by about 335 kcal per day from the years 1971 to 2000 with a significant increase in carbohydrate. This was partially fueled by an increase in the availability of commercially prepared low-fat convenience food items, which, although were low in fat, were often high calories and simple carbohydrates. The diet also tended to be high in highly processed white bread, white rice, and other rapidly digested carbohydrates, causing higher blood sugar levels and more hunger.

There have been numerous other studies that have looked at the use of low-fat diets to reduce body weight and comorbidities. A systematic review and meta-analysis of 33 randomized controlled trials demonstrated that diets lower in total fat were associated with lower relative body weight but the size of the effect varied. Greater reduction in total fat intake and lower baseline fat intake were associated with greater relative weight loss, lower body mass index, and waist circumference. The reductions in total fat intake were also associated with a small but statistically significant reductions in certain metabolic parameters including blood pressure, total cholesterol, LDL, and the ratio of total cholesterol to high-density lipoprotein cholesterol.

In spite of the inability to achieve and maintain a desirable body weight with the low-fat diet, it may become an important component of overall health and longevity. Onrnish and colleagues demonstrated that lifestyle intervention including a diet high in whole foods, plant-based protein, fruits, vegetables, unrefined grains, and legumes and low in fat (10%) and refined carbohydrate along with moderate aerobic exercise and stress management resulted in an increase in telomere length in men with biopsy-proved low-risk prostate cancer.

Low-Carbohydrate Ketogenic Diets

Carbohydrate restriction to induce weight loss has been extensively studied. The rationale for the restriction is that when the intake of carbohydrate is sufficiently reduced, there will be a corresponding reduction in insulin concentrations, which in turn will shift metabolism from lipogenesis to lipolysis, resulting in rapid weight loss. With a reduction in carbohydrate, there is a subsequent increase in the protein and fat content of the diet and production of ketones, which causes an increase in the satiety value and an overall voluntary caloric reduction. It is also possible that there is a metabolic advantage of inefficient protein and fat oxidation, which leads to extra energy loss as supported by the second law of thermodynamics. In many cases, lipolysis is maintained despite excess calories because glycerol from fat is needed as a gluconeogenic precursor. The exact carbohydrate level required to produce this metabolic shift is thought to be between 20 and 50 g per day in the initial (induction) phases of the diet in comparison with the carbohydrate content of the typical Western diet that often exceeds 300 g per day and may be in the form of simple, rapidly hydrolyzed carbohydrate.

There have been several randomized controlled trials (RCT) comparing weight loss and metabolic parameters of a low-carbohydrate ketogenic diet (LCKD) versus a low-fat diet. Sondike and colleagues examined the weight loss and the effects on cardiovascular risk factor of an LCKD in adolescents. Thirty-nine obese adolescents were randomized to receive either an ad libitum LCKD diet (<20 g day^{-1} of carbohydrate for 2 weeks and then <40 g day^{-1} of fat) or an ad libitum low-fat (LFD) diet (<40 g day^{-1} of fat) for 12 weeks. The LCKD subjects lost more weight than the LFD subjects (10 vs. 4 kg; $P<0.04$). There were no significant differences in the lipid profiles between the two groups and there were no serious adverse effects related to the intervention were reported.

Another RCT comparing an LCKD and a calorie-restricted low-fat diet was conducted to determine the effects on body weight, cardiovascular risk factors, and body composition in 53 healthy women. Twenty-two of 26 (85%) subjects from the LCKD and 20 of 27 (74%) subjects from the LFD completed the 6-month study, with both groups reducing their energy intake from baseline by approximately 450 kcal. Weight lost and reduction of body fat as measured by DXA were significantly greater in the LCKD group compared with the low-fat group at 3 and 6 months ($P<0.001$). There were no significant differences between groups in the effects on serum lipids, glucose, insulin, and leptin except triglycerides, which decreased significantly more in the LCKD group.

Samaha and colleagues randomized 132 severely obese (mean BMI, 43 kg m^{-2}) medical outpatients to either an ad libitum LCKD or a calorie-restricted LFD. Subjects received weekly group counseling sessions for 4 weeks and then monthly sessions, with 67% of LCKD subjects and 53% of LFD subjects completing the study. At 6 months, there was significantly greater weight loss (5.8 vs. 1.9 kg; $P=0.002$) and triglyceride reduction (20% vs. 4%; $P=0.001$) in the LCKD group compared with the LFD group. In addition, the diabetic subjects in the LCKD group demonstrated improved serum glucose (decrease of 25 vs. a decrease of 5 mg dl^{-1}; $P=0.01$) compared with their LFD group, whereas the nondiabetic subjects in the LCKD had improved insulin sensitivity (6% vs. -3%; $P=0.01$) compared with their LFD group. Seven LCKD subjects had a reduction of diabetic medication dosage compared with only one from the LFD group.

In a multicenter trial, 63 obese, healthy subjects were randomized to either the ad libitum LCKD or a reduced energy LFD (conventional diet) to examine the effectiveness of the LCKD. Each subject received a popular diet book and met with a dietitian at baseline and for three visits thereafter over the 1-year trial. Of the original 63 subjects, 37 completed the 12 months. The LCKD subjects lost more weight than the LFD subjects (7.0% reduction vs. 3.2% reduction; $P=0.02$) at 6 months, but the difference between groups was not statistically significant (-4.4% vs. -2.5%; $P=0.26$) at 12 months. The LCKD group experienced greater improvements in HDL cholesterol (increase of 11.0% vs. decrease of 1.6%; $P=0.04$) and triglycerides (decrease of 17.0% vs. increase of 0.7%; $P=0.04$) compared with the LFD group. Serum glucose and insulin measurements were not different between groups.

Yancy and colleagues conducted a number of studies to evaluate the effects of LCKD. In one study, the ad libitum LCKD combined with nutritional supplements was compared to a low-fat, low-cholesterol, reduced-calorie diet in hyperlipidemic individuals. LCKD participants were instructed to restrict carbohydrate intake to less than 20 g per day initially and gradually add carbohydrates back into their diet as goal body weight was approached. Energy intake was not restricted in the LCKD group and the emphasis was on the macronutrient composition of the diet. More subjects on the LCKD completed the study compared to the reduced-calorie subjects (75% vs. 53%; $P=0.03$). Weight loss was greater in the LCKD subjects who completed the study compared to the low-fat subjects (14% reduction vs. 9% reduction; $P<0.001$). The LCKD group also demonstrated beneficial changes in serum lipids: Triglycerides decreased by 42% and HDL cholesterol increased by 13%, whereas total cholesterol and LDL cholesterol did not change significantly. They conducted another trial in which community-dwelling overweight hyperlipidemic subjects randomly assigned to LCKD (<20 g) ($N=59$) or low-fat (<30%), low-cholesterol, reduced-calorie diet ($n=60$) for 24 weeks. Both groups received exercise and participated in group meetings. Patients in the LCKD group lost more weight, had a greater decrease in triglyceride levels, and had higher HDL-C levels. Levels of LDL-C remained stable in both groups.

Gardner and colleagues evaluated the 12-month effectiveness of four different weight loss diets among 311 overweight or obese, nondiabetic, premenopausal women. There was greater mean weight loss at 1 year in participants following the Atkins diet (4.7 kg) compared with those using the Zone low-carbohydrate (1.6 kg), Ornish very low-fat (2.2 kg), and LEARN (lifestyle, exercise, attitudes, relationships, and nutrition low-carbohydrate) (2.6 kg) diets. LDL levels were significantly reduced in the Atkins group, with no reduction in HDL levels or blood pressure. Insulin and fasting glucose levels did not differ among groups. Whether the improved risk profile was due to the absolute weight loss or diet composition is not clear as the study was not designed to answer this question.

A meta-analysis of very low-carbohydrate diets evaluated six trials with 447 overweight participants. In most cases, the control diet was a low-fat, calorie-restricted plan. Those following the low-carbohydrate plan had greater weight loss at six months, but no difference at 12 months. One of the concerns with the use of these diets was that there may be an increase in blood cholesterol, triglycerides, and LDL due to the high-fat composition of the diet. However, there was no significant difference in the levels of LDL between the diets. HDL and triglyceride levels improved at 6 and 12 months in subjects on the very low-carbohydrate diet.

In each of these well-controlled clinical trials, the LCKD demonstrated superior weight loss when compared to more traditional approaches. There are some adverse effects that could potentially occur even though they have not been observed in any of the clinical trials to date. These include the development of kidney stones, hypokalemia and hypomagnesemia, elevated fatty acids, and gout in susceptible individuals. When this diet technique is employed in individuals taking medications for diabetes mellitus or hypertension, meticulous monitoring is required in order to prevent hypoglycemia and hypotension as body weight is rapidly reduced.

Low-GI/Low-Glycemic-Load Diets

Related to the low-carbohydrate diet is the concept of the GI that was originally developed to aid those with diabetes manage their carbohydrate intake relative to insulin requirements. The index is a ranking of various carbohydrate foods, which measures the rate at which blood glucose levels rise when a particular food is ingested and how quickly the blood glucose levels drop. The GI should not be confused with the glycemic load, which is the mathematical product of the GI and the carbohydrate. Diets with a high glycemic load result in higher postprandial insulin concentration than those with a low glycemic load. Pure glucose has a rating of 100; thus, the closer a food is to 100, the higher the GI rating. Foods with a low GI rating will be absorbed more slowly, keeping blood glucose levels lower and more sustained. Certain low-carbohydrate diets such as South Beach, Zone, Sugar Busters, and Nutrisystem utilize the GI approach and are low in sugar and starch but not low in total carbohydrate. The diets are relatively high in fiber and are thought to be more satisfying than high-glycemic-index foods since they take longer to absorb and help increase the satiety value of the diet.

Several investigators have examined glycemic response, blood sugar, and insulin levels in subjects randomized to receive low- versus high-GI foods. The hormonal and metabolic responses to the low- and high-GI meals are different. Serum insulin concentrations are high following ingestion of the high-GI meal due to the rapid absorption of glucose. By contrast, plasma glucagon levels are suppressed. Additionally, the high-GI diet has been shown to result in a spike in counterregulatory (plasma epinephrine and growth hormone) hormones that trigger hunger. Weight loss with the low-glycemic-load diet has been shown to be greater than the low-fat diet, which has been associated with higher insulin concentrations. Low-glycemic-load diets have beneficial effects on HDL cholesterol and triglyceride concentrations but not on LDL cholesterol concentration. The use of the low-glycemic-load diet has been shown to produce larger reductions in HbA1c than those on the low-fat diet, which suggests that the quality and quantity of carbohydrate consumed can significantly enhance the effect of weight loss on HbA1c in patients with type 2 diabetes.

Use of the GI has been criticized due to some apparent irregularities. For example, white bread and whole wheat bread rank comparably on the index scale as do brown and white rice, yet clearly the whole grain choices are healthier. There are some scores that are confusing and inconsistent and will vary depending on how the food is prepared. Carrots, for example, are a nutrient-rich, high-fiber vegetable that can have a GI ranking of 47, plus or minus 16 depending on preparation. Pasta that is cooked al dente will rank lower than fully cooked pasta. Some candy and confections that include nuts have a better GI score than a potato because the composite score of the candy is made up of the lower carbohydrate content of the nuts plus the other ingredients in the candy. There are also variations within a food; ripe bananas have higher GI scores than underripe bananas presumably due to the changes in the sugar content during the ripening process. It should be noted that dietary foods are generally not consumed in isolation. When carbohydrates are paired with other foods, it impacts the glycemic load. Thus, ingestion of cheese and crackers together will produce a different GI than cheese or crackers alone. The fat content and food temperature will affect gastric emptying and GI. Thus, reliance on the GI/load can be helpful but can also be a source of confusion to many consumers.

Mediterranean Diet

Considering the relative lack of success of the low-fat diet and the questions with the long-term use of the low-carbohydrate diet, people became interested in the use of the Mediterranean diet when the Seven Countries Study showed low cardiovascular mortality rates in a cohort from Crete despite high levels of dietary fat intake (35–40% of total calories). The exact composition of the Mediterranean diet varies depending on the eating habits of the population in countries bordering on the Mediterranean Sea, but overall, it emphasizes fruits, vegetables, legumes, whole grains, nuts, olives, and olive oil along with some cheese, yogurt, fish, poultry, eggs, and red wine in moderation. Red meat is limited to no more than a few times a month. The diet is not simply a weight loss diet. Rather, it is a part of an overall healthy lifestyle that includes exercise, leisurely dining, and socialization during meal times. One of the major advantages of the Mediterranean diet is that most consider it to be palatable and compliance is generally good.

In a 2-year interventional trial, Shai et al. randomly assigned 322 moderately obese subjects to one of three diets: low-fat (<30%), restricted-calorie; Mediterranean (<35% fat), restricted-calorie; or low-carbohydrate ($<20\ g\ day^{-1}$), non-restricted-calorie. The rate of adherence to the assigned study diet was 95.4% at 1 year and 84.6% at 2 years. The 2-year adherence rates were 90.4% in the low-fat group, 85.3% in the Mediterranean diet group, and 78.0% in the low-carbohydrate group ($P=0.04$). The mean weight loss was 2.9 kg for the low-fat group, 4.4 kg for the Mediterranean diet group, and 4.7 kg for the low-carbohydrate group ($P<0.001$). Additionally, the relative reduction in the ratio of total cholesterol to HDL cholesterol was 20% in the low-carbohydrate group and 12% in the low-fat group ($P=0.01$). Among the 36 subjects with diabetes, changes in fasting plasma glucose and insulin levels were more favorable among those assigned to the Mediterranean diet than among those assigned to the low-fat diet ($P<0.001$). Although the rate of weight loss was greatest in the low-carbohydrate group, those following the Mediterranean diet were able to achieve substantial weight loss with favorable changes on other metabolic parameters.

The Lyon Diet Heart Study was a randomized, controlled trial of 605 free-living subjects with known coronary heart disease. Subjects were randomized to receive the Mediterranean diet or usual postinfarction low-fat diet. Participants in the Mediterranean diet group supplemented with alpha-linoleic acid, as a source of omega-3 fatty acids. Although the study was planned to be a long-term 5-year trial, it was terminated at 27 months' mean follow-up time because the benefits in the experimental group were so striking and included a 70% reduction in all-cause mortality including cancer, reduced cardiovascular disease events, and better weight loss than the control diet. The intake of dietary fiber was higher in the Mediterranean group, about 3 g, as well as a higher intake of antioxidants and B vitamins found in fruits and vegetables. The

Mediterranean group consumed significantly less lipids, saturated fat, cholesterol, and linoleic acid but more oleic and alpha-linolenic acids, which was confirmed by measurements in plasma. There were no significant differences between the groups in serum lipid levels, blood pressure, or BMI. High levels of serum alpha-linoleic acid were associated with improved outcomes. With the mean follow-up time of 46 months per patient, the initial beneficial effects of the Mediterranean diet continued compared with the group consuming the prudent low-fat diet.

Most of the studies on the Mediterranean diet were conducted in Europe. The first investigation of the Mediterranean diet to be conducted in the United States was published as part of the National Institutes of Health–AARP Diet and Health Study. There was an inverse association between adherence to a Mediterranean style diet and cardiovascular disease, cancer, and overall mortality rates.

Although the Mediterranean diet is palatable, some may find it more difficult to follow due to the inability to purchase fresh fruits and vegetables. The question becomes can these beneficial effects be replicated without the consumption of Mediterranean foods? The GISSI (Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto) trial, which showed that supplementation with $n-3$ polyunsaturated fatty acids (fish oil) after myocardial infarction (MI) reduced the risk of MI recurrence, stroke, and death by 10%. In another study, rates of MI in high-risk patients following a Mediterranean diet supplemented with soybean and mustard seed oils were significantly reduced. These studies focussed on the anti-inflammatory properties of the poly- and monounsaturated fats. Thus, the exact mechanism for the beneficial effects of the Mediterranean diet is unclear and may comprise a variety of factors including a higher intake of fiber, naturally occurring antioxidants, and omega-3 fatty acids along with a reduction of highly processed foods.

Prescribing Diet Modification Interventions

Unfortunately, there is no one diet that has been shown to induce and maintain a healthy body weight in all circumstances. Those individuals who select a non-evidence-based fad diet plan will most likely lose weight in the short term but often at the expense of nutrient deprivation and unsustainable weight loss. Selection and implementation of a weight loss program should be based on the best available evidence for achievable and sustainable weight loss, positive effects on metabolic parameters, and overall reduction of morbidity and mortality. This is not a simple decision. There are numerous factors to consider such as the degree of obesity and associated comorbidities as well as medications affecting appetite (Figure 1). There are also some data to suggest that the degree of insulin sensitivity determines the effectiveness of dietary macronutrient composition in inducing weight loss. In a 4-month feeding trial, a high-carbohydrate low-fat diet was more effective in inducing weight loss for insulin-sensitive

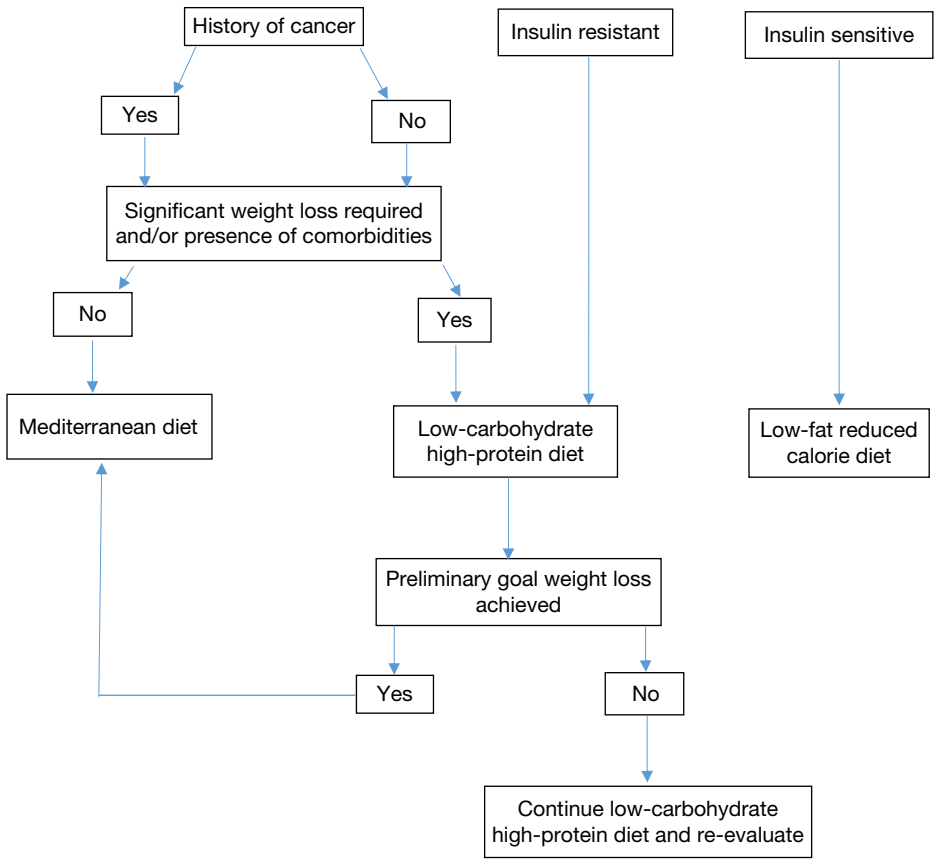

Figure 1 Proposed algorithm for prescribing weight loss diets based on metabolic and disease parameters.

women, but a low-carbohydrate high-fat diet was more effective for insulin-resistant women. Similar results were achieved by Ebbeling and colleagues in 6-month intensive intervention period with a 12-month follow-up period.

Obesity, as well as diets high in fat and red meat, has been linked to many cancers. Although a high-protein low-carbohydrate diet has been shown to produce the greatest weight loss in the shortest amount of time, this may not be the best choice for an overweight/obese individual with a history of cancer since these diets tend to be high in fat and often red meat. In this circumstance, the adoption of the Mediterranean diet may be more appropriate. This diet will result in a slower sustained weight loss and has the added benefit of being rich in foods that are high in antioxidants. Alternatively, a high-protein, low-carbohydrate diet can be used to induce rapid weight loss and then switched to a Mediterranean diet for continued and sustained benefits.

There are additional socioeconomic factors to consider, for example, the illiterate, totally noncompliant patient or those with limited financial resources who cannot or will not be able to follow a dietary modification program. There are several approaches that can be used. The patient can be instructed to eat half of their usual and customary diet and/or attempt to increase exercise simply by walking. The largest meal should be consumed early in the day. It may not be optimal, but it may be the best that can be achieved in this free-living situation. Some patients will do best with the use of a weight loss meal replacement formula such as Optifast (Nestle) provided once or twice daily plus one regular meal. If the diet is deficient in micronutrients, a daily multivitamin should be added. Additionally, the work or home environment should be considered. A construction worker or someone who works in a field may not have access to refrigeration making it difficult to bring lunch to work.

Summary

Obesity is a serious, complex, and highly prevalent global disease associated with increased morbidity and mortality. There are numerous factors that impact metabolism. These factors are interrelated and dynamic. Primary treatment should be directed at achieving and maintaining desirable body weight. Achievement and maintenance of a healthy body weight are difficult. Certainly, any diet that is hypoenergetic will result in short-term weight loss. Body weight can be reduced with a number of scientifically based weight loss diets if implemented correctly and with adequate compliance. The weight loss diet should be individualized for each patient based on BMI, metabolic risk factors, lifestyle, and cultural, religious, and food preferences. The diet should be nutritionally balanced and provide all necessary nutrients. A strong educational component is essential to include not only the mechanics of the diet but also portion control, eating in restaurants, and how to change behaviors for lifelong health. It is important to help the patient find a balance between food and physical activity for overall well-being and fitness. High-risk patients with multiple comorbidities should be medically supervised and carefully monitored. Ultimately, the best diet is the one the patient will follow and incorporate into their daily lives for lifelong maintenance of a healthy body weight.

Offal: Types and Composition

AM Mullen and C Álvarez, Teagasc Food Research Centre, Ashtown, Dublin, Ireland

© 2016 Elsevier Ltd. All rights reserved.

Introduction

According to a traditional definition, offal can be described as the internal organs and entrails of a butchered animal excluding muscle and bone. Marti published that offal is a term used to categorize parts of a butchered animal that 'falls off' the carcass when being trimmed, such as the organs and entrails. Offal classification includes the distinction between red and white offal. Red offal comprised parts that are directly edible, can be consumed in a recognizable form, and are considered to be delicacies in certain parts of the world. They are widely used in many processed meats and as ingredients in sausages and spreadable products like pâtés. On the other hand, white offal refers to parts that are edible but require further processing, such as the stomach and intestines.

Based on the FAOSTAT latest results, the most abundant species of animals in 2013, which were used for human consumption, were, in number of livestock, chicken (21 billion); cattle (1.5 billion); lambs (1.2 billion); pigs, ducks, and goats (1 billion each one); rabbit (0.9 billion); and turkeys (0.4 billion). Weight of meat production shows the most important is porcine (109 million of tons or Mt), followed by chicken (92 Mt), cattle (63.2 Mt), turkey (5.6 Mt), and goat (5.3 Mt). The same organization published that the most captured fish species in 2011 were anchoveta (8, 3 Mt), Alaska pollack (3.2 Mt), skipjack tuna (2.6 Mt), herring (1.7 Mt), mackerel (1.7 Mt), Japanese anchovy (1.3 Mt), and largehead hairtail (1.2 Mt). Based on these figures, it can be assumed that large volumes of offal are produced every day in both industries: meat and fisheries. Table 1 summarizes the main offal parts from the most consumed animal around the globe. In general, average values are presented; however, yield may vary widely depending on species, sex, live weight, and method of recovery.

The main data used in this article have been obtained from the online database provided by the Agricultural Research Service of the US Department of Agriculture, National Nutrient Database for Standard Reference (web link in table). The data presented in this article are for raw offal. For details relating the cooked offal, the reader is directed to the USDA database.

Proximate Analysis of Offal

Proximate analysis provides a breakdown of a material into its major constituents: water, protein, fat, carbohydrates, and ash. In terms of caloric intake, undoubtedly, proteins and fats are the most important component in offal. In general terms, protein and fat contents tend to be lower than that of meat cuts. Those exhibiting higher protein contents than meat have a higher content of connective tissue (ears, blood vessels, tongue, or tail). Offal with higher fat content includes products such as tongue, skin, and feet that also tend to have the lowest water content. Because of this composition, most offal supply less energy than the equivalent weight of meat.

Protein Content and Amino Acid Profile

The average protein content in offal, regardless the source, is generally between 15% and 18%, and they contain both essential (EAA) and nonessential amino acids. Table 2 shows the most common offal and the associated protein, EAA profile, and EAA content. EAA content can vary from 38% (in porcine jowl) to 49% (beef liver, porcine heart, or sheep spleen). These values are very close to the EAA level in lean meat, which is ~50%. The main difference can be found in lysine and histidine concentration: In meat, their average value is 9.8 and 5.1 g/100 g of total protein, respectively; in offal, the concentration is between 7–8 and 2–3 g/100 g, respectively. Apart from these two amino acids, from a nutritional point of view, offal provides a source of good quality proteins. In the specific case of blood, from either cattle and porcine, it is notably the great amount of EAA (close to 60%) that is even higher than meat.

In products with a high connective tissue component, protein content generally is higher than 20%, for example, cattle lips (22%), ear (22–24%), feet (21–26%), and liver (21–22%) or porcine skin (22%). Collagen and elastin are the principal type of proteins that can be found in those products rich in connective tissue, with the proportion ranging from 93% of total protein (skin), to 88% in blood vessels, to 71% in ears. As a result, these by-products contain a high amount of proline, hydroxyproline, and glycine. Due to the amino acid profile of the collagen proteins in particular, these tissues also tend to be poor sources of certain EAAs such as histidine, tyrosine, methionine, and cysteine. Also, many of these products can contain relatively low overall EAA content, for example, cow lips (17.9%), feet (21.6%), skin (23.3%), or tail (27.6%).

While many offal with protein content higher than meat have high portion of connective tissue proteins and hence low ESS, a remarkable exception is seen in the liver. This organ has protein content of around 20% depending on the species, and 50% of total protein content is constituted by EAA.

Fat Content and Fatty Acid Profile

Total fat content in offal is highly dependent on the type of organ; it varies from lower values such as 0.1% in blood, 1.4% in spleen, or 1.9% in lung to very high levels as 10.6% in brain, 15.5% in lamb tongue, 33.5% in pig tail, or even 69.6% in porcine jowl.

The proportions of fatty acids (FAs) vary with species, diet, age, and gender. In general terms, oleic acid is the most abundant FA in the animal body of lamb, cattle, and pigs (20–47%); while in poultry, the most abundant is palmitic acid (26%).

Fish oil, extracted from either liver, viscera, or by-products, is the richest source of monounsaturated FAs (MUFAs) and polyunsaturated FAs (PUFAs). In such products, <23% of total fats are saturated FAs (SFAs). Fish are the main source of eicosapentaenoic and docosahexaenoic acids (0.5–2% of total

DV		65 g	300 mg	<10%[a]	15–20%[a]	8–20%[a]		

The content of linoleic and linolenic acid is shown in those products where data were available.
A, cattle; B, porcine; C, lamb; D, chicken; E, duck. DV, daily value according to the US Food and Drug Administration.
[a]Recommended amounts of fats based on the fact that it must supply 20–35% of total energy intake.

fat). Cholesterol content in oil extracted from fish by-products is the highest one, reaching values over 700 mg 100 g^{-1}; this value is only higher in brain tissue, where it could be as high as 2200 mg 100 g^{-1} as in porcine brain.

Table 3 summarizes the fat and cholesterol content, as well the proportion of SFA, MUFA, PUFA, and essential FAs in the most common offal. Detailed FA profile can be found in the USDA National Nutrient Database for Standard Reference.

Carbohydrate Content

With the exception of liver, where carbohydrates in the form of glycogen can account for between 8.5% (beef) and 15% (chicken) of weight, the content in carbohydrates in offal usually is lower than 1%: which are the same levels that can be found in meat cuts. Low sugar content can present some advantages as it does not cause secondary degradation reactions like the reaction of Maillard during cooking or heat treatments, racemization, or cross-linking reactions.

Mineral and Vitamin Content

Next to protein and fat, the nutritional interest in offal meat lies in the mineral and vitamin profile. Offal can often be considered as a low-nutrient-value product; however, it can contain higher vitamin or mineral content than meat. In this section, it is demonstrated that the best animal sources of vitamins and minerals are actually offal tissue. Average mineral content in 100 g of raw bovine muscle is 2.4 mg of iron, 3.7 mg of zinc, 0.1 mg of cupper, 3 mg of iodine, 7 μg of selenium, and 11 μg of manganese. In addition, the same beef muscle can provide certain amounts of vitamins in the diet; although lipid-soluble vitamins are found at very low levels in meat or offal (with the exception of vitamin A in the liver), the content of

water-soluble vitamins could be enough to cover the daily value (DV) as in the case of vitamin B_{12}. For comparative purposes the, average value contents of some water-soluble vitamins in meat are: niacin, 6.7 mg; thiamine, 0.05 mg; vitamin B_6, 0.6 mg; vitamin B_{12}, 2 μg; and vitamin C, <1 μg. When we compare values in meat with those in offal (Tables 4 and 5), it is clear that offal are a very rich reservoir for this nutrients.

Mineral Content

Minerals are inorganic micronutrients. We need them in small amounts to help our body function properly. There are 16 minerals that are essential nutrients and must be supplied by the diet. These minerals are divided into two groups: major and trace minerals. Major minerals, like calcium, chloride, magnesium, phosphorus, potassium, sodium, and sulfur, are found in our body in amounts larger than 5 g. Trace minerals, like chromium, copper, fluoride, iodine, iron, manganese, selenium, and zinc, are found in our body in amounts <5 g.

The content of minerals in offal is often higher than in muscle tissue; as an example, liver and kidney are a good source of essential minerals for human diet as Fe, Cu, Zn, and Se, especially iron and zinc, that are presented in higher concentration in offal than in meat. A remarkable case is pork liver where iron content is 233 mg kg^{-1}, which is up to 23 times higher than in meat; kidneys from beef, pork, and lamb are an excellent source of selenium, which is four of five times more concentrated than in meat. Liver, regardless of species, is a good source of manganese; its concentration can be six to ten times higher than in meat cuts. Both meat and offal are good sources of iron, but it may not always be recognized by consumers that they are even better sources of zinc.

There are two types of dietary iron that can be consumed: heme iron and nonheme iron. Heme iron is found in meat and fish in the form of myoglobin or hemoglobin. Iron from plant sources is nonheme iron, though this is also present in animal tissue. Nonheme iron has a very low rate of absorption, which can be increased by co-ingestion with vitamin C or heme iron. Taking into account that iron deficiency is the most common nutritional disorders in the world (in both developed and developing countries) affecting a 25% of total offal may play a role in the enhancement of iron intake and absorption in the world.

Regarding fish by-products, calcium and phosphorus are the most abundant minerals commanding ~5.8% and 2.04% of the total weight in dry basis, respectively. As calcium is deficient in the most of the regular diets, consumption of whole small fish or addition of fish by-products to improve calcium intake can be nutritionally valuable.

In the same way that beneficial minerals are accumulated in the offal, certain heavy metals such as cadmium, lead, mercury, and arsenic can be detected in these organs at higher levels than it can be found in muscles. However, the concentration of these metals is strongly dependent on the environment and diet, with the environment in particular (mining, heavy, or chemical industry) having a strong influence. Liver and kidney seem to accumulate most heavy metal, followed by lung, heart, intestines, and brain. The liver and kidneys are target tissues

Table 4 Mineral content in raw offal expressed as mg 100 g^{-1} – with the exception of selenium that is expressed as μg kg^{-1}

for monitoring metal contamination in animals because both organs function in removing toxic metals from the body and therefore end up accumulating them.

Table 4 presents a summary of the mineral content in the most common offal according to species as well as the average mineral content in fish by-products.

Vitamins

Vitamins are a group of organic compounds that are essential to normal metabolic functioning in the body. They are not a source of energy and do not form a structural role in tissues. Instead they are essential as cofactors or coenzymes. Vitamins can be divided in two main groups depending on their solubility: those soluble in fat organic solvents and those soluble in water; they are known as fat-soluble and water-soluble vitamins, respectively. Vitamins A, D, E, and K form the fat-soluble group, with others being water-soluble. Sources of vitamins can be classified as high, rich, or excellent when their content in 100 g is higher than 20% of recommended DV according to the US Department of Agriculture; the term good is used when the content is 10–19% of DV (daily value).

Within the fat-soluble vitamins, the most abundant in the offal is vitamin A with liver and kidney having the higher amounts. One hundred grams of liver can provide 781% (veal), 492% (lamb), 433% (pork), or 338% (beef) of DV; meanwhile, the same amount of kidney provides 28% (beef), 6.3% (veal), 6% (lamb), and 4% (pork). The other three fat-soluble vitamins are absent or present at very low levels in meat and offal.

The most prevalent water-soluble vitamins in meat and offal are those from group B (thiamin or vitamin B_1, riboflavin or vitamin B_2, niacin or vitamin B_3, pantothenic acid or vitamin B_5, vitamin B_6, and cobalamin or vitamin B_{12}), together with folate and vitamin C. These have a low stability and loss after cooking can be detected depending on the time and temperature employed. The average content and DV of water-soluble vitamins in offal by species is presented in Table 5.

Thiamin is a cofactor for enzymes involved in carbohydrate and fat metabolism, and it can be found in high amounts in pork offal, especially in heart where a 100 g portion supplies 40% of the DV. Riboflavin acts as cofactor for enzymes of the Krebs cycle; liver and kidneys from pork and beef are an excellent source for this vitamin yielding more than 100% of DV in 100 g of product. Niacin is found in high concentrations in offal with highest levels in liver, kidneys, and spleen where values can range from 5.9 mg 100 g^{-1} (pork spleen) to 16.1 mg 100 g^{-1} (lamb liver). As comparison, niacin content in meat is ~5–7 mg 100 g^{-1}. Three pyridines (pyridoxine, pyridoxal, and pyridoxamine) and their 5′-phosphorylated derivatives that are interconvertible are known as B_6 vitamins; they play a role in protein and amino acid metabolism. Liver from beef and lamb are the best sources of vitamin B_6; however, the amount is quite similar to that found in meat cuts. Cobalamin or vitamin B_{12} is exclusively of animal origin and is created by bacterial fermentation in the gut; however, it can be found at

very high concentrations in pancrease, liver, kidney, brain, and heart. In beef liver, the content is such that 10 g can be sufficient to cover the DV.

With the exception that liver from pork and lamb and kidney from beef offal are not a good source of folate, the rest of offal rarely provides more than 3% of folate DV. Vitamin C can be detected as reduced ascorbic acid or oxidized dehydroascorbic acid; it is very susceptible to oxidation during the processing, storage, and cooking; maximum stability takes place at acidic pH between 4 and 6. Spleen and lungs are the most important source of vitamin C within offal products; 100 g of such products provides up to 75% of DV (beef spleen) or 64% (beef lungs).

Conclusion

An overview of the composition of various offal has been presented in this article with details presented on the protein, fat, mineral, and vitamin contents of the most relevant offal in terms of human consumption. While these products can be rejected by consumer for a variety of reasons, it is clear that they represent a valuable source of nutrition in particular for EAAs, heme iron, calcium, vitamins within group B, vitamin A, selenium, and even vitamin C. Some offal such as liver, kidney, heart, and spleen are richer in high-nutritive compounds than meat or meat products. Because of this, if offal has been correctly processed and cooked, and presented well there is much scope for increased consumer acceptance, which in turn can lead to better harnessing of products from livestock and increase the value for the meat sector. Data presented in this article and in 'Further Reading'/'Bibliography' can be supplemented by further in-depth analysis of the composition of macro- and micronutrients in offal from poultry or minority meat sources (as rabbits, camels, goats, etc.).

Olive Oil: Its Role in the Diet

A Historical Overview of Olive Oil

Cultivated olive probably developed about 6000 years ago from wild olive or acebuche (*Olea europaea* var. *oleaster*). Pliocene fossil remains of wild olives have been found in Italy, in higher Paleolithic strata in Northern Africa, and from Chalcolithic and Bronze Age in Spain. Archaeological remains locate the first cultivated olives in Asia Minor and from there spread towards Greece. However, other authors suggest that cultivated olive derives from *Olea chrysophylla*, a variety widely growing in the mountains in Ethiopia, Kenya, and Uganda. Its origin has also been suggested in Egypt and Ethiopia and then spread along Northern Africa. Nevertheless, genetic studies of existing trees indicate that its origin derived from cultivated olives from Palestine, Lebanon, Syria, Cyprus, and Crete.

Many ancient civilizations considered olive tree a sacred tree and carved wooden scepters of kings with olive wood, olive leaves were used to make fine crowns to distinguish the outstanding men, and olive nectar was a key element in food, beauty product, medical remedy, and substrate for lighting.

The Phoenicians started disseminating the olive throughout Mediterranean countries in the sixteenth century BC, beginning in Greece between fourteenth and twelfth centuries BC, and it was later introduced in Spain c.1050 BC. The Romans intensified olive cultivation throughout the Empire, especially in the Iberian Peninsula. Spain became the largest producer of olive oil that was mostly exported to Rome. In the Roman Empire, the olive tree cultivar was of strategic importance.

The Arabs arrived in the Iberian Peninsula in AD 711 and introduced new varieties to existing cultivars, encouraging oil production especially in the area of Andalusia. Etymology for the Spanish terms for oil 'aceite' and olives 'aceitunas,' among other terms, is from Arabic origin.

With the discovery of America, the olive culture passed the Atlantic. In 1560, olive cultivars began to grow in Mexico and later in Peru, California, Chile, and Argentina. In more recent times, olive cultivation has spread in widely dispersed geographic locations from its origin, such as Japan, China, Australia, and South Africa.

The progressive introduction of olive culture in territories inhabited by nomadic people led them to become sedentary tribes willing peace with the surrounding villages. Hence, olive became a universal symbol of peace.

The origin of the word 'olive' probably derives from the term elaiwa in a Cretan dialect, which derived from Ancient Greek term elaia (ελαια); the term for olive oil was elaialadah. Both terms come from the Semitic term ulu, which eventually led to the Latin oleum, precedent for the Romance languages word oli. This phonetic variant gave rise to the terms oil in English and öl in German.

Olive oil is an excellent culinary and gastronomic resource in the Mediterranean diet (MD). It has been used for medicinal purposes, alone or with addition of various substances and herbal remedies. Pliny the Elder and other medical texts of the Roman Empire document the uses of olive oil in different balsams and medicines. Later authors such as Averroes and Maimonides refer to the goodness of consuming olive oil in their medical works.

Olive Cultivation and Varieties

Wild olive tree is known as 'acebuche' (*Olea sylvestris*). It was one of the first varieties of olive trees in the Mediterranean area and after several crosses and upgrades originated the existing variety *Olea europaea*.

Olive trees are grown in warm, dry climates and olive harvest is collected in late fall, although in some varieties and in certain areas, the collection takes place in December. There are over 260 varieties of olive trees, among which 26 are the most representative varieties. These unique varieties are named according to the geographic origin. Usually, olive tree is a long-lived tree that can reach up to 500 years or more and bring extraordinary quality oil called 'ancient tree oil.' In the south of Catalonia, there are some 4400 trees aged 700–1000 years old and oil produced from these ancient trees is specially certified.

The most widely cultivated olive varieties are Picual, Cornicabra, Hojiblanca, Arbequina, Lenchin, Verdial, Empeltre, Moorish, Gordal or Queen, Manzanilla, and Farga.

Picual variety is the world's largest variety. Picual olive has a very high content of polyphenols, which gives great stability. Picual oil is characterized by fresh flavor and full-bodied, with a degree of bitterness and pungency.

Arbequina olive produces high-quality fruity oil. The Cornicabra variety, grown mainly in Toledo and Ciudad Real, produces golden oil with green tones, which contains 77% oleic acid. The Empeltre variety is grown in Aragon and produces high-quality oil. It is one of the oldest varieties of Spain. Farga olives are grown in Castellón, Valencia, Tarragona, and Teruel. Oil from ancient Farga olive trees is highly valued.

In Greece, Kalamata and Koroneiki varieties are among the best known. Additional varieties in Italy are the autochthonous Ascoli from Ascola and Leccino. Israel grows the biblical variety Barnea and two major varieties grown in France are Picholine and Nice.

Olive Oil Processing

Olive oil is extracted from the different varieties of olive (*Olea europaea*) yielding diverse quality and quantity oil depending on the ripeness, variety, type of collection, transfer, and storage. Olives generally contain between 25% and 32% oil; water content is 40–55% and olive pit with vegetal residues between

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00502-X

23% and 35%. All varieties are capable of producing excellent virgin olive oil if the collection process and milling have occurred on the same day and it is stored following proper procedures.

The oil extraction process does nothing to improve quality or nutritional content of olive oil, but the neglect of this process favors considerable loss of quality. In the traditional press method for olive oil production, olives are crushed and malaxed into a paste, which is spread on mats. Pressure is applied to squeeze out the oil and wastewater, leaving a material on the mats called pomace. The oil and wastewater are then separated by gravity. Steps followed in olive oil production are described in the succeeding text:

(1) *Collection*. It is a key process influenced by the appropriate time to pick the fruit when optimal level of maturation is reached and by the procedure used. The best system is the one that least impairs the olive tree and less damages the fruit.
(2) *Grading and washing*. Olives are transported to the mill and incorporated immediately to a cleaning process, removing leaves and foreign bodies, washing, and grading. A higher proportion of leaves increase the content of chlorophyll pigments, give a greener color oil, and alter the organoleptic, olfactory, and gustatory sensations.
(3) *Crushing*. Olives are passed to grinding and pressing–squeezing process to extract olive juice through the crushing, mixing, and centrifugation. Premium oil only is obtained when olives are collected and grinded the same day.
(4) *Malaxing*. At this stage, oil droplets are grouped. Extending this process reduces the content of antioxidant compounds. Malaxing should occur at as low temperature as possible but not lower than 20 °C, ideally between 25 and 30 °C. According to EC regulations, cold extraction takes place <27 °C.
(5) *Separation and centrifuging*. After crashing and grinding step, two or three products are extracted, oil and alperujo (two phases) or oil, pomace, and alpechin (three phases). Pomace oil is extracted by chemical means from alperujo. The first extraction liquid obtained in the initial phase consists of oil and alpechin, which are then centrifuged. The oil thus obtained belongs to the categories 'virgin' and 'extra-virgin,' provided that it satisfies the physicochemical and organoleptic characteristics. It has been reported that the largest loss of phenolic compounds takes place at the crushing stage (60% of phenolic compounds and 70% of oleuropein) but only 21% of antioxidant activity. Malaxation does not cause significant losses of phenolic compounds but affects the antioxidant activity (43% loss). The resulting pomace retains 26% of the phenolic compounds, 21% of the oleuropein, and 33% of the antioxidant activity.
(6) *Storage*. The resulting oil is transferred to stainless steel tanks for preservation and storage, where it is stored at 15 °C protected from light and external stimuli.
(7) *Packaging*. Containers for packaging olive oil are made of transparent glass, opaque glass (amber or green), plastic (PET), or tin-coated paperboard (e.g., Tetra Brik®). The freshness and quality of the aromas of olive oil deteriorate over time, but the rate of deterioration depends on the packaging. The content of phenolic compounds is better kept when containers prevent the passage of light and oxygen and are stored in the dark at temperatures between 16 and 18 °C. The choice of a container cap that prevents the passage of oxygen is very important as well. Cork taps are permeable to oxygen and can cause premature aging of oil.

Olive oils with higher content of polyunsaturated fatty acids are prone to a shorter life, while those containing higher proportion of saturated fatty acids have a longer life. Higher content of free fatty acids, greater peroxide value, or higher humidity also favors oxidation and shortens oil life. Conversely, more phenolic antioxidant content lengthens shelf life. Olive oil quality, if kept in good condition, can last for months or even years without rancid processes.

Virgin olive oils with high acidity or deteriorated organoleptic qualities due to the quality of the fruit or extraction processes used must follow a refining process. This procedure consists of a physical decolorizing action by absorbing bleaching earth and further filtration, removing excessive pigmentation, deodorization, and neutralization by a physical distillation under heating vacuum to remove compounds that may infer bad taste and odor.

In the refining process, the product is heated so the solvent evaporates completely. If the heating does not exceed 90 °C, the final product is not likely to contain polycyclic aromatic hydrocarbons like benzopyrene. The risk of benzopyrene contamination occurs when the heating method used exceeds 300 °C. Specific standards have been set in various regions of the world limiting the allowable amount of benzopyrenes in pomace olive oil. Within the European Union and in member states of the International Olive Council (IOC), the limit is 2 ppb or 2 $\mu g\,kg^{-1}$ as decided in Resolution RES-1/93-IV/05 Madrid in November 2005.

Types of Olive Oil and Quality Control

If the olive oil obtained exclusively by physical processes, that is, the juice of the olive, meets the requirements in terms of characteristics of acidity and organoleptic properties, it may be classified as extra-virgin olive oil. In 1959, the United Nations supported the creation of the IOC to oversee standards, research, and development regarding olive oil production and consumption worldwide following the adoption of the International Agreement on Olive Oil in 1956. IOC controls 85% of olive oil production worldwide and ensures the quality control of olive oil production. The IOC sets the standards but cannot enforce governments to adopt any regulation.

In the European Union (EU), Article 118 of Regulation (EC) No 1234/2007 delineates the various categories of olive oil and considers the terms describing the organoleptic characteristics referring to taste and/or smell of extra-virgin and virgin olive oils defined by the IOC in its revised method for the organoleptic assessment of virgin olive oils. These are also

included in Regulation (EU) No 29/2012 of 13 January 2012 on marketing standards for olive oil – which states that "consumers should be informed about the types of olive oil offered." In 2010, the United States adopted new standards for grades of olive oil and olive-pomace oil. Australia and New Zealand, which are not IOC member countries, approved a new olive oil standard in 2011.

Since extra-virgin olive oil is simply fruit juice without any additives, its quality and taste are influenced by the varieties of olives, the terroir where they were grown, and the decisions and production practices of producers (Table 1).

In order for an oil to qualify as 'extra-virgin,' the olive oil obtained exclusively by physical processes must also pass both an official chemical test in a laboratory and a sensory evaluation by a trained tasting panel recognized by the IOC. The olive oil must be found to be free from defects while exhibiting some fruitiness. Sensory analysis informs about bitterness, pungency, and astringency. Oleocanthal is the polyphenol most associated with pungency in the throat. Tyrosol is among polyphenols causing astringency, derivatives of oleuropein produce bitterness, and volatile compounds from the lipoxygenase pathway are responsible for complexity of flavor.

Cooking Techniques and Uses of Olive Oil

Currently, the culinary use of olive oil is not restricted to areas growing olive tree cultivars, but it is much appreciated and its use is associated with quality cuisine. Most common uses of olive oil are raw and for frying. When added raw without any heating, olive oil retains all its nutritional and organoleptic qualities. Olive oil is considered the fat of choice for frying, a cooking technique very common in countries surrounding the Mediterranean basin. There are two frying techniques, shallow and deep frying. In the first one, oil does not cover all the food surface and food needs to be turned around. With this procedure, food is impregnated with larger amount of oil. Deep frying is usually performed in fryers. Food is completely covered with oil and absorbs less oil. Fatty acids in oils are

Table 1 Categories of olive oil as described on Article 118 of Regulation (EC) No 1234/2007 (1), the International Olive Council (2), and the US Standards for Grades of Olive Oil and Olive-Pomace Oil, 2010 (3)

1. Virgin olive oils	Oils obtained from the fruit of the olive tree solely by mechanical or other physical means under conditions that do not lead to alterations in the oil, which have not undergone any treatment other than washing, decantation, centrifugation, or filtration, and to the exclusion of oils obtained using solvents or using adjuvants having a chemical or biochemical action or by reesterification process and any mixture with oils of other kinds
(a) Extra-virgin olive oil[1,2,3]	Virgin olive oil having a maximum free acidity, in terms of oleic acid, of 0.8 g per 100 g, the other characteristics of which comply with those laid down for this category
(b) Virgin olive oil[1,2,3]	Virgin olive oil having a maximum free acidity, in terms of oleic acid, of 2 g per 100 g, the other characteristics of which comply with those laid down for this category
Ordinary virgin olive oil[2]	(2) Virgin olive oil having a maximum free acidity, in terms of oleic acid, of 3.3 g per 100 g, the other characteristics of which comply with those laid down for this category This designation may only be sold if permitted in the country of retail sale. If not permitted, the designation of this product has to comply with the legal provisions of the country concerned
(c) Lampante olive oil[1,2] or US virgin olive oil not fit for human consumption without further processing[3]	(1) Virgin olive oil having a free acidity, in terms of oleic acid, of more than 2 g per 100 g, the other characteristics of which comply with those laid down for this category (2) Virgin olive oil having a free acidity, expressed as oleic acid, of more than 3.3 g per 100 g, the organoleptic characteristics and other characteristics of which correspond to those fixed for this category in the IOC standard. It is intended for refining or for technical use (3) Virgin olive oil having poor flavor and odor, a free fatty acid content, expressed as oleic acid, of more than 2.0 g per 100 g, and meeting the additional requirements outlined
2. Refined olive oil[1,2,3]	Olive oil obtained by refining virgin olive oil, having a free acidity content, expressed as oleic acid, of not more than 0.3 g per 100 g, the other characteristics of which comply with those laid down for this category
3. Olive oil – composed of refined olive oils and virgin olive oils[1,2,3]	Olive oil obtained by blending refined olive oil and virgin olive oil other than lampante olive oil, having a free acidity content, expressed as oleic acid, of not more than 1 g per 100 g, the other characteristics of which comply with those laid down for this category
4. Crude olive-pomace oil[1,2,3]	Oil obtained from olive pomace by treatment with solvents or by physical means or oil corresponding to lampante olive oil, except for certain specified characteristics, excluding oil obtained by means of reesterification and mixtures with other types of oils, the other characteristics of which comply with those laid down for this category
5. Refined olive-pomace oil[1,2,3]	Oil obtained by refining crude olive-pomace oil, having free acidity content, expressed as oleic acid, of not more than 0.3 g per 100 g, the other characteristics of which comply with those laid down for this category
6. Olive-pomace oil[1,2,3]	Oil obtained by blending refined olive-pomace oil and virgin olive oil other than lampante olive oil, having a free acidity content, expressed as oleic acid, of not more than 1 g per 100 g, the other characteristics of which comply with those laid down for this category

modified by heat during frying, which can lead to the formation of toxic by-products. The alteration undergone by vegetable oils when heated for frying is quicker and more intense the higher their content of polyunsaturated fatty acids and the higher the initial acidity of the oil. Olive oil has a high proportion of monounsaturated fatty acids (MUFA) and antioxidants that have a protective effect in this regard.

The ideal frying temperature is 180 °C. The boiling point of olive oil stands at 210 °C. An added benefit of olive oil is that it forms a thin surface crust around the food that is fried, preventing the entry of oil inside. Different oils should never mix for frying, since the mixture will alter the boiling point. Oil used for frying must be renewed often and filtered before reuse; oil should not emit smoke during frying.

Nutritional Value of Olive Oil

In olive oil, two different fractions can be distinguished, oil fraction and nonoily fraction. The oil fraction is the major portion, 98–99% of the total oil. It consists of triglycerides containing MUFA (55–85%), mainly oleic acid but not only. It also contains palmitoleic acid; saturated fatty acids (12.7%), such as palmitic, stearic, and arachidic acids; and polyunsaturated fatty acids (10.1%), including linoleic and linolenic fatty acids. It contains smaller amounts of free fatty acids, monoglycerides, diglycerides (DG), phosphatides, waxes, and sterol esters. The levels of fatty acids vary during the different maturation stages of the olives, the variety, and the growing conditions. It is generally accepted that cooler areas will produce oil with higher MUFA content than warmer climates. The proportion of linoleic acid in oils from warmer regions tends to be higher (Table 2).

The non-oil fraction or unsaponifiable fraction is only 1–1.5% of the total olive oil. At least 230 substances have been reported in this fraction, some of them with important physiological action, which also determines the organoleptic characteristics of olive oil. Virgin and refined oils differ in the composition of the minor compounds.

This fraction includes terpenes as squalene (136–700 mg per 100 ml) and carotenes, especially β-carotene and carotenoids that also contribute to the typical green-yellowish color of olive oil. Squalene accumulates in the skin and helps eliminate singlet oxygen ($^1O_2$) or reactive oxygen species generated by the action of ultraviolet radiation.

Pigments (chlorophylls and pheophytins) contribute to the color of olive oil and have been attributed antioxidant actions.

Tocopherols are also present in olive oil. α-, β-, γ-, and δ-tocopherols can be found. α-Tocopherol (vitamin E) accounts for 90–95% (5.1 mg per 100 ml^{-1}) of tocopherols in olive oil. Temperatures above 35 °C decompose vitamin E.

Sterols include campesterol, stigmasterol, and β-sitosterol. The latter represents 93% of the total and has a cholesterol-lowering action with competitive antagonism with cholesterol for its intestinal transport mechanism (Table 3).

Table 2 Energy, fatty acids, and fat-soluble vitamin content in olive oil (BEDCA, Spanish Food Composition Data Base)

		Olive oil
Energy (kJ (kcal))		3696 (887)
Total lipid (fat) (g)		99.9
Fatty acids, total monounsaturated (g)		73.3
Fatty acids, total polyunsaturated (g)		10.52
Fatty acids, total saturated (g)		13.81
Cholesterol (mg)		0
Vitamin A, RAE (μg)		3
Vitamin D (μg)		0
Vitamin E (α-tocopherol) (mg)		12
Vitamin K (phylloquinone) (μg)		60.2
***Percentage of different fatty acids in olive oil*[a]**		
	Fatty acid	%
SFA	Myristic (14:0)	0.0–0.05
SFA	Palmitic (16:0)	7.5–20
SFA	Margaric (17:0)	0–0.3
SFA	Stearic (18:0)	0.5–5
SFA	Arachidic (20:0)	0–0.6
SFA	Behenic (22:0)	0–0.2
SFA	Lignoceric (24:0)	0–0.2
MUFA	Heptadecenoic (17:1)	0–0.3
MUFA	Palmitoleic (17:1*n*7)	0.3–3.5
MUFA	Oleic (18:1*n*9)	55–83
MUFA	Eicosenoic (20:1*n*9)	0–0.4
PUFA	Linoleic (18:2*n*6)	3.5–21
PUFA	Alpha-linolenic (18:3*n*3)	0–0.9

SFA, saturated fatty acids; MUFA, monounsaturated fatty acids; PUFA, polyunsaturated fatty acids.

Modified from Guillén, N., Acín, S., Navarro, M. A., et al. (2009). Knowledge of the biological actions of extra virgin olive oil gained from mice lacking apolipoprotein E. *Revista Española de Cardiología* **62**(3), 294–304.

Phenolic compounds can be found in varying proportions (5–80 mg per 100 ml^{-1}) in extra-virgin olive oil. Simple phenols (tyrosol, hydroxytyrosol, and phenolic acids such as caffeic acid and vanillic acid), complex phenols (oleuropein and verbacósido), lignans (acetoxypinoresinol and pinoresinol), and flavonoids can be found. Oleuropein is responsible for the bitter taste of olives and gives a brown color to their skin. Hydroxytyrosol and tyrosol are potent antioxidants that prevent oxidation of LDL. Hydroxytyrosol inhibits platelet aggregation *in vitro*, plasma accumulation of thromboxanes, leukotriene production by neutrophils, and arachidonic lipoxygenase action. Phenolics in olive oil help eliminate reactive oxygen species generated in the fecal mass and thus protect the colonic mucosa. The phenolic content in olive oil varies depending on the variety of olive fruit (Coratina variety is the richest in phenolics), region where it is grown, climate, agricultural techniques used, maturity of the olive fruit at harvest, and olive oil extraction, processing, storage methods, and time since harvest. Cooking methods have also been shown to alter phenolic concentrations in virgin olive oil.

Other compounds such as alcohols, ketones, esters, ethers, and furans are volatile compounds that contribute to the characteristic flavor of olive oil.

Digestion and Absorption

Fats rich in MUFA such as oleic acid have been found to cause pronounced postprandial lipemia, with a tendency for large TG-rich lipoprotein particles. In humans, hydrolysis of olive oil triglycerides begins in the stomach where it is catalyzed by an acid-stable gastric lipase. Triglyceride hydrolysis continues in the duodenum, by the synergetic actions of gastric and colipase-dependent pancreatic lipases and bile secretion. Gastric lipolysis leads to the hydrolysis of 10–30% of ingested triglycerides, generating mainly DG and free fatty acids. This facilitates subsequent triglyceride hydrolysis by pancreatic lipase by allowing fat emulsification. Different lipid metabolites are quickly absorbed along the epithelial cells of the small intestine. Compared to diets rich in polyunsaturated fatty acids, olive oil suppresses gastric acid secretion and is a potent releasing factor of cholecystokinin peptide.

Bioavailability assays in animals and humans show that 55–60% of phenolics from extra-virgin olive oil are absorbed. Absorption of most minor compounds of (extra-virgin) olive oil takes place in the small intestine, as native or derivatives. Research has shown that the phenolic compounds hydroxytyrosol and tyrosol are absorbed after ingestion in a dose-dependent manner. Different polarities of the various phenolics have been postulated to play a role in the absorption of these compounds. Phenolics tyrosol and hydroxytyrosol are polar compounds, and it has been postulated they are absorbed via passive diffusion. It has been suggested that oleuropein glycoside may diffuse through the lipid bilayer of the epithelial cell membrane and be absorbed via a glucose transporter. Phenolic compounds, oleuropein glycoside and oleuropein and ligstroside aglycones, are converted to hydroxytyrosol or tyrosol and excreted in urine. Hydroxytyrosol and tyrosol themselves are sometimes conjugated to glucuronic acid and excreted in urine as glucuronides. Excreted phenolics (mainly in the form of hydroxytyrosol and tyrosol) have been determined to be 5–16% of the total ingested.

Patterns of Consumption

Worldwide, around 11 million hectares of olive cultivar is grown in 47 producing countries. World production of olive oil is estimated at 3.1 million tons according to the IOC for the season 2013–14 (between 1 October 2013 and 30 September 2014). Spain is at the forefront of the global ranking of

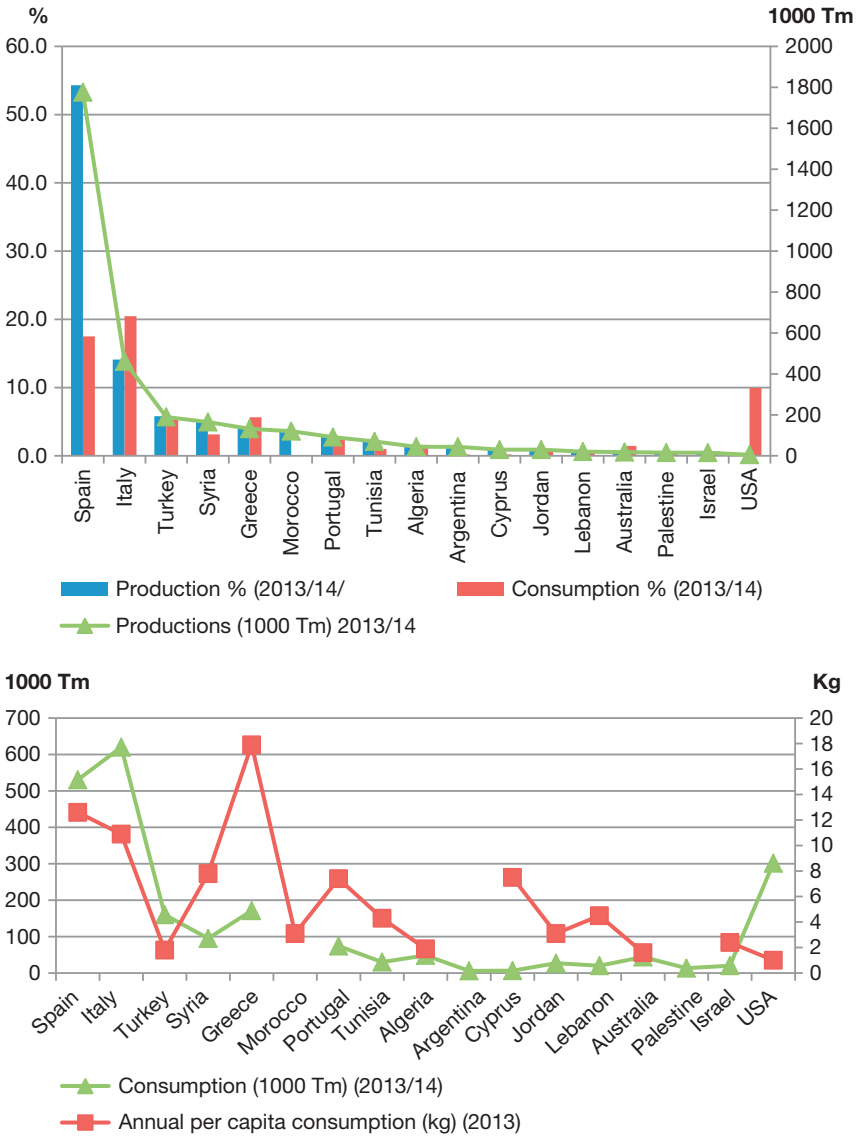

Figure 1 Olive oil production in highest producing countries in 2013/2014, percent production of world production by country, and percent consumption in the same period (a); olive oil consumption in highest consuming countries and annual per capita consumption in period 2013 (b). *Source*: International Olive Council.

countries producing olive oil since the mid-1990s, with 1.5 million tons in 2013–14, 50% of total world production. Two other Mediterranean countries, Italy and Greece, rank second and third, with 450 and 230 thousand tons of olive oil, respectively. Turkey, Syria, and Morocco also produce over 100 thousand tons and close to the top ten producing countries Tunisia, Portugal, Algeria, and Chile, with output ranging from 80 thousand tons of Tunisia to 32 thousand tons of Chile. Argentina and Jordan are between 25 000 and 30 000 tons, while Australia, Libya, Palestine, Lebanon, Israel, Albania, the United States, and Iran produce between 9000 tons of Iran and 19 000 tons of Australia. Italy and Spain are the main exporters of olive oil (Figure 1).

Currently, olive oil is consumed in 160 countries. In the last two decades, there has been increasing interest in olive oil in many countries, first as an echo of accumulated scientific evidence on possible beneficial health effects. On the other hand, its organoleptic properties have focused on culinary trends. In fact, new regulations regarding standards of quality control and marketing strategies have been debated among producing EU countries, the United States, and Australia.

Italy is the country with the highest consumption of olive oil, followed by Spain, the United States, and Greece, but considering per capita consumption, Greece leads the ranking with an average annual consumption of more than 24 l per person per year, followed by Spain, Italy, and Portugal. Countries in North Africa, southern coast of the Mediterranean Sea, show consumptions around 4.3 l per person per year for Tunisia and 3.1 l per person per year in Morocco. A consumption of 2 l per person per year is estimated in France, and the estimated

consumption in the United States is 1 l per person per year, slightly higher than in Canada (1.4 l per person per year) and the United Kingdom (1.1 l per person per year).

Differences in the consumption of olive oil are mostly explained by differences in food habits, cultural and gastronomic traditions, and income level, although to a lesser extent.

The US consumption of olive oil has tripled in the last 20 years, conditioned mainly by increased overall interest in the MD and by favorable health effects of olive oil and culinary properties, as evidenced by the abundance of information on these topics published in general media of general information, both on paper and online, on blogs, etc., published in recent years, which have been estimated at around 50 news per month.

Olive Oil, MD, and Health

Fats play an important role in the diet, providing calories; help in the absorption of fat-soluble vitamins A, D, E, and K; and contribute to add taste and texture to foods, as well as satiety and sense of fullness after eating a meal. There is sound evidence that it is not only the amount of fat content in the diet but also the quality of fat that has a relevant influence for health. Dietary fat affects the fat composition of cell membranes.

The authors of the Seven Countries Study, started in the 1950s by Ancel Keys and other researchers, reported that the people in Crete consumed some of the largest amounts of fat but had the lowest cardiovascular mortality rate and a long life expectancy. The finding led to the development of the concept of MD. The traditional MD is the dietary pattern prevailing among the people of the olive tree-growing areas of the Mediterranean basin before the mid-1960s. The traditional MD is characterized by high consumption of vegetables, fruits, and nuts, legumes, and unprocessed cereals; low consumption of meat and meat products; and low consumption of dairy products except for long-preservable cheeses and moderate alcohol consumption, generally wine during meals. Olive oil was then used liberally. Total intake of lipids could be high or moderate, but the ratio of monounsaturated to saturated lipids was high. Fish consumption depended on the distance from the sea but overall was moderate.

The MD should be understood as something else than a food pattern; it is a cultural model that involves the way foods are selected, produced, processed, and distributed. The MD has recently been acknowledged by UNESCO as an Intangible Cultural Heritage of Humanity. Unfortunately, current diets in Mediterranean countries are departing from the traditional MD.

The most widely researched health benefits of the MD are the reduction in cardiovascular disease, including peripheral artery disease, with strong evidence supporting a causal vascular protection. Other benefits extensively researched include the prevention of type 2 diabetes and metabolic syndrome, cognitive impairment, and unipolar depression. The EPIC study has also provided some benefits against cancer (Figure 2).

The *Pre*vencion con *Die*ta *Med*iterranea (PREDIMED) trial compares a low-fat diet to either the MD supplemented with either olive oil or that with nuts. Authors of this large trial have

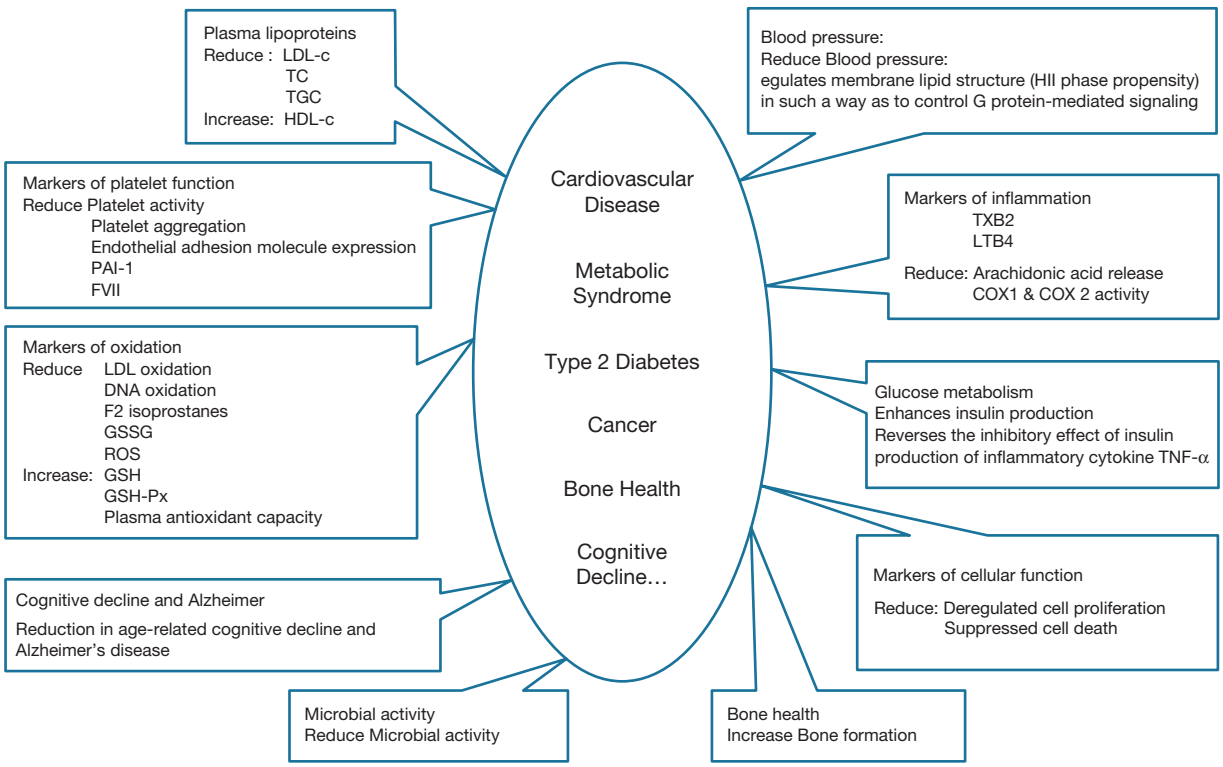

Figure 2 Health effects of olive oil and suggested mechanisms. *Sources:* Caramia G et al., 2012; Cicerale et al., 2010; Estruch R et al., 2013; López-Miranda J et al., 2010; Rees K et al., 2013; Salas-Salvado J et al., 2014; Widmer et al., 2014.

reported a significant reduction in cardiovascular disease events in the MD arms of the trial.

One of the most relevant aspects of the MD is the high content of unsaturated fats in its sources of fiber and protein, along a paucity of saturated fats. Olive oil, a good source of MUFA, contains phenolic compounds that may have antioxidant, anti-inflammatory, and antithrombotic properties. There is some evidence that oleic acid itself can reduce inflammatory markers like C-reactive protein. However, the main anti-inflammatory effects seem to be mediated by the antioxidants in olive oil, primarily oleocanthal.

The cardioprotective effects of olive oil are now thought to be attributed to the presence of its phenolic compounds obtained from the water-soluble fraction and include mostly the low-molecular-weight molecule hydroxytyrosol and also oleuropein, which are both potent antioxidants, free radical scavengers, and enzyme modulators. Two randomized, blinded crossover trials have assessed the antioxidant effect of dietary supplementation of extra-virgin olive oil in humans: EUROLIVE and the Virgin Olive Oil Study. Results show that not only does the MD improve endothelial function and reduce systemic inflammation, but also it improves endothelial progenitor cell numbers.

Early meta-analyses primarily evaluating the effects of fatty acids on surrogate markers for cardiovascular disease such as cholesterol indicated that MUFA intake increased lipid levels, including HDL. Phenolic compounds in olive oil protect blood lipids from oxidation and vitamin E protects cells from oxidative damage. A large meta-analysis suggests an inverse correlation between blood pressure and MUFA intake.

Beneficial effects of olive oil in the digestive system have been reported: minor reflux of gastric content, partial inhibition of gastric motility, increase of satiety, promotion of digestion of food, and prevention of the sudden increase in blood glucose after digestion. It reduces heartburn, which is a protective factor for the formation of gastric ulcers. Olive oil improves intestinal absorption of nutrients, particularly minerals, reduces intestinal absorption of cholesterol by competitive antagonism of sitosterol, and reduces intestinal reabsorption of bile salts, which stimulates the synthesis of cholesterol and stimulates hepatic synthesis of bile salts. It also stimulates the contraction of the gallbladder by stimulating hormone cholecystokinin (CCK-PZ), previously called pancreozymin, and moderately stimulates the exocrine pancreas.

Phenolic compounds in olive oil have shown antioxidant and anti-inflammatory properties, prevent lipoperoxidation, induce favorable changes of lipid profile, improve endothelial function, and show antithrombotic properties. Cohort studies in the Mediterranean suggest that dietary MUFA may be protective against age-related cognitive decline and Alzheimer's disease.

Notwithstanding the beneficial health effects of olive oil, it should be considered that olive oil is an energy-dense food and should be used in moderation in order to avoid excessive energy and fat intake. Olive oil should be used to replace other fat sources in the diet. Cooking techniques should be adjusted to get the flavor and the benefit of olive oil but avoiding excess fat. Beneficial health effects of olive oil are best gained when used in the context of a balanced and varied diet, rich in fruit and vegetables, such as the MD along with adequate levels of physical activity.

Table Olives: Origin and Production

Table olives are a traditional fermented vegetable with many centuries of history, particularly in the Mediterranean Basin, where this food has had a great influence on the culture and diet of many countries. Most likely, the culture of wild olive tree (*Olea europaea*) originated from Asia Minor, but the Phoenicians started disseminating the olive throughout the Greek isles and mainland. Later, the olive spread throughout the Mediterranean area reaching Tripoli, Tunis, Sicily, and southern Italy. The Roman civilization continued the expansion of the olive culture to the countries bordering the Mediterranean Basin. In Spain, olive growing was introduced by the Phoenicians at ~1050 BC. During the fifteenth and sixteenth centuries, the Spanish extended olive planting to America where there is nowadays an increasing production. Recently, the olive tree has also expanded to Australia, Japan, and South Africa.

The oldest written reference on the preparation of table olives is due to Lucius Columella in his manuscript '*De Re Rustica*,' in the year AC 54. Therefore, the production of table olives originally started at small domestic scale millennia ago, and it was a craft process until the middle of the twentieth century, when the mass fermentation and storage systems were introduced together with the pitting and stuffing automation. At this point, the progressive mechanization in the industries has led to a rapid expansion of the sector.

Nowadays, table olives are one of the most important fermented vegetables of the food industry, with a production above 2 400 000 tons year^{-1}. According to the last consolidated report for 2011/2012 season, most of the table olives were produced in the Mediterranean region with Spain (521 500 tons), Turkey (400 000), Egypt (384 500), Syria (172 000), Algeria (145 500), Greece (130 000), and Morocco (100 000) as the main contributors, although there were also important productions in Argentina (150 000), Peru (81 000), and the United States (26 000). Thus, table olive processing is worldwide spread and represents an important economic source for olive-growing countries.

Types of Elaborations

The olive fruit is a fleshy drupe. The major components (in average concentration (g kg^{-1})) in the flesh olive fruits are, depending of the olive variety and maturity degree, moisture (650–800), fat (100–300), sugars (30–60), proteins (10–20), fiber (20–50), ash (10–15), and phenolic compounds (30–60). Because of its peculiar characteristics, the presence of a bitter compound, it cannot be consumed directly from the tree. For this reason, diverse processes were developed to make them eatable; although sharing the same objective, they can slightly differ between areas of production. The Trade Standard Applying to Table Olives defines table olives as "the product obtained from suitable olive cultivars, processed to remove their natural bitterness, and preserved (by natural fermentation, heat treatment or preservatives) with or without brine until consumption."

According to the International Olive Council, table olives can be classified as a function of the type of olive fruit used (turning color, green, and natural black olives) and the method of processing used. Processing alludes to the system used for fruit debittering, the way they are kept, and the preservation procedure. The trade standard includes (i) treated olives (fruits are debittered using lye treatments, followed by fermentation in brine), (ii) natural olives (fruits are brined directly and the debittering process occurs only by dilution or natural hydrolysis), (iii) dehydrated or shriveled olives (fruits, regardless of lye treatment or not, are subjected to dehydration by salt, heat, or any other technological process), and (iv) olives darkened by oxidation (fruits are darkened by oxidation and preserved by sterilization).

Trade preparations may be offered in several presentations forms such as (i) whole, which includes cracked and split olives; (ii) pitted olives, which includes halved, quartered, divided, sliced, chopped (or minced), and broken fruits; (iii) stuffed olives, with different products (pepper paste, anchovies, etc.); (iv) salad olives, a mixture of olives with pieces of stuffing material and/or cappers; (v) olives with capers; (vi) olive paste; and (vii) other styles.

The most important table olive industrial preparations are (i) alkali-treated green olives (the so-called Spanish-style), which represent about 50–60% of production; (ii) ripe olives by alkaline oxidation (the so-called Californian-style); and (iii) untreated or directly brined olives (green, turning color, or naturally black). There are also many other traditional/industrial ways of processing table olives distributed around the world. In the succeeding text, a brief description of the main processing styles according to the volume of production is presented.

Spanish-style green table olives: In this type of elaboration, green fruits are treated with alkali, washed, and put in brine where they undergo lactic acid fermentation. The lye treatment consists of a NaOH solution (18–35 g l^{-1}), which penetrates up to 2/3 of olive flesh. The main goal of the debittering process is the chemical hydrolysis of the glucoside oleuropein, which is transformed into elenolic acid and hydroxytyrosol. The lye treatment also favors the solubilization of olive components (sugars, minerals, organic acids, etc.) from olive flesh into the liquid. Then, olives are washed to remove excess alkali and brined in a 100–120 (g l^{-1}) NaCl solution, which is rapidly enriched with the nutrients leached from flesh. The fermentation of this style of olive processing is usually spontaneous, with a predominance of lactic acid bacteria (LAB) and yeasts. Throughout fermentation, the main process is the transformation of sugars into lactic acid by LAB, which drops the pH up to values that make the product safe (below 4.5) by preventing growth of undesirable microorganisms (*Clostridium* and Enterobacteriaceae). Most of the olives are then commercialized as pitted, pitted/stuffed with diverse products from vegetal or animal origin, or pitted/sliced olives.

Ripe olives: In this type of elaboration, green or turning color fruits are stored in brine or acidic solutions or directly darkened by oxidation in an alkaline medium. Storage of olives for long periods of time can be achieved in diverse holding solutions at room temperature. In the case of olives kept in NaCl solutions (50–70 g l^{-1}), brines must be acidified with acetic acid or supplemented with calcium chloride to prevent olive softening. The initial stages of this type of storage are dominated by Gram-negative bacteria, but after 4–5 days, LAB begin to appear and the other groups of microorganisms to decline. This period in brine can be combined with the application of an aerobic process, which favors the growth of oxidative yeasts and reduce possibility of spoilage. On the contrary, in acidic solutions, the storage is achieved by a combination of acids (lactic or acetic) and food preservatives (sorbate or benzoate) or also using an aerobic process without preservatives. With this system, the Gram-negative bacteria and yeast growth is markedly reduced, while the growth of acetic bacteria and LAB is clearly favored. The darkening process consists in a series of alkaline treatments, which progressively penetrate into the olive flesh up to the pit, with washing periods between them to remove the excess of alkali. Then, a solution of ferrous gluconate or lactate is added for 10–24 h to fix the black color. Hydroxytyrosol and caffeic acid are mainly responsible for the color formation during darkening. Olives are then packed in light brine (20–50 g l^{-1} NaCl) with ferrous gluconate or lactate added. The product has a final pH above 4.6 and its preservation is only achieved by sterilization. The most common commercial presentations in retail are whole and pitted olives.

Directly brined olives: In this type of elaboration, green, turning color, or mature black fruits are directly brined, where they undergo spontaneous fermentation. Initial salt concentration in brines ranges from 50 to 100 g l^{-1} NaCl, according to the sensitivity of the olive cultivar, but its content must be periodically increased as salt is absorbed by fruits. Initial pH correction with acids (lactic or acetic) to prevent excessive growth of undesirable microorganisms is also fairly common. The leaching of nutrients from the olive flesh into the solution is slow because of the strong barrier of the untreated skin, but microbial growth begins just after brining. The debittering process in this type of elaboration is due to the hydrolysis of the bitter glucosides present in the fruits and their diffusion and solubilization into the brines. In green–turning color olives, the main groups of microorganisms involved in the fermentation are, like in other table olive processing, Enterobacteriaceae, yeasts, and LAB, but with a higher importance of yeasts instead of LAB because these last microorganisms are partially inhibited due to the presence of phenolic compounds. Usually, directly brined olives are offered as whole or cracked and sold in just brine or seasoned with vinegar, garlic, pepper, aromatic herbs, etc. They are relatively unstable and need pasteurization or addition of preservatives for their complete stabilization. In the case of natural black olives, they can be subjected to two fermentation systems: (i) the traditional anaerobic (sugars are quickly consumed as they pass into the solution, with a presence of both yeasts and LAB) and (ii) the aerobic process to prevent gas pocket formation (basically consists in the injection of air into the brine through a column device, which prevents the growth of anaerobic *Clostridium* and *Propionibacterium* and favors the growth of yeasts). After fermentation, olives lose most of their initial bitter taste and are ready for commercialization.

Dry-salted olives: This is a product obtained by mixing coarse salt and freshly harvested olives without liquid. The microorganisms present at the beginning of the process can be LAB, yeasts, Enterobacteriaceae, and *Pseudomonas*, but at the end of fermentation, only osmophilic yeasts are usually isolated. Dry-salted olives can also be obtained by drying in oven.

Patterns of Consumption

Table olives are strongly embedded in the Mediterranean culture and diet. Because of their daily intake, this food is considered as snacks/appetizers, albeit this fermented vegetable is also normally used as ingredient of some dishes. Thus, they can be ingested directly or in salads, cocktails, pate, and pizzas (slices). The Spanish Association of Processors and Exporters (ASEMESA) considers seven olives (about 25 g of olive flesh) as a satisfactory daily intake.

Spain, Turkey, Egypt, and other major table olive-producing countries are strongly committed with their national markets. In this way, only a few producers require importations to cover their internal demand (e.g., the United States and Italy). According to the last consolidated report for 2011/2012 season, the main consuming countries were Turkey (350 000 tons), Egypt (300 000), Spain (217 900), the United States (210 000), Italy (139 800), and Syria (132 000). Among the nonproducing countries with high demand for consumption of table olives, Brazil (101 500 tons), Russia (68 000), Germany (65 100), and the United Kingdom (41 600) are the leaders. The total worldwide consumption for 2011/2012 season was 2 552 000 tons.

Nutritional Value

Table olives should have all the benefits attributed to olive oil, as well as other important components with proved biological activities. In this way, olives are a good source of natural antioxidants (hydroxytyrosol, oleuropein, methyloleuropein, etc.) and triterpenic acids, all of them with unquestionable biological value. From the nutritional labeling point of view, olives are mainly constituted of moisture, fat, ash (mineral), fiber, and proteins. On the contrary, olives after fermentation process are low in carbohydrates.

Several works have recently revised the nutritional composition of table olives. The fat content ranges from 100 to 300 g kg^{-1} of flesh (in cultivars also destined to olive oil extraction or double use). Most of this fat is monounsaturated (50–190 g kg^{-1}) due to its abundance in oleic acid. It is followed by saturated fat (15–60 g kg^{-1}), with the palmitic acid as the most outstanding component of this fraction, and polyunsaturated fat (5–39 g kg^{-1}), with linoleic acid being the major contributor. Table olives have also small proportions of *trans* fat (0.8–4.4 g kg^{-1}), mainly elaidic acid. Therefore, table olives are a good source of monounsaturated fatty acids with a reasonable level of polyunsaturated fat. Fiber is also an important constituent of the flesh (20–50 g kg^{-1}). Some stuffing material (hazelnut, almond, etc.) can even produce an

increment in the fiber content. The levels of lactic acid are ~5 g kg^{-1} in Spanish green table olive flesh, but the proportion of sugars is negligible after fermentation. Average protein levels are between 10 and 20 g kg^{-1}, its proportion being obviously higher in the presence of animal origin stuffing materials (anchovies, salmon, etc.). Protein proportion is relatively low but has all the essential amino acids with lysine as the limiting amino acid, followed by cysteine and methionine.

Table olives are also a good source of minerals like calcium (3–8 g kg^{-1}), potassium (0.5–1.2 g kg^{-1}), magnesium (0.5–2 g kg^{-1}), and phosphorous (0.5–1.4 g kg^{-1}), containing important proportions of microelements (copper 1.7–11.0 mg kg^{-1}, zinc 1.5–3.6 mg kg^{-1}, and manganese 0.2–1.5 mg kg^{-1}). Fermented olives are a good source of phytosterols (200–520 mg kg^{-1}), β-sitosterol being the most abundant, vitamin E (13–52.3 mg kg^{-1}), and vitamin A (1970–13 870 μg kg^{-1}), which is particularly abundant in those presentations including red pepper as stuffing material. Therefore, a recommended daily intake of 25 g of olives provides to the metabolism, as mean values, 45 kcal, 0 g carbohydrates, 0.25 g proteins, 5.5 g fats, 0.65 g fiber, and 0.3 g of sodium.

Table olives are also a good source of biologically active compounds (polyphenols and triterpenic acids). The proportion of polyphenols depends on the type of presentation. The highest proportions were found in directly brined turning color Manzanilla (~1.5 g kg^{-1}), while the content in plain green Spanish-style was slightly lower (around 1.1 g kg^{-1}). Green Hojiblanca had concentrations in the range 0.35 (pitted)–0.70 (plain) g kg^{-1}. Both cultivars had markedly lower proportions when prepared as ripe olives (~0.25 g kg^{-1}). In general, directly brined olives are richer in polyphenols but the content decreases as the number of aqueous treatments for processing increases. Naturally directly brined olives from Kalamata and Thassos cultivars were also good source of phenols (1.0 and 0.7 g kg^{-1}, respectively). Triterpenic acids are also abundant in some table olives. In general, maslinic acid, which is present in higher proportion in the wax of olive skin, has proved to have important anticancer properties. The content of triterpenic acids in diverse commercial presentations of table olives ranged from 0.46 to 1.47 g kg^{-1} flesh. The levels of these acids are mainly influenced by the lye treatments, which solubilize them. Thus, naturally directly brined natural black olives are among the richer products in triterpenic acids with concentrations around 2 g kg^{-1}. The presence of these nutritional and functional compounds in table olives may contribute to their revaluation because of the promising bioactivity properties attributed these substances.

Maybe, the main drawback of table olives is their relative high content in sodium (5–18 g kg^{-1}), which is partially absorbed by the flesh during the elaboration process (lye treatment and brining). This is not a problem for persons with a high daily physical activity, but it is not convenient for persons with cardiovascular diseases. NaCl substitution by other mineral salts may be achieved during fermentation or in packing. The use of salt mixtures in 'Gordal' has shown to affect the sugar solubilization and the general fermentation profile. The sodium content (which decreased up to ~50%) was inversely related to the concentration of KCl and $CaCl_2$ used in the initial brine. Salt mixtures may be also used in packing. Seasoned packed cracked olives had up to 31% lower Na content, while the proportions of K and Ca in the product were doubled (>0.45 and >0.30 g kg^{-1}, respectively). Finally, table olives may also be fortified with other mineral nutrients. The use of 0.75 mg l^{-1} of $ZnCl_2$ in packing brine produced seasoned cracked table olives, which could be considered as a good source of Zn for metabolism (79% daily requirements per 50 g olive flesh). Therefore, these researches may lead to new commercial presentations with improved and healthier nutritional value.

Table Olives as Carrier of Beneficial Microorganisms

In the last years, diverse researchers have tried to turn olives into a delivery vehicle of probiotic microorganisms to the human body. The first study in this direction was carried out by inoculating olives with exogenous lactobacilli strains, as it was the case of the human-origin strain *Lactobacillus paracasei* IMPC2.1. This microorganism showed high adaptability to the fermentation process adhering to the surface of the olives and being recovered from the feces of people who were fed for 10 days with olives fermented in the presence of this bacterium. Thus, the Italian health ministry allowed its application as a starter culture in table olives. Various strains of *L. paracasei* have also been used for the fermentation of green olives, but always with exogenous bacteria to the olive fermentation process.

However, the greatest developments on the matter have been obtained recently thanks to the European project Probiolives (FP7-SME-243471). In the framework of this project, diverse native LAB strains were isolated from the fermentation of different types of table olives elaborations and molecularly identified and characterized according to their potentially probiotic characteristics. Although the project was originally aimed to obtain LAB strains with probiotic characteristics that could potentially be used as starter cultures during the fermentation, the results obtained have opened new and interesting research lines. In this way, recent studies have proved, using scanning electron microscopy techniques, that the capacity of fruits to act as vehicle was due to the formation of biofilm by microorganisms on the olive surface. This biofilm was a polymicrobial ecosystem, consisting essentially of lactobacilli and yeasts, which were attached to the skin of the fruit forming a community characterized by the excretion of a protective adhesive extracellular matrix mainly composed of exopolysaccharides (Figure 1). These exopolysaccharides isolated from olives have also shown the ability to inhibit the adhesion of the enterohemorrhagic strain *Escherichia coli* K88 to the intestinal mucosa of pigs. Thus, it could have a large application in both animal feed and humans for the treatment of diarrhea.

The study of mixed biofilms between yeast and LAB on olive surfaces is a recent issue, with a direct application because an excellent vehicle of beneficial microorganisms to the final consumer can be made from this food. Recent studies conducted with table olives found that the major species that are part of these mixed biofilm during fermentation were *L. pentosus* among LAB and *Geotrichum candidum*, *Pichia galeiformis*, *Candida sorbosa*, *Saccharomyces cerevisiae*, and *Wickerhamomyces anomalus* among yeasts, reaching population levels on the olives up to 8 $\log_{10}$ CFU g^{-1}. However, our knowledge of the genes regulating the different steps during biofilm formation, the interaction

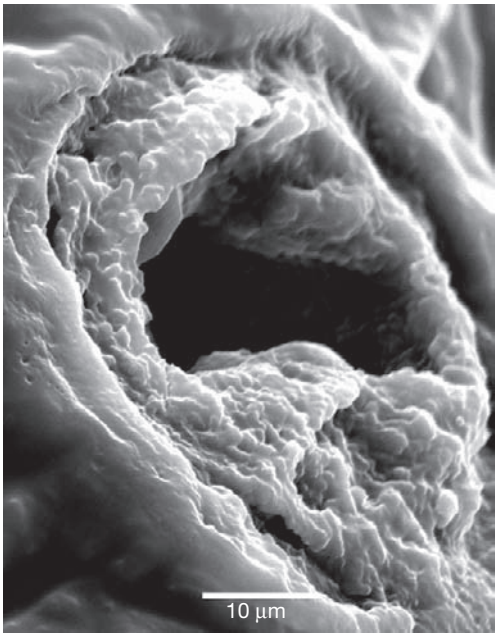

Figure 1 Photography of scanning electron microscopy showing bacteria cells adhered to Gordal olive stomata during fermentation.

between microorganisms, population dynamics, and composition of the matrix surrounding the microorganisms is still scant, despite the large application that both yeasts and LAB species play during table olive processing.

Organic Food: Effect on Nutrient Composition

E Rembiałkowska, Warsaw University of Life Sciences, Warszawa, Poland

© 2016 Elsevier Ltd. All rights reserved.

Introduction

There are several definitions of organic agriculture, for example, used by FAO "Organic farming is a holistic production management system which promotes and enhances agro-ecosystem health, including biodiversity, biological cycles, and soil biological activity" or IFOAM "Organic agriculture is a production system that sustains the health of soils ecosystems and people." The main idea is that organic agriculture is enhancing human and environment health because there is no use of synthetic fertilizers and pesticides. Legal regulations and principles of the organic food production are described in another chapter.

Organic food production is one of the fastest growing sectors with an increase of approximately 250% in 10 years. The global organic food market reached a value of € 45.8 billion in 2013; 47% of the global market was in Europe; there was increasing sale also in the United States and Canada. In Europe, the majority of the sales are occurring in the large economies (mainly Germany, France, the United Kingdom, and Italy). Although organic market growth rates are different across countries, it is clear that organic food is becoming a significant sector in the food production chain. Consumers are looking for organic food because they believe it has better nutritive value and taste; in addition, organic farming is more environment-friendly and provides better animal welfare. The main obstacles hampering the sale of organic products are high price premiums, insufficient availability, low confidence in certification bodies and organic labels, and satisfaction with current food source.

Factors Influencing the Quality of the Organic Food

Quality and safety of the organic food rely on many factors; they are presented in Figure 1.

Abiotic factors comprising the quality of the environment are basic for the food production in general and in organic food in particular. Air, groundwater, surface water, and soil have to meet high qualitative demands; first of all, the level of contamination with chemical unwanted substances has to be low and safe for plant production. Next, biotic factors as cultivars of plants and races of animals are important, as well as the occurrence of the diseases and pests. The methods of soil fertilizations together with the methods of animal raising are fundamental for the quality of the produced crops and animal materials. Here, the farmers' knowledge, skills, and scrupulousness are also of high importance.

The food processing methods are basic for the food products quality – in organic food processing, only c.50 natural substances are allowed, while in the conventional processing, several hundreds of the artificial synthetic substances are admissible. It makes the situation of the organic producers very difficult – the shelf life of the organic products is much shorter and the production is more expensive. On the other hand, the health merits of organic products are bigger.

Last but not least, the functioning of the control and certification systems is the basic factor guaranteeing the high quality of the organic products. The production process has to be in agreement with demands comprised by the relevant legal regulations. Strict control system is necessary in order to exclude the dishonest producers from the market; fraud is very seldom but sometimes happens, spoiling the whole sector.

If all described conditions are fulfilled, the high quality of unprocessed and processed organic food products can be expected.

Fertilization and Plant Protection as Factors Determining the Chemical Composition of the Obtained Organic Crops

In the organic crop production, there is a ban on the use of synthetic chemical crop protection products and certain mineral fertilizers (all N, KCl, and superphosphate) in order to diminish environmental impacts and the risk of pesticide residues being present in crop plants. The fertilization is based on organic fertilizers (mainly manure and composts) and legume crops in rotation (to enhance soil N levels). Crop protection is based on the preventative and nonchemical crop protection methods (e.g., the use of crop rotation, more diversified agricultural landscape, more resistant varieties, mechanical and flame weeding, and biological disease and pest control products).

The effect of such management on plant composition is strong, and nitrogen fertilization is considered as the main factor. Most of the obtained data indicate that the content of antioxidants is higher when plants are grown under limited N-fertilization regime (organic system and lower N-fertilizer dose). It is consistent with the GDBH (growth–differentiation balance hypothesis) – nitrogen fertilization is the key factor influencing growth and differentiation processes in plants. When nitrogen is less available, plants are growing slower and final biomass is lower, but differentiation understood as synthesis of many bioactive compounds important for plant metabolism is more intensive. As a result, the nutritive value of these plants is higher, which is important for human health.

Plant protection is also important, as the use of synthetic pesticides is diminishing the content of antioxidants in plants. The probable mechanism is that plants grown in organic system have to produce more polyphenols as the protective substances against pests, especially herbivorous insects, and diseases.

Methods of Animal Husbandry as Factors of the Animal Products' Quality

Organic raising of animals differs significantly from conventional breeding. First of all, it is necessary to apply grazing as far

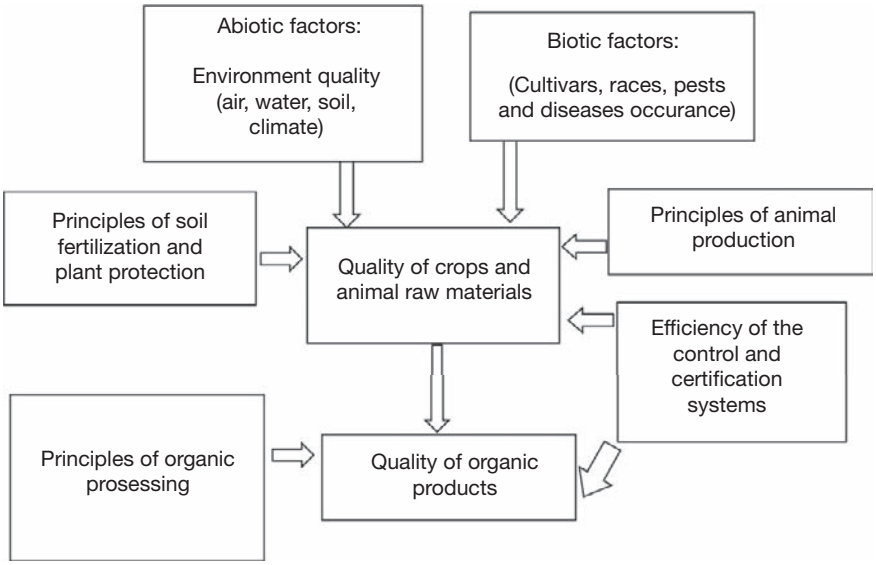

Figure 1 Factors influencing the quality of the organic raw materials and products, own elaboration.

as possible. This concerns mainly ruminant animals such as cattle, sheep, and goats; horses; to a lesser extent, swine; and poultry. However, all species of animals must be ensured a daily exercise in the air, outside the inventory building – this ensures a regular movement and the possibility of implementing the natural behavior for the species and social interactions. In addition, all species of animals have to be provided with a natural litter layer on the floor inside the inventory building – in most cases the cereal straw. Feed for animals must come only from organic production, without containing any synthetic ingredients. Described conditions ensure higher animal welfare in organic husbandry compared to the conventional one.

In the case of organic animal raw materials (milk, eggs, and meat), the main factors affecting their composition are animal nutrition and in particular a wide access to grazing in case of the ruminants (cattle, sheep, and goats). Animal feed made with fresh-stalk meadow grass affects the increased content of antioxidants and polyunsaturated fatty acids in milk and meat of animals from organic farming in comparison to the conventional one; animals in the last case have much lower access to open pasture and are fed to a large extent with silage and concentrates.

Comparison of the Content of Harmful Substances in the Organic and Conventional Crops

Nitrates and Nitrites

Source of nitrates V and nitrates III (nitrites) in raw materials and plant products are nitrogen fertilizers used in agricultural production. In the nitrates III, nitrogen is at +3 oxidation state, and in the nitrates V, nitrogen is at +5 oxidation state. Scientific reports confirm a higher content of nitrates in food from conventional production methods, where crop fertilization takes place with the use of synthetic fertilizers.

Mineral fertilizers have easily available forms, and as a result, the excessive intake and accumulation take place in the root system and next in the leaves and other plant organs.

In organic production, only organic fertilizers (compost, manure, and green manure) are applied; in such case, nitrogen is less available to plants. Organic fertilizer in the soil is first decomposed by microorganisms and edaphon; next, humus is created, which is composed of the organic–mineral compounds. This process allows the plant collection of nitrogenous compounds in adequate amounts and in appropriate plants for time.

Therefore, the concentration of nitrogen compounds proved to be significantly lower in plants from organic farming than from the conventional one – the concentration of total nitrogen by 10% lower, nitrates by 30%, and nitrites by 87%. Health danger of excessive accumulation of nitrates (V) in plants is due to the fact, among other things, that these compounds are easily turning into nitrites (nitrates III) and may cause serious disease called methemoglobinemia, dangerous especially for infants, young children, and older people.

In turn, nitrites may be subject to further chemical changes and can react with tertiary amines creating nitrosamines, which are carcinogenic and mutagenic, causing gastrointestinal disease and leukemia.

Pesticides

The use of pesticides that are synthetic compounds, not found in nature, increases yields through protection against pests and diseases. However, on the other hand, pesticides do not have impact only on the unwanted organisms. Residues of these substances accumulate in plants and move along the food chain, disturbing the balance of natural environment and damaging the animal and human organisms.

Health effects depend on the dose that has been taken by the body; however, it is known that pesticides, even at very low doses, can cause diseases such as cancer or birth defects. In order to cut down the intake of pesticides together with the polluted food, the maximum permissible residue level has been established (MRL). Unfortunately, the MRL is usually based on relatively short-term tests for checking the impact of the individual substances on the lab rats.

There is a lack of knowledge on the consequences of consuming a wide variety of pesticides, which a man is exposed during the whole life; the synergistic action of a mixture of these compounds is possible.

The way to reduce health risks from pesticides is to avoid their consumption, which is possible thanks to the consumption of products from organic production methods, where it is not allowed to use pesticides. This recommendation should be followed especially by pregnant women, breast-feeding mothers, and children under the age of 3. Organic products very clearly differ from conventional products in terms of both quantities and the incidence of pesticide residues.

Recent studies have shown that the probability of the detection of pesticide residues was four times higher in conventional crops than in organic ones. The comparison of the levels of pesticide residues in vegetables and fruits in different countries indicates that it depends on the general level of pesticide use in the country concerned; the highest values were reported in the United States, where it was used and high doses of pesticides were applied; slightly lower in Belgium; and the lowest in Sweden, where low dose of synthetic plant protection products was always applied.

The results of the presented study may lead to the conclusion that a diet containing mainly organic products can decrease the levels of pesticide residues in the tissues of the human body.

Studies have confirmed that, together with the increasing share of organic products in the diet of lactating women, the content of pesticide residues in breast milk decreased. It has also been found that in body fluids (blood and urine) of children eating conventional products, the organophosphate pesticides' residues were up to six times more than in the case of children fed organically. The data mentioned earlier indicate that consumption of organic products is an effective way to reduce exposure to pesticides.

Heavy Metals

Sources of heavy metals, including cadmium, lead, arsenic, mercury, and zinc, are industry, transport, municipal waste, and agriculture. For example, cadmium in soil and food can come not only from phosphorous mineral fertilizers used in conventional agriculture but also from industry and transport. Therefore, test results were previously ambiguous – generally, more cadmium has been found in the raw conventional materials than organic, but sometimes, it was the other way around.

Recently, however, in the latest meta-analysis based on a large amount of data, it has been shown that the raw organically grown materials contain significantly lower cadmium concentrations (on average by 48%) than the conventional plants. This is essential for health because cadmium is an extremely toxic element: it damages the kidneys, resulting in anemia, bone disease, and proteinuria, and also affects the cardiovascular system. Cadmium accumulates in the pregnant smoking mothers disturbing the development of the fetus; carcinogenic activity of cadmium was also noted in rats. In the case of other heavy metal (lead, arsenic, and mercury) concentrations, no significant differences between conventional and organic raw materials have been found. More research is needed to clarify what is the impact of such treatments as composting on the increase of the organic matter and pH in soil and on the possibility to cut down the intake of heavy metals by plants.

Mycotoxins

The source of mycotoxins in foods is mushrooms produced by genera *Aspergillus*, *Penicillium*, and *Fusarium*. Environmental conditions such as high temperature and humidity are beneficial for the development of fungi.

Mycotoxins in food can pose a serious risk to the health of the consumer, causing, among other, carcinogenicity and impairment of the functioning of the immune system. Results of studies comparing the contents of mycotoxins in organic and conventional products are divergent. Some research indicates lower contamination with mycotoxins in the organic products compared to the conventional products. In other studies, organic products were more contaminated with mycotoxins than conventional ones; however, these were minor differences, and the contents of mycotoxins never exceeded acceptable values. Much of the comparative studies were cereals, including wheat, the results of which indicated lower contamination of the organic grain than conventional ones. In organic farming, there are practices dwarfing the formation of mycotoxins in agricultural crops as, for example, proper crop rotation and cultivation of varieties resistant to the toxin-producing fungi.

Comparison of the Nutritive Compounds Content in the Plant Organic and Conventional Crops

Vitamin C

Vegetables are a very rich source of vitamin C, which belongs to the antioxidant compounds. Vitamin C participates in many metabolic chains in human body. It stimulates the immune system (most important function), enhances detoxification of the organism, impedes the initial stages of the carcinogenesis, and helps to fight against heart diseases, allergy, and diabetes. In one of the recently published meta-analyses, comprising 33 available scientific publications comparing organic and conventional systems, it was found that the organic crops contained on average 6% more vitamin C in relation to the conventional crops and it has significant difference. Similar results were obtained in two other new studies based on meta-analysis.

Secondary Metabolites

Secondary plant metabolites, which include phenolic compounds, are compounds with a high antioxidative activity and with a wide range of health-related properties, for example, anticarcinogenic.

Secondary metabolites are produced by plants in response to external stimuli, for example, the attack of pests and other stressful conditions. They fulfill the role of regulators for physiological changes occurring in the plant. On the other hand, humans need to consume plants containing secondary metabolites, because they help to prevent infectious and noninfectious diseases (the last also called civilization diseases). One of the big groups of plant metabolites are phenolic compounds not containing nitrogen in their molecule, such as

phenolic acids, flavonoids, and terpenoids (carotenoids and xanthophylls).

All these compounds play an important role in suppressing the development of cancer, preventing atherosclerosis, strengthening the walls of blood vessels, reducing the risk of stroke, supporting the immune system, and preventing bacterial viral and infections. The second group of secondary metabolites is compounds containing nitrogen in the molecule as alkaloids, amines, amino acids, glycosides, and nonprotein glucosinolates. Their impact on human health is less known than the previously described group of substances.

The most recent meta-analysis of different 343 investigations concerning the chemical composition of organic and conventional crops showed that the content of a number of key antioxidants in organic raw materials and based on these products is up to 60% higher than in conventionally grown plants.

In the case of carotenoids, this analysis showed significantly higher content in organic versus conventional fruits; for vegetables and cereals, the differences were not statistically significant. A lot of research on the peppers and tomatoes indicates that the level of lutein and beta-carotene is usually higher in organic crops than in conventional ones, while a reverse situation is found with the level of lycopene.

Mineral Compounds

The first review paper concerning the content of mineral compounds in organic and conventional vegetables has shown that organic crops contained a higher level of trace elements such as iron, magnesium, and phosphorus than conventional ones. This may be due to the fact that the soil cultivated according to the principles of organic agriculture contains more microorganisms, which may contribute to the increasing availability of necessary mineral compounds to the plants.

The latest elaboration on the basis of meta-analysis shows that organic fruits and vegetables contain on average 5.5% more minerals (primarily boron, copper, magnesium, molybdenum, potassium, phosphorus, selenium, sodium, and zinc) than conventional crops. This may be important for human health in the case of ingredients such as magnesium, potassium, selenium, and zinc, which are dietary deficiencies recognized for the countries of central Europe.

Carbohydrates, Dry Matter, Keeping Quality, and Proteins

Many studies show a higher content of total and reducing sugars in the organic versus conventional crops. The latest big meta-analysis also detected significantly higher concentrations of total carbohydrates and reducing sugars and moreover significantly lower concentrations of proteins, amino acids, and dietary fiber in organic crops/crop-based compound foods. It also detected significantly higher concentrations of DM (dry matter) in organic crops.

The content of sugars in fruits and vegetables is very important. For example, the more sucrose the sugar beets contain, the higher is the technological value of this crop. Sugar level in crops is also important for the nutritional value and sensory quality. In the case of dietary fiber, it is not so obvious. The diet of Europeans today is too little of this component, and organic crops – according to research – provide even less dietary fiber than conventional ones.

Organic crops usually contain more dry matter than their conventional counterparts, which follows from the effect of 'water swelling' – tissues of the conventional plants collect more water than those of organic ones, because the plants absorb a lot of water together with mineral fertilizers that are applied. The higher dry matter content in organic than conventional crops is positive because it means more energy and nutritive density of organic food, which contains less water, but more nutrients per unit of mass. The higher dry matter content translates to higher palatability of the organic crops due to the greater concentration of fragrance and taste, including essential oils. Less water in the tissues means also lower susceptibility of organic crops to decomposition processes during the keeping period compared to conventional materials. From a review of over 50 different studies, it appeared that conventional crops showed 38% loss of their initial biomass during the winter, while organic only 28%.

Several studies indicate that the amount of total proteins is lower in the organic crops than in the conventional ones. The latest meta-analysis showed a significant difference in this respect for cereals. However, the attention should be paid to the quality of the proteins in the organic crops, which is characterized by a higher content of essential amino acids (lysine, cysteine, and methionine), reflecting their higher biological value, compared to conventional crops. The differences in the composition of proteins and amino acids are derived from different nitrogen fertilizations used in the organic versus conventional systems.

Sensory Values of the Plant Products

Both regular consumers and specially trained panelists in many cases much better judge the sensory properties of organic crops than conventional ones. This mainly applies to vegetables such as carrots, potatoes, tomatoes, and peppers and fruits such as apples, black currants, grapes, and strawberries. Food preference tests carried out on rats have shown that animals given a possibility to select feed of organic or conventional origin clearly prefer and select more frequently organic feed, for example, wheat, carrots, and beetroots. These results are probably associated with a higher concentration of fragrance and taste in organic versus conventional crops, including the higher content of sugars and more favorable ratio of sugars/organic acids found in the organic crops.

Quality of the Animal Products from Organic versus Conventional Production

Milk

The composition of milk depends mainly on the diet and maintenance of animals, different in organic and conventional system. A number of studies have shown that proteins in organic cow milk are more beneficial than conventional milk; examples of these proteins are α-lactalbumin, β-lactoglobulin, and lactoferrin. Milk from the cows grazed or fed with fresh

feed, rich in different species of plants, is characterized by a significantly higher ratio of polyunsaturated fatty acids (PUFA) to saturated fatty acids (SFA) and a more favorable ratio of PUFA Ω-6 to Ω-3.

Organic milk contains more PUFA, CLA, cis-9, trans-11, t-vaccenic acid (TVA), and α-linolenic acid (LNA) compared with conventional milk. These substances are recognized as inhibiting development of atherosclerosis, cancer, and inflammatory processes.

During the period of grazing, cow milk from organic farms has a higher content of fat-soluble vitamins (A, D, and E) than the milk of animals that do not utilize pasture. The concentration of minerals in milk depends on their contents in soil and green fodder. Some reports indicate too low content of minerals in organic milk because of the prohibition on the use of the mineral components in the feed supplementation of cows. However, the milk from organic production should be considered as very valuable. Other things to determine are how much impact has the management of husbandry and how much natural fresh feed is produced without the participation of the synthetic mineral fertilizers and pesticides. Distinguishing of these factors in the experimental layout is very difficult due to the legal regulations, prohibiting to keep animals only within the buildings in organic farming.

Meat

The factors mentioned earlier have an impact on the quality of not only the milk but also meat from animals of organic farms. The main factors are also the composition of the feed and the animals' access to an open pasture for many months of the year, which mainly affects ruminants. Impact on the quality of the meat is similar as in the case of milk. The nutritional quality of organically produced meat is affected by organic diet and breeding conditions. A number of studies confirm the lower total fat content of organic farm meat and this means a decreased calorific value. Carcasses from organically reared animals have usually higher content of intramuscular fat, positively affecting sensory properties, better in comparison with the conventional meat, which has been confirmed in several studies. Moreover, the fatty acids' profile in organic meat is considered to be more beneficial to human health. Organic meat contains more favorable proportions of unsaturated fatty acids, including *n*-3 acids, and decreased level of saturated ones. The ratio of n-6:n-3 PUFA in meat from organic and conventional husbandry differs significantly, for example, in conventional beef[29] 2:1 and in organic one[4] 6:1. The last ratio is much more recommended for human health by nutritionists – consumption of organic meat can cause anticancer effects, stimulate the immune system, and prevent coronary heart diseases. A negative side is that organic animals have lower total weight of carcasses (lower weight gain) at the slaughter time, making organic husbandry less profitable from the economic point of view. Moreover, organic meat and meat products have higher TBARS value and faster lipid oxidation processes, shortening their shelf life period. Some consumers are complaining because of the lower tenderness in case of organic pork compared to the conventional meat.

Eggs

So far, relatively little research comparing the composition and nutritional value of eggs from organic and conventional production has been published. A few studies show that organic eggs have a lower unit weight than conventional eggs, which have proportionally thicker and stronger shell, smaller egg white, and bigger egg yolk. It has been proved also in the Netherlands, Denmark, and Italy that egg yolks from organically raised hens contained significantly more carotenoids than conventional ones; this was primarily lutein, as well as beta-carotene and zeaxanthin. At the same time, it has been demonstrated that the level of these valuable substances increased as the growing access of hens to natural pasture, confirming the impact of the consumption of roughage (grass and other plants) on the level and composition of carotenoids in eggs. Organic yolks contained also more α-tocopherol and flavonoids compared to the conventional ones.

In the Netherlands, it was found that carotenoid profile was so characteristic for eggs from organic farming that could be used to identify these eggs for the needs of the market. This is needed because of a commercial fraud that sometimes happens; organic eggs are more expensive, and dishonest traders try sometimes to sell conventional eggs as organic. This practice also applies to many other products, for example, wine and various fruits and vegetables. As in the case of milk and meat, the composition of fatty acids in eggs depends on the access of hens to the open pasture. The fatty acid composition of the yolk is significantly affected by pasture. The eggs of hens having bigger access to the pasture showed lower concentrations of polyunsaturated fatty acid (PUFA) *n*-6 and a higher percentage of PUFA *n*-3 than eggs of hens with limited access to the pasture.

Summary

Improper diet, unhealthy lifestyle, and food and environment contamination are the main causes of the so-called civilization diseases, also known as chronic noninfectious diseases: diabetes, obesity, atherosclerosis, cancer, and allergies. The prevention of these diseases and their treatment require not only the observance of proper diet (diet and lifestyle) but also eating the best quality food. From most of the comparative studies, it appears that food from organic production can bring beneficial effects in the prevention of the mentioned diseases.

Food with a high biological value contains the right amount of nutrients with the lowest content of harmful substances. Organic food has these features (Figure 2) – low content of contaminants and high content of vitamin C, carotenoids, and phenolic compounds having strong antioxidative properties.

In addition, higher content of sugar and dry matter in organic crops means that they have a higher technological quality and, at the same time, better and more intense flavor than the conventional ones.

Current research also indicates that despite the fact that synthetic fungicides are not used in the organic farming to combat fungal diseases, the level of mycotoxins in organic and conventional cereals is similar. Also, studies on the microbiological contamination indicate parallel level of pathogenic bacteria in organic and conventional crops. Therefore,

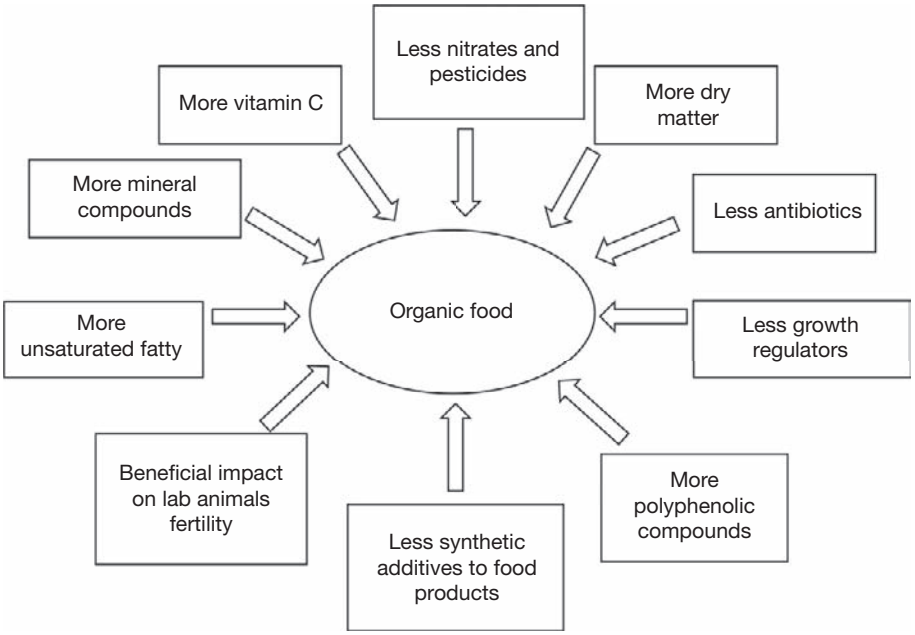

Figure 2 Quality features of the organic food in comparison to the conventional food, own elaboration.

consumption of organic products compared to conventional ones does not represent a higher risk to health, particularly if they are subjected to adequate heat treatment.

Described quality features of organic food (Figure 2) constitute a good basis to formulate a hypothesis that regular consumption of organic foods should positively affect the health of consumers. Preliminary results from the research on experimental animals suggest more favorable characteristics of fertility and survival rates of animals fed with organic feed compared to those fed with conventional feed. Also, studies in humans suggest that the regular consumption of milk and milk products from organic production by mothers of children up to the age of 2 was positively correlated with the lower incidence of atopic diseases among these children. Preliminary studies on large groups of consumers indicate, furthermore, that the persons eating predominantly organic products better evaluate their health status than the consumers basing on the conventional products.

The mentioned results seem to confirm the initial hypothesis of the positive impact of organic food on the consumer health, but further studies conducted on animals and on humans are necessary in order to confirm the preliminary results and to understand the mechanisms of the organic diet impact on animal/human health.

Organic Food: An Introduction

Agricultural products typically have a price dictated by the international commodities market and it does not meet often the income needs of farmers with small production volumes. To add value to these products, organic production may be an alternative way to increase the income, helping the rural development and environmental integrity.

It is widely recognized that patterns of food consumption have experienced rapid change over the past few years as the result of concerns on environmental sustainability, development, nutritional aspects, and also health issues. The consumption of organic food cannot guarantee itself to improve the consumer's health, but they can represent an important part of a sustainable and healthy diet.

Organic food can be defined as the product, both fresh and processed, obtained or made according to the standards of organic agriculture. According the International Federation of Organic Agriculture Movements (IFOAM) (2009), organic agriculture is a production system that sustains the health of soils, people, and ecosystems, using organic pesticides and avoiding, for instance, the use of antibiotics and growth hormones. It relies on tradition, innovation, and science, looking up to benefits for people and for the environment, promoting the quality of life of all stakeholders involved in this chain. The organic producer must respect established norms in all production stages, from the seeding process to packaging, always concerning about the process' impact on the natural environment.

The main difference between conventional and organic farming refers to the way of land use. The conventional one is based mainly on the inputs (insecticides, herbicides, fungicides, bactericides, and fertilizers are all based on soluble salts and organic raw materials). The organic farming technology is based on the process technology, based on food production without the use of pesticides and chemicals in a self-sustainable environmental fertilizer.

Among the various possible strategies, large and small producers have sought the development of organic market, the alignment with the global trends of organic production, and the appreciation of food safety, through the implementation of traceability programs, quality patterns, and certification. Apart from these systemic initiatives, it is still necessary to coordinate and support a large number of small organic producers, seeking strategies that allow better income opportunities and greater chances of inclusion of its production in distinguished distribution channels. Internationally, one of the successful strategies has been the adoption of certified organic system. Organic agriculture is one of the best practices in ensuring environmental sustainability; it sustains the fertility of soils, ecosystems, and sustains people's health. As an ultimate goal, this system helps to develop ways to protect small producers from the market fluctuations, guaranteeing better economical margins and greater sustainability in their activities.

Organics' Global Market

Despite the fact that the largest domestic markets of organic food are located in North America (the United States primarily) and Europe (mainly in Germany, with 7 billion euros in 2012), the largest number of organic producers, however, is located outside those markets.

In 2012, the distribution of the organic agricultural land was Oceania (32%), Europe (30%), Latin America (18%), Asia (9%), North America (8%), and Africa (3%), the principal countries being Australia, Argentina, the United States, and China. About one-third of the world's organic producers are located in developing countries and emerging markets. Data from 2012 show that organic producers (about 1.5 million) are located in Latin American, Asia, and Africa, with a higher production growth rate, especially in the food sector, such as fruits, vegetables, grains, herbs, and spices. India was the country with the largest number of organic producers in 2012, followed by Uganda and Mexico. Not only production but also demand growth in developing countries and emerging markets is also remarkable.

Organic Agriculture: The Origins

The history of organic agriculture began in the 1920s with the work of the British researcher Albert Howard on the agricultural practices in composting and use of organic fertilizers used by farmers in India. Around the same time, organic farming was widespread in France through the use of techniques such as crop rotation, green manures, manure, crop residues, straw, and other plant or animal wastes and natural control of pests and diseases. It also involved avoiding the use of fertilizers, synthetic fertilizers, and pesticides in the management of crops or artificial growth accelerators or fattening in the handling of animals, applying only the mandatory vaccines. The herbal medicine, homeopathy, and acupuncture treatments are used in cases of diseases. A similar concept is the biodynamic farming that began in Germany in 1924 with Rudolf Steiner and is based on harmonization and balance of the plant (land, plants, animals, and man) using the influences of the sun and moon. The farm is considered as a systemic organism and one should therefore only use organic elements produced there to establish the link between the forms of matter and energy in the natural environment. Mokiti Okada, in 1935, defined what would be a natural agriculture. According to his philosophy, there are spirit and feeling in all living things (plants and animals). Soil is the primary source of life and used the inputs available at the production site for composting it, thus strengthening its natural energy. Its goal is to get products for agricultural systems that are similar to the original ecosystem conditions. In parallel, the concept of permaculture was developed in Australia in 1971 by Bill Mollison; it consists of an integrated model of agriculture to the environment; however, it

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00506-7

also uses information on the direction of the sun and wind to determine the spatial arrangement of plants. These first movements are not similar to the current organic production because they had no standards, regulations, or interests in environmental issues and food safety. This set of production practices came to be known as alternative agriculture. This term originated in 1977, when the publication of a report containing an analysis of all unconventional streams of agriculture gathered under such generic name. This report was made by the Ministry of Food, Agriculture and Fisheries of the Netherlands and is known as the 'Dutch report.' In the 1980s, agroecology defines a set of alternative farming practices also incorporating a social discourse. Its authors Dr Miguel Altieri and Dr Stephen Gliessman, the University of California, the United States, emphasize the breadth of the concept dealing with complex interactions between people, cultures, soil, and animals. In the late 1980s and throughout the 1990s, the concept of sustainable agriculture became popular. This was very broad and full of contradictions and should be considered more as a goal to be achieved than simply a set of agricultural practices.

The various terms mentioned earlier in the text (organic, biodynamic, natural, permaculture, agroecology, sustainable agriculture, etc.) are considered forms of organic agriculture, provided that they suit the production methods and marketing standards. In short, these different streams are the basis of the current organic agriculture. A sustainable production system through the management and protection of natural resources, without the use of harsh chemicals to humans and the environment, keeping the increase of fertility, soil life, biological diversity, and respecting the cultural integrity of farmers are the core principles of organic agriculture.

Organic production, in the 1970s, is related to the philosophical movements linked to alternative forms of life in contrast to the consumerism of modern society. The products were sold directly from producer to consumer. With growing environmental awareness and the search for a healthier diet, there was an increase in the consumption of organic products. Similarly, production cooperatives of organic products were organized in the 1980s, as well as the emergence of restaurants dedicated to natural food. However, it was at the end of the 1990s that organic products are now sold in supermarkets. As in the rest of the world, the existence of a profitable and growing market has attracted new entrepreneurs, aimed mainly to the profits from the activity, and, while maintaining the technical principles of organic agriculture, the philosophy that originated from the movement is increasingly farther.

Organic Certification

Within the food market, information asymmetry is present; consumers do not have usually the same level of information that producers have about the product itself, and this may cause an opportunistic behavior or negotiations' difficulties. Every asymmetry implies incomplete information and increases transaction costs throughout the supply chain, resulting in losses for one or more agents. Thus, certification has emerged as an alternative to eliminate or reduce these asymmetries.

A certification can be understood as a clear definition of the attributes of a product, process, or service associated with instrumental guarantee that they fit into predefined rules before the transaction. The concern over food security has given rise to many requirements to ensure organic food patterns. Certification and traceability have become commonplace in this new context. This is linked to the specificities related to organic products: due to their intrinsic characteristics, the differentiation of organic products cannot be easily identified and evaluated. Organic food can be classified as credence good, as its key attributes cannot be evaluated by consumers even after purchase and consumption. This feature justifies the need for monitoring of the production by an independent agent as the certifying companies, which are responsible for the warranty offered with respect to established procedures for organic farming in an organic label. The organic label is not owned by the producer who receives it. The certifying organization is who owns it and both parties have to sign a contract. However, the label is an achievement of the producer and reflects that the productive system complies with national (and international standards in some cases) of organic production, but normally, even the internal standards are based on international ones. Therefore, their use must be nurtured so that their credibility is always preserved, and they can be recognized by consumers as a highly desirable notion and added value.

Assuring the Organic Standards

The IFOAM is a global organization that accredits certifiers, creating an acceptable international organic standard. It includes the International Organic Accreditation Services (IOAS), which is responsible for the accreditation of the certification bodies and ensures the equivalence of accreditation programs in an international standard. In 1972, the agency developed a guarantee scheme based on a democratic process of consultation with all the agents involved in organic production. This process resulted in a structure called the *Organic Guarantee System*, whose content is divided into (1) basic standards, (2) criteria for accreditation, (3) accreditation program, and (4) seal.

Certification audit process is the mechanism most widely used to protect organic farming from fraud. Public or private accredited certification bodies use internationally recognized criteria and procedures for conformity assessment such as the ISO 65, recognized by IFOAM, and the European standard CEC 2091/91, in addition to the technical requirements established by the specific country legislation for organic agriculture, if needed. The basis of the certification audit is that the conformity assessment has to be made by an independent body with no direct link with anyone who buys or produces. After approval, the certification body is responsible for including the producer in the official register list and allows him or her to use the label.

The certifying bodies draw up an institutional framework that can be called 'self-regulation,' since adherence to their respective certification programs is voluntary. This logic allows

some standardization of the requirements so that there are legitimacy and trustworthiness among agents in the market, particularly consumers, producers, traders, and certifiers themselves.

Concluding Remarks

The certification label of an organic food assures the consumers a product free of chemical contamination. It also ensures that this product is the outcome of an agriculture that works on behalf of the environment protection, besides biological and nutritional values. Furthermore, it also attends to social aspects related to the quality of life in the land (for producers) and in the community (for consumers). The label ensures that the whole process was checked.

However, the organic certification process has different standards depending on the country, representing the need of recertifying organic products according to the regulations of the importing country. In the European Union, for example, each country has a distinguished certifying body (usually private companies) and standards do overlap. In the United States, the Department of Agriculture is the main certifying body. On the other hand, each country in the European Union has different certification organizations. The lack of harmonization of production standards and control makes the organic certification process complex and involves high costs, especially for the exports. In this way, the organic production might represent a potential huge international market for producers from developing and emerging countries, but the decision of which certification to comply with involves several factors.

Large retailers perceived the importance of this growing market and offer a diversity of organic food products on their shelves. The supermarkets might help organic suppliers to get the certification. Besides the technical process, the knowledge of attributes more valued by consumers helps retailers to play the role of coordinators of the organic supply chain stimulating more small producers to adhere to organic certification, helping them to upgrade their production practices and improve their income. Street markets are an important distribution channel for organic product, but some of them use self-auditing. There is no third-party or certification body to control if the production processes really follow the organic production guidelines. In this way, consumers need to trust that no environmental damage was involved in the production of the food product.

The next step for organic production and control is a global standardization of the processes that will motivate more food producers to convert their conventional production to a more sustainable one, delivering a safe, healthy, and less expensive food to society.

Introduction

Osteoporosis is a disease characterized by a loss of bone mass (BM) and strength below the threshold level required for mechanical support of normal activity, as well as an increased occurrence of non-traumatic fractures. It is a disease that gradually causes the bones to become fragile and break easily. It is a metabolic bone disorder characterized by a diffuse decrease in the amount of bone. It affects both men and women, mainly as they grow older. Loss of BM occurs as a normal part of the aging process; however, in the individual with osteoporosis, the loss is so extensive that it falls below the threshold of a fracture. By their 30s, most people begin to slowly lose more bone than can be replaced. As a result, bones become thinner and weaker in structure.

Osteoporosis is the most common disease in elderly women, affecting millions of white women in the US. More than 25 million Americans have osteoporosis, and 80% of them are women. Women of northern European descent who have an inadequate dietary calcium intake are at the greatest risk of developing osteoporosis. Fractures that result from osteoporosis are a major and growing concern for public health systems. As the population ages, the number of fractures worldwide will double or triple in the next 50 years. Osteoporosis causes 1.3 million fractures, with 500 000 vertebral, 250 000 hip, and 240 000 wrist fractures costing $10 billion per annum. In addition to this direct expenditure on treatment, enormous economic costs and incalculable losses occur in terms of disability, pain, and premature death. Only about 25% of women over 45 years of age who sustain a hip fracture regain prefracture mobility.

An increased risk of falling contributes to a high incidence of fragility fractures in osteoporotic patients. Osteoporosis is likely to be caused by complex interactions among local and systemic regulators of bone cell function. The heterogeneity of osteoporosis is due to differences in the production of systemic and local regulators, enzymes that produce or inactivate local regulators, changes in receptors, nuclear transcription factors, and signal transduction mechanisms. An increase in the elderly population is directly proportional to the number of cases of osteoporosis.

Historical Background

Osteoporosis has probably existed throughout human history, but only recently – as the human lifespan increases – has it become a major clinical problem. In the early nineteenth century, Sir Astley Cooper – an English surgeon – noted the lightness and softness of bones, which is observed in the more advanced stages of life, making them prone to fractures. The term osteoporosis was first coined by Johann Lobstein at about the same time. Dr. Fuller Albright, an American physician and endocrinologist in 1940, described the postmenopausal osteoporosis, and proposed that it was the consequence of impaired bone formation due to estrogen deficiency. Furthermore, the concept of two forms of osteoporosis (one related to estrogen deficiency at the menopause stage and the other to calcium deficiency and aging of the skeleton) was proposed. This was replaced by the more recent concept stating that osteoporosis represents a continuum in which multiple pathogenic mechanisms congregate to cause the loss of BM and microarchitecture deterioration of the skeletal structure.

Hip fracture rates are the highest in Caucasian women living in temperate climates. These rates are somewhat lower in women from Mediterranean and Asian countries, and are lowest in African women. Countries like Hong Kong have seen significant increases in age-adjusted fracture rates in recent decades, while those in western countries largely appear to have reached a plateau. Within the last decade, genetic studies have facilitated the identification of many of the regulatory mechanisms that have been linked to osteoporosis.

Human Skeleton

The human skeleton is a collection of bones – held together by ligaments, tendons, muscles, and cartilage – in which crystals of calcium phosphate are embedded, providing a framework for the body. It holds and protects the organs. The adult skeleton consists of 206 bones. A newborn has more than 300 bones, but many of these fuse together as a child grows into an adult. Bones are of two types. First is cortical bone, also called compact bone. With a hard outer layer making up to 80% of the total BM, it gives white color to the bones. Second is the trabecular bone, also called cancellous or spongy bone. This forms the inside and makes up the remaining 20% of the total BM. It is light and porous, and makes up most of the bone material. This tissue also has space for blood vessels and bone marrow. Both cortical and trabecular bone contribute to the overall strength of a bone. The trabeculae function as a storage site for calcium phosphate crystals. As osteoporosis progresses, the cortex also thins and weakens. These bones can be injured easily, even without a serious accident or fall. Fractures have been known to result from an affectionate hug.

Bone Strength

Bone mineral density (BMD) is determined by the amount of bone present in the skeletal structure, that is, the higher the

BMD, the stronger the bones, and vice-versa. It is greatly influenced by genetic factors which, in turn, are sometimes modified by environmental factors and medications. Normally, BMD accumulates during childhood and reaches a peak by around age 25, which is maintained for about 10 years. After age 35, both men and women normally lose 0.3–0.5% of their BMD per year as part of the aging process. Estrogen is important in maintaining BMD in women. When estrogen levels drop after menopause, loss of BMD accelerates. During the first 5–10 years after menopause, women can suffer up to 2–4% loss of BMD per annum. This can result in the loss of up to 25–30% of their BMD during that time period. The accelerated bone loss after menopause is a major cause of osteoporosis in women, referred to as postmenopausal osteoporosis.

Osteoporosis: Role of Diet and Nutrition

Many nutrients and food components can potentially have a positive or negative impact on bone health. They may influence bones by various mechanisms, including: alteration of bone structure, the rate of bone metabolism, the endocrine system, and homeostasis of calcium and possibly of other bone-active mineral elements. Among the essential nutrients, vitamins A, B, C, and K also play important roles in bone health. Reduced levels of calcium, vitamins, estrogen, and physical activity have been implicated in the increased incidences of osteoporosis (Table 1).

Calcium

Calcium is one of the main bone-forming minerals, and an appropriate supply to bones is essential at all stages of life. Calcium is required for normal growth and development of the skeleton; 99% of the calcium in the body is in the skeleton. Inadequate calcium intake during childhood and adolescence can impair bone development and may prevent the attainment of optimal peak BMD during early adulthood. In older adults, inadequate calcium intake accelerates bone loss and likely contributes to the development of osteoporosis. Sufficient calcium intake is critical to achieving optimal peak BMD, which modifies the rate of bone loss associated with aging. Adequate levels of calcium may slow the development of osteoporosis, as it suppresses bone resorption and it promotes bone mineralization/calcification – leading to the strengthening of the bones. A very small amount of calcium is required for muscle contraction, nerve impulse transmission, and other regulatory functions of the body. Although the importance of calcium to bone health is well-recognized, adequate calcium intake alone is not enough to prevent bone loss; loss that could lead to osteoporosis and osteoporotic fracture.

In addition to the amount of calcium in the diet, the absorption of dietary calcium in foods is also a critical factor in determining the availability of calcium for development and management of bones. The calcium that is lost daily through the urine, sweat, and feces must also be replaced by the calcium from the skeleton. To prevent a reduction in BM, calcium intake and absorption must balance calcium losses. With increasing age, calcium absorption decreases, and is lower in women who have osteoporosis than in women who do not have osteoporosis. There is a need to identify the foods and the food ingredients that may positively influence calcium absorption, and to ensure the calcium's bioavailability from these foods. This approach is important for individuals who fail to achieve the recommended dietary level of calcium, and for those with a low efficiency of intestinal absorption of calcium.

The current recommended daily allowance of calcium is 1 g a day. It is recommended that women after menopause increase their calcium intake to 1.5 g a day to maintain calcium balance. Calcium in food occurs as salts, or with other dietary constituents in the form of complexes of calcium ions. Calcium

Table 1 Potential nutritional determinants of bone health

Beneficial factors	*Potentially detrimental dietary factors*
Nutrients	Dietary factors/nutrients
Calcium	Excess alcohol
Copper	Excess caffeine
Zinc	Excess sodium
Fluoride	Excess fluoride
Magnesium	Excess/insufficient protein
Phosphorus	Excess phosphorus
Potassium	Excess/insufficient vitamin A
Vitamin C	Excess n-6 PUFA
Vitamin D	
Vitamin K	
B vitamins	
n-3 fatty acids	
Protein	
Novel bioactive food compounds	
Whey-derived peptides	
Phytoestrogens	
Nondigestible oligosaccharides (especially inulin-type fructans)	

Source: Cashman, K. D. (2006). A prebiotic substance persistently enhances intestinal calcium absorption and increases bone mineralization in young adolescents. *Nutrition Reviews* **64**:189–196.

must be released in a soluble, and probably ionized, form before it can be absorbed. The increased bone resorption that occurs with reduced levels of calcium affects both cortical and trabecular bone. The incidence of fractures occurring at sites composed of substantial amounts of both cortical and trabecular bone (the hip, pelvis, proximal humerus, and tibia) increases slowly with aging until late in the life cycle, when it rises exponentially.

Phosphorus

Phosphorus is an essential bone-forming element. Its adequate supply is necessary throughout life. Both calcium and phosphorus are required for the appropriate mineralization of the skeleton. A depletion of serum phosphate leads to impaired bone mineralization and compromised osteoblast function. In the case of very low birth-weight infants, the dietary intake of phosphorus influences the risk of osteoporosis.

Magnesium

Magnesium is required for bone and mineral homeostasis, and in bone crystal growth and stabilization. Magnesium intake has been reported, in some of the studies, to be positively associated with both BMD and bone resorption markers in middle-aged women. Magnesium is one of the nutrients in fruits and vegetables that contribute to an alkaline environment, which may promote bone health by a variety of mechanisms, making it difficult to examine the effects of magnesium alone.

Fluorine

Fluorosis causes joint stiffness, limb deformities, and staining of the teeth. Due to naturally high levels of fluoride in drinking water, fluorosis occurs in several parts of the world, such as South Africa, Tanzania, and India. Because of its effects on stimulating osteoblastic activity and inhibiting bone crystal dissolution, there has been considerable interest in the use of pharmacologic doses of sodium fluoride for the treatment of osteoporosis. At levels below those associated with fluorosis, and when combined with a low calcium intake, high fluorine intake has been associated with widened bones, reduced BMD, and osteoporosis of cortical regions of the skeleton—possibly due to excessive urinary calcium excretion.

Vitamins

Vitamin D is synthesized in the skin when exposed to ultraviolet radiation from sunlight, and can be obtained from the diet. Older people tend to have reduced endogenous production of the vitamin for a variety of reasons, and they become more dependent on dietary sources to maintain adequate vitamin D status. Younger people also have a reliance on dietary sources of vitamin D, especially if they have limited exposure to sunlight or if they are dark skinned and are living outside of the tropics. It is a well-established fact that marginal vitamin D deficiency is common, and it increases the risk of osteoporosis. The active form of this vitamin increases the intestinal absorption of calcium and prevents urinary calcium loss. In the absence of vitamin D, calcium absorption is not efficient enough to satisfy the body's needs, even when calcium intake is adequate. Vitamin D deficiency contributes to accelerated bone loss, increasing fragility, and also neuromuscular impairment leading to the increased the risk of falling. Calcium and vitamin D supplementation is now advocated as the basic minimum for treatment of osteoporosis and secondary fracture prevention in women several years after menopause.

Among the vitamins, thinning of the cortices and loss of trabecular architecture are common features of stark vitamin C deficiency. Ascorbic acid is a cofactor in the hydroxylation of lysine and proline, and is therefore important in the cross-linking of collagen fibers in bone.

Vitamin K is a cofactor in the gamma carboxylation of glutamic acid, which is important in the production of osteocalcin—one of the main noncollagenous proteins of bone. Inverse relationships have been reported between low vitamin K intake in older people, BMD, and the risk of fragility fractures—possibly through an increase in the amount of osteocalcin produced in its under-carboxylated and less fully functional form.

It is reported that a high intake of vitamin A as retinol has been associated with hip fracture in Sweden. There are studies linking low intakes of vitamin B6 and other B-vitamins with low BMC and hip fracture.

Estrogen

Estrogen has a protective effect on the bone by suppressing resorption. Estrogen deficiency is a major contributory factor to the development of osteoporosis in women, and hormone replacement therapy (HRT) remains the mainstay for prevention of bone loss in postmenopausal women. Deficiency of estrogen causes bone loss after menopause in women in their 70s and 80s, as evidenced by the fact that estrogen treatment rapidly reduces bone breakdown in these older women. This effect occurs for several reasons. Estrogen improves calcium absorption in the intestinal tract and decreases calcium loss in the urine.

Increased levels of estrogen lead to elevated levels of vitamin D in the circulatory system in healthy human subjects. The hypothesis that the estrogen deficiency is critical to the pathogenesis of osteoporosis was based initially on the fact that postmenopausal women, whose estrogen levels naturally decline, are at the highest risk for developing the disease. Estrogen stimulates the production of calcitonin, which prevents removal of calcium from the bone. The level of estrogen required to maintain relatively normal bone remodeling in older postmenopausal women is lower than that required to stimulate classic target tissues, such as the breast and uterus.

Trabecular bone tends to be more sensitive than cortical bone to changes in the level of estrogen. Decreased levels of estrogen have been implicated in the high incidence of Colles' and vertebral fractures noted in women. These sites are composed primarily of trabecular bone. Clinical trials involving older individuals at high risk for calcium and vitamin D

deficiency indicate that supplementation of both can reverse secondary hyperparathyroidism, decrease bone resorption, increase BD, decrease fracture rates, and even decrease the frequency of falling.

Proteins

Protein intake is a determinant of urinary calcium excretion. Animal protein (which is rich in sulfur-containing amino acids) contributes to an acidic environment, leading to higher excretion of calcium in urine. High protein intakes have been linked with hip fracture because the consumption of protein, particularly in the form of meat and dairy products, is greatest in countries where hip fractures are common. A low protein intake was associated with the greatest bone loss. At present, there is no firm evidence on which to base recommendations about optimal protein intake for bone growth, or for the prevention of osteoporosis.

Physical Activity

Physical activity enhances bone strength by optimizing BMD, and improving bone quality reduces the risk of falling. Resistance training increase BM and prevents age-related declines in BMD. Bone atrophy with accentuated calcium losses has been reported after periods of inactivity, either from prolonged bed rest or from immobilization. The emphasis of physical exercise programs in elderly osteoporotic patients should be on improving muscle strength and balance. They should be encouraged to participate safely in any activity in a frequent, regular, and sustained manner. The exercises should be weight bearing and easy to complete and should fit into their daily routine. A program of walking, sitting, and standing exercises (or water aerobics) can be recommended to start with, and gradually increased to more rigorous activity. For patients with an osteoporotic fracture, physical exercise programs can help reduce pain and increase functional capacity. The program should increase the patient's ability to perform routine daily activities while minimizing the risk of further fractures. For patients with vertebral fractures, back flexion exercises have been found to be harmful and to increase the risk of new vertebral fractures. These patients will benefit from resistance exercises that strengthen back extensor muscles.

Lifestyle

An inactive lifestyle or extended bed rest tends to weaken bones. Cigarette smoking is bad for bones as well as the heart and lungs. Similarly, excessive consumption of alcohol increases the risk of bone loss and fractures.

Risk Factors for Osteoporosis

Low BMD is only one of several risk factors underlying osteoporotic fracture. Other factors include both skeletal and non-skeletal factors. The BMD in the later portion of life of an individual depends on the peak BMD achieved during growth, and the rate of subsequent age-related bone loss. Development of maximal BMD during growth and reduction of loss of bone later in life are the two main strategies of preventing osteoporosis. Consequently, any factor that influences the development of peak BMD or the loss of bone in middle-age will affect later fracture risk. The factors like low BMD, physical frailty, propensity to fall, and a history of fracture also appear to be strong predictors of osteoporosis.

Those factors that influence the BMD are broadly grouped into non modifiable factors (gender, age, body [frame] size, genetics, and ethnicity) and modifiable factors (hormonal status [especially sex and calciotropic hormone status], lifestyle factors including physical activity levels, smoking and alcohol consumption patterns, and diet). The interactions of these genetic, hormonal, environmental, and nutritional factors influence both the development of bone to peak BD at maturity and its subsequent loss.

Symptoms of Osteoporosis

Osteoporosis is often called a silent disease because bone loss occurs without symptoms. The lack of any symptoms may continue for decades because osteoporosis does not cause symptoms until a bone fractures. Patients may not be aware of their osteoporosis until they suffer a painful fracture. The symptom associated with osteoporotic fractures usually is pain at the site of fracture. The symptoms in men are similar to those in women. The disease remains unnoticed until the bones become so weak that a sudden strain, bump, or fall causes a hip to fracture, or a vertebra to collapse. Collapsed vertebrae may initially be felt or seen in the form of severe back pain or spinal deformities.

Diagnosis of Osteoporosis

The BMD refers to the amount of minerals in a specific area of the bones. It gives an overall picture of bone health. A BMD test compares the person's results with the optimal peak bone density of a healthy young adult of that sex. Tests are safe and painless, with no needles or other invasive instruments. Typically, the test is performed with a central dual energy x-ray absorptiometry machine. It also may be done with computed tomography or an ultrasound.

Treatment of Osteoporosis

A comprehensive treatment program includes a focus on proper nutrition, exercise, and safety issues to prevent falls that may result in fractures. Treatments with medication can be broadly divided into two categories: antiresorptive (or anti-catabolic) and anabolic agents. Antiresorptive drugs help slow bone loss, and studies show they can decrease the risk of fractures.

Antiresorptive agents (which include oestrogen), selective estrogen receptor modulators, and bisphosphonates reduce bone resorption (and subsequently bone formation), preserving BMD. Anabolic agents, including full-length parathyroid

hormone (PTH1-84) and teriparatide (PTH1-34), stimulate bone formation (and subsequently bone resorption), thereby increasing BMD. Strontium ranelate is another agent that reduces fracture risk. It has weak effects on bone remodeling and probably improves bone strength mainly through effects on bone material properties.

HRT may consist of estrogens alone, or in combination with progestin. Even at low doses, HRT helps to slow bone loss, reducing the risk of osteoporosis and fractures in women who have gone through menopause. HRT is safe and effective for most women under the age of 60 who have osteoporosis and who also need hormonal treatment to relieve the symptoms of menopause.

It was demonstrated in recent studies that HRT decreases fragility fracture risk by 20–35%. However, its discontinuation results in acceleration of bone turnover, decrease in BMD, and eventual loss of anti-fracture efficacy. It was also reported that even low doses of HRT protects bone turnover markers levels and prevents bone loss. At present, HRT is regarded as the acceptable treatment for osteoporosis only after all other treatments have been considered, and when all the risks and benefits have been carefully explained to the patient. It has also been observed in some of the studies that the HRT can also induce vaginal bleeding and breast tenderness.

Conclusion

Osteoporosis is a treatable disease and in some cases, preventable. It is a complex, polygenic disorder. The contributions of specific gene polymorphisms are likely to be relatively small, but may still be clinically important. If treatment begins early, patients can be spared pain and suffering, and will likely lower the overall health cost incurred from treatment of osteoporosis complications. Preventative and therapeutic treatment should be given before signs occur, or as early in the disease as possible. To keep pace with the modern developments in research, large cohort studies using standardized genotyping methodology are needed to better define the role of specific genes in pathogenesis of osteoporosis.

Oxidation of Food Components

R Mozuraityte and V Kristinova, SINTEF Fisheries and Aquaculture, Trondheim, Norway
T Rustad, Norwegian University of Science and Technology, Trondheim, Norway

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Originally, oxidation meant a reaction with oxygen to form an oxide, since oxygen was the first known oxidizing agent. However, later, the term oxidation has been expanded to include oxygen-like substances that accomplish parallel chemical reactions. Ultimately, the meaning has been generalized to include all processes involving loss of electrons.

Oxidation is defined as the loss of electrons or an increase in oxidation state by a molecule, atom, or ion. However, this definition is not completely correct, and oxidation should be referred to as an increase in oxidation state.

Many different components of food, lipids, proteins, nucleic acids, and different vitamins, are prone to oxidation. Since lipids and proteins are two of the major components in food, the focus of this article will therefore be on the oxidation of these components.

Lipid Oxidation

Lipid oxidation is a highly complex set of free radical reactions between fatty acids and oxygen, which results in oxidative degradation of lipids, also known as rancidity. Lipid oxidation intermediate products (free radicals) and end products (reactive aldehydes) may interact with other food constituents, such as proteins, sugars, pigments, and vitamins, and negatively modify their properties. The reaction mechanisms and the rate of lipid oxidation depend on many factors, such as fatty acid composition, the presence of prooxidants and antioxidants, type of lipid (triacylglycerols, phospholipids, and others), and storage conditions, for example, temperature, light, oxygen availability, and water activity.

Mechanisms of Lipid Oxidation

Lipid oxidation is initiated by the reaction of unsaturated fatty acid with oxygen (O_2) forming a primary oxidation product – lipid hydroperoxide (LOOH). Thermodynamically, atmospheric oxygen cannot react directly with double bonds on a fatty acid, because the spin states are different – the oxygen is in a triplet state ($^3O_2$), whereas the double bond is in a singlet state. Therefore, the reaction between an unsaturated fatty acid and oxygen (oxidation substrates) can only occur when one of the oxidation substrates is converted into an activated form – either a fatty acid radical ($L^\bullet$) or activated oxygen species – for instance, singlet oxygen ($^3O_2$), hydroxyl radical ($^\bullet OH$), or superoxide radical anion ($O_2^{\bullet -}$), the latter two belonging to a category of reactive oxygen species (ROS). Based on the reaction mechanism, lipid oxidation can be classified as

- enzymatic oxidation,
- singlet oxygen (light-induced) oxidation,
- autoxidation.

Enzymatic Oxidation

Several enzymes can catalyze lipid oxidation:

Lipoxygenases are iron-containing enzymes present, for example, in fish gill and skin tissues, beans, or grains. The enzymes catalyze the insertion of O_2 into an unsaturated fatty acid producing lipid hydroperoxides (LOOH).

Myeloperoxidases can initiate lipid oxidation in the presence of hydrogen peroxide and halides, such as bromides and iodides, and can be critical during the processing of meat/muscle tissues, when interaction between air (oxygen), blood, and lipids (oxidation substrates) is increased.

Singlet Oxygen (Light-Induced) Oxidation

In the presence of photosensitizers (porphyrins and riboflavins) and under exposure to light, the nonreactive triplet oxygen can be converted into reactive singlet oxygen ($^1O_2$). In addition, singlet oxygen can be formed chemically and enzymatically. Singlet oxygen can directly attack the —C═C— double bond on a fatty acid and thereby initiate photooxidation. Singlet oxygen-induced oxidation leads to the formation of both conjugated and nonconjugated hydroperoxides, which further decompose by the same mechanisms as peroxides formed from triplet oxygen in autoxidation (described in the succeeding text). The rate of lipid oxidation mediated by singlet oxygen is much higher than the rates in autoxidation, resulting in drastically increased rates of oxidation even at very low temperatures, which lowers the quality of foods during processing and storage.

Autoxidation

The most important mechanism in lipid oxidation is autoxidation, which occurs via free radical chain mechanism in an autocatalytic manner. It involves the reaction of unsaturated fatty acids with atmospheric oxygen and occurs in three phases: initiation, propagation, and termination.

In the initiation step, lipid radicals may be formed by thermal cleavage, by reactions with chemical oxidizers (activated oxygen species), or by interactions with transition metals or enzymes. Once an initial lipid radical is formed, it reacts with atmospheric triplet oxygen, generating peroxyl radicals. These act as chemical oxidizers and react with a new unsaturated fatty acid, thereby propagating the chain of autoxidation (Figure 1), which leads to branching reactions. The chain is terminated once the free radical is reacted into a stable molecule.

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00508-0

Primary Oxidation Products

The primary product of the autoxidation cascade is LOOH; each peroxide group is accompanied by the formation of conjugated diene structure on the fatty acid. The chain also produces intermediate and short-lived lipid radicals, such as $L^{\bullet}$ and $LOO^{\bullet}$. As the number of double bonds in polyunsaturated fatty acid (PUFA) increases, more complex mixtures of LOOH are produced. Lipid hydroperoxides are tasteless and odorless (Figure 2).

Secondary Oxidation Products

In the presence of metals and nonheme iron and at high temperatures, lipid hydroperoxides break down to an array of nonvolatile and volatile secondary oxidation products. As a result of this breakdown, new radicals are formed ($^{\bullet}OH$, $LO^{\bullet}$, and $LOO^{\bullet}$) that can reinitiate and branch the autoxidation reactions. $LO^{\bullet}$ can also be cleaved in a β-scission reaction into various nonvolatile and volatile secondary oxidation products. Peroxyl radicals ($LOO^{\bullet}$) of fatty acids or esters that contain three or more methylene-interrupted double bonds can be oxidized by cyclization into hydroperoxy epidioxides and bicycloendoperoxides, which then may be broken down into malondialdehyde.

Due to the variety of lipid hydroperoxides that can be formed during autoxidation and the type of oxidative cleavage of double bonds, the mixture of volatile secondary oxidation products formed after the breakdown of hydroperoxides is very complex. Volatile decomposition products from long-chain $n-3$ PUFAs from marine organisms have extremely low flavor threshold values and have readily detectable odors at very low levels of oxidation. During homolytic β-cleavage of the peroxides, aldehydes are left on the triacylglycerol or phospholipid molecule, and these aldehydes are called core aldehydes.

Tertiary Oxidation Products

In the final termination stage, relatively unreactive tertiary oxidation products are formed, including hydrocarbons, aldehydes, and ketones. However, unsaturated aldehydes and ketones may also undergo further oxidation forming volatile oxidation products. Additionally, hydroperoxy radicals formed during the propagation stage may react with triacylglycerols forming dimeric and trimeric triacylglycerols linked via peroxidic-type bonds.

Factors Influencing the Oxidation Rate and Mechanism

As the degree of unsaturation of fatty acid increases, the susceptibility to oxidation of fatty increases (Table 1).

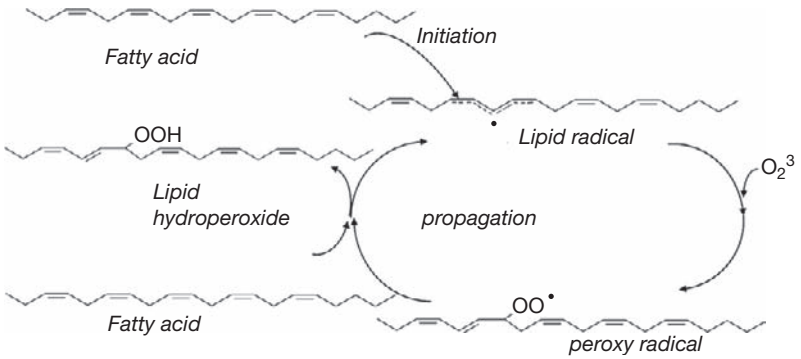

Figure 1 Autoxidation of fatty acids. Reproduced from Frankel, E. N. (2005). *Lipid oxidation*. Bridgewater: Oily Press.

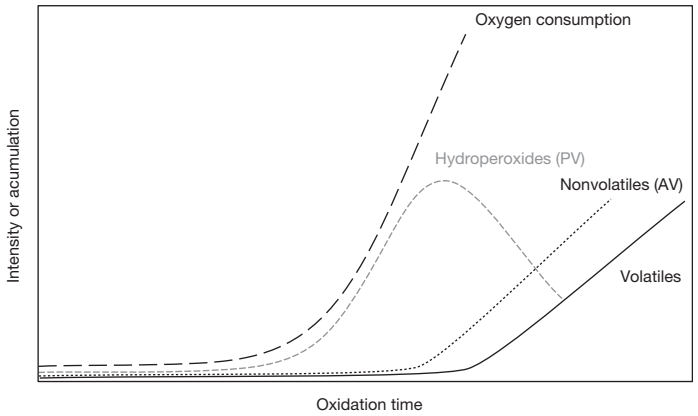

Figure 2 The kinetic curve of autoxidation of polyunsaturated fatty acids. PV, peroxide value; AV, anisidine value. Adapted from Kamal-Eldin, A. (2003). *Lipid oxidation pathways*. Champaign, IL: AOCS Press.

Table 1 Relative oxidation rates of unsaturated fatty acids subjected to photooxidation and autoxidation

	Degree of unsaturation		
Oxidation mechanism	*C18:1*	*C18:2*	*C18:3*
Autoxidation	1	27	77
Photooxidation	3×10^4	4×10^4	7×10^4

Oxygen

Oxidation of oils also increases with an increased amount of dissolved oxygen. The concentration of dissolved oxygen in the oil is dependent on the oxygen partial pressure in the headspace of the oil. Therefore, in order to stabilize unsaturated oils, oxygen should be omitted during processing and storage of unsaturated oils. Due to this, tall and narrow tanks are suggested for the storage of oils. Air-filled headspace in storage tanks should be held at a minimum, and all pipelines are recommended to be filled with inert gas.

Light

Photochemically induced oxidative changes are directly related to the light source, wavelength, light intensity, exposure time, and temperature. UV light was observed to be more harmful than visible light. Packaging of oils into colored (dark) glass containers or plastic vessels with UV absorbers efficiently reduces light-induced oxidation.

Temperature

Autoxidation of oils and decomposition of LOOH increase as the temperature increases. As a rule of thumb, autoxidation rates double for each increase in temperature by 10 °C. Therefore, variations in storage temperature will lead to significant reduction in shelf life.

Prooxidants and Antioxidants

Prooxidants

Prooxidants are compounds that initiate, facilitate, or accelerate lipid oxidation. Prooxidants are considered ubiquitous and are efficient in catalyzing lipid oxidation even at trace concentrations.

Transition Metals

Transition metals, such as low-molecular (free) iron and copper ions, are common catalysts of lipid oxidation. Iron is normally found in greater concentrations than copper, but copper is a stronger prooxidant than iron. Oxidizing metals ($M^{(n+1)+}$) decompose LOOH at rates several orders of magnitude slower than reducing metals (M^{n+}). Iron catalyzes lipid oxidation via the decomposition of LOOH into free radicals through redox cycling pathways. In the absence of oxygen, metal ions can still cause the breakdown of already formed hydroperoxides, facilitating the formation of secondary oxidation products (via β-scission), such as aldehydes.

Hemoproteins

Hemoproteins, that is, proteins containing a porphyrin structure with embedded iron atom, are known to catalyze lipid oxidation at much higher rates than low molecular weight iron. The most common heme compounds are derivatives of hemoglobin, myoglobin, catalase, and peroxidase. Hemoglobin and myoglobin are typically present in meat tissues and tissues rich in blood, such as organs.

In living tissues, hemoglobin exists in the reduced form (Fe^{2+}), either saturated with an oxygen molecule (oxyhemoglobin) or devoid of oxygen (deoxyhemoglobin). After death (postmortem), the concentration of oxy- and deoxyhemoglobin progressively decreases as it is converted (oxidized) to brown-colored methemoglobin (metHb) that does not have the ability to bind oxygen.

It is believed that intact porphyrin–Fe structure inside a pocket formed by surrounding proteins is an absolute requirement for heme-catalyzed lipid oxidation and that hypervalent iron complexes – mainly ferryl iron complexes (Fe^{4+}=O and Fe^{4+}(OH)) – are responsible for the rapid catalysis. The basic reaction mechanism involves binding of preformed LOOH to Fe^{3+}-heme, which generates the ferryl iron complex in a very fast reaction ($K \sim 10^9\ M^{-1}\ s^{-1}$). The LOOH is then decomposed either heterolytically or homolytically inside the heme pocket, producing lipid alcohols (R–OH) or $LO^{\bullet}$, respectively. The resulting ferryl iron complex is an extremely strong oxidant and rapidly abstracts H from either a new LOOH or the fatty acid directly, which generates lipid radicals for autoxidation reactions. The hypervalent iron complexes can be maintained by electron transfers, thus keeping their oxidizing power. Eventually, they are reduced back to Fe^{3+}-hemes.

The composition and arrangements of amino acids in the heme pocket, as well as heme pocket size and orientation, affect lipid binding and proton abstraction, while the protein structure and ligands influence electron transfer processes and stabilization of the ferryl iron complex. The reaction environment influences whether the LOOH cleavage is homolytic or heterolytic. Therefore, variable catalytic activity between different heme compounds and the same heme compounds from different animals has been observed.

Antioxidants

Antioxidants are compounds that prevent or delay lipid peroxidation. Antioxidants are usually classified into primary and secondary.

Primary antioxidants act as free radical scavengers via their ability to donate electron/hydrogen to peroxyl or alkoxy radicals, preventing them from reacting with a new fatty acid, thereby blocking the branching reactions in autoxidation. Tocopherols (vitamin E), ascorbic acid (vitamin C), and carotenoids (vitamin A) are common antioxidants in plants. Plant extracts are rich sources of natural antioxidants that contain compounds with multiple OH groups (phenolic acids, flavonoids, and anthocyanins), which act as hydrogen donors. Examples of these are rosemary extract where the active compounds are carnosol, carnosic acid, and rosmarinic acid or flavonoids found in green tea (catechins), red wine, seeds, and spices.

Secondary antioxidants act by a number of different mechanisms including metal chelation and scavenging of singlet oxygen and ROS. Examples are ethylene-diamine-tetraacetic

acid and citric acid, which complex iron and copper ions and thereby prevent metal-catalyzed lipid oxidation. Carotenoids absorb energy from singlet oxygen, transferring it to triplet oxygen, without changing their chemical structure (quenching) and therefore protect oil against light-induced oxidation.

Antioxidants assist to maintain low oxidative status of oils when added after an effective refining process, when most oxidation products and prooxidants have been removed from the oil. If the oxidation process in the oil is already started, addition of an antioxidant may only to some extent slow down oxidation or even have no effect.

Oxidation of Proteins

Oxidation of food proteins has received less attention than oxidation of lipids and the studies of oxidation of proteins have mainly been focused on the role of protein oxidation in age-related diseases.

The discovery that myofibrillar proteins in beef were oxidized led to many studies of protein oxidation in muscle foods. Early studies on protein oxidation in food showed that oxidation of food proteins could lead to significant losses in the functionality of proteins. Oxidation may lead to changes in both the primary and the secondary structures of proteins. Protein oxidation may lead to loss of solubility, changes in surface hydrophobicity, and changes in texture and affect water binding and also how susceptible proteins are toward proteolytic degradation. It has also been shown that some of the changes occurring during frozen storage of fish can be explained by protein oxidation.

The reactions between proteins and radicals in the presence of oxygen lead to changes both in the amino acid side chains and in the backbone of the proteins. The amino acids that are most often affected are cysteine, tyrosine, lysine, arginine, and histidine. The amino acids may be oxidized both as free amino acids and as part of the protein backbone.

The oxidation of proteins is believed to occur via a free radical chain reaction that is similar to the mechanism of lipid oxidation. However, there is an even higher complexity of pathways and therefore also a larger variation in reaction products. Reaction between a protein and a ROS leads to the formation of protein-centered radicals (called $P^{\bullet}$). In the presence of oxygen, this is converted to a peroxyl radical ($POO^{\bullet}$), and by abstracting a hydrogen atom from another molecule, it is converted to an alkyl peroxide (POOH). Further reactions can lead to the formation of alkoxy radicals ($PO^{\bullet}$) and hydroxy compounds. Protein radicals may react with other macromolecules in food like DNA, starch, lipids, and other proteins.

The thiol group in cysteine is highly susceptible to oxidation, and this may lead to the formation of sulfenic acid, sulfinic acid, and disulfide bonds. Oxidation of tyrosine may lead to the formation of dityrosine cross-linkages. The formation of disulfide and dityrosine cross-linkages may lead to both textural changes and reduced solubility. Oxidation of lysine, arginine, and histidine may lead to the formation of carbonyl groups. In addition to changes in the amino acid side chains, protein oxidation may also lead to breakage of the protein backbone.

Oxidation may change hydrophobicity, conformation, solubility, and susceptibility toward digestive enzymes – the latter may reduce nutritional value.

Some proteins are more susceptible toward oxidation than others and studies have shown that large proteins are more prone to oxidation than proteins with lower molecular weight.

There are several methods to determine protein oxidation, by detection of carbonyl groups, determination of changes in sulfhydryl groups, and formation of dityrosine. In addition, advanced methods like electron spin resonance, fluorescence spectroscopy, and high pressure liquid chromatography coupled with fluorescence detection as well as mass spectrometry have been used to increase the understanding of the mechanisms of protein oxidation.

As already mentioned, protein oxidation affects food properties, both texture and water-holding capacity. It has also been found that protein oxidation affected the gel strength of transglutaminase (TG)-mediated restructured meat. The combination of oxidation and high-salt content increased the TG-mediated cross-linking of myofibrillar proteins, probably because TG had increased accessibility to glutamine and lysine residues. A study on pork meat showed that mild oxidation of myofibrillar proteins improved gelling properties probably due to the formation of disulfide bonds; however, a negative effect was found on the water-holding capacity of the gels. Oxidizing agents are also used to improve baking properties of wheat (gluten) due to the importance of disulfide interchange for dough strength. Other studies have, however, shown negative effects of protein oxidation on the gel-forming properties of proteins showing that more studies are needed.

Several enzyme systems, the main ones are the calpains and the cathepsins, influence the tenderness of muscle foods. The only endogenous meat enzyme system that has been evaluated with regard to oxidation in meat is the calpain. The decrease in tenderness due to protein oxidation has been ascribed to either inactivation of μ-calpain or cross-linking of myosin resulting in strengthening of the myofibrillar structure.

Studies of lipid and protein oxidation in rainbow trout have shown that protein and lipid oxidation followed the same trend and that protein carbonyls developed together with the formation of LOOH indicating that these two processes occur simultaneously.

Protein oxidation has been studied during different food processing operations. For salted herring, cross-linking of myosin was found to be responsible for changes in texture, and an increase in protein carbonyls with increased ripening period was also found.

Storage of processed food such as pâtés and cooked sausages was also found to result in increased hardness; this has been ascribed to onset of protein oxidation, especially to the formation of cross-linkages between myofibrillar proteins. A relationship between protein carbonyls and instrumental hardness of sausages and packaging of beef in high-oxygen atmosphere has been found to have a negative effect on meat tenderness.

In rainbow trout stored at different storage temperatures, no protein oxidation was detected while storage at −20 °C resulted in the formation of protein carbonyls.

Controlling Protein Oxidation

The use of antioxidants – for instance, as part of the feed of the animals – has been found to increase oxidative stability of the food products. Reducing the PUFA/FA in animal tissues and supplementing the feed with antioxidants have also been

suggested as strategies to control protein oxidation. Different results have been found with regard to the effect of modification of the fatty acid composition in the muscle; some studies show only minor effect while the results of other studies indicate positive correlations between the ratio between PUFA and tocopherol as antioxidant. Therefore, controlling the protein oxidation by managing the feed composition seems to be a promising possibility. In a study on chilled mackerel, catechin was found to inhibit both lipid oxidation and protein oxidation; however, the antioxidative effect varied for the different myofibrillar proteins. It is also important to bear in mind that protein oxidation may lead to desired changes in food and might enable the production of foods with new and desirable textural properties.

Several recent studies on protein oxidation in food have led to increased understanding of both the mechanisms and the effect of protein oxidation on food quality. However, the existing methods for detection of protein oxidation are not sufficiently sensitive. There is therefore a need to develop new and sensitive methods to characterize the oxidation products generated during oxidation of proteins in food.

Introduction

Packaging plays an important role in the food processing industry to make the packed foods more convenient and to give the food greater safety assurance from microorganisms and biological and chemical changes such that the packed foods can have longer shelf lives. The demands of high-quality aseptic prolonged shelf-stable and safe foods have created huge development of aseptic processing and packaging (APP) systems.

APP of food products is one of the important processing operations in the food processing industry for producing and packaging the food products that can be rendered safe with an assured quality and extended shelf life. In general terms, APP is defined as the sterilization of the packaging materials and filling and hermetic sealing of commercially sterile products in an aseptic environment, which can prevent reinfection. For products expected with a long shelf life at room temperature, the package must also give complete protection against light and atmospheric oxygen. An APP system generally consists of sterilizer for the product, product filling assembly with ancillary piping and filler bowl, sterile gas lines and filters, aseptic packaging material sterilization zones to sterilize laminates of packaging materials/containers and lid materials, and a sterile zone where containers are filled and sealed. An overpressure of sterile air or inert gas is maintained in the aseptic zone to facilitate product removal and to deny any ingress from the environment. The term 'aseptic' is implemented when the unwanted organisms are either absent or excluded from the food product, packaging material, and product filling and sealing zone or other specific areas, while the term 'hermetic' signifies the suitability and compatibility of the packaging material to avoid the entry of microorganisms into the food package more specifically and/or prevent the passage of gas or vapor into or from the container, and these properties are totally dependent upon the mechanical properties of the packaging material. The most important example of an aseptic food is ultrahigh-temperature (UHT) processed milk, which undergoes a heat treatment at 135–150 °C for a varying holding period of 2–6 s, which changes per the type of food product. After sterilization, the food products are delivered through aseptic pipes to the product filling and sealing zone where the product is filled into presterilized containers under aseptic conditions, which assures a shelf life of about 3–6 months even if it is stored/distributed under ambient conditions. The types of food products that are processed by UHT treatment followed by aseptic filling include milk and milk products, drinks, concentrates, wines, teas, mineral water, nutritional beverages, sauces, fruit and vegetable juices, soups, tomato products, products with particulates, and ready-to-eat breakfast. The Tetra Pak system is the most widely used among the aseptic packaging systems, and the brick-shaped cartons fabricated from paperboard/polyethylene/aluminum foil lamination dominate the market.

The packaging materials used for filling perishable food products are normally produced under hygienic, but nonsterile, conditions. Contaminating microorganisms present in food packaging materials and equipment surfaces cause spoilage of aseptically packed food products. Therefore, sterilization of aseptic food packaging materials, food contact surfaces, and the environment directly surrounding these materials is of paramount importance. Sterilizing agents such as chemicals, heat, irradiation, or combinations of these will ensure the microbiological safety, stability, and quality of food over time. The agents to be used must destroy relevant microorganisms to the required level in the shortest possible time, be compatible with the food packaging materials and food contact surfaces, be easy to apply in the aseptic system, be inexpensive, be easy to remove from the treated surface, and, if residues are left, be within the accepted tolerance level.

Types of Aseptic Packaging Material

Commercial manufacturers of aseptic packaging include Tetra Pak, Scholle, and the Dole aseptic canning system (Table 1).

The types of aseptic packaging used for packing food products are discussed as follows:

- *Carton Boxes*: they are used to fill products under sterile conditions, which contain particulates. The carton boxes dominate among the packaging materials and are generally used to pack white milk and low- and high-acid food products such as fruit juices. Carton boxes are generally made of six layers that give an effective shelf life to the food products when packed aseptically.
- *Bags and Pouches*: pillow pouches are usually used for the packaging of milk, which is sealed from three sides, and it is also possible to pack products with particulates of 12 μ size.

Table 1 Aseptic packaging systems

System	*Package*	*Sterilizing agent*
Asepak	Bags	Heat
ASTEC	Bins and tanks	Pressurized steam
CKD	Cups	H_2O_2
Combibloc	Cartons	H_2O_2 + heat
Dole aseptic canning system	Steel/aluminum cans and lids	Superheated steam
DuPont Canada	Bags, pouches	H_2O_2
ERCA	Cups	H_2O_2 + heat
Evergreen	Cartons	H_2O_2 + heat
Gasti	Cups	High-pressure steam
Gaulin	Bags	Ethylene oxide
Hamba Manufacturing	Cups	Ultraviolet rays
Hassia	Cups	H_2O_2 + heat or pressurized steam
Ingko	Bags	Chlorine solution + heat
Inpaco	Pouches	H_2O_2 + heat
International Paper Co.	Rectangular packages	H_2O_2 + heat
Lieffeld & Lemke	Cups	H_2O_2 + heat
Liqui-Box Corp.	Bags	Gamma radiation
Mancini	Bags	Gamma radiation
Mead Packaging Co.	Cups	Citric acid + heat
Metal-Box Freshfill (Autoprod)	Cups	H_2O_2 + heat
Pure Pak Inc.	Cartons	H_2O_2 + heat, oxonia
Purity Packaging Co.	Cups	H_2O_2
Remy	Cups	H_2O_2 + heat
Remy	Bottles	H_2O_2 or oxonia
Scholle Corporation	Bags	Gamma radiation or ethylene oxide
Serac	Bottles	H_2O_2
Tetra Pak Inc.	Cartons	H_2O_2
Wright Sel	Bags	Gamma radiation or ethylene oxide

- *Cups and Trays*: these are used either premade or formed, filled, and sealed in thermoform/fill/seal machines. Usually, polypropylene-based multilayer materials with ethylene vinyl alcohol (EVOH) barrier are applied for this purpose.
- *Bottles and Jars*: glass bottles may be aseptically filled with food containing small particles, for instance, baby food. In recent developments, Tetra Top bottles, which combine the convenience of bottle and all the characteristics of carton packaging, can now be employed for packing thicker products for easy pourability. For the packaging of milk, a bottle made in the form of carton is made available in the form of Tetra Evero.
- *Metal Cans*: the Dole system is used for packing food products into cans made from steel/aluminum using aseptic filling. The existing slit filler, however, limits applications to liquids with very small particles, such as rice.
- *Plastic Cans*: an aseptic machine for filling and closing of two-piece plastic cans, 'gourmetans,' was recently developed. Cans and lids with easy opening features consist of polypropylene (PP)/EVOH/PP.
- *Composite Cans*: they are generally used to pack products and fruit juices containing fibers and not the particulates.
- *Retortable Carton*: an innovative packaging system is developed as Tetra Recart, which has utilized carton packaging for packing products like vegetables, tomatoes, soups, and sauces, which can stay fresh for about 24 months.
- *Bag-in-Box*: it is best suited for liquid and paste-like products for bulk packaging. In addition to the all conventional requirements, the bag-in-box aseptic system must have a flexible primary packaging, as rigid primary containers cannot guarantee sterility. It can be used for the packing of high- and low-acid products like fruit juices, concentrates, purees, tomato products, and milk and cream.

Factors that are considered vital in the case of the packaging material, which affect the shelf life of the products, are the strength of the seal, integrity of the packaging material, package shape, stiffness, and durability of the packaging material and barrier properties. Recent demands and the changing nature of consumers have driven the packaging material manufacturers to consider the special need of plastics, different types of closures and packs, environmental impact, raw material for packaging material, new product applications, and even alternatives for aseptic packaging.

Filler Sterilization

Aseptic fillers have sections containing sterile contact pipes and valves along with noncontact sections (sterile chambers) that need to be sterilized prior to production and must be able to maintain sterility. Aseptic fillers and associated pipes are usually sterilized with heat in the form of steam, and usage of saturated steam is the most dependable sterilant, as microorganisms are more resistant to dry heat, which necessitates higher temperatures.

Once sterilized, the product is transported under aseptic conditions to the aseptic filling equipment, and reinfection is avoided. The cleaning of aseptic transfer equipment is done by cleaning-in-place (CIP) systems, and its effectiveness depends upon the kind and concentration of detergent, time of circulation, and flow rate. Reinfection is possible only by leakage in the system, so attention is required to be paid on gaskets, membranes, cracks, and pinholes. Some aseptic filling plants use steam barriers in the aseptic transfer system, particularly so if a sterile tank is part of the transfer line and the steam barriers are controlled by thermosensors and/or inspection by the machine operator.

The packaging material is supplied in the form of reels that are then loaded in a magazine at the rear part of the Tetra Brik machine. The packaging material web (Figure 1) travels from the magazine, where a longitudinal seal strip is applied to one edge of the packaging material web by using hot air.

The longitudinal seal strip has the task to reinforce the longitudinal seal and to prevent the product from coming into contact with the paper layer of the packaging material. The packaging material web then passes through the hydrogen peroxide bath (30% concentration) at a temperature of 70 °C for about 7–8 s for effective sterilization. Excess H_2O_2 is removed by means of a pair of pressure rollers, which is followed by 'air knives.' Air knives are the narrow slits through

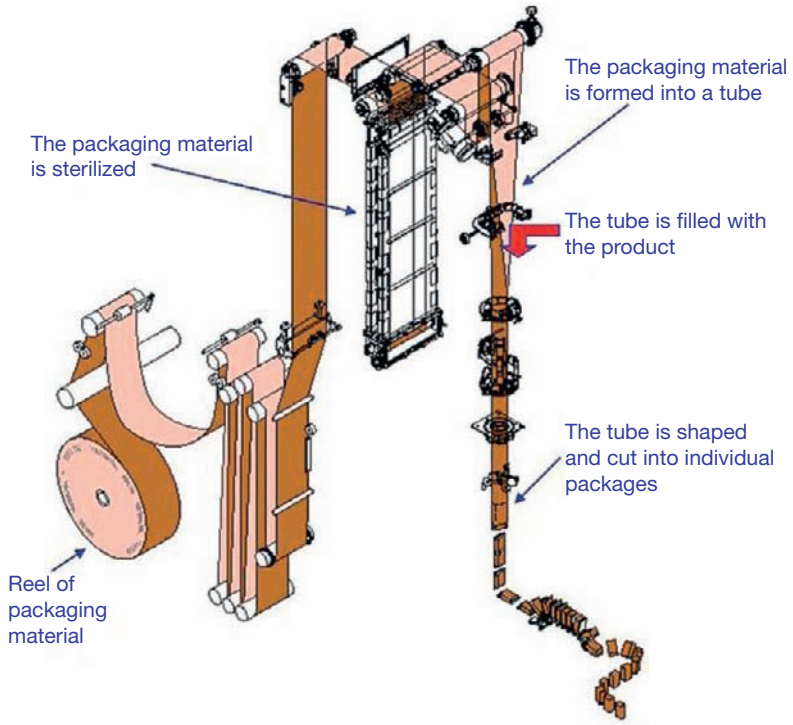

Figure 1 Packaging material web path in aseptic packaging machine.

which hot sterile air is blown, which dries the surface. The sterile packaging material first travels down in the aseptic chamber on the front side of the Tetra Brik machine. By means of forming rings, a tube is formed, which is longitudinally sealed, using hot sterile air or induction heating, and the product is supplied by means of a filling pipe inserted in the tube of the packaging material. In order to minimize foaming and splashing, the filling pipe extends below the product level, and a floating valve, or a regulating valve, helps to keep the product at a constant level. Two pairs of sealing and pressure jaws constantly pull the packaging material through the machine. The first step in the transversal sealing operation is the closing of the jaws around the cylindrical packaging material tube. The tube simultaneously acquires a rectangular shape by way of the volume flaps placed on the jaws. The transversal seals are performed below the product level to ensure a completely filled package, and the inner plastic coating (polyethylene) is heated up by induction heating. When the transversal seal has been executed, a knife releases each package from the tube. The package is transported to the final folder where the ears of the package are sealed with hot air at both the top and bottom.

Required Log Cycle Reduction

The sterilization process employed should be established in terms of the number of log cycle reductions for the most resistant organisms present on the food contact surfaces. Factors like the type of the food product, storage temperature, and expected shelf life decide the required log cycle reduction. For nonsterile acidic products of pH <4.5 and for sterile, neutral, and low-acid products of pH >4.5, a minimum of four- and six-log cycle reductions of bacterial spores is required, respectively. Commercial requirements for effective sterilization demand less than one faulty package out of 10 000 produced. Factors that affect commercial sterility are the efficiency of the sterilizer for food product and packaging material, initial microbial load of the raw material and packaging material, procedures of cleaning and sterilization of the plant and filling section, and service and maintenance of the plant and operational care. Another factor that is used in determining the appropriate value for container sterilization is container size. Smaller containers with a smaller food contact surface area will have correspondingly less initial contamination, and hence, a less severe sterilization process will be needed and vice versa. Calculations of minimum sterilization effects necessary are often based on the assumption that all microorganisms on food contact surfaces are bacterial spores.

However, even though the organism reduction rate of a system can be calculated with some confidence and precision, this cannot be used to give a precise measure of the proportion of nonsterile packs that will be produced by the systems. There are a number of reasons for this: (a) the proportion of nonsterile packs will vary according to pack size, that is, the larger the pack, the higher the proportion that will be nonsterile at a given rate of organism reduction, (b) the condition of the packaging material before sterilization will also affect the incidence of nonsterile packs, and (c) the failure of the sterilization process to kill the bacteria is not the only, or even the most important, cause of pack nonsterility. Other causes that may cause to produce nonsterile packs are physical defects in the packs, particularly in seals and seams, and technical failure in the aseptic packaging system.

Defective packages are generally classified as damaged caused by operation of the aseptic packaging machine, maintenance of the equipment, faulty packaging material, internal transportation, outer wrapping equipment, handling during storage, or no package defect detectable.

Packaging Materials and Food Contact Surface Sterilization Processes

The packaging material sterilization is dependent upon the type and concentration of the chemical used, contact time, and temperature during contact. The important sterilization processes for food packaging materials and food contact surfaces are as follows:

Chemical Sterilizing

Chemical sterilization is extensively practiced for sterilizing the food contact surfaces. In order to deliver the packaging material and contact surface commercially sterile, chemicals are used to kill bacterial forms (vegetative cells and spores), yeast, and molds. The chemical sterilizing agents that have been used for sterilizing packaging materials and food contact surfaces include the following:

- *Hydrogen peroxide*: Hydrogen peroxide (H_2O_2) is the most widely used chemical agent for the decontamination of food packaging materials and contact surfaces before aseptic filling and subsequently dried with hot sterile air (Figure 2).

The oxidative potential of hydrogen peroxide is the principle behind the antimicrobial effect. The lethal effect of H_2O_2 and heat for the sterilization of the surface of paperboard laminate cartons was used by Tetra Pak in 1961. The lethality of H_2O_2 is relatively low at room temperature but can be increased considerably by raising either the temperature to 85–90 °C or concentration. Most aseptic packaging systems use H_2O_2 at concentrations from 30% to 35%, followed by hot air (60–125 °C) to augment the sterilizing effect and to dissipate residual H_2O_2. The bactericidal effectiveness of H_2O_2 is influenced by the temperature, duration of treatment, pH, concentration, quantity applied to the packaging material per unit area, intensity of the radiant or irradiant heat or the temperature and quantity of the drying air, microbial load, and species of organisms present. Sterilizing effectiveness of H_2O_2 is usually assessed against spores of either *B. subtilis* or *B. subtilis* var. *globigii*. The action mechanism of hydrogen peroxide is credited to the formation of either oxygen or hydroxyl radicals. The lethal effect can be enhanced by heat, which also reduces the exposure time necessary for the lethal effect. Under commercial conditions, since the rapid rate of spore destruction is required to obtain the commercial sterility of the packaging material, several aseptic filling and packaging systems utilize hydrogen peroxide in conjunction with heat and/or other agents to sterilize the packaging material. Since regulation requires residuals of less than or equal to 0.1 ppm H_2O_2, hot sterile air is commonly used to dissipate hydrogen peroxide. Per US Food and Drug Administration, the concentration of H_2O_2 must not be >500 ppb at the time of filling and must be reduced to $\sim$1 ppb within 24 h for the packaging material used to pack the food products.

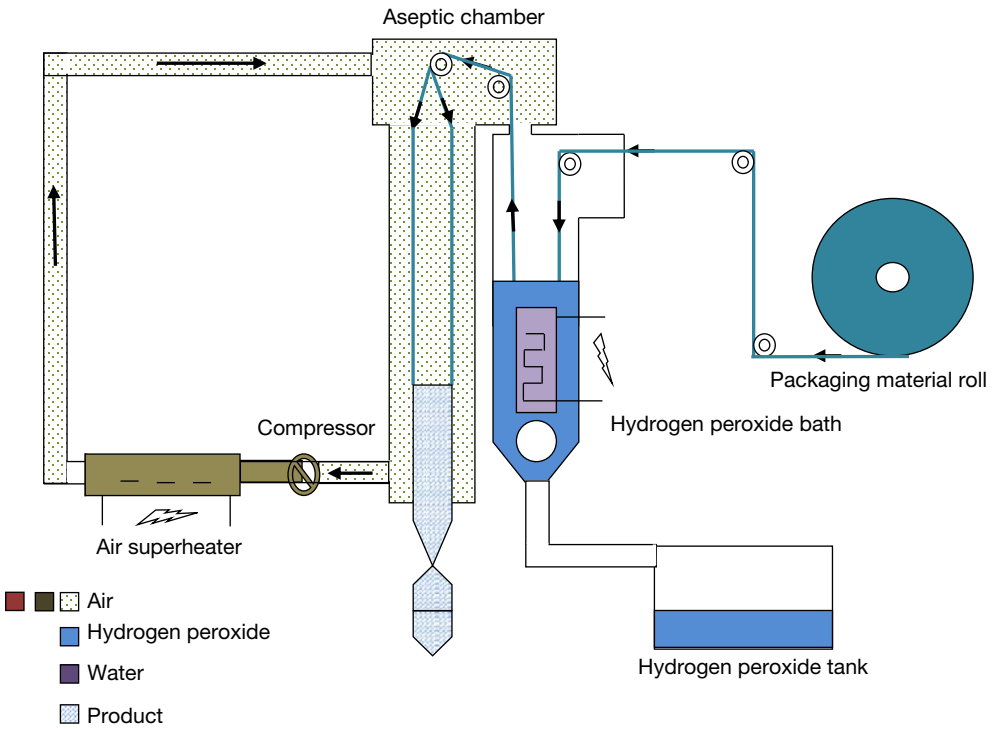

Figure 2 Sterile system of aseptic packaging machine using hydrogen peroxide.

There are three commercial methods for applying hydrogen peroxide to packaging materials: dipping, spraying, and rinsing.

- *Dipping*: It is universally used for the sterilization of food packaging materials when the packaging material is in the form of roll stock, and then the packaging material is immersed in a bath of 30–35% H_2O_2 solution containing a wetting agent to ensure uniform wetting of plastic surfaces, followed by heating to vaporize the peroxide before the filling operation. A large amount of the sterilizing liquid is removed mechanically, for example, by rollers or air blasts, and the remainder is generally removed by drying with hot sterile air or radiant heat. To increase the efficacy, especially in the case of dusty or slightly soiled materials, prior treatment of the material with rotating brushes or sterile compressed air jets may be used.
- *Spraying*: It is normally used for preformed containers in which sterilization is carried out by spraying or atomizing H_2O_2 into the containers. In this method, a measured amount of H_2O_2 solution (35%) is applied into each container through a nozzle to ensure that a uniform film coats the inside surface of the package. The peroxide is then dried using hot sterile air. The death rate is dependent on the volume of sprayed H_2O_2 (larger volumes require longer drying time) and the temperature of the hot sterile air. The new trend is to use a mixture of hot air (130 °C) and vaporized peroxide. Sterility of the aseptic zone during production is maintained by an overpressure of sterile air.
- *Rinsing*: It is used for prefabricated containers of an intricate shape, which are rinsed with an aqueous 30–33% H_2O_2 solution or a mixture of peroxide and peracetic acid (PAA). After spraying, the container is drained and then completely dried by hot sterile air and is used to sterilize glass containers, metal cans, and blow-molded plastic bottles. Live steam and disinfectant are used for presterilizing the filling station, piping, valves, and others into the filling chamber, followed by drying with hot sterile air, which is then maintained by an overpressure of a laminar sterile air flow.

- *Vapor-phase hydrogen peroxide (VPHP)*: The potential use of hydrogen peroxide vapor is to decontaminate surfaces that are hard to reach and complex surfaces giving good surface coverage of the material, and it is used as aqueous solution (30% w/w) that is evaporated into the heated carrier gas stream to produce hydrogen peroxide concentrations in excess of 4.5 mg l^{-1}. *Geobacillus stearothermophilus* and *Bacillus subtilis* are commonly used indicator organisms to verify the efficacy of VPHP sterilization. A 6-log cycle reduction can be induced within 1.2 min for the spores of *Bacillus subtilis* var. *niger* by using air saturated with H_2O_2 having a concentration of 7.6 mg l^{-1} at 70 °C. Sterilization of preformed containers by hydrogen peroxide vapor is cost-effective, as fewer amounts are adsorbed on the treated surface from the vapor phase. Flushing the vapor-treated surface with low-temperature sterile air free of H_2O_2 vapors can effectively eliminate residues, which can be used effectively for the in-line sterilization of aseptic packaging materials.
- *Corona discharge with hydrogen peroxide*: The sterilization effect can be achieved by using pulsed corona discharge in combination with H_2O_2 at atmospheric pressure. Positive ions and fine droplets (10–100 nm) of H_2O_2 are useful for sterilization, and bioindicator for estimating the sterilization effect is *E. coli*, and it is usually more than 100 times as compared with H_2O_2 alone. For high-speed sterilization of aseptic packaging materials, a combination of H_2O_2 droplets (30 wt%) and corona discharge is found to be very effective, with an added advantage of time reduction for soaking.
- *Food acids*: The shelf life of food products can be increased by inactivating the vegetative cells, spores, yeast, and molds that can grow at room temperature. PAA is a peroxide of acetic acid and, on decomposition, forms acetic acid and water, which is effective against spores of aerobic and anaerobic bacteria. PAA at a concentration of 0.1% is more effective than 23.6% (H_2O_2 solution) at room temperature. At 20–45 °C with a concentration of 0.5–1%, PAA can reduce the number of microbes on polyvinyl chloride (PVC) or polyethylene terephthalate (PET) bottles by 5–6 logs within 30 min. Synergistically, H_2O_2 (5.9%) and PAA (0.2%) can achieve a 4-log cycle reduction of the *B. subtilis* spore within 1.4 min at 20 °C. PAA can be used as a sporicidal agent in treating surfaces of both aseptic filling machine and packaging materials such as PET.
- *Ozone*: Ozone is a feasible alternative to H_2O_2 due to its wide range of antimicrobial properties against a wide spectrum of bacteria, fungi, viruses, protozoa, and bacterial and fungal spores. An added advantage of using ozone is that it does not leave any residues after its decomposition. Microbial cell inactivation is achieved by attacking the cell membrane and wall constituents (e.g., unsaturated fats), which ultimately leads to increased cell permeability of microbial cells and eventual death. Ozone can disinfect food contact surfaces, and its effectiveness can be evaluated by using spores of *B. stearothermophilus* as indicators. The antimicrobial property of ozone increases with a decrease in temperature; even at lower concentrations, a large amount of microbial populations can be killed within a short span of time. In recent years, the introduction of ozonation equipment for surface cleaning and disinfection in the food industry has made significant advances, and it has proved to be an effective sanitizer.

Physical Sterilizing Agents

Sterilization by chemical agents is a tedious method, and on several occasions, unacceptable amounts of residue on the packaging material may interact with polymers or the components of packaged food coming in contact with the surface of the packaging material. Hence, physical agents as alternative sterilization for the decontamination of packaging materials and food contact surfaces may be adopted, and some of them are discussed as follows:

- *Thermal sterilization*: Thermal sterilization processes generally use either moist heat (steam) or dry heat (hot air) as a sterilizing medium. Microorganisms, especially spores, show greater thermal resistance when exposed to dry heat than moist heat. The effectiveness of sterilization at 121 °C for 20 min using steam is equivalent to dry heat

sterilization at 170 °C for 60 min, which signifies that steam is much more efficient. Dry heat produces microbial death as a result of dehydration, followed by protein oxidation, while death by moist heat is caused by denaturation and coagulation of essential cell proteins.

- *Saturated steam*: Sterilization of metal cans and lids by saturated steam under pressure was used as early as 1920 in the United States, and saturated steam is also used for sterilizing thermostable plastic cups. A reduction by 5.5–7 log cycles can be achieved in bacterial spores by using a saturated steam at a temperature of 147 °C and 3.5 bar pressure with a contact time of 4 s. To attain adequate destruction in high-speed packaging units, the surface temperature of the material must reach 135 °C, and it is also necessary to select an appropriate steam sterilization cycle. Factors like microorganisms present (type and number), food package (type and size), type of packaging material, and also those that can influence the performance must be considered before selecting a steam sterilization cycle. Moist heat when used as a sterilant, on many occasions, can cause blistering or delamination of the laminates, which may directly affect the heat-sealing characteristics of plastics, causing leaky packets. Hence, saturated steam is a preferred method for sterilizing metal food contact surfaces downstream from the holding tube including sterile hold tank, homogenizers, fillers, and the aseptic packaging zone. Equipment sterilization can be attained by exposure of the surfaces to an appropriate time–temperature sequence (e.g., 30 min/121 °C) by superheated water, saturated steam, superheated steam, or other appropriate treatments prior to the start-up of the filling operation.
- *Superheated steam and hot air*: A major challenge of using superheated steam or hot air, instead of moist heat, as a sterilizing agent is the requirement of a higher time–temperature combination. To guarantee the sterilization when superheated steam or hot air is used, it is necessary to provide longer holding time and high temperatures, as the machines consist of relatively large masses of metal. Since the resistance of microorganisms to dry heat is much greater than to wet heat, much higher temperatures are needed for thermal inactivation by dry heat than for inactivation in a same time by wet heat. Spores of *Bacillus subtilis* are used as indicators in dry heat, and these spores are used commercially in sterility testing of aseptic fillers. The Martin–Dole process continuously sterilizes tinplate cans by passing through superheated steams (220–256 °C) at normal pressure for 45 s and a minimum time–temperature condition in superheated steam of 1 min at 177 °C or 10 min at 160 °C to give satisfactory container sterilization in an aseptic canner.

  Hot air is generally preferred as a sterilizing agent while sterilizing the paper-based packaging materials over superheated steam due to the drawbacks like delaminating, which are associated with superheated steam. Combi cans of cardboard laminates are sterilized using hot air at 145 °C for 3 min. Hot air at a temperature of 315 °C has also been used to sterilize paperboard laminate cartons and is suitable for products that have a pH < 4.6. *C. botulinum* is often used as an indicator for low-acid food products. Hot air sterilization units are commercially available and are used for the packaging of juices and beverages.

- *Heating by extrusion*: The coextrusion process is used to produce multilayer packaging materials for the aseptic packaging system by utilizing the heat required to form–fill–seal operation by thermoplastic resin. The high temperature attended by the resin during its forming assures the sterility of the packaging material. During the extrusion of plastic granules prior to the blow molding of plastic containers, temperatures of 80–230 °C are reached and maintained up to 3 min. Sterile air under a positive pressure maintains the sterility of the forming, filling, and sealing areas. Extrusion results in a three- to four-log cycle reduction in microbial spores, and therefore, extruded containers should only be aseptically filled with acidic products with a pH < 4.5, while for products with a pH > 4.5, the extruded containers must be further sterilized with H_2O_2/PAA. The heat of extrusion (230–240 °C) during the manufacturing/blow molding of plastic pouches/bottles is sufficient to guarantee its surface sterilization and can be affected by the initial microbial load of the granules and the environmental conditions surrounding the blow molding machine.

Irradiation

When neither heat nor chemicals can be used to sterilize a given material, irradiation is the best alternative and is used by manufacturers in Europe. Irradiation is used to sterilize bag-in-box (plastic or plastic–aluminum laminates), cups of cardboard or plastic, valves of metal or plastic, plastic or paper bags, cardboard, plastic tanks, rolls of plastic, aluminum, and coated cardboard. Irradiation involves the action of ionizing radiation or pulsed light (PL) and UV radiation and infrared rays to reduce the number of microorganisms. The types of ionizing radiation used are gamma rays, emitted from a radioisotope such as ^{60}Co or ^{137}Cs, or electron beams generated from an electron accelerator. The processing time for electron beam sterilization is generally shorter than that of gamma ray sterilization. As irradiation does not leave any residue on the treated surface nor affect the immediate environment, it appears to be a perfect solution for the sterilization of packaging materials.

Ionizing radiation: Ionizing radiation is becoming increasingly popular as the deep penetration properties of the gamma rays make it highly suitable for sterilizing the food packaging materials and the contact surfaces that cannot resist and get deformed or delaminated by the high temperatures of the sterilizing mediums. Gamma irradiation at a dosage of 25 kGy (2.5 Mrad) or more can assure the sterility of bag-in-box packaging materials in which acid food can be packed for bulk vending. The principle behind achieving the sterility is that when microorganisms are exposed, gamma rays disrupt the DNA structure of microorganisms present on the surface, which then eliminates the ability to reproduce life-sustaining cells. Besides gamma ray treatment, decontamination with accelerated electron beams has proved to be a safe and effective method for sterilization. Electron beams work by directing a

shower of accelerated electrons through a high-voltage emitter toward a target. The advantages of using the method are that it can be used at room temperature and also it reduces the usage of chemical agents. Implementing the ionizing radiations as a sterilant source imposes a challenge of high installation and uncertainty of the sterilization effect in the case of preformed containers. For commercial usage in decontaminating the food packaging materials by using ionizing radiations, factors like reduction in the cost of the equipment producing the radiations and the shielding of the radiations must be considered.

Pulsed Light

PL is used as a nonthermal technique for processing and increasing the shelf life of different food items, and it has also found its way in sterilizing food packaging materials and food contact surfaces. PL can be used to decontaminate surfaces by using very-short-time pulses of high-power broad-spectrum light and rich in UV-C light. The process is reported to be highly successful in killing bacteria, yeast, molds, viruses, and spores and in deactivating enzymes. The material to be sterilized can be exposed to at least 1 pulse of light (typically 1–20 flashes per second) having an energy density in the range of about 0.01–50 J cm^{-2} at the surface with a duration ranging from 1 μs to 0.1 s. Microbial inactivation by using PL occurs by several mechanisms such as photochemical and photothermal mechanisms, chemical modification and cleavage of DNA, protein denaturation, and alteration of cellular materials. With an increase in the light intensity and fluency, the lethal effect on spores is also increased. As compared with UV light (42 600 μW-s cm^{-2}), for achieving a sterilization effect of 99.999% for *B. subtilis*, PL only requires a dosage of 4500 μW-s cm^{-2}. The PL system can be deployed in the aseptic packaging machine that uses preformed containers like bottles, plastic jars, or paper packs for the packing of milk and juice products and where continuous sterilization of inner surfaces is required.

UV Irradiation

UV radiation is effective in inactivating vegetative bacteria but relatively ineffective in reducing bacterial spores, as a long exposure time is required to achieve desired sterility. Sterilization by UV irradiation is becoming increasingly prevalent, especially for packaging materials and machines that are less readily sterilized by H_2O_2. UV radiation promotes lipid oxidation in food; hence, safety issues need to be considered in designing sterilization processes. UV irradiation induces a mutation of DNA in microorganisms, which ultimately gives a germicidal effect. To accomplish four to six decimal reductions in microbial counts on a flat surface, a dosage of 250 mW cm^{-2} is required. The factors that assure the effectiveness of UV irradiation are smoothness of packaging materials and dust-free surfaces.

Combination of UV Irradiation with Hydrogen Peroxide and Heat

Sterilization of cartons can also be achieved by using H_2O_2 either alone or in combination with UV lamp. Spores are more resistant to UV, so to ensure an adequate sporicidal activity, a combination of H_2O_2 and UV radiation is used. The Liquid Pak system utilizes the synergistic effect for sterilizing the cartons to be used in the carton forming, filling, and closing system in a sterile chamber. The combination of H_2O_2 with UV can be used commercially for the sterilization of cartons during aseptic filling, as the UV irradiation promotes the breakdown of the peroxide into hydroxyl radicals, which results in the lethal DNA disruption of vegetative cells and resistant spores. The lethal effect of UV plus H_2O_2 treatment is affected by the concentration and temperature of H_2O_2, wavelength of UV radiation, and smoothness, reflectivity, and geometry of the surface being treated. The advantages of combined treatment include usage of a lower concentration (5%) of H_2O_2, minimum sterilization time, minimum H_2O_2 residue in products, chemical-free sterilization, and an alternative for high-temperature sterilization.

Control Points and Control Parameters for Effective Sterilization of Packaging Material

Control procedures and points are necessary to assure the repeatability and sterility of the packaging material. To ensure the reliability of the chemical to be used as sterilization medium, the concentration is measured either by the machine operator or by laboratory staff, usually only at the beginning of the packaging operation. The consumption of the sterilization agent must also be determined by the machine operator either at the end of the production run or, better, at regular intervals. The packaging area in which the packages are formed, filled, and sealed must be sterilized prior to the start of production and must be maintained during the entire production run. In this process stage, a number of control parameters are involved, which are essential for the safety and adequacy of the operation. Two positions can be selected when the packaging machine is prepared for cleaning, intermediate cleaning, or final cleaning. Intermediate cleaning can be used whenever the sterile product remains in the product line in which a steam barrier protects the sterile product from being contaminated by the cleaning solution and is to be done immediately after a stop, except when cleaning according to the final cleaning can be accomplished within 1 h. Final cleaning is used in order to clean all parts in contact with the product in the AP valve; cleaning of the steam barrier space must be done every day or as soon as production is finished.

Palm Oil

AJ Dijkstra

© 2016 Elsevier Ltd. All rights reserved.

Historical

There is fair agreement that the oil palm (*Elaeis guineensis* Jacq) originated in West Africa. It grows 10° north and south of the equator and its utilization as basic nourishment had always been of vital importance to the inhabitants of the equatorial regions in Africa; its existence is reported as long as 3000 BC, when palm oil was known to the Egyptians under Pharaoh's reign.

Africans probably brought the oil palm to Madagascar in the tenth century and slave traders introduced the oil palm to South America. The Dutch had a trading post in Ghana and the oil palms grown in the botanical gardens in Amsterdam may well have originated from Ghana. Two of the oil palm seedlings that were planted in 1848 in the botanical garden near the palace of the governor in Buitenzorg (now Bogor) on Java in the former Dutch East Indies came from Amsterdam. Two more came from Madagascar or the isle of Bourbon (now Réunion). These seedlings form the basis of the palm oil industry in Malaysia and Indonesia, their progeny having been widely distributed from 1853 onward.

The material bred from these palms is referred to as *Deli dura*. It is very stable and uniform in oil and kernel contents. The tree was freely distributed in Sumatra, and oil palm cultivation was introduced into Malaysia (then the British colony of Malaya) in 1910 by Scotsman William Sime and English banker Henry Darby.

The foundation of the palm oil industry is generally attributed to Adrien Hallet, a Belgian with some knowledge of the oil palm in Africa. In 1911, he planted palms of Deli origin in the first large commercial plantation in Sumatra. He also recognized that the avenue palms growing in Deli not only were more productive than palms in Africa but also had a fruit composition superior to the ordinary *dura* palms of the west coast. In the meantime, H. Fauconnier, who had been associated with Hallet, had established two palms of Deli origin at Rantau Panjang in Kuala Selangor in 1911 and 1912. These palms were in full bearing by 1917, and in that year, the first seedlings were planted on an area later to be known as Tennamaram estate. It was during this period that the *dura* palm and *pisifera* palm were crossed and that a hybrid progeny *tenera* was introduced to the oil palm industry.

A slow development of oil palm plantations occurred in Indonesia after World War I, followed by Malaya and Belgian Congo. By 1938, Indonesia had 90 000 ha and Malaya 30 000 ha under oil palm. After 1960, the area under oil palm increased rapidly in Malaysia, reaching 3.2 million ha by 2001. Developments in Indonesia were slower, with 2.4 million ha in 2001. These two countries are by far the largest producers of palm oil and the main suppliers to the world market. Plantation developments in Central and South America have reached about 500 000 ha in all, with Colombia, Ecuador, and Brazil having the largest areas. Total word area devoted to oil palm stands at 17 million ha at the end of 2013 with Indonesia on first place with 7 million ha, Malaysia second at 4.5, and Nigeria third at 2 million ha. As pointed out by the Malaysian Palm Oil Board, this accounts for just over 0.3% of the total world area used for agriculture and 6% of the area devoted to oil crops.

Botanical

E. guineensis is a monoecious, erect, one-stemmed palm tree, usually 20–30 m high, with an adventitious root system that forms a dense mat in the upper 35 cm of the soil with only a few roots penetrating deeper than 1 m. The stem is cylindrical and up to 75 cm in diameter and covered with petiole bases in young palms and smooth in older trees (>10–12 years old). Juvenile leaves are lanceolate and entire but gradually become pinnate; mature leaves spirally arranged, paripinnate, up to 7.5 m long; petioles 1–2 m long, spinescent, clasping the stem at base; and leaflets linear, 35–65 × 2–4 cm, up to 376 per leaf.

Inflorescences are unisexual, axillary, and pedunculate and until anthesis are enclosed in 2 fusiform or ovate spathes 10–30 cm long, with 3-merous flowers; the males have numerous cylindrical spikes forming an 15–25 cm long ovoid body and bearing flowers with 6 stamens, connate at base, with linear anthers, whereas the females are subglobose and 15–35 cm in diameter, with numerous lanceolate, spiny bracts, each subtending a cylindrical spikelet with 10–20 spirally arranged female flowers, each with two rudimentary male flowers. The stigma is sessile and 3-lobed. Fruits are ovoid–oblong drupes, 2–5 cm long, and tightly packed in large ovoid bunches with 1000–3000 fruits; drupes have a thin exocarp, an oleiferous mesocarp, and a lignified endocarp containing the kernel with embryo and solid endosperm.

The stem has a single growing point from which a leaf primordium develops about every second week. Succeeding primordia are separated by a divergence angle of 137.5° (Fibonacci angle), causing leaf bases to be arranged in various sets of spirals, of which a set of eight parastichies is normally obvious. Rate of leaf production is up to 40 per year in the first 2 years, dropping to a rate of 18–24 per year from year 8 onward. From leaf primordium to fully expanded leaf (2–10 m^2) takes about 2 years. The normal photosynthetically active life of a leaf is about 2 years, so under natural conditions, up to 50 leaves are present per palm. In plantations, this number is usually kept at about 40. In the first 2 years, lateral growth of the trunk dominates, giving a broad base up to 60 cm in diameter. After that, the trunk starts growing in height, 35–75 cm per year, reducing its diameter up to 40 cm.

The rate of height increment and rate of leaf production appear to be independent. All leaf bases contain inflorescence primordia, but the first fully developed inflorescence does not appear before leaf 20 and usually much later, some 3 years after germination. The length of male and female phases in

individual palms is very variable and irregular, but a population of palms shows clear seasonal trends.

The mean interval between sex differentiation and anthesis is around 20 months, and between anthesis of female flowers and fruit ripeness 4–5 months. Fruit ripening on the bunch proceeds simultaneously from top to bottom and from outer to inner fruits, and ripe fruits become detached. In well-managed plantations in Malaysia and Sumatra, on soils with a reasonable availability of nutrients and a good water-holding capacity under uniform and adequate rainfall, annual yields of bunches of 24–32 tons ha^{-1} are common.

Production of Palm Oil

The production of palm oil starts with a fresh fruit bunch (FFB). This is harvested in the plantation when it starts to drop loose palm fruits. So when these fruits are observed on the soil, a skilled worker uses a knife on a long stick to cut the FFB free from the palm tree so that it falls on the ground from a height that can be 25 m or more. The worker collects the loose fruits in a net, and a small lorry fitted with a crane that runs in between the palm trees collects the FFBs. At that time, the fruits have changed from almost black to a reddish orange.

The fruits are ripe some 14–17 weeks after pollination but pollination is a continuous affair. So bunches are ready to be harvested all the time. This means that each plantation parcel has to be visited every 6–8 days to detect the bunches that are ready for harvesting.

The small lorry may unload its FFBs onto a larger lorry that delivers the FFBs to the oil mill or rather 'palm oil separation plant' since the fruitlets are not milled like olive fruits are milled. Olives arriving at an olive oil mill are first washed and then sent to a hammer mill that crushes the stones in the fruits. When palm FFBs are processed, the kernels are left intact.

Large palm oil mills can have a capacity of 90 tons FFBs per hour. However, these FFBs can only be harvested and transported during daylight. This means that in practice, harvesting will commence at dawn and that the oil mill will be started up around noon, when the first FFBs arrive at the mill. The oil mill will continue processing until the last FFBs that have been delivered during that day have been processed and then shut down until fresh fruit bunches are delivered to the mill on the next day.

Accordingly, palm oil mills only operate about half of the time so that the 90 ton/hour plant will process some 300 000 tons of FFBs per year leading to a production of about 70 000 tons crude palm oil and 45 000 tons of palm kernel nuts. Assuming a yield of 30 tons FFBs per year this corresponds to a plantation of 10 000 ha or a piece of land of 10 km square requiring a fair number of lorries to transport the FFB to the oil mill.

Before and after the lorries have been unloaded, they pass over a weighbridge. This is especially important when the oil mill processes FFBs delivered by smallholders. At unloading, the FFBs are dumped into the intermediates storage that consists of an inclined hopper at the ramp that will hold 900 tons of FFBs (2 lines of 15 bays $\times$ 30 tons FFB).

This intermediate storage affects the crude palm oil quality because storing fruits causes the FFA of the oil to increase. The oil hydrolysis is enzyme catalyzed so it is unlikely that the FFA formed increases the rate of hydrolysis, but even so, care should be taken to minimize FFB storage and to maintain a first-in, first-out schedule.

The first process step in the palm oil mill is the sterilization of the FFBs. To this end, the bunches are loaded into cages that can be wheeled into an autoclave that can hold 3–10 cages of 1.5–7.0 tons per cage. After the autoclave has been closed, steam is introduced until a pressure of 2.5–3.0 bar has been reached. To expel air from the sterilizer, the pressure is released one or two times. Then, the pressure is held for 20–30 min or even longer and released so that the sterilizer cages can be forwarded to the thresher. This sudden release exerts a beneficial drying effect on the fruits. FFB sterilization is a fully automated batch process with a cycle time of 100–120 min including loading and unloading, thus permitting 12–14 batches per day. The patent literature and PIPOC conference proceedings describe several continuous sterilization processes but few of them have been realized industrially, if any.

The sterilization process leads to a condensate. The amount of steam is about 200 kg ton^{-1} FFB, some steam is flashed off, and some water is liberated from the FFB leading to a final liquid effluent of 150 kg ton^{-1} of FFB. This effluent contains some oil, equivalent to 0.5 kg ton^{-1} FFB.

During the sterilization process, the lipase enzyme is denatured, and at the same time, the fruits are loosened from the bunches and inside the fruits, proteins are coagulated so that the mesocarp structure is altered in a way that can be compared to the rendering of animal fats. After the sterilization process, the cages are hoisted and emptied in turn into the feed hopper of the thresher or bunch stripper. This is a slowly rotating horizontal drum fitted with bars that lift the fruit bunches and then drop them so that the loosened fruit separates from the bunches and is removed by a screw conveyor. The empty bunches leave the drum at the other side. However, they still contain some oil, which is estimated at 4.5 kg oil per ton FFB.

The screw conveyor feeds the fruits into a digester. This is a cylindrical vessel with a steam-heated jacket, where the oil and nuts are separated from the fruit pulp by gentle agitation by a paddle stirrer at a temperature of 90–100 °C for a period of 20 min. At the same time, cell walls in the fruit pulp are broken and oil droplets coalesce like during the malaxation step in olive oil production. The resulting mash is then fed to a continuous screw press in which the solid fraction consisting of fibers and nuts is separated from the liquid fraction consisting of fruit water and palm oil.

The separation is far from perfect in that the fiber/nuts fraction is wet and also contains an amount of oil that corresponds to 5.0 kg oil per ton FFB and that the liquid fraction contains some solids. This liquid fraction can be diluted with hot water such as the condensate of the sterilization process. Then, it can be screened to remove fibers and course contaminants before being pumped to a settling tank where the oil is collected as supernatant, clarified by centrifugal separators, and dried to a residual moisture content of $< 0.1\%$ in a vacuum dryer. At some stage, the oil is cooled to storage temperature of preferably 32–40 °C.

The solid fraction is dried and separated into nuts and fibers by a winnowing process in the depericarper. The fibers can be sent to the boiler house, or they can first be further dried so that the oil adhering to these fibers can be recovered by hexane

extraction and then sent to the boiler house. The nuts are cracked to recover the kernels from which the palm kernel oil is produced by screw pressing and solvent extraction.

Palm Oil Refining

Crude palm oil tends to have a low (5–20 ppm P) phosphatide content and a relatively high (>3%) FFA content. Accordingly, the most profitable way to refine this oil is by a combination of the dry degumming process that removes both phosphatides and color and physical refining. The latter process has the advantage that it almost completely avoids the entrainment of neutral oil, which is the case with soapstock.

In the dry degumming process, the oil is heated to 80–100 °C, mixed with 0.05–0.1% (w/w) phosphoric acid, and then mixed with up to 4% of bleaching earth. After a mixing period of 20–30 min, the spent earth is removed by filtration using pressure leaf filters. To minimize oil retention, the filters are blown with steam before being discharged.

When vegetable oils originating from oil seeds are bleached, the cost of bleaching can be reduced by mixing the spent earth with the oilseed meal and selling the earth at meal value. With palm oil, this is not possible so reducing bleaching earth usage is even more important for palm oil than for seed oils. Because the extent of color reduction in palm oil is quite large, the bleaching process can be made more efficient by using a countercurrent process such as the Öhmi-bleach process. In this process, oil is first of all bleached with spent earth, and afterward, the partially bleached oil is bleached with fresh earth to final bleached oil color. The spent earth resulting from this final bleaching step is then used in the prebleaching stage.

The physical refining of the bleached oil is invariably executed as a continuous process because then, the use of heat exchangers and thermosiphons allows a heat recovery of up to 90%. The vacuum stripping equipment can be fitted with a packed column to remove the bulk of the FFA with a minimal amount of steam by making it flow countercurrently through this column.

Because the distillate comprises the free fatty acids, its relative amount is much larger than in installations that deodorize neutral oil. The scrubber section of the equipment has to take this difference into account. Because the distillate can be sold at a higher price when its FFA content is high, a two-stage vapor scrubber/condensation system has been introduced. In a first, high-temperature scrubber, the least volatile compounds are condensed with a small fraction of the FFA. This fraction will contain the tocopherols and tocotrienols and can thus be sold as a tocol concentrate. In a second, low-temperature scrubber, the bulk of the FFA is condensed, thus yielding a valuable by-product that can be used in the oleochemical industry or as a raw material for biodiesel production. This second scrubber can also be one of two surface condensers operating alternately meaning that if one of these condensers is active as low-temperature condenser, the other is being heated to melt its surface condensate and to prepare it for taking over from the active one when that is 'full.'

A health aspect of palm oil refining that should be mentioned is the possibility of forming the potentially toxic fatty acid esters of 3-monochloropropanediol (3-MPCD) and glycidol (2-oxyranemethanol). Both 3-MPCD and glycidol are derivatives of glycerol, hence their occurrence in edible oils. Palm oil is more prone to their formation than other vegetable oils because the high FFA content of crude palm oil is accompanied by a relatively high diglyceride content. Using bleaching earth that has been activated with sulfuric acid rather than hydrochloric acid reduces/eliminates a source of chlorine and thus 3-MPCD formation. The use of naturally activated bleaching earth instead of acid-activated bleaching earth can also help. A slight reduction in deodorization temperature also helps and reduces the formation of *trans* isomers at the same time. Not that this is a serious matter for palm oil since it does not contain any linolenic acid, the fatty acid that is most prone to thermal isomerization to *trans* isomers, and only little linoleic acid.

The Composition of Palm Oil

Like other vegetable oils, palm oil consists mainly of triacylglycerols or triglycerides. However, before being isolated from the oil palm fruits, palm oil suffers some lipase-catalyzed hydrolysis that manifests itself in a relatively high free fatty acid content and a concomitantly high partial glyceride content. Because the relative molecular mass of a diglyceride is more than twice the relative molecular mass of a fatty acid, an FFA content of 1% corresponds to a diacylglycerol (DAG) or diglyceride content of >2%. This is only part of the story. A DAG molecule may be hydrolyzed further to produce another free fatty acid and a monoacylglycerol (MAG) or monoglyceride. This causes 1% FFA to correspond to 0.5% MAG. But then, kinetically, MAG formation will be slow since it requires DAG to be present, unless the hydrolysis rate constant of MAG is much larger than the DAG hydrolysis rate constant.

The stereochemical fatty acid composition of palm oil is given in Table 1.

As with most vegetable oils, there is a preference of the saturated fatty acids for the outer positions and of the unsaturated fatty acids for the middle, 2-position. However, the palmitic acid (16:0) content of the middle position at 24.5% is still substantial. This has repercussions on the triglyceride composition of palm oil. From this stereochemical fatty acid composition, it can be calculated that the tripalmitin content of the oil equals $(0.61)^2 \times 0.245 = 9\%$. This is higher than analytic data that show a tripalmitin content of 6%. In addition to the tripalmitin, palm oil also contains 1% of dipalmitoyl-stearoyl glycerol.

The high palmitic content of the 2-position also causes the P_2O triglycerides (dipalmitoyl-oleoyl glycerol) to contain a fraction of about 0.4 of the nonsymmetrical PPO triglyceride. This has implications for the crystallization behavior of confectionery fats in which palm oil fraction with a high P_2O content is used.

The phosphatide content of crude palm oil is low because the oil has been 'water degummed' during its production. It has been stated that only 4% of the phospholipids present in the palm fruit end up in the crude oil. The phosphorus content of crude palm oil is 5–20 ppm, but this includes inorganic phosphate that may have arisen from the enzymatic breakdown of phospholipids. The phosphatide composition of crude palm oil has been reported as listed in Table 2.

Crude palm oil is dark red because of the presence of carotenes. The quality specification of crude palm oil lists a maximum value of 600–700 ppm. This is very much lower than the values found in palm fiber extracts, which can be as high as 5500 ppm depending on the extraction solvent. The main component is β-carotene (56% of total) followed by α-carotene (35%). The carotene contents decrease during bleaching and, because they are thermally unstable, especially during the vacuum stripping process.

In comparison with other vegetable oils, palm oil has a rather low phytosterol content at about 700 ppm. Table 3 lists the sterols in crude palm oil and makes a distinction between free sterols and esterified sterols.

With respect to the tocols (tocopherols and tocotrienols), palm oil is similar to coconut oil in that it contains tocotrienols but the tocotrienol content in palm oil (530 ppm) is much larger than in coconut oil (30 ppm) (Table 4).

Given their volatility, some tocols will be vaporized during the vacuum stripping process. However, since this process is likely to be used for the physical refining of the oil, the resulting condensate will have a high FFA content and a very low tocol content. A two-stage scrubber should therefore be used to concentrate the tocols to a useful level.

Palm Oil Modification Processes

Four different processes have been developed to convert vegetable oils into fat blends with the required physicochemical properties. The most simple process involves blending two or more different components, like a hardstock and a liquid oil. In the partial hydrogenation process, a fraction of the double bonds present in the fatty acids are saturated or isomerized. This increases the solid fat content profile of the oil being hydrogenated to a level required for the intended application. Hydrogenation changes the fatty acid composition of an oil but does not alter its composition according to carbon number.

A third modification process is the interesterification process. In this process, the fatty acid moieties are reshuffled over the glycerol moieties so that the composition according to carbon number is likely to be affected but the fatty acid composition does not change. An oil with a high content of trisaturated triglycerides, such as a low IV palm stearin, has a high melting point. It gives products an often undesirable, waxy mouthfeel. This can be remedied by interesterifying this high-melting product with an oil that has a high content of medium chain fatty acids like palm kernel oil or with a liquid oil. These oils reduce the fraction of saturated long-chain fatty acids in the mixture and thus the fraction of high-melting triglycerides in the interesterification product. Whereas palm stearin on its own is not suitable as hardstock because of poor mouthfeel and palm kernel oil on its own is not suitable because of its low melting point, their interesterification product can be made to meet a whole range of hardstock requirements.

The interesterification reaction needs a catalyst. This can be a base like sodium methanolate or a lipase enzyme. The base-catalyzed process can be carried out as a batch process or as a continuous process; the enzymatic route is only continuous. The base-catalyzed process uses neutral oil as starting material, which in the case of soybean oil can be alkali-refined oil that has not yet been bleached but, in the case of palm oil, a neutral oil that is likely to have been degummed, bleached, and steam-refined. The oil to be used in the enzymatic interesterification process must be carefully purified to prevent the enzyme from being inactivated.

The importance of the interesterification process is growing because it provides an alternative to the partial hydrogenation process and offers the presumed advantage of avoiding the formation of *trans* isomers. That holds even stronger for the

fourth modification process, the fractionation process, which process can also claim to be purely physical.

The early fractionation processes of edible oils and fats used a solvent like acetone, hexane, or 2-nitropropane. Their flammability required X-proof fractionation plants, which are expensive. Solvent evaporation requires additional equipment and energy, which is also expensive. Consequently, the solvent fractionation process is only used for very special products that can carry the heavy fractionation cost. Besides, fractionation leads to two or more different products, only one of which may be the product that can carry the cost. The other fraction or fractions may have to be sold at much lower price.

The fractionation process consists of two steps: partial crystallization and separation. This separation is nearly always by filtration, thus leading to a filtrate, the olein, and a filter cake, the stearin. The filter cake will never consist of just fat crystals; there will always be some olein in between these crystals. The residual olein content of the filter cake determines the stearin properties and the yields of both fractions. The properties of the olein fraction, on the other hand, are mainly determined by the temperature down to which the crystallization was allowed to proceed.

In the solvent fractionation process, the liquid in between the crystals of the filter cake is a solution of olein in the solvent. Removal of that solvent by evaporation will leave relatively little olein so that the stearin properties are close to those of the pure crystals. This is called a selective fractionation. Working without a solvent in the so-called dry fractionation process formerly led to poor selectivity since the filter cake as obtained by a vacuum drum or band filter could contain as much as 70 wt% olein. Now, the use of membrane filter presses has greatly reduced the olein content of the filter cake to values close to 30%. This has improved the selectivity of the fractionation process so that it can now be used to produce products that formerly required solvent fractionation.

In the field of crystallizers, there has also been steady development. The early crystallizers used for the dry fractionation of oils and fats were cylindrical vessels, fitted with a central agitator and internal cooling coils near the outer walls. They had the disadvantage that on emptying, crystals remained between the

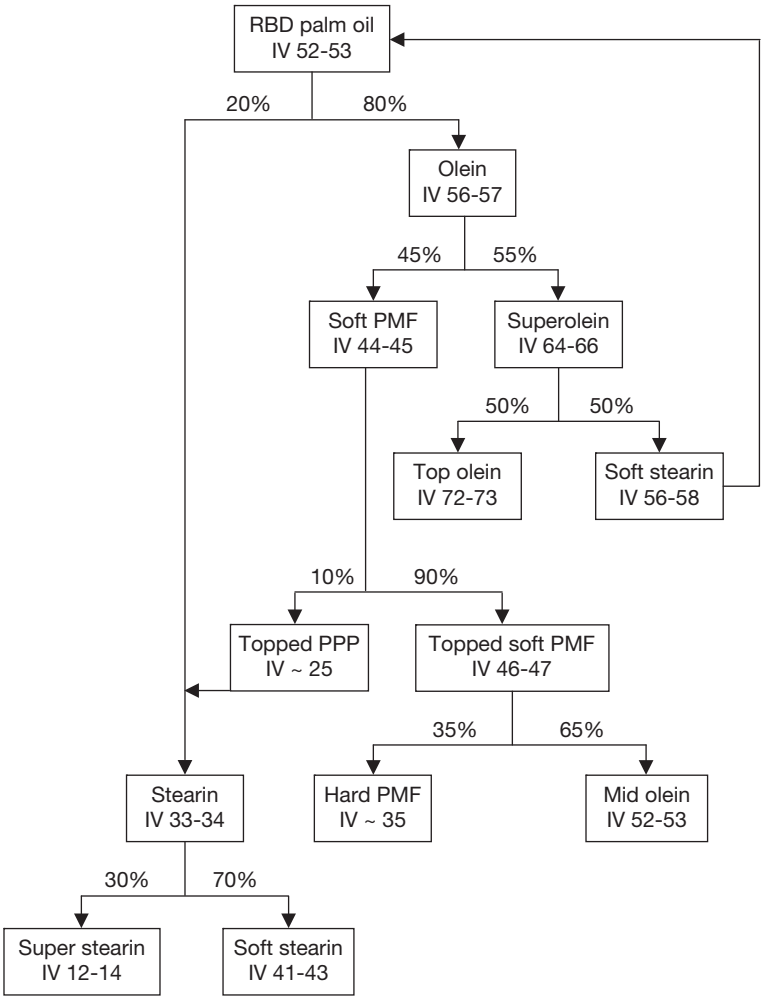

Figure 1 Multistage fractionation of palm oil. Adapted from Figures 12.11–12.13 in Chapter 12, Gibon, V. (2012). Palm oil and palm kernel oil refining and fractionation technology. In: Lai, O.-M., Tan, C.-P. and Akoh, C. C. (eds.) *Palm oil*, *production*, *processing*, *characterization*, *and uses*. Urbana, IL: AOCS Press.

coils and the wall and on top of the coils. So the coils were replaced by vertical, hollow fins that did not hold up any crystals.

However, the limited cooling surface did not permit fast cooling so that in a subsequent crystallizer design, the vessel was divided into coaxial annular compartments with annular cooling compartments in between. A centrally driven agitator extended into the compartments filled with oil. This design had the disadvantage that the linear speed of the agitator was much faster in the outer compartments than in the compartment closer to the central axis. It was also expensive to construct because the cooling compartments had to be fitted with a labyrinth for the cooling water.

The latest crystallizer design comprises a rectangular vessel, the contents of which are agitated by a bundle of cooling tubes that is moved slowly to and fro. This is the so-called Mobuliser®. This crystallizer has a large cooling surface per crystallizer volume and the agitation speed is uniform throughout the crystallizer. Its use has shown that there is no basic need to maintain the same temperature throughout the crystallizer. It therefore permits continuous crystallization with the warm, precooled oil being fed to the top of the crystallizer and the 'cold' slurry leaving at the bottom. This is the iConFrac® process developed by Desmet Ballestra in Belgium.

Its use has also shown that the replacement of the fast-moving agitator blades by the slow movement of the 'agitator *cum* heat exchanger' suppresses secondary nucleation. Consequently, the crystals that were formed initially go on growing at about the same rate so that they maintain a fairly uniform size. As a result, crystal slurries with a high solid fat content can still be agitated, and this allows a fractionation that formerly required two steps to be carried out in a single step. Whereas formerly, the first fractionation of palm oil would produce an olein with an IV of 58 and the second fractionation would produce a second olein with an IV of 62, this is now possible in a single step. This reduces the fractionation cost because it increases the throughput and lowers energy requirements. The more uniform crystals also improve the filter performance.

To make special, high-value products, palm oil is subjected to a multistage fractionation as illustrated in **Figure 1**. It shows that palm oil with an IV of 52–53 is first of all fractionated into a stearin and olein and that both fractions can be fractionated again. If the first olein fraction is refractionated, it yields a superolein, but as explained earlier, this can also be achieved in a single step. This superolein is already a commercial product that can be used as salad oil since it has a cloud point of 4 °C. It can also be refractionated to yield a top olein with an IV of 72–73 and a cloud point of −5 °C.

Figure 1 also shows how a palm mid fraction that can be used as cocoa butter equivalent (CBE) can be produced by multistage fractionation. The stages are the following:

- Palm oil: 80% palm olein (IV 56–57) plus palm stearin
- Palm olein: 45% soft PMF plus palm superolein
- Soft PMF: 90% topped soft PMF plus topped PPP
- Topped soft PMF: 35% hard PMF plus mid olein

The overall yield equals $0.80 \times 0.45 \times 0.90 \times 0.35 \times 100\% =$ 11%. This is not that much but fortunately, the CBE does not have to carry all the raw material and fractionation costs. One of the coproducts is the superolein that commands a premium over palm oil. The soft stearin (IV 41–43) that results from the fraction of the first stearin can be used in margarines and shortenings, and the first stearin and especially the superstearin are highly suitable fats for interesterification with lauric oils to provide hardstocks.

Fractionation is a versatile process that can be adapted to market requirements and opportunities. It also has the advantage that it is reversible. When the fractions do not live up to expectations, they can be mixed and reconstitute the starting material, which can then be subjected to a fresh fractionation.

Pantothenic Acid

RB Rucker, University of California, Davis, CA, USA

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Pantothenic acid (vitamin B_5) in its pure state is water-soluble, viscous, and yellow. It is stable at neutral pH but is readily destroyed by acid, alkali, and heat. It is an essential growth factor for both prokaryotes and eukaryotes and widely found in living materials. Pantothenic acid is ubiquitous in nature (derived from the Greek term pántothen, which means 'from all quarters'). The calcium salt, calcium pantothenate (white, odorless, and crystalline) is the form of pantothenic acid usually found in commercial vitamin supplements.

By the 1920s, it was appreciated that water-soluble factors or 'vitamines' were not a single entity, but compounds with differing functions. The first to be identified was thiamin, initially designated as B_1; the remaining compounds, including pantothenic acid, were found to be a complex of several factors. The identification of pantothenic acid as an essential dietary factor largely evolved from the efforts of research groups associated with Roger J. Williams, Conrad A. Elvehjem, and Thomas H. Jukes. Williams' group established that pantothenic acid was required for the growth of certain bacteria and yeast and later for animals. These observations were confirmed and amplified by Elvehjem and Jukes and coworkers. Next, Williams' group eventually isolated and partially characterized pantothenic acid using 250 kg of liver as starting material. By the 1950s, coenzyme A (CoASH), which contains pantothenic acid as a component, was identified as a cofactor essential for the acetylation of sulfonamides and choline and later of essential importance in the synthesis and oxidation of fatty acids. Pantothenic acid was next identified as a component of acyl carrier protein (ACP), a part of the fatty acid synthesis complex. More recently, there has been an appreciation that additional enzymes utilize pantothenic acid (usually in the form of 4′-phosphopantetheine) as their cofactor component (cf. Figure 1). Examples include 10-formyltetrahydrofolate dehydrogenase and enzymes important to polyketide synthesis. Polyketides are a large class of diverse compounds that are characterized by more than two carbonyl groups connected by single intervening carbon atoms, which include many plant and bacterial substances with antibiotic, anticancer, cholesterol-lowering, or immunosuppressive activity. Steps in the biosynthesis of polyketides share similarities with steps in the synthesis of fatty acids. Also, in addition to the major endoplasmic reticular pathways for fatty acid synthesis, mitochondria have recently been shown to synthesize fatty acids in a malonyl CoA/ACP-dependent manner. In eukaryotic cells containing mitochondria, the pathway resembles that in bacteria, that is, the fatty acid synthesis type II pathway.

Dietary Sources, Production, and Requirements

About 6000 tons of calcium D-pantothenate are produced annually. It is mainly used as an animal feed additive. It is also used for pharmaceutical, health care, and food products. D-Pantothenate (the active form) is prepared by chemical synthesis from D-pantolactone and calcium β-alaninate. However, racemic separation of L form and D form of the final product is often necessary (e.g., separation by chromatography or recrystallization). The commercial product resulting from the chemical synthesis is usually the calcium salt of D-pantothenic acid, calcium D-pantothenate. In addition, many of the current approaches take advantage of biotechnological preparation using microorganisms in which there is synthesis of only the D form of pantothenic acid. As a consequence, the separation of racemates (as is required in chemical synthesis) is not necessary.

It is estimated that most human diets provide 4–6 mg of pantothenic acid per day, which is sufficient to maintain normal serum levels. About 1–2% of the total body pool of pantothenic acid is excreted each day. The recommendation for the human requirement is based on the concept of adequate intake. An adequate intake is based on observed or experimentally determined approximations or estimates of daily nutrient intake or amounts to balance total excretion that result in no obvious metabolic perturbations and when a recommended daily amount cannot be determined.

The adequate intake recommendations for humans are, for 1–3-year-olds, 2 mg day^{-1}; 4–8-year-olds, 3 mg day^{-1}; 9–13-year-olds, 4 mg day^{-1}; 14-year-olds and over, 5 mg day^{-1}; and for pregnant and lactating women, 6 mg day^{-1} and 7 mg day^{-1}, respectively. For reference, human milk contains about 5–6 mg of pantothenic acid per 1000 kcal. These values are in keeping with the reported requirements for monogastric animals, that is, about 2–3 mg pantothenic acid per 1000 kcal or 4.2 kJ of typical diets. There is currently insufficient scientific evidence on which to base a tolerable upper intake level for pantothenic acid.

Availability, Absorption, and Metabolism

Intestinal Absorption, Cellular Uptake and Efflux, Plasma Transport, and Excretion

Pantothenic acid in food is usually present as CoASH or peptide-bound 4′-phosphopantetheine. In order to be absorbed, intestinal enzymes must hydrolyze these substances. This occurs by the sequential activity of two intestinal hydrolases, a pyrophosphatase and a phosphatase. Pantetheine, the product, can be further metabolized to pantothenic acid by another intestinal hydrolase, pantetheinase. There is a near-quantitative release of pantothenic acid or pantetheine from proteins and peptides, such as those derived from ACP. Following enzymatic release, the pantothenic acid or pantetheine absorption involves a sodium-dependent multivitamin transporter with a K_m for pantothenic acid intestinal uptake of 10–20 μM.

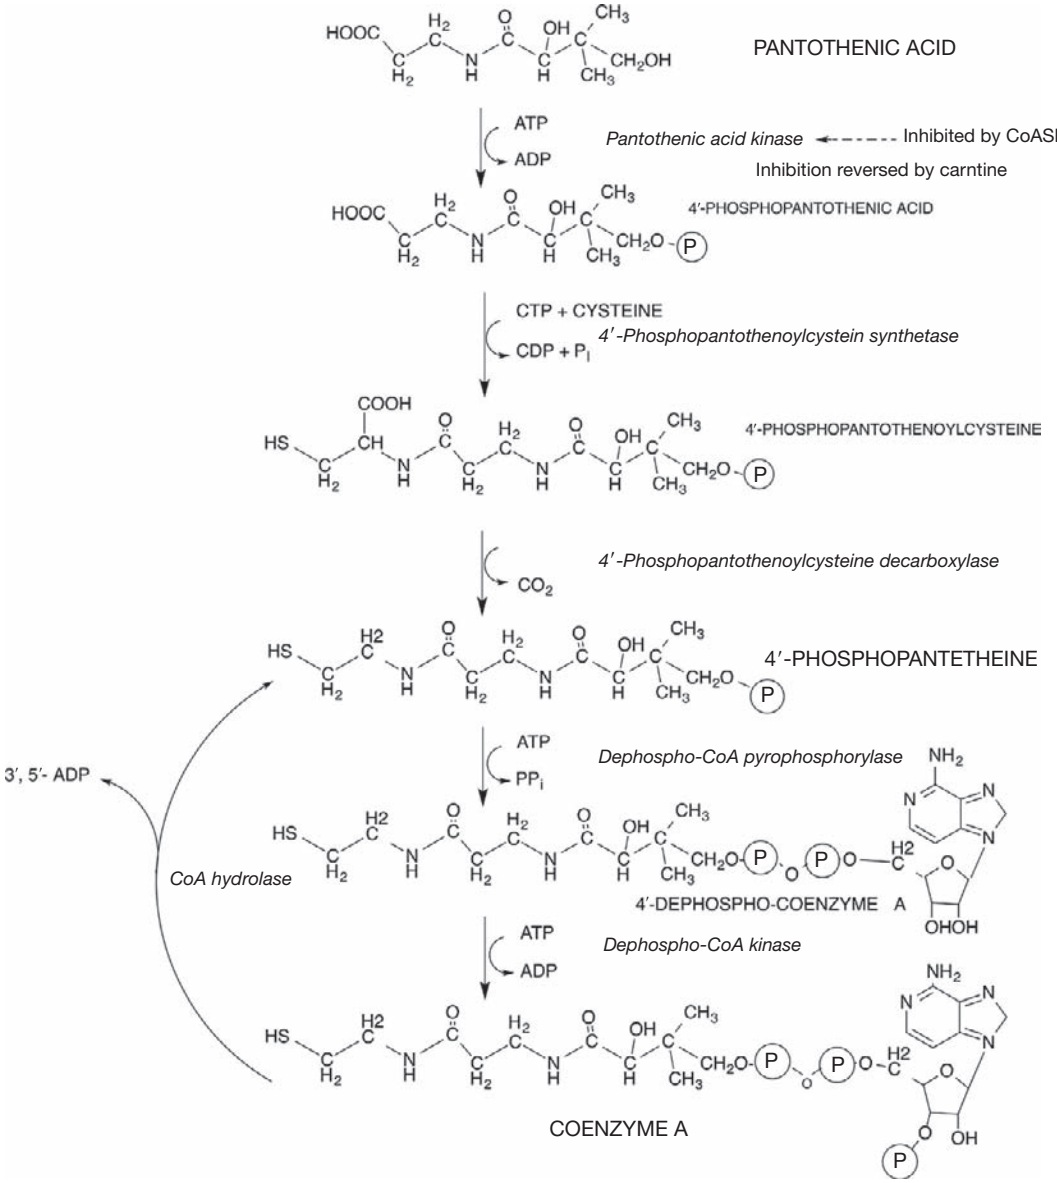

Figure 1 Pantothenic acid: metabolic conversion to coenzyme A and ACP. Forms of pantothenic acid that are important to the synthesis of coenzyme A (CoASH) and acyl carrier protein (ACP).

At a dietary intake of ~10–15 mg of CoA (the amount of CoASH in a typical meal), the pantothenic acid concentration in luminal fluid is ~1–2 μM. At this concentration, the transport system is not saturated, and as a consequence, pantothenic acid is efficiently and actively absorbed. In an analogous fashion, cells in tissues take up pantothenic acid from the plasma by a saturable process with an apparent K_ms in the low μM range. For example, kinetic analysis of human placental choriocarcinoma cells indicates the presence of a single saturable transport system with a Michaelis–Menten constant of ~2 μM. The dependence of uptake on the Na^+ concentration exhibits sigmoidal kinetics, indicating interaction of more than one Na^+ ion with the transporter. In the brain, pantothenic acid is transported through the blood–brain barrier by a low-capacity, saturable transport system with a half-saturation concentration approximately 10 times the plasma PA concentration. In the liver, the cellular concentration of free pantothenic acid is 10–15 μM and in the heart ~100 μM compared with the 1–5 μM concentrations observed in the plasma. For comparison, the concentrations of CoASH and ACP are 50–100 μM and 10 μM, respectively, in the cytosol of typical cells. In mitochondria, the CoASH concentration can be as much as 10- to 20-fold higher, that is, 70–90% of the total cellular CoASH content. Although much remains regarding the details of cellular influx, internal regulation, and egress from cells, pantothenic acid cellular uptake has been linked to protein kinase C activity and calmodulin-dependent regulatory and signaling pathways. As a final step in whole-body regulation, the vitamin is excreted in the urine primarily as pantothenic acid. This occurs after its release from CoASH by a series of hydrolysis reactions that cleave off the phosphate and β-mercaptoethylamine moieties.

Most Important Cellular Functions

As a component of CoASH and ACP, pantothenic acid is involved in over 100 known reactions central to intermediary metabolism. As a general rule, CoASH is involved in acetyl and acyl energy-related transfer reactions and processes related to oxidative metabolism and catabolism, whereas ACP is involved primarily in synthetic reactions, essential to either fatty acid or isoprenoidal structures. Moreover, CoASH-dependent acetylation of certain lipids, amino acids, and proteins is essential to many aspects of cell membrane formation and changes in protein structure related to compartmentalization and stability, for example, acetylation of histone.

Properties of CoASH and ACP Important to Function

The adenosyl moiety of CoASH provides a site for tight binding to CoA-requiring enzymes, while allowing the phosphopantetheine portion to serve as a flexible arm to move substrates from one catalytic center to another. Similarly, 4′-phosphopantetheine in ACP also functions as a flexible arm that allows for a systematic presentation of acyl derivatives to each of the active centers of the fatty acid synthase complex. It is also important to appreciate that intermediates arising from the transfer reactions catalyzed by CoASH and 4′-phosphopantetheine in ACP may be viewed as 'high-energy' compounds. Typical esters (O–CO–R) or amides (–N–CO–R) are thermodynamically more stable than thioesters (–S–CO–R). The double-bond character of the C–O bond in –S–CO–R does not extend significantly into the C–S bond. This causes thioesters to have relatively high-energy potential, and for most reactions involving CoASH or ACP, no additional energy, for example, from ATP hydrolysis, is required for transfer of the acetyl or acyl group. For example, consider that at pH 7.0, the $-\triangle G$ of hydrolysis is ~7.5 kcal for acetyl-CoA and 10.5 kcal for acetoacetyl-CoA compared with 7–8 kcal for the hydrolysis of ATP to AMP and pyrophosphate or ADP and phosphate. The terminal thiol group of CoASH and ACP is also ideally suited for nucleophilic substitution reactions involving activated carboxylic acids and α- and β-carbonyl functions.

Regulation of CoASH and ACP via Pantothenic Acid Kinase

Pantothenic acid kinase serves as a primary control point for pantothenic acid utilization. There are three distinct types of pantothenic acid kinase (PanK): PanK-I (bacterial), PanK-II (mainly found in eukaryotes and also in the *Staphylococci*), and PanK-III (also bacterial). The eukaryotic PanK-II enzymes occur as different isoforms (PanK1, PanK2, PanK3, and PanK4). Pank2, expressed in mitochondria and found on chromosome 20p13, is the best characterized of the various isoforms. Alternatively spliced transcript variants encoding multiple isoforms have also been observed for Pank2. Mutations (particularly in PanK2) can result in pantothenate kinase-associated neurodegeneration, such as Hallervorden–Spatz syndrome.

Feedback inhibition of the kinase by CoASH or CoA derivatives is a principal factor governing the flux through the subsequent steps in the CoASH synthesis pathway and defines the upper threshold for intracellular CoASH cofactor levels. Inhibition by acetyl-CoA is greater than that of free CoASH. The inhibition by free CoASH is uncompetitive with respect to pantothenate concentration.

In addition to regulation at the substrate level, PanK2 is regulated by tumor protein p53, also known as p53, a protein that is crucial in multicellular organisms, where it regulates the cell cycle and, thus, functions as a tumor suppressor. Peroxisome proliferator-activated receptors, such as PPARα, also influence pantothenic acid kinase activity. Using metabolomic approaches, for example, high-resolution NMR and mass spectrometry technology, it has been shown in humans that significant depletion of both pantothenic acid (as much as fivefold) and acetylcarnitine (as much as 20-fold) occurs in response to PPAR agonists, such as fenofibrate.

Substrates are added to pantothenic acid kinase sequentially with ATP as the leading substrate. The allosteric regulatory domain responsible for acetyl-CoA inhibition also binds the substrates, pantothenate and pantetheine, and the various small-molecule inhibitors and activators that can influence pantothenic acid kinase activity. As it relates to acetyl-CoA production and utilization, the sensitivity to carnitine is an important observation. Carnitine relieves the feedback product inhibition of pantothenate kinase through its role in transporting acyl groups from cytosol to mitochondria for β-oxidation. Carnitine has no direct effect by itself, but specifically reverses the inhibition by CoASH. In the heart muscle, the free carnitine content varies directly with the phosphorylation of pantothenic acid. Thus, the interactions involving carnitine are additional mechanisms for the control of CoASH synthesis and the regulation of cellular pantothenic acid content. Moreover, fasting and low insulin increase pantothenic acid kinase activity and the total content of CoASH.

Following 4′-phosphopantothenic acid formation, the remaining steps in CoASH synthesis are carried out on a protein complex (~400 000 Da) with multifunctional catalytic sites. Enzymatic features of the complex include dephospho-CoA pyrophosphorylase activity and coenzyme A hydrolase activity (Figure 1). Less is currently known about the regulation of ACP, often described as 'macro-cofactor.'

Health Effects

Symptomatic nutritional deficiencies of pantothenic acid are rare. Pantothenic acid deficiency in experimental animal models (both avian and mammal) results in impaired energy production, most likely due to low CoASH levels and impaired acetylcholine synthesis. Pantothenic acid deficiency can also cause hypoglycemia and an increased sensitivity to insulin. Given a requirement for pantothenic acid that appears to be ~5 mg day^{-1}, it may be predicted that 5–6 weeks might be required before signs of deficiency are observed in humans.

There is only a limited amount of clinical data for experimental pantothenic acid deficiency in humans. What is known about pantothenic acid deficiency in humans comes primarily from indirect lines of evidence. For example, malnourished prisoners of war (World War 2) experienced numbness and burning sensations in the extremities, which seemed reversed primarily following pantothenic acid supplementation, in contrast to other B vitamins. Moreover, the administration of

pantothenic acid kinase inhibitors, such as ω-methylpantothenate or calcium hopantenate, in combination with a diet low in pantothenic acid, exacerbates signs of pantothenic acid deficiency, such as numbness, burning sensations, and changes in lipid metabolism.

In animals, the classic signs of pantothenic acid deficiency include growth retardation and dermatitis, sometimes accompanied by the graying of hair and/or alopecia. A consistent finding, when a deficiency is severe, is progressive morphological and functional changes in adrenal glands. The adrenal cortex becomes enlarged, and there is a progressive depletion of ketosteroids. In later stages of pantothenic acid deficiency, adrenal atrophy occurs.

Pantothenic acid at abnormally high levels is well tolerated; the acute oral LD50 is 10 g kg^{-1} in mice and rats. A chronic intake of calcium pantothenate at 3% of the diet is the lowest observed adverse effect level in rats. At this level, enlargement of the testes, diarrhea, and hair damage may be observed. In humans, such a dose would be the equivalent of 2–3 g of pantothenic acid per day.

Sources and Production

Papaya (*Carica papaya* L.) belongs to the family Caricaceae and is the most economically important species of the genus *Carica*. Papaya is native to tropical America, and seeds of papaya were taken from the Caribbean, to Malacca or Philippines, then to India. Subsequently, papaya was introduced as a plantation crop to Australia, Hawaii, Sri Lanka, and other tropical and subtropical countries in the world. Papaya is an important fruit crop in the tropics and is cultivated for consumption in the fresh or processed form and for use in pharmaceutical, leather, and textile industry. The fruit is a good source of vitamins and minerals while being low in sodium, fats, and calories.

Global production of tropical fruits (excluding banana) reached 73.02 million metric tons (Mt) in 2010, and papaya ranked third with 11.22 Mt or 15.36% of the total annual tropical fruit production. Global papaya production is highly concentrated, with the top ten countries averaging 82.32% of the total production during the period 2008–10. India is the leading papaya producer, with a 38.61% share of the world production (2008–10), followed by Brazil (17.5%), Indonesia (6.89%), Nigeria (6.79%), Mexico (6.18%), Ethiopia (2.34%), Congo (2.12%), Colombia (2.08%), Thailand (1.95%), and Guatemala (1.85%). Economic value of papaya has potential to be exploited as an income generator besides providing food to the people. However, papaya industry in some tropical countries is still relatively small, and trees continue to be grown in backyards and home gardens mainly for local consumption. Commercial planting started during the last few decades in Malaysia, Thailand, the Philippines, Indonesia, and India with the introduction of new and better-yielding varieties. Constraints that hinder the expansion of the papaya industry in these countries include unavailability of suitable land for growing crops, pathogen infections, insufficient handling techniques, short life of the fruit, and plant quarantine restrictions imposed by some importing countries. Major papaya-exporting countries in the world are Mexico, Brazil, Malaysia, India, and the United States (mainly via re-exports). The major papaya varieties dominating the world trade are Solo, Sunrise, Maridol (red and golden), Red Lady, Linda, and Tainung.

Papaya is a large herbaceous plant generally with a single erect stem, which can grow up to 9 m, terminating with a crown of large leaves. There is a wide diversity of biological types of cultivated papaya. The plants can be dioecious, with male and female flowers on separate plants; monoecious, with male and female flowers on the same plant; or hermaphroditic, with male and female parts on the same flower. Papaya is a melon-like fruit, which varies greatly in shape and size. The skin of unripe fruit is smooth, green, and thin and changes to deep orange or yellow when ripe. The flesh varies from 2.5 to 5.0 cm in thickness and yellow to orange in color. Numerous round, black seeds with wrinkled seed coat are enclosed in a gelatinous membrane (sarcotesta), which is attached to the inner wall of the fruit.

One of the major problems faced in papaya fruit marketing is the identification of the optimum harvest maturity to ensure adequate fruit ripening and good eating quality. The harvest maturity depends upon distance to markets. To supply for the local markets, fruit may be harvested at one-quarter to one-half ripe or yellow stage. Fruit to be transported for long distances or exported are harvested at color break to one-quarter ripe, depending on the cultivar's ripening characteristics and season. Fruit should be harvested when peel color changes from dark green to light green and when one or two yellow streaks begin developing from the posterior side of the fruit to the pedicel end. This stage is known as color break stage, and fruit in this condition will continue to ripen normally after harvest. Fruit harvested before this stage will fail to show complete ripening, and those harvested after are more susceptible to damage and bruising during handling. The Hawaii grade standards require fruit to have 11.5% total soluble solids (°Brix) with color break stage normally meeting this standard. Papaya is harvested by hand alone or with knives or specialized tools, depending on the size and age of the tree. As the trees become taller, some form of harvesting aids such as poles and ladders must be used. A pole with a small hoop and a small mesh bag at the end will be useful to minimize the mechanical damage that can happen to the fruit during harvest. Harvested fruit could be collected in field bins made of a soft material or plastic crates to prevent damage to the papaya skin.

Grading and packing should be carried out as soon as possible after harvest. This should be done within 3 h after which the fruit should be kept under ambient tropical conditions (25–28 °C) to continue ripening or cooled and stored at 10 to −12 °C. Depending on the country of origin, some importing countries require the fruit be treated for fruit flies. Treatments are determined by importing country requirements and may include long exposure to hot water treatment or vapor heat treatment. Postharvest treatment with fungicides is used to prevent the development of anthracnose and phytophthora neck rot.

Papaya is packed in single-layer cartons, each with a net weight of 4–5 kg, depending on importer and importing country requirements. Internal packing materials can be included with shredded paper placed at the base of the carton and individual tissue wrap or with an expanded polystyrene sleeve. If papaya is intended for export, precooling should be done before shipment. Room cooling and forced air cooling are commonly used. Hydro cooling is also possible. However, rapid cooling after insect disinfestation treatments can lead to skin scalding. Optimum storage temperature for papaya is in the range of 7–13 °C with 90–95% RH. However, at the lower range of 7–10 °C, chilling injury may occur, while at 10–13 °C,

ripening occurs slowly. At the color break stage, papaya can be stored at 7 °C for 14 days and will ripen normally when transferred to room temperature. Papaya is a climacteric fruit with typical respiratory and ethylene production patterns during ripening. During ripening, the color, firmness, carbohydrate composition, and production of secondary compounds, which are responsible for fruit color and flavor, in papaya fruits change.

Papaya fruits are very susceptible to invasion by certain pathogenic fungi and bacteria due to high moisture and nutrients. The development of fungal infection during the postharvest phase can depend upon the physiological age of the fruit, mechanical injuries, and storage conditions. Anthracnose is a major cause for the postharvest loss of papaya particularly when attempting to extend the storage life. The causal organism *Colletotrichum gloeosporioides* is of common occurrence in home garden environments. Symptoms of the disease are known to be particularly destructive once ripening has been initiated. Incidence of the disease limits the storage life of the commodity in both local and export markets during the ripening process, storage, and transportation.

Patterns of Papaya Consumption

Papaya is rapidly becoming an important fruit crop as a fresh fruit or in the processed form. In Asia, green fruits are served in salads and as a vegetable or made into preserves. Papaya is processed into various forms such as slices for fruit salads and cocktails, dehydrated slices, chunks, and fruit leathers or bars. Papaya can also be processed into puree for juices, nectar, mixed drinks, and jams. Papaya provides a cheap source of vitamins and minerals in the daily diet of the people. The fruits of certain cold-hardy genera in the Caricaceae family are used as a source of food in Central and South America on a limited basis where the fruit might be consumed directly as fresh, roasted, or processed products. Supplements made from fermented papaya are known to have good nutraceutical properties. Papaya seed, which accounts for up to 50% of the waste from the fruit, can be ground into flour. The seed kernel flour is known for its high protein content and can moderate carbohydrate levels while having good water and oil absorption capacities. Papaya also has several industrial uses. Leaves and fruit are valuable sources of several proteins and alkaloids that have applications in the pharmaceutical industry. Of particular importance is papain, an important proteolytic enzyme that occurs in the milky latex produced by immature fruit. The latex is obtained by scarifying immature fruit to induce flow of the milky latex, which is then collected and dried prior to processing. Papain has several applications including its use in chewing gum, chill proofing of beer, tenderizing meat, and preparation of drugs for digestive ailments and treatment of wounds. It is also used in the textile and cosmetic industry. Papaya seed has been explored as a source of biodiesel in countries with high papaya production. The seed oil composition is familiar to that of olive oil and appears to be a suitable candidate for biodiesel production due to its appropriate proportions of fatty acids for cold flow properties and oxidative stability.

Availability, Absorption, and Metabolism

Being a nutritious fruit, papaya ranks first among 13–17 fresh fruits for vitamin C content per 100 g edible portion. It is reported that most of the papaya cultivars contain higher levels of vitamin C compared to passion fruit (1.4 mg/100 g), banana (8–20 mg/100 g), annona fruit (11.5–37.3 mg/100 g), and pineapple (0.93 mg/100 g). Papaya is an excellent source of provitamin A (carotenoids), which is important for good health especially on eye sight, helping to prevent early blindness in children. Papaya has more carotene compared with other fruits such as apple, guava, and plantain, which help to prevent damage by free radicals. Papaya ranks first among the fruits for vitamin C, vitamin A, riboflavin, folate, calcium, thiamin, iron, niacin, potassium, and fiber. The fruit is also popular with obese people who are into weight-reducing regimes since it is low in fat, carbohydrate, and calories. The antioxidant activity of fermented papaya is highly appreciated due to its nutraceutical properties (Tables 1 and 2).

Nonvolatile organic acids formed the major portion (about 80–90%) of total acidity in fruit. Citric and malic acids, present in equal quantities, are the predominant acids. However, the presence of tartaric, malonic, fumaric, and succinic acids has also been reported. The concentration of total and nonvolatile acids decreased during fruit development, reaching a

Table 1 Nutritional composition of papaya (per 100 g edible portion)

Nutrient	*Composition*
Water	90.8 g
Energy	32.8 k cal
Protein	0.6 g
Fat	0.1 g
Carbohydrates	7.2 g
Calcium	17.0 mg
Phosphorus	13.0 mg
Iron	0.5 mg
Vitamin C	57.0 mg
Carotene	666.0 μg
Thiamine	40.0 μg
Riboflavin	250 μg

Table 2 Vitamin C content of different papaya cultivars

Papaya cultivar	*Vitamin C content (mg/100 g^{-1} fresh weight)*
Maradol	46–82
Criolla	42–55
Tainung 01 Formosa	59.9–68.2

Laie Gold	51.2
Rainbow	51.8
Sunrise	55.6–187
Golden Solo	103.1
Baixinho do Santa Amelia	147–151

minimum at the ripe stage. An increase in total acidity observed during ripening is believed to be associated with an increase in free galacturonic acids. Tissue pH of papaya increases from 5.2 to 6.0 in 50% yellow fruit and then decreases to 5.2 in 100% yellow fruit.

During ripening, the color of the pulp turns yellow to reddish. Carotenoids content estimated as β-carotene showed a five- to tenfold increase in yellow-fleshed cultivars, between the mature green stage and the full ripe stage. In red-fleshed cultivars, however, the change in color is associated with a marked increase in lycopene content, which has the highest radical scavenging ability among carotenoids. The major difference between the yellow- and red-fleshed papayas is the complete absence of lycopene in yellow-fleshed types. The antioxidant properties of lycopene in red-fleshed papaya varieties have a greater contribution to human health than vitamin A. A recent report of Hawaiian papaya analysis revealed that other than vitamins C and A, papaya is an important source of magnesium. A cup of papaya (140 g) contains 8–11% of the dietary reference intake (DRI) of magnesium, and it would provide 80% and 96% of the DRI for vitamin C for the average adult male and female, respectively.

The principal carbohydrates in papaya fruit are sucrose, glucose, and fructose. In the early stages of fruit development, glucose is the predominant sugar, while at the preripe and ripe stages, sucrose increases by two- to fivefold, reaching higher levels than those of fructose and glucose. Early reports indicated much lower amounts of sucrose and higher percentages of glucose and fructose. This may be due to the presence of an invertase enzyme that is active during extraction. A recent evaluation where samples were heated in a microwave oven to deactivate the enzyme has given the distribution of sugar as 48.3% sucrose, 29.8% glucose, and 21.9% fructose. Papaya fruit contain a small amount of starch, which shows very little change during fruit development.

About 106 volatile components in small concentrations are present in papaya fruit. Amounts vary according to the cultivar and locality. Linalool has been found as the major volatile component. The relative proportions of different volatile components vary with the ripeness. The volatile compound methyl butanoate is considered responsible for the sweaty odor quality of papaya, but only methyl benzoate is described as having papaya qualities on odor assessment.

Softening of papaya fruit is characterized by an increase in the solubility of cell wall pectin, and the extent of softening depends on pectin depolymerization. The ripening of papaya, as characterized by changes in tissue softness, is believed to be initiated on the inner mesocarp tissues close to the seed and to progress outward. While pectin solubilization in inner and outer mesocarp tissues was comparable, pectin depolymerization appeared and begins earlier in the inner than in the outer mesocarp tissues. The polygalacturonase (PG) enzyme activity increases during ripening as the tissue softens. PG activity increased with the increasing depth of the mesocarp tissue and was the highest in the inner mesocarp tissue, suggesting that formation and activation of the enzyme began in the inner tissues and progressed toward the outer regions. The activity of β-galactosidase also increased during ripening, but unlike PG activity, it was found to be consistently higher in the outer mesocarp than the inner mesocarp. It is thought that β-galactosidase significantly contributes to pectin and hemicellulose modification and thereby softening of fruits.

Fatty acid content of phospholipids increased with increasing fruit maturity. The increase in the relative amounts of lower-melting point unsaturated fatty acids such as palmitoleic acid and linoleic acid among papaya phospholipids is thought to increase the resistance to chilling injury. Several thiol proteases, namely, papain, chymopapains A and B, and papaya peptidase, were found in papaya latex. The milky latex, which is most abundant in immature fruit, contains mainly papain and chymopapain. Both are active principles in breaking down or digesting protein. This property is being used by cooking meat with raw papaya to make it tender and digestible.

Polyphenol oxidase activity in papaya decreased during the climacteric rise and then increased up to the ripe stage. A decrease in bitterness during ripening could result from the decline in phenol content, but the peel still contained bitter compounds at the ripe stage.

Health Effects

Papaya extracts from various plant parts are well known for their medicinal properties and have been used as traditional medicine for the treatment of various diseases. The milky latex, which is most abundant in immature fruit, contains several thiol proteases, namely, papain and chymopapain A and B, and papaya peptidase. Both papain and chymopapain are active principles in breaking down or digesting protein. A number of volatile and aroma compounds have been identified from papaya fruit extracts. Papaya juice and fruit extracts are known to exhibit antioxidant and anti-inflammatory activities that could potentially provide protection against a number of debilitating cardiovascular and neurological disorders. Papaya juice extracts contain compounds responsible for relaxation of vascular tissues and may have beneficial properties in alleviating heart disease and related ailments. Carparine, an alkaloid found in papaya leaves, has also been used for medicinal purposes. Carparine is known to cause a strong depression in the activity of heart. A number of chemical compounds with antitumor properties have been isolated from papaya leaf, fruit, and seed extracts. Such bioactive compounds exhibited chemoprotective properties under *in vitro* and *in vivo* conditions. Microarray analyses of tumor cell lines treated with papaya leaf extract revealed the upregulation of several genes with immunomodulatory properties. Papaya fruit, leaf, and seed tissues are known to exhibit wide range of antimicrobial properties. The seeds and unripe fruit are rich in benzyl isothiocyanate, a sulfur-containing chemical that has been reported as an effective germicide and insecticide. Antibacterial properties of leaf and stem tissues have been attributed to the presence of cyanogenetic glycosides, which could be a potential source of the toxic cyanide compounds. Seed extracts have been demonstrated to exhibit properties against gram-positive bacteria. Papaya leaf and seed extracts exhibit significantly high levels of antifungal activities. Antifungal properties of papaya latex can be attributed to the presence of glycosidase compounds, which may cause a degradation of the fungal cell wall. Studies have demonstrated the synergistic effects of papaya latex with antifungal drugs, which could

potentially reduce the dose of such drugs administered to treat fungal diseases. Alcohol extracts of papaya leaves and seeds exhibit antifungal activity against a number of plant pathogens and could have potential applications for reducing postharvest diseases that lower fruit quality in storage and during transit.

Papaya extracts have been actively studied for their hypoglycemic properties. Papaya fruit extracts administered to test animals significantly reduced blood sugar and lipid levels. Similar results were observed with aqueous extracts of papaya seed. The hypoglycemic index of papaya leaf extracts revealed that an aqueous leaf extract significantly decreased blood glucose levels in diabetic rats and was attributed to either a decrease in intestinal glucose absorption or an increase in peripheral glucose utilization.

Crude extracts of papaya tissues are effective in controlling parasitic infections and have been attributed to the cysteine proteinases that are present in the latex that is released upon injury to the plant. Administration of extracts containing papaya latex was effective in controlling intestinal parasites in sheep and pigs. Both studies indicated the potential use of papaya latex as an oral application for controlling human parasites that were transmitted via soil. Treatment of free-range chicken with papaya latex significantly reduced nematode infections and resulted in a subsequent increase in weight gains and could be used to substitute currently used chemicals for nematode control in poultry. The hydrolase enzyme tightly bound to the water-insoluble fraction of crude papain, papaya lipase, is considered as a 'naturally immobilized' biocatalyst. Crude extracts of papaya seed were found to be effective in controlling pathogenic parasites of fish and could have potential application to reduce diseases occurring in aquaculture. In other studies, papaya seed extracts were effective in treating intestinal parasites in children without any apparent side effects.

Herbal preparations of papaya extracts have been evaluated for their ability to treat burn-induced wounds. Topical application of fermented papaya extracts significantly reduced inflammation in rats with burn wounds and accelerated wound healing. Such effects were attributed to the antibacterial and antioxidant activities of the extract applied to the wound region. The proteolytic fraction of latex from immature fruit of mountain papaya exhibited potential for skin regrowth of wound tissues. Similar properties were exhibited by latex obtained from *C. papaya*.

Fermented papaya extracts are reported to possess antiviral and neuroprotective properties. Extracts have also been used to treat malaria and amoebiasis. Crude extracts of papaya tissues are also reported to have galactopoietic and contraceptive activities. Crude papaya latex could be used as a catalyst for the synthesis of triacylglycerols resembling human milk via transesterification of vegetable oils.

Introduction

Foodborne diseases are a major cause of morbidity and mortality worldwide, representing a major public health problem due to their multiple implications. Knowledge of infectious etiological agents transmitted due to contamination of food consumption represents a major challenge in terms of control policies on the handling and marketing of food. Unfortunately, most of them are due to pathogens predominantly present and prevalent in developing countries and are the cause in many cases of diseases considered as neglected. Neglected diseases typically occur in developing countries, imposing a significant estimated burden. However, because in most of those countries such diseases are not notifiable and under surveillance, the real impact in terms of burden of public health can be difficult to determine.

Foodborne diseases can be caused by a wide range of etiological agents, including bacteria, fungi, viruses, parasites, and even prions. The relevance of foodborne parasitic diseases, caused either by helminths or protozoans, has been highlighted during recent years. In 2014, the World Health Organization (WHO) and the Food and Agriculture Organization of the United Nations, initially focussing on the ten foodborne parasites with the greatest global impact, developed a joint report 'Multicriteria-Based Ranking for Risk Management of Foodborne Parasites,' based on the burden on human health and other factors and including information on where they can be found. The top ten are

1. *Taenia solium* (helminth: cestode; pork tapeworm): In pork
2. *Echinococcus granulosus* (helminth: cestode; hydatid worm or dog tapeworm): In fresh produce
3. *Echinococcus multilocularis* (helminth: cestode; a type of tapeworm): In fresh produce
4. *Toxoplasma gondii* (protozoa): In meat from small ruminants, pork, beef, game meat (red meat and organs)
5. *Cryptosporidium* spp. (protozoa): In fresh produce, fruit juice, milk
6. *Entamoeba histolytica* (protozoa): In fresh produce
7. *Trichinella spiralis* (helminth: nematode; pork worm): In pork
8. *Opisthorchiidae* (helminth: trematode; family of flatworms): In freshwater fish
9. *Ascaris* spp. (helminth: nematode; small intestinal roundworms): In fresh produce
10. *Trypanosoma cruzi* (protozoa): In fruit juices

However, this is a global approach. In some countries and regions, some of them can be of higher relevance (e.g., in rural areas of Brazil *Trypanosoma cruzi* can be more risky than *Opisthorchiidae* which is not even endemic in the country; or the opposite in countries of Southeast Asia, where *Opisthorchiidae* infections can be prevalent but *Trypanosoma Cruzi* is not present).

Even more, its incidence and presentation depend largely on the sociocultural conditions of affected populations, such as feeding habits, and the main determinants of living and social conditions. This article aims to review the main pathophysiology, clinical manifestations, and etiological management of some of the most important foodborne parasitic diseases, five of the mentioned top ten risky foodborne parasites (*Taenia*, *Toxoplasma*, *Cryptosporidium*, *Trichinella*, and *Trypanosoma cruzi*), and three additional that are highly important in terms of prevalence, not just in developing countries but also in developed regions (*Giardia*, *Cyclospora*, and *Sarcocystis*).

Taeniasis and Cysticercosis

Cysticercosis is considered as one of the most fatal but also preventable parasitic diseases, caused by the larval stages of *Taenia solium* (cysticerci). The global burden of the disease and the possible clinical outcomes make cysticercosis an important foodborne and zoonotic disease that requires more attention, especially from the public health sector.

Transmission Mechanism and Pathophysiology

The transmission of *Taenia solium* is usually reported in well-known rural endemic areas like Asia, Africa, and Latin America, but lately it has been reported as an emerging infectious disease in some developed countries. Infection by *Taenia solium* larvae (cysticerci) occurs through the consumption of pig meat containing the parasites, by person-to-person transmission, or by autoinfection. In the case of taeniasis (intestinal infection caused by *Taenia*), once a human is infected by ingesting raw or undercooked cysticerci-infected meat, the adult form of this parasite can reside in the human intestine, where they reproduce into eggs. In a second cycle, these embrionated eggs can be ingested, and the oncospheres hatch, penetrate the intestinal wall, and disseminate to several tissues, developing cysts or cysticerci. The cyst can occur anywhere, but the most common localizations include muscles, subcutaneous tissues, or the brain.

Clinical Signs

A symptomatic patient with cysticercosis usually develop neurocysticercosis, in which seizures are the most common

manifestation. There are also several manifestations including headaches, neurological signs, or hydrocephalus. The diagnosis includes the traditional radiological finding of cerebral calcifications.

Treatment and Prevention

Treatment, particularly of neurocystocercosis, is complex, but is mainly focussed on the control of the seizures. The whole therapy includes anticonvulsants and steroids. The administration of anthelmintic drugs, especially albendazole, is considered the first-line treatment, with praziquantel as a second-line treatment.

Possible fatal outcomes in neurocysticercosis give this zoonotic disease a high relevance. Its epidemiology includes occurrence in developing and developed countries, and it is important that health authorities focus on the prevention and ultimately the eradication of cysticercosis.

Toxoplasmosis

Toxoplasmosis is considered one of the most important and common parasitic diseases worldwide. It is caused by a protozoan, *Toxoplasma gondii*, which owes its high global prevalence to its capacity of infecting all animal species and birds. *Toxoplasma* has been commonly associated with congenital disease since the 1930s, but it has taken longer to understand the real epidemiological and clinical implications of its foodborne transmission and its importance to human beings. The life cycle is complex, using the cat as the definitive host and humans as intermediate hosts.

Transmission Mechanism and Pathophysiology

Felids are the key in the life cycle of *Toxoplasma gondii* due to their ability to excrete oocysts (the resistant stage) in their feces. Human infection occurs from the ingestion of contaminated food, principally of undercooked meat containing tissue cysts of *Toxoplasma gondii* or by the accidental ingestion of oocysts from the environment. Meat containing the parasite may be derived from lambs, goats, pigs, and chickens, and environmental transmission occurs via food, soil, or water contaminated by cat feces.

Clinical Signs

Once a human gets the infection it tends to be chronic, with a wide spectrum of clinical manifestations, including an initial subclinical stage, characterized by nonspecific symptoms such as lymphadenopathy, fever, and malaise. The chronic stage is associated with syndromes such as epilepsy, Parkinson's disease, psychomotor deficits, and schizophrenia.

Treatment and Prevention

Toxoplasmosis treatment varies and depends on the severity of the illness, but currently the prevention strategies are playing an important place in the approach to the disease. In adults with mild disease, who have normal immune system function, treatment is rarely required, but in cases of severe disease or in immunosuppressed persons, a combination of antiparasitic drugs is a necessary intervention.

As part of a prevention strategy, the US Department of Agriculture recommends adequate cooking of food. For example, beef meat should be cooked at 71.1 °C (160 °F) for at least 10 min, and others like pork or lamb should be cooked at 62.8 °C (145 °F) or higher for at least 10 min, all of them with a 3 min rest at environmental temperature after the cooking process. Other recommendations include that all fruits and vegetables should be washed and peeled before eating, pasteurized milk should always be consumed, and untreated water should not be consumed.

Cryptosporidiosis

Cryptosporidiosis results from infection by *Cryptosporidium parvum* (Figure 1), a coccidian parasite. Worldwide, the prevalence is 1-4.5% in developed countries and 3-20% in developing countries.

Transmission Mechanism and Pathophysiology

Transmission is usually by the fecal–oral route but can also occur by aerosols. Sporulated oocysts are excreted in the feces throughout the illness and for several weeks afterward and are immediately infectious; they may survive for 2-6 months in a moist environment. Contaminated food or water can result in outbreaks, and transmission can also occur via contaminated fomites.

The largest outbreaks of cryptosporidiosis have been attributed to contaminated drinking water, from surface water, groundwater sources, recreational water, and swimming pools. Also outbreaks have occurred through consumption of contaminated food (raw milk and meat, farm-made apple

Figure 1 *Cryptosporidium*, acid-fast staining.

cider, fermented milk, salads, raw vegetables). Oocysts have also been found in shellfish, such as oysters.

Clinical Signs

Cryptosporidiosis is clinically characterized by profuse, watery diarrhea with cramping, abdominal pains, nausea, anorexia, flatulence, and malaise. Some individuals may also experience vomiting, weight loss, fever, or myalgia. It is generally self-limiting, resolving after 2-4 days, but in those who are immunosuppressed it may be chronic, debilitating, and severe.

Treatment

Drinking plenty of fluids to prevent dehydration is the main treatment strategy. Nitazoxanide has been FDA-approved for treatment in people with healthy immune systems.

Trichinellosis

Trichinellosis is caused by the nematode *Trichinella* spp., whose transmission to humans occurs by the ingestion of raw or undercooked meat from infected mammals, mainly pigs. However, other potential sources include horses, dogs, foxes, walruses, wild boars, and bears in countries where the consumption of these animals is popular.

Transmission Mechanism and Pathophysiology

Once the female *Trichinella* nematode releases the larvae in the intestinal mucosa of the host, they are disseminated by lymphatic and blood streams to the striated skeletal muscle, where they develop into infective muscle-stage larvae and may remain there for several years until the tissue is consumed by a new host. After the ingestion of contaminated meat, the larvae are released in the gastrointestinal tract of the new host, where they reach their adult stage and start reproducing. After a couple of weeks an immune response occurs in the host across the intestinal mucosa, which ultimately triggers the symptoms that characterize the intestinal phase of trichinellosis which has the possibility to migrate through the blood vessels into the striated skeletal muscle or systemic parenteral triggering phase trichinellosis.

Clinical Signs

The clinical spectrum of trichinellosis can range from a completely asymptomatic course to death. The clinical manifestations are closely related with the amount of inoculum, the response of the host, and the time of initiation of an appropriate treatment. The inflammatory response produced after infection occurs via Th2 cells, eosinophils being frequently found to determine the intensity and the presence of the severe clinical manifestations. The release of histamine and prostaglandins plays a major role in the inflammatory response, as their presence is closely related with clinical manifestations such as edema (for increased capillary permeability), urticarial reaction, and vasculitis. During the acute phase associated symptoms are nonspecific, including fever for 1-3 days, headache, chills, malaise, and gastrointestinal symptoms such as diarrhea and abdominal pain. Other important manifestations include facial edema, conjunctivitis, vasculitis, subconjunctival bleeding, petechiae, eosinophilic myocarditis (associated with sinus tachycardia), elevated cardiac biomarkers, and nonspecific conduction disturbances. Ventricular repolarization and thromboembolic disease are some of the more severe complications, which are presented during the systemic phase. Pain associated with eye movements is caused by infiltration of the extraocular muscles. In the chronic phase symptoms may appear as encephalitis and neurological manifestations and to a lesser extent, multiple cortical infarcts, anisocoria, facial paralysis, and Babinski reflex.

Treatment

Anthelmintics drugs of choice for treatment of trichinellosis are albendazole, as first-line drug. Another alternative includes mebenzazole; however, these drugs are contraindicated during pregnancy. Although pyrantel has no effect on newborn larvae and those who live on the muscle, it can be used in pregnant women and children in two 10-20 mg kg^{-1} doses separated by 2-3 days of dosing.

Chagas' Disease

Chagas' disease is caused by the protozoan parasite *Trypanosoma cruzi*. Transmission occurs mainly through triatomine bug vectors typically found in homes built with mud, so the disease tends to affect poor countries. The disease can also be acquired congenitally, by blood transfusions, by organ transplants, through biological accidents, and orally due to the intake of food contaminated with the parasite (due to feces of triatomine and complete triatomines). This has been particularly reported in fruit juice in Brazil and Venezuela, but also in other South American countries.

Transmission Mechanism and Pathophysiology

According to WHO, the definition of a case of Chagas' disease by oral transmission involves having excluded other forms of transmission, having epidemiological evidence that the affected were exposed to food or drink contaminated with the parasite, and the absence of chagoma. Oral transmission occurs by direct consumption of triatomines, breastfeeding, or consumption of food or beverages that have been contaminated by the feces of infected triatomine or infected secretions from the anal glands of marsupials. Some studies have estimated that the parasite can survive in such food between approximately 12 and 24 h before being consumed. Once ingested, the infection would occur through contact of metacyclic trypomastigotes (infecting form of the parasite) in the gastric mucosa, where the severity of the infection will depend on the amount of the seed and the host defense mechanisms at this level.

Clinical Signs

The oral transmission of Chagas' disease is usually associated with high severity and mortality. In the reported series signs and symptoms have been frequently dyspnea, fever, periorbital edema, headache, myalgia, cough, hepatomegaly, chest pain, abdominal pain, vomiting, palpitations, and edema in the lower limbs. The ECG findings include right bundle branch block, sinus bradycardia, and atrial fibrillation, while usually evident on echocardiography pericardial effusion, mitral or tricuspid insufficiency, impaired regional contractility, and/or left ventricular systolic dysfunction.

Treatment

The etiologic treatment may be with nifurtimox or benznidazole, the latter being the drug of first choice. The same is given at a dose of 5 mg kg^{-1} day^{-1} with a maximum dose of 300 mg daily for 60 days and can be extended for longer in patients weighing more than 60 kg. Such treatment should be initiated as soon as possible because the time of onset influences the prognosis. Currently multiple candidate drugs, used in other infectious and noninfectious diseases, are being tested and with anti-*Trypanosoma* activity, such as new antifungal azoles and some anti-arrhythmic drugs.

Giardiasis

Giardiasis, a gastrointestinal disease characterized by acute or chronic diarrhea, is caused by protozoan parasites of the genus *Giardia*. *Giardia intestinalis* is the only species known to cause illness in humans. This organism is carried in the intestinal tracts of many animals and people, which are considered to be the most important reservoir hosts for human giardiasis. Recently environmental and particularly climate conditions appears to be significantly associated with the epidemiology of giardiasis.

This infection is more prevalent in developing countries; the infection rate was typically 8-30% higher in children. Among adults, the prevalence was reported as with lower incidence. Approximately 60-80% of *G. intestinalis* infections are asymptomatic. Chronicity has been reported to occur in less than 4% of the patients.

Transmission Mechanism and Pathophysiology

Giardia spp. has two stages, cysts and trophozoites. The infection is acquired by ingesting cysts, which are excreted in the feces. Trophozoites are released from the cyst in the small intestine, where they multiply. Many of them are carried toward the colon and encyst along the way, in response to bile salts and other stimuli. Cysts can appear in the feces from 3 days to 3 weeks after infection.

Giardia cysts can be transmitted directly between hosts or on various fomites including contaminated water or food, which are responsible for many outbreaks; over 160 waterborne outbreaks of giardiasis and cryptosporidiosis have been reported, with the greatest documentation in the United States and United Kingdom. Individuals at increased risk include those who drink contaminated water or swallow surface water during recreational activities, children (especially in day care facilities), travelers to regions where human infections are prevalent, men who have sex with other men, and contacts of infected individuals.

Food-related outbreaks have been reported less frequently and often involve contamination by a food handler. Person-to-person transmission can propagate outbreaks, especially among young children.

Clinical Signs

Most *G. intestinalis* infections are asymptomatic, with affected individuals either clearing the infection spontaneously or shedding cysts subclinically.

Symptomatic cases are characterized by mild to severe gastrointestinal signs; some patients develop acute or chronic diarrhea, with loose, foul-smelling stools. The feces may have a greasy appearance, but blood is rarely seen. Other symptoms may include abdominal cramps or pain, bloating, flatulence, nausea, anorexia, vomiting, weight loss, or dehydration. Most infections are self-limited and last for a few days to a few weeks; however, cases may occasionally persist for months or even years. Chronic infections may lead to malabsorption syndromes that can include disaccharide deficiency and vitamin deficiencies, as well as severe weight loss and debilitation. Fatal cases have been related with extreme dehydration, mainly in infants or malnourished children.

Treatment

Giardiasis can be treated with a number of drugs; however, the best clinical results are with the nitroimidazole drugs: metronidazole, tinidazole, and ornidazole, which are highly effective. The recommended dosing for metronidazole is 250 mg t.i.d for 5-7 days; pediatric dose is 5 mg kg^{-1} t.i.d for 5-7 days. For tinidazole the adult dose is 2 g in a single dose, and the pediatric dose is 50 mg kg^{-1} in a single dose. Most common adverse effects of these drugs are headache, vertigo, nausea, metallic taste, urticaria, and disulfiram-like reaction with alcohol ingestion. Supportive care, such as fluid and electrolyte management, may also be necessary. Asymptomatic cases may be treated to reduce transmission of the organism.

Prevention strategies include good hygiene, such as hand washing, avoidance of fecal contact with skin or mucous membranes during sexual activity, and washing vegetables and fruits before eating them. Also, people with giardiasis should not swim in recreational water for at least 2 weeks after the symptoms end. In water, *G. intestinalis* cysts can be killed by a rolling boil maintained for 1 min.

Cyclosporiasis

Cyclosporiasis is an intestinal illness caused by the microscopic parasite *Cyclospora cayetanensis*.

Transmission Mechanism and Pathophysiology

The mature oocyst is ingested (infective form), then occurs as asexual and sexual reproductions in the small intestine's epithelium, producing immature oocysts. These oocysts must spend several days in favorable conditions to mature; therefore human-to-human infection is not possible. Transmission occurs by intake of mature oocysts present in water, vegetables, or contaminated food.

Most outbreaks have been related to the consumption of vegetables, raw raspberries and other berries, basil, and raw salads.

Clinical Signs

It causes acute and prolonged diarrhea in immunocompetents, traveler's diarrhea, outbreaks, and chronic diarrhea in immunocompromised patients. Main symptoms are fever $<38\,^{\circ}C$, nausea and occasional vomiting, and diarrhea of varying intensity, approximately five to seven stools per day. It can last 5–14 days but also 1 month or more.

Treatment

Indicated treatment for adults is cotrimoxazole (160/800 mg) twice a day and for children trimethoprim 8 mg kg^{-1} sulfamethoxazole 40 mg kg^{-1} divided into two doses per day, both groups for 7–10 days. In patients with HIV/AIDS, treatment must last until disappearance of symptoms. As an alternative, ciprofloxacin 500 mg twice a day for 1 week can be used.

Sarcocystosis

Sarcocystosis is known as an important zoonotic disease caused by intracellular protozoa of the genus *Sarcocystis*. It is recognized as a common parasite in the musculature of herbivores and carnivores, being described at first in a pig muscle. They have a two life cycle hosts according to prey and predator, being their potential definitive host: dogs, cats, and humans.

Transmission Mechanism and Pathophysiology

The intermediate host development of *Sarcocystis* occurs in both cardiac and smooth muscle that came in contact with humans by eating the meat or by the contamination of soils by feces of the host. Once they get into the human, they can cause a large spectrum of clinical manifestations including muscular *Sarcocystis*, representing the majority of the cases in the tropical or subtropical areas, and intestinal *Sarcocystis*, occurring more frequently in Europe.

Clinical Signs

The symptoms can be gastrointestinal nonspecific manifestations such as vomiting, diarrhea, and abdominal pain, occurring between the first 3-6 h after eating the meat. More serious symptoms include cardiomyopathy and bronchospasm.

Treatment and Prevention

There is no specific treatment for *Sarcocystis*, so prevention is the principal key of control of this disease. An adequate cooking process of the meat and not drinking untreated water are important strategies for prevention. A few drugs like sulfadiazine and pyrimethamine have demonstrated some efficacy.

Conclusion

Even though, parasitic diseases represent an important public health problem mainly in developing countries, little attention is given by governments and communities. Multiple routes of transmission have been described for each microorganism; waterborne and foodborne transmission are not the main route. However, because they are responsible for the occurrence of outbreaks, these transmission routes are the most important for public health, and efforts should be addressed to control them. Although environmental monitoring of water and food, and regulations to minimize protozoan parasite contamination of potable water have been implemented in many countries, the potential for contaminated food and water to cause extensive outbreaks still remains, due to the breadth of populations served.

Parasites in Food: Occurrence and Detection

LJ Robertson, Norwegian University of Life Sciences, Oslo, Norway

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Despite causing a high burden of disease and resulting in considerable suffering, parasitic infections have generally not received the same level of attention as other foodborne hazards. Nevertheless, in September 2012, an expert meeting was convened by FAO (Food and Agriculture Organization of the United Nations) and WHO (World Health Organization) that attempted to rank foodborne parasites in order of importance from a global perspective and identify most relevant transmission vehicles.

A total of 24 parasites (species, genera, or families) were ranked as listed in Table 1. Weighting was predominantly driven by public health importance; other factors included global distribution, potential for increases in disease rates, trade impacts, and socioeconomic effects of infection.

As demonstrated in Table 1, all classes of endoparasites are covered, with eight protozoa, seven nematodes (roundworms), five cestodes (tapeworms), and four trematodes (flukes) listed. Although protozoa and nematodes predominate, the three parasites ranked as being of greatest importance are all cestodes, due to the potentially severe pathology that may be caused when humans act as accidental, aberrant intermediate hosts in the parasites' life cycles.

Among the range of food matrices that are of relevance for these parasites, all the major food types are included, such as meat, fresh produce, fruit juice, milk, and fish. The latter includes both freshwater fish and marine fish, depending on parasite species. And it is also worth noting that for the Anisakidae, which includes the species *Anisakis simplex*, *Anisakis pegreffii*, and *Pseudoterranova decipiens*, the potential hazard to human health is limited not only to the possibility of infection occurring but also to the potential for gastroallergic reactions. Such reactions, which may be severe, are usually facilitated by a hypersensitivity reaction, most frequently to a major secretory/excretory antigen/allergen of the Anisakidae, and may even be activated if the parasite is not alive.

In the following sections, the eight most highly ranked foodborne parasites are described in greater detail. For each parasite, a brief overview of the parasite is provided (life cycle, prevalence, global distribution, and disease) and then some details on foodborne infection, including, where applicable, a description of methods of detection in the relevant food matrices.

The Highest-Ranked Foodborne Parasites

Taenia solium

Taenia solium is also known as the pork tapeworm because transmission to humans, the definitive host in the life cycle, is by ingestion of infective larval cysts in undercooked pork. Prevalence of *T. solium* infection varies greatly according to local practices regarding consumption of pork (occurs very rarely in Muslim or Jewish communities), as well as pig husbandry practices and general sanitation. *T. solium* is endemic in several developing countries, including Central and South America, sub-Saharan Africa, Southeast Asia, and Western Pacific. It is considered an emerging disease in United States and parts of Europe due to increased immigration and international travel; over 50 million people are estimated infected worldwide.

Although the sheer size of adult *T. solium* (between 2 and 7 m in length) inhabiting the human intestine sounds disagreeable, taeniasis produces only mild abdominal symptoms, the main clinical sign being passive passage of proglottids – the mature segments of tapeworm that pass out with the feces and contain around 50 000 eggs each. These eggs are infective to pigs and, when ingested, hatch in the intestine, invade the intestinal wall, and migrate to the tissues where they encyst into cysticerci. The cysticerci are infective to humans and, when ingested, develop into adult worms in the intestine, thereby completing the life cycle.

If *T. solium* eggs are ingested by humans (not pigs), they also hatch and invade the intestinal wall and migrate to the tissues and develop into cysticerci. They are more common in subcutaneous tissues but are also relatively common in the liver, eyes, and central nervous system (CNS). This clinical disease, cysticercosis, is far more serious than taeniasis, with symptoms resulting from the development of cysticerci. The most important clinical manifestation occurs when the cysticerci are in the CNS. This disease, neurocysticercosis, can result in various symptoms including epilepsy-type seizures, mental disturbances, and death. Ocular, cardiac, or spinal lesions and associated symptoms occur when cysticerci occur in those organs.

While taeniasis is exclusively a foodborne infection, associated with the consumption of undercooked pork containing the larval stages (cysticerci) of the parasite, cysticercosis requires consumption of eggs excreted from an infected human. This can be direct hand-to-mouth or via a vehicle such as food. It is particularly likely to occur when human excreta (night soil) is used for manure on vegetables that are not cooked before consumption.

Routine meat inspection of pigs for cysticerci is conducted at slaughter, and, if detected, the meat is condemned (or, in countries where infection is common, might be passed for cooking). The cysticerci are around 10×5 mm (pea size) or larger. Although relatively easy to see, it should be noted that in countries where they are not expected, inspection may be cursory and light infections may be overlooked.

No methods are in place for inspecting vegetables or other possible transmission vehicles for *T. solium* eggs; reduction of taeniasis by appropriate control of pork is a sensible approach to reducing cysticercosis and also encouraging thorough cooking to inactivate the tissue cysts (heating to a core temperature of at least 60 °C). Tissue cysts are also inactivated by freezing to

Table 1 Foodborne parasites ranked in order of global importance

Parasite	*Group*	*Order of ranking*

−10 °C or lower for at least 10 days. Additionally, use of human excreta for fertilizer on crops should be discouraged, particularly in places where taeniasis is endemic.

Echinococcus granulosus

Echinococcus granulosus is a small (3–5 mm) tapeworm, also called dog dwarf tapeworm, with canids as definitive hosts. A range of mammals are suitable as intermediate hosts, including sheep, goats, buffalos, cattle, camels, pigs, kangaroos, and cervids. Eggs passed in the feces of an infected dog may be ingested by an intermediate host, and the oncosphere that hatches in the intestine penetrates the intestinal wall and migrates into various organs, especially the liver and lungs. Here, it develops into a hydatid cyst that gradually enlarges, producing protoscolices and daughter cysts that fill the cyst interior. Canids are infected by consuming parts of an animal that contains these cysts. A common source of infection for dogs is offal from infected livestock.

Infection of humans occurs due to accidental ingestion of *E. granulosus* eggs from dog feces and results in the disease cystic echinococcosis (CE). The strain usually associated with human infection is the common sheep strain (G1). Transmission is influenced by extent of domestic and wildlife reservoirs and is closely affected by human activities, behavior, environmental factors, and local policies.

E. granulosus has a global distribution; endemic foci are found on every continent. However, local distribution and prevalence depend on the presence of large numbers of sheep, cattle, goat, or camel flocks (intermediate hosts) and close contact between them and canine definitive hosts. Prevalence of CE is highest in temperate zone countries, including several parts of Eurasia, Australia, some areas of America (especially South America), and North and East Africa.

Clinical manifestations of CE are variable and determined largely by site, number, and size (can be over 20 cm diameter) of cysts. Strain of parasite may also affect the symptoms. Nevertheless, unless cysts are located in the brain or eye, clinical manifestations of most cases of CE are generally mild for a considerable period. Most cysts (>65%) are located in the liver, followed by the lungs (25%), but cysts have also been reported from the spleen, kidneys, heart, bone, and CNS. For cysts in the liver, signs include hepatic enlargement, right epigastric pain, nausea, biliary duct obstruction, and vomiting. Pulmonary involvement can result in chest pain, cough, and hemoptysis. Although CE is rarely fatal, death may occur due to anaphylactic shock or cardiac tamponade. Furthermore, if a cyst ruptures, release of cyst contents can cause allergic reactions and produce fever and mild to fatal anaphylactic shock. It has been estimated that CE results in the loss of 1–3 million disability-adjusted life years (DALYS) per annum.

E. granulosus is not strictly a foodborne pathogen, and contact with infected dogs seems to be a common risk factor for infection. However, the eggs are highly resistant to environmental factors, remaining infective for many months in a moist environment. Thus, if eggs contaminate a food product that is not cooked before eating, then food may act as a transmission vehicle.

There are no data on the occurrence of *E. granulosus* eggs on food, and there is no standard method for analyzing food products for these eggs. Minimizing *E. granulosus* infection is directed toward breaking the life cycle. The main approaches are frequent deworming of dogs in endemic areas and not feeding raw offal to dogs or leaving raw offal accessible to scavenging canids.

Echinococcus multilocularis

The fox tapeworm, *Echinococcus multilocularis*, has a similar life cycle to that for *E. granulosus* but is mostly associated with a sylvatic life cycle, with foxes usually serving as definitive hosts. Other canids (e.g., dogs, raccoon dogs, wolves, and coyotes) may also act as definitive hosts. Various different genera of rodents (also some lagomorphs) may act as intermediate hosts, being infected by ingestion of eggs released from the tapeworms in the definitive hosts. A number of nonrodent mammals, including humans and pigs, may also be infected as aberrant or accidental intermediate hosts; in humans, this may result in the disease state known as alveolar echinococcosis (AE).

Data on the prevalence of AE in humans are scattered and patchy, probably partly due to diagnostic challenges, particularly in early stages of infection. *E. multilocularis* infection apparently does not occur in Australasia, Africa, and South or Central America, but countries in Asia and Europe, as well as North America, are important endemic areas. In particular, Russia and adjacent countries, various regions in China, and the Japanese island of Hokkaido are of importance. By far the

largest numbers of human cases are reported from foci in China, with prevalences ranging up to 4% in Gansu and northwestern Sichuan. Although the number of human cases of AE in Europe remains low, there appears to be widespread, expanding prevalence in wildlife and trends of AE in humans appear to follow parasite abundance in wildlife.

While the tiny (3–6 mm) adult *E. multilocularis* tapeworms normally cause little harm to canine definitive hosts, in intermediate hosts, including humans, ingested eggs develop to oncospheres, which penetrate the intestinal wall and are carried via blood to, in particular, not only the liver but also other organs where they form multilocular cysts. From ingestion of eggs to onset of clinical symptoms in people may be from months to years, or even decades, depending on cyst location and speed of growth. In most AE cases, metacestodes of *E. multilocularis* initially develop in the liver. These cysts, varying from a few millimeters to 15–20 cm or more in diameter, can also reproduce aggressively by asexual lateral budding. This gradual invasion of adjacent tissue in a tumorlike manner is the basis for the severity of AE. Metacestodes may also spread from the liver to other organs, such as the lungs, spleen, heart, and kidney. Symptoms of severe hepatic dysfunction appear in the advanced clinical stage, in addition to symptoms from other affected organs. While there is negligible acute morbidity, the chronic morbidity of AE is severe and potentially fatal.

As with CE, the proportion of AE cases that are actually foodborne is difficult to estimate, as diagnosis usually occurs long after infection; it is difficult to associate an infection with a foodborne event many years previously. However, the tapeworm eggs may contaminate various types of food, including fruits and vegetables. Although sensitive to desiccation and heat, the eggs are extremely tolerant of environmental conditions, including cold; freezing at −20 °C does not affect egg infectivity. Thus, there is a large potential for foodborne infection via raw produce. However, there are currently no tools for detecting *E. multilocularis* eggs on food. Current control regimes include deworming of dogs in endemic areas, monitoring prevalence in wild canids, and, in some areas, treating wild canids with impregnated bait.

Toxoplasma gondii

Toxoplasma is a protozoan parasite, infectious to practically all warm-blooded animals, including humans, livestock, birds, and marine mammals. Although the genus has only one species, *Toxoplasma gondii*, there are different genetic groups of differing virulence. *T. gondii* is perhaps the most widespread protozoan parasite affecting humans; between 1 and 2 billion of the world's population have been estimated to be infected at any one time. It should be emphasized that most of these infections do not cause clinical illness.

The life cycle of *Toxoplasma* is somewhat complicated, containing two distinct cycles, a sexual cycle and an asexual cycle. The definitive hosts are members of the cat family (Felidae); thus, the sexual cycle occurs only within the intestinal epithelial cells of felids. Oocysts are excreted unsporulated (uninfectious) in cat feces. Oocyst sporulation in the environment usually takes around three days, depending on factors such as temperature and humidity. Oocysts are environmentally robust and can retain infectivity in a cool damp environment for months.

The asexual cycle occurs when consumption of tissue cysts (see succeeding text) or oocysts results in infection of the intestine, and the tachyzoite form of the parasite multiplies asexually in the cells of lamina propria until the cells rupture, releasing tachyzoites into the surrounding tissues and resulting in systemic infection. Circulating tachyzoites infect new cells throughout the body, and after several more rounds of asexual division, tissue cysts are formed. Tissue cysts of *T. gondii* are microscopic (5–100 μm) and contain bradyzoites, which are infectious when ingested with the surrounding tissue. If ingested by a felid, then the sexual cycle occurs and the life cycle is complete; if ingested by any other host, then the asexual cycle occurs, as previously described. If a female host is pregnant when first infected, then circulating tachyzoites may move to the fetus (intrauterine or congenital transmission).

The clinical picture of *Toxoplasma* infection is greatly influenced by the immune status of the infected person and also by the virulence of the parasite strain. In immunocompetent people, *T. gondii* infection is usually asymptomatic but may cause mild to moderate flu-like illness. In some cases, ocular toxoplasmosis may occur, possibly with partial or total loss of vision. Ocular disease appears to be more severe in South America, presumably due to more virulent *Toxoplasma* genotypes. Although latent *Toxoplasma* infection is generally considered benign in the immunocompetent, some studies indicate that the parasite may affect behavior, being a contributory, or even causative, factor in various psychiatric disorders including depression, anxiety, and schizophrenia.

In the immunocompromised and immunodeficient patients, severe or life-threatening disease can result from acute *Toxoplasma* infection or reactivation of previously latent infection. Encephalitis is the most clinically significant manifestation. Congenital toxoplasmosis is another serious potential manifestation, usually occurring when *Toxoplasma* is passed to the fetus from a first infection acquired by the mother immediately before or during pregnancy. Symptoms commonly associated with transplacental infection include spontaneous termination, fetal death, and intracranial calcification. Congenitally infected children that are asymptomatic at birth may suffer from mental retardation or retinochoroidal lesions later in life.

With the exception of congenital transmission, most *T. gondii* infections are considered to be foodborne, although waterborne infection has been suggested to be the major source of *Toxoplasma* infection in developing countries.

There are three potentially infectious stages of *Toxoplasma*: tachyzoites, bradyzoites, and oocysts, two of which – bradyzoites and oocysts – are particularly relevant to foodborne transmission. Bradyzoites may be ingested with tissue of an infected intermediate host, while oocysts may be ingested with any foodstuff that has been contaminated with feces of an infected felid; this is particularly likely for fruit and vegetables that are eaten raw, and *Toxoplasma* oocysts are particularly robust, being able to survive in the environment for weeks or months.

Human infection via bradyzoites in meat depends on various factors, including prevalence of *Toxoplasma* infection in

meat animals (most livestock species are susceptible to infection), cultural factors regarding meat consumption and meat preparation, and factors of the person exposed (e.g., age and immunologic status). Parasite factors are probably relevant also. In some countries, sheep and goats are the most important hosts of *T. gondii* and the main source of infection to humans. In other countries, for example, the United States, lamb and mutton are relatively minor food commodities; of the major meat animal species investigated in the United States to date, pig (particularly organically raised) is the only species frequently found to harbor the parasite. Although poultry are also susceptible to *T. gondii* infection and theoretically pose a source of infection to humans, the relatively limited life span of poultry and the fact that they tend to be well-cooked before consumption limit their importance as sources of infection for humans. Game animals are also considered as potentially important sources of meatborne toxoplasmosis, particularly as such meat is often consumed undercooked; wild boar and venison are particularly implicated in Europe, while consumption of undercooked meat from marine mammals is an important risk factor for human infection in Arctic regions.

There is no systematic monitoring of meat for *Toxoplasma*, as the cysts are very small and can occur in almost all tissues. For high-risk groups, ensuring that meat is thoroughly cooked is important. Similarly, no standard method exists for monitoring for contamination with oocysts, although some research surveys have demonstrated quite widespread contamination.

Cryptosporidium spp.

Cryptosporidium spp. are protozoan parasites that have been reported from a large variety of different hosts, including humans, globally. Around 25 species of *Cryptosporidium* have been identified to date, of which approximately 50% have been reported as infectious to humans. However, most reported human infections involve *Cryptosporidium parvum* (an important zoonotic species, particularly associated with infections in calves) or *C. hominis*, which is found primarily in humans. Other species considered important for human infection in some areas are *C. meleagridis*, particularly in children in South America, but primarily considered as infecting turkeys, and *C. cuniculus*, also associated with infections in rabbits. Although prevalence data are patchy, *Cryptosporidium* infection has emerged as a global public health problem and has been reported from over 100 countries.

The life cycle of *Cryptosporidium* is direct (no intermediate host). When a viable oocyst is ingested by a susceptible host, it excysts in the small intestine where the resultant sporozoites invade epithelial cells and locate epicellularly (within the cell but not within the cytoplasm). Repeat cycles of asexual reproduction result in destruction of these cells and the production of vast numbers of parasites. A sexual cycle results in oocyst production. These are excreted in the feces and are immediately infectious but are also very robust and can survive for long periods under cool, moist conditions.

Cryptosporidiosis is an enteric disease, characterized by watery diarrhea, abdominal pain, and related symptoms. It is self-limiting in immunocompetent individuals, although a high relapse rate has been reported. However, in some immunocompromised patients, the symptoms may become chronic, debilitating and potentially life-threatening; drug development for this vulnerable group has been largely unsuccessful.

Waterborne transmission is important in cryptosporidiosis; numerous waterborne outbreaks of cryptosporidiosis have occurred worldwide due to oocyst contamination of drinking water sources. The largest waterborne illness outbreak of any kind in the United States occurred in 1993 when over 400 000 people acquired cryptosporidiosis in Milwaukee. More recently, around 27 000 people suffered from waterborne cryptosporidiosis in Östersund, Sweden, in 2010.

Although foodborne transmission of cryptosporidiosis is considered much less common than waterborne or person-to-person transmission, it is emerging as a public health issue. Several foodborne outbreaks of cryptosporidiosis have been reported, mainly in United States and northern Europe, and in some instances, tens or hundreds have been infected. Implicated foods have largely been fresh produce (e.g., ready-to-eat spinach, green onions, parsley, lettuce, and salad bar items), but there have also been outbreaks associated with apple cider and fresh milk. Some outbreaks have been attributed to contamination from infected food handlers, but others have implicated other contamination routes. Surveys performed worldwide have reported *Cryptosporidium* oocysts, albeit at low concentrations, on a wide variety of fresh produce items, in irrigation water, and also in shellfish. Different methods have been proposed and used in research products for the identification of *Cryptosporidium* oocysts on fresh produce, often in combination with the detection of *Giardia* cysts. A standard ISO method for the analysis of leafy green vegetables and berry fruits is under development and is based broadly on elution from the product, concentration of eluate, isolation from debris by immunomagnetic separation, and detection using immunofluorescent staining.

The likelihood of contamination of produce can be reduced by implementing appropriate measures both preharvest and postharvest and also at the consumer level. Although robust, oocysts do not survive prolonged freezing at below −15 °C and are killed by cooking.

Entamoeba histolytica

Many species of *Entamoeba* have been described, of which several may inhabit the human intestinal tract, but only *E. histolytica* is a proved human pathogen causing the disease amebiasis, although only around 10% of individuals infected with *E. histolytica* develop symptoms. *E. dispar* is considered apathogenic; *E. moshkovskii* may be pathogenic under some conditions. That these pathogenic and nonpathogenic species are morphologically indistinguishable means that the occurrence of amebiasis was previously overestimated, and therefore, older data or data not obtained with molecular tools are unreliable. Nevertheless, *E. histolytica* is considered to occur globally and is considered a particular health risk in countries where sanitation is poor. Disease burden has been estimated to be approximately 50 million infections, resulting in an estimated 40 000–110 000 deaths, annually.

The life cycle of *E. histolytica* includes the infectious cyst form and the trophozoite, the invasive, disease-causing stage. Following ingestion of an infectious cyst, trophozoites are released in the small intestine and multiply through divisions.

The trophozoites generally migrate to the large intestine, localizing to the cecum and adjacent ascending colon, where encystation occurs. Both trophozoites and cysts may be excreted in the feces, although the former rapidly disintegrate and are not considered infectious. Cysts, however, can survive for considerable periods outside the host, and thus, new infection can occur via contamination of food and water. *E. histolytica* is not considered as zoonotic.

For infected individuals who experience clinical amebiasis, symptoms range from mild colitis to severe invasive and/or disseminated infection. Amoebic colitis includes bloody diarrhea with multiple mucoid stools and abdominal pain. Chronic infection, with persistent nondysenteric diarrhea, has also been reported. Fulminating amoebic colitis occurs in about 0.5% of infections and is a serious form of invasive infection, usually presenting with profuse bloody diarrhea, abdominal pain, and fever. Colonic perforation and peritonitis may occur, and a mortality rate of around 40% has been estimated. Extraintestinal spread of *E. histolytica* trophozoites occurs through the portal venous system. Amoebic liver abscess (ALA) is the most common extraintestinal manifestation, and associated symptoms include fever, right upper quadrant pain, and hepatic tenderness, usually not concurrent with amoebic colitis. Spread to other sites is rare and usually occurs secondarily to ALA; pleuropulmonary amebiasis, amoebic brain abscess, and amoebic skin abscess have all been reported.

Although infection is generally considered to occur most frequently from ingestion of contaminated food or water, only a few outbreaks of waterborne amebiasis have been reported and no foodborne outbreaks. This could be because around 90% of people infected would not experience symptoms. Studies of parasitic infections in food handlers have often reported *E. histolytica* infection, and unhygienic food handling is commonly considered a contamination route. However, those very few studies that have investigated food for a range of parasites, including *Entamoeba*, tend not to report contamination with *E. histolytica* cysts, and no standard methods have been developed for examining food products for this parasite.

Trichinella spiralis

Trichinella spiralis is an intracellular parasitic nematode of mammalian striated muscles, found worldwide in many carnivorous and omnivorous animals. There is no stage in the life cycle that is external to the host (in the environment), and transmission is solely from ingestion of another infected host. Human infections are mainly associated with the consumption of undercooked pork, and the parasite is endemic in pig-breeding/pork-producing facilities in several countries in eastern Europe, Russia (some areas), China (various provinces), Southeast Asia (Laos and Thailand), and South America (except Brazil). Other species of *Trichinella* are also infectious to humans and are often particularly associated with specific geographic regions or species of game animal.

The life cycle commences with the ingestion of encysted larvae in the striated muscle tissue of another infected host. Following exposure to gastric acid and pepsin, the larvae are released from the cysts and invade the mucosa of the small intestine where they develop into adult worms, just a couple of millimeters in length. Hundreds of new larvae are produced and these are spread with the blood around the body, settling in the muscle cells where they become encapsulated into tissue cysts. These infective encysted larvae can survive for years in tissue and also remain infectious for several weeks in dead animals, thus enabling infection of carrion eaters.

Although animal infection with *T. spiralis* is considered asymptomatic, human infection causes a serious clinical disease, trichinellosis, which can cause much suffering and may be fatal. Symptoms of trichinellosis are related to life cycle stages, with enteric, migratory, and muscle phases. During invasion of the intestinal epithelium, abdominal pains, diarrhea, and vomiting may occur. During larval migration, symptoms may include fever, facial edema myalgias, rashes, and tachycardia. Establishment of larvae within the muscle cells and the encystment of muscle larvae are associated with symptoms such as myalgia and severe asthenia. The most frequently affected muscles are those of the cervix, trunk, and upper and lower extremities. The severity of muscle pain reflects the intensity of the infection, and mobility may be restricted. Severe myalgia generally lasts for 2–3 weeks. Although the infection is persistent, as dictated by the life cycle, only a few cases become 'clinically chronic' with recurrent muscle pain. Brain abnormalities have also been reported. Although case mortality is low, for severe infection without treatment, it may rise to over 10%.

Infection with *T. spiralis* can occur only via the foodborne route, and pigs are submitted to compulsory veterinary controls to ensure meat is *Trichinella*-free. EU regulations require that pigs are systematically sampled at the slaughterhouses, with samples taken from the predilection sites and examined by the recommended method, 'the magnetic stirrer method for pooled sample digestion,' which is considered to have the best sensitivity (EU Commission regulation EC 2075/2005; International Commission on Trichinellosis Recommendations). In this method, larvae are identified after artificial digestion of muscle samples from carcasses. Derogations from testing are possible for meat from domestic swine when the pig holdings have been officially recognized as *Trichinella*-free by the competent authorities. This requires compliance with a considerable number of rules. In industrial countries, most marketed pigs are reared in high-containment-level farms and consequently are *Trichinella*-free, but backyard pigs that have more environmental contact are more likely to be infected, and 'organic' pork is also more likely to be infected. Meat from domestic swine that has been frozen under the supervision of competent authorities can also be exempted of *Trichinella* examination.

Prevention of human infection is accomplished by meat inspection, meat processing, and prevention of exposure of food animals to infected meat. Although freezing can kill *T. spiralis* larvae, other species of *Trichinella* are resistant to freezing. Ensuring that pork is thoroughly cooked before eating ensures against infection with both *T. spiralis* and *Taenia solium*.

Opisthorchiidae

The Opisthorchiidae is a family of fishborne zoonotic trematodes that includes the Southeast Asian liver fluke (*Opisthorchis viverrini*), the cat liver fluke (*O. felineus*), and the oriental liver fluke (*Clonorchis sinensis*). For all these flukes, the definitive

hosts are fish-eating mammals (including not only humans but also cats and dogs). Millions of people have been estimated to be infected with these trematodes: approximately 15 million with *C. sinensis*, 10 million with *O. viverrini*, and about 1 million with *O. felineus*. Up to 700 million (10% of the global population) have been considered to be at risk of infection. Geographically, populations in Asia and Europe are most at risk, with *C. sinensis* endemic in southern China, Korea, Taiwan, northern Vietnam, and Russia; *O. viverrini* endemic in areas of Thailand, Laos, Cambodia, and central Vietnam; and *O. felineus* reported from the former USSR and central–eastern Europe, with endemicity in over 12 European countries.

The life cycles of these trematodes include two intermediate hosts; eggs excreted in the feces of the infected definitive hosts are ingested by the first intermediate host, a freshwater snail. In the snail, an asexual cycle occurs that enables considerable multiplication from the single miracidium released from the egg. The final stage is the cercariae, and these emerge from the snail host and seek out the second intermediate host that includes various species of freshwater cyprinid fish (e.g., carp) and penetrate their flesh. Here, they encyst as metacercariae. When these are ingested with undercooked or raw fish, then they excyst in the duodenum and ascend into the biliary ducts, where they develop into adults, later producing eggs and thereby completing the life cycle.

When humans are infected by consumption of fish containing viable metacercariae, the infection primarily results in hepatobiliary pathology, which may subsequently cause bile duct cancer (cholangiocarcinoma (CCA)). Benign hepatobiliary infection may be asymptomatic and is characterized by cholangitis, obstructive jaundice, hepatomegaly, cholecystitis, and cholelithiasis, most of which are mild. In heavy infections, acute symptoms might occur with epigastric pain, fever, jaundice, and diarrhea. However, the main characteristic of these infections is chronic morbidity, with chronic illness occurring in around 10% of infected individuals who may develop severe disease (weakness, abdominal pain, chronic cholecystitis, gall stone, pyogenic cholangitis, and abscess) and also CCA. Once CCA develops, it is usually fatal; curative treatment is not available, and even with surgical treatment, the prognosis is very poor. Most CCA patients survived less than 5 years, and it is a leading cause of death in Asia; both *O. viverrini* and *C. sinensis* are described as type 1 carcinogens.

Opisthorchiidae are transmitted to humans solely via the foodborne route, with the consumption of the flesh of freshwater fish that is undercooked or has been prepared by salting, pickling, or smoking, all of which may be insufficient to inactivate the metacercariae. In some countries, control programs have been instigated. Strategies combine public health aspects with socioeconomic and cultural dimensions. No standard method has been established for examining fish for metacercariae, but researchers have used artificial digestion methods followed by microscopy for identification.

Parenteral Nutrition

RS Torrinhas and DL Waitzberg, University of São Paulo, São Paulo, Brazil

© 2016 Elsevier Ltd. All rights reserved.

Definition

Parenteral nutrition (PN) therapy can be defined as a set of therapeutic procedures for the maintenance or recovery of nutritional status in malnourished patients or in those suffering from malnutrition risk either in hospital, ambulatory, or home settings. PN is provided through the intravenous administration of sterile and pyrogen-free solutions or emulsions composed of water, electrolytes, carbohydrates, amino acids, lipids, vitamins, and minerals, and packaged in a glass or plastic container, designed to support the synthesis or maintenance of tissues, organs, or systems.

History

The routine use of PN in clinical practice was initiated in 1968, after Dudrick and collaborators demonstrated the safety and efficacy of the prolonged central vein administration of a parenteral solution containing 50% glucose and 10% amino acids, combined with electrolytes, minerals, and vitamins, in achieving growth and body weight gain in children. Later on, it was found that the PN solution IV-infused with highly concentrated solutions of glucose could cause hyperglycemia, particularly in severely ill patients. This intercurrence was associated with adverse events such as immunosuppression and an increase in complications related to infection. Accordingly, the energy provided by glucose was replaced, in part, by the addition of parenteral fat emulsions. The parenteral administration of fat as a lipid emulsion (LE) formula, in combination with glucose and amino acids in a single bag constitutes the so called all-in-one PN.

Indication

PN is of utmost importance for the nutritional recovery of patients who cannot eat, should not eat, or may not be sufficiently fed by the enteral route. Providing PN perioperatively can reduce the morbidity of seriously malnourished surgical patients, and a meta-analysis of nine randomized clinical trials showed that PN can significantly decrease mortality in critically ill patients. However, the intestinal disuse due to the exclusive use of the parenteral route for nutrients supply can lead to the atrophy of the mucosa, and it can promote increased gut permeability and sometimes bacterial translocation.

Exclusive PN regimens or PN solutions complementary to enteral nutrition (EN) therapy are usually prescribed when oral or EN feeding is impossible, contraindicated, or insufficient. These indications apply to malnourished patients and those at risk of malnutrition with no gastrointestinal tract function, disorders requiring complete bowel rest, or those unable to achieve their energy targets by oral/enteral feeding after 2–8 days, respectively (see Table 1 for absolute and relative indications, and contraindications of PN). While used as a unique food source, the PN solution must contain all necessary macro and micronutrients to ensure the patient's homeostasis.

Indications of PN should also consider its possible negative influence on the evolution of the patient's disease or treatment, and the wishes and needs of patients and their families in critical situations such as terminal cancer without a clear prospect of improved survival or quality of life by using PN. For patients requiring PN for long periods without the need for hospitalization, home PN (HPN) is recommended and should be used in conjunction with EN whenever possible, in order to maintain the intestinal tropism. Indications for HPN have increased worldwide as an alternative to improve the life quality of patients with intestinal failure or insufficiency, but it implies adequate patient, family, and caregiver training, to avoid HPN-related complications, such as metabolic abnormalities, organ dysfunction, and derived infection of the central venous catheter, which is largely responsible for morbidity and mortality in these patients.

Planning

The formulation of the PN must meet the patient's energy–protein requirements and provide essential nutrients in adequate amounts to maintain life, cell, and tissue growth. These nutritional requirements may vary according to nutritional status, the disease, and the metabolic condition of patient, as well as the length of nutritional therapy. Therefore, the planning of PN therapy must calculate the energy and nutrient requirements on an individual basis, according to the patient's clinical condition.

The American Society of Parenteral and Enteral Nutrition (ASPEN) states that adult patients should receive 20–35 kcal kg^{-1} day^{-1}, divided into carbohydrates, proteins, and fats (see Figure 1 for a step-by-step guide). Vitamins, trace elements, and electrolytes for parenteral infusion in adults are offered based on the recommendations of the Dietary Reference Intakes (DRIs), which are accepted as a reference point to find the individual estimation of these micronutrients. As DRIs were formulated based on the needs of healthy subjects, patients with specific diseases may require increased amounts of certain micronutrients for wound healing, tissue recovery, and anti-free-radical production, which may be provided by diluting in saline and infusing these micronutrients through a peripheral vein.

In addition, beside standard formulas of PN, which are composed mostly of amino acids, glucose, lipids, and electrolytes, there are special formulations developed to address the specific needs of morbid conditions that involve metabolic disorders, such as liver and kidney diseases. The special solution for liver failure is rich in branched chain

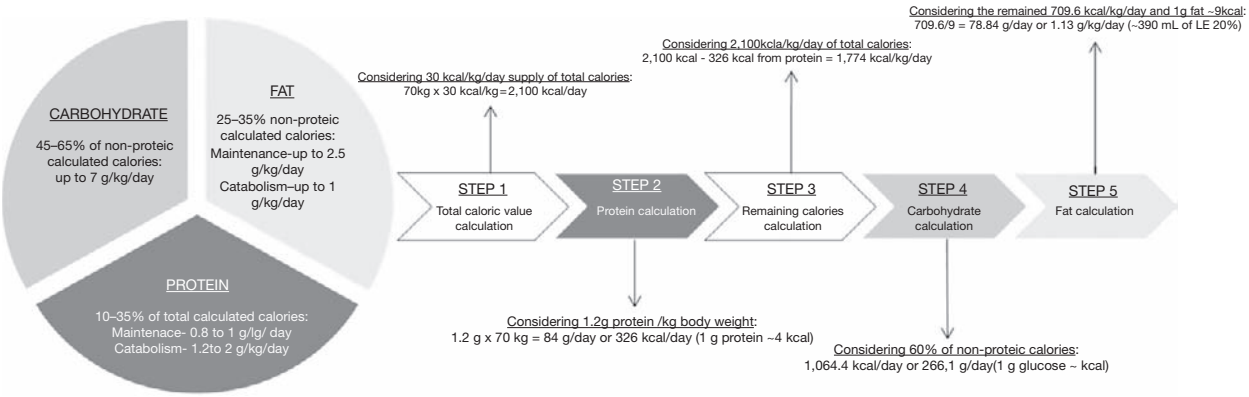

Figure 1 Steps for calorie distribution between carbohydrates, proteins, and lipids during parenteral-nutrition planning. Calculated based on a male patient with a 70-kg body weight and without specific restrictions regarding macronutrients and micronutrients.

Table 1 Indications and contraindications for prescribing parenteral nutrition

Absolute indications	*Relative indications*	*Contraindications*
Impossibility for enteral access due to gastrointestinal obstruction or prolonged ileus	Gastrointestinal bleeding requiring prolonged gastrointestinal rest	Functional gastrointestinal tract
Inability to absorb nutrients through the gastrointestinal tract due to massive intestinal resection (early stage)	Anorexia or severe mucositis due to chemotherapy, radiotherapy, or bone marrow transplantation	Hemodynamic instability
Inability to absorb nutrients through the gastrointestinal tract due to severe short bowel syndrome	Extensive surgery with a prediction of postoperative prolonged ileus for more than 5 days	Allergy to any of its components
Inability to absorb nutrients through the gastrointestinal tract due to active inflammatory bowel disease (requiring 5–7 days of bowel rest)	Severe diarrhea by malabsorption Severe pancreatitis requiring bowel rest for more than 5 days	Severe hyperlipidemia, blood clotting disorders, acute shock, and other unstable conditions (e.g., acute myocardial infarction, stroke, and severe sepsis), when their lipid component is used

amino acids (BCAAs), to increase the BCAA/aromatic amino acids (AAAs) ratio. In this condition, the decreased hepatic metabolism increases plasma levels of AAAs and peripheral metabolism, resulting in a decrease in BCAAs. This situation allows AAA and its metabolites to enter the brain, potentially favoring hepatic encephalopathy.

Special formulations for patients with renal failure are characterized by the highest amount of essential amino acids and histidine; one of them stands out by the addition of arginine, and another by containing small amounts of nonessential amino acids. The design of these formulations is based on the principle that the treatment of patients with chronic renal failure is benefited by offering low-protein diets and essential amino acid supplementation. However, due to metabolic differences between acute and chronic renal failure, offering solutions containing only essential amino acids cannot meet the protein needs of the patient.

Different formulations of LEs are also available as sources of fat in PN therapy and can be infused alone or associated to amino acids and glucose (3:1 system), as the source of non-glucose high-calorie energy and essential fatty acids. The different available LEs are distinguishable by the type and amount of fatty acids present in their composition, based on the availability of essential fatty acids and the property that certain fatty acids have to influence the immune response. Therefore, understanding the biological properties of the different fatty acids that comprise LEs is required to determine those that will contribute to the clinical evolution of the patient.

Critically ill patients are more susceptible to oxidative stress, alterations in cell-mediated immunity, inflammation, and thrombosis. Therefore, these patients may benefit from LEs based on fish oil containing adequate amount of the antioxidant alpha-tocopherol, as source of the potentially anti-inflammatory and antithrombotic omega-3 fatty acids, eicosapentaenoic and docosahexaenoic. On the other hand, LEs based on soybean oil should be avoided in this patient population, because they provide larger amounts of potentially proinflammatory and prothrombotic omega-6 fatty acids.

Another nutrient with pharmacologic functions available for PN is glutamine, which is considered to be an essential amino acid in some clinical conditions (i.e., a conditionally essential amino acid). Glutamine plays a key role in various stages of human metabolism, such as the transport of nitrogen and protein synthesis, and it serves as the energy source for rapidly proliferating cells such as enterocytes and immunologic cells. Due to its low water solubility, the parenteral use of glutamine is commercially available as dipeptides, in which glutamine may be associated with another amino acid, such as alanine (alanil-glutamine) and glycine (glycil-glutamine).

Recommendations suggest a dose of 0.3–0.5 g kg^{-1} of body weight for parenteral supplementation of glutamine; however, this dose may vary according to the individual condition and

patient needs. According to the Canadian Guidelines (2013), when the PN is prescribed to a critically ill patient, glutamine supplementation should be considered. However, the authors strongly recommend that glutamine should not be used for patients with shock or multiple organ failure.

Finally, when planning PN solutions, we must consider that, independent of the formulation, the nutrients are dissolved in water. Therefore, PN can also influence the patient's hydration. Considering that some clinical conditions can increase (i.e., fever, sunburn, and diarrhea) or decrease (i.e., renal and cardiovascular failure, respiratory disorders) the need for water, water content is part of the PN planning in order to provide adequate water amounts based on the patient's metabolic condition.

Administration

After planning the PN, in order to start, the patient must have an adequate central or peripheral venous access. The PN solution is usually administered into a large-diameter venous vessel, accessed via the jugular or subclavian vein. The peripheral route for the infusion of PN should be limited to the administration of PN solutions with low osmolarity (<850 mOsmol l^{-1}) to cover only part of the nutritional needs and mitigate negative energy balances.

PN should not be initiated before unstable conditions, such as hypokalemia, hyperhydration, hypotonic dehydration, metabolic acidosis, and hemodynamic instability, are corrected. There is no definitive available indication to define the ideal moment to start PN infusion, except for critically ill patients, but still without consensus between the available nutrition international society's guidelines. For these patients, the European Society for Clinical Nutrition and Metabolism (ESPEN) guidelines recommend starting PN after 24–48 h in subjects, with EN intolerance, who are not expected to achieve adequate nutrition within 3 days. On the other hand, ASPEN guidelines recommend PN before reaching 8 days of hospitalization, with the exception of patients who have malnutrition on hospital admission.

The infusion of PN is the individual responsibility of the nursing staff, who must be trained to properly attend the medical recommendations and follow the good hygiene protocols to ensure adequate and safe infusion. On both the first and last day of PN infusion, a half of the prescribed volume should be infused to allow metabolic, enzymatic, and hormonal adjustment and to avoid the occurrence of abnormalities, such as hyperglycemia and hypoglycemia, and electrolyte disturbances, among others.

Monitoring

During the period of PN infusion, the treatment efficacy should be monitored closely. PN is a complex procedure subject to complications that may jeopardize its benefits. The occurrence of adverse events (mechanical, metabolic, and infectious) and clinical changes that may require changes in the PN formulation should be controlled during PN infusion. In addition to specific laboratory tests to identify the risk of metabolic complications (see the main population risk for metabolic complications in Table 2, as well as the key laboratory tests to identify its risk in Table 3), it is necessary to periodically observe the degree of patient hydration; clinical signs of electrolyte disturbances; the occurrence of edema; changes in consciousness level; the thermal curve; the number

Table 2 Main population risk for developing metabolic complications related to parenteral nutrition

Population	*Metabolic complication*	*Main consequence*
Patients undergoing prolonged partial fast, whose body has adapted to the use of free fatty acids and ketone bodies as energy sources	Hypophosphatemia Hypomagnesemia Hypokalemia	Refeeding syndrome, with impairment of hematologic, neuromuscular, and respiratory functions
Patients with pre-existing diabetes or significant physiological stress	Hyperglycemia	Impairment of immune functions, with an increased risk of infectious complications
Patients receiving parenteral lipid emulsions, either alone or in 3-in-1 systems	Hypertriglyceridemia	Development of pancreatitis and altered pulmonary function

Table 3 Laboratory tests to measure the potential risk in developing metabolic complications related to parenteral nutrition (PN)

	Monitoring from the beginning of PN	
Laboratory test	*Stable patients*	*Critically ill patients*
Sodium, potassium, and chlorine	Three times per week	Daily or at physician criteria
Ionized calcium, phosphorus, and magnesium	Twice weekly	Daily or at physician criteria
Glucose	Daily	At physician criteria
Capillary blood glucose	Daily	Each 6 hours or at physician criteria
Plasma osmolarity	Weekly	Daily
Plasma urea and creatinine	Weekly	Twice weekly
Total protein and fractions	Weekly	Weekly
Total bilirubin and fractions	–	Weekly
Plasma ALT, AST, GGT, and alkaline phosphatase	Twice weekly	Weekly or as required
Hemoglobin, hematocrit	Weekly	Daily
pH and blood gas	–	Daily
Plasma triglycerides	Weekly when using lipid emulsion	Weekly
Urinary glucose	4–6 times per day	4–6 times per day
Density or urine osmolality	2–4 times per day	2–4 times per day
Hydrous balance	Each 12 hours	Each 6 hours

of bowel movements; the abdominal workup; the introduction of nutrients; concomitant pharmacological treatments; signs of PN intolerance; and anthropometric, hematological, and hemodynamic changes, as well as functional changes in organs and systems. Whenever possible, the urine-output monitoring and calculation of water balance should be accessed.

Table 4 summarizes the main PN-related complications, with an emphasis on etiology, symptoms, treatment, and prevention. Complications associated with PN include the risk of developing infections in the central venous catheter. The control of common infection symptoms, such local changes, leukocytosis, fever, and hyperglycemia, may support the early

Table 4 Complications related to parenteral nutrition (PN)

Complications	*Possible etiology*	*Symptoms*	*Treatment*	*Prevention*
Mechanical				
Pneumothorax	Inadequate catheter insertion	Tachycardia, dyspnea, persistent cough, and diaphoresis	Small pneumothorax can resolve spontaneously; larger pneumothorax may require a thorax drain	Catheter placement by experienced professional
Air embolism	Air entering in central venous system by inadequate opening of the infusion system	Cyanosis, tachypnea, hypotension, and heart murmur	Immediately turn the patient to his left side and lower the headboard, encouraging the air to remain in the right ventricular apex until reabsorbed	Placing and maintenance of CVC and the extreme care of the entire infusion system by an experienced professional
Venous thrombosis	Mechanical vein trauma, hypotension, high-osmolality solution, hypercoagulopathy, sepsis, trauma	Edema or pain in neck, in one or both arms, or in shoulders	Anticoagulation therapy with urokinase or streptokinase; remove CVC	Silicone catheter use, addition of heparin to PN when possible, low-dose warfarin therapy
Infectious				
Phlebitis	Peripheral administration of hypertonic solution (osmolality $\geq$900 mOsm kg^{-1}), infiltration of venous access	Redness, swelling, and pain in peripheral locations	Change the place of peripheral access	Minimize osmolarity of peripheral solution by using lipids as the primary source of calories and reducing the addition of electrolytes and other additives, if possible
Catheter-related sepsis	Improper CVC placement or maintenance care; contaminated solution	Systemic fever, chills, redness and swelling around the site of catheter insertion	Change the catheter placement	Development of strict protocols for CVC placement and care
Matabolic				
Hyperglycemia	Rapid infusion of concentrated glucose solution, sepsis, pancreatitis, postoperative stress, chromium deficiency, steroid use, advanced age	Blood glucose >200 mg dl^{-1}, metabolic acidosis, polyuria, polydipsia	Use insulin, reduce the concentration of glucose in NP	Start slowly and advance the infusion of NP
Hypertriglyceridemia	Supply of lipids exceeds the capacity of the bloodstream (>4 mg kg^{-1} min^{-1}); sepsis, multiple organ failure, severe hyperlipidemia	Serum triglycerides 300–350 mg dl^{-1} 6 h after beginning lipid infusion; high triglyceride levels in previously stable patients (e.g., sepsis)	Decrease the volume and time of lipid infusion; simultaneous infusion with glucose	Hyperlipidemia history before NP infusion; avoid lipid administration >2.5 g kg^{-1} day^{-1} or >60% of total calories
Refeeding syndrome	Excessive administration of carbohydrates and/or proteins in severely malnourished patients	Excess carbohydrates, CO_2 retention, cardiac tamponade, hepatic dysfunction Excess protein; blood urea nitrogen (BUN), excessive nitrogen excretion; high BUN/creatine ratio	Reduction of excessive supply of carbohydrate/protein	Avoid excessive administration of carbohydrate/protein

recognition of an infection episode related to the central venous catheter, and compliance with best practice during installation and the infusion of PN can reduce this risk.

Final Comments

Currently, PN therapy, for the specific treatment of malnourished patients who cannot use their oral and enteral routes for nutrient supply, provides more benefit than harm when performed according to the available guidelines. The new all-in-one concept, in which nutrients are premixed in a single bag, greatly promotes the safety, efficacy, tolerance, and convenience of PN. However, if done at the hospital pharmacy, this preparation must be carried out on demand, due to the limited stability of this mixture (24 h).

New commercial multichannel PN bags were designed to overcome this limitation and to ensure the PN solution stability by separating its reactive components in different chambers. The individual components of the PN are mixed in a closed aseptic system only at the time of their use, through the breaking of the seals separating these chambers. It is noteworthy, however, that multichannel PN formulations have the disadvantage of not being designed to meet every single patient's needs, mainly infants, in a personalized way, as traditional formulations can be. Therefore, multichannel PN bags must be used based on specific criteria.

PN therapy should not be seen as an emergency intervention and therefore must be designed to adequately meet the individual energy and nutrient needs of patients. PN planning and execution must be performed by qualified professionals from the very beginning, meaning parenteral route access, to a proper ending. Different clinical and biochemical markers should be closely monitored for these professionals to avoid potential mechanical, metabolic, and infectious complications related to PN throughout the infusion period. They also must consider the PN, for most patients, as a temporary treatment that should be discontinued as soon as conditions for oral or enteral diet reintroduction are achieved.

Passion Fruit

SW Wijeratnam, Industrial Technology Institute, Colombo, Sri Lanka

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Passion fruit is a tropical fruit belonging to the dicotyledonous family Passifloraceae. The name was given by Spanish missionaries to South America who used the exotic flower to describe and explain their religious convictions while trying to convert the indigenous inhabitants to Christianity. The most well-known types of this fruit are the purple passion fruit (*Passiflora edulis* Sims) also known as the granadilla (see Figure 1(a) and 1(b)), the granadilla (*Passiflora ligularis* Sims), the gulupa (*Passiflora edulis* Sims. Fo edulis), and the yellow passion fruit (*Passiflora edulis* var. flavicarpa Degener) (see Figure 2(a) and 2(b)). When mature, the passion fruit is round to oval, either yellow or dark purple fruit with a soft to firm, juicy interior filled with numerous seeds. The purple passion fruit (*Passiflora edulis*) is adapted to the coolest subtropics or to high altitudes in the tropics, while the golden passion fruit (*P. edulis* f. *flavicarpa*) is more suited to tropical lowland conditions. The fruit has many health benefits and is both eaten as a fresh fruit and consumed as juice. Passion fruit juice is often added to other fruit juices to enhance flavor and aroma.

Sources and Production

The origin of the edible commercial species of passion fruit is thought to have been on the edges of South American rain forests in the Amazon region of Brazil and possibly in Paraguay and North Argentina. The Inca people are known to have cultivated passion fruit plants in the Peruvian region around AD 1000, and the mashed fruit combined with water has been consumed in Peru, as a nutritious drink for many centuries.

Passion fruit was introduced to Europe in the seventeenth century by early travelers to the Americas and was grown as an ornamental plant under greenhouse conditions for its attractive flowers. Passion fruit became a naturalized crop in most of the tropical and subtropical world covering South Africa; Hawaii, California, and Florida; Sri Lanka; and Fiji by about the middle of the twentieth century.

Passion fruit requires a mild climate free from extremes of heat and cold and plenty of rain. Extreme cold and frosty conditions can damage vines permanently, while fruiting is poor in regions with very warm climates. The plant is now cultivated commercially in many tropical and subtropical regions for its sweet, seedy fruit. The edible fruit is borne on a shallow-rooted woody perennial vine, which climbs by means of axillary tendrils. The fruit itself is round or slightly oval with a hard, thick shell 4–7 cm in diameter. The fruit is produced on 'new growth' parts of the vine and careful pruning is required for optimum yield. The average productive commercial life of a vine is considered to be three-and-a-half years. Growth of the vine from seed to the flowering stage takes approximately 6 months. Fruits develop after the stages of flowering and pollination, which usually takes a further 70–80 days. The fruit may be harvested manually when ripe, but due to high labor costs, the fruit is generally harvested after it falls to the ground. In such situations, the fruit must be collected daily in order to keep it from pests and spoilage, which is enhanced by soilborne organisms.

While propagation of the plant can be carried out using cuttings, the propagation by seeds is generally the preferred method, as cuttings are prone to carrying diseases. Passion fruit flowers are cross-pollinated by insects. They are most effectively pollinated by different species of carpenter bees depending on locality. In locations where carpenter bee species are present, decaying logs are placed in plantations among the vines as they provide nesting spots and encourage colonization by bees. Cross-pollination encourages a greater variety of offspring with better resistance to disease, higher tolerance for climatic variations, and enhanced seed production.

There are two commercially grown varieties of passion fruit – the purple and the yellow (see Figures 1(a) and 2(a)). The passion fruit vine has a very distinctive, fragrant flower and alternate, finely toothed leaves, which are deep-green and glossy above, but they are paler and dull on the under surface (see Figure 3). Leaves can be tinged with red or purple, especially in the yellow form, are deeply lobed when mature, and can be 8–20 cm long. Fruits are round to oval in shape and, at maturity, are either yellow or dark purple in color depending on variety. Fruits have a thick peel and a soft to firm, juicy interior, which is filled with many seeds. The purple form has black seeds, while the yellow form has brown seeds (see Figures 1(b) and 2(b)). The pulp of purple passion fruit is less acidic and richer in aroma and flavor and has a higher proportion of juice (35–38%). It is grown in the United States, Kenya, and Australia, but is less well known although the fresh market for this variety is said to be growing. Most commercial production centers on the yellow variety, which has a more vigorous vine and generally larger fruit than the purple. Some of the older cultivars as well as some of the more recent ones are listed in Table 1. Variations in seasonality occur according to cultivar and location. In some areas, vines bear throughout the year although peak periods are observed. In Ecuador the harvest is year-round but the volume peaks during the period from March to September, while in Brazil, peak harvest occurs between November and February. In Colombia and Peru, harvest peaks between March and June. In India, the first peak occurs between August and December, with a second peak from March to May. During the latter, the fruits are somewhat smaller, with less juice. In Hawaii, passion fruits mature from June to January, with heaviest crops harvested between July and November.

Passion fruit production is reported under the category of minor tropical fruits together with lychees, durian, rambutan, and guava, which are traded in smaller volumes compared with the major tropical fruits such as avocado, mango, papaya, and pineapple, as reported by the FAO Economic and Social Development Department. Minor fruit crops are reported as

being traded mostly at the regional level. International trade classifications generally do not provide sufficient detail to desegregate global figures. FAO estimates that production of minor tropical fruits reached 15 Mt, or 24%, of total world tropical fruit production in 2000.

Passion fruit production statistics from other sources indicate an annual production of 0.852–1.2786 Mt year^{-1} of which only 0.5 Mt is produced in the developed world.

Major passion fruit-producing countries include Brazil, Ecuador, Colombia, Peru, Mexico, Australia, Zimbabwe, and Kenya (see Table 2). Over 95% of the production is the yellow form for juice extraction, while purple fruit contributes predominantly to the fresh market trade.

Patterns of Consumption

Passion fruit is grown in many tropical countries where it is a popular commodity. It is consumed in the fresh and processed form. Brazil accounts for 50–60% of world production and is the largest producer and consumer of fresh and processed passion fruit. Domestic consumption in Brazil is largely in the processed form as fruit drinks.

Ecuador is a major producer and is the largest global exporter of processed passion fruit juice. Colombia is also a major producer of passion fruit and is the largest exporter of fresh passion fruit to Europe, while Peru is becoming a leading producer and international exporter of passion fruit juice.

Indonesia is a large producer, but is not an established exporter, with fruit being consumed within the country. Although Kenya is considered a minor producer, significant exports of the fresh fruit are made to Europe as well as regional markets. Passion fruit production is being promoted in Queensland, Australia.

In many other tropical countries, passion fruit is grown largely for domestic consumption in both the fresh and processed form. In general, the sweeter purple passion fruit referred to as the granadilla is preferred for consumption as a fresh fruit, while the yellow passion fruit is grown mainly for the production of juice concentrate or single-strength juice, fruit preserves, and jams and as a flavoring agent. Apart from the unique flavor of the latter (Brix value range of 12–20), the comparatively high acid content of the juice (2.4%) is its most discouraging characteristic in the processing and development of value-added products. Passion fruit seeds are edible, and the oil extracted from seeds is consumed for medicinal and health purposes in some countries. Passion flowers are used to brew herbal tea, while the leaves are used as a vegetable in many Asian countries.

Figure 3 The passion fruit vine has deeply 3-lobed, finely toothed leaves, which are deep-green and glossy above, but paler and dull on the under surface with axillary tendrils originating adjacent to leaves.

Availability Absorption and Metabolism

Information on the availability of beneficial nutrients in individual fruit crops is important to researchers, dietitians, and nutritionists. Passion fruit is a rich source of a range of nutrients. The fruit contains a high amount of antioxidants and of fiber, which is effective in improving digestion and the nutrient-absorbing capacity of the body. Passion fruit has a high mineral content and is considered to be a useful source of provitamin A, ascorbic acid, riboflavin, and niacin. It has a high mineral content. In-depth analyses of nutrient composition of passion fruit are presented in Table 3.

Passion fruit pulp when consumed with seeds contains 24.5 g of fiber per cup, which is equivalent to more than 4 cups of bran cereal and more than 5 g of protein. Consuming the seeds also enables better absorption of vitamin A. On removal of seeds, the fiber content is reduced to 0.5 g with protein content reduced to less than 1 g. Passion fruit seeds are rich in polyphenolic compounds such as piceatannol and scirpusin B, and they deliver plenty of insoluble dietary fiber and

Table 1 Some common varieties of passion fruit[a]

Variety	*Description*
Australian Purple, or Nelly Kelly	A purple selection of mild, sweet flavor, grown in Australia and Hawaii
Common Purple	Naturalized in Hawaii; thick-skinned, with small seed cavity, but of fine flavor and low acidity
Sevcik Selection	A golden form of the yellow selected in Hawaii; a heavy bearer, but subject to brown rot and the juice, has a peculiar woody flavor
Kapoho Selection	A cross of 'Sevcik' and other yellow strains in Hawaii. A heavy bearer of large fruits but subject to brown rot; many fruits contain little or no pulp and the juice has the off-flavor of 'Sevcik' though not as pronounced
University Selection No. B-74	A Hawaiian hybrid between 'Pratt' and 'C-77,' usually yellow, occasionally with red tinges; resembles 'Waimanalo'; has good juice yield and very good flavor
Pratt Hybrid	Thought to be a natural cross between the 'Common Purple' and a yellow strain; subject to rot, but juice is of fine color and flavor, low in acid
University Round Selection	A Hawaiian crosses of 'Waimanalo' and 'Yee' – fruit smaller than 'Yee'; not as attractive but yields 10% more juice of very good flavor
University Selection No. B-74	A Hawaiian hybrid between 'Pratt' and 'C-77,' usually yellow, occasionally with red tinges; resembles 'Waimanalo'; has good juice yield and very good flavor
Waimanalo Selection	Consists of 4 strains: 'C-54,' 'C-77,' 'C-80,' of similar size, shape, color, and very good flavor, and 'C-39' as pollinator
Yee Selection	A yellow, round, very attractive, highly disease-resistant, but fruit has thick rind and low yield of juice, which is of very good flavor
Kahuna	Very large, medium purple fruit. Sweet, subacid flavor. Good for juicing. Vigorous, productive self-fertile vine. Produces over a long season. Large, attractive foliage
Purple Giant	Very large fruit, dark purple when mature
Brazilian Golden	Large, golden-yellow fruits, larger than standard forms. Flavor somewhat tart. Extremely vigorous vine, requiring cross-pollination. Extra large, fragrant flowers, white with a dark center, blooming during mid-summer. Produces one large crop beginning in late August or early September
Golden Giant	A large yellow-fruited cultivar that originated in Australia

Source: USDA National Nutrient database.

magnesium. Piceatannol and scirpusin B in passion fruit seeds provide antioxidant protection.

Vitamin A present in the fruit helps maintain cell growth, good vision, and a healthy skin. A cup of passion fruit contains up to 25% of the recommended daily allowance (RDA) of vitamin A per person. Carotenoids present in passion fruit include zeta-, beta-, and alpha-carotene, β-cryptoxanthin, and lycopene. These compounds are fat-soluble and help the body produce vitamin A.

Passion fruit contains vitamin C, which helps the body scavenge harmful proinflammatory free radicals, strengthens the immune system, and prevents premature aging, as it is a powerful water-soluble antioxidant. Passion fruit contains up to 30 mg vitamin C, per 100 g, with one cup providing a days' recommended requirement of this vitamin. However, being water-soluble nutrients, vitamin C and folate are prone to gradual depletion after harvest. Thus, a freshly picked passion fruit is more nutritious than one that has been stored and transported.

Daily requirement of iron is in the range of 8–12 mg for both women and men. Passion fruit is a rich source of nonheme, plant-based iron, and a cup of raw passion fruit can provide up to 4 milligrams of this micronutrient and will make a useful addition to the diet, particularly with respect to vegetarians. The vitamin C present in passion fruit facilitates iron absorption, prevents loss of iron, and increases the production of blood.

Magnesium ensures proper gene function and plays an important role in carbohydrate metabolism, heartbeat, and nerve transmission. It is also necessary for the development of strong bones. The RDA for magnesium in adults ranges from 310 to 420 mg, and a regular consumption of passion fruit seeds can make a significant contribution to an individual's daily magnesium intake. Consumption of adequate quantities of magnesium-rich foods is particularly important to people with an increased risk of magnesium deficiency. Incorporation of passion fruit seeds in the diet in such cases will be of benefit and will help combat risk factors that increase the likelihood of magnesium deficiency such as stress, high alcohol consumption, long-term use of certain diuretics, and the incidence of gastrointestinal disorders such as Crohn's disease.

Health Effects

Written records of the medicinal use of passion fruit date back thousands of years. The anti-inflammatory properties of passion fruit were understood by Native Americans who used the flowers to heal bruises and wounds and the leaves and root as a poultice for injuries and boils. Leaves, roots, and flowers were also brewed as teas to calm and help settle the nerves and encourage sleep. Including passion fruit consumption in the diet is credited with boosting immune function, improving eyesight, increasing skin health, regulating fluid balance in the body, lowering blood pressure, boosting blood circulation, and improving bone mineral density. It is also accredited with reducing signs of premature aging, improves sleeping habits, and eliminates asthma.

Fiber is an essential component of a healthy diet, since it facilitates healthy digestion of food and the regulation of bowel movements. Passion fruit is a good source of soluble

and insoluble fiber, both in the pulp and in the rind. Fiber acts as a bulk laxative, which moves food through the digestive tract and regulates bowel movements, thereby reducing exposure time of the colon to any toxins.

Passion fruit seeds provide protection against damage caused by the accumulation of free radicals in the system, which cause many degenerative and chronic diseases such as immune system problems, atherosclerosis, Alzheimer's disease, heart disease, arthritis, dementia, and diabetes. The body produces *metalloproteinase enzymes in response to* exposure to UV rays, which help repair sun damage. However, some of these enzymes are not beneficial as they degrade collagen and elastin, which leads to wrinkling of the skin. Free radicals are known to stimulate the production of the latter category of *metalloproteinase* enzymes. Thus, the free radical-destroying properties of passion fruit seeds also provide beauty benefits by removing free radicals from the body, thus preventing premature wrinkling of the skin caused by UV radiation.

The antioxidants present in passion fruit help with improving eye sight and protect the body from aging and other damages caused by free radicals, which are produced due to the increase in environmental pollution. High oxidative stress increases production of free radicals in the body. These free radicals damage normal cell DNA and are able to turn it into cancerous forms.

The antioxidants protect arteries from free radicals. Passion fruit being rich in flavanoids and vitamins A and C, when consumed at recommended levels, is reported as providing protection from oral and lung cancer. Vitamin A is also linked to eye health and the prevention of macular degeneration, cataracts, and night blindness, while vitamin C is highly effective in increasing immunity against common cold, flu, and infections. High sodium levels in the body increase the risk of high blood pressure, heart attack, and stroke. High amount of antioxidants also protects arteries from free radicals and proves to be highly beneficial to the cardiovascular system.

Soluble fiber present in passion fruit. 100 g passion fruit provides 27% of daily fiber required by the body and is known to improve digestion. Insoluble fiber acts as a bulk laxative, which helps protect the colon mucous membrane by decreasing exposure time to toxic substances as well as binding to cancer-causing chemicals in the colon. It is thus considered to be an effective colon cleanser as this fiber is capable of removing the toxins stored in the colon, which are responsible for the development of colon cancer.

Dietary fiber is also beneficial to the cardiovascular system as it helps remove excess cholesterol and reduce cholesterol levels in the blood. It increases high-density lipoprotein (HDL) referred to as good cholesterol and reduces low-density lipoprotein (LDL) referred to as bad cholesterol. A higher level of HDL:LDL ratio tends to prevent plaque formation in arteries, thereby reducing blockage of blood flow to the heart and preventing heart attacks. Insoluble fiber in passion fruit seeds promotes intestinal health. It has been observed that adding insoluble fiber from passion fruit seed to a fiber-free diet enhances the amylase activity, which converts complex sugars to simple sugars during digestion and reduces cecal pH and cecal ammonia content. Passion fruit seeds are rich in insoluble dietary fiber (64.1 g/100 g). Chau et al. had suggested that insoluble fiber from passion fruit seeds might offer an effective functional ingredient to promote intestinal function and health. A decrease in cecal pH and cecal ammonia content helps balance bacteria in the intestines and reduces the potential risk of tumors in the colon.

Potassium is a vasodilator and an important component of cells and body fluids. It relaxes the tension of blood vessels and promotes increased blood flow and helps regulate heart rate and blood pressure. Passion fruit contains 7% of RDA of potassium and when incorporated into the diet can help maintain the balance of sodium levels in the body. Fresh granadilla is rich in potassium, with 100 g of fruit pulp containing up to 348 mg of potassium, and is a valuable good source of minerals such as iron, copper, magnesium, and phosphorus, which are present in adequate amounts in the fruit.

Minerals such as iron, copper, magnesium, and phosphorus contribute to bone density and bone strength. Passion fruit is a rich source of these minerals and when incorporated into the diet will contribute to bone health and the elimination, prevention, or alleviation of the symptoms of osteoporosis and the associated pain and inflammation that occur when bones deteriorate with age and activity.

Medicinal harmala alkaloids such as harmine (monoamine oxidase inhibitors) present in passion fruit function as a sedative. This compound has been connected to a reduction in restlessness, insomnia, sleeplessness, and nervous anxiety.

Bioflavanoids present in the peel of the purple passion fruit have been found to have an expectorant, sedative, and soothing effect on the respiratory system. Extracts from the peel have been positively connected to a reduction in asthma attacks, wheezing, and whooping cough.

Pasta: Manufacture and Composition

B De Cindio and N Baldino, University of Calabria, Arcavacata di Rende (CS), Italy

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Pasta is one of the most diffused foods in the world, since it is one of the largest forms of wheat consumption. The use of durum wheat in pasta making, traditionally limited to local areas, mainly Italy, has increased throughout the last few decades. This is due to several specific characteristics, and among them, we recall nutritional value, low cost, easy storage, product consistency, and being synonymous with the Mediterranean diet. The amount of pasta consumed throughout the world is continuously increasing and reached about 13 million tons in 2011; thereof, nearly a quarter was produced in Italy. Italy can be undoubtedly considered the reference country for this product from all points of view. Pasta consumption was between 4 and 10 kg per capita per year for many countries in 2011, but this value was about 27 in Italy (UniPI data). A quite high number of both pasta and pasta machine producers are Italian.

Pasta may be considered a commodity product, because its storage does not require either any temperature-controlled device or a particular package. Even the preparation for consumption is very easy consisting essentially of rehydration performed at normal water boiling temperature and the addition of any suitable sauce. The consistency of pasta after cooking seems to be the most important claim of pasta quality for consumers. Pasta 'al dente,' for instance, is a classic requirement.

Pasta is made essentially with durum wheat, even though in some countries, it is allowed to use other flours or a combination of them. Legislation or production guidelines govern this matter: for example, in Italy, pasta is produced with a maximum of 3% of nondurum wheat; on the opposite, in the United Kingdom and Germany, there are no specific legislations governing pasta production, whereas in Austria, pasta can be made with durum wheat or other wheats. The choice of cultivars producing excellent semolina quality is linked to its capability to give a final product that maintains a good consistency after cooking. This is related to the protein and gluten content. In fact, a high-quality pasta should have a relatively high protein content, at least between 13.5 and 14.5 g/100 g, and a good balance between glutenins and gliadins, the two protein components of gluten.

Dough formation is obtained by mixing the right amount of water to semolina flour to create a homogeneous mass. Owing to the size of the granules, this stage can be very difficult to perform in the right way avoiding lumps and small spots of undissolved flour. Then, after mixing, water is removed by drying to achieve a final value of 12.5% w/w corresponding to equilibrium with the ambient air (relative humidity 60%). In these conditions, it is not necessary to use any particular package to prevent drying or wetting of the final product, as it is necessary, on the other hand, with bread or biscuit, respectively. Drying is one of the oldest methods for food preservation used by humans over the centuries. It uses damp warm air as a vector to extract water from the dough and is a crucial stage in the pasta production process.

Raw Materials

Pasta is made by mixing semolina and water under energy application at controlled temperature and moisture conditions. The main use of durum wheat (*Triticum durum*) is for pasta, and the end-product quality is related to the durum grain characteristics, which, in turn, are mainly determined not only by the genotype, but also by the environment (weather and nutrition) and crop management. Durum is generally considered to have the hardest kernel among wheats; it has an amber color and high protein content. Three different parts constitute the grain seed: the endosperm, the bran, and the germ. The kernel is constituted by almost 80–85% by weight by the endosperm. Inside, not only proteins and starch, but also, to a lesser extent, fibers, vitamins, and minerals can be found. The endosperm is rich in proteins and enzymes. Gliadins, glutenins, albumins, and globulins are the major proteins present. The glutenins and gliadins form the gluten complex, responsible for dough rheological properties. Moreover, the endosperm contains about 30% of glutamine and 10% of proline, followed by leucine (6.5%), another important amino acid, and minor quantity of other amino acids. Flour from the endosperm contains about 82% starch, which is present as granules of various sizes and shapes. Starch is the main carbohydrate present in the endosperm cells. The external layers and the internal kernel of the grain have their own specific chemical and morphological characteristics. In the bran, which is mainly composed by the outer layers of the caryopsis, the chemical characteristics are given not only by the concentration of fibers and in particular insoluble fibers (cellulose and hemicellulose), but also by minerals and proteins. Finally, the germ is rich in fats that can easily go rancid.

Starch

Starch, in the form of granules, is deposited in the cereals and comprises about 70% (w/w) of endosperm in wheat, and it is an energy source. The starch is a mixture of two polymers, amylose and amylopectin, classified as D-glucans. The molecular weight of amylose is around 250 000 and it is a mostly linear polymer of α-(1,4)-linked glucose with a degree of polymerization (DP) of 1000–5000 glucose units. The structure of this polymer was assumed to be mainly linear, but really appears to be partially branched. On the contrary, amylopectin is branched to a much greater extent than amylose, and the molecular weight is 10^7–10^8. The ratio of amylose to amylopectin is relatively constant, at about 23. Amylopectin is a much larger glucose polymer (DP 105–106) in which α-(1,4)-linked glucose polymers are connected by 5–6% α-(1,6)-linkages. Normal wheat starch contains 20–30% amylose and 70–80% amylopectin.

Starch granules in wheat are frequently classified into two size groups: large, elliptically shaped A granules (30–40 μm in dia) and small, round B granules (<10 μm in dia), which are formed later in the grain-filling process, which gives a durum

biphasic distribution. B starch granules make up about 25–30% of the total starch volume but about 90% of the number of starch granules. Intact starch granules are almost insoluble in water, but when heated in excess water, they gelatinize. Starch gelatinization causes the granules to swell and eventually to rupture. This change is detected by microscopy and differential scanning calorimetry in a ranging gelatinization temperature of ~50–70 °C. Upon heating, starch loses its rigid structure, becomes rubbery after its glass transition, and can readily absorb water. This causes an increase of viscosity as the granules swell and release soluble material from the granule. When the percentage of B granules is increased in durum starch, the dough absorbs more water, because the smaller B granules have a higher surface to volume ratio and are able to hydrate and swell more efficiently and bind more water than A granules. Therefore, increased B granule content should increase flour water absorption.

Proteins

Protein is considered the most important nutrient for humans and animals, as manifested by the origin of its name, from the Greek *proteios* for primary. The protein content of wheat grains may vary between 10% and 18% of the total dry matter. Wheat proteins are classified according to their extractability and solubility in various solvents. Proteins can be classified into albumin (water-soluble), globulin (soluble in salt solution), gliadin (extractable in aqueous ethanol solution), and glutenin (soluble in dilute acid), conforming to Osborne's protein classification. The largest fraction (80%) of durum is gliadins and polymeric glutenins, whereas the lesser fractions (20%) are albumins and globulins. The group of proteins in wheat that exerts the most influence on the strength and elastic properties of dough are the glutenins and gliadins (gluten complex). The polypeptide complex made up of glutenin, gliadin, and lipid is defined as the viscoelastic mass remaining after removal of the starch. The glutenin function is able to form an extensive 3-D network of molecules through disulfide bonding, hydrogen bonding, and hydrophobic interactions. All contribute to the formation of a cohesive elastic dough. The gliadin, being globularly shaped, acts as a lubricant between glutenin strands, allowing strength and extension of the network. Proteins, such as those present in gluten, are denatured by heat and extreme changes in pH. Hence, in order to retain its strong viscoelastic properties, wet gluten should be dried carefully. The distribution of total gliadins among the different types is strongly determined by wheat variety and growing conditions (soil, climate, and fertilization). The polymeric protein (glutenin) is mainly responsible for the elasticity of the dough, whereas the monomeric gliadins are the extensibility-related characters. Thus, the ratio of glutenin to gliadin can be directly related to the balance of dough strength and extensibility. The types of glutenins present can be undissociated (MW 15 000–150 000) and associated fraction (MW 150 000–3 000 000), many having extensive disulfide bonding. Reduction of the intermolecular disulfide bonds yields subunits, and their molecular weight can be high and/or low (HMW and LMW subunits). The degree of cross-linking by intermolecular disulfide bonds varies considerably leading to proteins with a wide range of molecular weights. Differences in the amino acid composition of the LMW and HMW subunits have been reported. The gliadin can be classified in α-, β-, γ-, and ω-gliadins, in order of their electrophoretic mobility or in α-, γ-, and ω-gliadins for the amino acid N-terminal sequence. The gliadin proteins have a higher content of proline residues than glutenin and yet do not display such strong viscoelastic behavior.

Finally, the nongluten proteins are albumins and globulins. The former are the smallest wheat proteins, followed in size by globulins, and it is covalently bound into the glutenin matrix.

Minor Elements

Lipids, nonstarch polysaccharides, enzymes, vitamins, pigments, and minerals are present in a small amount in wheat. Lipids are 1–3% (dry matter) of the grain and can be both starch-bound and non-starch-bound. They are able to associate themselves both with proteins, owing their amphipathic nature, and with starch, forming inclusion complexes. In durum, semolina free lipids are 64% of the total amount. They are important for the color of pasta due to pigments and lipoxygenase. In fact, a variable number and variety of pigments are present in wheat. The xanthophylls are present in a quantity of about 1.5 ppm. Lutein is a xanthophyll pigment, which is abundant in wheat and present also as its esters. Carotenoids are members of a class of hydrocarbons (carotenes), and their oxygenated derivatives (xanthophylls) consist of eight isoprenoid units. Flavones are almost insoluble in water, but soluble in 85% (v/v) ethanol and WSB (1-butanol saturated with water). They are present mainly in the bran and their color ranges from yellow to brown.

The yellow color of pasta is due to the pigments present in the endosperm with a slight reduction caused by the oxidation of yellow pigments catalyzed by the enzyme lipoxygenase. Protease is another enzyme capable of reducing the consistency of dough after mixing and resting. Cytase, lipase, phosphatase, and oxidase are other enzymes present in wheat germ.

Finally, grains are good sources of insoluble fiber. Similar values (3–8%) to those of soft wheat were found in durum wheat: cellulose (2.7% of dry weight), glucans (1%), arabinogalactan peptides, and arabinoxylans (7.6%). Then, pentosans, nonstarch polysaccharides, the main constituent of cell walls of the lignified bran layer, are mainly mixed arabinoxylans, and as a consequence of their interfacial activity, they play a crucial role in air entrapment. Vitamins, such as B_{12}, B_{16}, C, and E, and minerals are also present in durum wheat.

Pasta Dough: Forming and Development

The first stage of pasta production is mixing, and it appears to be very important. The durum wheat semolina is mixed with water in a paddle mixer, fed into an extrusor, then compressed, and extruded through a die. The rheological behavior of dough after extrusion is related to the gluten development matrix. In fact, the rheological properties of polymers reflect the degree and type of cross-linking of the polymers as shown in Figure 1. At the early stage of mixing, the water, in the right quantity to reach a final moisture content of about 33% on a wet basis, is distributed among

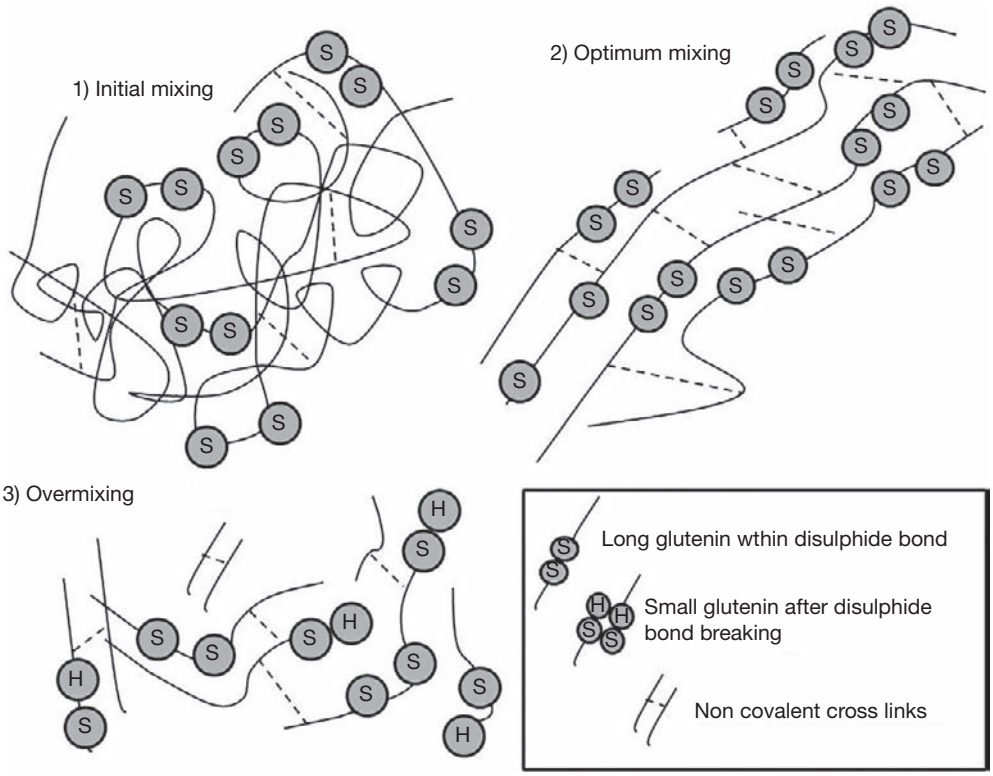

Figure 1 Model for structure of gluten.

the semolina particles. At the initial mixing time, glutenins, which are the long polymeric proteins, are folded, and the chains are in random orientation, but as mixing proceeds, more proteins become hydrated and the glutenins tend to align, because of the shear and stretching forces imposed by the paddles. For the network development, during mixing, the balance of gliadin and glutenin is very important so that chemical bonds may develop. In fact, the optimum dough structure involves bonds like disulfide and hydrogen bonds and cross-links involving dityrosine. Indeed, as reported in the literature, by adding hydrogen bond-breaking agents, it is possible to observe a drastic effect on dough rheology and the strengthening effect of heavy water compared to ordinary water. Another unique feature of hydrogen bonds is their ability to interchange under stress and thereby facilitate re-orientation of gluten proteins. Hydrophobic bonds result from the interactions of nonpolar groups in the presence of water. Their functionality is similar to that of hydrogen bonds, but the overall effect is much less. Disulfide bonds play a key role in dough formation and development. They form strong cross-links within and between polypeptide chains, thereby stabilizing hydrogen bonds and hydrophobic interactions. The interchange reaction requires a 'mobile' sulfhydryl-containing substance to initiate the series of disulfide interchanges. The total number of S—S bonds does not change; only their location in the glutenin molecule is altered. When the durum is hydrated and well mixed, the monomeric proteins, gliadins, form a matrix within the long polymer networks and contribute to resistance to extension and between protein polymers increase gluten viscous resistance and resistance to extension. Glutenins, and in particular omega-gliadins, seem to interact with the glutenins during dough processing through noncovalent interactions.

Then, when the dough is at the optimum mixing time, the gluten network has a maximum cross-linking of protein with disulfide bonds, the interaction between the polymer cross-links is becoming stronger, and, as a consequence, a maximum resistance to extension and restoring force after deformation can be observed. On the contrary, when mixing is too long, the dough can go beyond its optimum development; the cross-links begin to break due to disulfide bonds breakage. Consequently, glutenins depolymerize and become sticky.

Mechanical Properties: Rheological and Empirical Measurements

The mechanical properties of pasta dough and final pasta quality are determined by gluten network formation during mixing and then by durum wheat composition (low or high protein content), processing parameters (mixing time, energy, temperature, and speed rate), and ingredients (e.g., water and salt). Mixing time and energy input are used to adjust dough properties, but the optimum mixing time varies with durum semolina. The widespread belief is that a stronger dough requires a longer mixing time and greater energy input. During the mixing process, the dough goes from 'underdeveloped,' with a poor gluten structure; to 'properly developed,' with an appropriate gluten network; to, finally, 'overdeveloped,' with soft, extensible and sticky properties that is undesirable because of its reduced machinability. A level of work above

the optimum induces significant changes in the mechanical properties of the dough.

Dough properties are also determined by the amount of water added. An optimum water level is required to develop cohesive, viscoelastic dough with optimum gluten strength. Owing to a higher protein and dense particle content, a strong semolina requires a higher water level than a weak one. The heat generated by the frictional forces and the heat of hydration of the semolina during mixing cause a temperature increase, which influences the elastic properties of the dough. Temperature increase is mainly according not only to mixing speed, but also to the type of semolina and the type of mixer. It is well accepted that an optimal temperature should be 28–30 °C. In fact, when the temperature is relatively high, the dough becomes soft and viscous, showing less elastic properties, because elasticity and firmness change due to the fermentative activity increasing. If the temperature is relatively low, the dough becomes too hard to push and rather difficult to extend, with an evident loss of the final quality of the products.

The mechanical properties of pasta dough after mixing are measured in terms of gluten strength by several empirical instruments: farinograph, mixograph, and alveograph tests, eventually adapted or modified.

Even though these tests are purely descriptive according to the type of instruments, size and geometry of the sample, and the specific conditions under which the tests are performed, they are still useful, especially for the determination of the relative strength and extensibility of different cultivars. Fundamental tests are not widely used because they require complex expensive instrumentation and a high-level technician; often, they are time-consuming and difficult to maintain in an industrial environment; moreover, the deformation condition test may be inappropriate, and consequently, the interpretation of results may be rather difficult. Nevertheless, at present, the use of rheological measurements has increased because the apparatus has become less expensive and more automatized. Usually, with the same device, it is possible to perform small deformation dynamic oscillatory measurements at several frequencies, which are useful to characterize not only dough and wheat flour–water mixtures at equilibrium but also stress relaxation, creep, and creep recovery for investigating the fundamental mechanical properties.

Small deformation dynamic oscillatory measurements are performed under mild conditions to preserve the structure during the test, thus allowing one to obtain information on the bulk properties of the dough. From dynamic oscillation tests, it is possible to obtain the elastic modulus (G′) and the viscous modulus (G″), the former being in closer agreement to the cross-linked polymer behavior exhibited by such systems. This test method has been found very useful to study the effect of protein content, water level, mixing time, and the different amount of gluten in the dough. This experimental technique requires a linear link between stress and strain that usually is found at strain levels smaller than 1%. Beyond this limit, both the elastic and loss moduli G′ and G″ decrease. In the linear region, the frequency sweep tests have shown that the modulus follows a power law behavior. The water level and the protein/starch ratio influence the values of the moduli and, particularly, G′ that decreases when increasing the water. It should be noted that G′ is a good measure of the dough strength. By performing strain sweep tests, it appears that the storage modulus shows a significant increase as the proportion of starch in the dough increases. Moreover, the value of the phase angle tangent, defined as the ratio of G″ to G′, reveals that gluten–starch mixtures behave as elastic solids and consequently the linear strain region limit decreases exponentially as the starch content increases. G′ decreases with increasing protein and gluten concentration, whereas the opposite happens when constant water levels are used. Studies about the influence of mixing time still do not provide any general conclusions, and most of the works refer to empirical measurement of mixer motor torque, voltage, or power consumption during mixing as a qualitative indication of structural change. Many problems are involved, for instance, owing to a poor accounting for motor and drive losses, frictional and surface effects between the dough and the mixer, varying signal damping and data acquisition rates, effects of aeration on rheology, and rheological relaxation effects. Alternatively, measurement of rheological changes at some time after mixing can be performed.

To measure dough properties under uniaxial extension, often, a rather empirical but useful method is used, clamping the material at two ends and pulling or extending it by a hook at the center of the sample at a constant strain rate. During stretching, the material undergoes an extensional deformation up to its breakage known as the tensile failure. The stress–strain curves obtained show that stress increases with increasing strain and reaches a maximum at sample fracture point. It is often found that the stress increases are more than proportional to the strain thus showing a so-called strain hardening, which is very important for the final pasta quality.

Production Technology: From Mixing to Packaging

The transformation of durum into pasta involves dosing, premixing, mixing and extrusion stages, drying, and finally packaging. A sketch of the pasta production phases is shown in Figure 2. This sequence of operations was developed on an industrial automated scale in the early 1930s with the

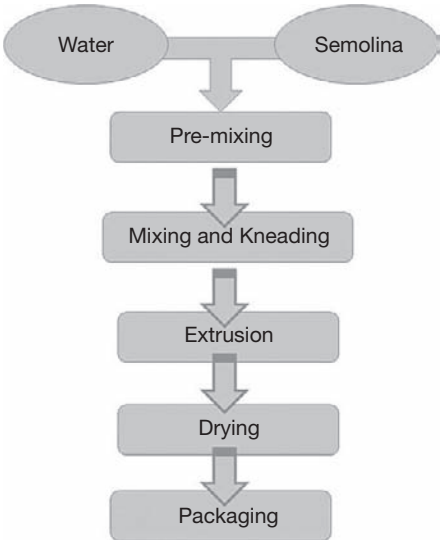

Figure 2 Dry pasta production line.

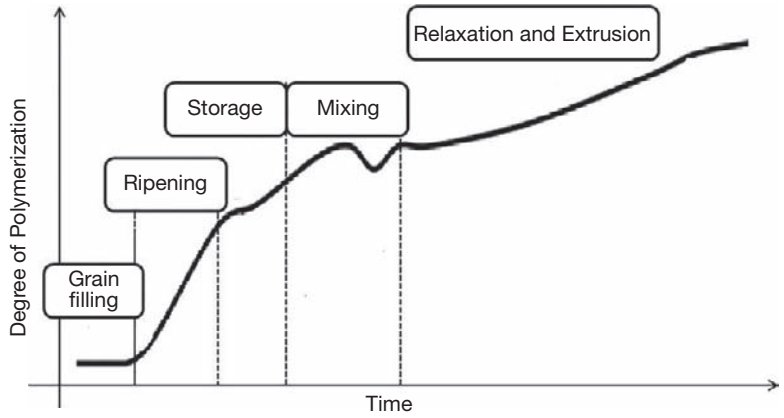

Figure 3 Degree of polymerization of glutenin protein.

introduction of the continuous press, then with the use of automatic dryers, and finally, in the mid-to-late 1940s, with the manufacture of continuous, automatic production lines. The resulting wet pasta is modeled as a network of proteins that encapsulates the starch granules, to produce a structure that has the minimum of cracks and voids. The pasta dough has completely developed disulfide bonds and then a gluten network, which continue the architecture development even during storage. Figure 3 shows a sketch of disulfide bond formation during the production process.

The initial raw material dosing is of primary importance for the subsequent dough formation and pasta manufacture steps. The water–semolina ratio determines the rheological behavior of the semolina dough and the mechanical energy input for each product. Semolina dosers can be volumetric or gravimetric, while water dosing can be achieved using either a mechanically or a volumetrically based system that is synchronized. Water temperature is controlled by a simple thermostatic system and usually ranges between 20 and 50 °C. All the components of solid and fluid dosers are built of stainless steel and food-grade materials. In some plants, water is supplied as small drops to facilitate semolina wetting. Then, a mixing–kneading process is used to produce homogeneously hydrated dough with a moisture content of ~33% (w/w). To obtain the most homogeneous hydrated mass possible, semolina and water first undergo high-speed premixing (using a single or double shaft, vertical or horizontal) to ensure intimate contact between semolina particles and water droplets. Further mixing takes place in the main mixing unit, generally under vacuum, before sending the mass to the extrusion section. A vacuum chamber is used to remove air bubbles from the pasta before extruding. If the air is not removed before the extrusion, the pasta dough shows small bubbles that reduce the mechanical strength.

In the mixer–kneaders, as well as in vacuum mixers, the residence times range from 10 to 15 min, according to the semolina particle size distribution. Once the first mixing phase starts, the gluten proteins are stretched, and as the temperature rises, an interlinked protein framework is established. After hydration and mixing, the wetted semolina particles are sent to the extrusion stage, where pasta dough development largely occurs. During extrusion, the pasta dough is transported by a suitably designed screw rotating inside a cylinder and a transition occurs from hydrated granular semolina to a homogeneous material, with an associated increase in specific weight along the screw from 750 to 1350 kg m^{-3}. The extrusion system consists of a screw-barrel subsystem, capable of transporting the dough and pushing it into a die that restricts the outflow of the dough. As a consequence, the die creates a back pressure along the screw, which results in dough development. Further energy input is transferred to the forming dough to push it through the die hole and to shape the product after the gluten network is completely developed. Single or double screws are normally used. The extrusion controls the rate of production and influences the overall quality of the finished product. Friction must remain at low levels to prevent dough temperature from exceeding 44 °C; thus, the cylinder and head of the extruder are cooled, avoiding starch damage. If the extruder temperature rises above 55 °C, the gluten becomes tough and stiff and forms an irreversible gel, with the consequence of making the pasta strands weaker. It is well accepted that to give the pasta some resistance to overcooking, the protein network must not be damaged. There are grooves along the sides of the barrel to increase the shear effect and make the dough adhere to the barrel, which generates a gentle kneading action.

Finally, the homogeneous dough is extruded through die holes designed to give the desired pasta shape and size. The material used to make dies is bronze with inserts made of Teflon or bronze, the design and construction of which are arts in themselves and influence pasta shape and smoothness. Fresh pasta is then dried in order to reduce its moisture content to about 12.5%, to reduce moisture to a water activity value where microbial growth is impossible and there is equilibrium with ambient conditions (a_w~0.60).

Nowadays, the majority of pasta-drying processes adopt air temperatures ranging from about 70 to 100 °C while keeping product temperatures between 60 and 90 °C. The difference between product temperature and air temperature is mitigated by air moisture content and ongoing evaporation through the water-removal process. Drying is the most difficult and critical step to control in the pasta production process. The objective of 12% is hard. Drying temperature and relative humidity increments are important factors in drying. Since the outside surface of the pasta dries more rapidly than the inside, moisture gradients develop across the surface to the interior of the

pasta. If pasta is dried too quickly, a crust is formed and the pasta may crack, giving the product a poor appearance and a very low mechanical strength. Cracking can occur not only during the drying process but also after several weeks in the package. If the pasta is dried too slowly, it tends to spoil or become moldy during the drying process. Therefore, it is essential that the drying cycle is successful: the pasta will be not only firm but also flexible enough so that it can bend to a considerable degree before breaking.

In the first phase of drying, the pasta is preheated under severe conditions to form a thin crust capable of preventing sticking between pasta pieces. Short pasta is then put on suitable trays, whereas long pasta hangs on sticks, and those devices come into the drier passing through zones at different temperatures and humidities in accordance with drying characteristic diagrams. Temperature and humidity are continuously measured, and signals are sent to the controlling unit to maintain drying conditions as programmed. Thermal energy is transferred to the pasta by airflow coming from ventilation units, and the product passes through successive drying and stabilization phases. Sometimes, it is necessary to perform humidification along the drier by adding moisture through steam injectors to eliminate residual tensions and enhancing product stabilization.

The last phase of the pasta-drying process is the cooling phase, where pasta is slowly brought to equilibrium with the ambient outer environment, making it ready for packaging. Outer panels, made of material with high insulation power, cover drying system modules. They may be covered with stainless steel sheeting with watertight portholes at the dryer end for inspecting the inside. The bottom sections of the dryers are equipped with a condensation collection and a removal system. The storage section has an air circulation system to maintain homogeneous temperature and humidity conditions during storage.

In the packaging phase, the product has to be free of contamination. Packages must protect the pasta from damage during shipment and storage. The principal packaging material is the cellophane bag, which provides moisture-proof protection for the product and is used easily on automatic packaging machines. It should be noted that the package itself is a necessary means of providing all the needed information to the consumer.

Pasta Drying: Process Parameter Setting and Control

During drying, it is required that the operating conditions of the process do not introduce any mechanical damage, so in the past, slow processes, characterized by high water content (70–80%) and not very high temperature (60–70 °C) of the extracting wet air, were used. The need to reduce process time and consequently plant productivity has driven pasta producers to use stronger conditions with temperature, even higher than 100 °C and low relative humidity. These severe process conditions can induce mechanical damage resulting in poor quality. Even though pasta drying is a very common technology, the operating conditions and the choice between slow and fast processes are very questionable. In fact, the final quality of dry pasta is largely affected by the temperature and humidity conditions during the drying process and by the drying velocity. During this stage, pasta is subject to rather severe conditions that are fully responsible for the end-product quality. According to the market request for high-quality production, severe process conditions can cause a so-called thermal damage that is evidenced by a poor texture, a decrease in the mechanical resistance, a lower nutrient content, a darker color, etc. This kind of product obviously does not fit with consumer expectations, even though safer from a microbiological point of view, owing to the poorness of most of the quality indices. Then, a correct design and conduction of the drying process are important, which requires an adequate model for describing the overall phenomena involved.

Some mathematical models have been proposed in the literature to describe and control the process, and an engineering approach seems to be helpful to simulate the process steps, making it possible to understand better the optimal process variables with the target of high product quality. The drying process involves a simultaneous heat and mass transport and, as a consequence, a humidity profile within the pasta dough with a volume contraction, which is proportional to the removed water. The volume shrinkage occurs by beginning from the external layers of dough, where free water concentration is smaller compared to the inside layers. The differential equations used for process modeling describe the fundamental two transport phenomena: heat is transmitted to the solid phase for liquid evaporation and water is transferred as liquid through the solid and evaporation phase. During this process, the external layers of the dough begin to lose water more quickly with respect to the inner ones, up to a determined value of humidity, and some tests showed that a humidity value of 15% is a threshold for dough behavior that is completely elastic. When humidity becomes $<15\%$, the external crust shows elastic behavior, while the inner layers still maintain the viscoelastic characteristics with the tendency to shrink. This causes the generation of stressed zones, which do not relax and can even cause pasta breakage. A careful control of the temperature and humidity is needed to prevent these conditions.

While there are a lot of both scientific and technological works dealing with pasta nutrient content, the literature is very poor about mechanical stability. In fact, on the one hand, this latter requires a deep knowledge of dough properties according to humidity and temperature; on the other hand, it is needed to know the kinematic field arising from the shrinkage following water removal. The so-called thermoviscoelastic effect can deeply influence shrinkage and final quality.

Conclusions

Pasta production has been summarized in terms of ingredients and production features. It appears that even though the food product is to some extent very old, nevertheless, its knowledge still requires hard work by both researchers and technologists. A good semolina is not directly transformed into an optimum dough, with the risk of frustrating the raw material choice by process damage. Actually, very automatized plants allow a very finely controlled process, but the best profile temperature/humidity is still found by trial and error. A thorough application of rheology and thermodynamics transport phenomena

with the aim of achieving high-quality products is the new frontier for pasta production.

Introduction

Pasta is an ancient food widely consumed in the world and represents one of the staple foods of the Mediterranean diet. There are many theories concerning its origin. Some researchers place its origin in the thirteenth century by Marco Polo, who introduced pasta in Italy upon returning from one of his trips to China in 1271. However, pasta dates much further back, maybe to the ancient Etruscans, who made pasta by grinding several cereals and grains and then mixing them with water, a blend that was later on cooked producing a tasty and nutritious food. The term 'macaroni,' which is currently referred to as a long type of pasta, is found in the documents of Roman writers since the first centuries 'after Christ.' However, both the Etruscans and the Romans baked their noodles in an oven, so boiled pasta had yet to be born in Italy. As the centuries went by, pasta continued to appear on the tables of Italy with different names. For example, in 1400, pasta was called 'lasagna' and pasta manufacturers were referred to as 'lasagnare,' while in 1800, their name turned into 'vermicellai.' Between 1400 and 1800, a new kind of pasta, that is, 'fidelli,' started being manufactured besides 'lasagne' and 'vermicelli.' 'Fidelli' were pasta threads with a cylindrical shape, and pasta manufacturers became known as 'fidellai.'

According to the American historian Charles Perry, who has written several articles on the origins of pasta, the first clear western reference to boiled noodles is in the Jerusalem Talmud of the fifth century AD written in Aramaic for which the term 'itriyah' was used. By the tenth century, 'itriyah' in many Arabic sources referred to dried noodles bought from a vendor, as opposed to fresh ones made at home.

Pasta Ingredients and Production

Pasta is mainly produced with wheat flour and water: eggs and/or other optional ingredients can also be added. Pasta manufacturers typically use milled durum wheat (semolina) although soft wheat flour and other cereal flours are also used. Pasta traditionally consumed in Italy is made exclusively with durum wheat flour, while in other countries, pasta made from soft wheat and/or other cereal flours are also frequently consumed. Durum wheat pasta is made from durum wheat semolina (*Triticum turgidum* L. var. *durum*) to which water is added, the reactant, that allows modification of gluten via the input of mechanical and thermal energy to produce pasta. Wheat proteins help with strengthening pasta structure by means of entangled aggregation. Starch, the major component of semolina and pasta, occurs in the form of granules dispersed within the protein network.

Pasta processing consists of three main operations: (1) hydrating and mixing–kneading of semolina to make a dough (formation of gluten network), (2) shaping the dough through extrusion, and (3) stabilizing the shaped pasta pieces, usually by drying. This sequence of operations is developed in an industrial automated scale. The process of hydrating and mixing–kneading of semolina produces a homogeneous hydrated dough that is essential for producing high-quality pasta. To obtain the most homogeneous hydrated mass, semolina and water first undergo high-speed premixing (using a single or double shaft, vertical or horizontal) to ensure intimate contact between semolina particles and water droplets. Further mixing then takes place in the main mixing unit, generally under vacuum, that removes air bubbles before the mass passes in the extrusion section.

After the dough is mixed, it is transferred to the extruder in order to obtain a specific form (spaghetti, macaroni, etc.) with the development of a continuous network of gluten protein that surrounds the starch granules. This process facilitates maintenance of pasta structure during cooking. The extrusion auger forces the dough through the die under high pressure, followed by cutting. The die holes are designed to give pasta the desired shape and size. Compression and extrusion are obtained with different machines. Until recently, most dies were made of bronze, which was relatively soft and required repair or periodic replacement. Recently, dies have been improved by fitting the extruding surface of the die with Teflon® inserts to extend the life of the dies and improve pasta quality.

Drying is the most difficult and critical step to control in the pasta production process. Drying consists of passing a flow of hot or warm air over the fresh pasta product, so that the thermohygrometric properties of the air progressively decrease the pasta moisture content at a level acceptable for dried pasta. Nowadays, the majority of pasta-drying processes adopt air temperatures in the range of about 70–100 °C while keeping product temperatures between 60 and 90 °C. The objective of drying is to lower the moisture content of pasta from ~31% to 12–13%, so that the finished product is hard, retains its shape, and can be stored without spoiling. Dried pasta stored at room temperature is stable for years at room temperature.

The best pasta is produced from durum wheat semolina, due to the dough excellent rheological properties, pasta superior color, cooking quality, and consumer acceptance. Whole grain wheat and other grains such as rice, buckwheat, barley, spelt, millet, oats, quinoa, and corn are also sometimes used to make pasta, which can be made also from more than one type of grain, and, in such a case, it is called 'multigrain.'

Pasta can be enriched, supplemented, or fortified or remain conventional. In recent years, several ingredients have been developed and are being used to improve the nutritional quality of pasta, for example, fibers, proteins, and vitamins.

On the basis of scientific evidence showing beneficial effects on health of whole grain product consumption, production of whole wheat pasta is increasing in recent years and many efforts have been made to improve its rheological and organoleptic properties and to implement its consumption even if this product is not yet widely consumed. Whole wheat pasta is

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00523-7

significantly higher in fiber and nutrients than its refined counterpart: during the refining process, wheat loses roughly 60% of its grain, a portion that includes its most nutritious components, the bran and the germ. Consequently, refined wheat provides less than half the amount of B vitamins, minerals, and fibers than whole grains. At present, there are no food labeling regulations setting the minimum whole grain content required for a given food to be considered whole grain. The Whole Grains Council recommends manufacturers to label as 'whole grain' only products containing a higher percentage of whole grain than refined grain (i.e., at least 51% whole grain). The HEALTHGRAIN Forum proposes two labeling categories, one for bread and pasta indicating 100% whole grain if the content of whole grain flour is almost over 90% of dry material and the other category for foods defined as 'rich in whole grain' where the amount of whole grain must be specified.

Production and Consumption

The last report of the International Pasta Organization (IPO) (www.internationalpasta.org/index.aspx) states that in 2012, about 13.5 million tons of dry pasta has been produced in the world. Among the pasta-producing countries, Italy ranks first with an annual production of about 3.33 million tons, followed by the United States (2.00 million tons), Brazil (1.19 million tons), Russia (1.08 million tons), and Turkey (1.00 million tons). The European Union produces 36.4% of pasta, followed by Central and South America with 21.9% and by North America with 16.9%; Asia and Australia are the countries with the lowest pasta production, that is, 1.8% and 0.4%, respectively. Italy is the first pasta-exporting country with about 1.8 million tons, followed by Turkey (~436 thousand tons), Belgium (~137 thousand tons), the United States (~133 thousand tons), and China (~109 thousand tons). Italy is the largest per capita/year pasta consumer in the world (26 kg), followed by Venezuela (13.2 kg), Tunisia (11.1 kg), and Greece (10.6 kg); Switzerland (9.2 kg) and Sweden (9.0 kg) consume more pasta per capita than the United States (8.8 kg).

Composition and Nutritional Qualities

Pasta is an important source of carbohydrates, especially starch. A portion of 100 g of uncooked pasta contains about 68.1 g starch, 4.2 g soluble sugars, 2.7 g fiber, 10.9 g protein, and 1.4 g fat, providing about 353 kcal (1478 kJ). Pasta also contains vitamins B_1 and B_2, as well as some minerals. In the United States, however, pasta is vitamin- and mineral-enriched. During cooking, some of the nutrients get lost either in the water or by heat, especially some starch, proteins, phosphorous, and vitamin B_1.

The biological value of proteins in durum wheat pasta is not particularly elevated given its low content of essential amino acids: in particular, wheat proteins are deficient in lysine. Based on high or low temperature used in drying, 100 g of pasta contains from ~22% to 26% lysine recommended dietary intake. However, pasta is usually consumed with other foods with different protein contents that improve the nutritional value of the pasta dish. The addition of eggs to the basic ingredients increases its protein content (about 20% higher compared to wheat pasta) and its biological value since eggs contain about 139% of the recommended dietary intake for lysine. However, the addition of eggs increases also the fat content of pasta.

Whole grain pasta contains fewer calories for 100 g of dry product (about 324 kcal per 1356 kJ) and supplies more fiber (~6 g) and 25% more proteins than the traditional refined pasta. Whole grain pasta is an excellent source of B vitamins and iron and provides significantly higher levels of the essential trace mineral selenium, a micronutrient with antioxidant properties. Whole wheat pasta also contains appreciable levels of alpha-linolenic acid. The most common whole grain pastas are made from whole wheat, brown rice, or buckwheat, but quinoa, spelt, and kamut are also used to make whole grain pasta. Not all whole grain pasta is made from 100% whole grain flour, however. Some are made from a mixture of whole grain flour and ground legumes and flax, ingredients that improve the product texture while boosting its protein and unsaturated fatty acid content.

Compared to wheat, buckwheat contains proteins with a high biological value due to a well-balanced amino acid composition (rich in lysine and arginine) and antioxidant molecules, such as rutin (a flavonol glycoside), which is recommended for people with capillary fragility. Corn pasta has about half as much proteins as traditional wheat pasta, but it is otherwise nutritionally comparable. Pasta from rice flour does not contain any gluten. Brown rice flour compared to white rice flour is made from rice that has only the inedible hull removed; therefore, it is high in fiber and produces pasta dough similar to whole wheat pasta, with the exception that dough made from brown rice flour is stickier. This kind of pasta is consumed in Asian countries and available in Asian markets or health food stores. Compared to common wheat, the composition of the kamut grain is richer in several minerals, including magnesium and zinc and selenium, a powerful antioxidant. Compared to wheat flour, kamut flour is also characterized by a percentage of vitamin E higher than 30%, as well as a higher content of proteins, lipids, and fatty acids. Oat and barley flours are mixed with wheat flour because they are rich in beta-glucan, a type of viscous fiber that improves pasta texture. Soy flour can be used to supplement proteins in macaroni and to produce a quick-cooking pasta product. Spaghetti with high protein and high lysine content can be obtained by adding up to 35% soy flour without adverse effects on flavor and texture and could result in greater acceptability of a soy-based diet.

Among the different types of pasta, the inulin-enriched pasta is to be counted for its content of nondigestible fructo-oligosaccharide with prebiotic effects.

Starch is the most abundant nutrient in pasta and the source of rapidly released glucose during digestion, regardless of the type of cereal used. The starch of pasta contains two major glucose polymers, amylose and amylopectin, which differ in the degree of polymerization (DP) of glucose chains and in the frequency of branches. In particular, wheat endosperm contains ~75–80% of starch as amylopectin and 20–25% as amylose. Amylose is a predominantly linear molecule with glucose chains linked through alpha-1,4 linkages in the range of 1000–2000 DP, while amylopectin is a complex and highly branched molecule in the range of 50 000–500 000 DP. In amylopectin, glucose units are linked in a linear way with alpha-1,4

linkages. Branching takes place with alpha-1,6 bonds occurring every 24–30 glucose units, resulting in a soluble molecule that can be quickly degraded since it has many end points for enzymes to attach onto. In contrast, amylose contains very few alpha-1,6 bonds or even none at all. This causes it to be hydrolyzed more slowly but to have a higher density and to be insoluble. In raw products, native starch occurs naturally as insoluble semicrystalline granules assembled in some way to form an ordered granular architecture and is not digested by human bowel enzymes. When it is heated in excess water, the starch granules undergo an irreversible phase transition, referred to as gelatinization, in which the highly ordered structure is disrupted.

The extent of starch gelatinization is the key factor in determining the digestibility and nutritional properties of starchy foods. The starch, before being absorbed in the small intestine, must be hydrolyzed to its monosaccharide components. The digestion of starch begins with salivary amylase, but this activity is much less important than that of pancreatic amylase in the small intestine. Amylase hydrolyzes starch, with the primary end products being maltose, maltotriose, and alpha-dextrins; some glucose is also produced. The products of alpha-amylase digestion are hydrolyzed into their monosaccharide components by enzymes expressed on the brash border of the small intestinal cells, the most important of which are maltase, sucrase, isomaltase, and lactase. However, starch digestibility is influenced also by the physical structure of food. In the case of pasta, molecular rearrangements of proteins may lead to the formation of large protein aggregates, which reduce pasta starch accessibility to the action of alpha-amylase during digestion that results in a lower but prolonged increase of blood glucose concentrations in the postprandial period. Addition of viscous fiber or inulin in pasta further reduces the rate of starch digestion.

Health Effects

Pasta is a key component of the traditional Mediterranean diet, a dietary pattern that confers health benefits compared to current Western dietary patterns.

Several decades of observational and intervention studies have clarified the characteristics of lifestyles able to prevent chronic diseases and extend longevity. It is well known that both an excess of calorie intake and an inappropriate composition of the habitual diet are relevant for the development of obesity and other chronic diseases. There is a general consensus among nutrition scientists and related experts concerning the optimal distribution of macronutrients: carbohydrates at 45–60% of calories, fats at 25–30% of calories, and proteins at 15–20% of calories. However, appropriate food choices may be more important than the overall amount of each of these macronutrients. This implies that avoiding extreme and/or unbalanced diets and favoring macronutrient-balanced eating patterns are as important as emphasizing the preferential use of unsaturated fats, whole grain and low-glycemic index (GI) foods, fiber-rich fruit and vegetables, and a combination of plant and animal protein sources.

The GI is a measure of the blood glucose-raising ability of the available carbohydrates in foods. A large body of evidence shows that a diet with a low GI may be able to prevent weight gain and reduce the risk of type 2 diabetes and coronary heart disease. GI is calculated by dividing the incremental area under the curve (AUC) of blood glucose concentrations, measured after the ingestion of a portion of the test food by the AUC of blood glucose concentrations achieved with a portion of the reference food (glucose or white bread). The test and the reference food must contain the same amount (50 g) of carbohydrate and are evaluated in the same group. This index was proposed for the first time in 1981 by Jenkins as an alternative system for classifying carbohydrate-containing foods.

Among carbohydrate-rich foods, spaghetti has a lower GI than bread, pizza, and other cereal foods. The average GI of durum wheat spaghetti from different manufacturers, cooked 10–15 min in water, is 46%. Other types of durum wheat pasta (i.e., macaroni, penne, and fusilli) or fresh pasta, made from soft wheat flour and eggs, also have a low GI that ranges from 32% to 47%. These values are also superimposable to those of whole grain boiled spaghetti (42%) and soy spaghetti (47%). As mentioned earlier, the low GI of these products is consistent with a low rate of starch accessibility to digestion, due to the formation of large protein aggregates surrounding the starch. This is relevant since it is able to reduce insulin secretion and consequently the risk of reactive hypoglycemia during the postabsorption period; moreover, it contributes to increase glucagon-like peptide-1 (GLP-1) that regulates postprandial satiety and glucose metabolism.

The majority of the intervention studies, mainly performed in high-risk subjects – obese subjects or people with insulin resistance/metabolic syndrome – and in diabetic patients, have shown that a low-GI diet induces favorable changes on body weight regulation, blood glucose, and insulin metabolism and lipid control.

A meta-analysis of randomized controlled trials has demonstrated that a diet with low GI, at least in the medium term (<6 months), promotes a greater weight gain and total fat mass loss compared to diet with high GI. This result has also been confirmed by a systematic review in which the authors evaluated the independent role in body weight reduction of GI and other variables of diet in healthy subjects, in glucose-intolerant subjects, and in type 1 and type 2 diabetic patients.

Epidemiological evidence also suggests that a diet with a low GI and rich in fiber contributes to diabetes prevention and to an improvement of the plasma lipid profile. The benefits of low-GI foods on blood glucose control and other metabolic parameters are particularly evident in intervention studies performed in diabetic patients and in other high-risk individuals compared to healthy subjects. In relation to blood glucose control, data clearly show that in diabetic patients, low-GI/high-fiber diets improve blood glucose concentrations, especially in the postprandial state, reduce the number of hypoglycemic events, and also lower the level of glycated hemoglobin. The beneficial metabolic effects of low-GI foods are independent of the fiber content. However, a combination in the diet of both low-GI and fiber-rich foods may enhance the beneficial effects of each component. These findings have led some food industries to develop new types of pasta rich in fiber, like those made from whole grain wheat flour or barley and oat flour. In particular, pasta made from whole grain wheat flour, beyond its content of dietary fiber, is also rich in oligosaccharides, minerals, vitamins, and antioxidant components that may have an additional beneficial influence on several biological functions. As a matter of fact, the habitual consumption of

whole grain foods is consistently associated with reduced risk of developing obesity, type 2 diabetes, and cardiovascular diseases in several epidemiological studies. These benefits have been related to multiple mechanisms; worth considering are (1) the lower energy content of whole grain products, as well as the higher satiating effect, favoring a lower energy intake per eating occasion and, in the long term, playing an important role in body weight regulation, and (2) the higher fiber, resistant starch, and oligosaccharide content fermented by gut microbiota with production of short-chain fatty acids (SCFA), as acetic, propionic, and butyric acids, which improve the control of glucose and lipid metabolism, decrease gastric emptying rate, and increase satiety. In particular, an intervention study, performed in subjects with the metabolic syndrome, showed that whole grain wheat pasta consumed in the context of a mixed meal significantly reduces postprandial insulin and triglyceride plasma levels, compared to refined cereal products. For these reasons, the consumption of whole grain foods in the diet has been included in the nutritional recommendations of the United States and other countries as a dietary strategy targeting the whole population.

Beneficial effects on glucose and lipid metabolism have been also reported in subjects consuming pasta made from barley or oat flour, two cereals particularly rich in beta-glucan, or pasta added with guar. These types of pasta, compared to traditional refined wheat pasta, induced an even lower increase of plasma glucose, insulin, and triglyceride levels in the postprandial period and decreased even more both fasting and postprandial plasma cholesterol concentrations. The benefits on glucose metabolism of barley and oat pasta are related to the high viscosity of beta-glucans, which delays gastric emptying and limits starch accessibility to digestive enzymes, thus prolonging nutrient digestion and absorption in the small intestine.

Finally, consumption of pasta enriched in fructo-oligosaccharides and inulin has been proposed as a useful tool to prevent inflammatory gastrointestinal diseases and colon cancer, thanks to its prebiotic effects. The prebiotic activity might have a beneficial impact also on fat storage, insulin resistance, and subclinical inflammation.

However, despite the potential health benefits of new pasta formulations, it needs to be underlined that the types of pasta commonly available in food shops represent a healthy choice among carbohydrate-rich foods for their low GI and high satiating ability. Moreover, according to the Mediterranean tradition, pasta is the main ingredient of a complex dish in which other ingredients are also present, among these being olive oil, vegetables such as tomatoes, and products of animal origin. When animal products like fish, cheese, and meat are present in the dish, their amount is usually small and it can be considered optimal from the nutritional standpoint, being a good source of low-GI carbohydrates, rich in fiber, and with a balanced content of high-quality proteins and unsaturated fats, not to mention micronutrients and polyphenols.

In conclusion, scientific evidence supports the health benefits of regular pasta intake, in particular if it is consumed in the context of a diet balanced for energy density and macronutrient distribution, according to the Mediterranean dietary pattern. In fact, pasta, due to its low GI, represents an ideal source of carbohydrates in the diet of healthy individuals, obese subjects, and diabetic patients. In this context, the alarm about the possible dangers of a high consumption of dietary carbohydrates certainly does not apply, on the basis of the available scientific evidence, to healthy carbohydrate-rich foods like pasta. In contrast, it is strongly advised to favor pasta consumption, in those countries where its consumption is low, in substitution of other carbohydrate foods with higher GI. Furthermore, in order to enhance whole grain intake in the daily diet, whole grain pasta consumption should be considered in addition or in substitution of refined grain pasta.

Pasteurization: Effect on Sensory Quality and Nutrient Composition

RP Lopes, MJ Mota, I Delgadillo, and JA Saraiva, University of Aveiro, Aveiro, Portugal

© 2016 Elsevier Ltd. All rights reserved.

The pasteurization concept emerged as a mild heat treatment that aims the removal of pathogenic and spoilage bacteria and inactivation of undesirable enzymes from food products, in order to assure food safety. This process derives from the discovery of Pasteur in 1857, when he observed that souring in milk could be delayed by heating it to 50.0–61.0 °C. Nowadays, thermal pasteurization is the method commonly used for food preservation and shelf life extension. The severity and duration of heat treatment depend on food type, equipment, and method used. However, thermal processing has several disadvantages, such as the destruction of nutrients, development of off-flavors, and other losses on product sensory quality. Despite this, thermal processing remains the prevailing method for food preservation due to its high availability, low cost, and effectiveness.

The consumer is increasingly demanding for nutritious, fresh-like food products, with high organoleptic quality and extended shelf life. Therefore, many efforts have been taken to optimize pasteurization conditions, in order to achieve bacterial inactivation and reduce the loss of nutrients. Additionally, novel technologies have emerged for food processing, in an attempt to complement or even replace conventional thermal pasteurization. These novel pasteurization methods include high pressure processing (HPP), high-voltage pulsed electric field (PEF), ohmic heating (OH), microwave (MW) and radio-frequency (RF) heating, ultraviolet (UV) exposure, irradiation, and membrane filtration.

Nowadays, the most well-established nonthermal processing technique is HPP, which uses pressures of 100–1000 MPa, at room temperature or below. As pressure has a limited effect on covalent bonds of low-molecular-mass compounds (e.g., color and flavor compounds), HPP allows a high retention of food quality attributes, namely, sensorial and nutritional properties. Therefore, food products treated with HPP usually have fresh-like characteristics, without added preservatives. However, HPP also has several disadvantages, such as the resistance of food enzymes, leading to possible enzymatic and oxidative degradation of food components during storage and distribution.

PEF is another well-established nonthermal processing technique that applies high-voltage electric fields for a short duration of time. This treatment results in the inactivation of enzymes and destruction of spoilage and pathogenic microorganisms, due to electroporation of cell membranes. Since PEF processing only causes a small increase in temperature, there is no appreciable loss of flavor, color, and bioactive compounds.

OH is defined as a process where electric currents are applied directly to the food. Heat is internally generated due to electrical resistance of the food to the current. The advantage is that much shorter heating times can be applied, and the food will maintain its nutritional and sensory characteristics.

Concerning MW and RF heating, electromagnetic waves of certain frequencies are used to generate heat within food products, resulting in a high and homogeneous heating rate and subsequently a shorter processing time. This advantage often yields an increased processing rate and/or an improved product quality. Comparing MW with RF heating, RF has a longer wavelength, and thus, RF power will penetrate deeper into products than MW.

UV exposure for food preservation is due to the absorption of short-wave UV light by microorganisms, inhibiting cell replication processes. When compared with thermal processing, UV presents several advantages, such as improved destruction of spores that are not susceptible to heat. But it also has limitations, including a very short penetration capacity and possible generation of free radicals by organic photochemical reactions. These reactions can adversely affect food, due to damage of vitamins and proteins, destruction of antioxidants, lipid oxidation, color change, and formation of off-flavors.

Irradiation is another method used for the preservation of food products, which allows microbial inactivation at an ambient temperature, avoiding the deteriorative effects of heat on flavor, color, and nutrient value of foods. However, it is often associated with the development of off-flavors, softening and increasing permeability of some fresh fruits and vegetables, since irradiation can affect all the major components of food, that is, carbohydrates, proteins, and lipids.

Membrane filtration is a preservation method mostly used for juice processing. The advantages associated with this treatment include the extension of shelf life of food with energy savings and reduced waste generation. However, it has high operational and maintenance costs, due to the need of membrane cleaning and replacement.

The aim of this article is to review the effect of conventional and nonconventional pasteurization techniques, specifically on nutritional and sensorial properties of several food products. For that purpose, information is organized into different food categories, which include fruits and vegetables, dairy products, eggs, meat and seafood products, and alcoholic beverages.

Fruits and Vegetables

Many fruits and vegetables are low-acid foods with very short shelf lives. However, their processing and subsequent storage may represent significant quality losses in terms of sensorial, nutritional, and functional properties. For instance, thermal pasteurization applied to carrots resulted in significant hardness decrease compared with raw carrots, leading to a final product that would certainly be rejected by the consumer. Therefore, application of nonthermal processing technologies on fruits and vegetables has been investigated, especially HPP and gamma irradiation. Table 1 shows the effects of thermal and nonthermal pasteurization treatments on sensorial and nutritional attributes of fruits and vegetables.

In most cases, gamma irradiation caused no changes in the organoleptic properties of vegetables and fruits. However, the effects of irradiation on these attributes depended on the applied dose. For instance, carrots irradiated at 1 kGy had no

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00524-9

Table 1 Nutritional and sensory effects caused by different pasteurization treatments in fruits and vegetables

Food products	*Pasteurization treatments*	*Nutritional and sensory effects*
Carrot	Thermal (70, 90, or 117 °C)	β-carotene bioaccessibility increased after intense thermal treatment (sterilization), but not with pasteurization
		Hardness was negatively affected by temperature
	Gamma irradiation (1 or 2 kGy)	No significant differences in ascorbic acid content and total carotenoids between irradiated and nontreated samples
		Irradiated and nontreated carrots were not differentiated by sensorial analysis
	Gamma irradiation (<2.0 kGy)	No significant effect on color, lightness, flavor, sweetness, odor, and taste
		During storage, overall acceptability of irradiated carrots similar to nontreated samples
	Gamma irradiation (2.0 kGy)	No effect on textural properties
		Slight increase in the sweetness
	Gamma irradiation (3.0 kGy)	Appearance scores were lower for irradiated samples than for nontreated ones
Cabbage	Gamma irradiation (0.5–3.0 kGy)	Appearance of irradiated cabbage was not significantly affected
Onion bulbs	Gamma irradiation (0.05–0.5 kGy)	No appreciable effects on the total free sugar content (sucrose, glucose, and fructose)
	Gamma irradiation (0.1–0.5 kGy)	Drastic reduction in ascorbic acid content
Garlic bulbs	Gamma irradiation (0.1 kGy)	No influence on the total sulfur and thiosulfonate content
Potato	Gamma irradiation (0.1 kGy)	Increase in sucrose content
		Ascorbic acid levels decreased during the initial period of storage
		Decrease in carotenoid content
		Aspartic acid, asparagine, threonine, serine, alanine, isoleucine, leucine, lysine, and arginine showed increases 24 h after irradiation, while glutamic acid, proline, methionine, and phenylalanine decreased
		Lysine content showed a sixfold increase after 1 week of storage, and at 1 month, the concentration was still three times higher than the control values
Sliced tomato	Gamma irradiation (1 kGy)	No significant effect on total carotenoid and ascorbic acid content
		40% decrease in α-tocopherol
Broccoli and mung bean sprouts	Gamma irradiation (1 kGy)	Appearance, color, texture, taste and overall acceptability did not undergo significant changes after 7 days of storage
Okra, baby corn, chaom, bird pepper, goat pepper, eggplant (brinjal), bitter cucumber, asparagus, and basil	Gamma irradiation (0.3, 0.6, or 0.9 kGy)	Organoleptically acceptable after 7 days of storage
Cucumber	Gamma irradiation (2 kGy)	No change in the organoleptic properties
Picked asparagus	Microwave (88 °C, 9 or 15 min) and thermal processing (88 °C, 30 min)	The required temperature for pasteurization was achieved twice as fast as conventional heating
		Microwave pasteurization reduced thermal degradation of asparagus
Leek, cauliflower, and green beans	HPP (200 MPa, room temperature, 5 min)	Increased proportion of folates in the monoglutamate forms, that is, higher folate bioaccessibility
Green beans	HPP (500 MPa, ambient temperature, 1 min)	Large retention of firmness and ascorbic acid content after treatment
		More intense green color after HPP treatment
		Green color of the HPP-treated vegetables turned into pale yellow
Apple, pear, orange, pineapple, carrot, celery, green pepper, and red pepper	HPP (100–400 MPa, room temperature, 5–60 min)	Rapid firmness loss during compression
		During the pressure holding period, the firmness either decreased further or recovered gradually
		At 100 MPa, pear was the most pressure-sensitive fruit, while at 200 MPa, apple was the most pressure-sensitive
Strawberry	HPP (200–800 MPa)	There is not an HPP treatment for the simultaneous retention of all flavor volatiles
		Acid retention was more effective at 400 MPa
		Alcohol retention was more effective at 800 MPa
		The most effective range of pressure for ketone retention was 200–800 MPa

(*Continued*)

Table 1 (Continued)

Food products	*Pasteurization treatments*	*Nutritional and sensory effects*
Raspberry	Gamma irradiation (0.5, 1, or 1.5 kGy, 60 °C)	Phenolic content increased after irradiation and decreased during storage Decrease in firmness No effect on most of the physicochemical and sensorial properties
Papaya	Gamma irradiation (0.5 kGy)	Irradiation caused a 2-day delay of ripening time Irradiated fruits ripened normally in terms of sugar content, color change, firmness, and general appearance
Grapefruit	Gamma irradiation (0.07, 0.2, 0.4, or 0.7 kGy)	Soluble solid and ascorbic acid contents of early-season fruit were not affected by irradiation Irradiation $\geq$0.2 kGy caused a reduction in soluble solid and ascorbic acid contents of late-season fruit Sensory qualities (such as appearance and flavor) of early-season grapefruit exposed to irradiation ($\leq$0.4 kGy) were similar to the control
	Gamma irradiation (0.3 kGy)	No considerable changes of the content of total soluble solids Decline in acid content Enhanced or maintained flavonoid content
Pineapple	Gamma irradiation (0.05, 0.1 or 0.15 kGy)	Maintained their texture better than the controls through storage
Apple	Gamma irradiation (1.5, 4.5, 5 or 6 kGy)	Higher doses of irradiation caused a decrease in ascorbic acid content
	Gamma irradiation (0.5–3.0 kGy)	Hardness of apples decreased during increasing irradiation dose and during storage
	Gamma irradiation (0.15–0.90 kGy)	Irradiation doses 0.30–0.90 kGy reduced apple firmness Doses of $<$0.30 kGy had no effect on apple firmness External color of apples was not affected
Melon	Gamma irradiation (2.5 kGy)	The sensory qualities were maintained within acceptable limits
Mango	Gamma irradiation (0.4 or 0.6 kGy)	Effect of irradiation on hardness was dependent on mango variety Gamma irradiation had no effect on skin or flesh color
Pears	Gamma irradiation (0.30–0.90 kGy)	Firmness loss due to irradiation was dose-dependent
Citrus	Gamma irradiation (0.15, 0.3, or 0.45 kGy)	Irradiation caused softening of some cultivars, while others remained unaffected The appearance of all cultivars was negatively affected with the 0.45 kGy dose, due to loss of glossiness
Papayas, rambutans, and oranges	Gamma irradiation (0.75 kGy)	Aroma and flavor tended to be more intense in the irradiated fruit Firmness decreased as a result of irradiation and storage
Pineapple and watermelon in cubes	Gamma irradiation (1 or 2.5 kGy)	Pineapple sourness was not affected Watermelon sweetness was not affected

changes in sensorial properties, while at 2 kGy, a slight increase in sweetness was observed, and at 3 kGy, a clear negative impact on carrot appearance was detected. The effect on apple firmness was also dose-dependent, since at lower doses (0.15–0.30 kGy), it did not change, while at higher doses (0.30–0.90 kGy), it was significantly reduced. This decrease in firmness was also observed for raspberries, pears, papayas, rambutans, and some cultivars of citrus fruits. Changes in flavor were observed for papayas, rambutans, and oranges, in which more intense flavor and aroma were developed after irradiation treatment (0.75 kGy). Regarding irradiation effects on fruit appearance, citrus fruits had loss of glossiness after treatments at 0.15, 0.3, or 0.45 kGy. In what concerns to nutritional properties, some changes have been identified in irradiated fruits and vegetables: (1) reduction of ascorbic acid content in onions, potatoes, apples, and late-season grapefruits; (2) increase in sucrose content, changes in amino acid contents, and decrease in carotenoid content in potatoes; (3) decrease in α-tocopherol content in sliced tomatoes; (4) increase in phenolic content in raspberries; (5) increase in flavonoid content and decline in acid content in grapefruits. However, several other studies report no nutritional changes in irradiated fruits and vegetables.

During HPP of fruits and vegetables, different pressure and temperature combinations can be used to achieve desired effects on texture, color, and flavor. The quality of HPP fruits and vegetables can, however, change during storage due to coexisting chemical and biochemical reactions, when endogenous enzymes or microorganisms are incompletely inactivated.

The effect of HPP (100–400 MPa, room temperature, 5–60 min) on firmness was evaluated on a great variety of fruits and vegetables (Table 1). A firmness loss was observed during compression, and, in some cases, firmness was recovered gradually during pressure holding time. Pectin methylesterase activity was suggested to be the major reason for the

increase in firmness. Upon HPP treatment, pectin methylesterase was liberated and contacted with the substrate, leading to demethylation. The de-esterified pectin was capable of forming a gel network with divalent ions resulting in increased hardness. However, this effect was more prominent in samples treated at 100 or 200 MPa, since pressures above 200 MPa caused the softening of most fruits and vegetables tested. HPP was also applied on green beans, showing no effect on firmness and ascorbic acid content. However, a more intense green color was acquired, which represents a positive feature for consumer acceptability. This green color turned into pale yellow during storage, showing that storage conditions of HPP products must be optimized to avoid the undesirable modifications that can occur. Application of HPP (200–800 MPa) on strawberry was not suitable for simultaneous retention of all important flavor volatiles: (1) Acids (such as butanoic acid, 2-methylbutanoic acid, and hexanoic acid) were better retained at 400 MPa; (2) alcohol retention was better at 800 MPa; (3) ketone retention was more effective at pressure ranges from 200 to 800 MPa. Therefore, the choice of HPP conditions should have in consideration which type of flavor volatiles are important to retain.

In terms of nutritional properties, HPP can be used to increase folate bioaccessibility in vegetables, since the pressure increased the proportion of monoglutamate folate (form with higher bioaccessibility) in leeks, cauliflower, and green beans. However, the resulting monoglutamate forms after treatment were degraded during storage at low temperatures; thus, it would be important to identify proper storage conditions to minimize this problem.

Few studies focus on MW pasteurization of fruits or vegetables. This approach has already been tested on picked asparagus, and the required temperature (88 °C) for MW pasteurization was achieved twice as fast as (15 min for 1 kW and 9 min for 2 kW) conventional heating (30 min). In addition, the thermal degradation of asparagus was more intense in samples subjected to conventional treatment than in MW-treated samples, showing that this technology has some potential for application in vegetables.

While not much information is available on the pasteurization of vegetable and fruit products, the application of thermal and nonthermal technologies for processing of purees and juices is extensively studied, as discussed in the next sections.

Purees

Table 2 shows the impact of different pasteurization treatments (conventional thermal processing, OH, MW, and HPP) on nutritional and sensorial properties of fruit/vegetable purees. Thermal pasteurization usually causes loss of several important nutritional properties, such as β-carotene, chlorophyll, and phenolic content. Deteriorative effects on organoleptic characteristics were also observed, more specifically in terms of color, viscosity, and flavor.

Spinach puree pasteurization by OH (10–40 $V\,cm^{-1}$) and thermal processing (60, 70, 80, or 90 °C, ≈2 min) was tested, and a more intense browning was observed in samples treated with OH processing. However, these samples showed higher retention of color and β-carotene and chlorophyll content. This increase could be caused by the possible enhancing effect of OH on β-carotene biosynthesis and the formation of chlorophyll derivatives. Therefore, OH could be applied on vegetable purees, resulting in high retention of some important attributes.

Few studies are available focusing on the MW pasteurization of fruit and vegetable purees. When intense MW treatments (in the range of 200–1000 W, 60–340 s) were applied on kiwi fruits, changes in consistency and viscosity were observed, as well as an atypical flavor and color. Regarding nutritional composition, MW (652 W, 35 s) applied on apple puree did not cause modification of total polyphenols and ascorbic acid during the treatment, but these parameters decreased during storage. In contrast, titratable acidity and viscosity were modified by the treatment, but not during storage. Samples also suffered oxidation during storage, since the treatment was not able to inactivate browning-related enzymes.

HPP has also been tested on fruit purees, usually allowing a higher retention of total antioxidant capacity, carotenoids, and polyphenolic content, when compared with thermally treated purees. HPP-treated samples also showed minor changes in color, viscosity, and aroma. However, some studies report modification of aromatic volatile profiles (≈800 MPa), possibly because of the generation of undesirable flavors.

Several studies were performed on HPP for tomato puree pasteurization. At 400 MPa, lycopene, β-carotene, and total carotenoid content were increased, while total antioxidant capacity was decreased. However, longer holding times led to different results: HHP treatments of 300/600 MPa for 60 min showed no effect in lycopene and β-carotene content, while total antioxidant capacity decreased after the first week of storage but, during the next 2 weeks, it was better preserved than in nontreated samples. The effects of HPP on important nutritional properties are also highly dependent on the pressure intensity: (1) Lycopene content increased (58%) at 500 MPa, while it remained stable at 700 MPa; (2) carotenoid content increased with a treatment of 600 MPa for 15 min, but it significantly decreased at 400 and 500 MPa, compared with thermal pasteurization. In all cases, HPP caused a less significant loss of ascorbic acid than thermal treatment. In terms of sensory properties, HPP (300, 500, or 700 MPa, 2 min) improved color and viscosity compared with thermal processing (75 °C, 4 min). This viscosity improvement was attributed to heat or enzymatic degradation of pectins.

Thermal pasteurization of strawberry purees increased viscosity, particularly when intense treatments were applied, being the taste quality usually superior in fresh puree, due to a greater aromatic intensity. The application of HPP on strawberry puree showed several advantages compared with thermal processing, including minor differences in color, low losses of ascorbic acid, no changes in anthocyanins, and high retention of phenolic compounds through storage. However, HPP caused modifications on volatile profiles, affecting the flavor of strawberry purees. For example, HPP at 400 MPa more than doubled the hexanal content (characteristic smell of foliage and grass), while HPP at 800 MPa resulted in a slight decrease in hexanal content. Additionally, at 800 MPa, the volatile compounds contributing to fresh strawberry flavor (nerolidol, furaneol, linalool, and some ester compounds) were decreased, but the most important flavor compounds (e.g., 2,5-dimethyl-4-hydroxy-2*H*-furan-3-one) were not affected.

Table 2 Nutritional and sensory effects caused by different pasteurization treatments in fruit and vegetable purees

Food products	*Pasteurization treatments*	*Nutritional and sensory effects*
Carrot puree	HPP (400–600 MPa, 10–30 °C, 15 min) and thermal (70 °C, 2 min)	Increase in total carotenoids and total antioxidant capacity compared with thermally treated and untreated samples
Spinach puree	Ohmic heating (10–40 V cm^{-1}) and thermal (60, 70, 80, or 90 °C, ≈2 min)	Ohmic heating caused more browning than conventional heating Ohmic heating allowed higher retention of color attributes, β-carotene, and chlorophyll content
Pumpkin puree	HPP (400 or 600 MPa, 5 min) and thermal (85 °C, 15 min)	No color changes at 400 MPa HPP caused lower color modifications compared with thermal treatment Higher carotenoid and polyphenol contents in HPP
Avocado puree	HPP (600 MPa, 23 °C, 3 min)	Decrease in pH No significant color modifications Increases in the activity of polyphenol oxidase and lipoxygenase may cause generation of undesirable flavors and nutritional losses
Tomato puree	HPP (300, 500, or 700 MPa, 20 °C, 2 min) and thermal (75 °C, 4 min)	Pressure-treated samples had improved color and viscosity compared with thermally treated ones Lycopene content increased at 500 MPa, but it remained unaffected at 700 MPa
	HPP (400 MPa, 25 °C, 15 min)	pH, °Brix, and viscosity were increased Ascorbic acid losses of ≈29% were found Lycopene, β-carotene, and total carotenoid contents were increased A significant decrease in total antioxidant capacity was obtained
	HPP (400–600 MPa, 10–30 °C, 15 min) and thermal (70 °C/2 min)	Lower decrease in ascorbic acid in HPP-treated tomato puree compared with thermally processed samples Significant increase in total carotenoids at 600 MPa, while a significant decrease was observed at 400 and 500 MPa
	HPP (300 or 600 MPa, 20 °C, 10–60 min)	No effect in the total concentrations of the main water-insoluble antioxidants, lycopene, and β-carotene Enhanced water binding Total antioxidant capacity decreased after the first week of storage, but it was better preserved during the next 2 weeks, compared with untreated samples
Guava puree	HPP (400–600 MPa, room temperature, 10–15 min)	Decrease in pectin content and turbidity at 400 MPa No significant changes in aroma Untreated and HPP-treated (400 MPa) samples had a decline in ascorbic acid content Ascorbic acid content remained stable in thermally treated samples and samples at 600 MPa
Nectarine puree	HPP (450 or 600 MPa, 10 °C, 5–10 min) and thermal (85 °C, 5 min)	pH, titratable acidity, and °Brix were not affected by HPP Thermal processing caused higher color changes than HPP Increase in zeaxanthin and lutein at 450 MPa, compared with other treatments HPP increased the total phenolic content and total antioxidant activity during storage
Strawberry puree	Thermal (75 or 90 °C, 15 s or 20 s)	Viscosity was increased as a consequence of more severe thermal pasteurizations Taste quality was superior in untreated puree, without significant differences among the thermally treated samples Thermally treated samples maintained their sensory quality during 2 months of storage at 3 °C
	HPP (400–600 MPa, 10–30 °C, 15 min) and thermal (70 °C, 2 min)	Color differences were minor for HPP-treated purees than in thermally treated ones HPP caused ascorbic acid losses of 5–9% No changes in anthocyanins (cyanidin-3-glycoside and pelargonidin-3-glucoside) Total antioxidant activity decreased after HPP
	HPP (400 MPa, ambient temperature, 20 min)	Hexanal content of strawberry puree more than doubled after HPP
	HPP (200, 500, or 800 MPa, ambient temperature, 20 min)	No significant changes in all the aromatic volatile compounds at 200 and 500 MPa Synthesis of new aromatic compounds responsible of the aroma at 800 MPa Slight decrease in the hexanal content at 800 MPa
	HPP (200, 400, 600, or 800 MPa, 18–22 °C, 15 min)	Ester compounds not detected in HPP samples
	HPP (600 MPa, 20 °C, 5 min) and thermal (88 °C, 2 min)	No significant difference between HPP and thermal pasteurization in terms of phenolic compounds after processing

Table 2 (Continued)

Food products	*Pasteurization treatments*	*Nutritional and sensory effects*
		Thermal pasteurization resulted in higher retention of phenolic compounds during storage
	HPP (800 MPa, 20 °C, 20 min)	HPP modified the flavor profile of strawberry puree Volatile compounds contributing to fresh strawberry flavor (nerolidol, furaneol, linalool, and some ester compounds) were decreased at 800 MPa HPP did not affect one of the most important flavor compounds in fresh strawberry (2,5-dimethyl-4-hydroxy-2*H*-furan-3-one)
Strawberry jam	HPP (400–600 MPa, room temperature, 10–30 min)	No changes in ascorbic acid content
Blackberry puree	HPP (400–600 MPa, 10–30 °C, 15 min) and thermal (70 °C, 2 min)	Color differences were minor for HPP-treated purees than in thermally treated ones No changes in anthocyanins (cyanidin-3-glycoside and pelargonidin-3-glucoside) Increase in total antioxidant content
Raspberry puree	HPP (200–800 MPa, 18–22 °C, 15 min)	No significant changes in anthocyanins (cyanidin-3-glucoside and cyanidin-3-sophoroside) Highest stability of the anthocyanins at samples treated at 200 and 800 MPa and stored at 4 °C
Raspberry, strawberry, and black currant purees	HPP (600 MPa, 5 min) and thermal (80 °C, 5 min)	Both physical treatments affected the volatiles of the berry fruits Thermal treatment had a more significant effect on volatile compounds than HPP
Persimmon fruit puree	HPP (50–400 MPa, 25 °C, 15 min)	Carotenoid content was increased, mainly due to an increase in β-carotene and β-cryptoxanthin Total antioxidant capacity was increased
Kiwi puree	HPP (400–600 MPa, room temperature, 10–30 min)	No changes in ascorbic acid
	Microwave (200–1000 W, 60–340 s)	Intense treatments (high power, long treatment periods, and a combination of these factors) affect the consistency, viscosity, color, and taste of the product
Mango puree	HPP (100–400 MPa, 20 °C, 15 or 30 min)	Viscosity of mango pulp increased at 100 and 200 MPa Reduction in viscosity was observed at 300 and 400 MPa
Apple puree	HPP (400 or 600 MPa, 20 °C, 5 min) and thermal (75 °C, 10 min)	Ascorbic acid was unaffected by thermal pasteurization and by HPP at 400 MPa Total phenolic content was stable at 400 MPa but was affected by HPP at 600 MPa and by pasteurization treatment HPP raised viscosity HPP caused discoloration during storage
	Microwave (652 W, 35 s)	Total polyphenols were not modified by the microwave treatment and suffered only a small decrease during storage Vitamin C remained unchanged by the treatment, but it was degraded during storage Titratable acidity and viscosity were modified by the treatment, but not during storage

The effects of HPP (600 MPa, 5 min) and heat pasteurization (80 °C, 5 min) on volatile compositions of raspberry, strawberry, and blackcurrant purees were measured by an 'electronic nose.' Both treatments affected the berry volatiles, but heat treatment had a more significant effect on volatile composition than HPP. Therefore, HPP treatment can pasteurize berry products while retaining their volatile profiles.

Juices

Most studies concerning the pasteurization of fruit/vegetable products were performed in juices. Thermal pasteurization is traditionally used for juice preservation, but it can cause detrimental effects on important attributes. The most frequent effects reported in literature were losses of bioactive compounds (vitamins, carotenoids, and phenolic compounds) and diminished sensory acceptance, due to changes in flavor profile (production of off-flavors and degradation of flavor compounds) and in color (nonenzymatic browning and loss of pigments). As other food products, the application of nonconventional pasteurization methods could bring significant improvement to processed fruit/vegetable juices (Table 3).

Several pasteurization methods were tested on apple juice. Ultrafiltration allowed the removal of microorganisms without compromising the physicochemical and sensorial properties, and thus, it can be suitable for apple juice processing. HPP in the range of 200–600 MPa showed no significant changes in total antioxidant activity, but a treatment of 400 MPa caused an increase in phenolic acids, particularly hydroxycinnamic

Table 3 Nutritional and sensory effects caused by different pasteurization treatments in fruit and vegetable juices

Food products	*Pasteurization treatments*	*Nutritional and sensory effects*
Apple juice	Ultrafiltration (2.5 nm pore size)	Juice retained total soluble solid, pH, and acid contents
	Ultrafiltration (4 nm pore size)	Color and flavor remained stable
	HPP (600 MPa, 60 °C, 30 min)	No changes in total antioxidant activity immediately after HPP and during storage
	HPP (200–600 MPa, 15–65 °C, 0.5–10.5 min)	Phenolic acids increased significantly after 10 min at 400 MPa
	PEF (50 kV cm^{-1})	No significant sensorial differences between PEF-treated and untreated juices
	PEF (35 kV cm^{-1}) and thermal (90 °C for 30 s)	PEF retained better most of the compounds responsible for the color and flavor of apple juice
		Phenolic compounds were better retained by PEF than by thermal treatment
	UV (30 W, 30 min) and thermal (72 or 94 °C, 26 s)	UV-treated samples had a 29% reduction in total phenolic content, which was much lower than that of thermal processing (48%)
		Juice color was less affected by UV than by thermal treatment
	UV (400 W, 120 min)	No variations were observed in pH, soluble solid content, formol index, total phenolics, and sugars after UV treatment
		Color of the juice from King David apples was unchanged by UV
		UV-treated juice from Golden, Starking, and Fuji apples showed changes in color
		The content of ascorbic acid in juices from Golden, Starking, and Fuji apples slightly changed, but juice from King David apples showed significant losses
Pineapple juice	HPP (600 MPa, 40–75 °C, 40 min)	At constant pressure, increasing temperature enhanced ascorbic acid degradation, for example, loss of 20–25% at 40 °C, 45–50% at 60 °C, and 60–70% at 75 °C
Blueberry juice	HPP (200–600 MPa, 20–42 °C, 5–15 min)	No significant changes in pH, °Brix, and color of HPP-treated juice
		Ascorbic acid losses lower than 8%
		Increase in total phenolic content after treatments at 200 and 400 MPa
		Total antioxidant activity decreased after treatments of 400 and 600 MPa
Watermelon juice	HPP (300–900 MPa, 60 °C, 5–60 min), UV (2421–9685 J l^{-1}, 3–12 min), and thermal (60 °C, 5–60 min)	HPP showed the lowest changes in color, viscosity, browning degree, and lycopene content of watermelon juice compared with the other treatments
Cantaloupe juice	Gamma irradiation (1–5 kGy)	Slight off-odor after treatment at 1 kGy
		Strong off-odor at 2 kGy and above
Pomegranate juice	HPP (400–600 MPa, 25–50 °C, 5–10 min)	Anthocyanin concentration was affected by pressure and temperature level
	PEF (35 or 38 kV cm^{-1}) and thermal (88 °C for 30 s)	No significant differences in pH, °Brix, anthocyanin content, and total phenolic content between the PEF-processed and nonprocessed juices
		PEF processing had significantly less impact in color than thermal processing
		PEF-treated juice had the same consumer satisfaction scores as the nonprocessed juice, being significantly better than the thermally processed samples
	Gamma irradiation (0–10 kGy)	At higher doses of 3.5–10 kGy, a decrease in the total content of anthocyanins was observed
Strawberry juice	PEF (35 kV cm^{-1}) and thermal (90 °C, 30 or 60)	Increase in ellagic acid content in PEF-treated juice during storage
		Less phenolic degradation by PEF (49%) than by thermal pasteurization (55%) after storage
Guava juice	HPP (600 MPa, 25 °C, 15 min) and thermal (95 °C, 5 min)	HHP maintained the original flavor distribution of the juice after treatment
		Heat processing caused a decrease in most of the flavor components
		HPP-treated samples showed differences in the concentrations of methanol, ethanol, ester, and aldehyde compounds during storage, probably due to residual enzyme activity
Mango juice	HPP (400 MPa, room temperature, 10–40 min) and thermal (80 °C, 30 s)	HPP-treated and nontreated samples had similar color values, which were brighter than heated samples
		Vitamin C loss of heated samples (29.1%) was greater than that of HPP samples (2.1–8.3%)
		Small increases in viscosity were observed in HPP samples

Table 3 (Continued)

Food products	*Pasteurization treatments*	*Nutritional and sensory effects*
		Both the HPP and the heated sample had less α-terpinolene and more myristic acid than the nontreated samples
Grape juice	Microfiltration (0.2 μm pore size)	Color and flavor were slightly changed
	HPP (300–900 MPa, 20 °C, 2–10 min)	No significant changes in browning index after HPP
	HPP (400–500 MPa, 2–40 °C, 10 min)	The sensory characteristics of HPP-treated juice remained more stable than untreated juice during storage
	HPP (300–900 MPa, 20 °C, 2–10 min)	HPP at 600 and 900 MPa slowed degradation of nonflavonoid phenolics during storage
Citrus juice	Ultrafiltration (1 nm pore size)	Aroma, color, and natural antioxidant content were preserved
	PEF (28 kV cm^{-1})	pH, °Brix, electric conductivity, viscosity, nonenzymic browning index, and HMF[a] practically did not change, compared with nontreated juices
		Color and volatile flavor remained unchanged for all samples
		No significant change in organic acid content
Mandarin juice	HPP (400 MPa, ambient temperature, 10 min)	HPP had little effect on the volatile flavor components
		Typical off-flavor of heat-treated mandarin juice was not detected in HPP-treated samples
Orange juice	HPP (600 MPa, 20 °C, 1 min) and thermal (85 °C, 25 s)	pH, °Brix, alcohol insoluble acids, ascorbic acid, and β-carotene concentrations were not affected after treatment and subsequent storage
		Color and viscosity were stable after treatment and storage
		The degree of clarification and browning index increased over time
	HPP (500–800 MPa, room temperature, 5 min)	HPP caused no significant differences in antioxidant capacity and ascorbic acid, carotene, and sugar contents
		Odor and flavor of HPP-treated orange juice were occasionally altered, depending on treatment and cultivar
	HPP (500–900 MPa, 60 °C, 10 min)	Turbidity was maintained after HPP for longer times
	HPP (600 MPa, 5 °C, 1 min)	No changes in sensory properties
	HPP (500 MPa, 35 °C, 5 min) and thermal (80 °C, 30 s)	Ascorbic acid degradation rates were lower for HPP juice, compared with thermal-pasteurized juice
		Color was not substantially affected by type of processing
		HPP juice had higher viscosity, and its sensory characteristics were judged superior
	HPP (600 MPa, 40 °C, 4 min) and thermal (80 °C, 60 s)	HPP juices had better retention of ascorbic acid and total antioxidant activity, compared with thermally treated samples
		HPP caused less intense flavor changes than thermal treatment
		Higher viscosity values were determined for HPP juice
	HPP (100–400 MPa, 30–60 °C, 1–5 min)	No changes in ascorbic acid content after HPP, but significant losses were observed during storage
		Total carotenoids increased after HPP and decreased during storage
		Increase in hesperetin concentration after HPP
		Increase in flavanones during storage
	HPP (400 MPa, 40 °C, 1 min)	Naringenin and hesperetin increased 20 and 40%, respectively
		No changes observed in total antioxidant capacity
		Flavanone concentration increased after HPP and decreased during storage
	HPP (400–600 MPa, 20 °C, 15 min)	Ascorbic acid losses lower than 6% after HPP
		First-order degradation kinetics for ascorbic acid and anthocyanin (cyanidin-3-glucoside) during storage
		The cyanidin-3-glucoside concentration was higher in HPP-treated than in untreated juice
	HPP (500–800 MPa, 25–50 °C, 1 min)	No significant changes in ascorbic acid after HPP
		Losses lower than 20% were observed during storage
		Color values remained stable during storage
	HPP (100–800 MPa, 30–100 °C, 0–90 min)	Pressure induced thermal degradation of folic acid
		Total antioxidant capacity decreased as a function of treatment time
	HPP (50–350 MPa, 30–60 °C, 2.5–15 min)	Increase in 20–43% in total carotenoids at 350 MPa
		HPP juice had better preservation in total carotenoids during storage than untreated samples
		Total antioxidant capacity decreased during storage

(*Continued*)

Table 3 (Continued)

Food products	*Pasteurization treatments*	*Nutritional and sensory effects*
		Vitamin A content of orange juice was increased by 38.74% after HPP treatment (400 MPa, 40 °C, 1 min)
	HPP (200–500 MPa, 30 °C, 1 min)	Vitamins B_1, B_2, B_3, and B_6 are stable during HPP
	HPP (600 MPa, 25 °C, 5 min)	Excess of ascorbic acid strongly protected folates against pressure and heat
	UV (298.9 mJ cm^{-2})	UV-treated juice retained folic acid and vitamin E
		Destruction of riboflavin and β-carotene (≈50%) was observed
	UV (0–100 mJ cm^{-2})	Color and pH were not significantly impacted by UV treatment
		Degradation of ascorbic acid was 17% under UV exposure of 100 mJ cm^{-2}
	PEF (40 kV cm^{-1}) and thermal (90 °C, 90 s)	PEF-processed juice retained more ascorbic acid, flavor, and color than thermally processed samples
	PEF (30 kV cm^{-1}) and thermal (90 °C for 3 min)	Some important volatile compounds suffered losses for the PEF treatments but always in less proportion than the heat-pasteurized juice
		PEF-treated juice retained a higher content of ascorbic acid than heat-pasteurized juice during storage
	PEF (30 kV cm^{-1}) and thermal (90 °C, 20 s)	Color variations during storage were greater in heat-pasteurized than in PEF-treated orange juice
		PEF-treated juice had less nonenzymatic browning than the thermal-pasteurized juice
		No significant variations in the HMF[a] content of the juices pasteurized or treated by PEF with respect to the untreated orange juice
	Gamma irradiation (0.89, 2.24, 4.23, and 8.71 gGy)	Irradiation reduced the concentration of acyclic monoterpenes during storage, following a linear decrease pattern with irradiation dose
	Gamma irradiation (0.5, 1.0, 2.0, and 3.0 kGy)	The production of several sulfur compounds was induced by irradiation
		Volatile sulfur compounds were involved in the development of irradiation-induced off-odor
	Ultrasonication (20 kHz, 2–10 min)	Ultrasonication had a minimal effect on color
		The treatment slightly decreased ascorbic acid content
Orange–lemon–carrot juice	HPP (500–800 MPa, room temperature, 5 min)	No significant differences in antioxidant capacity and ascorbic acid, sugar, and carotene contents
		A significantly more intense carrot aroma was reported after 800 MPa
Carrot juice	Ultrafiltration (1 nm pore size)	Aroma, color, and natural antioxidant content were preserved
	HPP (100–800 MPa, 30–100 °C, 0–90 min)	Folate is unstable at pressures higher than 500 MPa
	HPP (600 MPa, 75 °C, 40 min)	Small losses of carotenes after HPP
Carrot juice and kale juice	Gamma irradiation (1, 2, 3, and 5 kGy)	No differences in amino acid composition
		Decrease in ascorbic acid immediately after the treatments
		After 3 days of storage, ascorbic acid content was higher in irradiated samples than in nontreated ones
		Similar sensory scores between irradiated and nontreated samples
Carrot juice and tomato juice	HPP (250 MPa, 35 °C, 15 min) and thermal (80 °C, 1 min or 60 °C, 5–15 min)	HPP did not cause a significant change in ascorbic acid content
		Heat treatments resulted in a significant loss in antioxidant activity compared with HPP-treated and untreated samples
		Color changes were minor for HPP juices, but it was more intense for heat-pasteurized samples as a result of insufficient antioxidant activity
Tomato juice	HPP (500–900 MPa, room temperature, 3–9 min)	Total pectin content and viscosity were dependent on the pressure applied but independent of treatment time
		Generation of a strong rancid taste, possibly due to the production of *n*-hexanal
	HPP (100–500 MPa, 4–50 °C) and thermal (60 °C, 2 min)	Thermal pasteurization caused significant changes in color, viscosity, and antioxidant capacity, compared with untreated juice
		HPP treatments at and below 200 MPa maintained the color, total carotenoids, lycopene content, and antioxidant capacity
		HPP at 500 MPa improved the quality attributes
Vegetable beverage	HPP (100–400 MPa, 20–42 °C, 2–9 min) and thermal (90–98 °C, 15 or 21 s)	HPP retained significantly more ascorbic acid than thermal treatment
		No significant changes in total phenolics between HHP and thermally processed samples
		Less color changes in HPP-treated samples
		Total antioxidant activity decreased with increasing pressure

[a]HMF – hydroxymethylfurfural.

and procyanidin acids. Pasteurization with PEF showed several advantages relative to thermal treatment: better retention of phenolic compounds and most of the compounds responsible for color and flavor. Moreover, no significant sensory differences were detected between PEF-treated and nontreated juices. In what concerns to UV, two different treatments were applied to apple juice: (1) a less intense treatment (30 W, 30 min), which affected the total phenolic content and color, but in a much lower extension than thermally treated samples, and (2) a more intense treatment (400 W, 120 min), which caused no variation in total phenolic content, pH, soluble solid content, formol index, and sugars. The effect of the latter treatment on juice color was highly dependent on apple variety, as observed in Table 3.

Most studies on juice pasteurization were performed using orange juice, one of the most appreciated and consumed worldwide. HPP is extensively reported for orange juice preservation, showing minimal impact on the physicochemical, nutritional, and sensory properties, compared with thermal pasteurization or even with other nonthermal technologies. Despite no changes are usually observed in the sensory properties (color, turbidity, viscosity, odor, and flavor) of HPP juice, viscosity, odor, and flavor may be occasionally altered by HPP. In terms of nutritional properties, alcoholic insoluble acids, β-carotene, and sugar content were unaffected by HPP. On the other hand, carotenoid and flavanone contents were both increased after HPP treatment and decreased during storage. In particular, naringenin and hesperetin (two important flavanones in orange juice) significantly increased after HPP. Vitamin content, which is highly sensible to high temperatures, was unaffected by HPP. For example, vitamins B_1, B_2, B_3, and B_6 were stable after HPP treatments of 200–500 MPa. The effect of HPP on vitamin C (ascorbic acid) was not always in accordance: in most cases, no significant changes were observed, but some studies reported ascorbic acid degradation during HPP treatment and subsequent storage. For instance, after a treatment of 400–600 MPa, ascorbic acid followed a first-order degradation kinetics during storage. Even so, the loss of ascorbic acid was lower in HPP samples compared with thermally treated ones. In what concerns to vitamin A, its content was found to increase under HPP, showing an increment of 38.74% at 400 MPa. A particularly interesting case is the low stability of folic acid (vitamin B_9), since pressure induced its thermal degradation. However, an excess of ascorbic acid in orange juice protected folic acid from degradation. The impact of HPP was also evaluated in terms of other parameters of orange juice, such as degree of clarification, browning index, and antioxidant activity. The first two were found to increase after HPP treatment, while the latter remained stable or it was only slightly affected.

Several studies reported the use of PEF in orange juice, usually leading to good retention of important quality parameters. Comparing with thermally processed samples, PEF-processed juice was able to retain more ascorbic acid, flavor, and color after the treatment and also during storage. PEF pasteurization showed no impact on the juice flavor compounds, decanal and octanal, contrary to the observed for heat treatment. Other compounds, such as ethyl butyrate, suffered losses with PEF treatments but to a lower extent than with thermal pasteurization. Nonenzymatic browning was also lower in PEF-treated juice, compared with thermal-pasteurized ones. However, the hydroxymethylfurfural content (a typical product of non-enzymatic browning) showed no significant variations in thermally treated or PEF-treated juices with respect to untreated ones.

UV light can adversely affect food constituents and sensorial attributes. Few information is available on UV technology for orange juice pasteurization: (1) UV treatment of 73.8 mJ cm^{-2} may extend the shelf life, without significantly affecting the color and pH; (2) UV treatment of 298.9 mJ cm^{-2} was able to preserve folic acid and vitamin E contents while destroying riboflavin and β-carotene; and (3) UV treatment of 100 mJ cm^{-2} caused loss of ascorbic acid (17%), similarly to thermal treatment.

Irradiation of orange juice may induce undesirable chemical changes, leading to negative flavor changes, usually related to the production of volatile sulfur compounds. For instance, irradiation of 0.5–3.0 kGy induced an increase in methyl sulfide, methanethiol, dimethyl disulfide, and dimethyl trisulfide. On the other hand, carbon disulfide was reduced by irradiation, while hydrogen sulfide was not consistently affected. Different levels of irradiation (0.89, 2.24, 4.23, and 8.71 gGy) were shown to reduce acyclic monoterpene concentrations, following a linear decrease pattern with an irradiation dose and correlated with an increase in thiobarbituric acid-reactive substrates. It was suggested that many of the undesirable effects of irradiation could be reduced by using low temperatures, the addition of antioxidants, and a combination with other techniques.

The influence of sonication was already evaluated on the quality attributes of orange juice. Ultrasonic treatments of 20 kHz for 2, 4, 6, 8, and 10 min affected the color minimally and decreased the ascorbic acid content slightly. Therefore, ultrasonication may be used to extend the shelf life of orange juice, but more studies are needed to fully understand its effects on juice quality.

There are several other studies in literature analyzing the impact of pasteurization on different fruit/vegetable juices, being the results often similar to the ones previously analyzed. More detailed information about these studies is shown in Table 3.

Overall, nonconventional methods seem to be more suitable for the pasteurization of fruit and vegetable products relative to thermal processing. But it should be taken into account that different pasteurization treatments have different effects on each product, and therefore, the assessment of the most suitable approach should be performed on a case-by-case basis.

Dairy Products

Milk is remarkably rich in many essential food constituents, such as amino acids, lipids, sugar, vitamins, and minerals, and thus, it is particularly extend to microbial growth and consequent spoilage. Therefore, milk processing is essential to ensure safety and extend shelf life, being thermal treatment the most common pasteurization technique used. The main effects of processing techniques on nutritional and sensorial qualities of milk and dairy products are presented in Table 4.

Until now, bovine milk is the most studied milk type and, because of that, different pasteurization methods were tested, including HPP, PEF, UV, MW, and conventional thermal

Table 4 Effects of pasteurization techniques on the nutritional and sensory properties of milk and other dairy foods

Food products	*Pasteurization treatments*	*Nutritional and sensory effects*
Bovine milk	Thermal (73 °C, 30 s)	Denaturation of whey proteins Degradation of labile vitamins Changes in flavor (due to formation of sulfhydryl groups)
	Thermal (85 °C, 15 min)	Denaturation of whey proteins Alterations of casein micelle size Changes in milk viscosity
	Thermal (65 °C, 10 s or 72 °C, 15 s)	No significant differences in sensorial properties
	HPP (200 MPa, −4 °C, 10–30 min)	Decrease in vitamins C, B_2, and B_3 with increase in treatment time Increase in short-chain FFA[a] content with increase in treatment time No changes in viscosity
	HPP (100–600 MPa, 20–60 °C, 30 min)	Micelle size reduced Phosphate concentration increased Denaturation of whey proteins Gel formation rate and gel strength increased Organoleptic quality maintained or improved
	HPP (100–800 MPa, 20 °C, 0–60 min)	No changes in fat globule size Protein content and % total protein decreased Viscosity increased with pressure and treatment time increase
	HPP (400 MPa, 25 °C, 30 min)	No significant losses of vitamins B_1 and B_6
	HPP (100–400 MPa, 25–60 °C, 10–60 min)	No changes in lactose Increase in phosphate concentration Denaturation of whey proteins
	HPP (482, 586, or 620 MPa, 25 or 60 °C, 1–5 min) and thermal (25, 60, or 80 °C, 1–5 min)	Significant differences on volatile profile: ○ Thermal processing promotes the formation of methanethiol, hydrogen sulfide, methyl ketones, and aldehydes ○ HPP promotes the formation of hydrogen sulfide and aldehydes
	PEF (40 kV cm^{-1})	No detrimental degradation of taste and flavor
	PEF (34.7 kV cm^{-1})	No significant changes in color, viscosity, and density
	PEF (15–35 kV cm^{-1})	No significant changes in vitamins A, B_1, B_2, and E
	PEF (35.5 kV cm^{-1}) and thermal (75 °C, 15 s)	Similar denaturation of whey proteins in both treatments FFA[a] not affected by the treatments
	PEF (35 or 38 kV cm^{-1}) and thermal (63 °C, 30 min; 72 °C, 15 s or 97 °C, 10 min)	Casein micelle and fat globule sizes unaffected Rheological and coagulation properties change less in PEF treatment
	PEF (18.3–27.1 kV cm^{-1}) and thermal (63 °C, 30 min or 75 °C, 15 s)	Vitamins B_1, B_2, D, and E remain constant Vitamin C content decrease (in a greater extent on thermal treatment)
	HPP (400 or 500 MPa, 20 °C, 0–20 min), PEF (36 or 42 kV cm^{-1}) and thermal (63 °C, 30 min or 97 °C, 7 min)	Alterations in fat globule size and distribution: ○ Similar effects of PEF and thermal treatment ○ Fat globule flocculation with HPP
	UV (10.75 mJ cm^{-2}) and thermal (73.5 °C, 15 s)	UV decreased cholesterol content Vitamins B_2 and B_{12} reduction with thermal treatment, but no reduction with UV No significant changes in protein content Differences in sensorial properties, namely, increase in 'tallowy' flavor
	MW (80 or 92 °C, 15 s)	Similar volatile content between MW-treated milk and raw milk No adverse effects on milk flavor, taste, and odor
Ewe milk	HPP (100–500 MPa, 4–50 °C, 10 min)	Alterations in fat globule size and distribution FFA[a] content reduced Lightness (L*) decreased; (−a*) and (+b*) values increased
Goat milk	UV (15.8 mJ cm^{-2})	FFA[a] concentration increased, not enough to detect off-odors Significant differences in sensorial properties Production of volatile compounds (pentanal, hexanal, and heptanal) increased
Cheese made from bovine milk-treated	Thermal (63 °C, 30 min)	Effects on cheese: ○ Changes in texture (less firmer) for thermal milk cheese (due to higher moisture)

Table 4 (Continued)

Food products	*Pasteurization treatments*	*Nutritional and sensory effects*
		○ More intense flavor for raw milk cheese (than thermal milk cheese)
	HPP (345 or 586 MPa, 1–15 min) and thermal (72 °C, 15 s)	Effects on cheese: ○ Defects on HPP milk cheese texture (due to excess moisture) ○ No significant differences in flavor scores
	PEF (35 kV cm^{-1})	Effects on cheese: ○ Hardness and springiness increased in PEF milk cheese ○ No significant changes in cheese adhesiveness and cohesiveness ○ Significant differences in cheese flavor (compared with raw milk cheese)
	PEF (20 or 30 kV cm^{-1}) and thermal (63 °C, 30 min)	Effects on cheese: ○ PEF milk cheese has an intermediate concentration of free amino acids (between raw milk and thermal milk cheeses) ○ PEF milk cheese has a curd firmness value between raw milk and thermal milk cheeses
Cheese made from ewe milk-treated	Thermal (75 °C, 15 s)	Effects on cheese: ○ Lower FFA[a] content in thermal milk cheese ○ Volatile compounds and moisture similar in thermal milk cheese and raw milk cheese ○ Higher values of fracturability, elasticity, and hardness for thermal milk cheese ○ Flavor quality and intensity affected negatively by thermal treatment
Cheese made from goat milk-treated	HPP (500 MPa, 20 °C, 15 min) and thermal (72 °C, 15 s)	Effects on milk: ○ No changes in fat globule size Effects on cheese: ○ Free fatty acid content increased on raw and HPP milk cheeses ○ No significant differences in all sensorial analyses
Yogurt made from bovine milk-treated	HPP (100–600 MPa, 1 h)	Effects on yogurt: ○ Texture (rigidity and resistance to breaking) and syneresis resistance were improved

[a]FFA – free fatty acid.

treatment. Thermal processing influenced important nutritional properties, such as whey proteins and vitamin content, since these compounds are highly thermolabile. Additionally, the thermal treatment of milk caused changes on sensorial attributes (namely, viscosity and flavor), with the changes being more intense at more severe processing conditions. Due to the negative impact of thermal processing on milk quality, several nonthermal techniques have emerged.

Nonthermal techniques also influenced the nutritional properties of bovine milk: (1) denaturation of whey proteins with HPP and PEF processing caused a decrease in micelle size and release of the phosphate ion from the micelle matrix, increasing the free phosphate concentration; (2) FFA (free fatty acid) content increased with HPP and not with PEF processing, possibly as a result of lipolysis; (3) vitamins C, B_2, and B_3 content decreased, and vitamins B_1 and B_6 were not influenced with HPP; (4) vitamin C content decreased, and vitamins A, B_1, B_2, D, and E were not affected by PEF processing. On the other hand, UV processing caused no changes in the vitamin and protein contents of bovine milk. Regarding the sensorial properties of processed bovine milk, HPP, PEF, and MW maintained or even improved its organoleptic and rheological properties (compared with raw milk), while differences were detected with UV processing.

For other milk types, little information is available, being only HPP and UV applied on ewe and goat milk, respectively. In ewe milk, the FFA content decreased after HHP, while in goat milk, the FFA increased after UV processing. The sensorial properties of both milk types differed from raw milk after processing. Therefore, the milk type also influenced the effects of pasteurization on the nutritional and sensorial properties of food products.

The pasteurization of milk may affect not only its own nutritional and sensorial properties but also the characteristics of dairy products made from treated milk. The studies evaluating the effect of milk pasteurization for the production of dairy products (such as cheese and yogurt) are detailed in Table 4.

Egg Products

Egg products are an important source of amino acids, vitamins, and minerals. However, they are responsible for a large number of food illnesses, with *Salmonella* being responsible in most cases. In order to guarantee egg safety, conventional thermal

Table 5 Effects of pasteurization techniques on the nutritional and sensory properties of egg products

Food products	*Pasteurization treatments*	*Nutritional and sensory effects*
Liquid whole egg	Thermal (56.6–61.1 °C, 3.5 min)	Increase in viscosity Decrease in protein content
	HPP (100–400 MPa, 5 or 25 °C, 10 min)	No protein coagulation at 100–150 MPa Protein coagulation at pressures higher than 250 MPa
	HPP (100–400 MPa, 1–120 min, 20 °C) and thermal (60 °C, 2.5 or 3.5 min)	HPP affects physical properties Viscosity increases with increasing pressure and treatment time: ○ Noticeable increase at 350–400 MPa with formation of macroscopic coagulates ○ Viscosity increase with HPP is lower than with thermal treatment
	PEF (37 kV cm^{-1}) and thermal (66 °C, 4.5 min)	Protein content and conformation less affected with PEF treatment Decrease in foaming capacity in both treatments Increase in viscosity with thermal treatment Color was not affected by PEF but turns opaque with thermal appearance
	UV (4.2 J cm^{-2})	No significant changes in rheological properties No protein denaturation and aggregation
Shell eggs	Thermal (56 °C, 32 min)	Detrimental effects on quality Changes in protein structure and composition Increase in albumen opacity
Whole egg	HPP (50–600 MPa, 30 min, 25 °C)	Effect on egg yolk: ○ Gel formation ○ Retention of color ○ Increase in softness and adhesiveness Effect on egg white: ○ Irreversible denaturation of proteins Effect on whole egg: ○ Appearance of cooked eggs ○ No presence of cooked flavor ○ No formation of unusual amino acids ○ No destruction of vitamins
Egg white	HPP (100–700 MPa, 10–60 °C, 20 min)	Changes more pronounced at 400–700 MPa: ○ Increase in turbidity ○ Decrease in protein content
Egg yolk	HPP (100–500 MPa, 25 °C, 10 min)	Increase in viscosity Decrease in protein content

treatment may be used, but the range of temperatures applied is limited by the precipitation of soluble proteins (at 57 °C). In order to overcome this limitation, alternative nonthermal technologies are being explored for egg product pasteurization, and their effects on nutritional and sensorial properties are represented in Table 5.

The thermal pasteurization of liquid whole egg and shell egg caused a decrease in protein content, due to denaturation, aggregation, and coagulation, causing deterioration of functional properties, changes in color (which becomes more opaque), and increased viscosity. In fact, viscosity is normally used as an indicator of pasteurization impact: an increment of 20% resulted in undesirable quality changes.

HPP and PEF applied on liquid whole eggs also affected the protein content and physical properties. However, these changes were observed to a lesser extent than thermal treatment. Nevertheless, the most suitable treatment for liquid whole eggs seems to be UV, since the viscosity and protein content were not significantly affected.

HPP was also applied to whole egg pasteurization (without shell), resulting in protein denaturation and consequent viscosity increase in both egg white and yolk. While the yolk color was retained after HPP, the egg white had an increased turbidity. As a result, the HPP whole egg had the appearance of cooked eggs, indicating the possibility of cold cooking with pressure. But, when compared with heat-treated (boiled) eggs, this cooking process is advantageous, since there were no development of sulfur flavor, no formation of unusual amino acids, and no destruction of vitamins. Therefore, HPP can be applied to whole eggs, allowing the retention of the nutritional properties of raw eggs but with the appearance of cooked eggs.

Meat and Seafood Products

Meat and seafood products have a rich nutrient matrix, being a suitable environment for the proliferation of microorganisms. In consequence, adequate pasteurization methods are needed

to extend the shelf life without compromising quality. The specific purpose of these techniques is the elimination or reduction of *Listeria monocytogenes* on meat products and *Clostridium botulinum* and *Vibrio vulnificus* on seafood products.

As most food products, meat and seafood are usually processed by thermal treatment, but heat causes the degradation of vitamins, coagulation and denaturation of muscular proteins, and changes in textural properties. The color of meat depends on the myoglobin form present in the muscle: reduced or deoxymyoglobin (purple-red), oxymyoglobin (red), and metmyoglobin (brown). Thermal processing caused color changes since it favored the metmyoglobin formation due to myoglobin oxidation. For example, in case of meat, there were changes from red to brown/gray and from red to red/pink in noncured and cured products, respectively. In addition, temperatures above 70 °C promoted hydrolysis and oxidation of polyunsaturated fatty acids, increasing free fatty acid contents. Consequently, the formation of different volatile compounds occurred, and thus, there was flavor modification from fresh to cooked and, in some cases, development of rancidity.

Several novel processing technologies have been applied to the preservation of meat and seafood products (Table 6). HPP was widely applied and, in case of meat products, different

Table 6 Effects of pasteurization techniques on nutritional and sensory properties of meat and seafood products

Food products	*Pasteurization treatments*	*Nutritional and sensory effects*
Pork and poultry	HPP (0.1–800 MPa, 5–30 min, 10–50 °C)	Lipid oxidation induced by pressure increasing Color changes: ○ Increase in lightness and decrease in redness No significant changes in aroma profile
Beef and poultry	HPP (0.1–800 MPa, 1–20 min, 10–70 °C)	Lipid oxidation induced by pressure increasing Increase in hardness Color changes: ○ Increase in lightness No significant changes in aroma profile
Beef	HPP (100–500 MPa, 5 or 10 min, 25 °C)	Texture changes: ○ Meat tenderization with pressurization
	HPP (520 MPa, 260 s, 10 °C)	Increase in proteolytic activity Texture changes: ○ Meat tenderization ○ Increase in toughness
	HPP (50–600 MPa, 20–300 s, 10–30 °C)	Color changes: ○ Increase in lightness ○ With pressures up to 350 MPa, redness increases, but with pressures up to 600 MPa, it decreases
Minced beef	HPP (100–500 MPa, 2–30 min, 10 °C)	Color changes: ○ Increase in lightness and decrease in redness
Poultry	Gamma irradiation (0–10 kGy)	Significant decrease in thiamine content Color changes: ○ Increase in redness
Beef and pork	Gamma irradiation (0–10.5 kGy)	Increase in lipid oxidation Denaturation of proteins Production of sulfur-containing volatiles, causing off-odors Color changes: ○ Formation of brown, green, and bright-red colors in fresh meat
Dry-cured ham and loins	HPP (200–800 MPa, 3–15 min, 20 °C)	Decrease in lipid oxidation Decrease in proteolytic activity Flavor changes, turning saltier Color changes: ○ Increase in lightness and decrease in redness after pressurization
Dry-cured ham slices	HPP (600 MPa, 6 min, 15 °C)	No significant changes in oxidation stability and protein content Texture changes: ○ Increase in hardness and chewiness Color changes: ○ Increase in lightness Flavor changes: ○ Increase in odor intensity and saltiness

(*Continued*)

Table 6 (Continued)

Food products	*Pasteurization treatments*	*Nutritional and sensory effects*
Cooked ham	HPP (100–700 MPa, 10 min, 5–40 °C)	No significant changes in physicochemical composition: ○ Protein profile and content ○ Fatty acid composition and cholesterol content ○ B-group vitamin content ○ Mineral composition, only a decrease in calcium and iron content Increase in syneresis No significant changes in texture, color, and sensory evaluation
Cured ham	RF (60 MHz)	Quality improvement compared with hot water processing Decrease in moisture loss
Ham slices	RF (27.12 MHz)	Decrease in moisture loss No significant change in color parameters No changes in sensorial quality
Dry-cured loins and ham slices	Gamma irradiation (0, 5, or 10 kGy)	Increase in lipid oxidation Changes in color parameters: ○ Samples with a redder appearance
Raw sausages	HPP (100 or 300 MPa, 5 or 20 min, 6–8 °C)	Decrease in protein content Texture changes: ○ Decrease in hardness Color changes: ○ Increase in lightness
Cooked sausages	HPP (500 MPa, 5 or 10 min, 65 °C) and thermal (80–85 °C, 40 min)	Texture changes: ○ Increase in cohesiveness and decrease in firmness on HPP sausages No significant changes in color parameters in both cases HPP sausages with better acceptance in sensory analysis, due to better appearance, taste, and texture
Fermented sausages	HPP (400 MPa, 10 min, 17 °C)	Changes in textural properties: ○ Increase in cohesiveness, chewiness, and springiness
Turkey frankfurters	IR (70, 75, or 80 °C)	No significant changes in color Change of color: ○ Surface turns slightly brownish
Surimi	Thermal (90 °C, 30 or 60 min)	Texture softening – loss of firmness Changes in color, turning yellowish No changes in flavor
Anglerfish	HPP (150–200 MPa, 5 min, 0 °C)	Cooked appearance
Bluefish	HPP (100–300 MPa, 5–30 min, ambient)	Decrease in protease activity Decrease in firmness with pressure increase Changes in color (higher L-values and lower a- and b-values)
Carp	HPP (100–500 MPa, 10 min, 20–22 °C)	Decrease in hardening Visual differences: loss of transparency and higher L-value
Cod	HPP (150–200 MPa, 5 min, 0 °C) HPP (100–800 MPa, 5 or 20 min, 0 °C or ambient)	Cooked appearance Decrease in protease activity with pressure increase Decrease in oxidative stability with pressure increase Denaturation of proteins Increase in hardening with pressure increase Cooked appearance
Hake	HPP (200–400 MPa, 15 min, 7 °C)	Cooked appearance
Mackerel	HPP (150–200 MPa, 5 min 0 °C)	Cooked appearance
Octopus	HPP (200–400 MPa, 15 min, 7 or 40 °C)	Decrease in protein content Increase in shear strength
Oysters	HPP (400–800 MPa, 5 min, 0 °C) HPP (100–800 MPa, 10 min, 7 or 20 °C)	Cooked appearance No significant inhibition of lipases Increase in shear strength More voluminous, shucked Increase in L-value
Prawn	HPP (200 MPa, 10 min, 7 °C)	Increase in shear strength Earlier browning Opaque muscle

Table 6 (Continued)

Food products	*Pasteurization treatments*	*Nutritional and sensory effects*
Plaice and pollack	HPP (150–200 MPa, 5 min, 0 °C)	Cooked appearance
Salmon	HPP (150 or 200 MPa, 30 or 60 min, 1–5 °C)	Changes in rancidity Increase in cutting strength Changes of color (increase in L-value and decrease in a-value)
Salmon trout	HPP (150–200 MPa, 5 min, 0 °C)	Cooked appearance
Sardine	HPP (100–400 MPa, 30 min, ambient)	Changes of color (increase in L-value and decrease in b-values and variable b-values)
Sea bass	HPP (100 or 300 MPa, 5 min, 10 °C)	No inhibition of proteases No changes in protein profile
Sea bream	HPP (200–400 MPa, 10 min, 20 °C)	No significant changes in protein Changes in texture; decrease in elasticity
Sheephead	HPP (100–300 MPa, 0–30 min, ambient)	Changes in color (increase in L-value) Cooked appearance
Squid	HPP (150–400 MPa, 15 min, ambient)	Production of biogenic amines delayed Skin reddening and muscle whitening
Tuna	HPP (150–200 MPa, 5 min, 0 °C)	Cooked appearance
Turbot	HPP (100–200 MPa, 15–30 min, 4 °C)	Decrease in protein content No effect on fatty acid content Changes in oxidative stability of lipids Changes in color (increase in L-value) Cooked appearance

effects were observed for different products, such as fresh meat, cured meat, and sausages.

For fresh meat, HPP induced lipid oxidation, with higher effects when higher pressures were applied. Proteolytic activity was also increased, mainly due to the activation of two enzymatic systems: cathepsins and calpains. Since these enzymes are also responsible for meat tenderization, HPP induced changes in texture. HPP also increased hardness and toughness, possibly due to modifications in the structural properties of meat proteins. Regarding sensorial properties, HPP caused no changes in aroma profile, while color was significantly affected. Meat discoloration was a result of myoglobin denaturation and oxidation. Therefore, HPP for fresh meat has disadvantages to final product acceptability, since drastic sensorial modifications were observed relatively to fresh meat.

Different effects were observed after HPP application on cured meat and sausages. For example, the application of HPP on dry-cured ham and loins decreased lipid oxidation and proteolytic activity, changing color, texture, and flavor (turns saltier). On the other hand, both nutritional and sensorial properties of HPP cooked ham were not changed. Therefore, these products were less modified by pressure, which resulted in good sensory acceptance.

Other novel techniques have already been studied for the pasteurization of meat products, such as irradiation, RF heating, and IR. Irradiation had deteriorative effects on meat quality by decreasing the vitamin content, increasing lipid oxidation, denaturing proteins, and changing color and flavor. RF applied to cured meat products reduced the moisture loss and did not change sensorial properties, being therefore advantageous for its pasteurization.

HPP was tested for the preservation of different seafood products, as observed in Table 6. The main effect of HPP was the modification of visual characteristics, due to the development of a cooked appearance. Texture was also affected by pressure: firmness and hardness increased and elasticity decreased, which are usually caused by the denaturation of cytoskeletal proteins. In addition, HPP affected the oxidative stability of lipids, with increasing pressure inducing oxidative reactions, possibly because of the presence of metal ions that promote lipid autoxidation.

Since HPP effects are different according to the food matrix, different seafood products show different pressure sensibilities. For example, the application of HPP to sea bass and sea bream caused no change in protein profile and proteolytic activity. Another example is HPP application to raw oysters, which caused denaturation of the adductor muscle, inducing the shell to open spontaneously. Thus, oysters were shucked with HPP, reducing the need of manual shucking and increasing the amount of meat removed from the shell. In addition, this treatment extended the shelf life of oysters while retaining its sensory characteristics. For all these reasons, the application of HPP to oysters is increasingly utilized.

As a conclusion remark, for fresh meat and seafood, even the novel processing techniques may cause drastic changes in visual properties, which may affect the overall consumer acceptability. However, for cured meat, these novel techniques seem to be a good method for its processing since nutritional and sensorial properties are mostly retained.

Alcoholic Beverages

Thermal pasteurization is usually applied to ensure the microbiological safety of beer. However, such as observed for other food products, thermal treatments cause the development of off-flavors and degradation of important quality parameters. Despite the influence of thermal pasteurization (70 °C,

30 min) on beer volatile profile, differences between pasteurized and nonpasteurized samples were attenuated during storage. Naturally, the negative impact of thermal pasteurization was more pronounced at higher temperatures: beer treated at 60 °C had more intense flavor and higher aldehyde content, compared with higher temperatures (72 and 84 °C). However, beer treated at 60 °C showed lower flavor stability through storage compared with samples treated at higher temperatures, possibly because heat improved the oxidative stability of beer.

Several studies have tested the application of HPP on beer (Table 7), in order to minimize the negative effects of processing on aroma and flavor. HPP effects on beer are highly dependent on several factors (such as beer type, pressure level applied, and holding time), but the main attributes of beer (ethanol content, density, extract, fermentation degree, and pH) were not affected by pressure. In most cases, color, foam durability, bitterness, and flavor were also stable during HPP treatment, but some studies reported changes in these parameters. Comparing HPP with thermal processing, several differences were observed in terms of their impact on beer quality. Heat treatment significantly changed color and permanent haze relative to nontreated and HPP-treated samples.

A study performed with PEF (22 kV cm^{-1}) on beer pasteurization showed a significant increase in the amount of several metallic ions, which caused a significant degradation of flavor and mouthfeel. Therefore, PEF pasteurization, as well as conventional thermal processing, showed a negative impact on the nutritional composition and organoleptic properties of beer. In consequence, HPP seems to be a more suitable technology for beer pasteurization, since it allows the development of a microbiologically stable product with sensorial properties similar to nontreated beer.

The development of spoilage microorganisms in must and wine causes great economic losses in the wine industry. Unlike beer, wine is not treated with heat, due to its temperature sensitivity, except in the case of lower quality wines. Therefore,

Table 7 Nutritional and sensory effects caused by different pasteurization treatments in beer, red wine, and white wine

Food products	*Pasteurization treatments*	*Nutritional and sensory effects*
Beer	Thermal (70 °C for 30 min)	Pasteurization influenced beer volatile profile after processing During storage, the differences between the volatile profiles of pasteurized and nonpasteurized beers disappeared Pasteurization had a positive influence on beer oxidative stability
	Thermal (60, 72, or 84 °C)	Pasteurization at 60 °C led to a more pronounced flavor, higher aldehyde content, and lower flavor stability compared with higher temperatures
	HPP (300, 500, or 700 MPa, 5 min)	No change in color, foam durability, and the spectrum of flavor materials Potential for arising the turbidity decreased at 300 and 500 MPa and increased at 700 MPa Filterability became better (filtration time decreased to 50%)
	HPP (600 MPa, 5 min) and thermal (60 °C, 10 min)	No effect on main chemical constituents of the beer HPP had no significant effect on color contrary to the thermal treatment HPP retained permanent haze throughout storage
	HPP (300, 400, 500, or 600 MPa, 20 min)	Increase in the foaming and haze characteristics of the beer
	HPP (200, 250, 300, or 350 MPa, 20 °C, 3 or 5 min)	Main attributes of the beer were not affected The color, protein sensitivity, and chill haze changed as pressure and time increased No effect on bitterness up to 300 MPa
	HPP (350 MPa, 20 °C, 3 or 5 min) and thermal (60 °C for 15 min)	Similar results in terms of pH and color for HPP and heat during storage HPP-treated samples had lower bitterness and protein sensitivity and higher chill haze than the thermally pasteurized samples
Beer	PEF (22 kV cm^{-1})	Significant increase in the amount of Cr, Zn, Fe, and Mn ions in the beer samples Degradation of flavor and mouthfeel
White wine	HPP (200–400 MPa)	No change in viscosity Optical density of HPP-treated wine was lower than that of nontreated samples Oxidation took place in HPP-treated samples during storage
	HPP (300–600 MPa, 20 °C)	No variation of the color parameters
Red wine	HPP (100–350 MPa, 25 °C, 0–30 min)	No differences in the aroma, taste, mouthfeel, and overall sensory quality between HPP-treated and nontreated samples
	HPP (600 MPa, 70 °C, 10 min or 1 h)	Decrease in the concentration of malvidin *3-O*-glucoside No differences in anthocyanic composition or antioxidant activity
	PEF (5 kV cm^{-1})	Higher color intensity, total polyphenol index, and total anthocyanic composition after treatment No differences in sensory attributes After 12 months of storage, there were no significant differences in the content of monomeric anthocyanins between both wines; however, the content of flavan-3-ols, flavonols, and hydroxycinnamic acids and derivatives was higher in PEF-treated wine
White wine and red wine	HPP (400 or 500 MPa, 4 °C or 20 °C, 5 or 15 min)	No effect on polyphenol oxidase activity, alcohol level, total and volatile acidity, free and total SO_2, protein stability, malic acid, lactic acid, reducing sugars, and pH No organoleptic differences between nontreated and HPP-treated wines

the addition of sulfur dioxide (SO_2) is a usual practice to final product preservation, but it must be moderated because of the negative effects on human health. In order to solve this problem, HPP and PEF were tested on wine pasteurization (**Table 7**).

White wine treated with HPP (200–400 MPa) showed no differences in viscosity compared with nontreated wine, while the optical density decreased with HPP. During storage, HPP-treated samples had higher oxidation levels, which increased the optical density values, but these values were still lower than in nontreated wine. Sensory evaluation showed significant flavor differences between sulfide-added and HPP-treated wines, with the latter being easily recognized by the tasters because of the oxidation. The application of HPP treatments in the range of 300–600 MPa in white wine resulted in no relevant variation of the color parameters compared with nontreated wine. In a study performed in both white wine and red wine, HPP-treated (400 or 500 MPa) wine showed no changes in the physicochemical and sensory parameters.

In terms of nutritional composition, the application of HPP on red wine had no effect on anthocyanic composition and antioxidant activity. However, significant differences were observed in the concentration of malvidin 3-*O*-glucoside. PEF technology (5 kV cm^{-1}) was also tested for red wine pasteurization, causing no differences in sensory attributes. However, color intensity, total polyphenol index, and total anthocyanic composition were increased by this treatment.

In general, HPP and PEF seem to have a great potential interest for wine pasteurization, since they are able to reduce microbial growth while minimizing the impact of processing on wine quality.

Pasteurization: Principles and Applications

G Tucker, Campden BRI, Chipping Campden, UK

Introduction

Milk is the most widely consumed pasteurized food and the process was first introduced commercially during the 1930s. Treatments of the order of 63 °C for 30 min were used. Modern milk pasteurization uses an equivalent process of 72 °C for 15 s (in the United Kingdom) and is usually delivered through a heat exchanger. Pasteurization is nowadays used extensively in the production of many different types of food, which includes fruit products, pickled vegetables, jams, soups, sauces, and ready meals. Food may be pasteurized in a sealed container as with in-pack processing or in a continuous process analogous to an aseptic filling operation.

The aim of a pasteurization process is to reduce the number of pathogenic and spoilage organisms by a specific amount, usually 5 or 6 log reductions. This, together with one or more microorganism growth hurdles, is sufficient to ensure that a satisfactory shelf life is attained.

Pasteurization treatment for foods involves the delivery of a thermal process that is less severe than the full sterilization process of 3 min at 121.1 °C. This is the F_0 3 concept that has its origins in canning. F_0 3 is applied to ambient stable low-acid foods in which mesophilic strains of *Clostridium botulinum* could grow. Examples of pasteurization processes could be 70 °C for 2 min for a short shelf life chilled food or 93.3 °C for 5 min for an ambient food with pH control. Thus, a requirement is that there is at least one additional preservation hurdle present within the food or its environment that prevents microorganism numbers reaching levels at which they pose a threat to health or reduce the food quality below an acceptable level. Pasteurized foods represent one of the largest groups of preserved foods and include foods such as

- fruit juices and smoothies;
- canned fruit products;
- cooked chilled and frozen foods;
- baked products;
- beer and soft drinks;
- ice cream and dairy products;
- pies, pasties, and pastry products;
- cooked meat, fish, and poultry products.

As mentioned previously, the efficacy of heat in destroying organisms is influenced by various factors. It is for this reason that mild heat alone cannot be used to produce safe stable pasteurized foods.

The following statements are usually true:

- Most spore-forming bacteria are inhibited by a combination of pH less than 4.5 and a_w less than 0.90.
- Acid-tolerant spore-forming bacteria will survive and grow at pH > 3.8. This includes many of the butyric anaerobes, a group of bacteria that under anaerobic conditions can ferment sugars to butyric acid, and includes *Bacillus macerans* and *Bacillus polymyxa*.
- Some xerophilic and osmophilic spore-forming yeasts and molds can grow below a_w 0.85.
- Antimycotic agents (preservatives) have been successfully used in foods to prevent the outgrowth of yeasts and molds.
- *C. botulinum* does not usually germinate and grow in foods with a pH of less than 4.5 or a water activity (a_w) of less than 0.94, although some experimental conditions have shown growth and toxin production by *C. botulinum* at pH < 4.5.
- Chilling is only a short-term barrier to microbial growth.

Pasteurization Values

Mathematical analysis of pasteurization is similar to that for sterilization, except for the fact that the target microorganisms are less heat-resistant. Some pasteurization processes are described by pasteurization units (PU), similar to the F_0 value for a low-acid product. The PU concept was originally designed for the pasteurization of beer where yeasts are the target microorganisms. It has since expanded to include many types of food product, and so the term *P*-value is more general and used widely. Calculation of PUs is useful to give the process a reference thermal exposure, but there is no international minimum as there is for low-acid canned foods (i.e., F_0 3).

A target *P*-value for a process to achieve is calculated from microorganism heat resistance data. This is characterized by the *D* and *z* concept, where *D* is the decimal reduction time (min) and *z* is the kinetic factor (°C). *D* is the time it takes to reduce the microorganism population by one log, at a constant temperature (T_{ref}). It is correct to refer to *D* as D_T because the value is at the reference temperature only. *z* is the temperature change required to change the D_T by one log, in effect changing the killing power of the process by a factor of 10.

The first step is to decide on the target microorganism for the pasteurization process, which will be based on the relevant hurdle to growth for that food and its environment. Literature sources are invaluable in making this decision. **Tables 1–3** present a selection of industrially relevant data for pasteurization processes. These are the heat resistance data used to set up the target *P*-value.

Data on microorganism heat resistance are usually taken from work published by researchers, because it is time-consuming and expensive work. It is rare for food companies to commission heat resistance studies unless the food product is unusual or there is a reason to justify lowering the process severity. Using values from the literature, the time required to process a product to achieve a specific reduction in microbial load can be calculated using eqn [1]:

$$P = D_T \cdot n \qquad [1]$$

where *P* is the required pasteurization value (min); D_T is the *D*-value at the reference temperature, T_{ref} (min); and *n* is the number of log reductions required (usually 6).

Organism	*Heating substrate*	*Heating temperature (°C)*	D-*value (min)*	z-*value (°C)*
Byssochlamys fulva	Grape drink	93	5.0	7.8
Saccharomyces cerevisiae (ascospores)	Buffer (pH 4.5)	60	22.5	5.5
Zygosaccharomyces bailii (vegetative cells)	Buffer (4.5)	60	0.4	3.9
Zygosaccharomyces bailii (ascospores)	Buffer (4.5)	60	14.2	3.9

Preservation by Pasteurization

Manufacture of a pasteurized food can be broken down into two basic processes:

(1) The food is heated to reduce the numbers to an acceptably small statistical probability of pathogenic and spoilage organisms capable of growth under the intended storage conditions.
(2) The food is sealed within a hermetic package to prevent reinfection. Preservation methods, such as traditional canning, seal the food in its package before the application of heat to the packaged food product, whereas other operations such as aseptic, cook–chill, and cook–freeze heat the food prior to dispensing into its pack.

Retorting and canning are terms that are still widely used in the food industry to describe a range of thermal processes where the food is heated within its package to achieve a commercially sterile packaged food. The heating usually takes place in retorts that are batch or continuous hot water- and/or steam-heated pressure cookers. The principal concept of food retorting is to heat a food in a hermetically sealed container so that it is commercially sterile at ambient temperatures. In other words, so that no microbial growth can occur in the food under normal storage conditions at ambient temperature until the package is opened. Once the package is opened, the effects of retorting are lost, the food will need to be regarded as perishable, and its shelf life will depend on the nature of the food itself.

Hurdles to Microbial Growth

Food preservation is the process of treating food to stop or slow down spoilage (loss of quality or nutritional value) caused or accelerated by microorganisms and/or intrinsic enzymes. A number of hurdles to microbial growth are described, including water activity, pH, storage temperature, and the use of preservatives such as salt and sugar. These can be used alone or in combination.

Heat treatment is an extremely effective means of food preservation, but a full sterilization of the food is not always appropriate, as the nutritional value, texture, and/or color of the food could be unacceptably changed. In these instances, a mild heat treatment, together with at least one other method of food preservation, is used. When a combination of two or more food preservation factors is used, generally, each factor

can be used at a slightly lower level. Using more than one food preservation factor or hurdle is termed 'hurdle technology.' Hurdle technology uses the intelligent combination of different preservation factors or techniques to achieve multitarget, mild, but reliable preservation effects. It is usually more effective than single targeting and allows hurdles of lower intensity, with the benefits of improved product quality.

The number of already applied and potential hurdles for the preservation of foods amounts to over 100. As our understanding of the mode of action of food preservation improves, factors such as microbial metabolic exhaustion, stress reactions, and homeostasis are taken into account when considering food preservation. The traditional methods of heating, chilling, drying, curing, acidification, oxygen removal, fermenting, and adding chemical preservatives are frequently used (see Table 4), but newer methods like pulsed technologies and 'natural' preservatives are also being employed. To use all of these food preservation methods, a good understanding of the biochemistry of the mode of action is required.

The most commonly used hurdles are discussed in the succeeding text (those that have relevance to pasteurization are in bold and are discussed in the following sections):

1. Control of the load of microorganisms
2. Use of restrictive pH
3. Use of anaerobic conditions
4. Use of low temperatures
5. Drying/low water activity
6. Chemical preservation
7. Irradiation

Control of the Microorganism Loading

Shells, skins, membranes, and fat are the natural defenses that prevent microbial contamination of meat, fish, fruit, and vegetables prior to harvesting. Once these barriers are removed, there are a number of methods that can be used to physically remove microorganisms from foods, which include the following:

- Washing of raw foods, which is an important part of most ingredient preparation but may result in increasing the microbial load if the water used for washing is not clean. Washing can also increase the food's moisture content and thus increase the spoilage potential.
- Trimming includes the removal of spoiled portions. It is an important step in ensuring that the load of an ingredient batch is kept as low as possible.
- Filtration is limited to clear liquids but is used successfully with some fruit juices, beer, wine, soft drinks, and water.
- Centrifugation or sedimentation is used in some milk and juice production.

Reducing the initial microbial load is critical because it determines the extent of heat process time and temperature that must be applied to achieve the condition of commercial sterilization. Although it is important to ensure that a food process starts with a low load, it is also important to understand why each step of a process is being done, because this helps to understand the importance of that step. This is where the HACCP plan is used to ensure levels of microbial contamination are low. However, it is important to note that even if microorganisms are removed from food, various preformed enzymes and/or toxins might remain and present problems.

Use of Restrictive pH Levels

Most microorganisms grow best at neutral pH (6.5–7.5) and only a few are able to grow at $pH < 4.0$. Bacteria are more fastidious about their pH requirements than are yeasts and molds. The fact that pH can limit microbial growth is a basic principle of food preservation and has been used for thousands of years. Fermentation and pickling extend the shelf life of food products by lowering the pH. The fact that no known spore-forming pathogenic bacteria can grow at $pH < 4.6$ is the basis for the food sterilization principle for low-acid foods.

Under normal conditions of storage, bacterial spores that survive commercially adequate processing are incapable of development in acid foods, and this fact has led to the adoption of the term 'commercial sterility.' This indicates that the microbiological condition is not necessarily completely sterile, but is a safe, marketable food. Commercially sterile food may be defined as food, which has been so processed, that, under ambient storage conditions, will neither spoil nor endanger the health of the consumer.

Table 4 Selected food preservation techniques and their effect on spoilage microorganisms

Method	*Effect on microbial growth or survival*
Refrigeration	Low temperature to retard growth
Freezing	Low temperature and reduction of water activity to prevent microbial growth, slowing of oxidation reactions
Drying	Reduction in water activity sufficient to delay or prevent microbial growth
Vacuum and oxygen-free modified atmosphere packaging	Low oxygen tension inhibits strict aerobes and delays growth of facultative anaerobes
Modified atmosphere packaging (enriched CO_2)	Specific inhibition of some microorganisms
Addition of weak acids, for example, sodium lactate	Reduction of the intracellular pH of microorganisms
Sugar preservation	Too high osmotic pressure for most microbial survival
Ethanol preservation	Ethanol is toxic to microorganisms and causes inhibition of growth or death
Addition of preservatives (e.g., nitrite or sulfite)	Inhibition of specific groups of microorganisms by interfering with cell membrane functioning
Irradiation	Delivery of ionizing radiation to disrupt cellular RNA
Pulsed electric field processing	Short bursts of electricity for microbial inactivation

Table 5 Suggested *P*-values (T_{ref} 93.3 °C, z 8.9 °C) for fruit and vegetables

Product	*pH*	P-*value (minutes at 93.3 °C)*
Lemon juice	2.5	0.1
Plums	2.8	0.2
Pickled vegetables	3.0	0.5
Greengages	3.2	0.8
Mandarins	3.2–3.4	1.0–2.0
Grapefruit juice	3.2	0.2–0.4
Apricots	3.2–4.0	1.0–8.0
Apples	3.3	0.2–0.6
Orange juice	3.5–3.8	0.2–0.6
Pineapples	3.5	0.6–0.8
Strawberries	2.3–4.0	0.8
Jams	3.5	0.8
Sauerkraut	3.5–3.9	0.5
Pickled gherkins	3.5–3.8	0.5–1.0
Sweet cherries	3.8	0.6–2.5
Nectarines, peaches	4.0	1.5–8.0
Pears	4.0	1.3–10.0
Tomatoes	4.2–4.5	2.0–10.0
Tomato paste	4.2–4.5	1.0–5.0

Products of different pH can support the growth of different spoilage organisms, and so different *P*-values are often used. Table 5 provides processes for products over a wide range of pH ($2.5 < pH < 4.5$).

Another source of information was the National Food Processors Association (the United States) that gave the following recommendations for processing acid products that may contain butyric anaerobes (e.g., tomatoes):

For products between pH 4.0 and 4.3, the process should be equivalent to 5 min at 200 °F (93.3 °C):
P-value > 5 min (T_{ref} 200 °F, z 15 °F; T_{ref} 93.3 °C, z 8.3 °C).
For products between pH 4.3 and 4.6, the process should be equivalent to 10 min at 200 °F (93.3 °C):
P-value > 5 min (T_{ref} 200 °F, z 15 °F; T_{ref} 93.3 °C, z 8.3 °C).

Low Temperatures

There are categories of temperature sensitivity of microorganisms that help to define and position the thermal processes that are applied to foods:

- Psychrotrophic (cold-tolerant), which can reproduce in chilled storage conditions, sometimes as low as 4 °C. Having evolved to survive in extremes of cold, these are the easiest to destroy by heat.
- Psychrophilic (cold-'loving'), which have an optimum growth temperature of 20 °C.
- Mesophilic (medium range), which have an optimum growth temperature between 20 and 44 °C. These are of greatest concern with ready meals.
- Thermophilic (heat-'loving'), which have an optimum growth temperature between 45 and 60 °C. In general, these organisms are only of concern with ready meals produced or stored in temperate climates.
- Thermoduric (heat-enduring), which can survive above 70 °C, but cannot reproduce at these temperatures.

Table 6 Minimum growth temperatures for some pathogenic bacteria

Organism	*Minimum growth temperature (°C)*
Bacillus cereus	4.0
Clostridium botulinum (psychotropic)	3.3
Escherichia coli 0157	7.0
Listeria monocytogenes	−0.4
Salmonella species	4.0
Staphylococcus aureus	6.7
Vibrio parahaemolyticus	5.0
Yersinia enterocolitica	−1.0

Most of the pathogenic microorganisms fall within the mesophilic category, such as *Salmonella*, *Listeria*, and *Escherichia coli O157*, and so food production conditions will be designed to minimize their growth and survival during manufacture. The scheduled thermal processing conditions of low temperature and time are designed specifically with the intended storage conditions that dictate microorganism growth.

Low temperatures are used to retard chemical reactions such as the actions of food enzymes and to slow down or stop the growth and activity of microorganisms in food. The lower the temperature, the slower will be the chemical reaction, the enzyme actions, and the microbial growth. A temperature below 0 °C will prevent the growth of any microorganisms although in practice 3 °C is often considered to be a temperature sufficiently low to control (stop) microorganism growth. Low temperatures are inhibitory to growth, rather than lethal to the microorganisms. Table 6 presents minimum growth temperature for selected microorganisms.

Two of the main categories of heat-preserved chilled foods are those with shelf life less than 10 days and those in which the shelf life can go beyond 10 days, sometimes up to 30 days. Foods given these processes are varied and include ready meals, fruit products, ready-to-eat cooked meat, fish, and poultry products. Food products with up to 10-day chilled shelf life are, currently in the United Kingdom, required to receive a pasteurization treatment at least equivalent to 2 min at 70 °C. These products include cooked poultry, meat as an ingredient for chilled foods, ready meals, a wide range of pies and pastries, and soups and sauces for the high-quality end of the market. Microorganisms of concern with this group of foods are the aerobic pathogens; these include *Listeria monocytogenes*, *Salmonella* spp., and *E. coli*. These organisms exist only as vegetative cells and as such are relatively easy to kill by heat.

As shelf life is extended beyond 10 days, the possibility exists that those psychrotrophic strains of *C. botulinum* can grow. Sous vide was one of the first technologies to take shelf life beyond 10 days. It originated in France as a mild thermal process (e.g., 70 °C for 40 min) for the manufacture of high-quality foods sold to the catering sectors. More recent sous vide processes have targeted the psychrotrophic strains of *C. botulinum* that have required the process severity to be increased beyond 70 °C for 40 min. A process equivalent to 10 min at 90 °C is designed to achieve at least 6-log reductions in numbers of *C. botulinum* spores.

Frozen storage stops multiplication of microbial cells. The water activity (a_w) of the product will drop due to crystallization of the available water. Although there might be an initial decrease in cell numbers due to ice crystal formation, which may rupture the cells, many microorganisms may survive freezing and continue proliferation and growth once the product is thawed. The spoilage potential of the product will actually increase on thawing, as the texture changes and drip water forms. Either a frozen ready meal is likely to have been pasteurized as a complete meal, or the individual components will be pasteurized separately and then combined prior to being frozen.

Freezing does not destroy microbial toxins and viruses. Food that shows signs of microbial spoilage is not necessarily poisonous, and food that contains microbial toxins does not always appear spoilt. When low temperature is used for food preservation, either solely or in conjunction with mild heat processing, it is important to note the 'use by' date.

Dehydration or Low Water Activity

Microorganisms cannot grow in a water-free environment, because enzyme activity is absent, and most chemical reactions are greatly slowed down. This is the principle behind dehydration or low-water-activity foods.

Fresh vegetables, fruit, meat, and fish have naturally high moisture content, which averages about 80%. Drying reduces the amount of moisture, thereby limiting the numbers and types of microorganisms that can grow, and reduces the rate at which they can do so. There are different methods of drying that can reduce the moisture content slightly or virtually complexly, depending on the desired effect, for example,

- sun drying;
- drying by mechanical means, for example, hot air drying, spray drying, and roller drying;
- freeze drying, sublimation of water from a frozen food by means of a vacuum.

Some foods (e.g., jams and marmalades) have relatively high moisture content, but the moisture is chemically bound (to sugar in the case of jam) and not available to the microorganisms. A measure of the availability of water is called *water activity* and is defined by the ratio of the water vapor pressure in the food substrate to the vapor pressure of pure water at the same temperature and is denoted by a_w. Pure water has a water activity of 1.0, while most fresh foods have a water activity of about 0.99.

In general, bacteria require a higher a_w than yeasts and molds. Most spoilage bacteria cannot grow at $a_w < 0.91$, with *C. botulinum* having a minimum growth level of 0.94. *Staphylococcus aureus* has, however, been found to grow at a_w as low as 0.84. The lowest reported a_w value for a bacterial growth was 0.75. Most spoilage molds cannot grow at $a_w < 0.80$, with the lowest reported a_w for any mold growth at 0.65 and for yeasts at 0.61.

High-salt and high-sugar mixtures preserve food because they either kill the microorganisms directly due to the difference in osmotic pressure or bind the free water and lower the water activity, so that there is no water left for the microorganisms to use for growth. They effectively dry the product out. With salt or sugar, one can theoretically preserve food for decades without it being consumed by bacteria. The value of this method to reliably preserve food cannot be understated. Before refrigeration (about 100 years ago), sugar preserves were one of the only ways to keep fruit throughout the winters. Similarly, salt was, and still is, used to preserve fish, meat, and vegetables for many months.

In thermal processing, it is common to use low water activity as a hurdle technology that is applied in combination with a thermal process. Modern jams contain sufficient acidity and sugar to avoid the need for a full sterilization process; however, a mild pasteurization process is required to provide a shelf-stable product. Other examples of low water activity in combination with a mild process include pesto, sun-dried tomatoes, and fermented meats such as salami. Heat treatment targets yeast and mold, which requires processes equivalent to 5 min at 70 °C for the 6-log reduction.

Chemical Preservation

Some chemicals have specific antimicrobial activity and can be used to control the growth of microorganisms in food. Naturally occurring antimicrobial chemicals are present in herbs and spices and have been used traditionally for thousands of years. More recently, as our understanding of food science has improved, a range of specific active chemicals are used. The use of chemical preservatives is strictly controlled by legislation in the appropriate country, as is the quantity that may be used.

Chemical preservatives may inhibit microorganisms by interfering with the cell membranes (influencing cell permeability), enzyme activity, and/or genetic mechanisms. Most chemical preservatives have the highest activity at low pH.

Properties required of an ideal chemical preservative include the following:

- Wide range of antimicrobial activity
- Nontoxic
- Economical
- Must not affect the sensory qualities of a product
- Kill rather than inhibit

Examples of chemical preservatives are many and include the following:

- Benzoic acid, propionic acid, sorbic acid, and their salts
- Sulfur dioxide and methyl and ethyl parabens
- Nitrates and nitrites
- Antioxidants, for example, BHA, BHT, and TBHQ
- Antibiotics, for example, pimaricin (Delvocid) and nisin (Nisaplin) (however, no antibiotics of medical significance may be used in foods)

The mode of action of preservatives can be very specific and varies from compound to compound, and so the desired effect must be carefully considered when using preservatives. It is common to apply a mild heat treatment to the food product in addition to the hurdle of the preservative. Process times and temperatures do not tend to be as defined as with hurdles such as low pH or low a_w. An example of this is the baking process in which products exit the oven with microbiologically clean

surfaces. Recontamination from airborne yeast and mold spores can happen during cooling and packaging, and so growth of these organisms is controlled using propionic acid.

Organic acids

Acetic acid (vinegar) is known to cause disruption of the cell membrane. It also causes denaturation of proteins inside the cell. Acetic acid is highly effective and widely used as an acidulant and preservative. Only some bacteria (*Acetobacter* spp. and some lactic acid bacteria) and some yeast and mold are resistant to acetic acid. The growth of most food poisoning bacteria is inhibited by 0.1% acetic acid. Many pickles, mustards, and dressings use acetic acid in their formulation, with a pasteurization treatment of 2 min at 70 °C for products below pH 3.7.

Sorbic acid causes membrane damage of many microorganisms and disrupts enzyme activity inside the cells. It is widely used to inhibit the growth of yeast, mold, and some aerobic Gram-positive bacteria. It is, however, relatively infective against lactic acid bacteria. Sorbic acid is more effective at low pH and has virtually no effect above pH 6. It is widely used in pH-controlled drinks, such as fruit squashes, with a mild process of 2 min at 70 °C.

Benzoic acid has a similar mode of action to sorbic acid but is used mainly to control the growth of yeast and mold (at levels of 0.05–0.10%). Often, both benzoic and sorbic acids are used together so their effect is increased.

Propionic acid is similar in action to the other organic acids but is used primarily to inhibit mold growth (0.05–0.10%). It is also effective against many bacteria. It is most commonly used in baking to prevent ropiness caused by *Bacillus subtilis* survival through the baking process.

Sulfites and nitrites

Sulfites in the form of sulfur dioxide, bisulfites, or metabisulfites are used extensively to control the growth of undesirable microorganisms in fruit, fruit juice, wine, meat, fish, and pickles. At low pH (<4.0), it inhibits yeast and mold, and at higher pH values, it inhibits spore-forming bacteria. As the pH gets lower, more of the compound is in the sulfur dioxide form (from bisulfite form). The sulfur dioxide is believed to pass through the cell membrane by diffusion and then disrupt normal cell metabolism.

Nitrites enter the cell via the cell membrane and disrupt normal metabolic pathways and cellular respiration via formation of a variety of complex compounds. Nitrates are mainly used to inhibit bacterial growth. The effectiveness is related to pH, with lower pH being more effective. Nitrites are used widely with meat products so that a lower process can be applied than the full sterilization F_0 3, usually of the order of F_0 1.

Antibiotics

Nisin is a peptide antibiotic produced by some strains of *Lactococcus lactis*. Its inhibitory effect is restricted to Gram-positive bacteria where it causes death of the target organism by cell lysis. Nisin can be used to prevent the spoilage (by *Clostridium* and *Bacillus* spp.) of cheese, milk products, some canned products, cured meats, and alcoholic beverages.

Introduction

Health benefits of fruit always seem to be in the news. Fruits are excellent functional foods as they are high in antioxidant and nutritional compounds. The regular consumption of fruit as part of a balanced diet has been associated with health benefits in different epidemiological studies. In fact, there is consensus among nutritionists and medical professionals that increased consumption of fruits will result in improved health. The health benefits associated with fruit are mainly associated with the bioactive components contained within them. There has been a growing interest in bioactive substances because of their antioxidant potential and association between their consumption and the prevention of some diseases. These health effects have been associated with reduced risk of diabetes, cancer, stroke, arthritis, Alzheimer's disease, vision problems, obesity, arthritis/joint pain, high cholesterol, and aging. A clear inverse relationship between the consumption of fruits and the incidence of cardio- and cerebrovascular, degenerative, and proliferative diseases and mortality has been demonstrated in many studies. Here, we report the nutritional value and health-promoting characteristics of peaches and nectarines.

Phytochemicals in fruit are thought to act as complex mixture rather than individually to provide protective health benefits through a combination of additive and/or synergistic effects. These phytochemicals can interact in many different ways, during food intake as part of a complete meal, changes in the gastrointestinal tract, interaction with gut microbiota, and interaction with other food constituents (lipids, proteins, carbohydrates, vitamins, etc.). The phytochemical content of fruit is influenced by numerous factors such as genotype, rootstock, climatic conditions, agronomic practices, harvesting time, and postharvest conditions.

Peaches and nectarines are a rich source of bioactives including ascorbic acid (vitamin C), carotenoids (provitamin A), and phenolic compounds. The bioactive compound profiles in peaches and nectarines show similar trends. Peaches can be categorized into clingstone and freestone varieties. Clingstone peaches are primarily used for processing, while freestone peaches are consumed fresh. Clingstones differ from freestone peaches in that they are considerably firmer in texture and, owing to a lack of the enzyme polygalacturonase, the stone clings to the flesh. Here, we report the nutritional value and health-promoting characteristics of peaches and nectarines.

Sources and Production

Peach originated in China and not Persia (now Iran) as its botanical name might reveal. Peach trees were introduced into Europe 2000 years ago from Persia and were brought to North America in the sixteenth century. Peaches are frost-sensitive, semihardy perennials of the Rosaceae. Peach trees require a chilling period of at least 25–42 days to induce flower production. Peach trees can tolerate cold winter temperatures, but flower buds are less cold hardy. Spring frosts can cause flower drop and trees may not be productive in growing seasons where spring frosts occur during flowering. Peaches are somewhat drought-tolerant but require irrigation during extensive periods of heat. Irrigation is particularly necessary during flower and fruit development, as flower buds and fruit will senesce if the tree begins to wilt. Peach is self-fertile and naturally self-pollinating; however, cross-pollination is also possible; nectarine and peach trees can cross-pollinate. From a genetic perspective, peaches and nectarines are almost identical; nectarines differ from peaches as they possess a recessive gene that prevents pubescence from forming on fruit. Peach trees may begin fruiting after 1 year if a rootstock is used; however, trees are usually short-lived and usually do not fruit for more than 15–20 years if conditions are favorable.

After apples, peaches and nectarines are the second most economically important fruit crop in the European Union (EU) and the most important within the genus *Prunus*. China is the leading producer of peaches and nectarines followed by Italy, the United States, and Spain. The top peach-exporting countries are Spain, Italy, EU, and the United States. The top four peach importers are Germany, Russia, France, and Poland. Canada is the 8th-largest importer of peaches producing about 25 000 tons of peaches annually and hence ranks well below the top 20 peach-producing countries. Peach and nectarine production in the EU lies in access of 4.2 million tons. Spain is the second-largest producer of nectarines and peaches in Europe producing over one million tons annually. Peach production and breeding is a growing industry and is the most dynamic among the temperate fruit crops with new cultivars being released yearly.

Fruit Anatomy and Development

Understanding peach fruit anatomy and development is a crucial component of studying the nutritional value of this crop. The nutrients in peach are not evenly distributed throughout the fruit. Therefore, identifying the key nutrients in each part of the fruit is essential in determining the parts of the fruit that harbor particular health benefits. Furthermore, peaches undergo a variety of physiological and biochemical changes throughout fruit maturity. These changes influence the relative type and amount of phytochemicals and bioactive compounds that accumulate in peach fruit over time. Peach fruit anatomy consists of two main organs, the seed and the pericarp. The seed consists of the endosperm, embryo, and seed coat, while the pericarp consists of the endocarp, mesocarp, and exocarp. The majority of health-promoting compounds in peach fruit are found within the pericarp.

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00527-4

Peach fruit undergoes three distinct stages, stages I, II, and II, of development where growth can be explained by a double sigmoid pattern. Fruit in stage I undergoes rapid cell division followed by a rapid increase in the volume of the pericarp as a result of cell expansion toward the end of this period. In stage II, the pericarp remains predominantly quiescent in terms of growth and development, while the embryo develops rapidly. Stage III is marked by the completion of endocarp development and a rapid increase in pericarp volume, which is mainly due to cell expansion. Most bioactive components of the fruit develop and accumulate in the endocarp, mesocarp, and exocarp of the fruit during stage III. Early-maturing cultivars tend to have a reduced stage II period of development, and hence, maturity resumes at a faster pace. However, this phenomenon may have implications in the relative amounts of phytochemicals present in early-maturing varieties compared with mid- or late-maturing varieties.

Fruit maturity and ripening are marked by several biochemical and physiological changes. Fruit maturity precedes fruit ripening, and these two events are separately controlled. Fruit maturity is defined as fullness of development, can only occur while the fruit is attached to the tree, and is marked by termination of cell expansion and the cessation of dry matter accumulation. Fruit maturation occurs unevenly from the tip down and from the inside outside. Ripeness is defined as readiness for use, can occur while the fruit is attached or detached from the tree, and is marked by fruit softening, coloration, and development of aroma.

Consumer Consumption Trends of Peach and Nectarine

Identifying peach and nectarine consumption frequencies between nationality, age, and gender groups is important in understanding studies related to health benefits associated with these fruits. Several studies have evaluated peach consumption frequency within different European countries in relation to age and gender. In one study, 499 respondents from five countries answered questions relating to frequency of peach and nectarine consumption. France had the highest consumption of peach and nectarine where 48% of respondents declared a peach consumption of 3–5 per week with 40% eating more than 5 fruits per week. The lowest peach intake was declared in Germany followed by Poland. Data analysis of self-reported fruit intake shows significant differences between nationalities. Women declared a higher peach consumption than men. Peach and nectarine consumption decreased with age with the lowest consumption occurring in individuals between 16 and 35 years of age. In general, there has been reduced intake of fruit by the younger generation and a persistent tendency of lower frequency of fruit consumption among men than women. In some Europeans countries, an association between lower fruit intake as reported by men and a higher risk of chronic diseases in this group has been identified. This trend indicates an urgent need for a targeted informational campaign on the beneficial effects of fruit consumption on health.

Availability, Absorption, and Metabolism

Bioactives are compounds that produce physiological effects when present in living material. These compounds exert physiological benefits that relate to promoting health and preventing effects of a disease. Bioactive compounds must withstand digestion by the gut that would otherwise destroy the active structure of the compound, therefore, rendering it physiologically inactive when ingested. Sometimes, however, the inactive part of the compound becomes active once consumed. This phenomenon is a result of the action of digestive enzymes present in the gastrointestinal tract. In some cases, bioactives may not be absorbed by the digestive tract, but still exert their physiological effect within the digestive tract. Usually, however, the bioactive compound must be absorbed from the gastrointestinal tract into the blood circulatory system. The compound is then carried via the blood circulatory system to target organs where the bioactives can exert their effect. Functional foods are defined as foods that contain bioactives and consumed as part of a normal diet. Plants are a rich source of bioactive compounds. Fruit-derived bioactive products are becoming accepted because of their abundance and low cost. Furthermore, these products are becoming more and more popular due to the wider acceptability of plant products as a result of religious, social, or moral reasons that prevent many people from consuming animal-derived products. Fruit-derived bioactives show antimicrobial activity, anticancer activity, anti-inflammatory activity, immunostimulatory activity, and antioxidant activity. Peaches and nectarines are a rich source of bioactives including ascorbic acid (vitamin C), phenolic compounds, carotenoids (provitamin A), anthocyanins, and dietary fibers (DFs).

Vitamin C is a water-soluble antioxidant and is referred to as an antioxidant vitamin. Humans are unable to synthesize vitamin and, therefore, are entirely dependent upon dietary sources to meet their daily Vitamin C needs. More than 90% of the vitamin C in the human diet is supplied by fruits and vegetables. The vitamin C content in peach and nectarine flesh ranges between 1 and 14 mg of AsA per 100 g of FW depending on cultivar. These values are higher when peach peels are included in the test because skin tissues have more vitamin C to protect the fruit from outside stress caused by light and oxidation. The ranges of total ascorbic acid in mg per 100 g of FW were 5–14 (white-flesh nectarines), 6–8 (yellow-flesh nectarines), 6–9 (white-flesh peaches), and 4–13 (yellow-flesh peaches). The genetic background of the genotype assessed is a much more important factor compared to the climatic conditions and cultural practices used in producing fruit with high vitamin C content. There appears to be no correlation between vitamin C and any other phytochemical trait. There are no clear differences in the vitamin C content between peaches and nectarines, but the vitamin C content of white-flesh peaches is significantly higher than that of yellow-flesh fruits. Vitamin C does no show significant correlation with relative antioxidant capacity (RAC). Studies also indicate a positive correlation between vitamin C and TA due to the contribution of ascorbic acid to the fruit acidity.

The sugar content of peach fruit largely determines consumer acceptance and can be a good indicator of physiological maturity and ripeness. Peach fruits contain three main sugars; the dominant sugar is sucrose, and glucose, fructose, and sorbitol are also important components of the sugar content making up 54–75%, 4–11%, 9–21%, and 3–25% of the total soluble solid content (SSC) of fruit, respectively. 65–85% of

the soluble solids (SSs) of fruit are sugars, and therefore, SSC is a good indirect measure of fruit sugar content. SSC is typically measured on a refractometer and recorded as a unit of degree Brix. Hence, Brix is a measure of the sugar content of an aqueous solution; 1 °Brix is 1 g of sucrose in 100 g of solution. When measuring the sugar content of fruit, SSs other than sucrose are present in solution, and therefore, SSC measurements are only an indirect assessment of the sucrose content within fruit. Sucrose is important as an energy source and as a preservative of fruit flavors. Fructose is rated higher (1.75) than sucrose (1) and glucose (0.75) in terms of sweetness. Cultivars that have a high fructose percentage present the highest sweetening power. Sorbitol plays an important role in the texture and flavor of peach and nectarine. Sorbitol is an interesting polyalcohol in terms of nutrition for special dietary purposes like diet control or dental health.

Acids present in peach and nectarine fruit are mainly malic acid, citric acid, quinic acid, and shikimic acid. Malic acid is the most abundant acid at maturity (42.92–84.30% of the total acid content), followed by quinic acid (14.56–57.54%), citric acid (3.72–31.61%), and shikimic acid (0.14–1.89%). However, some studies have reported citric acid and quinic acid to be the second and third most abundant organic acid, respectively, in most peach and nectarine cultivars. Some studies suggest that quinic acid imparts a slightly sour and bitter taste and has antibacterial properties beneficial to health. Titratable acidity tends to be higher and pH lower in yellow-flesh peaches compared to white-flesh cultivars.

Carotenoids are lipid-soluble compounds that cause yellow, orange, red, and violet colors in various kinds of fruits. The bioactives present in carotenoid are classified into carotenoid hydrocarbons (carotenes) and carotenoid alcohols (xanthophylls). The prevention of chronic disease such as cardiovascular disease and skin cancer may be prevented via the provitamin A activity of some carotenoid. In peaches and nectarines, the main carotenoids present are carotene and cryptoxanthin. Carotenoids are more abundant in peel tissues than in flesh tissue. In peach and nectarine, carotenes are more abundant than cryptoxanthin. Yellow cultivars contain close to ten times more carotenoids (95–197 mg per 100 g serving) than white-flesh cultivars (8–18 mg per 100 g).

Phenolics are natural plant metabolites, which are found in many fruit, including peaches, and function as plant defense against insect and animal herbivory and oxidative damage. Fruit phenolic compounds play an important role in peach and nectarine quality because they have a role in the visual appearance of the fruit (pigmentation and browning), taste (astringency), and health-promoting properties (free-radical scavengers). Additionally, phenolics can be used to increase the shelf life of food and inhibit the growth of pathogenic microorganisms due to their natural antimicrobial properties. Phenolic compounds are not uniformly distributed within the tissue of fruits. Most phenolics are concentrated in the epidermal and subepidermal layers of fruit. Phenolic distribution is an important aspect of the overall phenolic composition and antioxidant capacity because peach skin is usually not eaten and, therefore, does not contribute to the human diet intake. The distribution of phenolics in the peach is 30% in the flesh and 70% in the peel, and on average, unpeeled fruit contained 1.5-fold higher levels of phenolics than peeled fruit. Phenolics in fruit are mainly in soluble free form (62–96%); however, 2–46% of phenolics existed in bound-E forms and 2–24% in bound-W forms. Bound phytochemicals cannot be digested by human enzymes and may survive stomach and small intestine digestion to reach the colon, providing site-specific health benefits.

Nectarines and peaches generally exhibit identical phenolic profiles, containing the same individual compounds. However, some studies found higher phenolic content in peaches than in nectarines and higher phenolic content in white-flesh fruit compared with yellow-flesh fruit. These findings support the idea that white-flesh varieties have significantly higher antioxidants content than yellow-flesh peaches and nectarines. However, it is important to note that these findings differ among studies, with some studies finding no significant difference in phenolics between white- and yellow-flesh fruits. Peaches and nectarines contain larger quantities of chlorogenic acid than neochlorogenic acid. Some peach and nectarine cultivars that contain high levels of phenolics have a corresponding bitter taste, which indicates that too high a level of phenolics may be detrimental.

Many reports suggest that phenolic compounds are mainly responsible for the antioxidant activity of peaches and nectarines, as described in many studies for stone fruits in general. Recently, much attention has been given to antioxidants as an eligible parameter for fruit quality. Cells in humans and other organisms are constantly exposed to several types of oxidizing agents. Some of these oxidizing agents are necessary for life. Overproduction of oxidants can result in oxidative stress, which is associated with chronic diseases. Therefore, increased consumption of fruits containing high levels of antioxidants (mainly phytochemicals) is recommended to prevent or slow the oxidative stress caused by free radicals. RAC of flesh samples among peach and nectarine cultivars ranges between 100 and 1000 μg of Trolox per g of FW. RACs of peach and nectarine samples that include the peel range between 700 and 6000 μg of Trolox per g of FW. Therefore, the antioxidant capacity of the peach fruits decreases when they are peeled. The antioxidant activity of peaches and nectarines ranges from 2074 to 13 505 μg of Trolox per g of FW in red-flesh peaches and between 437 and 1128 μg of Trolox per g of FW in lighter-flesh peaches. By increasing the phenolic content of nectarines and peaches by genetic manipulation, breeders can increase the antioxidant capacity of these fruit. However, there is a limit after which increased phenolic concentration may cause undesirable levels of astringency in these fruits. Due to the notable health benefits associated with nectarines and peaches, these fruit should be included in the range of fruits selected by consumers to meet the recommended two to four servings of fruits per day.

Anthocyanins are one of the primary components responsible for the flesh and skin coloration pattern of peach fruit. Anthocyanins are a class of flavonoids that are synthesized via the phenylpropanoid pathway. This important class of water-soluble vacuolar pigment is found in all tissues of higher plants including leaves, stems, roots, flowers, and fruits. They are odorless and nearly flavorless and give rise to red, purple, and blue tinges to tissues where they are expressed; color largely depends on pH. In peach, anthocyanins are localized in vacuoles of the epidermis or the flesh. Although anthocyanins contribute to

the mainly reddish tinge of mature peach fruit, they are independent of the skin ground color, which is influenced by other pigments that cause a yellow or white coloration pattern that lies below the coloration pattern expressed by anthocyanins. Anthocyanins play a major role in the appearance, taste, and flavor of fruits, including peach and nectarine. Anthocyanins are well known for their health-promoting properties. In addition to their colorful characteristics, they have potent antioxidant properties modulated by their different hydroxylations and glycosylations. The two most common anthocyanin pigments found in peach and nectarine are cyanidin-3-glucoside (major component) and cyanidin-3-rutinoside (minor component). However, other anthocyanins, namely, cyanidin 3-acetyl glucoside, cyanidin 3-galactoside, peonidin-3-glucoside (1.1–1.2 mg per 100 g), and peonidin derivatives (1.9–11.5 mg per 100 g), have also been identified in some peach and nectarine varieties in smaller amounts.

Total anthocyanins in peeled peach and nectarine varieties greatly vary among peach and nectarine genotypes (0.1–26.7 mg of cyanidin-3-glucoside equivalents per kg of FW). These values are much higher if peach peels are included in the analysis because peach peels contain higher levels of anthocyanins than flesh. The anthocyanin content greatly depends on the red pigmentation of the flesh. Genotypes with red flesh have higher anthocyanin content. There are no clear differences in anthocyanin content between peaches and nectarines, but the anthocyanin content in the flesh of white-flesh peaches is significantly higher than that of yellow-flesh fruits. These findings could be explained by the red pigmentation due to anthocyanins in white-flesh fruit, particularly in the flesh area surrounding the stone in some varieties. By contrast, anthocyanin content in the peel is reportedly higher in yellow-flesh fruits than in white-flesh fruits.

DFs refer to carbohydrate polymers containing ten or more monomeric units that are neither digested nor absorbed in the small intestine. DFs possess many health-benefiting properties. They can help decrease intestinal transit time, increase stool bulk fermentable by colonic microflora, reduce blood total and LDL cholesterol levels, prevent stroke, reduce postprandial blood glucose, reduce insulin levels, and prevent constipation. Approximately 25–38 g per day is encouraged to promote health benefits associated with fiber. DF consists of cellulose, lignin, hemicellulose, pectins, gums, and mucilages, and all of these components are present in the cell wall material of fruits. Total dietary fiber (TDF) is subdivided into insoluble dietary fiber (IDF) and soluble dietary fiber (SDF) depending on their solubility in water. TDF, IDF, and SDF play an important role in human nutrition. Presently, the food composition tables give crude fiber (CF) content but not DF content. The TDF values are much higher than the CF values of corresponding fruits. According to various studies, the CF values for peach fruit using the CF and TDF methods were found to be 1.2 and between 1.9 and 3.9 g per 100 g of peach fruit tissue, respectively. This variation could be due to differences in the methodology applied for the determination of fiber content in foods.

Fresh Versus Processed Fruits

Most consumers believe that fresh fruits have more vitamins, minerals, and phytochemicals than processed fruits, and therefore, processed fruits are nutritionally inferior to fresh products. However, the commonly held belief that 'fresh is best' may not be the case. In fact, many some studies demonstrated that processed fruits are nutritionally similar and sometimes have more nutrients compared to their fresh and frozen counterparts. This misperception may limit consumer food choices considering that many products, including peaches, are seasonal, which limits their availability. In reality, processed peaches can deliver high-quality, nutrient-dense foods on a year-round basis, instead of the limited seasonal availability of fresh peaches.

Fruits are typically composed of over 90% water. Once harvested, fruits begin to undergo higher rates of respiration, which results in moisture loss, quality deterioration, and potential microbial spoilage. Harvesting separates the fruit from the tree, which is its source of nutrients, and therefore, the fruit uses itself as a source of calories. Many fresh fruits, including peach, have a shelf life of a few days before they are unsafe or undesirable for consumption. Storage and processing technologies are used to transform perishable fruits into safe, delicious, and stable products. To slow down respiration and increase shelf life, fruits are refrigerated. Freezing, canning, and drying allow fruit to be consumed year-round and transported safely to consumers worldwide. Processing arrests the progression of respiration, which then stops the consumption of nutritious components, the loss of moisture, and the growth of microorganisms.

Freezing and canning processes may preserve the nutrient value of fruit. Water-soluble and oxygen-labile nutrients such as vitamins C and the B may be lost during the initial thermal treatment of processed fruit. These nutrients are relatively stable during subsequent canned storage owing to the lack of oxygen. Initially, frozen products lose fewer nutrients due to the short heating time in blanching, but they may lose more nutrients during storage due to oxidation. Phenolic compounds are water-soluble and oxygen-labile. Changes in moisture content during storage, cooking, and processing may misrepresent changes in the nutrient components of fruit. Retention of nutrients is highly dependent on cultivar, production location, maturity stage, season, and processing conditions. Fresh fruits, including peaches, usually lose nutrients more rapidly than canned or frozen products.

According to some studies, the nutritional content of canned peaches is comparable to that of fresh peaches. In one study, the vitamins and phytochemicals were found to be present at statistically significantly higher levels in canned cling peaches versus fresh freestone (vitamin C, antioxidants, and folate), higher but not statistically different levels (vitamin A), or lower but not statistically different levels (vitamin E, total phenolics, and total carotenoids). There were no statistically significant changes in nutrient content during storage for 3 months (Table 1). Therefore, canned peaches can provide comparable nutrient levels to the consumer as fresh peaches.

Health-Promoting Benefits

Promoting longevity and health span has always been attributed to the consumption of fruits containing high antioxidant capacities and other bioactive components. One of the greatest environmental factors that affect life span is human diet. The

addition or increase of certain fruits to the human diet has been shown to have human health benefits including an increased life span. One study has evaluated the effects of nectarine fruit extract on *Drosophila melanogaster* life span. In this study, wild-type flies were fed with standard, dietary restriction, or high-fat diet supplemented with 0–4% nectarine extract. Life span, food intake, locomotor activity, fecundity, gene expression changes, and oxidative damage indicated by the level of 4-hydroxynonenal–protein adduct were evaluated in the flies. Supplementation with 4% nectarine extract extended life span, increased fecundity, and decreased expression of some metabolic genes. Nectarine extract reduced oxidative damage in wild-type females fed with high-fat diet. Together, these findings suggest that nectarine promotes longevity and health span partly by modulating glucose metabolism and reducing oxidative damage. These results suggest that nectarines and likely peaches might promote a healthier, longer life by modulating glucose metabolism and reducing oxidative damage.

The anticancer activity of many fruit extracts has been studied using *in vitro* cell line model systems and *in vivo* systems. Fruit consumption provides an array of bioactive phytochemicals that can help lower the risk of cancer. A cohort study regarding the effect of fruit and vegetable intake on head and neck cancer risk in the United States showed that those volunteers placed in the first tertile of peach and nectarine consumption, together with other Rosaceae fruits, had a decreased risk of head and neck cancer.

Different plant species have compounds that are active against cancer propagation by blocking cell cycle progression and/or inducing apoptosis, which is directly associated to DNA fragmentation. A desirable feature of these bioactive compounds is that they have selective cytotoxicity against cancer cells while not affecting normal cells. In stone fruits, many phenolics have been reported such as anthocyanins, hydroxycinnamic acids, flavan-3-ols, and flavonols. The main flavonols reported in stone fruit include chlorogenic acid, neochlorogenic acid, catechin, epicatechin, and quercetin 3-rutinoside. Many of these phenolics act as antioxidants, antimutagenics, and anticarcinogenics.

To demonstrate the effectiveness of peach fruit phenolics to treat cancer, one study evaluated the phenolic composition of the yellow-flesh peach 'Rich Lady' (RL). RL extracts were collected from mature firm fruit and used to study their effects at suppressing cancer cells in mice. The extract from RL contained a mixture of polyphenolics like chlorogenic acid, neochlorogenic acid, cyanidin 3β-glucoside, quercetin 3β-rutinoside, quercetin 3β-glucoside, and catechin derivatives. Peach RL extracts (0.2–1.6 mg CAE per day) did not exert adverse effects on body weight gain and appearance of major organs including in the nonxenografted controls, which confirms their lack of toxicity. Results showed that treatment with peach phenolics (0.8–1.6 mg CAE per day) inhibited tumor growth of the highly metastatic MDA-MB-435 cells of xenografted animals after 12 days compared to the xenografted control group. However, only tumor volume (v) but not tumor mass (m) was reduced. The inhibitory effects of peach phenolics on tumor growth were accompanied by decreased blood vessel formation compared to the xenografted control, which is characteristic of angiogenesis. This observation indicates that tumor volume decreased and not mass due to the effects in density of the tumor tissue (m/v).

The mixture of phenolics present in some peach fruit variety extracts may constitute a novel chemopreventive tool in the combination therapy when primary cancer is diagnosed because these polyphenols do not have toxic side effects. The generated phenolic extract dose information for mice in *in vivo* studies could be converted to equivalent human intake and considered as a reference for future clinical studies by using the body surface area normalization method. For example, the use of 6.17 mg kg^{-1} per day of peach fruit phenolic extract from

the genotype RL will potentially decrease breast cancer cell volume and mass in humans. Therefore, for an average human adult weighing 60 kg, the intake of RL peach phenolics would be ~370.6 mg day^{-1}. The phenolic content for an average RL peach fruit is in the range of 111.6–180 mg per fruit. Therefore, the human equivalent dose of phenolic extract required to suppress breast cancer volume and mass (~370.6 mg day^{-1}) could be supplied by consuming only two to three peach fruits a day. Alternatively, supplements free of sugars could be supplied by an aqueous or peach phenolic extract powder if sugar intake is a concern.

In a second study, polyphenolic extracts and fractions of selected peach genotypes were evaluated for cell viability and antiproliferation activity *in vitro* against an estrogen-independent MDA-MB-435, which is a very aggressive and invasive breast cancer cell line, and estrogen-dependent MCF-7 breast cancer cell lines, which are less aggressive and invasive compared to MDA-MB-435, and one noncancerous breast line MCF-10A. The extracts showed a phenolic dose-dependent cytotoxic effect against MDA-MB-435, weak activity against MCF-7, and small or no activity against MCF-10A. HPLC analysis of the peach fruit extract from the genotype BY00P6653, which had the strongest anticancerous effects from the genotypes used, revealed four fractions. The first fraction (F-I) contained hydroxycinnamic acid derivatives including chlorogenic acid and a caffeic acid derivative, which is likely neochlorogenic acid. Chlorogenic acid and caffeic acid derivatives are reported to have anticarcinogenic activity on hepatic, HL-60, U937, and Jurkat cells as well as apoptosis-inducing activity on leukemia cells. The second fraction (F-II) contained anthocyanins with cyanidin-3-glucoside, the most abundant combined with small amounts of flavonols. The third fraction (F-III) contained quercetin derivative compounds. The fourth fraction (F-IV) contained polymer compounds, mainly polymerized anthocyanins.

Metalloproteinases (MMPs) are important targets in breast cancer progression as they play a role in the degradation of the extracellular matrix facilitating tumor invasion and metastasis. The gene expression of MMPs in tumor tissues was investigated. Treatment with peach phenolics (1.6 mg CAE per day) inhibited gene expression of MMP-2, MMP-13, and MMP-3 down to 0.68-, 0.57-, and 0.54-fold of the xenografted controls. These findings indicate that peach phenolics downregulated the gene expression of MMPs.

Obesity is a serious health issue affecting both developed and underdeveloped nations. The factors associated with increased occurrence of obesity include diminished physical exercise and an increased consumption of saturated fats and refined carbohydrates. Obesity is associated with several clinical complications and diseases including insulin resistance, hypertension, inflammation, oxidative stress, and dyslipidemia. Several *in vitro* and *in vivo* studies have demonstrated the antilipidemic and antiobesity effects of polyphenols, including suppression of adipogenesis and adipocyte proliferation, inhibition of fat absorption, and modulation of energy metabolism and inflammation. Research suggests that dietary polyphenols can modulate the composition and metabolic activity of intestinal microorganisms. This modulation may be involved in the underlying mechanisms for the associated health benefits. This hypothesis is supported by the close association between energy harvest, obesity, and the complex assembly of microorganisms residing in the intestinal tract.

Peach and plum fruits contain high amounts of polyphenols, which possess antiobesity effects. Successful treatment of obesity using polyphenols is thought to involve an alteration of the intestinal microbiota. Zucker rats have been very well characterized as a model for studies of obesity and are an attractive animal model for studies of the gut microbiota. These rats possess a mutation in the leptin receptor and develop metabolic syndrome symptoms, including insulin resistance and dyslipidemia, at 4–5 weeks of age. Obese individuals have been shown to contain distinctive intestinal microbiota when compared to nonobese subjects. In one study, three groups of Zucker rats were used to study the effects of polyphenols on obesity by assessing the weight gain by each of the rats and conducting qPCR analyses of their fecal material. The rat groups were an obese control group, a lean group, and a peach group. Rats in the peach group were fed with carbohydrate-free fruit juices from peaches or plums, while the control group and lean group were given water. Fecal samples were taken after 11 weeks of control or fruit juice was administered. The qPCR analyses identified statistically significant differences in the abundance of several fecal bacterial groups between treatment (peach and plum) and control and lean groups. This study suggested that the consumption of carbohydrate-free peach and plum juices containing polyphenols as well as vitamins and minerals has the potential to modify fecal bacterial composition in an obese animal model. These changes, in turn, may contribute to the prevention of obesity in rats and potentially in other animals.

Antiallergic inflammatory property of peach extract has been demonstrated in some model systems. Mast cell-derived mediators play an essential role in the initiation and progression of the allergic inflammatory reactions connected with atopic asthma and other allergic disorders. The mast cell-based *in vivo* allergic inflammation model and its possible mechanism of action were investigated using ethanol extract of fruits of peach. Fruits of *Prunus persica* (FPP) were found to dose-dependently inhibit compound 48/80-induced systemic anaphylaxis (used as a model of induction for systemic fatal allergic reaction – the synthetic mast cell stimulator) and immunoglobulin E-mediated local allergic reactions. Anaphylaxis is a life-threatening syndrome induced by the sudden systemic release of inflammatory mediators like histamine, heparin, and various cytokines from mast cells.

In this study, mice were injected with compound 48/80 and monitored for 1 h, after which the mortality rate was determined. The injection of compound 48/80 into mice induced fatal shock in all animals. When FPP was intraperitoneally administered for 1 h at a concentration of 10–1000 mg kg^{-1} body weight, the mortality with compound 48/80 was dose-dependently reduced. The effect of FPP on the compound 48/80-induced serum histamine release was also investigated in this study. FPP was administered at concentrations between 10 and 1000 mg kg^{-1} 1 h before the compound 48/80 was injected. When compound 48/80 was injected, there was marked increase of serum histamine release, and this induction was inhibited by FPP treatment in a dose-dependent manner. The results of this study demonstrated that FPP has antiallergic inflammatory properties. FPP inhibited mast cell-mediated allergic

reactions and decreased PMACI-stimulated expression of pro-inflammatory cytokines, therefore suggesting that FPP might be useful in the treatment of allergic inflammatory diseases.

History of Peanut Cultivation

Several earlier works provide a detailed account of the history of peanut cultivation. Briefly, people native to Brazil, Bolivia, and Peru were cultivating wild peanut species well before the cultivated peanut, *Arachis hypogaea* L., existed. Since 1977, explorations to collect *Arachis* germplasm in South America revealed numerous sites where hunter-gatherer–farmers had transplanted the wild species, *A. stenosperma* Krapov. and W.C. Gregory, to new sites and maintained it as a semi-cultivated crop. Many of these sites are located in the littoral, south of Rio de Janeiro, extending to near Puerto Alegre. This same species was found growing near old Jesuit mission ruins in central Brazil and also northward to São Félix. All of these sites are distant from the native site of this species in central Brazil, near Barra do Garças. Another species that is still cultivated by native tribes in the western Mato Grosso of Brazil is *A. villosulicarpa*. Archaeological evidence in north Argentina and in Peru indicates that wild *Arachis* were being cultivated well before the cultigen existed.

Little doubt remains that the cultivated peanut that is so widely distributed around the tropics and warmer temperate parts of the world today originated in the gardens (fields) of hunter-gatherer–farmers in the time frame of 3500–3800 BP. The strongest evidence that *A. hypogaea* did not evolve in the wild is the fact that the cultigen cannot survive indefinitely without man's intervention. The location of the formation of *A. hypogaea* is not determined, and some discussion has mentioned that the same event of cultivar formation could have occurred twice in different locations, thus possibly accounting for the two subspecies recognized today: *A. hypogaea* ssp. *hypogaea* and *A. hypogaea* ssp. *fastigiata*. Molecular biology has aided in identifying the two wild species that were probably the parents of the cultigen: one, *A. duranensis* Krapov. and W.C. Gregory, contributing the A genome and the other, *A. ipaensis* Krapov. and W.C. Gregory, contributing the B genome.

Recorded history of peanut cultivation begins with the discovery of the Americas by Columbus because the natives on the islands were growing peanuts for food. A significant amount of selection and differentiation occurred in the plantings as farming techniques and farmers' knowledge advanced from 3800 BP to 1500 AD. As the conquests progressed, several accounts document natives growing peanuts. Hammons cited 24 recordings of peanut cultivation in the new world from 1502 to 1697. The first recording of peanut in Europe was in 1574 by N. Monardes, but most likely, it was there earlier. From Spain and Portugal, the peanut was spread across Africa, Asia, and China. Archaeological evidence from China indicates that the peanut may have been carried from the west coast of the Americas with ancient Chinese sailors and was grown in China during the Han dynasty, well before the time of Columbus. The evidence of these visits to the Americas is questionable, but many different authors refer to the possibility. The peanut reached Australia in 1870 with Chinese gold diggers.

There is no documented evidence that the native peoples of what is now the United States were growing peanuts when the colonists arrived. Thus, the crop probably came to the colonies with early settlers or more likely with the slaves as the peanut was sometimes used to feed slaves during the journey from Africa to the Americas because it required a small amount of space.

Consumption Trends

Peanuts are ranked fifth in the world for total oil production and are produced for edible oil and food in more than 100 countries worldwide. Because of its adaptability and high nutritional value, peanuts remain an important crop for small farmers in South America, Africa, India, and China, as well as many island nations. It is grown for home consumption as whole peanut, cooking oil, and the meal remaining after the oil is removed. It is also sold or bartered for other essential needs, including other foods. For modern, mechanized farming, peanut production has become an important cash-crop business in countries such as Argentina, Australia, Brazil, and the United States. However, China remains the leading producer of peanuts (~15 million metric tons per year) in the world simply due to the large number of farmers growing peanuts. India remains second in production (8+ million metric tons) for the same reason, with Nigeria ranking third (3.8 million metric tons) and the United States fourth at 1.9 million metric tons. The total world production of peanuts increased steadily between 1963 and 2012 from 15 879 053 to 41 269 156 tons, respectively, according to FAO statistics.

In the United States, the first people reported eating peanuts were slaves. Peanuts, however, became more mainstream during the pre-Civil War period, with consumption steadily escalating after the Civil War. By the twentieth century, the medical profession convinced Americans that peanuts not only tasted good but were a healthy food. Currently, four different market types of peanuts are cultivated, including Runner, Virginia, Spanish, and Valencia. The Runner types are generally grown in the Southeast (Georgia, Florida, Alabama, and Mississippi). The Virginia types are grown in the VC region (Virginia, North Carolina, and South Carolina). The Southwest (including Oklahoma, Texas, and New Mexico) is the source of Spanish and Valencia peanuts. Overall, in the United States, 83% of the production area was planted with Runner cultivars in 2012, whereas Virginia peanuts were produced on 15%, Spanish 1%,

and Valencia 1% of the production area. The primary use of Runner-type peanuts is to produce peanut butter. Based on the peanut stock and processing report compiled by the USDA National Agricultural Statistics Service (NASS), the primary products of shelled peanuts were 60.6% peanut butter, 19.8% peanut snacks, 18.7% peanut candy (includes peanut butter manufactured for candy), and 0.9% other products from 2010 to 2012.

Botanical Description of Peanut

Early descriptions of the peanut showed drawings/pictures of the peanuts growing on the roots of the plant and had nothing to do with the aboveground stems and flowers. Smith was one of the first to correct this error and described the peanut as an herbaceous legume, annual in growth habit but can be maintained for long periods if the fruits are removed regularly. Rao and Murty presented a technical description of the *Arachis* genus.

The fruits can be very small or quite large, and seed size is directly related to fruit size. The seed has two fleshy cotyledons covered by a testa, or skin, beneath which are several layers of parenchyma cells that include a one- or two-layer integument. At the base of the cotyledons is an embryonic plant with a straight axis, unlike other legumes, with a developed taproot primordia and two to four embryonic quadrifoliate leaves. As the seed germinates, the hypocotyl lengthens to push the cotyledons upward and the taproot down. As the cotyledons reach light at the soil surface, the hypocotyl stops growing and becomes fibrous, drying to a stemlike tissue as the plant ages. Meanwhile, buds on the central axis in the axel of the cotyledons initiate growth to form the cotyledonary lateral branches. The main axis (epicotyl) continues to grow, as do the taproot and secondary root. Two main differences develop at this point to distinguish the two subspecies – *A. hypogaea* ssp. *hypogaea* and *A. hypogaea* ssp. *fastigiata*. The *A. hypogaea* ssp. *hypogaea* will not produce inflorescences on the main axis and the first one to three, usually two, nodes of each cotyledonary lateral will not have inflorescences either. However, subsequently vegetative (V) and reproductive (R) nodes will occur 2×2, in alternating fashion. In *A. hypogaea* ssp. *fastigiata*, nodes of the central axis will/may exhibit inflorescences, and each node of lateral branches will/may also have inflorescences, referred to as sequential branching. Generally, the main axis of *A. hypogaea* ssp. *hypogaea* is relatively short, and those of *A. hypogaea* ssp. *fastigiata* are taller. These branching patterns hold true in primitive germplasm collected in South America, but in modern cultivars that have been intercrossed between the two subspecies, the branching pattern is less consistent.

Inflorescences are generally reduced to less than 2–3 mm in length and under some environmental conditions may grow to as long as 200 mm. Also, some *A. hypogaea* ssp. *fastigiata* types have inflorescences that are 40–70 mm. The number of flowers in an inflorescence varies from four to an observed thirteen.

Flowers are typically papilionaceous, with a calyx tube that varies in length due to genetics and environment (temperature); two calyx bracts, one axial and one abaxial (front and back); a large standard petal and two wing petals on either side of the keel petal that encloses the stigma; and the nine or ten anthers. The anthers are of four types: two sterile, three larger oblong biloculate, one oblong uniloculate, and three or four globose, like a ball on a stick.

The ovary is at the base of the calyx tube on the inflorescence in the leaf axil and has ovules that develop a typical *Polygonum*-type embryo sac containing two polar nuclei, three antipodal nuclei, two synergids, and the egg nucleus. The difference for the peanut ovary is that it can contain multiple ovules. In most modern cultivars, the most common is two or three, but in primitive germplasm, the range is from one to seven ovules per ovary, the larger numbers occurring in the *A. hypogaea* ssp. *fastigiata*. If fertilization is withheld or incompatible pollen is applied, the sexual apparatus degenerates, and apomictic embryo sacs have been observed and documented, but apomictic reproduction has not been confirmed.

The process of development from flower bud through fertilization, embryo development, fruit development, seed formation, and maturation for the peanut is a bit unusual. As a flower bud develops on an inflorescence the day before the flower becomes mature, the calyx tube initiates growth, raising the bud vertically into the air. This growth accelerates so that by sunrise of the day, when the flower opens and the anthers dehisce, the tube is 40–150 mm long. At anthesis, the filaments are elongating, dispersing the pollen the length of the stigma where the pollen grains will germinate and grow down through the style to the ovule(s). Fertilization occurs within 6–16 h after dehiscence, and the zygote will divide two or three times but then become dormant. At that time, a meristem at the base of the basal ovule becomes active and begins to divide and grow, forming what is called the peg. The growth of the peg is positively geotropic and, depending upon the distance to the soil, will grow into the soil a few days later, with the ovule(s) and embryo(s) at the tip of the peg. As the peg continues growth into the soil, it will reach a point where the peg tip is in total darkness, and then, the meristem will position the ovule(s) horizontally and cease growing. When the growth of the peg ceases, the embryo becomes active again and growth continues until it becomes a mature seed. Seed growth and maturation will usually take from 70 to 150 days past fertilization of the egg(s).

The harvested seeds have varying lengths of dormancy, from almost none in some *A. hypogaea* ssp. *fastigiata* types to several months in some *A. hypogaea* ssp. *hypogaea* types.

Nutrient and Chemical Properties

Regular peanut consumption has positive impacts on human health. The nutrient composition is presented in Table 1. Dietary intake of peanut seeds provides a significant source of protein, tocopherol (vitamin E), antioxidants, flavonoids, folate, fiber, and edible oil. Flavonoids such as quercetin, kaempferol, and genistein vary significantly among peanut lines. Resveratrol, a phytoalexin, is a powerful antioxidant reported to have anticarcinogenic properties. The resveratrol concentration varies considerably in different peanut products (e.g., roasted, ground, and boiled peanuts). Factors such as agronomic, postharvest conditions and the degree of roasting can influence chemical composition, as well as sensory properties. Therefore, specific

Table 1 Mean concentration of selected nutrients in raw peanuts

Nutrient	*Amount per 100 g*
Water (g)	6.50
Energy (kcal)	567
Protein (g)	25.80
Total lipid (g)	49.24
Carbohydrate (g)	16.13

nutrients in cultivars produced in different environments and processed for an assortment of food products found in the market will vary.

Cultivated peanuts (*A. hypogaea* L.) are important oilseed crops worldwide, because they typically contain 50% oil in the seed. The majority (~80–90%) of the extracted oil is composed of saturated, monounsaturated, and polyunsaturated fats in the form of three primary fatty acids, palmitic (C16:0), oleic (C18:1), and linoleic (C18:2) acids, respectively. The fatty acid composition in the oil extracted from peanuts tends to range between 36% and 80% oleic acid and 2–43% linoleic fatty acid. In general, high-oleic lines are characterized by 74–80% oleic acid (C18:1) and less than 7% linoleic acid (C18:2), whereas normal-oleic peanuts can range from 30% to 60% oleic acid and greater than 10% linoleic acid. In normal-oleic peanuts, the fatty acid composition can vary, depending on genotype, seed maturity, and environmental conditions such as time of year planted, seasonal variation, insect damage, and soil conditions.

The flavor, stability, shelf life, and nutritional quality of peanuts and peanut products are dependent on the fatty acid composition (ratio of saturated, monounsaturated, and polyunsaturated lipids) of the extracted oil. Unsaturated fats, especially polyunsaturated fats, are prone to oxidation over time, leading to the production of aldehydes, ketones, and hydrocarbons with noxious odors and off-flavors in stored peanut products. Peanuts that have a high percentage of oleic acid (monounsaturated Ω-9 fatty acid) and a low percentage of linoleic acid (polyunsaturated Ω-6 fatty acid) in the oil are less susceptible to rancidification, which results in a longer shelf life for stored food products. Therefore, an emphasis from manufacturers and consumers has been placed on breeding peanuts with high oleic acid and low linoleic acid.

Due to the efforts of the peanut breeding program in Florida in the 1980s, the first high-oleic peanuts F435-2-1 and F435-2-2 were identified having oleic levels (~80%) comparable to that found in olive oil (*Olea europaea* L.), and since its discovery, the majority of high-oleic peanut cultivars have been derived from F435 or F435. Studies following the discovery of the F435 high-oleic peanut established that the trait segregated in either a digenic (15:1) or a monogenic (3:1) fashion-dependent on the normal-oleic parental genotype (ol1ol1Ol2Ol2 or Ol1Ol1Ol2Ol2). In most normal-oleic US Runner- and Virginia-type cultivars (predominantly *A. hypogaea* subsp. *hypogaea* var. *hypogaea*), one of the mutant alleles, ahFAD2A, is often fixed in the homozygous state, so that the high-oleic characteristic behaves as if controlled by a single gene pair. Although numerous high-oleic cultivars have been developed whose pedigrees include F435 as the high-oleic donor, elite high-oleic cultivars are still needed to thwart disease and abiotic challenges that exist in different environments. Due to shelf life stability and health benefits, some countries (i.e., Australia, Argentina, South Africa, and Israel) are mostly or solely producing high-oleic peanut products for consumption. Breeding multiple traits of interest, such as disease resistance and other quality traits, into high-oleic cultivars can be time-consuming due to the generation time, phenotyping for the traits of interest, and maintenance of large populations that are needed to obtain desired trait stacking. This can potentially be overcome by selecting lines with the desired genotypes at key loci by using molecular markers, a process known as marker-assisted selection (MAS). MAS has been effectively utilized to select high-oleic lines in large peanut populations.

Nutrient Availability and Absorption

Lipids within peanuts are aggregated in globules that are contained within the cellular matrix of the parenchyma. To fully access this lipid (i.e., emulsify and transport it from the intestinal lumen into the enterocyte), the cell walls must be disrupted. These structural elements are resistant to enzymatic and microbial degradation in the human gastrointestinal tract. Thus, mechanical destruction by chewing is an important process to access the cellular lipid. The availability of other components, especially fat-soluble nutrients, would be similarly affected.

In part because chewing is not thorough, absorption of lipids from whole peanuts is incomplete. The analysis of fecal fat and energy reveals both are elevated when whole peanuts are incorporated into the diet, relative to fecal losses with a comparable diet containing no peanuts. Additionally, the energy and fat loss is greater compared to when peanut oil, flour, or butter is consumed. Fecal fat increases by just over 5% with whole peanuts and is elevated by 3–4% with peanut butter, oil, and flour. This is associated with an increase in fat loss of just over 5.0 kcal g^{-1} for whole peanuts and 4.4 kcal g^{-1} for peanut butter and products (oil and flour). There is a daily energy loss of about 37 kcal day^{-1} with whole peanuts, 19 kcal day^{-1} with butter and oil, and 1–2 kcal day^{-1} loss with flour. The fat loss represents just over 50% of the energy loss, suggesting losses of carbohydrate and protein also occur. With very high intake of peanuts, fat losses may be greater. In one trial providing peanuts at a level that provided 95% of dietary fat energy, the percent daily dietary fat excretion approached 18%, with values for butter and oil at 7% and 4.5%, respectively.

The composition of the diet excluding peanuts also influences the energy absorbed from the peanuts. High fiber content reduces energy absorption, because the fiber binds with fatty acids in the intestinal lumen, leading to increased

excretion. In one trial, the increment in fat excretion amounted to 1% with whole peanuts, 2.8% with peanut butter, and 2.7% with peanut oil. The food matrix in which peanuts may be embedded also modifies chewing behavior, which alters the distribution of resulting peanut particle sizes and, as a result, lipid bioaccessibility.

Processing of peanuts may alter the energy yield as well. Roasting makes the peanut more brittle, so when chewed, it will be more likely to fracture into smaller particles. This would be expected to enhance the efficiency of energy and nutrient absorption. However, roasting also alters sensory properties, and in one trial, this led to reduced chewing and larger particle sizes in the bolus about to be swallowed. Flavors added to peanuts (e.g., salt, sugar, and spices) alter the palatability of peanuts and modify oral processing time and effort as well. The addition of salt and a sweetener (honey-roasted) may reduce chewing time, resulting in larger particle sizes before swallowing. Collectively, it is clear that processing practices differentially alter energy availability from peanuts, but data are too incomplete to predict the net effect of these multiple influences.

Metabolism

Incorporation of peanuts in the diet may increase energy expenditure. This does not occur via increased physical activity or an increase in the thermogenic effect of feeding, the energy required to digest and utilize food energy. Rather, they appear to increase resting energy expenditure. Daily consumption of peanuts (500 kcal day^{-1}) for 19 weeks raised resting energy expenditure 11% in one study. Another trial reported that daily consumption of peanut oil in a shake that provided 30% of daily energy requirements led to a 5% increase in resting energy expenditure among overweight individuals, but not lean individuals. The increment was 11% among males. While the increment in resting energy expenditure is small, because this component accounts for approximately 75% of daily expenditure, small changes are of potential importance. A mechanism for this effect has not been identified.

There are data, not uncontested, indicating that there is a hierarchy wherein unsaturated fat is preferentially oxidized relative to saturated fats. An early study noted greater satiation effects with polyunsaturated fats than with other types of fats. This prompted speculation that the rapid oxidation of unsaturated fats generates a satiation signal. Because peanuts are a rich source of both poly- and monounsaturated fatty acids, it was hypothesized that this would contribute to their high satiety value. However, this has not been substantiated. At present, the satiety value of peanuts is attributed to the synergy between its chemical and physical components.

Impact on Appetite and Obesity

Epidemiological data generally reveal an inverse association between nut consumption and BMI or body weight. Often, the peanut contribution to these findings cannot be determined. Studies measuring the effect of including peanuts as part of a moderate-fat diet for the purpose of weight loss report similar weight declines between individuals consuming peanuts and moderately reducing fat intake and those who reduce dietary fat intake to a greater degree, but did not include peanuts in the diet. The peanut consumers also had improved blood lipid profiles, while less robust declines were noted in the group not consuming peanuts.

Because snacking is a large portion of energy intake in the United States and elsewhere and peanuts are frequently consumed as snacks, it is important to determine their influence on energy intake and body weight when eaten in this manner. The limited available data indicate peanuts consumed as a snack do not have any differential impact on appetitive ratings and energy intake when compared to peanuts ingested as part of a meal. However, they tend to promote more precise dietary compensation when consumed as a snack. That is, individuals eat somewhat less energy over the day when peanuts are consumed as a snack compared to when they are included as part of a meal. Compensation scores of approximately 50% are reported when peanuts are consumed with a lunch meal, whereas this improves to 74% when peanuts are eaten as an afternoon snack.

Strong dietary compensation is also observed when peanuts are provided with no dietary recommendation about when they are to be consumed during the day. In one trial, participants given approximately 500 kcal day^{-1} peanuts compensated for two-thirds of the energy the nuts provided. That is, when peanuts were incorporated into the diet, roughly 330 kcal of the usual intake was omitted. Due to this compensation, weight gain was minimal. A weight gain of 1.0 kg was observed, while the predicted gain was 3.6 kg. Other studies have reported dietary compensation values ranging from roughly 50% to greater than 100%. Peanut oil alone elicits a weaker, yet still significant, effect on compensation. Approximately 46% of its energy was offset by reduced intake at later eating occasions. Thus, other components of the whole nut contribute to the compensatory dietary response.

The high satiety value of peanuts is likely attributable to multiple properties. They are high in fiber, which enhances satiety by multiple mechanisms including activation of stretch receptors by augmenting gastric distention and slowing gastrointestinal transit. Peanuts are also a good source of protein and fat, and these nutrients stimulate the release of gut peptides associated with satiation. Additionally, as a solid food, peanuts require greater masticatory effort, which may contribute to satiety.

Collectively, consumption of peanuts in moderation does not have a major impact on energy balance and thus weight gain due to three main factors: Approximately 55–75% of energy from nuts is offset in the diet by reduction of energy intake of other foods after peanut consumption, another 10–15% of the energy contained in peanuts is excreted in the feces due to its low bioaccessibility, and approximately 10% of their energy is hypothesized to be lost as a result of increases in resting energy exposure following frequent peanut consumption.

Impact on Glucose Regulation

Peanut consumption may help to moderate blood sugar concentrations and reduce the risk of developing type 2 diabetes.

Individuals consuming five or more combined servings of peanuts and tree nuts per week reduced their risk for developing diabetes by 27%, and those consuming the equivalent amount of peanut butter had a reduction of 21%. The moderating effect of whole peanut and especially peanut butter consumption on glycemia was recently documented in a trial demonstrating that the inclusion of peanut butter in a high-glycemic-index breakfast meal significantly reduced the excursion of blood sugar after the morning and midday meals relative to the breakfast without added peanut butter. The effects were of slightly lower magnitude with whole peanuts, but consistent with responses to the peanut butter. Over the approximately 8 h study period, the incremental area under the blood glucose curve was 18.7% and 14.4% lower for the peanut butter and whole peanut treatments compared to the breakfast without peanuts.

The components of peanuts responsible for the glycemia-moderating effects have not been established but are hypothesized to include their high total lipid, unsaturated lipid, protein, fiber, and phytochemical contents. All could slow gastric emptying of carbohydrate and its rise in the circulation. Additionally, peanut products in the intestinal lumen may stimulate the release of gut peptides such as GLP-1 with incretin effects; that is, they enhance insulin release and activity. Likely because the lipid and other nutrient contents of whole peanuts are not fully bioaccessible, ground peanut (butter) shows even greater effects on glycemic control than whole nuts. Studies with mixed nuts, though not including peanuts, eaten with meals indicate the reduction of glycemia is dose-dependent and occurs in normoglycemic and diabetic individuals.

Impact on Cardiovascular Health

Because cardiovascular disease is the leading cause of death in developed countries and will be in developing countries in the next few decades, the benefits of nut consumption on the cardiovascular system have been well studied in both epidemiological and interventional studies. Epidemiological evidence consistently reveals that individuals with the highest mixed nut intake have a roughly 35% reduced risk of coronary heart disease as a result of improved blood lipid profiles and vascular reactivity. The contribution of each nut type in such studies is difficult to ascertain; however, an independent effect of peanuts has been demonstrated. Increasing peanut consumption was associated with reduced risk of coronary heart disease in women enrolled in the Nurses' Health Study. Participants consuming peanuts at least twice a week were 43% less likely to develop heart disease. Trends linking intake of other nuts with a decreased incidence of heart disease were less robust when peanut consumption was removed from analyses.

In an 8-week free-feeding intervention trial, serum triacylglycerol concentrations decreased by up to 20% in healthy participants consuming 500 kcal of peanuts daily; total cholesterol in the same study decreased by 7.2%. Other studies report lower, but significant, decreases in serum triacylglycerol concentrations, for example, 13%. Another study, comparing the health effects of daily consumption of peanuts in various physical forms over 4 weeks, revealed a significant increase in high-density lipoprotein (HDL) cholesterol, from 530 mg l^{-1} at baseline to 560 mg l^{-1} across the peanut forms. This study also noted that individuals with initially elevated cholesterol concentrations had significantly greater decreases in serum low-density lipoprotein (LDL) cholesterol and total cholesterol than individuals with lower resting concentrations.

The component of peanuts responsible for lipid lowering is not well characterized. Reductions in LDL cholesterol following frequent peanut consumption are greater than expected given the fatty acid profile of peanuts alone. Trace minerals may contribute to lipid lowering and cardiovascular disease risk. Additionally, peanut consumption increases dietary intake of magnesium, folate, alpha-tocopherol, and copper, all of which have been associated with a decreased risk of cardiovascular disease. In particular, alpha-tocopherol is thought to act as an antioxidant that can inhibit the oxidation of LDL cholesterol and thereby mitigate its promotion of atherosclerosis. Folate reduces homocysteine levels, a risk factor for coronary heart disease. Magnesium is required for lipase activity, promoting lipid clearance from the circulation, and it helps reduce platelet aggregation. Copper can prevent lipoprotein oxidation and maintain enzymes crucial for preventing free radical formation in the circulation.

Recent work indicates that daily consumption of peanuts may also lead to a decrease in blood pressure. In a 12-week intervention where participants consumed 42 g of peanuts daily, diastolic blood pressure decreased by approximately 2.0 mmHg. The proposed mechanism of blood pressure reduction with peanut consumption draws on their high arginine content. Arginine promotes increased circulating levels of nitric oxide, and this relaxes smooth muscle and improves blood flow.

Peanut Flavor

Realization of the health benefits attributed to peanuts requires their regular consumption. Implementing such a dietary change is potentially problematic as regular consumption of a single food may lead to monotony and rejection of the item. To combat this problem, peanuts are marketed in a variety of flavors (e.g., salted, honey-roasted, and spicy). Recent work indicates that the palatability of peanuts offered as either a single flavor or varied flavors is well maintained over a 12-week period. Further, the health benefits were not compromised by the addition of the flavors. Concerns have been expressed that the addition of salt may exacerbate hypertension, sugar can contribute to wider swings of blood sugar and contribute to obesity or diabetes, and spices may enhance stress responses. However, no such adverse effects have been documented. Indeed, as noted earlier, blood pressure was significantly reduced after 12 weeks of peanut consumption, regardless of the addition of salt or other flavorings to the peanuts. The absence of deleterious health effects is likely attributable to the low concentration of flavor ingredients actually added to the peanuts. Because they are on the surface of the nut, they have a strong sensory impact, so small quantities can impart strong flavor sensations.

Peas and Lentils

AM Ramírez Ojeda, Universidad de Córdoba, Córdoba, Spain

Introduction

Legumes are a food group consisting of nearly 19 000 species consumed by both humans and animals due to their low cost, high protein contents, complex polysaccharides, and minerals. However, legumes also contain other substances that may lower its nutritional value, such as enzyme inhibitors, oxalates, phytates, and polyphenols. Mediterranean countries in particular are noted for their high consumption of legumes in the form of beans, chickpeas, peas, and lentils, usually available in two forms – dry and overcooked. Furthermore, lentils in particular are highly valued in the countries of Southern Europe. All varieties that are grown and produced in these countries are of the species *Lens esculenta*.

About a third of the lentils produced worldwide is in India and consumed in the Indian domestic market. The biggest consumers are in Asia, North Africa, Western Europe, and parts of Latin America. Canada is the largest exporter of lentils in the Americas, with the main production region being Saskatchewan. The Palouse region of Eastern Washington and the Idaho Panhandle region, with their collective commercial center in Pullman (WA), constitute the largest lentil-producing region of the United States. Algeria and Egypt are the largest importers of lentils, followed by Bangladesh, Sri Lanka, India, and Pakistan. In Europe, the largest importers are Spain, France, Italy, and Germany. Finally, in Latin America, the countries of the Andean Community and Brazil all imported about 140 000 tonnes of lentils.

The FAO reported the world production of lentils in 2008 at 3.874 million tonnes, with the largest producer being India (with 29.0% of global production), followed by Canada (24.5%), Turkey (14.5%), Australia (5.7%), the United States (4%), and China (3.9%), together accounting for 81% of the global production of lentils. The National Agricultural Statistics Service (NASS) reported that in 2007, US production was 154 500 tonnes in North Dakota, Montana, Washington, and Idaho combined. Canada estimated its 2009–10 production to be a record 1.5 million tonnes.

In the case of peas, they are produced in almost every country in the world. Canada is the largest producer (about 25% of total world production) and the main exporter (40% of total world exports) of dry peas in the world. More than half of all Canadian pea production is exported as seed without subject to any processing. About 10% of the peas produced are used as seed for crops. Whole and cracked seeds are also used for stews and soups and as canned food. The cover is added to breads rich in fiber; however, most peas become animal feed. The largest use of dried peas in Europe and North America is in the food industry, where whole seeds are ground and mixed with cereal flours to produce food products. The main use of peas in Asia and South America is for human consumption, where the whole or cracked seeds are first boiled and then eaten.

Carbohydrates

The concentrations of total carbohydrates found in lentil flour and pea flour are between 625 and 657 mg g^{-1} dry matter with a higher concentration in peas than in lentils. Among these carbohydrates, starch stands out as the major component, with percentages of between 59.1% and 53.6%, respectively, of the total carbohydrate content. However, the digestibility of this starch is affected by many factors and is generally low. Among these factors, we can include firstly granule size, which is mainly defined by the relationship between the surface area and volume. As the grain size increases, the contact between the substrate and amylases decreases and thereby the rate of enzymatic digestibility ($r = 0.791$, $p < 0.05$). This result is consistent with the fact that peas, with an average granule size of about 20 μm, present a lower digestibility than lentils with starch granule diameters of about 17.5 μm.

A further factor that also influences the digestibility of starch is the degree of crystallization of the granule. Starch consists of amylose chains, a linear polymer made of glucose units linked through α-1,4, and amylopectin chains and a branched polymer consisting of glucose units linked by 1,4 bonds α-bonded to the branching main chain by α-1,6 glycosidic bonds. These chains may be in the amorphous phase or the crystalline phase. The higher the content of amylopectin in the structure of the starch granule, the higher the crystallinity ($r = 0.914$, $p < 0.01$). Similarly, the presence of amylose reduces this crystallization degree ($r = 0.775$, $p < 0.05$). It is expected therefore that the existence of a higher crystallinity in starch granules will decrease the rate of enzymatic digestion by hindering access to glycolytic enzyme substrate. Accordingly, several studies have shown an increased presence of amylose in peas and lentils, which justifies its rapid hydrolysis.

This starch digestibility can be improved by cooking treatment. Thus, it has been observed that the digestibility can alternate between 37% and 42% in the case of raw legumes, 70–77% for the standard cooked variation (100 °C for 90 min), and even 87–91% with autoclaving at 121 °C for 10 min. However, it is not apparent that increasing the cooking time leads to enhanced starch digestibility. This improvement in the digestibility of starch could be attributed to hydrolysis as a result of heat treatment and the destruction and removal of antinutritional substances, such as phytic acid and tannins, thus creating more space in the matrix, increasing the susceptibility to enzymatic attack. Heat treatment can also decrease the percentage of resistant starch from 2.4% to 1.9% for peas and from 3.3% to 2.5% for lentils. The fraction of starch that is not hydrolyzed by amylases after approximately 2 h resists enzymatic digestion and becomes part of the dietary fiber. Germination treatment can also decrease the resistant starch content by reducing the concentration of α-amylase inhibitors.

Fiber

Dietary fiber is a concept widely used to refer to a complex mixture of indigestible polysaccharides including cellulose, hemicelluloses, oligosaccharides, pectins, gums, waxes, and lignin commonly found in the cell walls of plant cells. The properties of dietary fiber in relation to human nutrition are associated with distinct physiological responses including viscosity, water-holding capacity, fermentability, bulk, and the ability to bind bile acids.

Dietary fiber can be classified into two groups based on solubility in a pH-controlled enzyme solution, each one with distinct physiological properties and nutritional benefits. Insoluble fiber is mainly related to intestinal transit, thereby improving laxation. In addition to this, insoluble fiber is fermented in the large intestine by promoting the growth of flora in the intestine (prebiotic effect). The formation of short-chain fatty acids originating from the fermentation process can also prevent the development of colon tumor cells. Moreover, the soluble dietary fiber can help to lower blood cholesterol (hypocholesterolemic effect) and regulate blood glucose levels. Several human studies have shown that the inclusion of pea fibers can decrease blood glucose peak. Pea fibers have been also used in the treatment of hypercholesterolemic patients.

The total dietary fiber content ranges between 180 and 350 g kg^{-1} for peas and 90 and 300 g kg^{-1} for lentils. Within this content, the highest percentage is represented by the insoluble fraction (about 70% of total dietary fiber) comprising cellulosic glucose, poor lignin, and xyloglucans (predominant hemicelluloses in dicotyledonous plants). Arabinoses (also known as rich pectins) are abundant in the soluble group of dietary fibers.

Another important group of compounds of dietary fiber also found in significant concentrations in lentils, peas, and other pulses is α-galactooligosaccharides, also known as the raffinose family oligosaccharides.

Finally, with regard to simple carbohydrates, the following sugars have been identified in the flour of lentils and peas: monosaccharides (0.085–0.124 fructose, 0.042 glucose, and mainly 0.722 galactose and 0.305–0.521 ribose g/100 g) and disaccharides (0.647–0.697 sucrose, 0.039–0.191 maltose and 0.159 melibiose g/100 g). Saccharose concentrations were also analyzed with results between 20.8 and 31.9 mg g^{-1} in dry matter. Also found in oligosaccharides is alpha-galactoside and within this, the family of rafinosas. But in this last group, the links between monosaccharides are produced by links α -1,2, which cannot be digested by humans, becoming part of dietary fiber as discussed in the succeeding text.

These carbohydrates are characterized by intestinal gas production in humans, that is, cause flatulence consumption, because the gastrointestinal tract does not synthesize α-galactosidase, the enzyme acting on these oligosaccharides. High concentrations of raffinose, stachyose, and verbascose were found in raw lentils (RL).

Processed lentils and peas can reduce the concentration of these oligosaccharides responsible for flatulence. Soaking them for 3–12 h can show reductions of up to 75% of content. Thus, it appears as if soaking can reduce the raffinose family oligosaccharides and ciceritol by 75% in cooked lentils and peas soaked for 3–12 h. Furthermore, cooking also reduces levels of saccharose, raffinose, and stachyose. Germination can also cause a decrease in these substances that results in an increase in the activity of alpha-galactosidase. It has been shown that an addition of commercial α-galactosidase enzyme or endogenous action to pea flour and lentil flour reduces the same raffinose, stachyose, and verbascose substantially (from 41% to 100%), as well as ciceritol in lentils.

It has also been shown that both culture and the environment have an effect on the sugar content of lentil seeds. Thus, different concentrations of raffinose family oligosaccharides between cultivars may be due to differences between biosynthetic enzyme and raffinose family oligosaccharides. However, there is so far no comparative study. It has been observed that the total concentration of lentil-cultured raffinose family oligosaccharides may also vary according to different environmental conditions. According to the results shown, it can be ascertained that lentils, which receive less precipitation, show higher content of raffinose family oligosaccharides compared with those who received more precipitation in their environment. However, no conclusive correlation between the surface area in which they were grown and the concentration of raffinose family oligosaccharides was obtained.

Proteins

Legumes have a high protein content, with lentils recording between 22% and 31% and peas between 26% and 32% (expressed as dry matter). Yet, despite this high protein content, its quality is not as high as proteins of animal origin. It should be noted that there are factors that influence the lower digestibility of these proteins, such as the presence of protease inhibitors and very compact quaternary structures, which make difficult the action of enzymes. Similarly, some authors observe the existence of noncovalent interactions or disulfide bonds between the proteins as being associated with the fraction of insoluble dietary fiber.

Another factor that affects the quality of protein in peas and lentils is their deficiency in many essential amino acids. With regard to the content of amino acids, it has been found that RL and peas are rich in aspartic acid, glutamic acid, asparagine, and arginine. However, as with other legumes, they are deficient in sulfuric amino acids, such as methionine, cysteine, and tryptophan. Therefore, the combination of vegetables (which contain a high proportion of lysine compared with cereals) and foods rich in sulfuric amino acid, such as cereals, is a common practice that provides all essential amino acids. This combination increases the nutritional quality of protein available so that it is similar to the values found in animal proteins.

As is the case for starch, the nutritional value of these proteins can also be increased during culinary preparation, because protease inhibitors are inactivated by heat and other structural changes occurring that facilitate access to the enzymes, thus promoting digestive absorption of proteolysis and nitrogen compounds.

Germination treatment may also increase the protein content of free amino acids depending on the circumstances in which it is conducted. With respect to lentils, it has been observed that in the presence of light during germination, higher amounts of free amino acids and protein–protein

amino acids may occur (with some exceptions), which would not be found if germinated in darkness. However, in peas, the opposite effect has been observed. It has also been found that germination time affects the content of free amino acid proteins in legumes differently. Thus, a study shows that in lentils, germination time primarily increases the content of serine, asparagine, glycine, threonine, proline, and valine. In peas, the amino acid contents that are increased over time are proline, histidine, and tyrosine. In both peas and legumes, the content of other amino acids, such as lysine, over time decreases during germination, in both the presence and the absence of light. These changes in the amino acid content during germination could be related to the hydrolysis of proteins, synthesis, and reorganization.

Germination involves the mobilization of reserves of protein in the cotyledons, along with the synthesis of new proteins for shoot growth. The new proteins can be composed of various amino acids stored in protein, altering the amino acid content pattern with respect to the raw legume. Furthermore, amino acids produced by the hydrolysis of protein reserves are not only used exclusively for the synthesis of new components but also used as an energy source, especially in the early stages of germination.

Furthermore, the results indicate that bleaching, sterilization, and storage of peas show no effects on the protein content, compared with that of fresh peas. Nor are losses observed in the total protein content in bottled or canned peas stored under different conditions (10 °C and room temperature) for a period of 6 months. However, a slight variation is produced in the total amino acid in legumes. The results suggest that Maillard reactions or other reactions occurred, including hydroperoxides formed from occurring unsaturated fats.

Lipids

As with many plant foods, lentils and peas have a low fat content ranging from 0.7% to 6.1%. When it comes to the lipid profile of RL, mono- and polyunsaturated fatty acids – unsaturated oleic, linoleic, and linolenic – stand out at a rate of about 20%, 38%, and 7%, respectively, compared with the total of fatty acids. The contents of saturated fatty acids, more atherogenic potential, are about 0.5%, 18%, and 2% for myristic, palmitic, and stearic fatty acids, respectively. Similarly, a fatty acid profile present in raw peas has a content of 13% oleic acid, 35% linoleic acid, and 5.5% linolenic acid. The percentage of saturated fatty acids is approximately 22%, highlighting palmitic acid (14%). In the case of canned peas, with a heat treatment applied prior to being cooked, linoleic acid remains the principal fatty acid.

In some varieties of peas, it has been observed that this fatty acid profile may vary depending on the size of the seed. In the early stages of growth (peas with a size of between 4.7–7.5 mm and 7.6–8.2 mm), the ratio of unsaturated to saturated fatty acids increases slightly due to a series of changes in enzyme systems involved in the biosynthesis of fatty acids. Afterward (pea size of 8.3–8.8 mm), this ratio stabilizes and finishes by declining sharply in the final stage (pea size of 8.9–10.2 mm). Accordingly, some industries order these peas for the manufacture of flours, as this latter size would be the required size in order to decrease the susceptibility to autoxidative deterioration.

The content of fatty acids increases during storage because of the lipolysis of triglycerides, polar lipids, and sterol esters, although a higher temperature of storage favors all these processes. It has been observed in red lentils that the percentage of free fatty acids can reach up to six times its original levels within 16 weeks at a storage temperature of 40 °C, while storage temperatures at 10 or 20 °C show no increase in fatty acids. Meanwhile, the moisture content of lentils also influences this lipolysis of fat as a decrease of moisture content from 17.5% to 12.5% increases the content of free fatty acids by a factor of 3, rather than 6 at 40 °C. Furthermore, the material in which they are packaged also changes the conditions of all these aforementioned processes. When packaged in glass jars, the concentration of free fatty acids is significantly higher than in a container of lacquered tinplate. While this influence of packing material has not been sufficiently studied, it is possible that the transparent nature of the glass containers favors the action of light on lipolysis from fat.

Trace Elements

Many legumes, such as lentils and peas, have relatively high levels of phosphorus, magnesium, iron, zinc, and copper. However, the mineral bioavailability of pulses is generally poor, as a result of its low digestibility, high content in dietary fiber, or antinutritional components, such as phytic acid, oxalates, and polyphenols, all of which can interfere with mineral absorption. Thus, an *in vitro* study to determine mineral bioaccessibility, using a simulated gastrointestinal tract, found iron dialyzability percentages of 2.6% for chickpeas and lentils. In the case of zinc, zinc dialyzability percentages were better, being 32.2% and 48.5% for chickpeas and lentils, respectively.

Phytate is the major storage form of phosphorus in legumes. The inhibitory effect of phytate on the absorption of minerals in the small intestine is due to the formation of insoluble mineral–phytate complexes. It has been found that phytate concentrations ranged between 0.06 and 0.33 g per 100 g for peas and between 0.08 and 0.30 g per 100 g for lentils, which causes high content but is still however lower than those found in beans (between 0.34 and 0.58 g per 100 g). However, the negative effect of phytic acid on mineral bioavailability depends on the amount of phytic acid present in the legume as a molar ratio of phytate/mineral. Phytate/zinc molar ratios below 5 are designated as high zinc availability, ratios within the range of 5–15 as moderate availability, and ratios above 15 as low availability. In the case of iron, phytate/iron molar ratios are recommended as being lower than 1 for good bioavailability. A phytate/mineral molar ratio for zinc and iron of around 18 and 2.1 in lentils and 22 and 6.5 in peas, respectively, has been reported, which is in accordance with the low rates of mineral bioavailability found in these legumes.

Oxalate salts are very insoluble at intestinal pH, and it has been widely documented that oxalic acid decreases the absorption of minerals in monogastric animals. The oxalate content of cooked peas ranged between 6 and 4 g per 100 g and in

lentils, around 8 g per 100 g. Although the concentration of antinutritional substances is again lower than those determined in other legumes such as beans (85–26 g per 100 g), also, it is expected that this oxalate content affects the decrease in its bioaccessibility in the intestinal lumen.

Peas and lentils are also rich sources of polyphenols – natural antioxidants that can replace synthetic antioxidants used in food. It has been observed that the seed coat of lentils has a higher content of flavonoid compounds than cotyledon that is primarily rich in nonflavonoid compounds. The ability of the polyphenols to decrease mineral bioavailability has been studied mainly with regard to iron and calcium. It has been observed, however, that not all polyphenols have the same capacity to reduce mineral absorption. Thus, several studies suggest that flavonoids and their polymers do not interfere with iron absorption in humans, whereas polyphenols with a high galloyl ester content exhibit a potent inhibitory effect. In this sense, it can be seen that these areas of study need to be further researched.

Different studies have evaluated the effect of a series of treatments such as soaking, cooking, extrusion, and germination to reduce the inhibitory capacity of phytic acid, oxalate, and polyphenols on mineral bioavailability. These treatments can promote or inhibit the development of phytases, significantly affecting the hydrolysis of phytic acid.

One study shows that during the soaking, all phenolic components identified in peas and lentils decrease drastically. This decrease was due to leaching of water-soluble phenols into the soaking water. Likewise, traditional cooking of lentils (cooking by boiling (the ordinary method)) can reduce the concentration of tannins and phytic acid by up to 25%. Cooking lentils in the autoclave results in a reduction of 33–46% for tannins and 28–52% for phytic acids, with losses increasing in line with increased cooking time (10–90 min) and increases in temperature (121–128 °C). Meanwhile, the germination of lentils and peas increases the activity of endogenous enzymes (such as hydrolases, polyphenol oxidases, and phytases) resulting in a reduction of phenolic compounds and degradation of phytic acid forms with a lower content of phosphate groups, as inositol tri- and tetraphosphates with less chelating ability. Various *in vitro* and *in vivo* studies show that these treatments improve the mineral bioavailability of these legumes.

Phytic acid can also be reduced by endogenous phytase activity, which works by breaking inositol hexaphosphate into different forms that possess less mineral chelating ability, thus leading to an increase in iron dialyzability resulting from this enzymatic dephytinization in lentils. Similar results were found for pea flour, with enhanced iron absorption after treatment with exogenous microbial phytase, leading to inositol hexaphosphate levels below those reported by other authors.

A study using an exogenous microbial phytase in optimum conditions (pH 5.5 and 37 °C) shows dephytinization and subsequent removal in the soaking solution after transformation and the effect on iron bioavailability meal in pea (*Pisum sativum* L.). This experiment was conducted on rats by examining the chemical composition of pea flour and the digestive and metabolic utilization of the mineral mentioned.

The rats were fed with three types of diets: raw pea meal, raw pea meal that underwent soaking treatment without phytase, and raw pea meal that underwent soaking treatment with phytase.

Soaking pea flour leads to a considerable reduction in the iron content (33%), while a smaller reduction in the iron content (7%) is observed, associated with a higher total phosphorus concentration that is obtained with an additional phytase treatment. The digestive utilization by growing rats of iron from raw pea meal and soaked peas was negligible but increased significantly as a result of treatment with phytase. The low absorption of iron obtained by the first two dietary treatments during an experimental period of 10 days was not reflected in any hematologic indexes (red cell count, hemoglobin, and hematocrit) or tissues (the femur, heart, and kidney) studied, with the exception being the sternum.

Finally, an *in vivo* study using growing rats observed a significant increase in digestive calcium utilization as a result of lentils being germinated for 6 days.

A total of 40 rats were divided into four groups of ten, and each group was fed with one of the four types of diets: control, diet containing casein (20%) + methionine (0.5%), the tested diet with raw lentils (RL), and diet with dry-heated lentils (HL) and germinated lentils (GL).

It has been reported that diets containing lentils provide a lower quality of the protein casein, due to lentils being deficient in sulfuric amino acids. The macropeptides that may be formed during consumption reduce calcium absorption. Therefore, a low absorption of calcium in sprouted lentils was expected, because the protein quality is lower when compared with RL or HL. However, this increased absorption can be explained due to the possible effects of germination on other factors such as fiber, phytic acid, and oxalic acid.

The results show a drastic drop in hemicellulose. This indicates that it is possible to achieve maximum absorption of calcium when lower hemicellulose content in the diet was found. Also, the content of inositol hexaphosphoric acid or phytic acid (IHP) was decreased compared with HL. It is possible that this decrease plays an important role, since the absorption of calcium in sprouted lentils was 20% higher than in animals fed with RL. Furthermore, rats fed with GL also showed a major transformation of phytic acid. It has been shown that calcium bioavailability is related to the levels of phytic acid. In GL, the transformation of phytic acid increased significantly, which can be translated into a greater total phosphorus content, expressed as a percentage of total phosphorus present as IHP (% IHP-P/total P), following the reduction of 26% of IHP per g of dry matter. Thus, the results show increased calcium absorption in sprouted lentils (value of 82) that had a lower content of IHP, compared with diets of HL.

It has been shown that the Ca/P ratio affects the absorption of Ca. A low Ca/P ratio observed in RL and HL compared with lentils from the control diet can be a cause of the low absorption of calcium (see **Table 1**).

Vitamins

Different literature sources show lentils and peas as good sources of soluble B vitamins, especially niacin and pantothenic acid. However, they are deficient in vitamin C, carotene, and retinol. With respect to folic acid, although readily

occurring in natural sources, the folic acid is not actually available due to binding with other biomolecules to the form complexes.

It has been shown that concentrations of thiamine, riboflavin, and niacin can be more changed during processing than before consumption. Study shows a percentage reduction in the content of thiamine (54–62%) and niacin (25–61%) during soaking and cooking of lentils and peas, with the percentage of losses being greater the higher the rate of hydration.

However, one study shows that germination produces no significant change in the content of thiamine in lentils and peas, while an increase in the content of riboflavin of between 20% and 135% for lentils and from 60% to 166% in peas is observed – possibly due to an increase in microbial activity.

These changes in the vitamin content of these legumes can be explained by several factors. In relation to losses during soaking, these are easily accountable, based on their solubility in water soaking, with the loss being greater the weaker the strength of its link to cell structures. Accordingly, thiamine (consisting of a pyrimidine ring and a thiazole ring interconnected by a methylene bridge) and niacin (in the form of nicotinic acid and/or nicotinamide) are simpler chemical molecules with a higher water solubility than riboflavin – this is associated with complex molecular structures such as flavin mononucleotide and flavin adenine dinucleotide, which account for the lower solubility. Cooking also increases the loss of these water-soluble vitamins as a result of high rates of leaching due to the high cooking temperatures achieved and the increase in levels of sodium ions (see Table 2).

Antinutritional Substances

Despite the potential nutritional value of pulses as a relatively inexpensive source of significant amounts of protein, carbohydrates, vitamins, and minerals, the use of these as a food source has been limited due to the presence of certain antinutritional factors. These include the presence of phytic acid, condensed tannins, and polyphenols, as discussed in the preceding text, plus protease inhibitors (trypsin and chymotrypsin) and α-amylase inhibitors, which reduce the digestibility of proteins and carbohydrates.

Protease Inhibitors

Protease inhibitors have been extensively investigated in legumes, as they may have an important impact on the nutritional value of these pulses. Protease inhibitors may inhibit the function of digestive enzymes, mainly acting on trypsin and chymotrypsin (it may affect other enzymes although to a lesser extent). This results in affecting the digestive utilization of the protein, causing pancreatic hypertrophy, and instigating weight loss and nitrogen removal in feces.

Although the values of trypsin inhibitor activity were observed in both peas and lentils, these are lower than those in other legumes. Thanks to their character, these thermolabile protease inhibitors may be reduced by standard cooking procedures of seeds, such as soaking, or conventional low-pressure cooking. One study shows how the roasting and boiling of flour,

lentils, and peas affect the activity of trypsin inhibitor. The roasting and boiling processes reduced the activity of trypsin inhibitor; a maximum of 95.6% reduction was found in roasted shelled green lentils, while the lowest (37.8%) was found in the flour of boiled shelled yellow peas. The effects of roasting do not significantly differ from those of boiling, except for red lentils with husks, which had the lowest values of trypsin inhibitor activity after roasting compared with those after boiling.

Furthermore, it has been shown that during the soaking process, certain losses are produced in the trypsin inhibitor activity as a result of the leaching process. In soaked peas and lentils, this treatment can produce a reduction of trypsin inhibitor by up to 15.4%. Variations in the percentage of losses of the inhibitor can be attributed to changes in the permeability of the seed shell that allows antinutritional solubilization of this substance in the soaking liquid. Germination for 72 h can also potentially reduce the occurrence of trypsin inhibitor by between 58% and 76%. However, treatment by extrusion processing produces a greater reduction (about 95%).

Inhibitors (α-Amylase)

α-Amylase plays an important role in the metabolism of carbohydrates, by hydrolyzing the type of linkages between monosaccharides and providing glucose as an energy source for humans and animals. It has been shown that the inhibitor reduces α-amylase digestion of starches, thus reducing postprandial glucose, and increases the circulation of insulin. This can be beneficial in treatments for obesity or diabetes mellitus; however, in other cases, it decreases the nutritional and energy values of these foods.

Soaking was observed to have reduced the activity of alpha-amylase inhibitor. This may be due to leaching in the steepwater. Similarly, germination for 72 h was also found to have reduced the activity of α-amylase inhibitor by up to 48%; this reduction may become a complete extrusion treatment.

Pectin and Health

L Wicker, Louisiana State University AgCenter, Baton Rouge, LA, USA; Korea University, Seoul, South Korea
Y Kim, Korea University, Seoul, Korea

Sources and Production

In the food industry, commercial pectin is broadly segregated into high methoxyl, a degree of esterification (DE) greater than 50%, or low methoxyl (LM), a DE of less than 50%, and is typically used as a gelling and stabilizing agent in jams, jellies, preserves, confections, and beverages. In the food science literature, pectin is typically described based on solubility. The high DE pectin is water-soluble; low DE pectin is soluble in chelator-containing extractants (CSP); insoluble pectin, also called protopectin, is soluble in dilute acid, dilute alkali, or more concentrated alkali. The latter is likely to include other cell wall fractions such as hemicellulose and xyloglucans. The commercial pectin extraction and isolation process are often tailored for specific functions in foods and beverages. The main commercial sources of pectin are apple pomace, citrus peel and pulp, and sugar beet pulp, which provide an abundant supply of raw materials as a functional or bioactive ingredient in food. However, pectin is ubiquitous in plant material, and alternative sources with unique functional properties are described in the literature. The heterogeneity of pectin structure *in situ* and the more holistic understanding of structure–function relationships of pectin have led to multifaceted research in the area of pectin and health.

Patterns of Consumption

Conventionally, pectin is consumed as an ingredient in food products, most notably jams, jellies, and preserves. Historically, the commercial value of pectin was based on the 'jelly grade' of pectin and categorized based on the gelling mechanism and on the rate of gel formation from ultrarapid set pectin to slow set pectin. More recently, pectin is fractionated by viscosity, charge, and charge distribution, according to use in specific applications, such as stabilizing acidified dairy drinks, stabilizing colloidal dispersions and emulsions, increasing water-holding capacity in gelled foods like yogurts and sour creams, and controlling ice crystallization in low-fat frozen dairy desserts. Pectin is rich in whole fruits and vegetables and is an excellent source of soluble dietary fiber with health benefits. A diet rich in whole fruit and vegetable foods is rich in health benefits associated with pectin and other bioactive ingredients such as phenolic compounds. As a stabilizer or texturizer in food products, there is not likely to be a sufficient amount of pectin to have a quantifiable health benefit in foods. However, commercially extracted pectin is added to further processed foods, such as baked goods, cereals, and beverages, and can favorably influence health outcomes. Pectin is also used as a dietary supplement and consumed in tablet form or topically added to foods. Despite the known health benefits of consuming fruits and vegetables, consumers do not typically consume the recommended daily servings. Further, food products enriched in added dietary fiber, such as pectin, are not as palatable and often not consumed as an integral part of the healthy diet and healthy lifestyle for many consumers. Developing food products that meet the consumers' criteria of taste, cost, and convenience, and still provide health benefits, remains the food product challenge for favorably influencing the consumption of health-promoting, pectin-rich foods.

Availability, Absorption, and Metabolism

Pectin is a water-soluble fiber and is virtually nondigestible during passage through the upper gastrointestinal (GI) tract. Upon entrance to the colon and the diverse microflora and under the anaerobic conditions, colonic bacteria metabolize pectin to generate microbial by-products, including short-chain fatty acids (SCFAs). Despite the limited metabolism of pectin in the stomach and small intestinal tract, pectin exerts an influential, systemic effect by the interaction with other constituents of food and body fluids. These include lowering of lipid and cholesterol levels, lowering serum glucose and moderating the glycemic index, exerting anticarcinogenic activity, and increasing the viscosity and gut transit time, thereby influencing nutrient absorption and, potentially, satiety. Viscous fibers like pectin may be involved in the cell signaling of gut hormones associated with hunger (ghrelin) or satiety (glucagon-like peptide and peptide YY) and potentially regulate food intake. Because pectin passes the upper GI system virtually intact, there are applications of pectin related to the ability to serve as a delivery vehicle to the colon of nutraceuticals or drugs via emulsions or as hydrogels. Finally, although it is less well documented, pectin binding and delivery of phenolic compounds may have a systemic antioxidant effect and protection until delivery to the colonic bacteria. Dietary fiber is defined in several ways, and the conventional definition is based on the solubility or insolubility in water or digestibility or solubility in detergent containing solvents of different pH. Pectin is a diverse polysaccharide, and health benefits are linked with different structural domains in yet undefined variables. Molecular weight, charge and charge domain, substituent sugars, sugar linkages, and the presence of phenolic compounds influence the digestive fate of pectin and subsequently influence the availability, absorption, and metabolism of other nutrients and body fluids. Linking known health benefits with known structural domains would greatly facilitate the fractionation of pectins tailored for specific health benefits.

Health Effects

Structure of Pectin and Health

Pectin is a complex polysaccharide composed of a backbone of α-1,4 linked D-galacturonic acid units, interrupted α-1-2-L-rhamnose inserts, and neutral sugar side chains. Pectins may also be esterified with the methyl ester at carbon six or

acetylated at positions two or three, and some pectins contain ferulic acid and protein. Pectin is typically classified in domains composed of homogalacturonan (HG), rhamnogalacturonan I (RG-I), rhamnogalacturonan II (RG-II), xylogalacturonan (XG), arabinogalactan I (AGI), and arabinogalactan II (AGII). In some pectins, such as sugar beet pectin, the arabinose and galactose residues may be substituted with ferulic acid, which, in addition to a substantial amount of protein, contributes to the strong emulsifying activity of sugar beet pectin. RG-I is rich in rhamnogalacturonan, which is substituted with neutral sugar side chains of galactosyl and arabinosyl residues, as single units or as polymers of arabinans, AGI, or AGII. Other cell wall proteins are associated with AGII and are known as arabinogalactan proteins. The RG-II region consists of at least 12 different side chains and more than 20 different linkages and is highly conserved. XG is similar to HG except that it is has branches of single xylose or short β-1,4-linked xylose chain. HG is the predominant domain in commercially extracted pectins. Acidic hydrolysis at temperatures near 60–90 °C for times up to 6 h in the commercial extraction process results in pectin rich in polygalacturonic acid of high molecular weight with less substitution of side chains than possible with more gentle extraction techniques. HG is also called the 'smooth region,' due to the fact that it is composed of the simplest α-1,4-galacturonic acid backbone with partial methyl esterification and acetylation but with few neutral sugar side chains attached. With milder extraction conditions, the neutral sugar side chains and diversity of pectin structure are better preserved and are more reflective of pectin structure *in situ*. While the health benefits of pectin and other dietary fibers are well documented with *in vitro* to clinical trials, the exact nature of the health effects are not well defined. A part of the uncertainty is surely related to the heterogeneity of pectin structure within the cell wall architecture of plant material and the further heterogeneity of pectin structure associated with pilot or commercial extraction techniques. Another contribution to the uncertainty is the void of pectin structural information and incomplete methods on sample preparation, such as rehydration, as part of the scientific literature dealing with health and wellness. Future trials on the health effects of pectin that include physicochemical characterization would greatly facilitate the understanding of the mechanism of the beneficial effects of pectin. In addition, knowledge of pectin domains of structure that have beneficial health outcomes would facilitate the development of pectin fractions with specific, tailored functions. In the development of health-promoting, fiber-rich foods, the product developer is limited in the amount of fiber that can be added and still makes a product that does not adversely affect the palatability. If the bioactive domain of pectin can be identified and isolated from the ballast, then potentially more consumer-friendly, fiber-rich foods can be developed (Figure 1).

Pectin as Soluble Fiber

The primary health benefit of pectin is as a source of soluble fiber. Increased fiber consumption is inversely connected to cancer, cardiovascular disease (CVD), type II diabetes, obesity, and other chronic diseases of inflammation. The

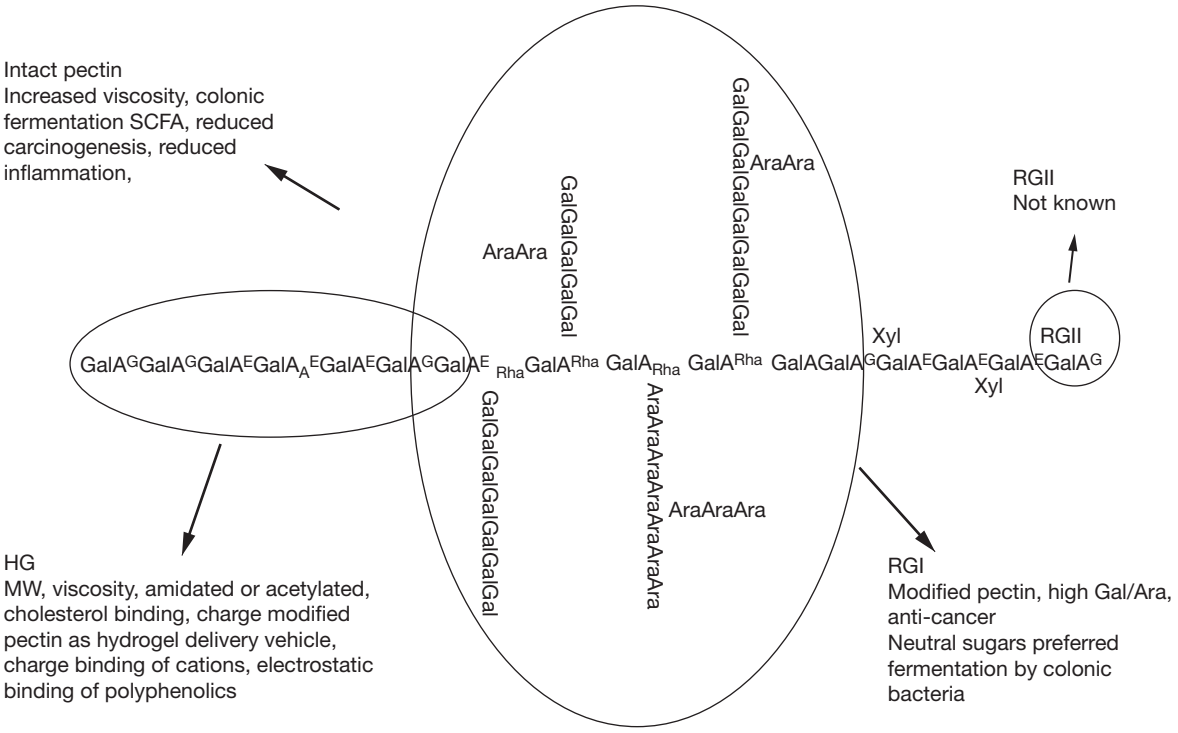

Figure 1 GalA^E and GalA^G and GalA$_A$ refer to esterified, deesterified, and amidated galacturonic acids, respectively. HG refers to the homogalacturonan region. RG-I consists of rhamnogalacturonan backbone with side chains of arabinose, galactose, and other neutral sugars. Only the arabinan and galactan side chains are shown. GalA-Xyl refers to the xylogalacturonan region. RG-II is a highly conserved structure; individual sugars are not shown.

FDA allows two health claims associated with increased fiber consumption. In addition, the health claims for fiber also are dependent on other dietary changes. The FDA recommendation for fiber intake is 25–35 g day^{-1} with 6 g soluble fiber. The health claim associated with anticancer properties also recommends a diet with increased consumption of fruits, vegetables, and whole grains; the health claim associated with decreased CVD has the additional recommendation for a diet low in saturated fat. While soluble fiber, including pectin, is virtually nondigestible in the upper gastrointestinal system, it increases viscosity, increases gut transit time, and influences nutrient absorption in the upper GI. There is some evidence that smaller oligomers of pectin can be absorbed in the small intestine, but the majority of pectin transits to the large intestine for metabolism by the colonic bacteria and production of SCFAs. Additionally, the production of gut hormones and increased satiety by delayed gastric emptying are linked with the increased viscosity of soluble fiber. While pectin and other fiber sources have an associated health claim, it is difficult to elucidate specific bioactivity with specific pectin structures. Pectin itself is a heterogeneous molecule; strong structural information is typically not provided in research studies; isolation processes and subsequent modifications yield unique structures. The next sections deal with pectin's role in preventing cancer and CVD, the impact on fermentation by colonic bacteria, and pectin as a colonic delivery vehicle (Table 1).

Pectin and Cancer

As a soluble fiber source, there are several modes by which pectin influences the development of cancer. The increase in viscosity in the GI system by soluble fiber reduces the contact between the mucosal cells and potential carcinogens. Dietary fiber increases the binding of potential carcinogens and increases the level of antioxidants. The fermentation of dietary fiber in the colon and production of SCFAs have anticarcinogenic properties. Of the studies on dietary fiber and cancer, few deal specifically with pectin to generate significant scientific agreement on efficacy. An exception in the area of pectin and anticancer activity is the binding of pectin to galectins, specifically a prometastatic protein, galectin 3 (GAL3). GAL3 is a small, 30 kD protein, with a carbohydrate recognition domain (CRD) at the C-terminus. It is present extra- and

intracellularly, and its presence on the cell surface and in the cytoplasm or nucleus will vary according to the type and stage of cancer. GAL3 involvement in cancer is multifold and ranges from inhibition of cell death, regulation of cell growth, differentiation and apoptosis, to stabilization of beta-catenin, which promotes cell migration and invasion. Pectin, and specifically modified pectin, binds the CRD domain of GAL3 and inhibits the ability of GAL3 to promote cell aggregation and migration and to prevent apoptosis. Animal and clinical trials have established the efficacy of this modified pectin, and other modified pectins are available commercially. The pectin modification involves chemical treatment that results in the hydrolysis of the pectin backbone to form oligomers, saponification of the methyl ester, and removal of arabinose from the RG-I domain. The likely result is a small oligomer of pectin that can be absorbed in the upper GI tract, with a galactose-rich RG-I domain that recognizes the CRD on GAL3 and prevents the multiplicity of GAL3 involvement in the development and metastases of various cancers.

Pectin and CVD

Risk factors of CVD include high blood serum cholesterol, hypertension, obesity, and type II diabetes. A diet high in dietary fiber is associated with a reduced risk of CVD. Important effects of dietary fiber include increased bile acid excretion and lowering of total and low-density lipoprotein (LDL) cholesterol. The sources of serum cholesterol are *de novo* synthesis and the diet, with the former accounting for about twice the cholesterol contributed by the diet. Cholesterol is removed from the body primarily by excretion, conversion to bile salts, and synthesis of steroid hormones. Dietary fiber reduces blood serum cholesterol by preventing the reabsorption of bile salts into the enterohepatic circulation, by increased excretion, and by inhibition of cholesterol synthesis in the liver by SCFAs, produced from the fermentation of fiber in the colon. The high viscosity in the digestive tract contributed by dietary fiber may influence cholesterol levels in two ways. High viscosity may result in the formation of larger micelles that are not as effectively absorbed. Also, dietary fiber moderates the glycemic response and less insulin is produced. Less available insulin, as an activator of the rate-limiting enzyme in cholesterol synthesis, results in less cholesterol synthesis.

Pectins with different physicochemical characteristics, such as molecular weight and DE, have varying viscosities and charges. The degree of polymerization (DP) of the HG region and the absence of the methyl ester influence the size and charge, respectively. High-molecular-weight pectin is more viscous than low-molecular-weight pectin, and charge modified pectin forms more viscous to gelled systems. The influence on total cholesterol, high-density lipoprotein (HDL) cholesterol, LDL cholesterol, and bile acid binding varies with the type of pectin, suggesting that pectin structure influences the propensity to reduce CVD. Highly charged, LM, viscous pectin had no effect on LDL cholesterol but increased fecal bile acid excretion. Total cholesterol was decreased more effectively by high methoxyl pectin than LM (higher charge) pectin, but neither had an effect on HDL cholesterol or triglycerides. While the beneficial effect of pectin on markers of CVD is well documented, the absence of physicochemical characterization hinders the elucidation of how dietary pectin minimizes CVD.

Most typically, studies that evaluate pectin and cholesterol-lowering effects report at most the manufacturer specifications of molecular weight and DE. However, it is likely that molecular weight, charge domains, and substitutions influence bile acid and cholesterol binding. When pectins with different structural domains were evaluated for the binding of bile acid or cholesterol, the nature of binding seemed to be hydrophobic. The binding of bile acid was more favorable for pectins with a high DP, high methoxyl, or randomly charged pectin and substituted by amidation or acetylation. The hydrophobic nature of the interaction was confirmed by NMR, showing that cholesterol binding to pectin was at ring A of cholesterol at a hydrophobic pocket formed at uronic residues between C-3 and C-5 on pectin chains.

Pectin and Colonic Bacteria

The human gut contains over 10^{14} microorganisms; the beneficial bacteria and those found in healthy individuals include bifidobacteria, lactobacilli, Firmicutes, *Eubacterium*, and Bacteroidetes. The gut microbiome is a dynamic ecosystem, and the disease state, inflammation state, age, weight status, level of physical activity, and diet influence the colonic flora. Diets high in dietary fiber favorably influence the balance of beneficial bacteria and minimize the etiology of pathogens. The pervading role of the gut microflora in chronic diseases of inflammation and the potential to manipulate the gut flora with lifestyle and dietary changes have catalyzed interest in the structure–function relations of dietary fiber, like pectin, and synergism with other food constituents. Notably, the low bioavailability of polyphenolic compounds, like anthocyanins, is incongruent with the favorable effects that are documented in diets that are rich in anthocyanins. Recent research suggests that many of these polyphenolics that bind dietary fibers, including pectin, are protected during passage through the upper gastrointestinal tract and likely enter the colon to provide local and systemic antioxidative and anti-inflammatory effects during transit.

Pectin as a dietary fiber source is metabolized by the gut microflora and the production of SCFAs, such as propionate, butyrate, and acetate. The heterogeneity of pectin that results from source and preparation methods greatly influences the gut microbes and potential health implications. Parent pectin can be subdivided into fractions that are smaller in molecular weight, are charged, are neutral, have varying ratios of galacturonic acid to rhamnose or varying ratios of galacturonic acid to neutral sugars, have varying amounts of ferulic acid or other phenolic compounds, or are modified to be more linear or branched. All are fermentable, but different fractions show different rates of fermentation and stimulate the growth of different bacteria, but not in a systematic way. In some cases, SBP arabinooligosaccharides with degrees of polymerization greater than eight stimulated *Bifidobacterium* spp. but enzyme-treated potato fiber, with MW values greater than 100 kDa, also stimulated *Bifidobacterium* spp. The presence of phenolics, like ferulic acid, and neutral sugar sides seemed to be more closely associated with rapid and complete fermentation than charge or molecular weight.

Pectin as Hydrogel or Emulsion-Based Delivery Vehicles

Pectin has unrealized potential as a delivery vehicle of hydrophilic and hydrophobic bioactives for protected transit through the upper gastrointestinal system and colonic delivery. The highly charged LM pectin forms gels with cations, such as calcium, via the egg-box structure. Pectin methylesterase (PME) deesterifies the pectin methyl ester to carboxylic acid group, and if sufficient total charge or zones of charge are created, the ionized carboxylic acid groups on adjacent chains of pectin form a gel via an egg-box structure. The pattern of deesterification will vary according to extrinsic conditions such as pH, ionic strength, temperature, and type of PME isozymes and result in variations of multichain and multiattack and single-chain and single attack. Modification conditions and source of enzymes influence the pattern of deesterification; fungal PMEs and NaOH saponification tend to yield random patterns, and plant PMEs tend to form blockwise deesterification patterns. The extent and pattern of deesterification influence the total charge and charge distribution, which in turn influence the propensity to gel with cations, such as calcium. Even within pectins that are LM and at a similar total charge, block deesterified pectins show higher encapsulation efficiency and lower release rates under upper GI conditions than commercially prepared, NaOH-saponified pectins. Whether commercial LM or PME-modified pectin is used to encapsulate addenda, results are consistent that addenda are stable against release during transit through the upper gastrointestinal system. Fermentation by colonic bacteria facilitates the release of addenda and influences the gut flora.

Sugar beet pectin, and to a much lesser extent, citrus and apple pectin, has been studied for the emulsifying activity and encapsulation of bioactives. The entrapment of hydrophobic bioactives in an o/w emulsion, stabilized and protected by pectin during gastric transit, offers excellent potential as a delivery vehicle for colonic fermentation that would be superior to any emulsifiers that are small-molecular-weight amphiphiles or any protein-based emulsifier. SBP is unique to other pectins in that it is acetylated, which minimizes the gelling ability but contributes to the hydrophobic nature and thus the amphiphilic nature of SBP. SBP also contains ferulic acid, within the RG-I domain, which may contribute to hydrophobic interactions at the oil surface. In addition, SBP contains up to 15% protein, compared with 1–2% protein in citrus or apple pectin. The emulsifying activity is thought to reside in the protein moiety of SBP, and it remains the most consistent variable associated with emulsifying activity. However, other intrinsic variables, such as molecular weight and neutral sugar side chains, and extrinsic variables, such as pH and type of oil, contribute to the emulsifying activity and subsequent encapsulation of bioactives, in a yet undefined manner.

Conclusions

As a dietary fiber source, pectin serves a critical role in health and wellness. Despite the heterogeneity of pectin structure depending on the source, extraction methods, and use, pectin contributes to health, not only in sustaining health primarily as a dietary fiber but also in treating disease conditions such as cancer or CVD. Much of the beneficial effect of pectin relies on the viscosity and gelling ability of pectin, which is preserved as much as possible by commercial extraction methods. The identification of specific domains of structure that are more favorable to treating cancers and CVDs, minimizing inflammation, and promoting the growth of specific, beneficial bacteria in the colon are emerging areas of high interest. The latter suggests that much of the dietary fiber relies within small structural domains, and the other portions are ballast. Continued research into the structure–function relationships of pectin would facilitate fuller use of the potential of pectin in health.

Pectin: Properties Determination and Uses

B De Cindio, D Gabriele, and FR Lupi, University of Calabria, Arcavacata di Rende (CS), Italy

Introduction

Pectin is generally considered as a safe food ingredient: according to European Union regulation (EC 1333/2008), it may be used under 'quantum satis' conditions, that is, it has to be used at a level not higher than the necessary amount, according to the good manufacturing practice. The US Food and Drug Administration (FDA) recognizes it as GRAS, that is generally regarded as safe; the Joint FAO/WHO Expert Committee on Food Additives (JECFA) attributed to pectin a 'not specified' acceptable daily intake.

Its name comes from the Greek word 'pektos,' which means firm and hard, suggesting pectin's ability to form hydrogels. Pectin properties are strictly related to its microstructure even though this is not yet completely understood. Two main descriptions of pectin structure are currently proposed: The first one is commonly accepted, while the other is quite new and has been discussed in the last few years. The traditional explanation of pectin structure assumes that the polysaccharide is mainly constituted of α-(1–4)-linked D-galacturonic acid chains (GalA, at least 65% for commercial aims) also called homogalacturonan, interrupted by 1,2-linked rhamnose units. From the rhamnose units, side chains of different neutral sugars branch off, forming the so-called hairy region. A different nomenclature can also be used to identify the traditional structure of a pectin. Thus, *rhamnogalacturonan II* is attached to the main chain of homogalacturonan. They consist of complex side chains attached to the GalA residues of the backbone of homogalacturonan, as shown in **Figure 1(a)**. In the same figure, the structure called *rhamnogalacturonan I* consists of the repeating disaccharide [→4)-a-D-GalA-(1→2)-a-L-Rha-(1→] to which a variety of different glycan chains (principally arabinan and galactan) are attached to the rhamnose unit residues.

According to the alternative description of the pectin structure, homogalacturonan could also be considered as a long side chain of *rhamnogalacturonan I* (**Figure 1(b)**).

It is commonly accepted that the carboxyl groups of the galacturonic acid units are, to a certain extent, esterified with methanol. The degree of methyl esterification (DM) is commonly used to classify pectin into high-methoxyl (HM) pectins, containing more than 50% esterified carboxyl groups (DM > 50), and low-methoxyl (LM) pectins with < 50% esterified carboxyl groups (DM < 50).

Since, in higher plants, pectin normally has the capability of being a hydrating agent and cementing material for the cellulosic network, pectin is widely used for its thickening and gelling properties. Generally, the main sources of pectin are apple pomace and citrus peel, but recent investigations have suggested many other sources for pectin extraction such as sugar beet pulp, mango peel, grapefruit, cocoa husks, palm fruit, gold kiwifruit, and others (see **Table 1**).

Industrial Pectin Extraction

In plant structure, in particular in the wall cell, pectin is present as an insoluble pectic substance or protopectin. Protopectin is a complex structure in which pectin is attached to other cell wall components such as cellulose, hemicellulose, and proteins by covalent bonds, hydrogen bonds, and/or ionic interactions. The residual carboxyl groups are partly neutralized with cations of calcium, potassium, and magnesium, naturally included in the plant tissues.

Pectin extraction is commercially carried out by treating the raw material with hot mineral acid at a pH value of about 2. The process time is determined according to both the raw materials adopted and the type of desired product. The pectin extract, not easily separated from the viscous liquid phase where it is contained, is further clarified through filtration and then concentrated under vacuum in order to provide efficient concentration at low temperatures without damaging the pectin. Powdered pectin is produced by mixing the concentrated liquid with an alcohol, such as isopropanol, methanol, or ethanol. The resulting mass is a gelled material, which is, then, pressed and washed to remove the mother liquid, dried, and ground. An alternative precipitation process uses colloidal aluminum hydroxide, with the main advantage that pectin does not have to be concentrated to be separated from the matrix. The extract is cooled and mixed with a solution of an aluminum salt and ammonia or sodium carbonate to reach a pH of about 4. Pectin flocculates and tends to float on the liquor, and, therefore, it is separated by a screen or by flotation and finally pressed to remove as much as liquor as possible. In order to remove aluminum traces, the pectin mass is suspended in alcohol and treated with acid in a series of stages and then partially neutralized before drying. The final pectin is generally characterized by a DM close to 70; lower values can be obtained either by modifying the extraction conditions or by using a subsequent hydrolyzation by the action of acid. If the hydrolyzation is carried out in the presence of ammonia, some of the esters groups are converted into amide groups, obtaining the so-called amidated LM pectin.

HM pectin is produced in the largest amount (∼62% of the total production in 2011), followed by LM pectins (32%), whereas amidated pectins are a small fraction (only 6%) of the total production.

It is worth noting that acid hydrolysis is a nonselective process; therefore, reducing DM leads to a reduction of chain length. A more selective process could be based on enzymatic deesterification; in fact, it was observed that pectin methylesterase (PME) can reduce the DM without affecting the molecular weight. According to the source of PME (e.g., from citrus fruits or from fungi), a blockwise or a random deesterification can be obtained.

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00531-6

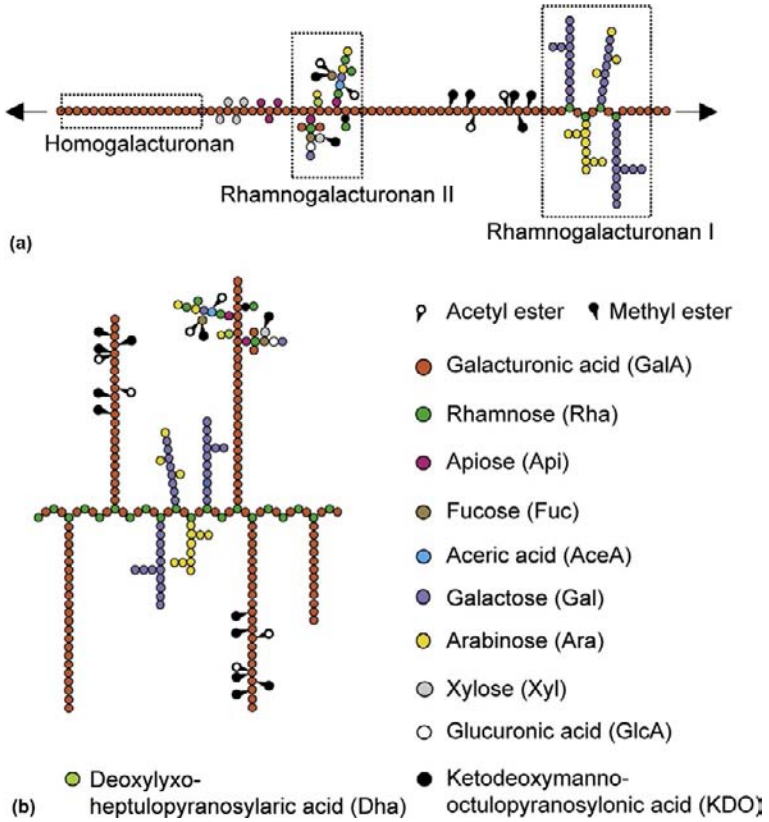

Figure 1 Schematic representations of the conventional (a) and recently proposed alternative (b) structures of pectin. It is important to note that the polymers shown here are intended only to illustrate some of the major domains found in most pectins rather than definitive structures. Reproduced from Willats, W. G. T., Knox, J. P. and Mikkelsen, J. D. (2006). Pectin: new insights into an old polymer are starting to gel. *Trends in Food Science and Technology* **17**, 97–104, with permission from Elsevier.

The improved and deep knowledge about chemical composition of pectin and process conditions for its extraction and also for modifying its structure in order to tune the final properties of gelled systems are enlarging the field of use where this additive can be employed.

Pectin Properties

The main industrial use of pectin is related to the gelling ability of this polysaccharide and to the gelation mechanism that is determined by the degree of methoxylation. LM pectin has a high number of free carboxylic acid groups; they can interact with divalent ions forming strong links between the pectin chains and, therefore, creating the gel network structure usually represented as an 'egg box' (see Figure 2).

Besides the primary interactions, which can be established by pectin chains through the methyl-esterified groups, also secondary interactions among free carboxyl groups should be considered to widely explore the final properties of gels. In fact, according to the literature, three possible kinds of links can be formed in LM pectin: a weak hydrophobic interaction between methyl-esterified groups, hydrophilic interactions between undissociated carboxyl groups and hydroxyl groups via hydrogen bonds, and stronger interactions like ionic linkages with divalent ions.

HM pectin is characterized by a high number of methyl-ester groups: it is generally accepted that the gelation occurs through the cross-linking of the polymer in junction zones, in which not only mainly hydrogen bonds are significant but also hydrophobic interactions between the methyl-ester groups form a high-ester pectin gel. Since the pectin chains are negatively charged, they normally repel each other. A low pH is, therefore, necessary for high-ester pectin gelling because of chain repulsion and the impossibility of forming hydrogen bonds between ionized pectin chains. Moreover, the water activity of the system also has to be lowered to attain sufficient hydrophobic interactions to stabilize the molecular network. Cosolutes like sucrose are usually added for this purpose. Thus, typically, high-ester pectins will only form gels when the pH is below 3.6 and soluble solids are above 55%.

Gelation phenomena depend on biopolymer characteristics (intrinsic parameters) such as polymer molecular weight, galacturonic acid content, degree and pattern of methoxylation, degree of acetylation, and degree of amidation.

Table 1 Pectin content of some fruits

Fruit	*% Pectic substances (wet weight)*
Apple (*Malus* spp.)	0.5–1.6
Apple pomace	1.5–2.5
Banana (*Musa acuminata* L.)	0.7–1.2
Beet pulp (*Beta vulgaris*)	1.0
Carambola (*Averrhoa carambola*)	0.66
Carrot (*Daucus carota*)	0.2–0.5
Giant granadilla (*Passiflora quadrangularis* L.)	0.4
Guava (*Psidium guajava* L.)	0.77–0.99
Lemon pulp (*Citrus limon*)	2.5–4.0
Lychee (*Litchi chinensis* S.)	0.42
Mango (*Mangifera indica* L.)	0.26–0.42
Orange peel (*Citrus sinensis*)	3.5–5.5
Papaya (*Carica papaya*)	0.66–1.0
Passion fruit (*Passiflora edulis* S.)	0.5
Passion fruit rind	2.1–3.0
Peaches (*Prunus persica*)	0.1–0.9
Pineapple (Ananas *comosus* L.)	0.04–0.13
Strawberries (*Fragaria ananassa*)	0.6–0.7
Tamarind (*Tamarindus indica* L.)	1.71
Thimbleberry (*Rubus rosifolius*)	0.72
Tomato fruit (*Lycopersicon esculentum*)	0.2–0.6

Pectin Molecular Weight Determination

Molecular weight strongly affects pectin behavior and it is, therefore, an important parameter for pectin characterization. It is worth noting that it should be better to discuss the molecular weight distribution, or an average molecular weight, to take into account that commercial pectin is made by different molecules with different molecular weights.

High-pressure size exclusion chromatography (HPSEC), also known as gel permeation chromatography, is probably the most common technique adopted for molecular weight determination: it is based on the different elution times, from a packed column, of molecules having different volumes. A detector (usually a refractometer), at the exit of the column, is used to determine the polymer amount. A preliminary calibration of the system has to be carried out using (monodisperse) polymers with a known molecular weight. Even though the system is fast and simple, it is a measure of volume rather than of mass. In order to avoid the calibration procedure, the same system can be equipped with a light scattering detector.

A different procedure is based on the determination of polymer intrinsic viscosity ($[\eta]$) that can be considered as a measure of the polymer hydrodynamic volume. This property can be obtained by measuring (usually through capillary viscometry) the viscosity of diluted polymer solutions and extrapolating the experimental data to zero polymer concentration, according to the well-known Huggins (eqn [1]) or Kraemer (eqn [2]) equations:

$$\frac{\eta_{sp}}{c} = [\eta] + k'[\eta]^2 c \qquad [1]$$

$$\frac{\ln(\eta_r)}{c} = [\eta] + k''[\eta]^2 c \qquad [2]$$

where c is the polymer concentration and η_{sp} is the specific viscosity that can be obtained from the relative viscosity η_r (i.e., the solution, η_{sol}, to solvent, η_s, viscosity). Intrinsic viscosity can be related to the so-called viscometric average molecular weight by using a two-parameter empirical correlation (the Mark–Houwink equation). The parameters, depending on the solvent–polymer pair, can be estimated by a calibration with polymers with a known molecular weight. It is worth noticing that this procedure, widely adopted for synthetic polymers characterization, is based on some assumptions, concerning polymer behavior, including the electrical neutrality of the chain. On the contrary, many polysaccharides, including pectin, exist in aqueous solutions in a dissociated form, and the presence of charges makes the relationship between viscosity and polymer concentration more complex. Consequently, salts are usually added to the solution to reduce these effects.

With the aim of improving the molecular weight estimate, an intrinsic viscosity detector can be coupled to HPSEC and multiangle laser light scattering.

Degree and Pattern of Methoxylation

The degree of methoxylation is an important parameter that strongly affects pectin behavior and, as a consequence, is one of the most used, even at commercial level, to describe different pectins. The most known determination is based on a titration procedure suggested by Joint FAO/WHO Expert Committee on Food Additives. Titration allows also the determination of galacturonic acid content.

Alternative methods were also suggested in the literature, for example, the alkaline hydrolysis to split the ester linkage and the following determination of methanol released using high performance liquid chromatography (HPLC) analysis, nuclear magnetic resonance (NMR) spectroscopy of pectin solutions, capillary electrophoresis (CE), and infrared spectroscopy. In particular, some authors used Fourier transform infrared spectroscopy (FTIR) and found that the absorbance of the ester carbonyl groups increased with increase in the DM and that the band area seemed linearly related to the DM.

The distribution of methoxylated units is also an important parameter when gelation of LM pectin, occurring through calcium ions bridges, is considered. It was observed that the bonds are stable when blocks of at least seven nonesterified galacturonic acid units are available; therefore, the greater the number of nonesterified units close each to the other, the greater the interaction among different polymer chains. One method, largely adopted in the literature to determine the so-called degree of blockiness (DB), is based on a selective depolymerization performed by using an endopolygalacturonase degrading GalA backbone only when more than four adjacent non-methyl-esterified GalA units are present. The length of the resulting pectin segments is evaluated through high-performance anion exchange chromatography. The larger the DB, the more blockwise-distributed are the esterified units. Alternative methods are based on high-frequency H-NMR spectroscopy by dissolving pectin in deuterated water.

Degree of Acetylation and Amidation

The degree of acetylation is important because a large number of acetylated groups reduce the gelling properties of pectin, thereby improving, apparently, its emulsifying characteristics. The degree of amidation affects calcium reactivity toward pectin and therefore the gel properties, and according to the current regulation, it cannot exceed 25% of total carboxyl groups of pectin.

Both parameters are determined, at industrial level, by using the titration procedure suggested by JECFA, even though it is quite time-consuming.

The degree of amidation was also measured, in the literature, using a CE or an FTIR method based on the different absorption wavelengths, at pH 6, of methyl esters, free carboxyl groups, and amide groups. Some authors investigated also the distribution pattern of amidated groups, by using a method similar to that described for the distribution pattern of methoxylated groups.

The degree of acetylation can be also determined by using HPLC with a resin-based column.

Industrial Uses of Pectin

Pectin is mainly used in the food area where in 2011, jams, fruit preparations, and confectionery covered ~60% of the total pectin market (more than 47 000 tons of pectin produced in 2011) evidencing the significant role played by this biopolymer as a gelling agent; pectin is also used as a thickening agent and stabilizer in beverages (25% of the market) and dairy products (4%).

Its best-known use is probably in jams, and often, pectin is the only permitted gelling agents in these products. According to type and quality of fruit, the required amount of pectin can change; for instance, cherry and strawberry usually require a large addition, whereas lower amounts are necessary for apple or blackcurrant. Typical values usually range between 0.2% w/w and 0.4% w/w. In addition to commercial jams, particular products, to be used as fillings or topping in bakery, are usually made. In this case, the products have to meet the specific requirements of the particular use; therefore, the amount and type of pectin are significantly determined by the specific case.

In the confectionery industry, pectin is used to make flavored candies. Usually, a neutral pectin (i.e., without specific flavor) is added to a mixture of water and sugar, and an external flavor is then added.

In beverages, pectin is often used to give texture to juices or soft drinks, mainly when a low sugar content could yield a low viscosity and therefore be unattractive to the consumer. In the dairy industry, pectin is used to stabilize dairy beverages, drinkable yogurts, and drinks containing both milk and fruit. In these systems, owing to heat treatments and acidification, casein particles are altered and unstable dispersion (with potential separation phenomena) can be obtained. Pectin seems to stabilize these products probably owing to electrostatic interactions with casein particles.

Recently, pectin was used also to prepare edible films or coatings to improve the shelf life of portioned fruits and vegetables by creating a barrier able to reduce water and oxygen transfer.

Even though use in food is still dominant, it is worth noting a growing use of this polysaccharide in novel areas, such as pharmaceutical (or biomedical) products (~5%), where pectin properties seem potentially interesting for many uses. For example, they were investigated as potential carriers for controlled drug delivery in nasal, oral, and ocular applications, for cancer-targeted drug delivery, in tissue engineering, and as a base for bone substitutes.

Nasal drug delivery is commonly used to deal with local diseases (such as allergy and congestion), and it is often based on liquid systems, which have very low residence time; therefore, different systems could be more useful. Pectin has shown itself to be very interesting owing to its mucoadhesive properties, which allow a controlled release of the active ingredients on the mucosal surface. In oral drug delivery, pectin gels have exhibited interesting characteristics because they are able to be resistant against digestive enzymes and to be degraded by intestinal microflora. In ocular uses, the pectin ability to gel at low pH is suitable to promote the gelation of pectin solution inside the eye (allowing a controlled release of the drug) owing to the low pH of the tears and their electrolytes content. The cancer-targeted delivery seems due to the interaction between the galactan component of the

polysaccharide and galectin-3 (Gal3), a component involved in many steps of cancer progression. Owing to these interactions, pectin itself seems able to inhibit cancer growth, and it could be useful to deliver, in a specific way, conventional anticancer drugs. In bone tissue engineering, pectin gels seem able to promote the nucleation of a mineral phase yielding a final system more similar to the bones than other systems are.

Finally, recent studies have investigated the use of pectin to remove heavy metals in remediation technologies and as gelling (and stabilizing) agents in cosmetic emulsion production.

Pectin Gel Properties

Since the main effect of pectin in food (and also nonfood) products is based on the structure and texture, it is important to be able to determine some characteristics, such as the use of pectin to form gels, the setting time, and the gel strength, as a function of the adopted operating conditions.

From the industrial point of view, some standard empirical procedures are commonly adopted to characterize the strength of commercial pectin gels; the most common are the SAG method, the Leatherhead Food Research Association (LFRA) texture analyzer, the Food Industry Research Association (FIRA) tester, the Bostwick consistometer, and different universal testing machines. In addition to the strength of the gel, other parameters such as the setting temperature and the setting time are determined by using the SAG method. Since the pectin gelation is affected by solute content and pH level, standard values for sugar amount, pH, and cation addition have to be adopted. Nevertheless, they can be different depending on the adopted empirical procedure and on the pectin type (LM or HM).

The IFT SAG method is, maybe, the most used for standardization of HM pectin, it was adopted by the Institute of Food Technologists (IFT) in 1959, and it estimates the gel strength through the definition of SAG grade. A pectin solution, prepared in standard conditions (i.e., 65% sucrose, pH value 2.3), is poured in specific vessels (the Ridgelimeter glasses) and allowed to cool down at room temperature. After 24 h, the gel obtained is placed on a plate and the change of the height, under its own weight, in 2 min is measured by using the Ridgelimeter. From this value, the SAG grade (°SAG) is calculated according to the following equation:

$$^{\circ}\mathrm{SAG} = \frac{A}{B} \cdot F \qquad [3]$$

where A and B are the amounts of sugar and pectin in the gel and F is a factor depending on the Ridgelimeter result (i.e., the 'sagging percentage'). F can be obtained by specific figures or tables as a function of the sagging percentage; for example, a gel having a sagging percentage of 23.5% is considered as standard and $F = 1$, a gel with higher percentage has $F < 1$, and a gel with lower percentage has $F > 1$. The pectin concentration, to be used in the test, is chosen assuming an expected (or estimated) grade and assuming $F = 1$.

A similar procedure is adopted to estimate the so-called setting time. A warm pectin solution, containing pepper grains, is poured in a glass immersed in a water bath. Periodically it is removed from the bath and the potential presence of a gel is checked by slightly twisting the gel by moving the tube. When the gel is formed, the pepper grains, owing to the viscoelastic properties of the material, swing back before going to rest. The time necessary to observe this behavior in the system considered is assumed as the gel setting time. The setting temperature can be estimated by using a similar procedure, measuring the temperature occurring inside the system. Based on the setting time, commercial pectins can be classified as rapid set, medium rapid set, slow, and extra slow set. Anyway, this classification is quite arbitrary and it can change from producer to producer.

These procedures are extremely empirical and, therefore, strongly affected by the practical experiences and by the adopted standard conditions. For example, the SAG degree is time-dependent, being determined 2 min after inversion of the gel from the recommended glasses dimensions, and it is based on an inhomogeneous and complex deformation of the sample. As a consequence, alternative methods, based on more fundamental measurements, have been investigated.

Pectin Gels: The Sol–Gel Transition

A significant contribution to the knowledge of biomolecular structure in several biopolymer is given by rheological techniques that are able to relate macroscopic parameters to material microstructure. Rheological techniques, such as small-amplitude oscillations, being nondestructive tests, seem very suitable to investigate the change of behavior during the gelation process and the final microstructure. During these tests, a sinusoidal deformation (or a stress) is applied to the sample and the resulting stress (or deformation) is measured and, as result of the test, two dynamic moduli are obtained: G' is defined elastic (or storage) modulus and is related to the energy stored in the sample, whereas G'' is defined viscous (or loss) modulus and is a measure of the energy dissipated during a cycle. Small-amplitude oscillations are used to investigate the linear viscoelastic behavior of the material and, therefore, the material microstructure.

Dynamic tests in linear conditions are widely adopted to investigate gelation phenomena and gel microstructure, and different methods were proposed to determine the sol–gel transition.

From a theoretical point of view, the 'critical gel' behavior (i.e., the material at gel point) was well described by Winter and coworkers that gave the experimental demonstration of a power law behavior of dynamic moduli. This criterion has been applied to many different gel systems, both chemically and physically linked polymers, finding a good agreement.

Nevertheless, other criteria, often simpler than Winter's, were proposed in the literature, and, probably, among them, the most used is the crossover of dynamic moduli at a constant frequency. This simple method suggests that the crossover of loss and storage modulus can mark the transition from a liquid-like to a solid-like behavior without invoking the onset of a gel. It is considered, sometimes, questionable because the G'–G'' crossover may be a function of frequency, whereas an intrinsic property of the material, such as the real gel point, should be independent of frequency. Nevertheless, being a simple method, it was applied to many systems.

However, the crossover value seems to be a function of biopolymer concentration. Therefore, in some situations, it cannot be easily detected because it does not occur in the investigated temperature window being G' greater than G'' since the beginning of the test even if the initial temperature is larger than 90 °C.

Independently of the pectin and according to the literature, it is generally assumed that in a time cure test of pectin gels (small-amplitude oscillatory test carried out decreasing temperature at a fixed cooling rate and maintaining linear viscoelastic conditions), storage modulus G' first increases rapidly and subsequently more slowly approaching pseudo-equilibrium, whereas the loss modulus G'' is always lower than G'. With increasing pectin concentration, the largest changes occur at an earlier stage, while, if pectin content is lowered, the sharp increase of G' is preceded by a period of time during which G' increases slowly.

The incipient gelation, at constant temperature, can be evaluated by time sweep tests (analysis of moduli during time, in linear viscoelastic conditions). At the beginning of the tests, pectin aqueous solutions show a typical liquid-like behavior, with G'' higher than G'. As time goes by, G' progressively increases, and a crossover of moduli is encountered. It seems that crossover clearly decreases with pectin increase following a pseudo-power law behavior.

Different rheological methods were, also, proposed in the literature to determine the pectin gel point. Some authors suggested the extrapolation, to the temperature axis, of storage modulus values in the rapid increase zone. Other authors assumed the transition as the temperature value where the phase angle was halved, while in some other literature references, a 'structure development rate (SDR)' was evaluated, based on the first derivative of storage modulus, to describe the junction formation and, therefore, the material gelification. In a recent work on LM pectin gelation, moreover, the determination of two new parameters could be complementary or alternative for the classical gel point identification: the initial structuring temperature and the critical structuring temperature that can be estimated on the basis of the SDR.

SDR is defined as

$$\mathrm{SDR} = \frac{\mathrm{d}G'}{\mathrm{d}t} \qquad [4]$$

and it is a simple and efficient way to describe gelation rate of these systems clearly evidencing, also, the way in which temperature affects the magnitude of G' and, most of all, its rate of change with time.

Pectin Gel Strength as a Function of Operating Conditions and Intrinsic Factors

Pectin gel characteristics are affected by both intrinsic properties, related to biopolymer structure, and operating conditions. Different mechanisms are involved in gelation of LM or HM pectin; therefore, it can be useful to discuss separately their effects on final gel.

LM pectin gels

Low-ester pectin gel formation is the result of ionic linkage through calcium bridges between carboxylic groups from two pectin chains. This linkage, generally, takes place upon cooling a pectin solution of calcium. Even though a number of positive ions can link pectin molecules, especially magnesium and potassium, calcium is particularly effective in gelling carbohydrates, mostly because its ionic radius (0.1 nm) is big enough to coordinate with oxygen atoms and because of flexibility with regard to the direction of its coordinate bonds. One of the most important intrinsic factor, in pectin gelation, is the DM value because a significant number of nonmethoxylated GalA units have to be present to promote the formation of calcium bridges. Nevertheless, the DM is not sufficient to describe pectin–calcium interactions because it gives only the total fraction of GalA units. On the other hand, according to the recent literature, a relevant role is even played by GalA distribution: when a blockwise pattern is present, stronger gels are formed, owing to the larger number of units involved in junction zones. On the contrary, a random distribution yields less strong gels, probably owing to shorter and weaker junction zones. It seems that at a constant DM, gel strength depends on DB, and a maximum strength can be obtained for a specific pattern that results in the maximal cross-link density. For these reasons, both DM and DB should be known even though the latter is more difficult to estimate. Gel strength is also affected by chain length, that is, the molecular weight: it was observed that, decreasing the polymer length, a weaker gel is obtained, owing to the lower number of junction zones. Under a critical molecular weight, it seems that gelation cannot occur. Finally, the degree of acetylation and degree of amidation modify gel properties: acetyl groups decrease the propensity to gelation of pectin (highly acetylated pectins cannot gel), whereas amide groups, introduced during demethoxylation, improve gel formation owing to the presence of hydrogen bonds among them.

Concerning operating conditions, the ratio between calcium and biopolymer plays a relevant role in pectin gelation; usually, it is described by defining the stoichiometric ratio R:

$$R = \frac{2[\mathrm{Ca}^{2+}]}{[\mathrm{COO}^{-}]} \qquad [5]$$

It was observed that gel strength increases with R value up to 0.5 because a larger number of calcium ions are available for junction formation. When $R = 0.5$, theoretically, all calcium ions are involved in egg box formation. For larger R values, the calcium can be available for less specific and weaker interactions that should not improve significantly gel strength, even though positive effects were observed by some authors. Finally, for further relevant increases in R, a decrease in gel strength is observed probably because of a too fast local gelation yielding phase separation phenomena. The increase in calcium content also increases the temperature of gel formation. When calcium level is kept constant and pectin concentration is modified, an increase in gel strength is observed with increasing fraction of polysaccharide. Nevertheless, when the pectin concentration becomes too high (i.e., a low R value is obtained), a decrease in gel consistency can be also observed.

LM pectin gels are in a wide range of pH values, at least from pH 3 to 6. At low pH, hydrogen bonds and hydrophobic interactions significantly contribute to gel formation, and for pH lower than 3.5, gelation can occur even without calcium

addition. At high pH (approximately larger than 4.5), gel properties are less dependent on pH level.

Cosolute addition is less relevant than in HM pectin anyway; also, in this case, some effects can be observed, owing to their interaction with water, and increase in gel strength, when adding sugar, was observed also for LM pectin. Nevertheless, the effects are according to the specific adopted solute.

High-ester pectin gel formation is due to the presence of hydrogen interactions and hydrophobic bonds between polymer chains, and therefore, it is affected by factors able to modify these interactions.

HM pectin gels

HM gel formation is favored by low pH solutions able to prevent the dissociation of carboxyl groups and, by the addition of sugar (from about 55 to about 80%) thanks to which pectin chains are available to cross-link, to form hydrogen bond and the other hydrophobic interaction. In fact, cosolutes promote pectin gelation by bonding water, which become less available to maintain carbon chains in solution and, as a consequence, induce them to build the network. So far, it is well understood that pH variation effect is very important for final gel properties: at first, if pH is above the value of pK for the acid groups, charges of the carbon chain are negative, because of dissociation, and allow gelation to be prevented. If pH is gradually lowered, very high sugar content (about 80%) is necessary to form weak gel structures, and gradually, sugar content can be reduced if pH is lowered as well. At a pH value below 3, for pectin with a DM above 72%, a gel can be formed starting from a sugar content of about 55%.

Considering this experimental evidence, it can be deduced that, fixing the sugar content, the effect of pH is evidenced by a loss of strength above a certain critical value and a decrease of setting temperature with the pH increase.

During gelation, the structure development is important for producing many food products. For example, in jams, rapid-setting pectin is necessary to ensure the entrapment of large pieces of fruit within structure network to ensure a proper distribution in the product. Moreover, if clear gels have to be produced, no air bubbles should be included in the network: this could be achieved through the use of slow-setting pectin.

Apart from pH value dependence, another important factor affecting strength and setting of HM pectin gels is the kinds of sugar used as cosolute for gel formation, as well as their concentration. In fact, it is known that glucose can be successfully substituted by sucrose, fructose or corn syrups, maltose, or liquid cosolutes as glycerol, xylitol, and sorbitol. According to the literature, polymer–cosolute interactions, in competition with polymer–polymer interaction, are lowered by cosolute–cosolute interactions, which are weaker for liquid cosolutes than for solids: Therefore, in general, if gels are formed with solid cosolutes, strong cosolute–cosolute interaction are expected, and, as a consequence, a stronger gel system is formed thanks to an improvement in polymer–polymer interaction.

Pectin Interfacial Activity

Even though pectins are mainly known and used for their bulk properties, that is, as thickening and gelling agents able to entrap water, recently, their interfacial characteristics were investigated with the aim of understanding if they are usable to modify the structure of interfacial layers (air/water or oil/water) as other biopolymers (such as protein) can do. Interesting results were found mainly for sugar beet pectin, even though these polysaccharides have poor gelling properties owing to their high content of acetylated groups. On the contrary, significant interfacial activity (at oil/water interface) was observed for pectin with different DM and molecular weight values. The origin of these properties is so far not completely understood: some authors attribute them to the number of acetylated groups that should enhance the hydrophobic behavior of the polymer; nevertheless, also, pectin from other sources (such as citrus pectin) with a low degree of acetylation seems to exhibit interesting emulsifying characteristics. It seems that a significant role should be played by the protein fraction of pectin; in fact, it is known that proteins exhibit good interfacial activity, and therefore, they could be the main responsible of pectin interfacial behavior. From an experimental point of view, the most promising results were observed for HM pectin, probably owing to the larger number of hydrophobic methoxyl groups, and for low-molecular-weight polymers, probably because smaller molecules can diffuse faster from the bulk to the interface. Even though pectin interfacial activity has still to be investigated, current results suggest potential interesting uses for pectin also in this area.

Peppers and Chilies

AAO Xavier and A Pérez-Gálvez, Consejo Superior de Investigaciones Científicas (CSIC), Sevilla, Spain

Introduction

The terms 'pepper' and 'chili' have been used to nominate different types of plants and plant products, all of them with pungent fruits or seeds. It was originally used to designate seeds of *Piper nigrum* from the *Piperaceae* family, commonly known as black, green, and white peppers. Nevertheless, this article primarily discusses chilies and peppers from the *Capsicum* genus from the *Solanaceae* family, which includes potatoes, tomatoes, tobacco, and petunias. They are native to the tropics and subtropics of America, and the first record of their consumption dates from approximately 9000 years ago in Mexico. European visits to the New World by shipping routes in the period between 1492 and 1600 disseminated this ancient crop around the world. Nowadays *Capsicum* is an important agricultural crop with numerous varieties widely cultivated.

Capsicum genus includes a large range of species from sweet green bell peppers to habanero peppers, the reason why their naming terminology is confusing, and names like pepper, chili, chile, aji, paprika, and capsicum are often used. These species are classified by characteristics of the fruit like pungency, shape, color, flavor, size, and use. The name chili or 'chile' is generally applied in the current literature to those fruits that are pungent, and they are used as fresh or dry fruits and also in powder form. Chili is mainly spread out in tropical regions of America, Asia, and Africa, where they are valued for their flavor and pungency, representing a culinary tradition and a cultural symbol. There is a gradation of pungency, and some varieties show a slight pungent taste or no pungency at all. The nonpungent species are commonly known as peppers, sweet peppers, or sweet bell peppers (used as fresh) and are preferred by consumers from Europe and North America, although they have been spreading to the tropics through a Western influence on its diet.

Capsicum Fruits

Botanic

Among the 31 species identified in the *Capsicum* spp. genus, five are domesticated, including *Capsicum annuum*, *C. baccatum*, *C. chinense*, *C. frutescens*, and *C. pubescens*. *C. annuum*, *C. chinense*, and *C. frutescens* are the most widespread in America and the world. *C. annuum* specie includes most of the Mexican chilies like *poblano* and *jalapeño*, most of the hot peppers of Africa, and the various cultivars of sweet peppers grown in temperate countries. These fruits are used to extract paprika and paprika oleoresin, products applied currently in cuisine, food industry, drugs, and cosmetics. Because *C. annuum* is not well adapted to humid countries, it was replaced by *C. frutescens* and *C. chinense*. *C. frutescens* is cultivated in Latin America, Asia, and Africa either for fresh consumption of intact fruits or oleoresin extraction. This specie produces peppers known by the names of *malagueta*, *tabasco*, and *arbol*. *C. chinense* is extensively cultivated in West India and South America and includes Scotch bonnet and habanero peppers. This specie is characterized by its flavor and pungency, although nonpungent forms of *C. chinense* are grown commercially in Amazonia. The other two domesticated species, *C. baccatum* and *C. pubescens*, are practically unknown outside America. They are prevalent in Andean South America and southern Brazil.

Morphology and Anatomy

Fruits of *Capsicum* are conical or semispherical berries with different sizes (a few grams up to 250 g) depending on the varieties, and wild peppers have smaller fruits than domesticated species. Size and pungency are genetically independent characters. The space between mesocarp and endocarp is full of air, and the interior has two to four central ribs that support the seeds. Fruits that have a thick pericarp are consumed fresh, whereas those with a thinner pericarp are consumed dry or after grinding. The pericarp has an impermeable outer cuticle to protect the fruits and retard water losses, which contributes to extend their shelf life. This cuticle is indigestible and firm, so frequently it is removed before the canning process.

Sensory Characteristics

The color of *Capsicum* changes according its variety and ripening stage, starting from green, yellow, or white in unripe fruit turning to red, dark red, brown, and almost black in the ripe stage. Cells of mesocarp of immature fruit contain chlorophyll, carotenoids as lutein and neoxanthin, and occasionally anthocyanins, so the color of unripe fruits usually varies from creamy white to green. Overall, during fruit ripening, levels of chlorophyll are reduced, whereas carotenoids as capsorubin and capsanthin (red carotenoids), and β-carotene and β-cryptoxanthin (yellow carotenoids) are massively synthesized, and consequently most of ripe fruits show intense red color (Table 1). Concentration of carotenoids in ripe red pepper is estimated as being 35-fold higher than in unripe fruit. Capsanthin, capsorubin, and cryptocapsin are ketocarotenoids characteristic from *Capsicum* genus. During ripening, carotenoids undergo diverse degrees of esterification with different fatty acids, a process that confers to them more stability.

Pungency of chilies is conferred by capsaicinoids, an alkaloid group that includes capsaicin and dihydrocapsaicin, which represents 90% of the total capsaicinoids. Chemically they are amides of vanillyamine and carboxylic acids with 9–11 carbon atoms and are responsible for spiciness of pungent peppers. These compounds are synthesized in the epidermal cells of the placenta and accumulate in cuticle covering the placenta. Cuticle rupture spreads capsaicinoids over the seeds and internal wall of fruit, which leads to the belief that these are pungent parts of fruit. Three structural characteristic

Compound	*Group*	*Structural formula*
Capsorubin	Carotenoids	
features make capsaicin one of the most pungent compounds known: the vanillyl group, the acid–amide linkage, and the alkyl side-chain. Any alteration in one of these groups supposes a decrease in pungency. The capsaicinoid burning sensation is produced by binding to vanilloid receptors VR-1, responsible for pain perception. A repeated exposure to capsaicinoids leads to desensitization of these receptors. Determination of pungency is very important for consumers and industrial purposes. The Scoville Organoleptic Test is a method that measures pungency by human perception, expressing pungency value in Scoville heat units. Measurement is correlated to capsaicin content, so a sweet pepper containing no capsaicin has a Scoville rating of zero, whereas hottest chilies like *habanero* have a rating about 200 000 or more. Because human perception of pungency is subjective, a modern universal scale was built by the American Spice Trade Association (ASTA) based on measurement of capsaicinoids amount by high-performance liquid chromatography. Pungency is expressed as ASTA units and can be easily converted to the most common scale of Scoville units by multiplying the content of each capsaicinoid by a conversion factor.

Although color and pungency are the most valuated aspects of chilies and peppers, aroma has also been focussed on as an important attribute for quality of fruits and vegetables and consequently their acceptance by consumers. The characteristic aroma of the *Capsicum* is due to the presence of droplets of volatile oils in the mesocarp, which are a combination of methoxypyrazines, aliphatic alcohols, and esters, with more than 125 volatile compounds currently identified both in fresh and processed fruits. Like pigment concentration, the volatile composition depends on the maturity stage of the fruit. Immature fruits have grassy and herbal aromas attributed to compounds as 2-isobutyl-3-metoxypyrazyne and hexanal. As fruit ripening, their concentrations decrease or disappear, whereas levels of compounds responsible for sweet aroma increase. Among volatile compounds present in ripe peppers are octanal (fruity), *trans*-2-hexenal (sweet), 2,3-butanedione (caramel), 3-carene (red bell pepper, lemon), and 1-penten-3-one (pungent/spicy).

Nutritional Composition and Absorption

Composition of nutrients of *Capsicum* genus varies extremely according species, variety, stage of maturity, and part of plant consumed (Table 2). Raw vegetables contain about 90% water, 6–9% carbohydrates, and very low or no content of fat and protein, so their consumption does not suppose a great caloric intake. On the other hand, after cooking and drying processes, they supply more calories than equal amounts of fresh peppers due to water losses. In general, these fruits are good sources of phytochemicals like vitamin C, E, and A, as well as phenolic compounds and carotenoids.

Vitamin C

Fresh peppers are among best sources of vitamin C in the human diet. In fact, 100 g of green sweet peppers can provide practically 100% of recommended daily intake (RDI) of vitamin C for both adult males and females (ages 19–70 years), which are 90 and 75 mg day^{-1}, respectively. Furthermore, the same quantity of red and yellow sweet peppers supposes an intake of two and three times the RDI of vitamin C, respectively. In general, an increase in the ascorbic acid content is observed for fresh fruits as fruit mature. Nevertheless, the drying process results in losses of almost 50% of vitamin C content, whereas canned *Capsicum* retain about 70% of initial content.

Vitamin A and Carotenoids

The content of vitamin A depends on the presence of carotenoids with provitamin A activity, so it is strictly related with the maturation stage and color of fruits. In general peppers are good sources of the provitamin A carotenoids as β-carotene, α-carotene, β-cryptoxanthin, and oxygenated carotenoids as lutein. As capsorubin and some carotenoids present in ripe stage do not exhibit provitamin A activity, not even red peppers provide higher amounts of vitamin A, if compared with its corresponding green variety. Studies concerning the nutritional composition of chilies and peppers report concentrations of carotenoids that can provide 60% of RDI of vitamin A for an adult, by consumption of 100 g of fruits. However, steps in the processing of red pepper fruits into paprika like trituration and heating, as well extraction with an organic solvent or oil, produce pigments that are much more labile. Moreover, heat increases the rate of thermo-oxidation reactions, which are highly effective in thermal degradation of carotenoids. As a result, manufactured products of *Capsicum* may not contribute

as significantly to vitamin A ingestion as fresh fruits because losses of carotenoids with provitamin A activity occurs.

Only a part of carotenoids ingested is really absorbed, and the magnitude of this fraction depends on several factors related to the chemical structure of carotenoid, food matrix, and host. Absorption of carotenoids is similar to other dietary lipid compounds and occurs in three phases: solubilization, micellization, and absorption. After ingestion, they are released from food matrix and grouped into fat droplets in gastric emulsion, where they undergo enzymatic hydrolysis. A reduction in the size of droplets occurs, and carotenoids are incorporated into mixed micelles formed from lipids and bile salts, and then they are transferred into intestinal mucosa cells. Data regarding bioavailability of carotenoids from peppers and chilies are still scarce and controversial. Generally, xanthophylls as lutein and zeaxanthin are most bioaccessible both from fresh and dried fruits of *C. annuum*. From fresh fruits, more than 80% of lutein and zeaxanthin are absorbed, whereas β-carotene and β-cryptoxanthin show rates of about 25%. On the other hand, amounts of carotenoids absorbed from paprika (dried fruits) from different cultivars are lower, ranging from 33% to 49% for β-carotene, from 20% to 41% for β-cryptoxanthin, and from 25% to 49% for zeaxanthin.

Phenolic Compounds

Fruits of *Capsicum* are rich in phenolic compounds, and many authors have worked to elucidate their phenolic composition, which still remains incomplete. Capsaicinoids are the most important group of phenolic compounds because they characterize *Capsicum* fruits. The major flavonoids are glycosides of quercetin and luteolin, and some studies also report the presence of derivatives of cinnamic, coumaric, and caffeic acids.

Phenolics from *Capsicum* present a great bioavailability (about 70%) as compared with other fruits and vegetables. This occurs probably because pepper fruits do not contain proanthocyanidins, which are phenolic compounds resistant to the action of digestive enzymes. The remaining phenolics (nonbioaccessible) could reach the colon and be fermented. Data regarding capsaicinoids show that capsaicin is

preferentially absorbed in the jejunum part of small intestine, and it is a fast and nonenergy consumed absorption. *In vivo* research showed that capsaicin could be detected in the circulation 10 min after ingestion.

Health Effects

The *Capsicum* plant has been historically employed in traditional medicine and currently has being used in modern herbology and conventional treatments, principally due to its antimicrobial, anticonvulsive, and sedative properties. First reports date back to Mayan and Azteca civilizations, which used fruits from the pungent and nonpungent peppers in treatment of asthma and coughs, as well as relieving sore throats and toothaches. Positive health benefits from *Capsicum* fruits are related to their phytochemical composition because they have high content of compounds as carotenoids, capsaicinoids, phenolics, and ascorbic acid. Many of these compounds are antioxidants that exert their biological effects through free-radical scavenging, protein binding, and interaction with human signal transduction pathways.

Several biological effects and pharmaceutical properties, including antioxidant, anticarcinogenic, and anti-inflammatory effects, have been attributed to capsaicinoids. It is known these alkaloids act in pain mechanism by depletion of substance P and other neuropeptides from sensory nerve terminals. This fact justifies *Capsicum* application as a neuropharmacological tool in preventing chronic pain associated with postherpetic neuralgia, diabetic neuropathy, and also in topical creams to treat chronic pain syndromes and osteoarthritis. Studies showed the effectiveness of capsaicinoids in the treatment of cystitis, human immunodeficiency virus, and disorders related to sensory nerve fibers. Intake of capsaicinoids at low levels has been related to a decrease in myocardic and aortic cholesterol levels. Moreover, ingestion of capsaicin can reduce body-fat mass in dose-dependent ways by decreasing the desire to eat, as well as protein, fat, and carbohydrate intakes. It enhances energy metabolism by stimulation of the sympathetic nervous system. Some authors associated ingestion of 5 g of fresh capsicum with lower plasma glucose levels and maintenance of insulin at basal levels and attributed this effect to capsaicin content (about 26.6 mg capsaicin/5 g *Capsicum*).

It is well known that carotenoids play important biological functions as potent quenchers of singlet oxygen and effective scavengers of reactive of oxygen and nitrogen species (ROS and RNS), compounds that are implicated in pathogenesis of chronic degenerative diseases such as cardiovascular diseases and some types of cancer. In fact, capsanthin and capsorubin, major carotenoids in the *Capsicum* genus, have been reported in literature to quench singlet oxygen, suppress free radical induced lipid peroxidation, and suppress generation of superoxide and nitric oxide. An *in vivo* study showed the antitumor-promoting activity of capsanthin and its mono and diesters. Moreover, this carotenoid showed strong quenching activity for singlet oxygen and effective ability to suppress the generation of ROS in mouse skin by irradiation of ultraviolet A. Lutein, a carotenoid predominant in green peppers and immature fruits, is involved in prevention and delay of progression of age-related macular degeneration and cataracts.

Ascorbic acid, first isolated from paprika, is probably the most effective and least toxic antioxidant identified at the biological system. Similar to other phytochemicals presents in *Capsicum* fruits, it seems to be important in protecting against such oxidative stress-related diseases as coronary heart disease, cancer, and cataracts, as well as in the natural aging process and modulating immune system function. High intakes of acid ascorbic have been related to lower blood pressure. In addition, it acts in iron metabolism by preventing formation of insoluble iron compounds or reducing ferric to ferrous ions, then enhancing iron absorption.

Production and Consumption Patterns

Capsicum is an important agricultural crop around the world, not only due to its economic relevance as a flavoring and coloring agent to the food industry and cuisine, but also for the nutritional value of the fruits, medicinal applications, and ornamental uses. The average annual world production from 2000 to 2011 was about 25.7 million tons for green products (fresh) and 2.9 million tons for dry products (Table 3), with an average annual growth rate of 3.2%. Data from 2011 point to China as the largest producer of fresh products with more that 50% of world production. In turn, India stands out as major producer of dry products (42%), and the top 10 producers accounted for about 80% of production. This country produced more *Capsicum* than it consumed, so 17% of the 1.2 million metric tons were destined for export.

Despite the fact that *Capsicum* is the most consumed spice in the world, its consumption tends to be concentrated within a few countries. The top 5 consumers of *Capsicum* absorbed 54% of the market, and India heads it with 941 000 metric tons consumed in 2009. Rounding out the list are Thailand, Pakistan, Bangladesh, and China. Market composition of the top 10 consumers and producers is very similar, with nine countries in common. The differences are the United States and Peru, which only appear on the top 10 consumers and producers lists, respectively. Considering per capita consumption, Bosnia and Herzegovina is at the first place with 5.5 kg year^{-1}, followed by Jamaica (3.7 kg year^{-1}), Peru (3.6 kg year^{-1}), Ghana (3.2 kg year^{-1}), and Bermuda (3.1 kg year^{-1}).Only

Thailand, Myanmar, and Ghana appear in both lists of top 10 consumers and top 10 per capita consumers.

Global Uses in the Food Supply

Chilies and peppers are used worldwide as a spice, salad, complementary dish, medicine, industrial product, or decoration. Their primarily application is in the food industry, which in developed countries comprises about 55–60% of fruit production, whereas 35–40% are consumed by the retail sector and about 10–15% by the catering sector. In developing markets the main consumers of peppers are households.

Capsicum is employed in the food industry to improve taste, color, or aroma of sauces, soups, processed meats, snacks, frozen dairy desserts, candies, gelatins and puddings, soft drinks, and alcoholic, and nonalcoholic beverages. The most economically important species are *C. frutescens* and *C. annuum*, and intensity and quality of color, as well pungency, are the main characteristics determining commercial value of pepper fruits. They are generally processed and used as natural colorant in the form of paste, concentrated extracts (oleoresin), or powder (paprika), which can increase shelf life of fruits from days to months. Paprika is a fine, brilliant, and red-colored powder obtained by dehydration and milling of red-fruited cultivars. It is valuated for its coloring power by spectrophotometric measuring. The higher the coloring capacity, the higher the price. Oleoresins are red-colored oils produced from dried or ground fruits of red pepper. The traditional process is carried out by extraction using organic solvents followed by distillation to remove the solvent. This product is considered by some food manufacturer as more aseptic (less contamination by microorganisms, insects, etc.) and more standardized than paprika (regarding pungency).

Besides applications in food industry, the nonpungent species, named sweet peppers, also are used in fresh form. They are eaten raw in salads or can be processed, cooked, or fried like vegetables and consumed together with other foods. Most pungent peppers are considered spices or condiments and are used in small quantities for seasoning food, as well as commonly pickled in salt and vinegar.

There are applications of *Capsicum* not related to food supply. Pungent species are used to produce defensive spray because the irritant effects of capsaicinoids are dangerous for mucosa. Some herbal formulas contain *Capsicum* as a synergistic agent, like general tonics, laxatives, and sedatives. In addition, these plants are currently used in aquariums for koi fishes or in zoos for improving the feather color of flamingoes.

Pesticides and Herbicides

S Ensley, Iowa State University, Ames, IA, USA

© 2016 Elsevier Ltd. All rights reserved.

Pesticides and herbicides are intended to keep our food supply safe. Ideally, the pesticides and herbicides we use on our foods will eliminate the target pest without contaminating the food itself. Pesticides and herbicides are designed also to prevent pests from lowering the yield of the food we produce. Maximum yields are expected from the inputs required to raise a food crop.

The Food and Agriculture Organization (FAO) has defined a pesticide as "Any substance or mixture of substances intended for preventing, destroying or controlling any pest, including vectors of human or animal disease, unwanted species of plants or animals causing harm during, or otherwise interfering with, the production, processing, storage, transport, or marketing of food, agricultural commodities, wood and wood products or animal foodstuffs, or which may be administered to animals for the control of insects, arachnids or other pests in or on their bodies. The term includes substances intended for use as a plant growth regulator, defoliant, desiccant, or agent for thinning fruit or preventing the premature fall of fruit, substances applied to crops either before or after harvest to protect the commodity from deterioration during storage and transport."

Herbicides specifically refer to products used to control plants and not other pests.

Insects, animals, plants, fungi, bacteria, and viruses all can have a negative impact on our food supply. Pesticides used to control these include herbicides, insecticides, insect growth regulators, nematicides, termiticides, molluscicides, piscicides, avicides, rodenticides, bactericides, insect repellents, animal repellents, antimicrobials, fungicides, and antimicrobial disinfectants. There are always compromises when using pesticides and herbicides on our food supply because there are no pesticides or herbicides that do not involve a risk. Biologically based pesticides can be safer than traditional pesticides but even these are not without risk. The biological pesticides include pheromones and microbial pesticides. Natural products are not necessarily without risk, and synthetic products can be just as safe as natural products.

Pesticide Use

There is a long history of human's use of pesticides. Elemental sulfur was the first known pesticide that was used about 4500 years. A 4000-year-old Hindu text mentions the use of poisonous plants for pest control. The heavy metals, arsenic, mercury, and lead, were used on crops to kill pests in the fifteenth century. In the seventeenth century, nicotine sulfate from tobacco leaves was used as an insecticide.

From the 1900s to the 1950s, arsenic-based pesticides were the main pesticides used. One of the first uses of a chemical as a pesticide was 1,1,1-trichloro-2,2-di(4-chlorophenyl)ethane (DDT). In 1939, Paul Müller, a Swiss chemist, discovered the insecticidal action of the organochlorine, DDT. Organochlorines were extensively used during WWII and after, but they were replaced in the United States by organophosphates and carbamates by 1975.

Herbicides became common in the 1960s, led by "triazine and other nitrogen-based compounds, carboxylic acids such as 2, 4-dichlorophenoxyacetic acid, and glyphosate. A list of pesticides and the targets are listed in Table 1."

Pesticides Containing Minerals and Metals

The Chinese used sulfur around 1000 BC to control bacteria and mold. Sulfur is used today in fungicides to control diseases on agricultural and ornamental plants. The Chinese also used arsenic-containing compounds to control insects. Arsenic has a history of use as an insecticide and herbicide and also as a medicine. Arsenic trioxide has been used as a herbicide in the late 1800s, and lead arsenate, containing both lead and arsenic, was used as an insecticide prior to the development of synthetic pesticides following WWII. Arsenic in the form of chromated copper arsenate (CCA) was used as a wood preservative from the 1940s to 2003 when it was voluntarily removed from the residential market. Wood treated with CCA is still available primarily for industrial use. CCA is still registered with the EPA for the treatment of wood products that may be found in residential settings like shake shingles, wooden shingles, and structural members other than decks. In the agricultural market, CCA-treated wood is used in posts, sawn timbers for fence posts, or structural supports.

Plant-Based Pesticides

Nicotine from tobacco leaves was used in the late 1600s as an insecticide and is still in limited use as a pesticide. *Pyrethrum*, derived from the chrysanthemum plant, is used as an insecticide. Synthetic pyrethrins have been developed that are more potent. Strychnine from the strychnine tree, *Strychnos nux-vomica*, is used as a rodenticide. Rotenone, from the root of *Derris elliptica*, is used as an insecticide and fish poison. These natural pesticide products are potent chemicals and in some cases more potent than synthetic products.

Chemicals Used as Pesticides

The primary chemicals used as early pesticides include organochlorines, organophosphates, carbamates, and sulfonylurea herbicides.

The development of DDT as an insecticide during WWII started the era of chemicals used as pesticides. The synthetic chemistry advanced rapidly in the 1930s, and by the early 1940s, a range of new pesticides called the organochlorine

Table 1 Types of pesticides and the targets

Pesticide	*Target*
Algicide	Algae
Avicide	Birds
Bactericide	Bacteria
Fungicide	Fungi
Herbicide	Plants
Insecticide	Insects
Miticide	Mites
Molluscicide	Snails
Nematicide	Nematodes
Rodenticide	Rodents
Virucide	Viruses

insecticides were developed. These very potent organochlorines were originally developed as potential chemical warfare agents. After WWII, the organophosphate and carbamate compounds were repurposed as insecticides, and many organophosphate and carbamate insecticides continue to be used today.

Herbicides were developed after WWII to increase food production and as possible warfare agents. In 1946, the first commercially available chlorine-based herbicides were marketed to kill broad-leaved plants. This class of compounds includes 2,4-D (2,4-dichlorophenoxyacetic acid) and 2,4,5-T (2,4,5-trichlorophenoxyacetic acid). 2,4,5-T was used extensively during the Vietnam War as Agent Orange to defoliate the jungle. During the manufacturing process, 2,4,5-T was often contaminated with the persistent and very toxic chemical called dioxin, TCDD (2,3,7,8-tetrachlorodibenzo-p-dioxin). Dioxins, like other chlorinated compounds including DDT, bioaccumulate in body fat and persist in the environment for many years. Dioxins are classified as carcinogens and are also known to affect the reproductive and immune systems. The organochlorines biomagnify in the food chain. Larger predators accumulate more of these chemicals than the prey in the food chain.

The US Environmental Protection Agency (EPA) canceled the use of 2,4,5-T in 1979 in the United States, but 2, 4-D is still a widely used herbicide.

Neonicotinoids are the newest class of insecticides with widespread use in crop production. The neonicotinoid insecticides include imidacloprid, acetamiprid, dinotefuran, thiamethoxam, nithiazine, and clothianidin. From 2000 to 2010, neonicotinoid insecticides have been the fastest growing class of insecticides in modern crop protection because of their widespread use against a broad spectrum of sucking and certain chewing pests. Neonicotinoids have a relatively low risk for nontarget organisms and the environment, a high target specificity to insecticide, and versatility in application methods. The neonicotinoids have been implicated in the colony collapse disorder in bees, but this has not been proved. The neonicotinoids have a wide safety margin in mammals, and the insecticidal activity can be targeted so this class of compounds can have wide future use as an insecticide.

Fipronil, a phenylpyrazole, is also a new generation of insecticides. Fipronil, like the neonicotinoids, can be applied at very low dose rates.

Biologically Based Pesticides

Biopesticides are certain types of pesticides derived from such natural materials as animals, plants, bacteria, and certain minerals. For example, canola oil and baking soda have pesticidal applications and are considered biopesticides. At the end of 2001, there were approximately 430 registered biopesticide active ingredients and 1320 products.

The most widely used microbial pesticides are subspecies and strains of *Bacillus thuringiensis*, or Bt. The genes for Bt have been inserted in the genome of plants, and these plants are called genetically modified organisms (GMOs). Each strain of this bacterium produces a different mix of proteins and specifically kills one or a few related species of insect larvae. While some Bts control moth larvae found on plants, other Bts are specific for larvae of flies and mosquitoes. The target insect species are determined by whether the particular Bt produces a protein that can bind to a larval gut receptor, thereby causing the insect larvae to starve. Biochemical pesticides include substances, such as insect sex pheromones that interfere with mating as well as various scented plant extracts that attract insect pests to traps. Because it is sometimes difficult to determine whether a substance meets the criteria for classification as a biochemical pesticide, the EPA has established a special committee to make such decisions.

Glyphosate

Glyphosate, N-(phosphonomethyl)glycine, is a widely used nonselective herbicide discovered by a Monsanto chemist, John Franz, in 1970. Monsanto has marketed glyphosate as a product called Roundup. In 2007, glyphosate was the most used herbicide in agriculture in the United States and the second most used herbicide in the lawn and garden market. Glyphosate inhibits an enzyme involved in the production of tyrosine, tryptophan, and phenylalanine in plants but not mammals. It is absorbed through foliage and translocates to growing portions of the plant. Crops have been produced that are glyphosate-resistant; this resistance allows the crop to be sprayed with glyphosate, but the crop will be unaffected and only the weeds in the field will be killed. There are concerns that glyphosate can cause adverse health effects in humans from acute and chronic exposure. More data however are needed to completely answer this question.

Health Effects

Human Health and Pesticides

The World Health Organization estimates that 3 million workers in agriculture in the developing world have severe poisoning from pesticide use. Of the 3 million exposed, 18 000 die. One of the worst pesticide-associated death losses occurred in Bhopal, India, on December 2, 1984. Methyl isocyanate leaked from a Union Carbide plant producing carbaryl and killed 2259 people immediately and over 8000 died from gas-related diseases. Long-term, low-dose exposure to pesticides has been linked to human health effects like immune

suppression, hormone disruption, reproductive abnormalities, cancer, and diminished intelligence. In studies conducted from 2001 to 2011 in Asia and Africa, dichlorodiphenyltrichloroethane (DDT) was found in concentrations exceeding the Codex Maximum Residue Limits/Extraneous Maximum Residue Limits for milk (20 ng g^{-1} lipid wt. whole milk) in human breast milk. Pesticides can cause risks for human fetuses.

There were 3017 calls about pesticide exposures in the 2010 Annual Report of the American Association of Poison Control Centers' National Poison Data System (NPDS): 28th Annual Report. Pesticides were included in 3.3% of calls about poison exposure.

Suicide using pesticides is a major public health problem in the developing world. The World Health Organization recognizes pesticide poisoning to be the single most important means of suicide worldwide. In areas of the world where pesticide poisoning is a public health concern, the use of pesticides has to be balanced with the agricultural uses. A classification of toxicity of oral and dermal dose of pesticides is given in Table 2.

Environmental Effects

Pesticide use results in widespread distribution of chemicals that regulatory agencies evaluate for risks to environmental and human health. The widespread concern for pesticide use and the impact on human and animal health initially occurred with Rachel Carson's publication of Silent Spring in 1964. Approximately 245 000 000 kg of active pesticides was applied in the United States in 1964. Worldwide, approximately 3 billion kg of pesticides is applied each year at a cost of over $40 billion.

From 1992 to 2011, pesticides were found at concentrations that exceed regulatory limits in waterways that drain agricultural, urban, and mixed land use watersheds. For agricultural and mixed land use waterways, the proportions of waterways contaminated with pesticides did not change from 1992 to 2001 compared to 2002–11. During this same time, pollution of urban streams increased 53% largely because of fipronil and dichlorvos. More than 400 different pesticides are used in the United States every year.

In Europe, the effect of pesticides on the environment is measured by microcosm and mesocosm studies. These studies are dependent on the no observed effect concentrations (NOECs). The studies using these systems are artificially constructed systems from portions of natural ecosystems. These systems assess the effect of chemicals on the ecosystem. The statistical reliability of the conclusions from these studies depends on the power of the test conducted. Laboratory studies are useful but must be accompanied by field studies to evaluate all the complex interactions that occur in nature.

Economics

Human health and environmental cost from pesticides in the United States is estimated at $12 billion. This estimate is from 2009. Losses associated with pesticide use in the United States include impacts on public health; livestock and livestock product losses; development of pesticide resistance in pests; crop pollination problems; honeybee problem; bird, fish, and other wildlife losses; and the governmental cost of reducing the impact on the environment and society.

In the United States, there are approximately 500 million kg of over 600 different pesticides applied at a cost of $10 billion. In 2009 alone, an investment of approximately $10 billion dollars in pesticide control saved $40 billion dollars in US crops annually.

Regulation

International

At a conference of the United Nations Food and Agriculture Organization in 1985, a code pertaining to pesticide use was adopted. The International Code of Conduct on the Distribution and Use of Pesticides created voluntary standards of pesticide regulation for different countries. The code was updated in June 2013.

Pesticide safety education and pesticide applicator regulation are methods of protecting the public from pesticide misuse. Education and regulation have the potential to reduce the risk of pesticides by using less toxic pesticides. Integrated pest management (IPM) is the use of multiple approaches to control pests. IPM recognizes the more widespread impacts of an action on an ecosystem.

The United States

The Environmental Protection Agency (EPA) is responsible for regulating pesticides under the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) and the Food Quality Protection Act (FQPA).

Table 2 WHO classification of toxicity of pesticides

Class	*Description*	*LD50 for the rat (mg kg^{-1} body weight)*			
		Oral		*Dermal*	
		Solids	*Liquids*	*Solids*	*Liquids*
Ia	Extremely hazardous	≤5	≤20	≤10	≤40
Ib	Highly hazardous	5–50	20–200	10–100	40–400
II	Moderately hazardous	50–500	200–2000	100–1000	400–4000
III	Slightly hazardous	>500	>2000	>1000	>4000

Reproduced from Dawson, A. H., Eddleston, M., Senarathna, L. et al. (2010). Acute human lethal toxicity of agricultural pesticides: a prospective cohort study. *PLoS Med*, 7, e1000357.

The EPA regulates pesticides under two main acts, both of which amended by the Food Quality Protection Act of 1996. The US Department of Agriculture (USDA) and the US Food and Drug Administration (USFDA) set standards for the level of pesticide residue that is allowed on or in crops.

Pesticides are applied at individual sites, but chemicals can be widely distributed by atmospheric drift, runoff, and movement through the food chain. The EPA evaluates the risks and benefits of pesticides to human and environmental health.

Pesticides and Herbicides: Residue Determination

Y Picó, University of Valencia, Valencia, Spain

Introduction

Pesticides are a general class of chemicals or biological agents used to control, repel, attract, or kill pests. They are often classified according to the organism they are used to control. Although the term pesticide is frequently used interchangeably with insecticide, it has a much broader meaning. In addition to insecticides, pesticides comprise herbicides, fungicides, fumigants, rodenticides, nematicides, algicides, and molluscicides. This group includes more than 1000 substances active against pests that present different chemical structures and properties. Herbicides are a broad category of pesticides that cover nearly 70% of all pesticides used by farmers, the reason why sometimes this group deserves a special attention.

In the present agricultural practice, pesticides provide an unquestionable benefit by increasing the agricultural production. However, each year, 140 000 tons are sprayed onto crops in the European Union (EU) alone, and even though pesticides are degraded or dissipated, certain amount remains in crops and vegetables. Then, food is the primary source of pesticide exposure for humans. Raw materials are directly contaminated through the application and transmission of the pesticide and its residues through the food chain.

Pesticide residue is defined by the World Health Organization as "any substance or mixture of substances in food for man or animals resulting from the use of a pesticide and includes any specified derivatives, such as degradation and conversion products, metabolites, reaction products, and impurities that are considered to be of toxicological significance." The sustainable use of pesticides is achieved through fixation of the maximum residue limits (MRLs). These limits restrict the concentration of a residue permitted on a commodity and constrain the type of commodity on which it is allowed. It is the responsibility of the government authorities to register and set MRLs and to implement pesticide residue monitoring programs in order to control the pesticide quantity in food and to enforce tolerances.

In this context, analytic methods are needed to screen, quantify, and confirm pesticide residues in food for both research and regulatory purposes. In the recent years, significant evolution was noted in the extraction and determination of pesticide residue analysis in food. Since years ago, some major premises and basic rules have made up these analyses, in such a way that they were reliable, rapid, and feasible. Multiresidue methods (MRMs), which determine a wider range of multiclass pesticides as possible, are preferred over single-residue methods because the products applied and the regularity of the treatments are generally unknown and residues of more than one pesticide can be present in samples.

This article provides a review of the current status of the routine methods in the monitoring and control of pesticide residues and discusses the analytic problems arising at each stage of the procedure. Reported information is focused on the methodology applied in the screening of pesticide residues within the monitoring programs and its innovations. The role of mass spectrometry (MS), a universal and selective approach, within this field is highlighted. This article examines the capabilities of MS to determine pesticide residues in food and its possibilities to compensate the lacks still presented by the MRMs. Consideration is given to new developments and future trends.

Multiresidue Methods

A number of analytic methods designed to determine multiple pesticide residues have been developed since the 1950s and 1960s. Chromatographic methods represent the most suitable approach for determining pesticide residues in food samples, and MRMs represent an efficient and widely used approach for pesticide analysis. In general, MRLs in most of the current legislation are in the range 0.01–10 mg kg^{-1}, depending on the commodity–pesticide combination, the lowest level being characteristic of banned or very toxic compounds – because it is considered that this would be the minimum limit of detection. However, these MRLs can be even lower for some particular cases, as for baby food.

The low parts per billion level at which a pesticide residue should be analyzed in a complex food matrix, such as fruits, vegetables, milk, meat, or eggs, represents a major analytic challenge. Another problem that should be considered in residue analysis concerns the pesticide metabolites and/or degradation products included in the residue definition that need to be detected by the analytic methods. Most pesticides are oxidized, reduced, or hydrolyzed by different mechanisms to more polar forms. In addition to these known metabolites, the presence of unknown metabolites may interfere with the analysis, and further identification of these unknown and confirmation for each compound are required. Pesticide residue definitions are periodically revised to incorporate all metabolites of concern. The analysis of the metabolites is so complicated that there are two residue definitions established: one used for monitoring and enforcement and the other for risk assessment to ensure better evaluation of the risk for human beings.

An ideal method for residue analysis should be sensitive, selective, accurate, precise, automated, cheap, applicable to a wide range of pesticides and matrices, and capable of providing unambiguous structural information. However, such ideal methods are not encountered in practice. Analytes must be isolated from matrices and then enriched before the final determination to eliminate matrix components and to ensure the appropriate sensitivity. The complete procedure for determining pesticide residues in food is complex and consists of several stages, which, together with the different possible analytic techniques, are summarized in Figure 1. Of these possibilities, this article will only describe those used for routine monitoring.

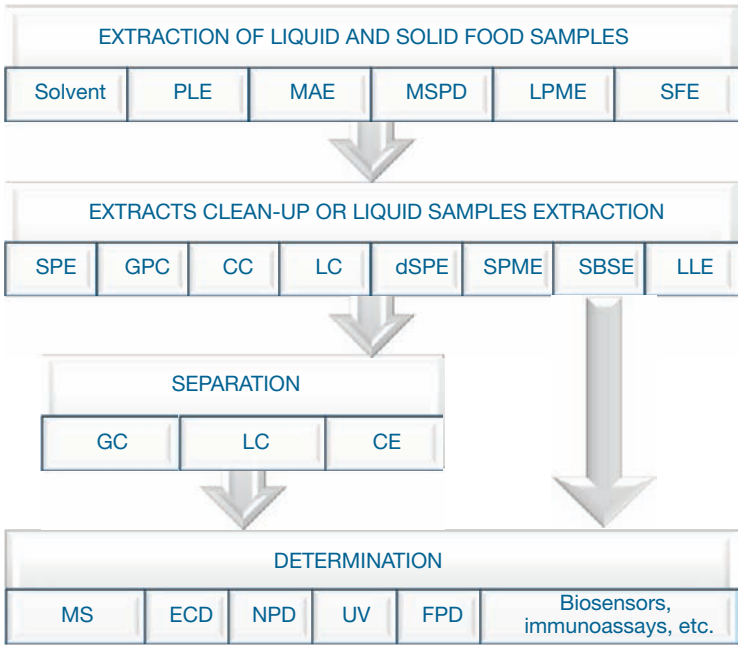

Figure 1 The main stages in analytic procedures for pesticide residue determination in food.

Extraction

Factors relating to the choice of the extraction procedure are (a) the determination techniques, (b) the nature and number of pesticides, and (c) the complexity of the matrix. The first prominent MRM, the Mill's method, was developed at the Food and Drug Administration (FDA) in the United States during the 1960s to measure nonpolar organochlorine pesticides in nonfatty food. The Mill's method utilized acetonitrile extraction and acetonitrile/water partitioning. Follow-up research in the 1970s used NaCl for more efficient extraction and partitioning.

The disadvantage of the Mill's and other similar methods was their inefficiency as screening procedures. These methods are too complex, labor-intensive, and time-consuming, and, many times, they do not generate relevant data in time to prevent contaminated foods from entering the marketplace (it should be taken into account that most food samples are highly perishable). These schemes required an amount of chemicals and toxic solvents that is usually greater by a factor of 10^8–10^{10} than that of the pesticide to be determined. Furthermore, increasing polar and/or thermodegradable pesticides should be incorporated into the existing MRMs.

In this sense, the increased sensitivity, selectivity, and specificity of analytic instrumentation for the final determination of pesticide residues have reduced the sample treatment. Nonselective detectors in gas chromatography (GC) or liquid chromatography (LC) (such as nitrogen–phosphorus detector (NPD), electron capture detector (ECD), or UV) need more extensive sample cleanup. In contrast, current MS techniques in combination with GC or LC simplify, or even eliminate, the cleanup of the sample extract.

Solid-phase extraction (SPE) methods have been used since the 1980s to replace liquid–liquid extraction (LLE) methods, which have been limited due to mounting environmental and health concerns.

The amount of research on the ways to reduce solvent usage and laboratory time has increased since the 1990s, and several alternative extraction methods including matrix solid-phase dispersion, supercritical fluid extraction, liquid-phase microextraction (LPME), stir bar sorptive extraction, and solid-phase microextraction have been introduced. However, at the moment, these methods are not robust and reliable enough to replace more conventional solvent extraction.

The efficiency of the extraction methods could be improved by the application of alternative sources of energy such as microwaves or high temperatures, which are applied in techniques such as microwave-assisted extraction and pressurized liquid extraction. However, the additional amount of laboratory material, as well as the extra energy required, is not proportional to the provided efficiency increment. Manual or mechanical shaking and ultrasounds are preferred to guarantee an appropriate efficiency.

During the 2000s, new advanced technologies incorporating a rapid and simple pretreatment step were developed to detect pesticides in foods. These methods are characterized for being as generic as possible, achieving the extraction of the majority of pesticides and even the extraction of other toxic organic compounds from food such as antibacterials, mycotoxins, and toxins. The required specificity will be provided by the determination technique. Among these types of procedures, the quick, easy, cheap, effective, rugged, and safe (QuEChERS) method has become the most popular. This two-step system based on partitioning with acetonitrile, followed by a dispersive SPE (dSPE) cleanup with primary–secondary amine (PSA) and/or other sorbents, provides a clean extract appropriate for both GC and LC. This approach has been verified and

modified at several US FDA (AOAC Official 2007.01 Method) and EU (European EN 15662 Method) laboratories, and the method now is widely accepted for many types of pesticide residue samples. Reviews of QuEChERS are starting to appear in the literature, and the original method has evolved into a flexible template for modification in several applications. Validation and proficiency data are available for a wide variety of pesticides in several common food matrices. Commercially available QuEChERS extraction and dSPE products in a variety of standard sizes and formats make this approach even simpler. The straightforwardness of this method is schematized in Figure 2.

Currently, QuEChERS methodology makes possible the simultaneous determination of more than 800 pesticides and even other contaminants in crops. This extraction procedure conforms to the principles of green analytic chemistry because it

- enables a wide range of analytes to be determined in a single analysis using MRMs;
- ensures maximum removal of interferences from extracts;
- yields high recoveries of compounds, is very sensitive, and guarantees good precision; and
- consumes the smallest possible amounts of chemical reagents, especially organic solvents.

Despite the widespread use of the QuEChERS method in the control of pesticide residues, the extraction step is not yet a closed chapter. The current trend toward the use of smaller amounts of sample and organic solvents will continue to develop in the future to save the bottleneck that still represents the extraction of samples.

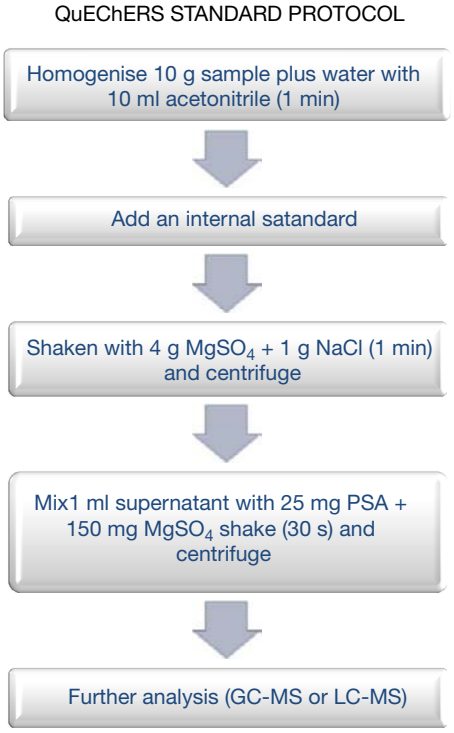

Figure 2 Scheme of the Mill's and QuEChERS multiresidue methods.

Cleanup methodology

Food extracts contain, in addition to pesticides, many other compounds, mostly coming from the matrix, which produce several analytic problems. Their loading onto chromatographic columns can deteriorate the separation efficiency and cause irreparable column damage. Furthermore, with nonspecific detectors, these compounds can interfere with the detection systems and give rise to false-positives. Therefore, direct analysis is not always possible without further purification for cleaning up the extract and enriching the target analytes. LLE, gel permeation chromatography, column chromatography (CC), and even LC (either normal- or reversed-phase) were extensively developed in the past to further purify trace pesticides from crude extracts.

If the determination is carried out by MS, these coextracted materials are responsible for the matrix effect characterized by enhanced or more frequently suppressed analyte signals that can heavily affect detection and quantification. Despite these effects, nowadays, there is a trend to keep the cleanup part as simple as possible or even eliminate it. LPME has been used as an alternative to LLE for cleanup and as a replacement for CC; SPE with small commercial cartridges is often applied after the different extraction techniques to purify the extracts of fruits, herbs, and other vegetable samples. An effective cleanup step is still required in order to eliminate interfering compounds (mainly lipids and pigments) present in the extracts. However, currently, laborious and time-consuming cleanup procedures are being replaced with LPME, SPE, and dSPE.

dSPE was included as a novel cleanup technique for the QuEChERS. It is based on the addition of the sorbent material into an extract aliquot to remove the matrix interferences, which is then separated from the extract bulk by centrifugation. In this way, dSPE avoids passing the extract through a SPE column, using a much smaller quantity of sorbent and solvent, saving time and labor. Mostly, PSA was used as dSPE sorbent that could remove various polar organic acids, polar pigments, some sugars, and fatty acids. Further research modified the original method with changes of sorbents used in the dSPE step. Modified QuEChERS cleanup steps with GCB or C_{18} as sorbents were reported; in these cases, sterols and pigments, such as chlorophyll, may be absorbed by GCB and nonpolar interfering substances like lipids could be removed by C_{18}. Although the dSPE cleanup is faster and easier, it is not as effective as the use of SPE columns. dSPE procedure could not be sufficient in removing food colorings such as chlorophyll, carotene, and water-soluble materials. In some cases, the QuEChERS was modified, changing dSPE to more conventional SPE.

Although the current trend is to reduce to the maximum cleanup process, routine practice highlights its extreme importance to obtain a correct identification and quantification of pesticides in food. However, this is a long and tedious stage of the process that is difficult to optimize. Currently, it is still needed to reach a balance between the spent time and the quality of the results.

Determination

Since the early 1970s, most routine pesticide residue determination has been conducted by GC with different detectors, ECD, NPD, flame photometric detector, etc. During the

1980s, these detectors were quickly replaced by MS detector, given that this detector is very specific and provides enough structural information to achieve confirmation of compound identity.

However, since the 1990s, there has been a clear trend to increase the number of LC applications in pesticide residue analysis, both in specific/individual methods and in MRMs, especially after the introduction into the market of robust, easily operated LC–MS instruments that provide a new way of analyzing pesticides that is more sensitive and efficient and with greater scope (~80% of currently used pesticides can be determined by without long and tedious derivatization). Furthermore, LC–MS showed better performance than GC for all pesticides except organochlorine. However, GC is still an unquestionable tool within pesticide residue determination since LC has some disadvantages compared with GC such as lesser resolving power.

Capillary electrophoresis emerged some years as an interesting alternative but it is not applied in routine monitoring, mostly because it is always less sensitive than LC or GC.

There are also nonchromatographic or miniaturized methods for residue detection. These methods consist of a wide variety of techniques. For illustrative purposes, these may be divided into 'biological'- and 'physical'-based methods, depending on whether or not biological reagents are involved. Biological techniques include immunoassays, biosensors, bioassays, and enzyme assays. However, these techniques, despite their interesting prospects within the field, are not well suited for multiresidue analysis because they can only be used to simultaneously determine a limited number of compounds.

MRMs enabling the determination of pesticide residues at low concentration levels need highly sophisticated MS instrumentation. The first mass spectrometer available to determine pesticide residues at trace level was the quadrupole. However, the development of new mass spectrometers has created the appropriate background to improve the scope of the MRMs. Within this situation, two emerging trends in the mass analyzer design are valuable to get better quality and quantity of structural information:

- High-resolution (HR) or high-accuracy mass spectrometers, which calculate elemental composition because they can determine the exact mass of analytes, are a tool to identify unknown substances in the samples. These instruments easily provide the full-range mass spectrum with high sensitivity. Most used in pesticide residue determination are the time of flight (ToF) and the orbitrap.
- Tandem mass spectrometry (MS/MS) allows the mass spectrometer to isolate an ion and fragment it to obtain its mass spectrum again. The mass spectrometers capable of carrying out MS/MS only with nominal mass are the triple quadrupole (QqQ), ion trap (IT), and quadrupole–linear ion trap (QTrAP). The quadrupoles have the inconvenience of low sensitivity using scan, but ITs and QTrAPs can provide full-range mass spectra with appropriate sensitivity. Furthermore, the hyphenation of different mass analyzers has also achieved the possibility of combining HR and MS/MS as it is the case of the quadrupole–ToF (QqToF) and the QTrAP-orbitrap.

These mass analyzers can be combined indistinctly with either GC or LC. However, orbitrap is still considered as a research tool within LC–MS. Thanks to these combinations and their wide range of possibilities, two types of analysis can be established, depending either on the way the analysis is approached or on its final purpose; the determination of pesticide residues may be targeted and nontargeted as schematized in Figure 3. Each of these analyses can be performed by either LC or GC and by either nominal or HRMS with some limitations that will be discussed later in the text.

Target analysis

This is a conventional analysis based on establishing a method with standards prior to analysis and monitoring real samples. Target analysis can be carried out with all types of mass spectrometers, and commonly, it achieves better sensitivity because the chemical background is reduced using selected ion monitoring in low-resolution quadrupole or selected reaction monitoring (SRM) in MS/MS. The main problem to confirm the identity of the compounds in these cases is the presence of isobaric interferences that are compounds with the same nominal mass and different chemical structure. The normal practice to confirm the identity of the compounds is to select several characteristic fragments (commonly three). Better specificity is obtained for MS/MS because even if several coeluting compounds have identical molecular mass, usually (nominal) isobaric ions can be distinguished by the SRM experiments, because the fragmentation in the collision cell frequently results in different product ions. The main advantages of MS/MS are their very good quantitative capabilities and their great sensitivity in the SRM mode and the possibility to select simultaneously multiple transitions. For this reason, QqQ mass analyzers have been the most often applied MS detectors. It should be kept in mind that target analysis can also be carried out using HRMS. In this case, the background signals produced from sample matrix and LC solvent clusters are reduced by the use of very narrow mass ranges for the extraction of the chromatogram.

Nontarget analysis

All compounds eluted from the analytic column are detected and identified without any previous selection. This nontarget approach has the advantages of identifying unexpected pesticides and metabolites as components present in the sample and allowing the proposal of their elemental compositions. In general, this approach is limited by sample treatment step and also by ionization mode. Only compounds working on selected ionization conditions and compatible with the sample-extraction procedure can be detected.

Any instrument able to provide full spectrum in an m/z range can be used for nontarget analysis, including quadrupole. However, HRMS has opened new possibilities because the accurate mass measured allows us to obtain the empirical formula of the pesticide facilitating its identification. Extensive screening and searching of a wide range of pesticide residues or even other compounds can be afforded using databases. Depending on the detector degree of sophistication, these databases include library search, isotopic signature information, element-specific information from isotopic signatures, relative intensities, and areas from isotopes (ratios and

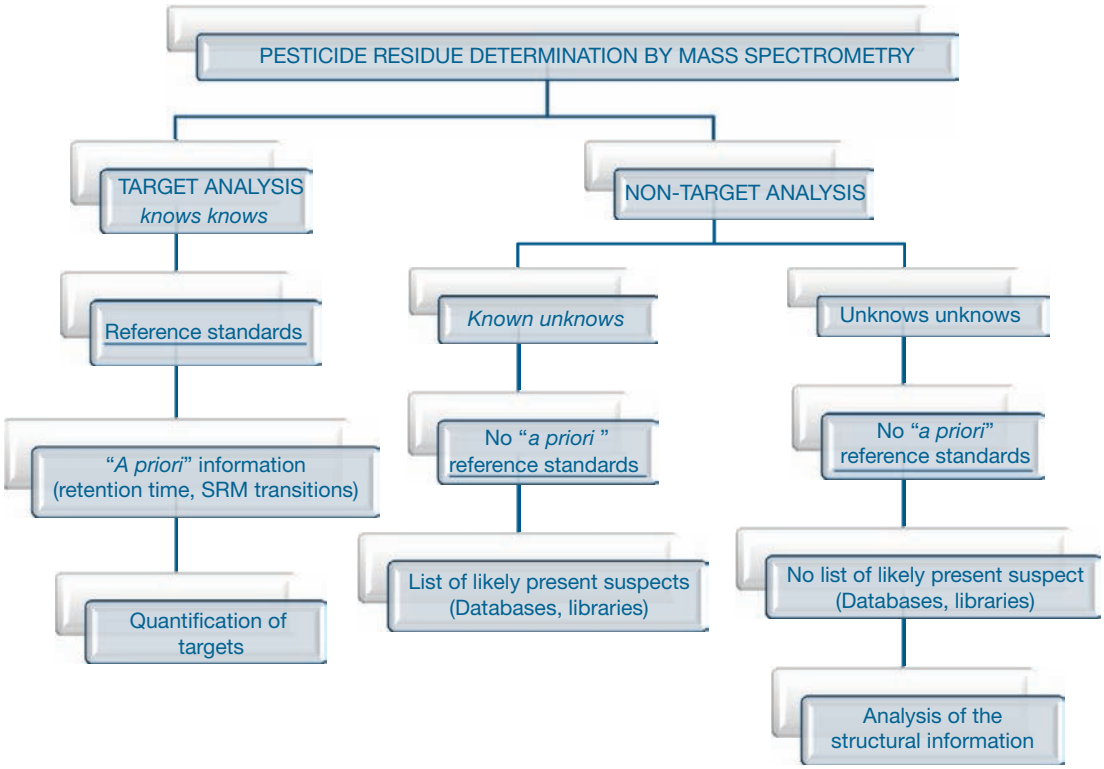

Figure 3 Target and nontarget pesticide residue determination.

abundances), making an accurate identification of the compounds without the 'a priori' need of analytic standards.

The acquired full-scan MS data can be used to retrospectively examine data for nontarget pesticides and/or metabolites. The information of the accurate molecular ion, isotopic pattern, and detected fragment ions can be used to characterize the structure of nontarget ions. Figure 4 shows the residue of imazalil in an apple sample, detected and identified in a nontarget way by GC-ToF-MS. Accurate mass confirmation automatically performed for four representative ions and the library forward match (>700 used as criterion) led to the confirmation of the identity of imazalil with mass errors below 1.8 mDa for all ions. In addition, the structures proposed for at least four fragment ions observed in the EI spectrum were compatible with the chemical structure of imazalil. The injection of reference standards allowed the presence of imazalil in the samples to be confirmed.

Gas chromatography–mass spectrometry

Nowadays, more than 60% of the pesticide residues are still detected by GC. With more benefits such as simple manipulation, fast speed, and high separating efficacy, GC is widely used to analyze volatile and thermostable pesticide residues with relatively small molecular weight, such as organochlorine, organophosphorus, and pyrethroids.

Typical GC–MS methods use a relatively long, narrow-bore analytic column (30 m, 0.25 mm i.d.), which generally requires >30 min run time per sample, especially when analyzing >100 GC-amenable pesticides. However, faster chromatographic separation reduces the analysis time, which can be translated in a significantly increased sample throughput. Among the alternatives, low-pressure GC–MS has advantages of increased ruggedness, sensitivity, and speed (150 pesticides were separated in <6.5 min) with the only sacrifice of reduced chromatographic separation efficiency.

Another possible approach to faster GC is to optimize selectivity (ability to distinguish between compounds) with respect to the utilization of time. Two-dimensional (2D) GC coupled to ToF-MS (GC × GC-ToF-MS) provides an additional separation because coeluting peaks, resulting from a one-dimensional separation, can be separated by a second column possessing a different stationary phase. The resulting GC × GC chromatograms form narrow peaks and require a mass spectrometer such as high-speed ToF to be fast enough to scan enough data points for each peak. This high-speed ToF only provides nominal mass differently to the high-resolution ToF. This approach is not extensively used within the pesticide residue field because the difficulties in processing the high amounts of obtained information.

For analytes amenable to GC–MS, identification of nontarget compounds is sometimes feasible with low-resolution quadrupoles, as forward-search methods enable library searching (e.g., the large library of the National Institute of Standards and Technology). However, to obtain an unbiased dataset, full-spectrum acquisition techniques are required. Single-quadrupole and QqQ instruments generally do not operate in full-scan mode when applied to residue analysis because of the lack of sensitivity. IT instruments normally have higher sensitivity in scan mode, but they have low selectivity because they acquire mass spectra in nominal mass, a drawback that also applies to single-quadrupole and QqQ analyzers.

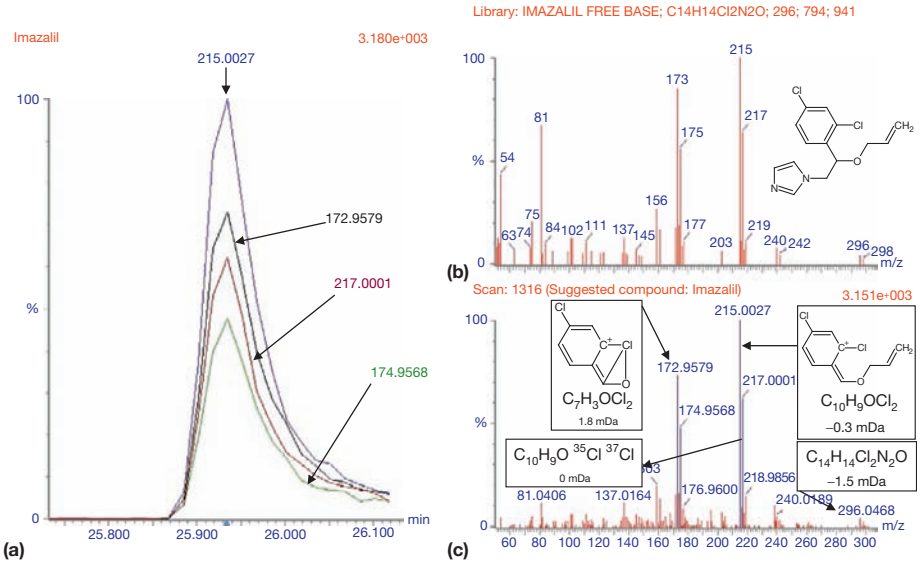

Figure 4 Identification of nontarget imazalil in apple. (a) Extracted ion chromatograms for four imazalil ions used for deconvolution. (b) Library mass spectrum of imazalil at nominal masses (match 839). (c) Deconvoluted accurate mass spectrum of imazalil from the sample and chemical structures proposed for four representative EI fragment ions together with mass errors. Reproduced from Cervera, M. I., Portolés, T., Pitarch, E., Beltrán, J. and Hernández, F. (2012). Application of gas chromatography time-of-flight mass spectrometry for target and non-target analysis of pesticide residues in fruits and vegetables. *Journal of Chromatography A* **1244**, 168–177, with permission from Elsevier.

GC has been combined with HR-ToF-MS (GC-HR-ToF-MS) for nontarget screening of GC-amenable pesticides. This MS analyzer provides the selectivity and the sensitivity required for efficient, wide-range screening, as it combines high, full-spectral sensitivity with high mass resolution to measure accurately the mass of any ionizable component in the sample. Elemental compositions can be proposed with low mass errors (typically below 5 ppm). ToF-MS can provide a notable amount of chemical information in a single experiment, so this technique is very attractive for performing nontarget analysis, as illustrated in Figure 4.

Liquid chromatography–mass spectrometry

LC–MS has become one of the reference techniques in pesticide residue analysis, matching to the GC or even surpassing it. The column is the soul of an LC system. Traditional LC columns are 50–300 mm long and have internal diameters between 3 and 4.6 mm. However, the combination of LC and MS has been a motor in the miniaturization of the LC columns as the MS interfaces require low flow rates (to form smaller droplets in the electrospray). Miniaturization in LC is also an important strategy and is mostly based on reducing the inner diameter of the LC columns or the particle size. Medium, narrow-bore LC columns (50×2.1 mm) and intermediate flow rates (~ 0.2 ml min^{-1}) are often ideal.

The reduction of the particle size, the emerging issue in the field of pesticide separation, is the introduction of new ultra-high-performance liquid chromatography (UHPLC) platforms. This instrument has been shown to give superior chromatographic resolution, reduced analysis time, and increased response. The low degree of band broadening in UHPLC also benefits mass spectrometric detection, concentrating the analyte at the peak center and thereby increasing response. Thus, UHPLC coupled to MS offers improvements in performance for quantitative analysis over existing high LC–MS/MS methodologies. Pesticide residue analysis in food can also benefit from the high sample throughput obtained in UHPLC methods, keeping the high multiresidue capability required for such applications. Although UHPLC technology was launched only recently, many applications to determine pesticide residues can be found, which illustrates the interest in this technique. It has almost replaced most conventional LC. 2D LC approaches have also been developed to improve separation between pesticides and also can favor the separation between pesticides and matrix compounds. These 2D systems are simpler than their GC homologous and shown better perspectives within the field.

LC–MS/MS is most widely employed for the simultaneous qualitative and quantitative profiling of multiple classes of pesticides because of its high sensitivity and selectivity. Compound identification and quantification largely depend upon separation and the uniqueness of the precursor–product ion transitions selected for SRM. This approach has been the most widely applied for the simultaneous determination of individual or multiple classes of pesticides and their metabolites. It has allowed the determination of a great number of pesticides and metabolites, especially polar ones that were previously difficult or even impossible to analyze.

This approach, however, does not enable to identify nontargeted compounds. In other words, the detection of analytes for which a reference substance is not available is a rather complicated (or even impossible) task. Another problem encountered when using a number of MS/MS is moving an analyte out of an originally fixed time window, which requires its readjustment.

ToF-MS, QqToF-MS, and orbitrap in combination with LC are used in HR mode (typical mass error <2 mDa), which provides better discrimination of background and more accurate identification of unknown peaks in a sample, even if analytic standards are not available. The ToF capability of interrogating full-spectrum data postacquisition seems more interesting, as it also allows screening for unexpected metabolites at the time of injection without reanalyzing the sample. Unlike GC–MS, LC–MS still does not have commercially available or standardized spectral libraries due to the absence of a normalized interface. The differences in ionization between existing interfaces, together with variability in results, depending on the composition of the mobile phase or the cone voltage applied, make it difficult to use standardized libraries. This means that it is necessary to build homemade libraries to facilitate searching, focusing on particularly relevant compounds.

The application of a hybrid QqToF-MS technique to pesticide residue analysis in food allows an unequivocal confirmation of the contaminants detected. Eliminating false-positives and avoiding interpretation ambiguities are possible because of its unique characteristic of generating full-scan product ion spectra with exact masses. The main fields of application are the identification of unknowns and elucidation of structures proposed for transformation products, where the amount of information obtained allows secure identification of the identity of compounds.

Conclusions and Future Trends

In the recent years, the detection technology of pesticide residues in food has developed rapidly. At present, some new analytic methods and techniques are making great progress, especially in the multiresidue analysis for many types of pesticides. Particularly, extraction procedures that are simple, generic, and ecofriendly have been fully implemented thanks to the advances in the determination techniques. Nowadays, extraction is not the narrow bottleneck that was before.

MS has clearly modified the strategy applied for the quantification of pesticide residues in food, biological, and environmental samples. MS is now playing a pivotal role in solving analytic problems concerning pesticide residues. Because both GC–MS and LC–MS allow the achievement of high-throughput analysis with high sensitivity and selectivity, the sample preparation can be simplified and sped. The enhanced selectivity of MS/MS techniques is almost mandatory for complex sample matrices like fruits and vegetables.

With the introduction of QqQ-MS, IT-MSn, LIT, ToF, QqToF, and orbitrap instruments, all major classes of pesticides can be detected, identified, and quantified satisfactorily. Currently, the first option is typically QqQ-MS or LIT-MS in multiple SRM for target pesticide analysis. However, the gradual introduction of the newly developed accurate mass spectrometers, such as the QqToF or the orbitrap, with the distinctly enhanced selectivity and the possibility of calculating elemental composition will improve the performance of the analysis and open the door to the identification of nontarget and unknown pesticides and metabolites.

No doubt, in the next decade, LC–MS and GC–MS will develop new analytic tools for the characterization of a pesticide in parts per trillion levels or lower, and the detection of a pesticide with a very low threshold will be among the leading options.

Pesticides and Herbicides: Types of Pesticide

H Karasali and N Maragou, Benaki Phytopathological Institute, Athens, Greece

© 2016 Elsevier Ltd. All rights reserved.

Introduction

The use of synthetic pesticides started in 1948–49 with the use of 1,1,1-trichloro-2,2-bis (chlorophenyl)ethane (DDT; Figure 1) for malaria and hexachlorobenzene (BHC) for locust control. Since then, pesticides play a key role in agriculture and animal husbandry. Following the end of the Second World War and the introduction of synthetic organic insecticides for the control of insect pests, a great number of companies took up the research for the synthesis of new pesticides, mainly insecticides. In 1950, more than 30 companies in the United States and Europe were involved in pesticide discovery, and by the end of 1960, this number had risen to 50 companies. The next decade, this number declined slightly. Later on, there has been a substantial degree of reduction in agrochemical companies. There were many reasons for this steady reduction, among them the most important was the increasing regulatory requirements as regards the human and environmental safety leading to escalating costs in the development and registration of new products.

Pesticides are defined by the FAO (Food and Agricultural Organization) as substances or mixtures of substances intended for controlling, preventing, destroying, repelling, or attracting any biological organism deemed to be a pest. The term pest includes insects, mice, and other animals, weeds, and fungi, among others. Pesticides are usually chemical substances, although they can be sometimes biological agents such as viruses or bacteria. The term 'pesticides' is often used as a synonym for plant protection products, which are mainly used in agriculture to keep crops healthy and prevent them from being destroyed as a consequence of disease and infestation. However, pesticides include also the class of biocides that are used for similar purposes but in fields other than agriculture. For example, pesticides have been used in the human health sector for the control of insect-borne diseases such as malaria, dengue, and encephalitis, especially in tropical countries.

Plant protection products were initially applied to cereal crops, and now, they are used in the agriculture sector including horticultural, ornamental, and vegetable crops. The active portion of a plant protection product, known as active ingredient, is usually the only component of the formulation listed on the label and is generally formulated by the manufacturer as liquid or solid formulation. The most widely available formulation types are listed in Table 1. The active ingredients used in plant protection products are the chemicals or microorganisms including viruses that are the essential component enabling the product to be effective. For example, they may destroy unwanted plants in the case of herbicides or protect the plant against insects or fungi that destroy plants or reduce crop yields.

Agricultural yields strongly depend on crop protection measures. Great productivity gains can be achieved in agriculture with the use of pesticides. Indeed, they are needed to meet the world's demand on foodstuffs, and there are no other alternatives that can be used in such a large scale. Pesticides help farmers and growers to produce good-quality food at reasonable prices. The main purpose of pesticide use is to

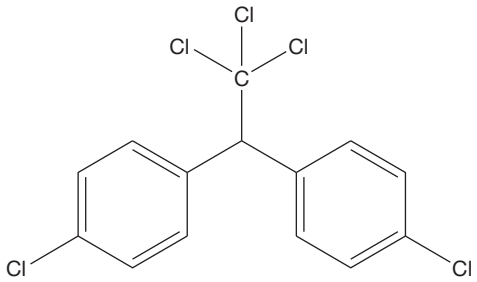

Figure 1 Molecular structure of DDT.

Table 1 Catalog of the most widely available pesticide formulation types and their international coding system as reported in the 'Manual on development and use of FAO and WHO specifications for pesticides'

Formulation types	*Definition*
Capsule suspension (CS)	A stable suspension of capsules in a fluid, normally intended for dilution with water before use
Dustable powder (DP)	A free-flowing powder suitable for dusting
Emulsifiable concentrate (EC)	A liquid, homogeneous formulation to be applied as an emulsion after dilution in water
Emulsion, oil in water (EW)	A fluid, heterogeneous formulation consisting of a solution of pesticide in an organic liquid dispersed as fine globules in continuous water phase
Granule (GR)	A free-flowing solid formulation of a defined granule size range ready for use
Oil dispersion (OD)	A stable suspension of active ingredient(s) in a water-immiscible fluid, which may contain other, dissolved active ingredient(s), intended for dilution with water before use
Water-soluble granule (SG)	A formulation consisting of granules to be applied as a true solution of the active ingredient after dissolution in water, which may contain insoluble inert ingredients
Soluble concentrate (SL)	A clear to opalescent liquid to be applied as a solution of the active ingredient after dilution in water
Technical material (TC)	A material resulting from a manufacturing process comprising the active ingredient, together with associated impurities. This may contain small amounts of necessary additives
Water-dispersible granules (WG)	A formulation consisting of granules to be applied after disintegration and dispersion in water
Wettable powder (WP)	A powder formulation to be applied as a suspension after dispersion in water

increase food security, with a secondary goal being an increased standard of living. Other benefits from their use include reductions in agricultural labor and energy expenses.

However, pesticides have also negative impacts on human health and the environment. Humans are exposed to pesticides by different routes, such as inhalation, ingestion, and dermal contact, which may result in acute or chronic health problems. Additionally, the environmental contamination from pesticides provokes nontarget species poisoning and disturbance of the ecosystems. For these reasons, the pesticide regulatory authorities have established regulations for their authorization, proper use, and disposal.

In this article, several types of pesticide classification are presented, and certain related definitions are given for clarification purposes. Their main adverse health effects and the environmental contamination and its impact are described. Finally, current regulations are reported with emphasis to those of the European Union.

Definitions

A pesticide formulation is a mixture of different components prepared properly for safe use. Definitions regarding basic terms, useful to understand what components constitute a pesticide product, are presented and are based on those outlined in the 'Manual on development and use of FAO and WHO (World Health Organization) specifications for pesticides' published in November 2010 (second revision of the first edition), prepared by the FAO/WHO Joint Meeting on Pesticide Specifications.

The term 'pesticide' is considered to embrace active ingredients in any form, irrespective of whether, or to what extent, they have been formulated for application. The term is usually associated with materials intended to kill or control pests (insecticides, fungicides, herbicides, etc.), but it also embraces certain materials to control the behavior or physiology of pests (e.g., insect repellents and insect growth regulators) or of crops during production or storage.

The term 'active ingredient' refers to the component(s) of a formulation responsible for the direct or indirect biological activity against pests and diseases or in regulating metabolism/growth. A single active ingredient may be composed of one or more chemical or biological entities that may differ in relative activity. A formulation may contain one or more active ingredients.

'Formulation' is a pesticide preparation containing technical-grade active ingredient(s) and formulant(s) in a form suitable for use.

'Formulant' is any substance, other than the technical-grade active ingredient, intentionally incorporated in a formulation.

In most of the cases, pesticide products contain impurities; among them, only the case of what is a relevant impurity should be clarified. As 'relevant impurity' is considered a by-product of the manufacture or storage of a pesticide, which, compared with the active ingredient, is toxicologically significant to human health and the environment, it is phytotoxic to treated plants, affects the stability of the pesticide, or causes any other adverse effect. In order to be clarified, an impurity may be nonrelevant in one pesticide product and relevant in another, even though it occurs in both, because relevance is determined by hazards relative to those of the active.

Classification of Pesticides

Pesticides can be classified in a number of ways. Basically, they can be divided into plant protection products and biocidal products. The former are used in agriculture to protect crops and in forestry to protect trees from pests and diseases. In contrast, the field of application of biocidal products involves human and veterinary hygiene, food preservatives, and antifouling products, among others, but not agriculture and related areas. Both of these main categories can be further classified according to the target organism, the chemical structure, and the source of the active substance. Another classification concerning the formulation type of pesticides has already been illustrated in Table 1. Other classifications involve the developmental stage affected, acute and chronic toxicity, general action on pests, biochemical or physiological activity, and application method. The most representative classifications of the general term pesticides are described in the succeeding text. At the end of this section, a classification concerning only biocidal products is presented in Table 2.

Target Pest Species and Pesticide Function

One of the most typical classifications of pesticides is based on the type of pest against which they are directed. The main categories are herbicides, insecticides, and fungicides, which are applied in order to kill weeds, insects, and fungi, respectively. Other types of pesticides are rodenticides, bactericides, nematicides and acaricides. Plant growth regulators are also included in the category of pesticides.

Among the different types of pesticides, herbicides are the most widely used, accounting for more than 60% of all pesticides applied in the agricultural sector. The first systemic herbicides 2,4-dichlorophenoxyacetic acid (2,4-D), 2,4,5-T, and MCPA had been discovered before the Second World War around 1940. These compounds killed selectively many weeds in small quantities and in a relatively inexpensive way. For that reason, herbicides were considered among the greatest scientific discoveries of the twentieth century. In 1951, Willard called 2,4-D "the catalyst which generated the recent and continuing explosive reaction concerning plant control by chemical means." Half a century later, it remains one of the most widely used herbicides in the world. The finding of the first hormone herbicides was a multiple independent discovery. A group of scientists in the United Kingdom and separate groups in the United States made the discovery, without knowledge of the others' efforts. In 1945 started the market of 2,4-D in the United States, under the trade name Weedone, and ICI in the United Kingdom began selling MCPA as Methoxone. Since then, the annual commercial production of herbicides grew from less than one million pounds in 1945 to more than 30 million in 1952 and to more than 60 million in later years.

The increasing demand of food for the world's ever-growing population coupled with allocation of arable lands for biofuel production necessitates increasing global agricultural yields. Because weeds are responsible for the major part of agricultural

losses worldwide, maintenance of world agricultural production is directly dependent on the chemical control of weeds. Thus, research for new herbicides with different modes of action from herbicides already available in the market is increasingly important.

Chemical Structure

Based on their chemical structure, pesticides can be classified as organic and inorganic compounds. Organic pesticides are complex chemical compounds with a carbon backbone in their molecular structure, often bonded to heteroatoms such as oxygen, phosphorus, sulfur, chloride, and fluorine, whereas inorganic pesticides consist of the inorganic compounds of sulfur, copper, and other elements. Although the earliest chemical pesticides were inorganic, the vast majority of modern pesticides belong to the class of organic compounds. Organic pesticides can be further divided into many other subcategories based on their functional groups, with the most characteristic ones presented in the succeeding text.

Organochlorines

The organochlorine pesticides (OCPs) are insecticides and characterized by three types of compounds: DDT analogs (Figure 1), benzene hexachloride (BHC), and cyclodiene compounds. OCPs are persistent and toxic chemicals, belonging to the group of persistent organic pollutants (POPs). Although these compounds were widely used in the 1940s in large quantities, they were banned in developed countries in the 1970s because of their high persistence in the environment and their harmful effects in human health. OCPs are semivolatile compounds, and they have the ability for wide range transportation in the environment and bioaccumulation in food crops and animal tissues. They tend to move from warmer to colder climate regions, even as far as the poles.

Organophosphates

The organophosphate pesticides are the general name for esters of phosphoric acid. They are broad-spectrum compounds, with a very specific action, characterized by their high water solubility in comparison with OCPs. Because of that, they are readily hydrolyzed and dissipate from soil within a few weeks after their application. This group of pesticides is highly applied worldwide due to their low persistence and high effectiveness. Organophosphate pesticides are generally regarded as safe for use on crops and animals due to their relatively fast degradation rates. Their ability to degrade made them an attractive alternative to the persistent OCPs previously described. Although organophosphates degrade faster than the OCPs, they have greater acute toxicity, posing risks to people who may be exposed to large amounts. Organophosphate pesticides irreversibly inactivate acetylcholinesterase, which is essential to nerve function in insects, humans, and many other animals. They have been characterized as compounds with very high acute toxicity to bees, wildlife, and humans. Recent studies suggest a possible link to adverse effects in the neurobehavioral development of fetuses and children, even at very low levels of exposure. In this class, well-known compounds such as parathion, malathion, chlorpyrifos (Figure 2), diazinon, dichlorvos, phosmet, and azinphos-methyl are included.

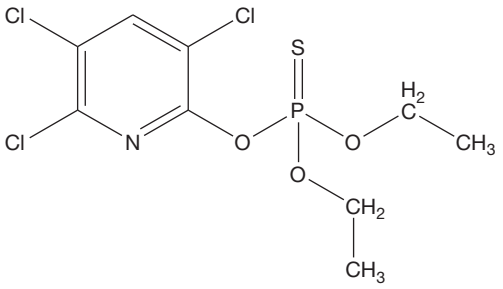

Figure 2 Molecular structure of chlorpyrifos.

Triazines

Triazines belong to one of the most important group of herbicides that is widely used throughout the world. These compounds are applied in agriculture as selective pre- and postemergence weed control for corn, wheat, barley, sorghum, and sugar cane, but they are also widely employed for nonagricultural usage (railways and roadside verges). In some cases, they are used in combination with other herbicides. Triazine herbicides and some of their transformation products are considered as one of the most important classes of chemical pollutants owing to their widespread use and toxicity. Moreover, some compounds of this chemical family are highly persistent in all environmental media and in organisms. Additionally, atrazine, one of the most representative members of triazines, has been classified as a possible human carcinogen. Other representatives of this group are the herbicide simazine and the insecticide cyromazine.

Ureas and substituted ureas

Urea and substituted urea herbicides belong to one of the most important agricultural herbicide groups. Diuron, linuron, and isoproturon are representative compounds of this class that have been widely used in agriculture. There are several subcategories of substituted ureas with phenylureas being the most important one. The general structure of a phenylurea herbicide is phenyl–NH–C(O)–NR_2. The phenyl ring is often substituted with chlorine or bromine atoms, but methoxy, methyl, trifluoromethyl, or 2-propyl substitution is also possible. Phenylurea herbicides are used as selective and nonselective herbicides in substantial amounts, including the use as systemic herbicides to control broadleaf and grassy weeds in cereals and other crops.

Sulfonylurea constitutes another group of substituted ureas, which belongs to the group of selective herbicides with the following general structure R_1–NH–C(O)–NH–SO_2–R_2. R_1 and R_2 are generally substituted by heterocyclic rings. The mode of action of these herbicides consists of inhibiting acetolactate synthase – a key enzyme in the biosynthesis of branched amino acids (valine, leucine, and isoleucine). They are low-dose herbicides used to control broadleaf weeds in cereals exhibiting very low acute and chronic mammalian toxicities.

Benzoylureas are also a group of substituted ureas introduced in the early 1970s. This group belongs to the class of insect growth regulators that act on the larval stages of most insects by inhibiting or blocking the synthesis of chitin. Diflubenzuron is the prototype of benzoylurea chitin synthesis inhibitor insecticides. Benzoylureas are characterized by low acute toxicity to mammals along with their high biological

activity, and for that reason, they are included in integrated pest management programs.

Representatives of the group of ureas and substituted ureas, widely used in agriculture, are diuron, linuron, and isoproturon.

Carbamates

Carbamate herbicides were developed during the early nineteenth century, but their effects were discovered in 1932. Carbamates are organic compounds derived from carbamic acid (NH_2COOH). Specifically, they are esters of carbamic acid. Carbamates and thiocarbamates represent a broad group of herbicides that are applied to soil as preemergence. They are used to control annual grasses and broadleaf weeds in dome horticultural crops. They are inhibitors of the acetylcholinesterase enzyme, which terminates the action of the neurotransmitter acetylcholine. They are normally decomposed quickly in soil by microorganisms. This group includes pesticides such as carbofuran, aldicarb, oxamyl, and methomyl (Figure 3). Carbamates contain two oxygen atoms ROC(=O)NR_2. There are analogs of carbamates with both oxygen atoms replaced by sulfur, which are called dithiocarbamates (RSC(=S)NR_2). There are two different structurally isomeric types of thiocarbamate: O-thiocarbamates (ROC(=S)NR_2), where the carbonyl group (C=O) is replaced with a thiocarbonyl group (C=S), and S-thiocarbamates (RSC(=O)NR_2), where the R–O– group is replaced with an R–S– group. O-thiocarbamates can be isomerized to S-thiocarbamates.

Chloroacetanilides

Chloroacetanilides are an important class of preemergence herbicides used to control annual grasses and broadleaf weeds in various crops; some are soil-incorporated and others surface-applied. Chloroacetanilides represent a large group of herbicides with the general chemical formula $C_xH_yClNO_2$. These compounds are aniline derivatives where the nitrogen is a tertiary amine forming an acetanilide-based compound. On the alpha carbon of the amide functional group is a chlorine substituent. Because of this halogen, chloroacetanilides are considered halogenated alkyl compounds. Each herbicide differs in that their amide side-chain substituents to the benzene ring are of different lengths and types. Because of their structural similarities, these herbicides are expected to possess comparable physical/chemical properties, transformation mechanisms, modes of action, and selectivities. Among them, alachlor was one of the first herbicides widely used, while other important chloroacetanilide pesticides are acetochlor, metolachlor, and dimethenamid.

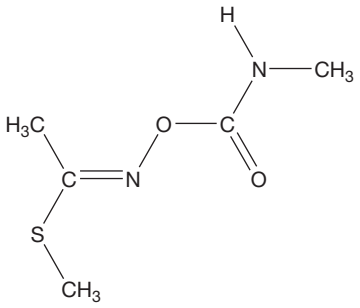

Figure 3 Molecular structure of methomyl.

Pyrethrins and pyrethroids

Pyrethrin and pyrethroid pesticides are insecticides that are mainly used in and around households, in mosquito control, and in agriculture. Their use has increased worldwide with the declining use of organophosphate pesticides, which are more acutely toxic to birds and mammals. Pyrethroid pesticides were developed as a synthetic version of the naturally occurring pesticide pyrethrin, which is found in chrysanthemums. They have been modified to increase their stability in the environment. Some synthetic pyrethroids are toxic to the nervous system.

Pyrethrins are divided into two groups: the natural and the synthetic pesticides. Natural pyrethrins – a single pesticide active ingredient, containing six components with insecticidal activity (pyrethrins I and II, cinerins I and II, and jasmolins I and II) – are botanical insecticides derived from chrysanthemum flowers most commonly found in Australia and Africa. They work by altering nerve function, which causes paralysis in target insect pests, eventually resulting in death. On the other hand, pyrethroids are synthetic chemical insecticides whose chemical structures are adapted from the chemical structures of pyrethrins and act in a similar way to pyrethrins. Pyrethroids are modified to increase their stability in sunlight. They include insecticides such as bifenthrin, cyfluthrin, lambda-cyhalothrin, and cypermethrin.

Source

Pesticides can be classified into natural and synthetic according to their source. In synthetic pesticides, the active compound is produced artificially by chemical synthesis, whereas natural pesticides are derived from naturally occurring sources such as plants, animals, and bacteria. A representative of naturally occurring pesticides is the pyrethrum, a complex of chemicals extracted from *Chrysanthemum cinerariaefolium*. Some other examples are nicotine and nicotinoid alkaloids that come from tobacco.

Biopesticides is a term widely used for natural pesticides that encompass also certain minerals like baking soda. Biopesticides are also known as biologicals, biological pesticides, biocontrol agents, or biochemical pesticides. This class of pesticides plays an important role in providing pest management tools in areas where pesticide resistance, niche markets, and environmental concerns limit the use of conventional chemical pesticide products. They can be used as insecticides, fungicides, herbicides, nematicides, plant or animal growth regulators, plant strengtheners, biostimulants, biofertilizers, and more.

Biopesticides can be distinguished into the following major categories: 'microbials' based on living organisms such as bacteria, fungi, viruses, and viroids; 'macrobials' based on macroorganisms; 'botanicals' based on plant extracts; and 'biochemicals,' covering naturally occurring substances that control pests by nontoxic mechanisms and may contain pheromones and other semiochemicals, as well as other natural products such as hormones, minerals, and enzymes. As an example, the most widely used microbial pesticides are subspecies and strains of *Bacillus thuringiensis* (Bt). Each strain of

this bacterium produces a different mix of proteins that specifically kills one or a few related species of insect larvae. While some Bt's control moth larvae found on plants, other Bt's are specific for the larvae of flies and mosquitoes. The target insect species are determined by the protein produced by each particular Bt that can bind to a larval gut receptor, thereby causing the insect larvae to starve.

Although biopesticides are used globally, the regulations involved in their registration processes vary at a regional or national level worldwide. In Europe, they can be regulated as agrochemicals under Regulation EC 1107/2009 or as biocides under Regulation 528/2012.

Biocidal Pesticides

According to the Directive 98/8/EC of the European Parliament and of the Council of 16 February 1998, biocidal products are defined as active substances and preparations containing one or more active substances, put up in the form in which they are supplied to the user, intended to destroy, render harmless, prevent the action of, or otherwise exert a controlling effect on any harmful organism by chemical or biological means. Biocidal products are authorized according to EU Regulation 528/2012, which is different from the regulation concerning the authorization of plant protection products, EU 1107/2009. According to the Biocidal Products Regulation (BPR) 528/2012, biocidal products are classified into 22 product types grouped in 4 main categories: disinfectants, preservatives, pest control, and other biocidal products. Table 2 presents a detailed classification of the biocidal products.

Human Exposure and Health Effect

People are exposed to the described types of pesticides through various ways. The population that receives the greatest exposure is the pesticide handlers, the workers that mix, load, and apply the formulated pesticides. The primary route of their exposure is through the skin and subsequently through inhalation of contaminated air. Families of pesticide handlers are also a vulnerable group with increased potential of exposure. Their exposure may involve the storage and mixing of concentrated formulations near home and several 'take-home' pathways, like the introduction of contaminated clothing into home and poor hygienic practices. On the other hand, the general population may be directly exposed, through inhalation or dermal contact, to pesticides during the application for agricultural or residential pest control and during public or domestic use for sanitation purposes. Exposure to pesticides may also occur via consumption of contaminated water and food.

The exposure to pesticides has been associated with a wide range of adverse effects to human health, from skin irritation to several types of cancer, with the last one being the dominant and the most severe reported effect. Additionally, an elevated rate of other diseases, such as diabetes, neurodegenerative disorders like Parkinson's and Alzheimer's diseases, and reproductive disorders and birth defects, has also been associated with pesticide exposure.

As already stated, one of the most severe potential risks for human health that has been associated with pesticide exposure is several types of cancer like prostate cancer, non-Hodgkin's lymphoma, leukemia, multiple myeloma, breast cancer, and brain cancer. Moreover, parents' exposure to pesticides at work has been related to kidney cancer in children, particularly for high and prolonged exposures, and to brain tumors in children and young adults.

Pesticide exposure has also been linked to neurotoxic effects, particularly with Parkinson's disease. Additionally, prenatal exposure and to a lesser extent postnatal exposure to organophosphate pesticides have been associated with neurodevelopmental and behavioral deficits in preschool and school children.

The reproductive and endocrine systems are also deemed to be adversely affected by organochlorine and organophosphate pesticide exposure among other groups of pesticides. Concerning diabetes, although it has been reported that organophosphates increase the risk of type 2, evidence relating nonpersistent pesticides to diabetes in Asian populations has been found to be equivocal.

Regarding the reported adverse effects of pesticide exposure, it should be pointed out that there are many limitations in the epidemiological studies, and the necessity for further research in order to draw more reliable conclusions regarding the human health risk assessment is frequently highlighted in the literature.

Table 2 Types of biocidal products

Disinfectants	*Preservatives*	*Pest control*	*Others*
Human hygiene	Preservatives for products during storage	Rodenticides	Antifouling products
Private area and public health area disinfectants	Film preservatives	Avicides	Embalming and taxidermist fluids
Veterinary hygiene	Wood preservatives	Molluscicides, vermicides, and products to control other invertebrates	
Food and feed area	Fiber, leather, rubber, and polymerized materials preservatives	Piscicides	
Drinking water	Construction material preservatives	Insecticides, acaricides, and products to control other arthropods	
	Preservatives for liquid-cooling and processing systems	Repellents and attractants	
	Slimicides	Control of other vertebrates	
	Working or cutting fluid preservatives		

Environmental Effect

Pesticide and herbicide application leads inevitably to environmental contamination through direct application of the products and also through spray drift and runoff. The adverse environmental effects of this contamination include nontarget organism poisoning and disturbance of the sensitive ecosystems. The severe adverse effects of the indiscriminate use of pesticides, particularly of DDT, were already described in *Silent Spring* of Rachel Carson (1962). Pesticide environmental contamination has been associated with reproductive and developmental effects in wildlife like birds, reptiles, and amphibians, classifying some pesticides as potential endocrine disrupters. The presence of pesticides may also disturb sensitive marine ecosystems. A representative example of such an environmental impact is that of the Great Barrier Reef in Australia, the largest reef system in the world, which has been seriously contaminated by pesticides. It should be noted that the environmental pesticide contamination has even more severe adverse effects when the active substance or its harmful metabolites are persistent, since this creates a permanent and cumulative hazard to the environment and eventually to human health.

Regulations

Authorization of Plant Protection Products

Authorities worldwide establish regulations and guidelines regarding the authorization and use of pesticides in order to protect the environment and human safety. In the European Union, pesticides are authorized according to Regulation EC No 1107/2009, concerning the placing of plant protection products on the market. According to this regulation, substances should only be included in plant protection products if they present a clear benefit for plant production and harmful effect on human or animal health or any unacceptable effects on the environment are not expected.

An active substance is permitted to be used in plant protection products only if the approval criteria related to mutagenicity, carcinogenicity, toxicity for reproduction, and endocrine-disrupting properties are satisfied according to EC 1107/2009. Additionally, the active substance must not be considered a POP, a persistent bioaccumulative and toxic substance (PBT), or a very persistent and very bioaccumulative substance (vPvB), according to specific criteria. Provided that these requirements are fulfilled, an evaluation of the environmental fate of the active compound of the pesticide and its metabolites and a corresponding environmental risk assessment, along with a human health risk assessment, are performed in order to authorize a pesticide product for specified agricultural uses.

In addition to these evaluations and in order to ensure the lowest possible consumer exposure to pesticide residues in treated products such as fruits, vegetables, cereals, milk, eggs, and animal tissue, maximum residue levels (MRLs) are established by Regulation (EC) No 396/2005. According to EFSA, the MRLs are the upper legal levels of a concentration for pesticide residues in or on food or feed. MRLs are derived after a comprehensive assessment of the properties of the active substance and the residue levels resulting from the good agricultural practices defined for the treated crops.

Apart from the aforementioned prerequisites, the product is evaluated as regards its intended use and efficacy, its identity, composition, physicochemical and technical properties, and finally the existing methods for identification and quantification of the active substance and its degradation products in the commercial formulations, food, and environmental and biological samples.

In the United States, pesticides must be registered with the Environmental Protection Agency (EPA), which regulates the use of pesticides under the authority of two federal statutes, the Federal Insecticide, Fungicide, and Rodenticide Act and the Federal Food, Drug, and Cosmetic Act. Registration assures that pesticides will be properly labeled and that, if used in accordance with specifications, they will not cause unreasonable harm to the environment.

In order to harmonize the data requirements for pesticide registration among different countries, FAO and WHO have adopted an International Code of Conduct on the Distribution and Use of Pesticides, which was last updated in 2013.

Monitoring and Market Control

According to Regulation EC 1107/2009, member states should carry out official controls in order to enforce compliance with the regulation. There are specific provisions for the controls regarding the production, packaging, labeling, storage, transport, marketing, formulation, parallel trade, and use of plant protection products. For the control of the pesticide products regarding the determination of the active ingredient, relevant impurities, and their physicochemical properties, competent authorities apply the official CIPAC methods (Collaborative International Pesticides Analytical Council) in case they are available. These methods are collaboratively tested by laboratories all over the world, and after their evaluation and adoption, they are published in the CIPAC handbooks. There are detailed specifications proposed by the FAO and WHO that pesticides must comply with, like the tolerance of the active ingredient content and limits for their physical properties.

Enforcement methods for the determination of pesticide residues in food of plant and animal origin and environmental (water, soil, and air) and biological samples are also required by the regulation. The required methods need to be reliable, sensitive, specific, and confirmatory, taking into consideration that the MRLs of pesticides in these complex matrices involve low concentrations ($\mu g\, kg^{-1}$). The most widely applied analytical techniques for enforcement purposes that fulfill these requirements are gas and liquid chromatography coupled to mass spectrometry (GC–MS/(MS) and LC–MS/(MS)). Other analytical techniques for the determination of pesticide residues involve immunoassay techniques and capillary electrophoresis. Prior to the determination of the pesticide compounds by the aforementioned techniques, a sample preparation step including isolation of the compounds of interest and purification of the sample is required. The isolation of the target compounds can be accomplished using an extraction solvent performing solid–liquid or liquid–liquid extraction, depending on the physical state of the sample. Other extraction techniques utilizing supercritical fluid and accelerated solvent extractions are also used. Subsequently, for the purification of the liquid extract, solid-phase extraction is the predominant technique applied.

In conclusion, high-tech instrumentation, sensitive and robust analytical methods, qualified personnel, good laboratory practice, and interlaboratory tests are very significant for the successful implementation of the market control of pesticide products and the monitoring of pesticide residues.

Closing Remarks

Taken all together, it becomes apparent that the proper use of pesticides can improve significantly the quality of human life in various ways. However, special attention should be drawn on the awareness of pesticide users regarding the precautionary statements and the label directions, which must be followed with consistency, in order to eliminate the adverse effects of pesticide misuse.

Pesticides and Herbicides: Types, Uses, and Determination of Herbicides

AV Herrera-Herrera, M Asensio-Ramos, J Hernández-Borges, and MÁ Rodríguez-Delgado,
Universidad de La Laguna (ULL), La Laguna, Spain

Introduction

Herbicides or weed killers are chemicals used to kill or control the growth of undesired plants by acting as plant-hormone mimics, which can control the cell enlargement or division, bud or shoot formation, root initiation, etc. An ideal herbicide should kill the unwanted weed while maintaining the target crop relatively unharmed, favoring the normal development of the species of interest.

The benefits of the use of herbicides in agricultural production are unquestionable. However, their presence in the surface of food products constitutes a potential risk for consumers. In fact, this has become a constant cause of concern for the different regulatory agencies around the world, which have made efforts to establish good agricultural practices (GAPs) and GAP-based maximum residue limits (MRLs) that ensure suitable nourishment from a toxicological point of view.

Although current herbicides are not highly persistent, the principal problem is that several farmers do not follow GAPs and employ them in a concentration higher than that advised, or even collect the crops before the security harvest interval has been reached. To achieve the compliance of the current legislations and to monitor the presence of these harmful substances in edible materials, a good number of analytic researchers have focused their efforts on the development of robust methodologies that permit the determination of low concentration of herbicide residues in food matrices.

This article pretends to provide a general vision of the types, uses, and mode of action of the most utilized herbicides and to present an overview of the different extraction techniques that have been used for their isolation and preconcentration from foods and of the separation or detection strategies employed for their later quantitation.

Types and Uses of Herbicides

Herbicides are a subtype of pesticides that can be itself classified into other groups depending on its moment of application, activity, selectivity, mode of action, and chemical family.

Classification by the Time of Application

Regarding the moment of application, herbicides can be classified into early preplant or preplant-incorporated, preemergence, and postemergence herbicides. Early preplant and preplant herbicides (e.g., sulfentrazone, atrazine, and alachlor) are added to the soil months, weeks, or days before the crop of interest is planted. In this way, the dissipation of the pesticide by photodecomposition or volatilization is avoided. Preemergence herbicides (e.g., acetochlor, prodiamine, and glyphosate) are applied to soil after planting the crop and before its germination in order to prevent the growth of foreign weeds by the inhibition of a key enzyme, while postemergence herbicides (e.g., fluazifop-p-butyl, paraquat dichloride, and glyphosate) can be used to kill weeds that have already germinated and small seedlings. Despite this classification, a herbicide can be used as both pre- and postemergence depending on the crop, the soil, and the climatological conditions, among others.

Classification by Activity

Depending on the way they act, herbicides can be categorized as contact or systemic. Contact herbicides (e.g., diquat, bentazon, and glufosinate) affect only the part of the weed on which they are physically deposited, not moving throughout the plant tissues. They are in general very rapid and effective to remove annual weeds. On the contrary, systemic herbicides (e.g., glyphosate, imazaquin, 2,4-D, and dicamba) are completely absorbed through the foliage or roots of the foreign plant and transported through the phloem to other parts of it. They are effective against all types of weeds but are especially useful to control perennials' growths.

Classification by Selectivity

Herbicides can also be distinguished by their selectivity against the crop of interest. In this way, selective herbicides respect a specific plant while destroying other extraneous weeds (e.g., butachlor for rice and metribuzin for potato). On the other hand, nonselective herbicides cause death to all sprayed plants (e.g., glyphosate), so they are normally applied to noncultivated soils or with extreme precaution to avoid the damage of the crop of concern.

Classification by Mode of Action

Another interesting way in which herbicides can be classified is attending to their mode of action, which particularly depends on the biological processes that they inhibit in the target undesired plant.

In this way, herbicides can act as inhibitors of the photosynthesis of the weed (e.g., paraquat and atrazine), producing free radicals, membrane destruction, necrosis, and desiccation. They can also inhibit the synthesis of pigments (e.g., acifluorfen and diflufenican), interfering with the enzymes and causing the loss of protection against radicals. Some herbicides can avoid the formation of amino acids (e.g., glyphosate and glufosinate) or the synthesis of lipids (e.g., dalapon and sethoxydim) that negatively affects the cell membrane and increases the susceptibility to the attack of pests. Still, more aggressive are probably those that hinder cell division interfering in the mitosis (e.g., asulam and

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00536-5

alachlor) or the inhibitors of growth (e.g., 2,4-D and dicamba), which mimic plant hormones, forming tumors and eliminating absorption and translocation mechanisms.

Classification by Chemical Family

As can be assumed, herbicides comprise a very large group of pesticides with different functional groups and structures. For this reason, chemical classification is perhaps the most complex and extensive, but it is not absolute, since certain herbicides could be classified into different groups and other compounds within these groups may not be herbicides. However, they are usually divided in the following families:

- Aliphatic carboxylic herbicides (acids, esters, and salts)
- Amides (including anilides, sulfonamides, and thioamides), amino acids, and quaternary ammonium salts
- Benzoic and phthalic herbicides (acids, esters, and salts)
- Benzonitriles
- Carbamates and thiocarbamates
- Cyclohexanediones
- Dinitroanilines
- Diphenyl ethers
- Halogenated herbicides
- Imidazolinones
- Inorganic herbicides (including arsenical herbicides)
- Phenols (including dinitrophenols)
- Phenoxy herbicides (acids, esters, and salts)
- Pyridines and pyridazines
- Ureas and sulfonylureas
- Triazines
- Other herbicides

Figure 1 shows the chemical structure of some representative herbicides belonging to the different groups previously mentioned.

Herbicide Determination

Extraction Methods

Sample preparation is probably the most important step of any analytic method especially when dealing with complex matrices as foods. In general, when analyzing liquid food samples like wine, fruit juices, and milk, less sample treatment is normally required: filtration, pH adjustment, dilution, centrifugation, etc., followed by a simple extraction procedure if the analysis cannot be directly performed. However, when solid or semisolid samples like fruits, vegetables, or cereals are considered, the first step in sample preparation is the extraction of the target analytes from the matrix. The amount of coextracted substances is usually high, especially for nonvolatile lipids, which in some cases can damage the analytic instrumentation. For this reason, a postextraction cleanup of the extract is nearly always necessary.

Classical methodologies for the extraction of herbicides from solid or semisolid food matrices often consist in a solid–liquid extraction (SLE) carried out by homogenization of the sample with an organic solvent or water (depending on the herbicide's properties) and a cleanup of the extract, normally by liquid–liquid extraction (LLE), column chromatography (Florisil, alumina, silica, etc.), gel permeation chromatography (GPC), or even tandem combination of them. In this way, different families of herbicides have been determined in fruits, vegetables, cereals, and other food matrices.

Though such classical approaches are still used up to some extent, they have been replaced over the years by an initial solvent extraction assisted by pressure (pressurized liquid extraction), microwaves (microwave-assisted extraction (MAE)), or ultrasounds (ultrasound-assisted extraction (UAE)), followed by a cleanup procedure that is usually done by solid-phase extraction (SPE). In this sense, SPE's benefits over LLE or GPC cover the lesser consumption of solvents, the higher analyte enrichment or preconcentration, and the specificity of the stationary phases. For this purpose, typical commercially available stationary phases have been used and selected depending on the mechanism of interaction between the sorbent and the analytes of interest: bonded silica sorbents for acidic herbicides; graphitized carbon black for neutral, basic, or acidic herbicides; polymeric resins for polar ones; etc. However, the trends in SPE have been lately focused on the use of more selective sorbents that avoid the retention of other interfering sample components. In this respect, immunosorbents, carbon nanotubes, and especially molecularly imprinted polymers (MIPs) have reached importance in the last decade. MIPs constitute one of the most selective ways to extract and clean food extracts, since the retention of foreign molecules is avoided.

Miniaturized sorbent-based extractions, for example, solid-phase microextraction (SPME) and stir-bar sorptive extraction (SBSE), have been much less used in this field for several reasons. On the one hand, commercially available SPME fibers are mechanically fragile, are less stable in highly acidic or alkaline samples, and lack selectivity, a fact that has been partially solved by the preparation of tailor-made fibers covering metal wires with MIPs. However, in SPME, like in SBSE, extraction is normally carried out under nonequilibrium conditions and absolute recoveries are expected low, also in pesticide analysis and especially for complex matrices like foods.

Regarding other techniques based on the use of sorbents, matrix solid-phase dispersion (MSPD) emerged as an alternative and direct extraction approach for the determination of the main herbicide families in different solid, semisolid, or liquid–viscous food matrices, using diverse solid support materials (C_{18}- or C_8-bonded silica, Florisil, NH_2-silica, or even MIPs). This technique includes sample homogenization, sample architecture disruption, fractionation, and purification in a single step, so it overcomes the disadvantages of SPE and SPME in which liquid extracts are mainly needed. However, in some cases, after elution, an additional cleanup step (washing of the column prior to elution, an SPE in the same column or in a different one – which is called co-column clean-up, etc.) has been found necessary, depending on the nature of the solid support, the sample matrix, and the elution solvent.

Although such recent approaches provide clear advantages over classical methods, the truth is that current trends in sample preparation tend to minimize extraction time and to develop simpler and cheaper extraction methods. In this respect, since its introduction in 2003 for the determination of pesticides in vegetables, the 'Quick, Easy, Cheap, Effective, Rugged, and Safe' (QuEChERS) method has been extensively

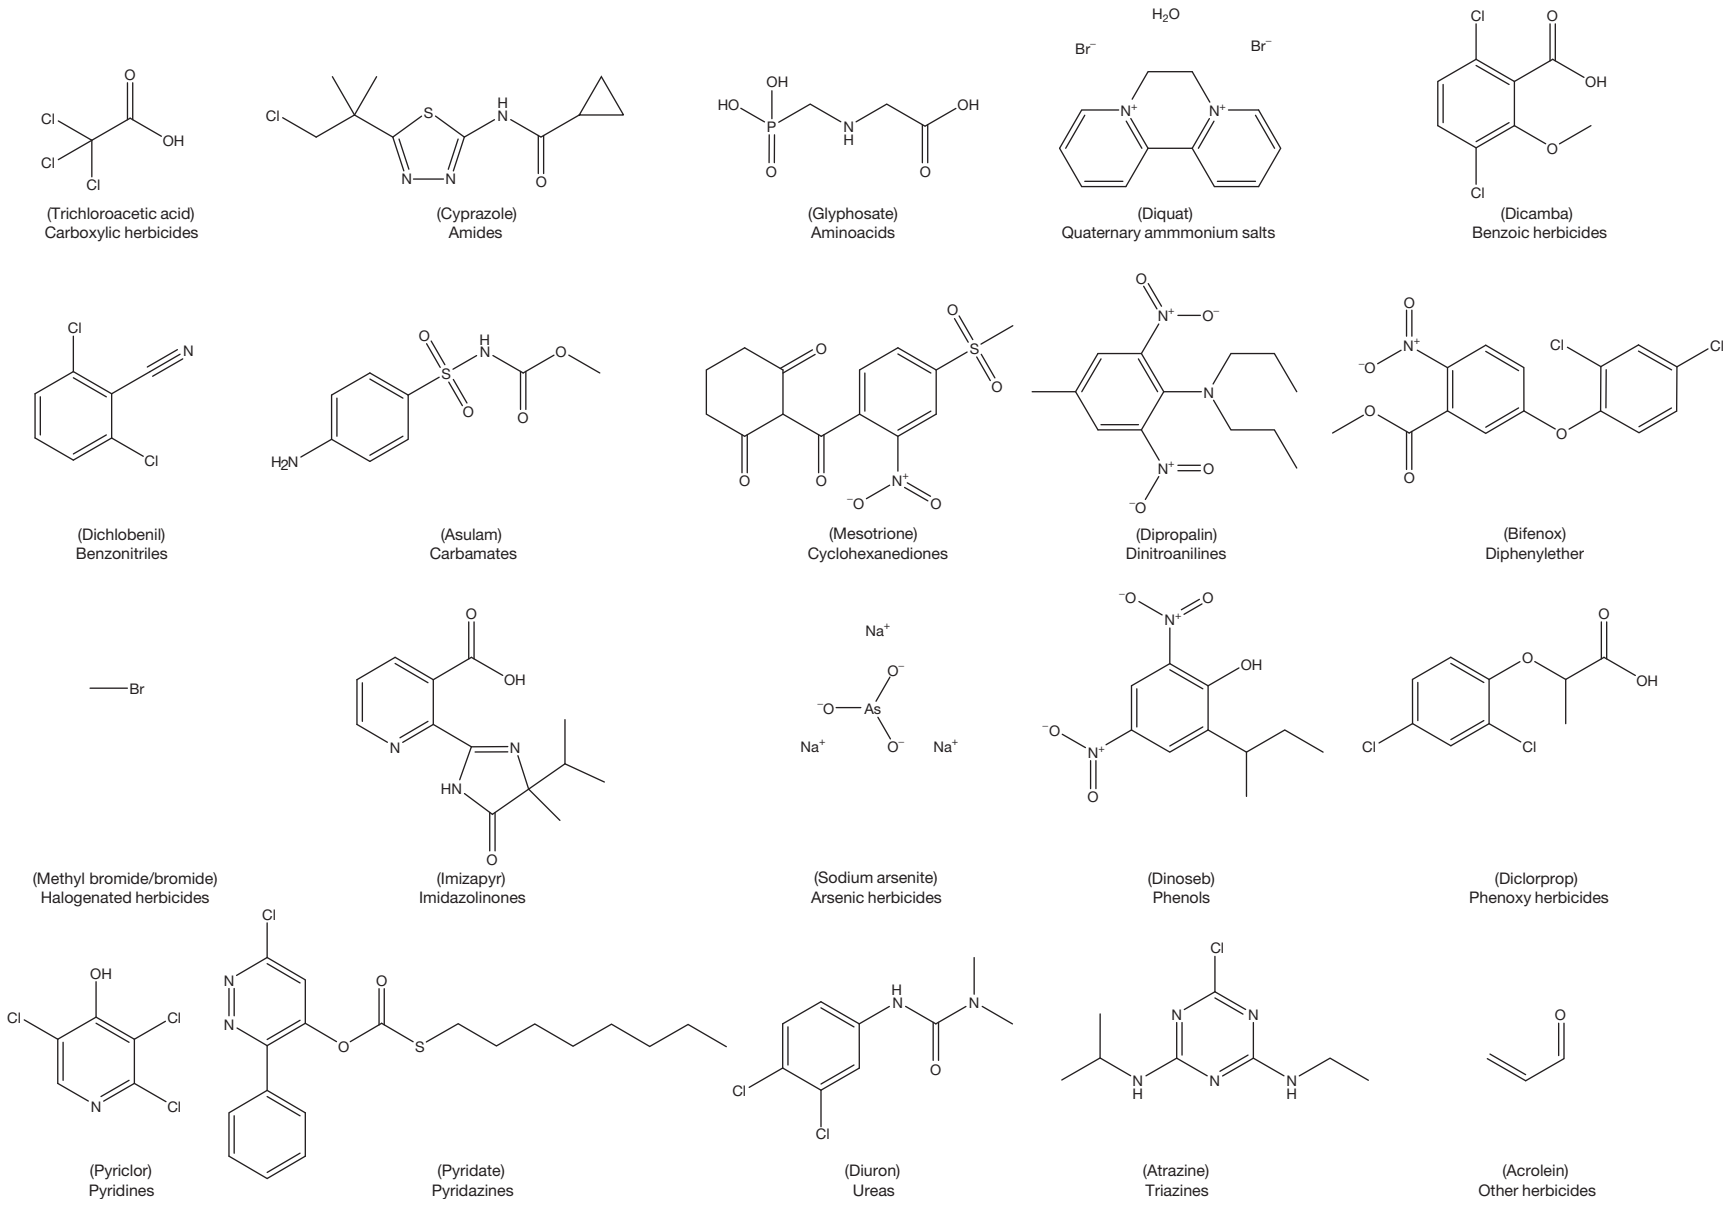

Figure 1 Representative examples of herbicides (between parentheses) belonging to different chemical families.

used also for other agroalimentary matrices. It is very effective and has permitted to cover a wide range of analytes, from highly polar to nonpolar pesticides, and highly acidic and basic substances, just studying slight modifications of the two principal steps of the method: ACN extraction/partitioning and dispersive SPE. In general, this method provides good results in terms of time, solvent expense, and laboriousness with respect to other extraction/cleanup techniques, being also very successful as a multiclass pesticide analysis option, herbicides obviously included.

Another important tendency in this field has been the miniaturization of the extraction devices and the diminution of the consumption of harmful solvents. In this sense, liquid-phase microextraction (LPME) techniques in its different application modes (single-drop microextraction, dispersive liquid–liquid microextraction (DLLME), and hollow fiber-LPME (HF-LPME)) have lately experienced a huge success. However, the application of LPME to food matrices requires an aqueous media, which means that a previous extraction of the analytes (MAE, UAE, etc.) should be developed followed by a suitable reconstitution in water. Regarding the analysis of herbicides in food, DLLME and HF-LPME have been the LPME modes that have found higher application.

Nowadays, the real aim is to achieve very low LODs, avoiding matrix interferences using rapid and easy-performance extraction procedures with low consumption of solvents, reagents, and sample. However, the selection of an extraction/cleanup combination depends also on the separation technique considered and on the characteristics of the detection system, which will be discussed later in the text.

Separation Techniques

In the literature, a great number of methods to separate and determine herbicides in food can be found. Such methodologies include chromatographic techniques (gas chromatography (GC) and liquid chromatography (LC)), electromigration methods (capillary electrophoresis (CE), capillary electrochromatography (CEC)), electrochemical and spectrophotometric techniques, biochemical assays, and immunoassays. Among them, both chromatographic and electrophoretic techniques have been the most popular and they have been frequently combined with mass spectrometry (MS) to identify and quantify a great variety of herbicides.

It is worth mentioning that these techniques have been used to determine herbicides in different food matrices of vegetable origin like cereals, tubers, vegetables, legumes, fruits, nuts, flours, oils, pasta, bread, fruit juices, and coffee; food matrices of animal origin as milk, fish, shrimp, honey, and infant formulas; or even in alcoholic beverages as beer and wine. It is also important to highlight that, although in some cases the developed methods have focused only on the analysis of herbicides, in most manuscripts, they have been determined together with other pesticides, metabolites, degradation products, or even with other organic contaminants as phenolic compounds or antibiotics.

Analysis by LC

LC has been one of the most widely used techniques to analyze herbicides in foods for both individual and multiresidue analyses. In the majority of the methods, LC has been performed in reversed-phase columns based on chemically modified silica stationary phases with C_{18}, C_8, or even NH_2 and pentafluorophenyl. However, other separation modes, for example, mixed mode, ion exchange, or hydrophilic interaction chromatography, as well as MIP stationary phases, have also been occasionally used for the separation of selected amino herbicides (diquat, paraquat, chlormequat, mepiquat, etc.). It is noteworthy to mention that in some cases, particles with diameters lower than 2 μm have also been used, exploiting the important advantages of ultrahigh-performance LC, such as higher separation efficiency and lower retention time.

Regarding the detection systems, UV/DADs have been widely employed due to their inherent characteristics. In this sense, herbicides tend to present maximum absorption in the 190–310 nm region. On the contrary, very few herbicides (e.g., bentazone, some phenoxy acid herbicides – 2,4-D, 2,4-DB, MCPA, MCPB, mecoprop, and dichlorprop – naphthylacetic acid, and flurecol) show native fluorescence, and as a result, the use of fluorescence detection is subjected to the application of a previous derivatization step employing, for example, *o*-phthalaldehyde, 2-mercaptoethanol, 9-fluorenylmethyl chloroformate, or dansyl chloride, which can be done either pre- or postcolumn. Besides, electrochemical detection has also been selected though in a very low number of occasions, for example, for the determination of 2,6-diethylaniline and 2-(1-hydroxyethyl)-6-ethylanyline (metabolic products of alachlor) or ethylene thiourea, which are electrochemically active.

However, and as it also happens for the analysis of other organic compounds, MS is the preferred detection system for the analysis of herbicides in food. The selection of a particular LC-MS interface is often determined by the matrix properties, instrumentation availability, and personal preferences derived from experience. The preferred interface selected to couple LC to MS is, without any doubt, the electrospray ionization (ESI) interface, although several examples using atmospheric-pressure chemical ionization (CI) can be found. Both positive and negative modes have been used depending on the analyte and ionization conditions. In this regard, certain compounds of the families of the amides (e.g., alachlor, propyzamide, butachlor, and flufenacet), triazines (e.g., ametryn, cyanazine, simazine, and terbutryn), ureas and sulfonylureas (e.g., amidosulfuron, diuron, and chlorimuron ethyl), carbamates and thiocarbamates (e.g., butylate, carbetamide, and molinate), imidazolinones (e.g., imazapyr or imazaquin), quaternary ammonium salts (e.g., mepiquat, diquat, or paraquat), nitriles (e.g., bromoxynil or ionoxynil), diphenyl ethers (e.g., bifenox), phenoxy herbicides (e.g., quizalofop-p-ethyl), and other herbicides (such as lenacil, metosulam, and oxadiazon) have been determined in the positive mode, while herbicides belonging to the phenoxy acid (e.g., 2,4-dichlorobutyric acid, dichlorprop-p, and MCPA), sulfonylurea (e.g., flazasulfuron), amide (e.g., oryzalin), and other families (e.g., picloram, dicamba, and bentazon) have been determined in the negative ionization mode. Moreover, several herbicides have also been determined in both ionization modes (such as fluroxypyr, pentachlorophenol, glyphosate, propanil, clopyralid, and fluazifop). Regarding the mass analyzer used for tandem MS (MS/MS), the triple quadrupole (QqQ) is the most used for pesticide analysis (and also herbicides) because it was early

commercialized, is easy to operate, and has a small size. Also, quadrupole ion trap, ion trap (IT), and time-of-flight (TOF) analyzers are among the most used for herbicides determination.

Analysis by GC

GC has been widely used for the analysis of herbicides due to the adequate volatility and high-temperature stability of many of these compounds. In this way, various herbicides have been separated by GC, basically pesticides belonging to the following families: amides (e.g., alachlor, isoxaben, or propyzamide), carbamates and thiocarbamates (e.g., chloropropham, molinate, and prosulfocarb), dinitroanilines (e.g., trifluralin or fluchloralin), triazines (e.g., simazine, ametryn, or cyanazine), ureas (e.g., diuron, amidosulfuron, and tribenuron-methyl), and phenoxy herbicides (e.g., MCPA, dichlorprop-p, and haloxifop). The examples of the separation of diphenyl ethers (e.g., oxyfluorfen), quaternary ammonium salts (e.g., difenzoquat methyl sulfate), pyridines (e.g., clopyralid or fluroxypyr), imidazolinones (e.g., imazamethabenz-methyl), and other herbicides (e.g., metribuzin and oxadiazon) by GC can also be found. The columns more frequently used for this purpose are based on (5%-phenyl)-methylpolysiloxane and 100% dimethylpolysiloxane or phenyl arylene polymer (virtually equivalent to (5%-phenyl)-methylpolysiloxane), although columns based on trifluoropropyl polymer, (50%-phenyl)-dimethylpolysiloxane, (5%-phenyl-polysilphenylene)-siloxane, (1%-phenyl)-methylpolysiloxane, or (14%-cyanopropyl-phenyl)-methylpolysiloxane have been used in certain applications.

Among the different detectors that can be used in GC, flame ionization detection (FID) has been selected when a more specific detector was not available, since an intensive cleanup step is usually needed. Besides, flame photometric detection (FPD), which is more appropriate for the analysis of triazines or carbamates containing sulfur or phosphorus in their structure, has been used several times in combination with other detection techniques. On the other hand, electron capture detection (ECD), which is very sensitive for halogenated compounds, has been used to determine polyhalogenated herbicides like oxyfluorfen, fluchloralin, diuron, or oxadiazon and herbicides derivatized with methyl iodide–triethylamine (1/1, v/v), diazomethane, or pentafluorobenzyl bromide (among others). Some examples are flumetsulam, dicamba, and picloram. Finally, nitrogen–phosphorus detection (NPD) has also been used in some applications for the determination of herbicides containing nitrogen atoms. This is the case of pesticides like anilofos, ametryn, vernolate, or terbacil.

Nonetheless, an important number of works have also used MS and MS/MS detection alone or in combination with other detection systems like FID, FPD, ECD, or NPD. In most of these applications, ionization has been carried out via electronic impact although it is also possible to find examples that employ CI. These ionization modes have been used in combination with either IT, TOF, or QqQ analyzers.

Regarding derivatization for GC analysis, herbicides that have hydroxyl, carboxylic, or amino groups (e.g., benzonitriles, phenoxy acids, or phenylureas) are those that often require such step. A particular case is the determination of glyphosate. Due to its high polarity and water solubility, it requires exhaustive derivatization pretreatments as the use of trifluoroacetic anhydride and trifluoroethanol or diazomethane, isopropyl chloroformate, and diazomethane or heptafluorobutyric anhydride and 2-chloroethanol, because standard derivatizations in GC are ineffective. Despite this, it is also noteworthy that, in general, a large number of pesticides (much higher than in most applications with other techniques) have been determined in a single run by GC, due to the high-separation power of this technique for multiresidue routine analysis.

It is important to mention that several herbicides, for example, some quaternary ammonium salts, ureas, and their metabolites or degradation products, are not amenable by GC-MS, not even by subjecting them to a derivatization process.

Analysis by CE

Despite the fact that in the literature, there are a large number of manuscripts devoted to the analysis of herbicides in environmental matrices by CE, the number of articles that deal with the determination of herbicides in food matrices is still scarce compared to those using LC or GC.

CE represents an interesting alternative because it offers not only high-separation efficiency but also short analysis time, low consumption of solvents, simplicity, and almost all pesticides may be determined without derivatization (unless it is necessary to facilitate the detection). By contrast, the major drawback is the low sensibility associated with the short optical path length of the capillaries when UV–vis detection is used and the small sample volumes injected. The use of sensitive detectors and/or online preconcentration techniques (*stacking* and *sweeping* modes) allows solving this problem, and in fact, both stacking and sweeping procedures have also been used in the determination of herbicides. Regarding the stacking phenomena, electrokinetic injection has been mainly used, although normal stacking mode, large volume sample stacking, or stacking with reverse migrating micelles has also been applied in several occasions.

Among the different operational modes of CE, capillary zone electrophoresis (CZE), micellar electrokinetic chromatography (MEKC), nonaqueous CE (NACE), and CEC have been used to separate herbicides. Although CZE prevails over the rest, especially for pesticides that have ionizable groups, the separation of closely structurally related polar herbicides in aqueous solution is difficult. NACE has been assayed to overcome this problem, since the acid–basic properties of the analytes change in organic media and the existence of other phenomena that do not occur in the aqueous background electrolytes is useful to discriminate separation. MEKC, which is based on the interactions between the analytes and the micelles present in the separation medium, can be used to separate both charged and neutral solutes with either hydrophobic or hydrophilic properties, which is perhaps the reason why it has been widely used in this field. Among the available micellar agents, sodium dodecyl sulfate has been the most employed in these methodologies (even used in NACE applications), although others like tetradecyltrimethylammonium bromide have also been used. With respect to CEC, despite the potential advantages of the inclusion of a stationary phase, its use to determine herbicides in foods has not been very common.

Due to the ease of handling, simplicity, and low cost, UV-Vis/DAD is the most extended detection mode in these CE applications. Nevertheless, and as it was previously mentioned,

the low sensibility of CE has favored the use of more sensitive detectors, such as MS or MS/MS. The interface that has been normally used in these cases is also the ESI but modified to add a sheath liquid that helps to maintain the electric circuit and the analyzers varied from quadrupoles to ITs. There are also some applications that used alternative detectors such as those based on electrochemiluminescence for the determination of amine herbicides like isoproturon, linuron, glyphosate, or aminomethylphosphonic acid (major metabolite of glyphosate).

Analysis by other techniques

The need of rapid and accurate analytic methodologies to determine herbicides in foods has rapidly led to the development of techniques alternative to LC, GC, or CE. Among them, immunoassays and biosensors have been those that attracted more interest and further development.

Immunoassays, which are based on the recognition reaction between the molecule of interest (antibody) and the antigen adsorbed onto a specific support, offer rapid, sensitive, and relatively low-cost measurements while reducing the need of sophisticated equipment. Perhaps, this is the reason for its extensive development in this type of applications. Among them, methodologies based on enzyme-linked immunosorbent assays (ELISAs) are those that have achieved higher success. In some cases, ELISA experiments could take several hours and its implementation could require a set of stationary devices. For this reason, novel formats of immunoassays, such as immunobiosensors (including optical, piezoelectric, and electrochemical immunosensors), fluoroimmunoassays, and immunomembranes, have also been tested. However, the vast majority of these methods are limited to a single analyte or to a small group of analytes structurally closely related, due to the specificity of antigen–antibody recognition. In fact, without any doubt, a great number of manuscripts are devoted to the analysis of triazine herbicides (mainly atrazine). However, if cross reactivities or matrix interferences are not observed, the immunoassays could be an interesting alternative.

Regarding the use of electrochemical methods and apart from electrochemical immunosensors, several authors have developed different methodologies based on voltammetry, polarography, or amperometry. For this purpose, several different electrodes (based on gold, highly boron-doped diamond, graphite-poly(tetrafluoroethylene), MIPs, or mercury drop) have been used. As also happened with immunoassay techniques, almost all published manuscripts are devoted to the analysis of a single compound or a low number of structurally related ones (mainly nitrogenous herbicides like paraquat, cyanazine, propazine, or pendimethalin). Besides, and due to the nature of the electrodes, many of the methods have been developed to analyze liquid matrices have also been tested after a suitable extraction process. The principal disadvantage of these methods is the possible adsorption of the reagents or products of the electrochemical reaction onto the surface of the electrode, decreasing the sensitivity and reproducibility of the procedure.

Finally, spectroscopic and spectrometric techniques have also been used to determine herbicides in several occasions. Thus, the advantages of different methodologies, such as

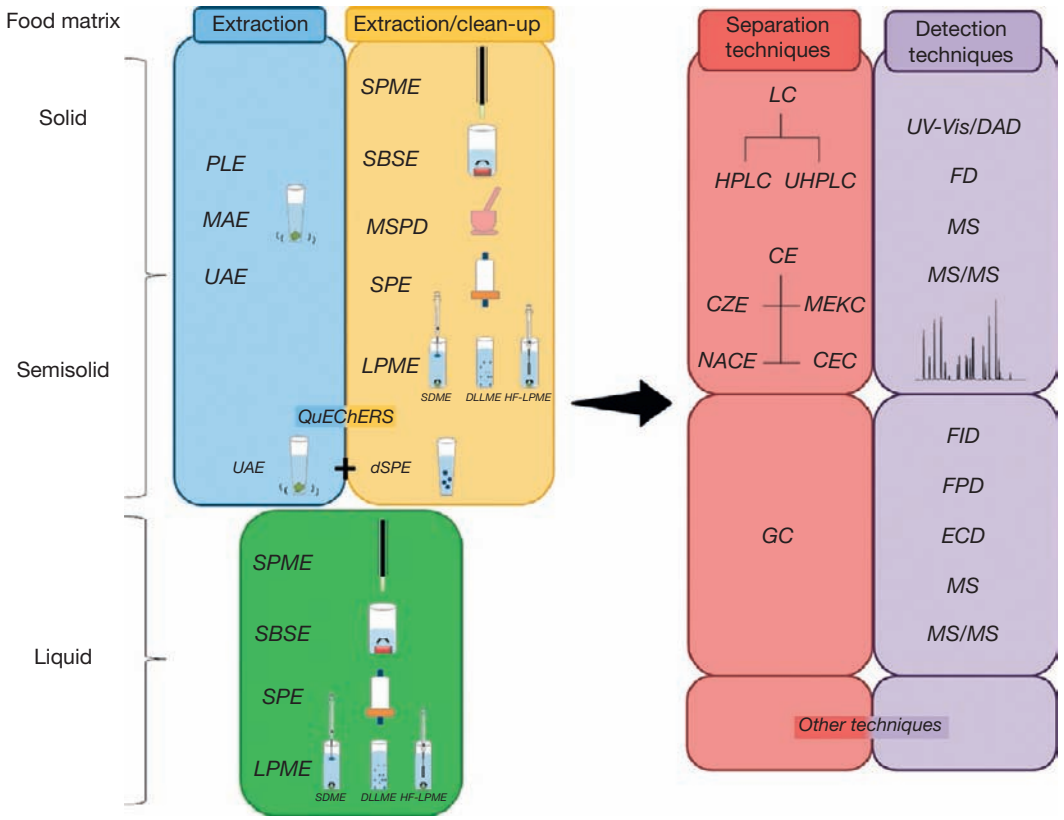

Figure 2 Schematic representation of the different methodologies applied to herbicide determination in foods.

Raman spectroscopy, MS, MS/MS, fluorescence, UV–vis spectrophotometry, and plasma ionization MS, have been exploited. In many papers, the sample introduction was made by means of automated flow injection. The mentioned methods have the advantage of being less time-consuming, but on the contrary, only one or two herbicides are determined (except for MS and MS/MS detectors).

Figure 2 shows a schematic summary of the different extraction and separation methodologies applicable to the herbicide determination in liquid, solid, and semisolid food matrices.

Conclusions

The analysis of herbicides and, in general, pesticides is a relevant issue because of their controversial use in agriculture being focused on the development of new and effective analytic methods able to determine such compounds at the required MRLs.

Herbicides, which can be classified depending on different criteria, comprise a big number of compounds of diverse structures and properties. As a result, there is not a universal analytic method for their determination and different strategies are applied depending on the food sample and also on the determination technique.

In general, herbicides are initially extracted from food by different procedures: SLE (assisted or not by ultrasounds, microwaves, etc.), LLE, or sorbent-based extraction techniques (SPE, SPME, MSPD, etc.). A suitable cleanup or a second extraction may also be necessary, depending on the application. The procedure is simpler when samples are liquid. Afterward, it is very frequent to analyze the final extract using a separation technique, being GC and LC the ones of choice, although CE and other procedures/techniques like immunoassays or biosensors have also been used with success.

In general, it is clear that new analytic methods are constantly being developed/suggested on this challenging subject. Like in any other field, suitable and continuous revision of the literature is extremely necessary to achieve a general overview of its past, present, and future.

Definition and Basics

pH Basics and Notional Definition

The acidity and alkalinity of aqueous media, where most reactions in nature occur, depend (according to the Arrhenius definition of acids and bases) on the concentration of the hydronium (H_3O^+) and hydroxyl (OH^-) ions. The former is quantified by the more general concept of pH, initially proposed by the Danish chemist Søren Peder Lauritz Sørensen in 1909 and revised in 1924 to adjust definitions in relation to the electrochemical cells used for its measurement. The pH is notionally defined for any medium as the decimal logarithm of the reciprocal of the hydrogen ion activity, α_{H^+}, in that medium:

$$\mathrm{pH} = -\log_{10}\alpha_{H^+} = \log_{10}\left(\frac{1}{\alpha_{H^+}}\right) \quad [1]$$

It is only for very dilute solutions that the pH can be directly related to proton concentration:

$$\mathrm{pH} = -\log_{10} c_{H^+} \quad [2]$$

This approximation holds for pure water where, due to its self-dissociation constant being $K_w = 10^{-14}$ at 25 °C, proton and hydroxyl concentrations are as low as 10^{-7}. Thus, pure water at 25 °C has a pH value very close to 7; therefore, a value of pH = 7 defines a 'neutral' medium where the proton and its hydroxyl counterion are present in equal concentrations. Media with pH < 7 are characterized as acidic, whereas those with pH > 7 as alkaline. The common pH range is between 0 and 14 since cases with H^+ or OH^- concentrations higher than 1 M are not often encountered. It should be stressed that a standard pH reference value has been set by IUPAC with respect to which primary and operational standard solutions are further defined; this is the value of pH = 4.21 for a 0.05 mol kg^{-1} potassium hydrogen phthalate aqueous solution.

Operational pH Definition

The notional definition of pH according to hydrogen ion activity (eqn [1]) is based on the fact that pH is accurately determined by pH-sensitive ion-selective electrodes, which, strictly speaking, respond to activity rather to concentration changes. Ideally, the electrode potential, E, of a pH-sensitive electrode follows the Nernst equation, which, for the hydrogen ion, can be written as

$$E = E' + \frac{RT}{F}\ln(\alpha_{H^+}) = E' - \frac{2.303RT}{F}\mathrm{pH} \quad [3]$$

where E is the measured potential, E' is a formal electrode potential (i.e., the constant value of the electrode potential for $\alpha_{H^+}=1$ and the specific electrode/solution conditions for each case), R is the gas constant, T is the temperature in Kelvin, and F is the Faraday constant. It follows that the potential of such a pH-sensitive electrode is a linear function of the pH when the latter is defined in terms of activity.

According to the international standard ISO 31-8, the standard methodology for pH measurements involves the construction of a liquid junction-free galvanic cell where the pH-sensitive electrode is the hydrogen electrode ($Pt/H_2/H^+$: H_2 gas bubbled at 1 atm through a H^+-containing solution in contact with a high surface area Pt electrode) and the reference electrode is a Ag/AgCl in a KCl solution. The following notation refers to such a cell:

$$\mathrm{Ag|AgCl|concentrated\ solution\ of\ KCl,}$$
$$\mathrm{test\ solution|H_2(g,\,1\,atm)|Pt}$$

where vertical lines denote the interface between two different phases. The cell is filled with a standard solution of known pH/hydrogen ion activity, pH_s, and its electromotive force (emf), E_S, is measured. Then, the test solution is replaced by the sample solution of unknown pH_x and the new emf of the cell, E_X, is measured. It follows (applying eqn [3] twice and taking into account that the same reference electrode is used) that the pH of the unknown solution is a linear function of the difference between the two measured emf values:

$$\mathrm{pH_X} = \mathrm{pH_s} + (E_S - E_X)/(2.303RT/F) \quad [4]$$

Equation [4] describes the operational definition of pH.

The pH values of the standard solutions (of both primary and secondary/operational standards), used in the operational definition of the pH of unknown solutions, are estimated by direct measurements of the emf of cells similar to the one described earlier, following the methodology adopted by IUPAC Recommendations 2002.

Buffer Solutions

A (pH) buffer solution refers to an aqueous solution containing a mixture of a weak acid and its conjugate base or vice versa. The most outstanding characteristic of a buffer solution is its ability to keep its pH almost constant with the addition of a small amount of strong acid or base. This is the reason that buffer solutions are applicable in a variety of chemical procedures where the prevention of changes in the pH of a solution is needed. Many living organisms grow in a relatively small pH range, and in order to keep the pH constant, they utilize a buffer solution (e.g., blood). This remarkable property of buffer solutions is attributed to the presence of equilibrium between the acid HA and its conjugate base A^-:

$$HA \rightleftarrows H^+ + A^- \quad [5]$$

According to Le Chatelier's principle, the addition of a small amount of strong acid to this equilibrium mixture will

Table 1 Standard buffer solutions at 25 °C

Buffer solution composition	*pH value*
Potassium tetraoxalate (0.05 m)	1.68
Potassium hydrogen tartrate (saturated)	3.56
Potassium hydrogen phthalate (0.05 m)	4.01
Potassium dihydrogen phosphate (0.025 m) + disodium hydrogen phosphate (0.025 m)	6.87
Potassium dihydrogen phosphate (0.08695 m) + disodium hydrogen phosphate (0.03043 m)	7.41
Borax (0.01 m)	9.18
Calcium hydroxide (saturated)	12.45

Source: Bates, R. G. (1964). *Determination of pH: theory and practice* (1st ed.), p. 123. London: Wiley; Westcott, C. C. (1978). *pH measurements*, p. 81. Michigan: Academic Press.

force the equilibrium to shift to the left side of reaction [5]. In this way, the concentration of the hydrogen ion increases by less than the amount expected for the quantity of strong acid added. On the other hand, if a portion of strong alkali is added to the mixture, the hydrogen ion concentration decreases by less than the amount expected for the quantity of alkali added, since more protons are produced as reaction [5] is shifted to the right.

Table 1 gives the characteristics of seven standard buffer solutions that cover the usually encountered pH range (between ~2 and 12).

Measurement

pH Meters

pH is a measurable parameter and the electronic device that is used for measuring the pH of a liquid (or in special cases of semisolid compounds) is called a pH meter. The most important component of a typical pH meter is its special measuring probe (a glass electrode or, for special applications, an ion-selective field-effect transistor (ISFET)), which is connected to an electronic meter that measures and displays the pH reading. All pH meters are calibrated against buffer solutions of known hydrogen ion activity. The use of a set of buffer solutions (operational pH standards) has been proposed by IUPAC.

A crude estimate of pH in laboratories can also be performed by pH indicators and sometimes in connection with holographic pH sensors, which allow the measurement of pH colorimetrically.

Glass Electrode

Construction and principle

.The most widely used pH meter is based on the glass electrode, which belongs to the large family of ion-selective electrodes, that is, electrodes that contain a material sensitive to changes with respect to the concentration of ions in the test solution, in such a way that the potential drop between the electrode and the outer surface of the material depends on this concentration. Glass electrodes are the main components of potentiometric sensors and are used in the determination of univalent cations. The glass electrode used in pH measurements has a glass bulb membrane with a typical three-component composition of 72% SiO_2–22% Na_2O–6% CaO (or 80% SiO_2–10% Li_2O–10% CaO for highly alkaline media).

The interaction of the protons in solution with the surface of the glass membrane is based on the ion exchange property of the latter since, when its main silica component comes in contact with water, it is hydrated and dissociates to Si–O– and this in turn can be partially protonated:

$$\mathrm{Si-O^- + H_3O^+ \leftrightarrows Si-O-H + H_2O} \qquad [6]$$

The name of the glass electrode may be misleading to the nonspecialist operator in that two misconceptions may sustain: that a pH meter contains a single electrode and that the electrode material is made of glass. Both of these are obviously not true: glass is an ion conductor and not an electronic one (hence, it is not an electrode material) and a potential difference can only be measured between two points (hence, there are two electrodes in a pH meter). In reality, the voltage between the two sides of the glass membrane is measured with the help of two electrodes immersed in the solutions on either side of the membrane. In Figure 1, where (a) a simple glass electrode coupled with a reference electrode and (b) a combined system of them are shown.

The glass electrode is made of a plain glass or plastic tube with the pH-sensitive specialty glass membrane (~0.1 mm thick) blown from its melt and sealed at the end of the tube. The latter contains an internal standard acidity solution (typically 0.1 N HCl, sometimes with the addition of a AgCl saturated solution too) and an internal reference electrode, RE_{in} (typically a Ag/AgCl salt-covered wire electrode). The glass membrane is in contact with the test/sample solution, and in the plain configuration of Figure 1(a), the second external reference electrode, RE_{ext} (again a Ag/AgCl electrode), is also immersed in the test solution. Alternatively, the external electrode can be placed in an external tube, concentric to the glass electrode tube and containing a KCl solution, which is in contact with the test/sample solution via a porous ceramic frit (Figure 1(b)); in that case, the system is termed as a combination pH electrode. Hence, a pH meter consists of an electrochemical cell that, in the case of a combinatorial system, can be denoted as

$$\mathrm{Ag/AgCl\ (RE_{in})|0.1\ N\ HCl|glass\ membrane|sample\ solution\ (H^+_s)||KCl\ solution|Ag/AgCl\ (RE_{ext})}$$

with vertical lines signifying the interface between two different phases and the double vertical line an electrolytic junction. The measured potential, E, between the two cell terminals can then be written as

$$E = E_{in} - \Delta E_m - \Delta E_{lj} - E_{ext} \qquad [7]$$

where E_{in} and E_{ext} are the potentials of the reference electrodes, ΔE_m the potential drop between the two sides of the glass membrane, and ΔE_{lj} the liquid junction potential drop at the electrolytic junction. Since E_{in}, E_{ext}, and ΔE_{lj} are expected to be constant, eqn [7] becomes

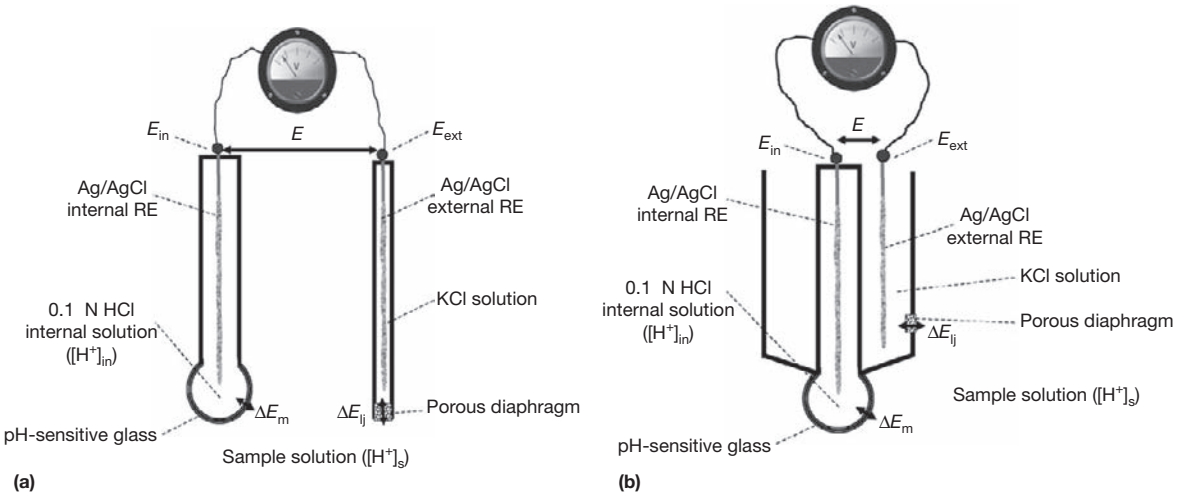

Figure 1 Schematic representation of a pH meter comprised of (a) a glass electrode coupled with a separate reference electrode and (b) a combined system.

$$E = E_{const} - \Delta E_m \quad [8]$$

The ΔE_m potential drop is due to the development of different surface concentrations of chemisorbed H^+ at opposite glass surfaces, as a result of the establishment of different equilibriums for reaction [6], due to different bulk solution concentrations in the internal and sample solutions.

This potential drop may be given by the Nernst equation for the potential of a concentration cell:

$$\Delta E_m = 2.303\frac{RT}{F}\log\frac{[H^+]_{in}}{[H^+]_s} \quad [9]$$

Taking into account that $[H^+]_{in}$ is a constant and known quantity and that for the sample solution it holds $pH_s = -\log [H^+]_s$, eqn [9] becomes

$$E = E'_{const} - 2.303\frac{RT}{F}pH_s \quad [10]$$

indicating that the pH is a linear function of the measured potential.

The specific form of the equation ($y = a + bx$) is behind the need for a two-point calibration of glass pH meters, using two buffer solutions of known pH values (typically around 4 and 7). It should be noted that, since the pH of standard buffers is reported with two decimal places accuracy, pH readings should also be rounded to two decimals.

As the resistance of such a cell (primarily due to the glass membrane) is very high (in the 10^7–10^9 Ω range), the corresponding pH meter cannot be equipped with a common voltmeter, but instead, a high impedance device is needed. The commercialization and widespread use of pH meters was only possible when cheap, miniaturized electronics, based on field-effect transistors, became available and were employed in the demanding electronic part of the device.

The most serious practical limitation of the common glass electrode is its inability to work at pH values above ~11 as a result of the 'alkaline error,' that is, the interference from alkali metals such as Na^+ and K^+ usually present in alkaline media and competing with H^+ for silica sites due to their similar size. Specialty glasses, rich in Li, partially alleviate this problem. Other problems encountered include attack by high F^- levels, noble metal deposition, protein deposition, and debris fouling of the ceramic frit. Cleaning the surface of a fouled glass electrode can be done by brief immersion in HF, but nowadays, replaceable affordable glass membrane tips have appeared in the market too.

ISFET pH Sensors

Construction and principle

There are certain applications for pH measurements where the use of glass cannot be tolerated and miniaturization is also essential. Among these, food testing and biomedical testing are the most usual cases where breaking of the thin glass membrane of a glass electrode would be catastrophic and inclusion of the meter in a catheter is often needed. The first of these requirements is fully met by nonglass pH electrodes, whereas the second one can be partially met if, together with a miniature pH-sensing device, a miniaturized reference electrode is also used. The most typical nonglass electrodes (apart from the Sb-based ones) are those based on ISFETs, which originated from the metal oxide semiconductor field-effect transistors (MOSFETs) that are widely used in modern electronics.

A MOSFET consists of a semiconductor (e.g., a p-type Si) covered by a thin insulating layer of an oxide (e.g., SiO_2) and four metal terminals: the substrate (located at the free face of the semiconductor), the source and drain (located between the other face of the semiconductor and the oxide), and the gate (located on top of the oxide layer (Figure 2(a))). The application of an appropriate gate voltage V_G changes the charge/conductivity of the semiconductor channel between the drain and the source. For example, for an enhancement-mode MOSFET (where the semiconductor is not heavily doped) and for a p-type semiconductor, a positive V_G bias above a certain threshold value V_T results in the mobile hole h^+ intrinsic carriers being pushed away from the oxide/semiconductor interface into the bulk of the latter; this leaves behind a thin

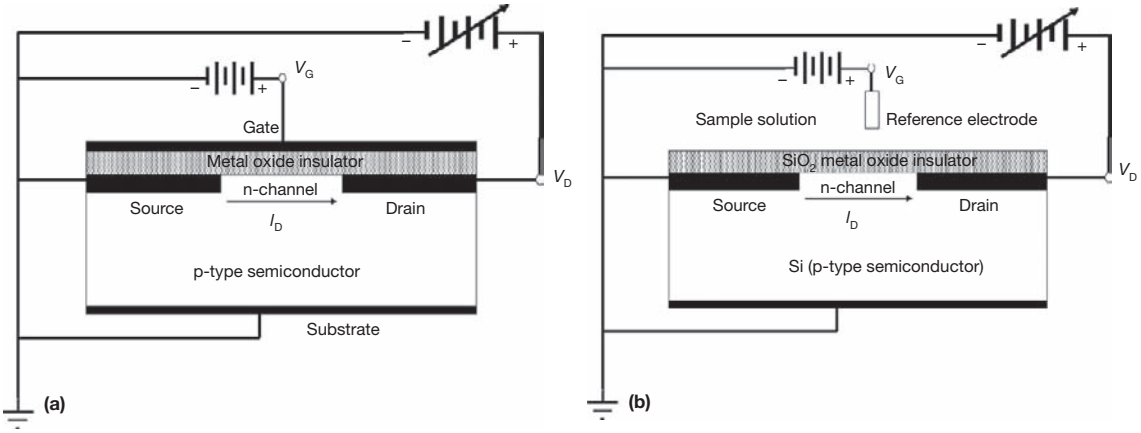

Figure 2 Schematic representation of (a) a MOSFET device and (b) of a SiO_2-based ISFET used for pH measurements.

electron-rich (n-type) channel between the gate and drain terminals. If a positive bias, V_D, between the drain and the source is applied, then the electrons flow through the n-channel giving rise to a drain current, I_D. For a constant value of V_D, this drain current depends on the gate bias V_G (more accurately on expressions containing its difference from the threshold potential, $V_G - V_T$).

In an ISFET used as a pH meter, the gate electrode terminal is replaced by a reference electrode, and the sample solution is between this electrode and the insulating oxide, which is pH-sensitive (e.g., SiO_2, $Si_3N_4O_x$, Al_2O_3, or Ta_2O_5), as depicted in Figure 2(b). (For other ion-sensitive ISFETs, there is an additional ion-selective membrane on top of the oxide layer.)

In an ISFET pH meter, changes in the pH of the sample solution alter the surface potential of the oxide layer (via ion exchange reactions similar to [6]), which in turn modifies V_T and, as a result, the drain current I_D. There are two modes of operation: a constant V_G voltage operation whereby I_D is monitored via a current follower circuit and a constant I_D current mode, whereby the changes in V_G needed to maintain a constant I_D via a feedback circuit are recorded. In either case, the measuring circuit need not be characterized by a very high impedance, as is the case of the potentiometric glass electrode. A practical implication of this is that the meters of a glass and an ISFET electrode are not interchangeable in a straightforward manner.

The voltage output of a pH ISFET (either after conversion to V_T values or as directly related to changes of V_G, depending on mode of operation) should theoretically follow a Nernstian dependence on sample proton concentration. However, most of the metal oxide materials used do not exhibit the Nernstian/maximum sensitivity of $\sim 59\ \text{mV dec}^{-1}$ (e.g., SiO_2 has a $30\ \text{mV dec}^{-1}$ value, $Si_3N_4O_x$ has $\sim 55\ \text{mV dec}^{-1}$, and only Ta_2O_5 approaches the theoretical value).

The reduced sensitivity is perhaps the only drawback of ISFET pH meters (the other is their higher cost) with respect to the glass electrode. However, their nonfragile property (especially if a miniaturized reference electrode is also embedded in an all-plastic body), their fast response time, and their ability to operate at extreme pH values make them the only viable solution for many applications.

pH Indicators

pH indicators are halochromic compounds, weak acids or bases, that occur as natural dyes and indicate the concentration of H^+ (H_3O^+) ions in a solution through color changes. They exist in the form of dissolved dyes, which are added directly to the solution or dye-infused paper strips, which are dipped into the solutions and then removed for comparison against a color–pH key. The general idea of pH indicator functionality is that the nondissociated form of the indicator has a different color than the ionic form of the indicator. It must be stressed that the color of the indicator changes over a range of hydrogen ion concentrations, which is called the *color change interval*. The corresponding pH interval (for an acid indicator) is between $pK_a + 1$ and $pK_a - 1$, where K_a is the indicator's acid dissociation constant. Equation [11] describes the dissociation of an acidic pH indicator HA_{ind}:

$$HA_{ind} + H_2O \leftrightarrows H_3O^+ + A_{ind}^- \qquad [11]$$

In eqn [11], HA_{ind} represents the acid form and A_{ind}^- the conjugate base of the indicator. It must be stressed that the ratio of these determines the color of the solution and connects the color to the pH value. The weak protolyte pH indicators have a pH that can be calculated from the Henderson–Hasselbalch equation:

$$pH = pK_a + \log \frac{A_{ind}^-}{HA_{ind}} \qquad [12]$$

From eqn [12], it can be deduced that in the case where $pH = pK_a$, both acid and conjugate forms are present in a 1:1 ratio. When pH is above the pK_a value, the concentration of the conjugate base is greater than the concentration of the acid, and the color associated with the conjugate base dominates. In the opposite case, where pH is below the pK_a value, the converse is true. More precise measurements are possible if the color is measured by spectrophotometry. pH indicators work efficiently at their designated pH range, and they are usually destroyed at the extreme ends of the pH scale due to undesired side reactions. In Table 2, some common indicators are summarized.

Table 2 Common pH indicators

Indicator	*pH range*	*Acid*	*Base*
Thymol blue	1.2–2.8	Red	Yellow
Pentamethoxy red	1.2–2.3	Red-violet	Colorless
Methyl yellow	2.9–4.0	Red	Yellow
Methyl orange	3.1–4.4	Red	Orange
Bromophenol blue	3.0–4.6	Yellow	Blue-violet
Tetrabromophenol blue	3.0–4.6	Yellow	Blue
Alizarin sodium sulfonate	3.7–5.2	Yellow	Violet
Bromocresol green	4.0–5.6	Yellow	Blue
Methyl red	4.4–6.2	Red	Yellow
Bromocresol purple	5.2–6.8	Yellow	Purple
Chlorophenol red	5.4–6.8	Yellow	Red
Bromophenol blue	6.2–7.6	Yellow	Blue
p-Nitrophenol	5.0–7.0	Colorless	Yellow
Azolitmin	5.0–8.0	Red	Blue
Neutral red	6.8–8.0	Red	Yellow
Cresol red	7.2–8.8	Yellow	Red
α-Naphtholphthalein	7.3–8.7	Rose	Green
Thymol blue	8.0–9.6	Yellow	Blue
Phenolphthalein	8.0–10.0	Colorless	Red
Thymolphthalein	9.4–10.6	Colorless	Blue
Nile blue	10.1–11.1	Blue	Red
Alizarin yellow	10.0–12.0	Yellow	Lilac

Applications

The measurement of pH is important for many applications in medicine, biology, chemistry, agriculture, forestry, environmental science, oceanography, civil engineering, chemical engineering, water treatment and water purification, food science, and nutrition.

pH in Nature

The role of pH in nature is closely related to that of water, and as such, it is extremely important for living organisms and the environment. The pH of natural water and soils controls the form of life sustained in these environments. The pH of the various parts of plants and living organisms defines their function, whereas that of foodstuffs their taste and function once in the food chain.

Examples of the environmental importance of pH are acid rain (a result of industrial pollution, with detrimental effects on life and buildings) and ocean acidification as a result of increased carbon dioxide emissions (detrimental to living organisms in aquatic environments). Typical examples of biological processes involving pH changes include the production of carboxylic acids, such as lactic acid by muscle activity, the protonation of phosphate derivatives such as ATP, and the function of the oxygen-transport enzyme hemoglobin. Finally, an example of pH-related properties of foodstuff is the acidity of some juice fruits due to the presence of citric acid.

Living Systems

pH is extremely important for living systems through its role in biochemical reactions. The pH of various parts and fluids of an organism is regulated by the acid–base homeostasis. For example, human blood should have a pH value in the 7.36–7.42 range, mainly controlled by the bicarbonate/carbonic acid buffer. A pH change as low as 0.2 pH units can result in death (via acute acidosis or alkalosis).

Certain definite pH values are needed for the activation of many enzymes in the body and the trigger of associated reactions. The parts and fluids of the human body have pH values that span the entire pH range, starting from gastric acid (pH = 1.0), to human skin (pH = 5.5), urine (pH = 6.0), and blood (pH = 7.4), to pancreatic fluid (pH = 8.1).

Food and pH

pH is also very important for foodstuff in many perspectives. It is a factor of major importance in water absorption, emulsification, and gelation of different protein sources. It affects significantly the physical and chemical properties of food ingredients such as proteins, sugars, and amino acids, to mention a few.

The vast majority of foodstuffs, apart from egg whites and soda crackers, have a pH value < 7. Alkaline foods (pH > 7) are limited, though the pH of some staple foods lies in the range of 4.5–7.0. Generally, foods that are products of plant origin have a pH that is lower than those of animal origin. On the basis of their pH, foods can be classified as high-acid (pH = 3.7), acidic (pH = 3.7–4.6), medium-acid (pH = 4.6–5.3), or low-acid (pH = over 5.3). The pH of some food is listed in Table 3.

pH gives also information about food stability and preservation. It can be used to retard microbial spoilage that could happen in the presence of some pathogens such as bacteria, molds, and yeasts. Microorganisms usually show their best growth rate in the pH range of 6.5–7.5. Furthermore, the growing capability of molds and yeasts lies in a much broader pH range than that of microorganisms such as bacteria. In consideration of the fact that almost all of the pathogenic agents and most of deterioration bacteria cannot grow at pH < 4.5, foods are divided into two categories, which are low-acid or acidic. The *low-acid foods* with pH > 4.5 are less stable. Their stabilization by heat treatment demands a heat sterilization to remove all pathogens and corruption, including bacterial spores. *Food acids*, at pH < 4.5, are relatively stable. Their stabilization by heat treatment needs less severe procedures, such as pasteurization, in order to eliminate mold, yeast, and some acidophilic bacteria.

The reduction of pH of food products is usually necessary and can be carried out using two methods. One of them is acidification, which is a direct method, and its aim is to lower the pH by adding organic acids, such as acetic acid or vinegar and citric acid or lemon. The second method, which is an indirect method, utilizes microorganisms for fermentation. *Fermentation* is a food preservation procedure that uses selected nonpathogenic microorganisms producing acid or alcohol to alter food organoleptic and/or antibacterial characteristics.

Table 3 pH values of some foodstuffs

Foodstuff	*pH*
Apple, eating	3.30–4.00
Bananas	4.50–5.20
Beans, vegetarian, tomato sauce, canned	5.32
Bread, white	5.00–6.20
Bread, Boston, brown	6.53
Bread, whole wheat	5.47–5.85
Cabbage	5.20–6.80
Carrots	5.88–6.40
Cauliflower	5.60
Cheese, Camembert	7.44
Cheese, Cheddar	5.90
Cheese, Cottage	4.75–5.02
Cheese, Parmesan	5.20–5.30
Cherries, California	4.01–4.54
Chicken	5.8–6.4
Cornflakes	4.90–5.38
Eggs, new-laid, whole	6.58
White	7.96
Yolk	6.10
Fish	6.5–6.8
Garlic	5.80
Grapes	2.80–3.80
Grapefruit	3.00–3.75
Honey	3.70–4.70
Ketchup	3.89–3.92
Lemon juice	2.00–2.60
Milk, cow	6.40–6.80
Milk, goat's	6.48
Milk, peptonized	7.10
Mushrooms	6.00–6.70
Mustard	3.55–6.00
Olives, black	6.00–7.00
Onions	5.30–5.80
Oranges, Florida	3.69–4.34
Peaches	3.30–4.05
Peanut butter	6.28
Pears	3.50–4.60
Peas, chick	6.48–6.80
Peppers	4.65–5.93
Pineapple	3.20–4.00
Potatoes	5.40–5.90
Rice (cooked)	6.00–6.80
Salmon, fresh, boiled	5.85–6.50
Sardines	5.70–6.60
Soy Sauce	4.40–5.40
Soybean milk	7.00
Spaghetti, cooked	5.97–6.40
Spinach	5.50–6.80
Strawberries	3.00–3.90
Tea	7.20
Tomatoes	4.30–4.90

Introduction

Phytochemicals are plant secondary metabolites, that is, substances that have little or no role in photosynthesis, respiration, or growth and development. In humans, they are nonnutrient xenobiotics that are quickly eliminated. The majority of phytochemicals are antioxidant compounds.

Phenolic compounds ('phenols' and 'polyphenols') comprise a major class of phytochemicals. They are essential to plants for pigmentation, growth, reproduction, resistance to pathogens, and several other functions. Hence, phenolic compounds are ubiquitously present in the plant kingdom, representing the main source of exogenous-dietary antioxidants in our diet. In general, dietary – exogenous – antioxidants are effective at very low concentrations, while at higher concentrations, most of them act as pro-oxidants possibly due to their involvement in the initiation reactions. Recent studies indicate that plant-derived phytochemicals, ingested by humans at subtoxic doses, induce mild cellular stress responses. This dose–response phenomenon, characterized by a low-dose stimulation and high-dose inhibition, is described in biology and medicine as 'preconditioning' or 'hormesis' and results in inducing the expression of genes that encode several cytoprotective proteins, including antioxidant enzymes, protein chaperones, phase-2 enzymes, and neurotrophic factors.

The terms 'phenol' and 'polyphenol' are defined chemically as substances that possess at least an aromatic ring bearing one (phenol) or more (polyphenol) hydroxyl substituents. However, in the strict context of plant phenolics, such a definition is not satisfactory, since it would include terpenoid compounds like the phenolic carotenoid 3-hydroxyisorenieratene and the phenolic female sex hormone estrone.

Phenolic compounds are synthesized mainly through shikimate and acetate pathways and are generally found conjugated to sugars and organic acids, with conjugates linked to hydroxyl or aromatic carbon moieties. Besides glucose, which is the most common conjugate, galactose, rhamnose, xylose, arabinose, and glucuronic or galacturonic acids are also found. The structure of plant phenolics and polyphenols varies from simple molecules, such as phenolic acids, to highly polymerized compounds, such as proanthocyanidins. Several thousand different compounds have been so far identified (among them over 8000 flavonoids), bearing a large range of structures, and many of them occur in food.

According to number and arrangement of carbon atoms, naturally occurring plant phenolics can be classified into flavonoids and nonflavonoids. In addition, traditionally processed foods and beverages, such as coffee, red wine, and black tea, may contain products of their transformation that are described as 'derived polyphenols.' Different types of phenolics predominate in certain foods; for example, flavan-3-ols are the main phenolics found in tea, flavanones in citrus fruits, and isoflavones in soy, whereas other phenolic compounds, such as gallic acid and quercetin, are ubiquitously found in plant foods.

Several classes of phenolics have been categorized on the basis of their basic skeleton: C6 (simple phenols and benzoquinones), C6-C1 (phenolic acids), C6-C2 (acetophenones and phenylacetic acids), C6-C3 (hydroxycinnamic acids, coumarins, phenylpropenes, and chromones), C6-C4 (naphthoquinones), C6-C1-C6 (xanthones), C6-C2-C6 (stilbenes and anthraquinones), C6-C3-C6 (flavonoids and isoflavonoids), $(C6\text{-}C1)_2$ (hydrolyzable tannins), $(C6\text{-}C3)_2$ (lignans and neolignans), $(C6\text{-}C3\text{-}C6)_2$ (biflavonoids), $(C6\text{-}C3)_n$ (lignins), $(C6)_n$ (catechol melanins), and $(C6\text{-}C3\text{-}C6)_n$ (condensed tannins). Flavonoids (Figure 1) are the most widespread among the phenolic compounds. The most abundant subclasses of dietary flavonoids are flavones, flavonols, flavanones, flavan-3-ols, anthocyanidins, and isoflavones (Figure 2). Dietary flavonoids found in relatively lower amounts are flavan-3,4-diols, dihydroflavonols, aurones, coumarins, chalcones, and dihydrochalcones.

Bioavailability of Phenolic Compounds

Food components are categorized to nutrients and nonnutrients with distinguished roles in human body. Nutrients are mainly utilized as substrates for energy production, while nonnutrients exhibit a variety of other biological functions essential for human homeostasis. Plant-derived foods, for example, fruits, vegetables, and whole grain fruits, contain large quantities of nonnutrient phytochemicals that have been extensively studied for their beneficial health effects on the prevention of chronic inflammation, cardiovascular diseases, and some types of cancer.

Phenolic compounds are the most studied type of phytochemicals. The majority of *in vitro* studies consent that phenolic compounds are potent antioxidant and anti-inflammatory agents, but they must be biologically available in order to exhibit their health functions *in vivo*. Transport through the gastrointestinal tract, release from the solid matrix, absorption across the gastrointestinal epithelium, and transport into the circulation are the normal paths of dietary phenolics.

In line with other nutrients and nonnutrients, ingestion of phenolic compounds is followed by both bioaccessibility and bioavailability. Bioavailability is a concept that comes from a fusion of the words 'biological' and 'availability' and was initially defined as "the fraction of administered drug that can reach plasma and body tissues in an unchanged form." When it comes to the bioactivity of food components intended for oral ingestion, either as food supplements or as parent foods, the impact of bioavailability is crucial since the digestive tract constitutes the primary barrier between an active ingredient and the systemic circulation. The internal environment of the digestive tract (e.g., pH and microbial flora) can also affect absorption. Thus, bioavailability should always be considered when the effects of ingested food components are studied in animal

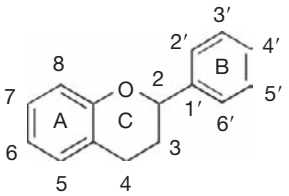

Figure 2 Main subclasses of dietary flavonoids.

models or human clinical trials. In order to be available for absorption in the gastrointestinal tract, the food component must also be bioaccessible. The term bioaccessibility refers to the amount of any food constituent that is readably present in the gut, as a consequence of its release from the solid matrix, and that may be able to pass through the intestinal barrier.

The 'rule of five' introduced by Lipinski et al. (2001) describes the ideal molecular properties of a drug molecule for gastrointestinal absorption. According to this rule, a molecule displays optimal absorption if it has (a) a molecular weight of less than 500 Da, (b) no more than five hydrogen bond donors, (c) no more than ten hydrogen bond acceptors, and (d) an octanol–water partition coefficient (log P) less than five. Molecules absorbed by specific transporters are an exception to this rule. Additionally, the presence of adjuvants, for example, food, can also affect bioavailability. Catechin is an example of phenolic compound that meets the aforementioned rule for oral bioavailability.

The bioavailability of phenolic compounds has been extensively reviewed in the bibliography. A great number of reviews are focusing on phenolic compounds from individual sources, such as green tea, cocoa, beer, wine, and fruits, while others discuss the bioavailability of phenolic compounds in total. Nevertheless, the overall bioavailability of phenolic compounds is relatively low, mainly due to their low absorption in the gastrointestinal tract, instability, biotransformation within the gut, excessive metabolism, and rapid clearance from the body. As described earlier herein, phenolic compounds occur mostly as soluble conjugates (glucosides) and insoluble forms covalently bound to cell wall structural components. Absorption for bound phenolic compounds in the gastrointestinal tract greatly depends on the liberation of sugar moieties. Food processes such as fermentation, malting, thermoplastic extrusion, and enzymatic, alkaline, and acid hydrolyses occasionally assisted with microwave or ultrasound treatment have potential to release phenolics associated to cell walls. Additionally, food processing may modify the naturally arranged microstructure of most plant foods. Phenolic compounds can be present in the matrix as individual molecules, either bound to cell organelles or entrapped in complex macromolecular matrices with other macronutrients such as carbohydrates or proteins. The food matrix affects bioaccessibility and bioavailability.

Overall, the main factors affecting the bioavailability of phenolic compounds in humans are (a) environmental factors (e.g., sun exposure, and degree of ripeness) and food availability, (b) food processing (e.g., thermal treatments, homogenization, lyophilization, cooking and culinary methods, and storage), (c) food-related factors (e.g., food matrix), (d) interactions between food components (i.e., bonds with proteins or with polyphenols with similar mechanism of absorption), (e) chemical properties (chemical structure, concentration in food, and amount introduced), (f) host-related factors such as intestinal factors (e.g., enzyme activity, intestinal transit time, and colonic microflora), and systemic factors (e.g., gender and age, disorders and/or pathologies, genetics, and physiological condition).

In vitro evaluation of the activity of phenolic compounds does not have to be in accordance with the activity demonstrated in humans. Bioactivity is influenced by metabolic transformation and bioavailability and the main reason is that phytochemicals are processed as xenobiotics.

There are several *in vitro* approaches for evaluating bioavailability of phenolic compounds, which use a barrier membrane separating the donor compartment, that is, the gastrointestinal lumen from the receiver compartment, that is, the blood circulation, through which the molecule has to pass. Thereafter, an analytic method of appropriate selectivity and sensitivity is used to quantify the amount of components transported across the membrane. The *in vitro* assimilation approaches have been developed as simple, cheap, and repeatable tools for the study of food component bioavailability. These models aim to reproduce the absorption processes in humans, and the stability of the *in vitro* conditions achieved is their major advantage. Nevertheless, there is a significant limitation; the intestinal mucosa is not only a barrier on a physical sense but also a biochemical barrier, which carries out a series of complex metabolic reactions that are part of the presystemic metabolism and affect bioavailability.

There are various types of models including those based on physical reproduction of the membrane (artificial membrane),

those based on cell cultures and isolated organs, and those using isolated or reconstituted cell membranes. Data obtained from the last two types of studies demonstrate higher correlation with those obtained from *in vivo* trials.

In the case of models based on cell cultures, the human colon cancer cells type 2 ($CaCo_2$) are more commonly used. Although this cell line originates from human adenocarcinoma colonocytes, when cultured under appropriate conditions, these cells differentiate into polarized monolayers that present morphological and functional characteristics of intestinal absorptive epithelium, including intercellular tight junctions and apical microvilli, and carriers for nutrient as well as efflux proteins and a number, but not all, of phase-2 enzymes required to xenobiotic disposition. Other cell lines, such as Madin–Darby canine kidney cells, rat fetus intestinal cells (2/4/A1), and pig kidney epithelial cells (LLC-PK1), are also used.

Furthermore, suspension brush border membrane vesicles prepared from the intestinal tissue of mammalians (e.g., pigs, rabbits, chickens, rats, mice, and humans) are used to study the transport of compounds through the cell membrane. A weakness of this model is that it predicts only the step of the absorption process that occurs on the interior of the membrane.

In order to detect and quantify the compounds transported across the gastrointestinal barrier, the most common analytic methods used are gas and liquid chromatography with UV or MS detection. For *in vivo* studies, MS detection is more appropriate than UV detection because of the high sensitivity of the method. Finally, both sensitivity and selectivity are significantly enhanced when tandem mass detectors are used (MS–MS).

In vivo evaluation of bioavailability provides safer conclusions about the fate of phytochemicals in humans. These studies are usually conducted in mammalian models (e.g., mice, rats, dogs, and monkeys), nonmammalian models, and human clinical trials. Blood, urine, and/or feces samples are collected at regular time intervals usually until 24 h after ingestion. The phenolic compounds, as well as their metabolites, are detected in the biological samples, while total plasma antioxidant capacity is usually evaluated. One limitation of these studies is that the methodology includes a high-dose consumption of the particular food or compound(s) after implementing a washout diet restricted in phytochemicals. Such high doses may cause different pharmacokinetics from the usual followed by ingestion of normal food quantities. Additionally, the restriction diets may be difficult to implement for several days leading volunteers to withdraw from the study.

Despite disadvantages, bioavailability studies serve to understand the different absorption mechanisms, as well as which phenolic compounds are absorbed intact or have to be first transformed. For example, it was initially assumed that the glycosylated phenolic compounds are not able to cross the enterocyte wall due to their hydrophilic nature. Now, the presence of specific transporters that assist their transmembrane transport is well documented.

Digestion and Metabolism of Phenolic Compounds

The first step of digestion is mastication, a process that turns food to smaller pieces facilitating partial release of food components and passage through the esophagus toward the stomach. The salivary secretion contains digestive enzymes that help the release of phenolic compounds. Hydrolysis of glycoside flavonoids already starts in mouth by means of β-glucosidase activity; however, its effectiveness depends on the sugar type present in the molecule. Most flavonoids in food occur as *O*-glycosides. Glucose is the most common glycosidic unit, and also glucorhamnose, galactose, arabinose, and rhamnose may occur. Glucose conjugates are rapidly hydrolyzed as opposed to others such as those of rhamnose. Absorption may as well occur in the oral mucosa. Tea catechins are detected in the salivary phase at levels ranging from 74.8% to 99.5% of undigested samples, indicating good stability under oral biochemical conditions *in vitro*. Degalloylation, that is, the conversion of epigallocatechin gallate to epigallocatechin, occurs in the oral cavity, which leads to subsequent absorption through the oral mucosa. A catechin esterase activity that converts epigallocatechin gallate to epigallocatechin has been identified in the saliva. A plethora of polar and hydrophobic compounds can rapidly reach the blood circulation, bypassing the gastrointestinal tract, while possible underlying mechanisms have already been studied. Interaction with proteins (glycoprotein mucin, albumins, immunoglobulins, and lactoferrin), also present in the salivary secretion, can lower bioaccessibility. Chemical structure seems to affect the degree of this interaction. *In vitro* interaction of catechin with saliva proteins is stronger than that of epicatechin, an observation mostly attributed to the stereochemistry of flavan-3-ols. Similarly, procyanidin dimers linked through a C(4)–C(8) interflavanoid bond present greater affinity for saliva proteins than those linked through C(4)–C(6). Esterification of a galloyl group to the C(3) hydroxyl function of (−)-epicatechin or to the epicatechin moiety of procyanidin dimer B2 increases the binding affinity to proteins.

In the stomach, peristalsis and chyme production under low pH environment generally enhance the release of phenolic compounds from the food matrix. Hydrolysis and/or transformation, such as hydrolysis of proanthocyanidin oligomers or cleavage of sugar moieties in the stomach, may occur and facilitate bioaccessibility. Gastric pH plays significant role in phenolic compound stability. Total phenolic content in fruit juices is decreased at least 47% after *in vitro* digestion compared with predigestion. Significant reductions in gallic, caffeic, and ferulic acid levels are observed after digestion of pineapple and red fruit juices, probably due to poor stability to pH changes. Anthocyanins are stable in the acidic conditions of the stomach but are less stable at the elevated pH of the small intestine. Generally, flavonols and proanthocyanidins remain intact, but they may also be broken down when pH is substantially low in the stomach. Among all the flavonoids, the flavan-3-ols exist as aglycones and pass intact into the duodenum without requiring the action of β-glucosidase prior to absorption. Phenolic compounds may show different stability to pH changes when tested solely, meaning that the interaction with other food components can affect the stability during digestion. Codigestion of raspberry extract with other foodstuffs such as bread, breakfast cereal, ice cream, and cooked minced beef alters bioavailability. In particular, the total phenol content is slightly reduced by codigestion with ice cream or breakfast cereal but is not affected by codigestion with bread or minced beef. In the case of small phenolic compounds lightly bound to food matrix, absorption is also observed in the stomach.

Absorption across the enterocyte wall depends strongly on the food matrix, the physiology, and the anatomy of the consumer, as well as the characteristics of phenolic compounds, such as molecular dimension, polymerization, stereochemistry of the glycosidic moiety, and hydrophobicity. In particular, procyanidin dimer and trimer may cross the gut barrier, but procyanidin polymers do not. While phenolic compounds are not subjected to major transformation in the stomach, as the chyme passes to the alkaline environment of the duodenum, partial degradation and loss of phenolic compounds occur. Anthocyanins, flavonols, and flavan-3-ols are unstable in the alkaline environment of the small intestine, which results in 43%, 26%, and 19% reduction, respectively. Deglycosylation, glucuronidation, methylation, sulfonation, and hydroxylation of flavonoids take place. Epigallocatechin gallate may also be oxidized to dimerized products possessing higher superoxide radical scavenging activity than epigallocatechin gallate itself. The food matrix can buffer the pH and oxidation of the flavanols may occur only to a limited extent during intestinal transit. It has been documented that vitamin C significantly increases the stability of flavanols incubated with intestinal juice *in vitro*. Galloylated catechins are rapidly eliminated, not by degalloylation, a process not less occurring in humans, but rather excretion of these compounds in bile (feces). Similarly, phenolic acid esters such chlorogenic acid cannot be degraded in the small intestine due to the absence of esterases; therefore, they are only metabolized by the colonic microflora.

Regarding phenolic compound glycosides, two main absorption paths have been proposed: (a) along the gastrointestinal tract and (b) inside the enterocytes. Metabolisms along the gastrointestinal tract are mainly aiming at deglycosylation. Phenolic compound glycosides are more hydrophilic than their corresponding aglycones and cannot readily cross the enterocyte cellular wall via passive diffusion. For this purpose, hydrolase enzymes available in intestinal lumen, brush border, and enterocyte cleave the glycosidic moieties. This deglycosylation also takes place by microbiota in the colon. Lactase–phlorizin hydrolase (LPH), a brush border enzyme on the surface of enterocytes, is very potent toward flavonoid-*O*-β-D-glycosides. Consequently, the aglycone products with their lipophilic nature can cross the cell membrane via passive diffusion.

Inside the enterocyte, phenolic compound glycosides are transported across the membrane cell wall via an active sodium-dependent glucose transporter. There, glycosidic moieties are cleaved by cytosolic β-glucosidase, and the aglycone forms are either passed to the bloodstream via passive diffusion or transformed to phase II metabolites. Conjugation of phenolic compounds into glucuronides, sulfates, or methyl conjugates is the most studied pathway. These phase II metabolites are either effluxed into the gut lumen or transported to the bloodstream via apical and basolateral multidrug/lipid transporters, respectively. As xenobiotics, phenolic compounds undergo phase II transformation in the small intestine, liver, and bile contributing to detoxification. This transformation with conjugation in hydroxyl groups of glucuronidic acid, sulfate, and/or methyl is mainly catalyzed by UDP-glucuronosyltransferases, sulfotransferase, and catechol-*O*-methyltransferase mainly found in the liver. There is evidence that conjugation retains bioactivity of phenolic compounds but is generally weaker than that of the aglycone form. For example, quercetin-3-glucuronide, one of the three major plasma quercetin conjugates, is able to delay the Cu(II)-induced oxidation of human low-density lipoprotein, but two other major conjugates (quercetin-3-sulfate and 3-methylquercetin-3-glucuronide) are ineffective.

There are significant differences between the administration of drugs (usually at a high dose) and the consumption of dietary phenolic compounds (usually at a low dose). Drugs saturate the metabolic pathways that rely on phase II metabolism and circulate in the blood in the unconjugated form. In contrast, dietary phenolic compounds are not able to saturate these metabolic pathways and undergo conjugation. However, when phenolic compounds are administered at high doses, they can be found in free-form in the blood. For example, after the intake of a large dose of (1)-catechin, free (1)-catechin is detected in the plasma after 30 min. On the other hand, after the consumption of a few milligrams of (1)-catechin, normally present in red wine, catechin is found only in the conjugated form.

Absorption of flavonoid glycosides also depends on the type of sugar moiety. Quercetin-3-*O*-rhamnoglucoside is slower absorbed than quercetin-4-*O*-glucoside, since the glycoside is absorbed in the small intestine, while the rhamnoglucoside in the colon after hydrolysis by the gut microbiota.

Undigested polyphenols pass into the large intestine, where they are degraded by the colonic microflora. The colon contains 1012 microorganisms per cubic centimeter, which have catalytic and hydrolytic potential. Biotransformation in the gut depends on phenolic compound chemical structure, microbiota population, and food consumed. Generally, phenolic compound polymers degrade to phenolic acids; flavonols produce hydroxyphenylacetic acids; flavones and flavanones degrade to hydroxyphenylpropionic acids; and flavanols produce both phenylvalerolactone and hydroxyphenylpropionic acids. Procyanidins are also degraded to phenolic acids of lower molecular weight. Additionally, colonic bacterial enzymes catalyze reactions of hydrolysis, dehydroxylation, demethylation, and decarboxylation. For example, quercetin-3-*O*-rhamnoglucoside and quercetin-3-*O*-rhamnoside are hydrolyzed by a-rhamnosidase and β-glucosidase. Bacterial enzymes (β,D-glucuronidase, β,D-glucosidase, and a,L-rhamnosidase) also deconjugate phase II metabolites produced in enterocytes and hepatocytes. Then, the bacterial derivatives can be absorbed into the circulation and transported to the liver, where they are subjected to first-pass and phase II metabolism.

Human clinical trials and animal studies confirm that phenolic compounds and their metabolites are found in various tissues, for example, brain, endothelium, heart, kidney, liver, pancreas, prostate, uterus, ovary, mammary gland, testes, bladder, bone, and skin tissues. Nevertheless, only a small amount of ingested phenolic compounds is detected in tissues, while excretion is rapidly occurring via urine and bile within 24 h after consumption. The biological activities of phenolic compound metabolites may also be different from those of the parent compounds depending on their transformation (methylated, sulfated, or glycosylated). However, these metabolites account for the increase in total plasma antioxidant capacity. Further bioavailability studies are needed to elucidate the pharmacokinetics of dietary phenolic compounds and how they are distributed to peripheral tissues and exert their biological effects.

Phenolic Compounds Health Effects

Research on the health effects of polyphenols has developed significantly in the past decades, supporting their antioxidant, anti-inflammatory, and antimicrobial properties in humans. However, their role in human health is centered chiefly in the prevention of atherosclerotic disease and the resulting cardiovascular disease or some forms of cancer. The antioxidant properties of polyphenols in chemical and biological assays have been most widely studied, and it has become clear that the mechanisms of action of polyphenols go beyond their radical scavenging capacity. Many clinical trials have shown that to some extent, their properties evidenced in observational studies or shown *in vitro* may apply to entire organisms, yet their effect in human disease remains a controversial topic.

Effects on Atherosclerosis

Based on the 'oxidation theory' for atherosclerosis, polyphenols have attracted considerable attention as preventive and therapeutic agents as there is sufficient evidence that consumption of polyphenol-rich foods results in a reduction in oxidative stress and myocardial infarction biomarkers. Observational studies serve to correlate dietary polyphenol intake with disease prevention or disease risk reduction. An example of such is the Zutphen Elderly study, in which intake of flavonoids (30 mg day^{-1}) was correlated with 50% reduction in cardiovascular disease mortality compared with 19 mg day^{-1} flavonoid intake. However, observational studies are based upon measurements of micronutrient intakes through the use of dietary recall questionnaires that may be imprecise. Thus, the strong hypotheses driven by such observations are verified by *in vitro* or *in vivo* intervention studies.

Oxidized LDLs are associated with the pathogenesis of atherosclerosis. Oxidation takes place when naturally occurring antioxidant agents such as alpha-tocopherol and carotenes that normally inhibit LDL oxidation do not occur. The role of oxidized LDLs in atherosclerosis, and consequently in cardiovascular disease, is manifold as they induce cell adhesion molecule expression in aortic endothelial cells and subsequently enhance endothelial cell expression of chemotactic and adhesion molecules and stimulate T cells through the major histocompatibility complex and CD4+ helper T-cell receptor. Further, they trigger proinflammatory cytokine secretion that increases smooth muscle cell proliferation, activates monocytes, and increases T-cell proliferation. Under the stimulation of oxidized LDLs, activated macrophages influence the expression of mediators of endothelial activation, such as nitric oxide. Besides, the aldehydic products of LDL oxidation exert a direct toxic effect on the endothelium and platelets. Several *in vitro* studies strongly suggest that polyphenols protect LDL from oxidation. Additionally, LDL oxidizability is reduced after consumption of several natural products that are rich in polyphenols, such as not only olive oil and its oleuropein and hydroxytyrosol or red wine with its quercetin and resveratrol but also grape juice or tea or cocoa. Flavonoids have been found to act against LDL oxidation, and their antioxidant capacity is related to their chemical structures. The most hydrophilic do not bind LDL molecule; instead, they either scavenge free radicals; or act as chelating agents; or protect vitamin E, carotene, and lycopene in the LDL particle; or preserve serum paraoxonase activity, which itself promotes hydrolysis of lipid peroxides. Concerning isoflavones, present mainly in soy products, the clinical results are controversial, as some studies do show that they are effective inducers of *ex vivo* LDL oxidation after supplementation, while others do not.

Apart from oxidation of LDLs, the vascular endothelium plays a key role in atherosclerosis, particularly in the regulation of vascular tone by the release of vasodilator substances, mainly nitric oxide and prostacyclin, and vasoconstrictor substances, mainly free radicals and endothelin. In normal endothelium, nitric oxide mediates vasodilation, platelet desegregation, and antiproliferation and inhibits inflammation. In endothelial dysfunction, vasoconstriction, inflammation, proliferation mediated by several growth factors, platelet aggregation mediated by adhesion molecules, such as selectins, and thrombosis result in detrimental functional consequences and adverse long-term effects, including vascular remodeling. Endothelium dysfunction of the coronary arteries may cause or contribute to myocardial ischemia. The clinical trials carried out as to the potential of dietary flavonoids to counter heart disease risk by inhibiting platelet aggregation result in contrasting evidence. Hence, no clear effectiveness has been shown after dietary supplementation with genistein- and daidzein-rich soy in males or quercetin and apigenin in platelet aggregation, despite the increase in respective plasma concentrations. In coronary artery disease patients, no alterations in platelet aggregation have been observed by acute or chronic tea consumption, regardless of the fact that plasma flavonoids increased with both acute tea consumption and chronic tea consumption. Contrarily, cocoa or chocolate supplementation in healthy subjects not only increased plasma flavonoid levels but also decreased platelet aggregation, increased plasma prostacyclin, and decreased plasma leukotrienes in humans, evident of an antithromboembolic activity. In human trials, isoflavones were found to significantly increase forearm vascular resistance, lower postocclusion peak flow velocity of the brachial artery, and reduce arterial stiffness with improved systemic arterial compliance attributable to a reduction in total peripheral resistance and a corresponding reduction in central pulse wave velocity.

Moreover, the capacity of polyphenols to modulate gene expression has been investigated. Nutrients can influence gene expression directly or via gene promoters, via control of regulatory signals in nontranslated regions, and via posttranscriptional pathways. All the genes encoding proteins and the genes associated with transcriptional activation and signals modulating the transcription of the respective genes are potential candidates for gene–diet interaction. Phenolic compounds have been found to modulate the expression of cyclooxygenase-2 through suppression of activator protein-1, to increase the expression of serum high-density lipoprotein-associated paraoxonase 1 and of antioxidant enzymes, to downregulate vascular endothelial growth factor in human aortic endothelial cells, and to downregulate inflammatory cytokine gene expression in mononuclear cells and in macrophages.

Chemopreventive properties of phenolic compounds

Carcinogenesis is generally recognized as a complex and multistep process in which oxidative stress and inflammation play

crucial roles, and distinct molecular and cellular alterations occur. The factors affecting cancer may be not only genetic but also environmental, including a large body of physiological and biochemical factors, such as ultraviolet and ionizing radiation, smoking, viruses, bacteria, parasites, and mycotoxins contained in foods. Carcinogenesis may result from the action of any one or a combination of chemical, physical, biological, and/or genetic insults to cells. Independently of the etiologic factor, cancer is characterized by uncontrolled cell proliferation. Unlimited cell proliferation results in the development of a cell mass known as tumor, characterized as benign when lacking the ability to invade neighboring tissue or metastasizing or malignant when being anaplastic, invasive, and metastatic. The process of carcinogenesis may be divided into at least three stages: initiation, promotion, and progression. Initiation results from an irreversible genetic alteration, most likely one or more simple mutations, transversions, transitions, or deletions in DNA. Promotion is reversible and does not involve changes in the structure of DNA but rather in the expression of the genome mediated through promoter–receptor interactions. The final irreversible stage of progression is characterized by karyotypic instability and malignant growth.

Chemoprevention is a new approach to cancer prevention. Cancer chemoprevention attempts to inhibit the progress of the disease by using natural or synthetic substances. In terms of chemoprevention, many food components of the Mediterranean diet gained the 'food-borne anticarcinogens' title due to the phenolic phytochemicals with chemopreventive properties they contain. Phenolic compounds have been shown to interrupt or reverse carcinogenesis by acting in intracellular signaling network molecules involved in the initiation and/or promotion but also may arrest or reverse the progression stage of cancer. Those 'food-borne anticarcinogens' can be defined as either 'blocking agents,' which act immediately before or during the initiation of carcinogenesis by chemical carcinogens, or 'suppressing agents,' which act after initiation during the prolonged stages of promotion and progression. Blocking agents scavenge reactive oxygen species (ROS) by potentiating the antioxidant enzyme system, inhibiting carcinogen activation or enhancing their detoxification and excretion. Suppressing agents may prevent DNA damage, induce cell-cycle arrest or apoptosis, and inhibit inflammatory invasion or angiogenesis.

Many forms of cancer are attributed to oxidative stress meaning the presence of free radicals, which affect genes involved in cell apoptosis and proliferation and cause oxidative damage to proteins, lipids, and DNA. Prolonged oxidative stress and increased ROS production is one of the characteristics of cancer cells, shown in both *in vitro* and *in vivo* experiments and attributed to hypoxia where tumor grows or increased glucose metabolism. Hence, the chemopreventive activities of polyphenols are believed to be closely related to their ability to scavenge ROS. Further, phenolic compounds have been found to reduce the proliferation of cancer cells. For example, resveratrol has been found to regulate the concentrations of major molecules of the cell cycle, thereby interrupting cell growth phase in G1/S via upregulation of cyclins D1/D2/E and Cdk2/4/6, or to inhibit cell growth in phases S and G2/M through the inhibition of Cdk7 and p34Cdc2 or cyclin B and Cdk1 in the case of prostate cancer.

Very recent research suggests that dietary polyphenols act as chemopreventive agents in part due to their ability to modulate epigenetic alterations in cancer cells. The epigenome is nowadays considered just as important as the genome to normal development. Epigenetics is defined as the study of heritable changes in gene function that are not dependent on DNA sequence. The molecular basis of epigenetic processes is complex involving modifications of histones, DNA methylation, positioning of histone variants, and gene regulation by noncoding RNAs. Cancer development is owed to the epigenetic modifications triggered by carcinogens and metabolites. Epigenetic modifications are potentially reversible, and therefore, controlling cancer development at this stage is of immense importance. Flavonoids may act at this stage; however, the mechanism of how they do regulate epigenetic modifications in cancer cells is a topic still in its infancy. Catechol-containing coffee phenolics caffeic acid and chlorogenic acid have been shown to be demethylating agents. Acting as demethylating factors, phenolic compounds may inhibit chronic inflammation that has its molecular basis in epigenetic modifications on the one hand and underlies several forms of cancer on the other. Further, they act as chemopreventive factors by inhibiting cancer-linked inflammatory enzymes such as cyclooxygenase or lipoxygenases and other factors such as nuclear factor kappa B, the synthetase of nitric oxide or the activator protein-1. Specifically, the nuclear factor kappa B is one of the most important target molecules for phenolic compounds functioning as a transcription factor for at least 200 genes encoding proteins committed to inflammation, cytokines, chemokines, adhesion molecules and enzymes, cell proliferation, differentiation, and apoptosis. This molecule is activated in many tumors, suggesting that it is an important molecule in carcinogenesis and in tumor promotion and progression stages and augmenting the chemopreventive role of the phenolics that inhibit its activation.

Conclusive Remarks

Considerable progress has been made concerning our knowledge of phenolic compounds derived from foods, specifically the digestion, absorption, and bioavailability of these phytochemical compounds. Their contribution to disease risk reduction or disease prevention is supported by the evidence of absorption and bioavailability. Although research on their health effects is often contrasting and in the case of epigenetic modifications even in early infancy, their use in the future as agents to induce cardiovascular risk reduction or chemoprevention of various human cancers may be a strong possibility from a clinical standpoint. Since there is a significant unmet need in the existing disease prevention and treatment strategies, the evolution of treatments with phenolic compounds that are absorbed and bioavailable in human tissues and with relevant effectiveness offers an exciting opportunity to reduce the global burden imposed by cardiovascular events and cancer and remains a scientific challenge. If these agents are well absorbed, have no toxic effects, but have high efficacy against targeted disease, with known mechanism of activity, they may realistically be complementary treatment options for subjects in high risk.

Phenolic Compounds: Occurrence, Classes, and Analysis

M Murkovic, Graz University of Technology, Graz, Austria

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Dietary phenolic compounds comprise a huge number of substances having several common structural features. They not only do have specific functions in the plant cell or plant organ but also can interact with the human metabolism being either health-promoting or toxic. In the food, these substances can have specific functions. In some cases, they can be used as food colorants (e.g., quercetin being yellow and anthocyanins being red or blue). However, due to the phenolic group, they can act as antioxidants being very effective oxygen radical quenchers.

The biosynthesis of polyphenols in plants is based on the shikimate pathway. The aromatic ring systems in flavonoids – ring B and chromane – are originating from phenylalanine. Ring A is formed from three units of malonyl CoA. The phenylpropanoid biosynthesis leads to p-coumaroyl-CoA, which is the first key intermediate in the further synthesis of higher polyphenols (naringin, flavonols, anthocyanins, and flavanols). A detailed representation of the biosynthetic pathways of flavonoids can be found at the KEGG pathway database (Reference pathway, map 00941).

Phenolic compounds are needed in plants for a variety of tasks that comprise pigmentation, growth, reproduction, and resistance to pathogens. They are also responsible for UV light protection, serve as signal compounds and internal regulators or chemical messengers, and act as defense against fungal pathogens and phytophagous insects.

Polyphenols contribute not only to the chemical and textural properties of foods but also to the sensory properties. These are the constituents that contribute mostly to astringency and bitterness. Astringency and bitterness are elicited from a variety of foods including nuts, fruits, chocolate, tea, wine, and beer. Alpha acids are the principle bitter compounds in beer, whereas in the other foods, catechin, epicatechin, and the oligomers (proanthocyanidins) are the primarily responsible constituents for astringency and bitterness. The bitter taste is a result of the interaction of the respective compounds with specific taste receptors, whereas astringency is perceived through touch, via mechanoreceptors. In contrast to bitterness, astringent compounds are chemically defined as compounds precipitating proteins (e.g., tannins).

Phenols

Due to their specific chemical structure, the phenols can act as antioxidants. In contrast to their action in physiological systems, they can interact directly with the radicals of oxidized foods and thereby inhibit or reduce further oxidation. Depending on the position and number of hydroxyl groups, the number of conjugated double bonds, and glycosylation, they have different reduction potentials resulting in stronger or weaker antioxidants. In the case of flavonoids, the critical structural features for an optimal antioxidant potential were identified as (i) the presence of a catechol group in the B-ring (Figure 1), (ii) a 2,3-double bond, and (iii) 3- and 5-hydroxy groups adjacent to the 4-keto structure.

Phenolic Acids

The phenolic acids can be divided into two groups, that is, the hydroxybenzoic acids (Figure 2) and the hydroxycinnamic acids (Figure 3). Either they can be found as free substances in, for example, fruits and vegetables, or they are conjugated, mainly in grains and seeds. The conjugates can release the phenolic acids upon acid, alkaline, or enzymatic hydrolysis.

Hydroxybenzoic acids are typically found in berries at low concentrations. Blackberries contain up to 250 mg kg^{-1} comprising protocatechuic acid, *p*-hydroxybenzoic acid, and gallic acid, red raspberries and sweet cherries up to 40 mg kg^{-1}, and gooseberries up to 20 mg kg^{-1}. Other fruits contain significantly lower amounts, if any. In general, *p*-hydroxybenzoic acid and protocatechuic acid are the dominating hydroxybenzoic acids in ripe fruits. In the literature, a huge variation in the content of phenolic compounds can be found. This might be due to a number of parameters that are not described in detail and that comprise, for example, the variety, state of ripeness, geographic location, and climate during ripening. This is true for the other phenolic compounds as well.

The free hydroxycinnamic acids are found in low concentrations in the plant foods. Normally, they are conjugated with quinic acid forming chlorogenic acid (5′-caffeoylquinic acid), cryptochlorogenic acid (4′-CQA), or neochlorogenic acid (3′-CQA). They can also be linked to glucose as esters (e.g., p-coumaroyl glucose) or as glycosides (p-coumaric acid glucoside).

Quinic acid esters are mainly found in blueberries (<2000 mg kg^{-1}); kiwis, cherries, and plums (<1000 mg kg^{-1}); eggplants and pears (<600 mg kg^{-1}); peaches (<400 mg kg^{-1}); and apples (<500 mg kg^{-1}). Glucose conjugates are occurring at lower concentrations, for example, in tomatoes (<100 mg kg^{-1}) and in strawberries, raspberries, gooseberries, and black currant (30–60 mg kg^{-1}). Exceptionally high amounts of chlorogenic acids are found in green coffee (*c*.65 g kg^{-1} in arabica and 100 g kg^{-1} in robusta coffee). During roasting, the content of chlorogenic acids is reduced by 50–70%.

Isoflavones

Food products containing isoflavones are limited to soybeans and products thereof. The first specific reaction in the biosynthesis of isoflavones in plants is the 2-hydroxylation, coupled to aryl migration, of a flavanone. The worldwide application of soybeans as food and feed resulted in an uncountable number of varieties optimized for practically all culinary, nutritional, and technological purposes. It is not only the protein and oil

content but also the isoflavones concentration in the soybeans and products and many other traits relevant for agricultural production and further processing. Isoflavones can act as antioxidants and have an estrogenic activity.

The two dominating isoflavones in foods are daidzein and genistein. These compounds are only found in foods containing soy products. Up to 1.4 g kg^{-1} occurs in soybeans and products thereof. This includes also glycitein, which is a similar compound methoxylated at C6. Daidzein and genistein can be used as indicators for the presence of soy in foods. Due to the high variation of the isoflavone content in soybeans, it is difficult to determine the exact percentage of soy as ingredient, but a rough estimate is possible. In addition, it can be used as an indicator for adulteration (Figure 4).

Flavonols

Flavonols are flavonoids that have a double bond between C2 and C3 and a carbonyl at C4. Having this large conjugated double bond system, these compounds absorb in the visible range, which means that they appear yellow. They have a strong absorption in the range of 340–380 nm, which is

especially useful for attracting insects that are sensitive to UV light. The flavonols are occurring widespread in the plant kingdom and therefore also in plant foods. The flavonols are strong antioxidants as they have all the molecular features mentioned earlier. Normally, the flavonols are glycosylated, preferentially at C3 as mono-, di-, or triglycosides. Glucuronidation is also possible. The most widespread flavonol diglycosides are rutinosides (e.g., rutin). Rutinose is a disaccharide in which rhamnose is glycosidically bound to glucose by a $1 \rightarrow 6$ linkage.

The total alimentary daily uptake of flavonols (calculated as aglycones) is *c.*13 mg. The concentrations in the foods vary strongly. In grapes (*Vitis vinifera*), the content of the glycosylated flavonols is in the range of 10–100 mg kg^{-1} depending mainly on the grape variety. Good sources of flavonols in the diet are onion (350–1200 mg kg^{-1}), kale (<600 mg kg^{-1}), broccoli (40–100 mg kg^{-1}), tomatoes (<200 mg kg^{-1}), apples (20–40 mg kg^{-1}), berries (15–160 mg kg^{-1}), tea infusion (20–45 mg kg^{-1}), and red wine. In vegetables, the intensive green color is a good indicator for higher flavonol content. There are large differences between different varieties in their flavonoid content. Among cruciferous crops, curly kale is known for the highest flavonoid content.

Flavanols

Flavanols are often called catechins. There is no double bond between C2 and C3 and no carbonyl in the ring C (C4). As a result, the flavanols have two chiral carbons (C2 and C3) and therefore four possible diastereomers: (+)-catechin (2*R*,3*S*), (−)-catechin (2*S*,3*R*), (+)-epicatechin (2*R*,3*R*), and (−)-epicatechin (2*S*,3*S*).

(+)-Catechin and (−)-epicatechin are commonly found in plant foods. The two monomeric flavanols and their analogs (gallocatechins) are occurring abundantly in tea leaves (green tea, 25–35% in dry leaves), cocoa beans (*c.*1.4 g kg^{-1}), and grape seeds (*c.*1.7 g kg^{-1}). In addition, the flavanols are found in many fruits like grapes (*c.*10 mg kg^{-1}), apples (*Malus domestica*, 30–100 mg kg^{-1}), apricots (*Prunus armeniaca*, *c.*10 mg kg^{-1}), and different berries (10–100 mg kg^{-1}) (Figure 5).

Anthocyanidins

The anthocyanidins comprise a group of flavonoids that have a specific absorption in the visible range. At low pH, the chroman ring is charged positively resulting in a strong absorption at *c.*520 nm. At pH values above 4.5, the charge is lost concomitantly with a significantly reduced absorption. Because of the intensive red color of the anthocyanins, they are used as colorant for acidic food mainly. The anthocyanins are strong antioxidants and therefore of limited stability. Depending on the glycosylation at the positions 3, 5, and 7, the stability increases with increased glycosylation and bulkiness of the carbohydrate moieties. A further stabilization can be obtained by copigmentation with hydroxycinnamic acids (caffeic acid) or with intramolecular copigmentation, which can be observed in the anthocyanins of the black carrot.

Due to the intensive absorption of the anthocyanins at around 520 nm, it is very easy to identify anthocyanin-rich foods. Especially, some berries are intensively colored. Cyanidin is the most widely spread anthocyanidin, which occurs in nearly every anthocyanin-containing fruit. Some fruits contain many different anthocyanidins, and they show also a great variety in glycosylation (grapes, blueberry, crowberry, and bilberry). The anthocyanins can be located in the skin of the fruits but could also be distributed throughout the whole fruit. High concentrations of anthocyanins can be found in eggplant (*Solanum melongena*), blackberry (*Rubus fruticosus*), black currant (*Ribes nigrum*), blueberry (*Vaccinium corymbosum*), bilberry (mainly *Vaccinium myrtillus*), elderberry (*Sambucus nigra*), chokeberry (*Aronia melanocarpa*), black crowberry (*Empetrum nigrum*), grape (*Vitis vinifera*), and cherry (*P. avium*). The concentration ranges from 1000 to 5000 mg kg^{-1}. Medium concentrations are found in rhubarb (*Rheum rhabarbarum*) with 1000–2000 mg kg^{-1}. Lower concentrations are occurring in strawberry (*Fragaria* × *ananassa*), plum (*P. domestica*), red cabbage (*Brassica oleracea*), and onions (*Allium cepa*) with concentrations of 10–1000 mg kg^{-1} (Figure 6).

Proanthocyanidins

The proanthocyanidins are a class of compounds that are condensed flavanols. The name originates from the acid hydrolysis during which anthocyanidins are formed and a red color appears. There are different groups of proanthocyanidins that refer to the linkage of polymerization. Type A is an interflavonoid linkage with the bridges $4\beta \rightarrow 8$ and $2\beta \rightarrow O \rightarrow 7$ (e.g., proanthocyanidin A2, epicatechin-$(2\beta \rightarrow 7,\ 4\beta \rightarrow 8)$-epicatechin). This A-type linkage is not as common as the B type, which has a single linkage of the type $4\beta \rightarrow 8$ (e.g., proanthocyanidin B1, epicatechin-$(4\beta \rightarrow 8)$-epicatechin). In B-type proanthocyanidins, α-configurations are also possible (B3, catechin-$(4\alpha \rightarrow 8)$-

catechin; B4, catechin-(4α→8)-epicatechin; B6, catechin-(4α→6)-catechin; or B8, catechin-(4α→6)-epicatechin). Procyanidin C1 is a B-type proanthocyanidin. It is an epicatechin trimer found in, for example, grapes (*Vitis vinifera*).

High concentrations of oligomeric proanthocyanidins (dimers and higher) can be found in cocoa-containing products (cocoa beans contain *c*.70 g kg^{-1}), apples (*M. domestica*; 500–1000 mg kg^{-1}), and chokeberries (*Aronia melanocarpa*; 6 g kg^{-1}). Grape seeds contain mostly monomers and dimers (*c*.4 g kg^{-1}) whereas in the juice, the higher oligomers and polymers are dominating. Polymeric proanthocyanidins are mainly found in cranberries (*Vaccinium macrocarpon*; with a total amount of *c*.4 g kg^{-1}) or chokeberries (*c*.6 g kg^{-1}). In different kinds of nuts (hazelnuts, almonds, and pistachios), the polymers are also dominating with a total amount of *c*.5 g kg^{-1}; walnuts contain significantly less proanthocyanidins (*Juglans regia*; < 1 g kg^{-1}). Data on foods containing proanthocyanidins can be found in a specialized database of the USDA (United States Department of Agriculture, http://www.ars.usda.gov/SP2UserFiles/Place/12354500/Data/PA/PA.pdf) (**Figures 7** and **8**).

Analysis

Identification and Analysis of Phenols in Foods

The identification of the substance of interest is essential before the analysis. As liquid chromatography is the method of choice for the analysis of phenols, there are a range of detectors that can give some structural information. As long as reference substances are available, the UV/vis absorption spectra in addition to the retention time can be very helpful for identification. This has been widely used in flavonoid analysis (**Table 1**). Besides the UV absorption, the detection of the polyphenols can also be done electrochemically due to their low potential of oxidation. Especially, the coulometric detection not only is sensitive but can also be very selective resulting in high-quality chromatograms. Furthermore, the hyphenation of chromatography with mass spectrometry gives the possibility of deeper analysis of the molecular structure. In addition, when analyzing a selective fragmentation pattern – as can be done by using a triple quadrupole mass spectrometer – detailed information on glycosylation and the aglycone can be obtained. The use of very high-resolution liquid chromatography in combination with high-resolution MS (mass accuracy 1–5 ppm, resolution > 60 000) is the state of the art of unambiguous identification of these compounds.

If no or limited structural information is available, it will be necessary to use nuclear magnetic resonance (NMR) with the limitation that high amounts or concentrations of the

Table 1 UV absorption of flavonoids

	Band II (nm)	*Band I (nm)*

Isoflavones	245–275	310–330
Flavanones	230–270	300–330
Anthocyanidins	270–280	465–560
Flavanols	207–280	–

substances of interest are needed. A comprehensive collection of NMR data on food phenols can be found in the database MetIDB (http://www.metidb.org). However, this approach will allow a definite elucidation of the phenolic compound. The identification of the plant metabolites can be done by liquid chromatography hyphenated with mass spectrometry. The recently commercially available high-resolution high performance liquid chromatography (HPLC) in combination with MS/MS is an excellent tool for identification and quantification. For the more polar (water soluble) compounds, the application of hydrophilic interaction liquid chromatography (HILIC) can be advantageous. This type of separation can also be used as orthogonal method for reversed-phase (RP) chromatography. Especially, the recent advancements of 2-dimensional (2-D) liquid chromatography can be applied for complex separations like procyanidins in apples or cocoa.

Extraction of Phenols for Analysis

In plant foods, the phenols are located in different organs and within the cells in vacuoles. The biosynthesis is normally taking place in the cytosol.

For efficient extraction, it is necessary to break up the structures and cells as completely as possible. In addition, the phenoloxidases present within the cells in the chloroplasts or in plastids – as it was shown for apples – start oxidizing the phenols (mainly o-diphenols) as soon as they come in contact with the substrates. Normally, the phenoloxidases are quite thermostable (up to 90 °C) and have a pH optimum at *c.*6.5. Therefore, it is difficult to inactivate the enzymes without compromising the polyphenol content. Using low-pH solvents, these enzymes can be inactivated and the concomitant stabilization of, for example, anthocyanins in acidic conditions can result in high recoveries of the analytes during extraction. Ascorbic acid can also be used to limit the activity of phenoloxidases, and especially, the combination of ascorbic acid with divalent cations (Mg^{2+}) can be used to stabilize the analytes during the extraction.

Freeze-drying of the food samples prior to grinding can also be advantageous for two reasons. On one hand, the phenoloxidases cannot catalyze the oxidation without water, and on the other hand, the polarity of the extraction solvent is not changed during the extraction. Care has to be taken when the pH of the solvent is optimized since it will be changed due to the cellular internal buffer systems that will be extracted as well. The selection of the solvent depends on the type of phenol and also on the glycosylation. For extraction of more polar compounds like the glycosides, acidified mixtures of water with methanol or ethanol are commonly used. This combination also limits the coextraction of proteins and other biopolymers. The clarified (Carrez solutions) and centrifuged extract can be purified further using solid-phase extraction (SPE) or can be analyzed directly.

Besides the direct (or Soxhlet) extraction, it is possible to increase the efficiency by using ultrasound or higher temperatures. Automated procedures like accelerated solvent extraction using higher temperatures and pressures can improve the efficacy. The use of supercritical solvents (e.g., CO_2) can also be advantageous since this can easily be combined with a subsequent SPE (e.g., C18) for the purification of the extracted analytes. The complete extraction of the phenols can be a challenging task due to the limited solubility of some of the phenols or the strong interaction with food structures or other food components (e.g., interaction of catechins with proteins).

HPLC Analysis

The columns used for HPLC analysis in literature are almost exclusively RP. Elution systems are usually binary, with an aqueous acidified polar solvent such as aqueous acetic acid, phosphoric acid, or formic acid and a less polar organic solvent such as methanol or acetonitrile. Isocratic elution is mainly used for routine analysis if only a few polyphenols want to be determined. Recent developments in HILIC broadened the applicability to the analysis of highly polar substances and also for polyphenols. HILIC separation is characterized by a highly polar stationary phase and a moderate polar eluent. The eluents are normally composed of high concentrations of acetonitrile and low concentrations of water. In this mode, water is a strong eluent, which means that during a gradient run, the water content of the eluent increases in contrast to RP separations.

For detection and quantification after separation, the absorption of UV or visible light is normally used. For flavonoids, two absorption bands are characteristic: the first one in the range of 240–285 nm, which is believed to arise from the A-ring, and the second one with a maximum in the range of 300–550 nm, which arises from the absorption of the B-ring. Since the absorption spectrum depends on the chemical substitution and the conjugated system, the different groups of flavonoids (flavanones/isoflavones, catechins, flavones/flavonols, etc.) have distinct absorption bands. The anthocyanins show absorption above 500 nm, whereas the catechins have only a small maximum at 280 nm and no absorption at higher wavelengths.

In general, the analysis can be limited to the determination of the aglycone after acidic hydrolysis or the substances are analyzed as they are present in the foods. This means that the glycosylation and conjugation to phenolic acids have to be considered in the analytic methods. In some cases, the aglycones (e.g., anthocyanidins) are more sensitive to oxidation and care has to be taken to protect these compounds during the analysis using even more powerful antioxidants or reducing the exposure to light and oxygen.

The analysis of the phenols is not only necessary in foods but also in metabolically relevant tissues in humans or experimental animals. In general, the concentrations are

significantly lower in the biological samples, and in many cases, the phenols are metabolized by the organism or the intestinal microorganisms. The result is a conjugation different from the naturally occurring glycosides. The breakdown of the carbon backbone is also common by the intestinal bacteria leading to smaller molecules that can also interact with the metabolism.

Other separation techniques can also be used (e.g., capillary electrophoresis and thin layer chromatography). Both of these techniques can also be hyphenated to mass spectrometry so that structural information can be obtained. Especially, thin layer chromatography is powerful since a simple setup for 2-D chromatography is available, and in addition, post-separation derivatization can give additional information or can add selectivity to the analysis. The limitation of thin layer chromatography is definitely the limited sensitivity compared to HPLC.

Occurrence

The concentrations of phenols in plant foods can be found in several databases that are available online like the eBASIS database, USDA database for the flavonoid content of selected foods, Japanese database, and the phenol database initiated by INRA (French National Institute for Agricultural Research). These databases do collect data not only on the occurrence of phenols but also on chemical properties or biological activities. NMR data of phenols can be found in the database MetIDB.

The concentrations of the phenols in foods vary enormously. Depending on the species, variety, harvesting time, state of ripeness, climate, and many other factors, the variation can be two orders of magnitude or even higher. A comprehensive overview of the data is given in the aforementioned databases.

Conclusion

Phenolic compounds from plant foods are a group of substances that are of interest because of their interaction with the human metabolism and their interaction with other food constituents. The main activity is related to the scavenging of different radicals and thereby inhibiting the oxidation of unsaturated fatty acids. Different chemical groups comprising phenolic acids, flavonoids, and many other phenols (e.g., tocopherols, phenylethanoids, stilbenoids, lignans, coumarins, and chalcones) show this common reactivity. Due to the high antioxidant activity, these compounds are not stable in foods during storage, preparation, and processing. They have specific sensory as well as textural properties that contribute to the appearance and taste of these foods. During breeding of new varieties, the content of the phenols was reduced significantly. This is due to the taste and the enzymatic browning that is related to the phenols. Today, we have more stable varieties and better-tasting varieties but with a lower content of potentially health-promoting substances.

Phospholipids: Physiology

T El-Bacha and AG Torres, Federal University of Rio de Janeiro, Rio de Janeiro, Brazil

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Phospholipids are ubiquitous molecules that participate in innumerous cellular events. The major chemical feature of phospholipids is their polarity, and for that, they are part of the lipid class of polar lipids. The biochemical and physiological properties of phospholipids are largely related to this chemical feature, which is named amphipathy, meaning phospholipids interact both with lipids and with water and other polar compounds. Mammalian cell membranes contain more than 1000 different phospholipids, presenting both structural and regulatory functions. Phospholipids exert structural functions in cellular membranes, which vary in phospholipid composition, according to cell and organelle functions. Phospholipid regulatory functions are both direct and indirect, through their metabolites. Phosphatidylcholine (PtdCho) was the first phospholipid to be discovered, and it was originally named lecithin after the Greek word *lekithos* (egg yolk). Because phospholipids were considered for a long period mostly serving structural functions in membranes, along with methodological difficulties, research interest in these compounds was delayed. It was then in the mid-1940s when the biosynthetic pathway of phospholipids was described that phospholipid research started to develop. The role of phospholipids in cell signaling events was initially described in the early 1970s with the association of membrane phosphoinositide turnover with intracellular calcium stores. Nowadays, it is well established that phospholipids participate in a broad range of cellular events such as apoptosis and regulation of mitochondrial physiology and that phospholipid-derived messenger molecules are crucial for the transduction of extracellular signals to intracellular events.

Distribution of Phospholipids among Organisms, Organelles, and Membranes

Phospholipids are polar lipid compounds in which both fatty acids and phosphoric acid are esterified to an alcohol (Figure 1). Phospholipids are divided into two classes: phosphoglycerides or glycerophospholipids, in which the alcohol is glycerol, and sphingolipids, in which sphingosine is the alcohol. Base groups such as choline, ethanolamine, inositol, and serine are esterified with the second acid group of phosphoric acid of the glycerol or sphingosine. The charges provided by the base (positive) and the acidic phosphate (negative) form the hydrophilic head, and hydrocarbon chains form the hydrophobic tail of the phospholipids (Figure 1). These physical–chemical properties allow phospholipids to spontaneously form special structures in aqueous media. Among these structures, extended bilayers with a hydrophobic core are major constituents of all cellular membranes, and micelle-like structures are seen in blood lipoproteins and cellular lipid bodies and are necessary for lipid and liposoluble vitamin absorption.

PtdCho and phosphatidylethanolamine (PtdEtn) are the most abundant phospholipids in blood plasma and organelle membranes from yeast to mammalian cells (Figure 2). In bacteria, the predominant phospholipid is PtdEtn. On the other hand, phosphatidylserine (PtdSer) is found mainly in the plasma membrane and in the Golgi apparatus and cardiolipin in mitochondrial membranes. Besides the differences in phospholipid distribution among organisms and organelles, there is a distinct distribution among organs. For example, in the brain, 45% of total phospholipids are PtdEtn, whereas this phospholipid accounts for 20% of total phospholipids in the liver. The maintenance of this distinct distribution of phospholipids among organelles, cells, and organisms requires a fine regulation of phospholipid synthesis, remodeling, transport, and degradation.

All cellular membranes show very different lipid composition between the inner and outer leaflets (e.g., Figure 2). Phospholipid asymmetry in membranes has obvious implications for membrane function, because it impacts on several of its physical–chemical properties. For instance, membrane asymmetry affects surface charges, and membrane phase transition, which is related to membrane fluidity and mobility of membrane components. A common feature of mammalian cell membranes is that the aminophospholipids PtdEtn and PtdSer and phosphatidylinositol (PtdIns) are concentrated in the cytoplasmic leaflet, whereas the outer leaflet is greatly enriched with PtdCho and sphingolipids (Figure 2). Conversely, exposure of PtdSer to the outer leaflet induces apoptosis and serves as a signal to phagocytes to target and destroy cells. The distinct asymmetrical distribution among the leaflets of cellular membranes is kept by the activity of three phospholipid exchange proteins (or translocators): flippase, floppase, and scramblase. Flippases and floppases translocate membrane phospholipids against concentration gradients, using energy from ATP. The former move aminophospholipids (PtdSer and PtdEtn) from the outer to the inner leaflet, whereas the latter translocate PtdCho, sphingolipids, and cholesterol in the opposite direction. In contrast, scramblases are less substrate-specific and facilitate lipid translocation along concentration gradients and without ATP use.

Metabolism of Phosphoglycerides

The bulk of phosphoglyceride synthesis occurs in the cytoplasmic leaflet of the endoplasmic reticulum (ER) and to a lesser extent in the Golgi complex. In the case of phosphatidylethanolamine (PtdEtn), part is synthesized in the mitochondria (Figure 3).

Usually, phosphoglycerides contain a saturated fatty acid esterified at the *sn*-1 position of glycerol, whereas an unsaturated fatty acid is esterified at the *sn*-2 position, forming a diacylglycerol (DAG) moiety (Figure 1). The fatty acid chains usually have an even number of carbon atoms with up to 80% being 16–20 carbon atoms long. In most phosphoglycerides of cell membranes, the fatty acid at the *sn*-2 position is polyunsaturated (e.g., arachidonic acid, eicosapentaenoic acid (EPA), or docosahexaenoic acid (DHA)). This structural feature of phospholipids is very important in membrane function and in cell signaling events. The degree and the amount of unsaturated fatty acids have a direct influence on membrane fluidity. Moreover, 20-C unsaturated fatty acids in the *sn*-2 position in glycerol are precursors of cell signaling molecules.

Phosphoglycerides are named after the moiety attached to the phosphate group esterified at the *sn*-3 position of glycerol (Figure 1). The simplest phosphoglyceride, phosphatidic acid (mostly phosphatidate in physiological pH), contains only phosphoric acid attached to the DAG. Phosphatidate is the precursor of all phosphoglycerides and also triacylglycerol. It is synthesized *de novo* from the dual acylation of glycerol 3-phosphate using acyl-CoA as fatty acid donor (Figure 3). Glycerol-3-phosphate acyltransferase (GPAT) and 1-acylglycerol-3-phosphate acyltransferase catalyze, respectively, the first and the second acylation of glycerol 3-phosphate. GPAT is specific for saturated fatty acids and 1-acylglycerol-3-phosphate acyltransferase is specific for fatty acids with one or two double bonds. Glycerol 3-phosphate arises either from glycerol or from dihydroxyacetone phosphate, which is produced in glycolysis. This fact highlights the intimate association between energy metabolism and phospholipid synthesis. Besides *de novo* synthesis, phosphatidate is produced via DAG phosphorylation by DAG kinases or via degradation of PtdCho by phospholipases.

Upon its synthesis, phosphatidate is used directly to synthesize PtdIns or cardiolipin, or it is dephosphorylated to DAG,

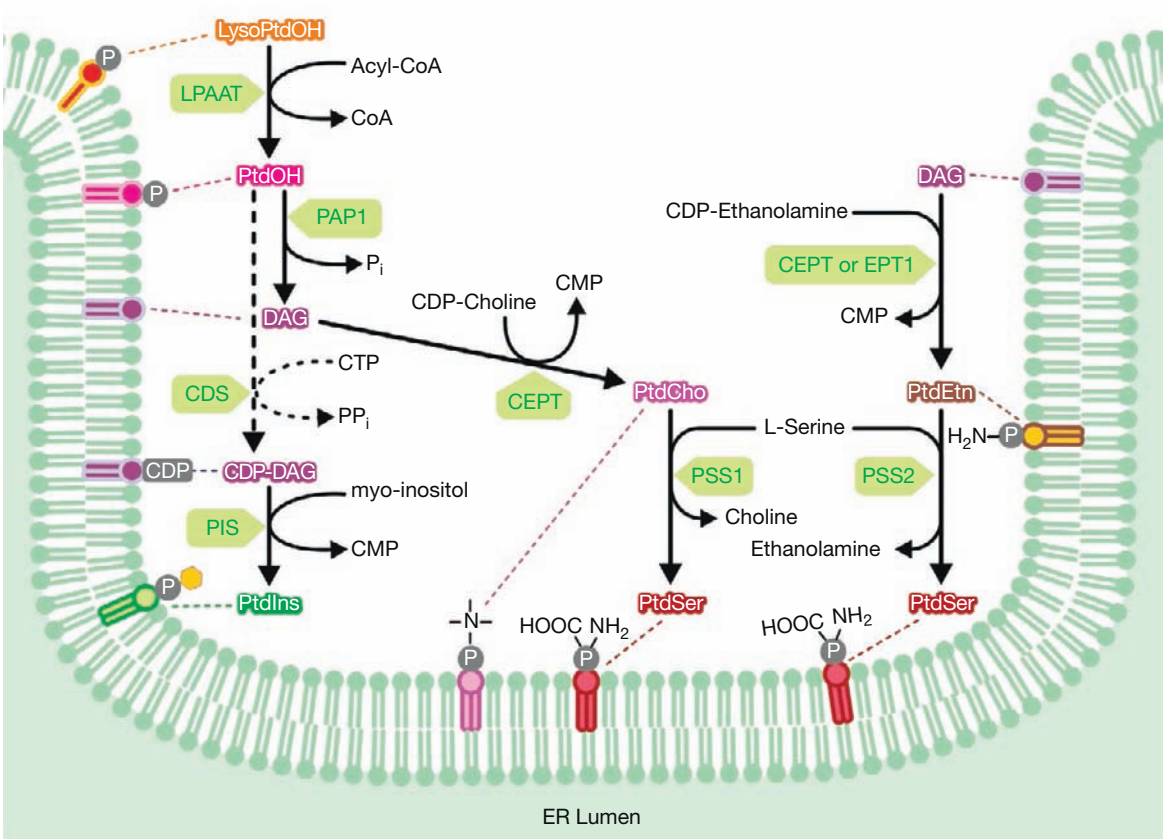

Figure 3 Phosphoglyceride synthesis. Phosphoglycerides are predominantly synthesized in the cytoplasmic leaflet of the ER membrane. PtdOH is the precursor of phosphoglycerides. LysoPtdOH produced from glycerol 3-phosphate is acylated to PtdOH. PtdOH is used directly to synthesize PtdIns. PtdOH dephosphorylation produces DAG, the precursor of PtdCho, PtdSer, and PtdEtn. PtdCho is also made in the Golgi complex, and PtdEtn is also produced in the mitochondria from PtdSer. See text for details. by phosphatidate phosphohydrolase, for the synthesis of PtdCho or PtdEtn (Figure 3).

Phosphatidylcholine

PtdCho is the precursor of various signaling molecules and it is the major phospholipid in bile. The first step in PtdCho synthesis is phosphocholine production from choline and ATP. Phosphocholine then reacts with cytidine triphosphate (CTP), producing cytidine diphosphocholine (CDP-choline). This reaction is catalyzed by choline-phosphate cytidyltransferase. The phosphocholine group is then transferred from CDP-choline to DAG by choline phosphotransferase, producing PtdCho (Figure 3). PtdCho can also be synthesized by methylation of PtdEtn, with S-adenosyl methionine (SAM) as the methyl donor. Phosphatidylethanolamine *N*-methyltransferase catalyzes this reaction. The importance of this pathway for PtdCho synthesis is evident in vitamin B12 and/or folic acid deficiency, which affects the production of SAM, decreasing the formation of PtdCho.

Phosphatidylethanolamine

PtdEtn is synthesized in a similar manner. Phosphoethanolamine reacts with CTP producing cytidine diphosphoethanolamine (CDP-ethanolamine), and the phosphoethanolamine group is transferred from CDP-ethanolamine to DAG (Figure 3). PtdEtn can also be synthesized by decarboxylation of PtdSer in the mitochondrial intermembrane space (IMS). This reaction is catalyzed by PtdSer decarboxylase, an enzyme located at the inner mitochondrial membrane. Since PtdSer is synthesized in the ER, its translocation to the mitochondria is a crucial step for PtdEtn synthesis by this pathway. Indeed, this pathway seems to be important for cellular functions since mitochondrial membranes are enriched with PtdEtn, despite that this phospholipid is found in most subcellular compartments.

Phosphatidylserine

PtdSer is synthesized in the ER. PtdSer synthases 1 and 2 catalyze the synthesis of PtdSer from PtdCho and PtdEtn,

respectively, in a calcium-dependent exchange reaction with L-serine (Figure 3). PtdSer is confined to the inner leaflet of cellular membranes. Under certain pathophysiological conditions, PtdSer is exposed to the outer leaflet. One such condition is apoptosis, which is one form of programmed cell death. Exposure of PtdSer functions as an 'eat me' signal, which is recognized by phagocytic cells. Moreover, increased PtdSer exposure in platelets regulates the blood coagulation cascade, and it is associated with tumor progression.

Phosphatidylinositol

PtdIns is synthesized from phosphatidate, rather than DAG. Phosphatidate is converted to the high-energy phosphoanhydride intermediate CDP-diacylglycerol in the ER by the enzyme CDP-DAG synthase. PtdIns synthase (CDP-DAG–inositol 3-phosphatidyltransferase) catalyzes the direct reaction of CDP-diacylglycerol to *myo*-inositol, thus forming PtdIns. PtdIns is unique among phosphoglycerides since it undergoes reversible changes to its inositol head group. Inositol can be phosphorylated on positions 3, 4, and 5, producing polyphosphoinositides. PtdIns and polyphosphoinositides comprise the phosphoinositide family, and their role as mediators of signal transduction is crucial (see succeeding text). PtdIns is present in most organelle membranes, but its concentration changes considerably. This fluctuation occurs due to the role of PtdIns in signal transduction and is regulated by phosphoinositide kinase, phosphoinositide phosphatase, and phosphoinositide synthase activities.

Sphingolipids

In place of glycerol, sphingosine is the long-chain amino alcohol of sphingolipids (Figure 1). Additionally, unlike glycerol, regarding phosphoglyceride synthesis, sphingosine is not a substrate for sphingolipid synthesis. Sphingomyelin is the major sphingolipid in mammalian cells, and it is synthesized from ceramide and PtdCho by sphingomyelin synthetase. Myelin is a complex structure composed of sphingolipids and proteins and surrounds some neurons and their axons. Myelin provides for the high rates of conduction of electrical activity along nerves.

Remodeling of Phosphoglycerides: Phospholipases and Acyltransferases

PtdCho (and most phosphoglycerides) in cell membranes presents a very long polyunsaturated fatty acid at the *sn*-2 position of glycerol. This is achieved by the concerted activity of two classes of enzymes: phospholipases and acyltransferases (Figure 4). Phospholipases hydrolyze phospholipids on water–lipid interfaces. Phospholipase A2 specifically removes the fatty acyl group at the *sn*-2 position, producing a lysophosphoglyceride and a nonesterified fatty acid. Then, acyltransferase reesterifies the available hydroxyl group from the glycerol residue with another fatty acid. This fatty acid is in the acyl-CoA form, and it is usually arachidonic acid.

Incorporation of phospholipids in the plasma membrane occurs mainly through membrane fusion with secretory vesicles. Additionally, membrane phospholipids are turned over through the action of membrane enzymes with phospholipase, lysophospholipase, and acyltransferase activities. Phospholipid remodeling, achieved by sequential removal and re-esterification of the fatty acyl group at the *sn*-2 position, is called the Lands cycle (Figure 4). The concerted activity of phospholipase A2 and acyltransferases (acyl-CoA:lysophospholipid acyltransferase) is crucial for cellular function for several reasons. As previously described, phosphoglycerides are synthesized from phosphatidate and DAG. Upon synthesis, these molecules present at the *sn*-2 position a fatty acid with one or two double bonds. Therefore, the formation of more

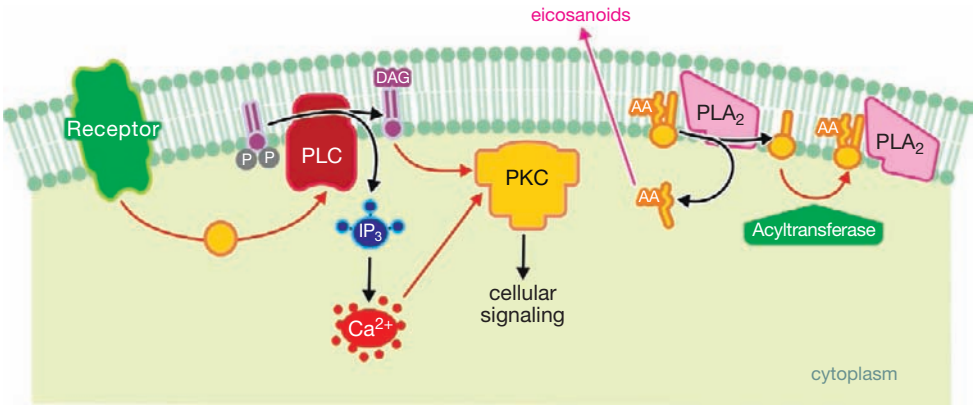

Figure 4 Phospholipids in cell signaling and membrane remodeling. Activated membrane receptor (e.g., G protein-coupled receptor or tyrosine kinase receptor) activates PLC, which in turn cleaves phosphoinositides in cell membranes generating DAG and IP_3. IP_3, a soluble mediator, induces the increase in intracellular calcium. Calcium and DAG activate PKC, a membrane kinase involved in many regulatory functions. Another phospholipase, PLA_2, can also be activated by membrane receptors, leading to hydrolysis of fatty acids at the *sn*-2 position of glycerol, producing free fatty acids and lysophospholipids. Lysophospholipids, by the action of acyltransferases, can be reacylated, maintaining cell membrane composition. AA is shown as the fatty acid at the *sn*-2 position that is both hydrolyzed from and acylated to the glycerol moiety of the phospholipid. AA (or EPA) serves as substrate for lipoxygenases and cyclooxygenases to produce eicosanoids, which are important signaling molecules. Lysophospholipids are also signaling molecules involved in a wide variety of cellular events (see text for details). PLC, phospholipase C; purple PP, phosphoinositide biphosphate; DAG, diacylglycerol; PKC, protein kinase C; IP_3, inositol triphosphate; AA, arachidonic acid; PLA_2, phospholipase A_2.

unsaturated phosphoglycerides occurring via the Lands cycle is crucial for the building of typical cellular membranes. Long-chain polyunsaturated fatty acids in cellular membranes play very important roles for increasing membrane fluidity and as signaling molecules.

Cellular membrane fluidity increases the rate of lateral movement and activity of proteins. The amount and the degree of unsaturation of fatty acids in the component phospholipids affect membrane fluidity. The higher the number of double bonds, the higher membrane fluidity is. By evaluating phospholipids' fatty acid composition in a particular tissue, one can suppose the importance of membrane fluidity and channel and transporter activities to cell function. In this regard, the brain and retina have high contents of the very long-chain polyunsaturated fatty acids, AA, EPA, and DHA. These fatty acids are essential for cognitive and visual functions.

Another important reason for membrane phospholipid remodeling is removal of oxidized PUFA. Unsaturated and especially highly unsaturated fatty acids, such as AA, EPA, and DHA, are readily oxidized or peroxidized by superoxide anion and other reactive oxygen species (ROS). Hydroperoxides are extremely reactive and can promote oxidative damage to membrane proteins, which may disturb membrane structure and function and possibly integrity. Phospholipase A2 targets the removal of oxidized fatty acids and terminates the propagation of membrane oxidation, thus protecting the membranes from peroxidative damage. Acyltransferase regenerates the phospholipid by esterifying a new, undamaged fatty acid to the lysophosphoglyceride. Interestingly, glutathione peroxidase acts concertedly in this pathway. The oxidized free fatty acid coming from PLA2 activity reacts with reduced glutathione, by the action of glutathione peroxidase. Therefore, the concerted action of PLA2 and glutathione peroxidase is important for the integrity and function of cellular membranes.

Phospholipids in Cell Signaling

DAG, phosphoinositides, lysophospholipids, eicosanoids, and ceramides are some of the fatty messenger molecules derived from phospholipids. Phosphatidylinositol in its biphosphorylated form is abundantly present in the inner leaflet of the plasma membrane. Upon external stimulation of some receptor types, phospholipase C is activated, which promotes the hydrolysis of PtdIns biphosphate into inositol triphosphate (IP_3) and DAG. IP_3, which is soluble, binds to a receptor on the ER and leads to the release of calcium. Increased cytosolic Ca^{++} signals to several cellular processes. DAG, which remains in the membrane, activates protein kinase C (PKC), a kinase attached to the cell membrane. PKC stands for protein kinase Ca-dependent. Therefore, activation of PKC is achieved by both DAG and IP3 signaling (Figure 4). PKC participates in different important cellular events. Receptors that activate PLC are G protein-coupled receptors, of which catecholamines are classic agonists, and also receptors from the tyrosine kinase family, which have growth factors as natural agonists. Therefore, PtdIns and its phosphorylated forms participate in the signaling cascade of hormones such as epinephrine and insulin. Consequently, phospholipid-derived mediators are involved in the regulation of several cellular functions.

Another important class of fatty messenger molecules derived from phospholipids is the so-called eicosanoids (Figure 4). The prefix *eicosa-* stands for their, and precursor fatty acids', chain length. Eicosanoids are potent inflammatory mediators derived from 20-C highly unsaturated fatty acids, AA and EPA. PLA2 activity on the *sn*-2 position of membrane phospholipids generates two products: arachidonic acid (or EPA) and lysophospholipid (Figure 4). Arachidonic acid and less commonly EPA serve as substrates for lipoxygenases and cyclooxygenases, producing the eicosanoids. Eicosanoids of the even series, with an even number of double bonds, come from AA (20:4$n-6$), and those coming from EPA (20:5$n-3$) are of the odd series. Generally, the former eicosanoids are proinflammatory and strongly stimulate platelet aggregation. In contrast, odd series eicosanoids are anti-inflammatory and much less aggregatory. This underlies part of the strong effects of habitual dietary intake of *n*-3 PUFA for the prevention of inflammation-related chronic diseases, such as atherosclerosis. These effects are especially strong in the Western world, where $n-6$ PUFA in the diet is in great excess over $n-3$ PUFA, in several cases at over tenfold.

Lysophospholipids, produced by hydrolysis of membrane phospholipids, also participate in cell signaling. Differently from DAG, lysophospholipids are partially water-soluble and therefore might bind to cytosolic ligands or be secreted and act in autocrine and paracrine signaling. Cellular action of lysophospholipids depends on several structural features, such as the group in glycerol *sn*-3 position, the fatty acid, and if it is esterified in the *sn*-1 or *sn*-2 position, among other factors. For instance, lysophospholipids are signaling molecules involved in many diverse processes from vascular and neuronal development to tumor progression. Additionally, blood lysophospholipids are carriers of DHA to the brain.

Ceramide can be produced by the activity of specialized phospholipases, named sphingomyelinases, on sphingomyelin phospholipid. Ceramide is a signaling molecule presenting a potent tumor suppressor activity, since it induces apoptosis and cell cycle arrest.

Cardiolipin and Mitochondrial Physiology

Mitochondria are organelles that synthesize ATP via oxidative phosphorylation and also regulate cell survival and death. Perturbations in mitochondrial structure directly affect mitochondrial functions. The mitochondrion has a complex structure containing two membranes: the inner membrane (IM) and outer membrane (OM). The OM forms a highly permeable smooth lipid surface of mitochondria. The IM, in contrast, is extremely folded and presents higher protein and lower lipid contents compared with the OM. The mitochondrial IM is virtually impermeable and, therefore, highly selective to only few compounds. As for all membranes, phospholipid distribution in mitochondrial membranes is asymmetrical (Figure 5). Regarding OM distribution, in rat liver mitochondria, PtdCho is equally distributed between both leaflets. Additionally, PtdIns and PtdSer are preferentially oriented toward the IMS, whereas cardiolipin is exclusively exposed to the cytoplasmic side. As for the IM distribution, PtdCho and PtdEtn are equally distributed between the two leaflets, and cardiolipin and

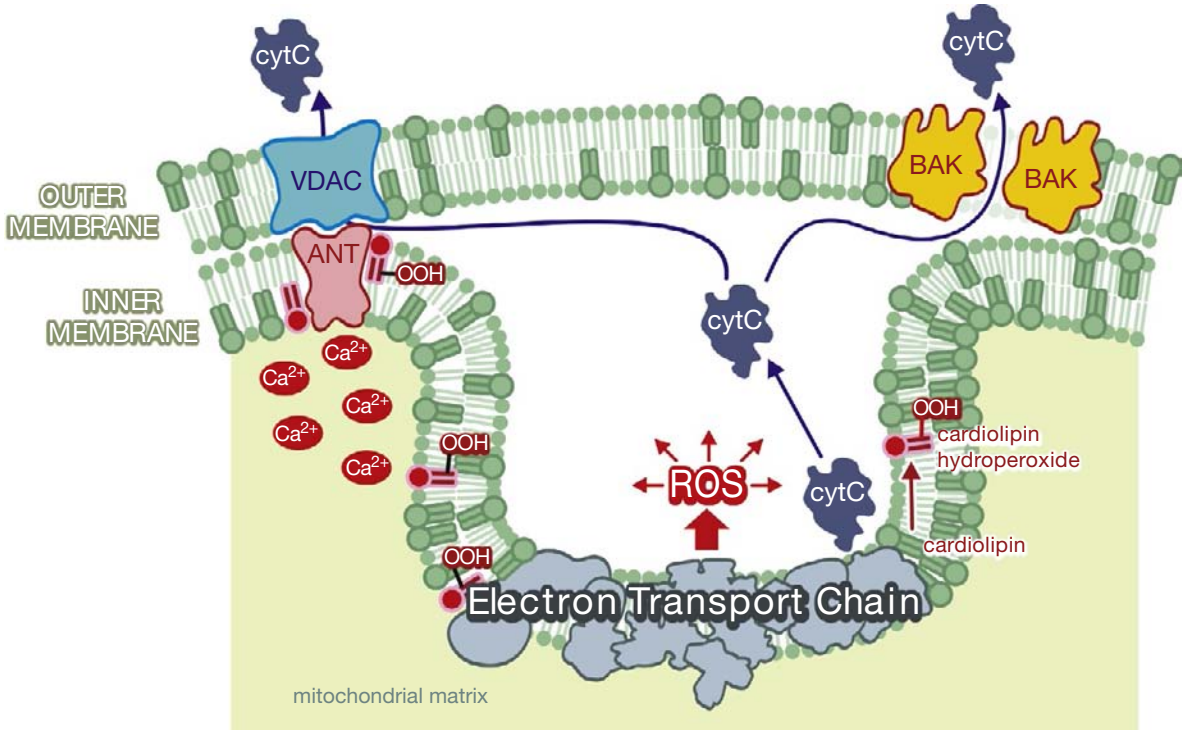

Figure 5 Oxidized cardiolipin and cytochrome *c* release from the mitochondria. Reactive oxygen species produced by the electron transfer chain induces cardiolipin oxidation. Oxidized cardiolipin causes alterations in the mitochondrial inner membrane structure, which promotes detachment of cytochrome *c*. Cytochrome *c* is then released into the cytosol through the mitochondrial outer membrane, via permeability transition pore, represented by ANT and VDAC or Bax–Bak oligomerization. Calcium ion influx into the mitochondrial matrix also induces the formation of permeability transition pore and cytochrome *c* release from the mitochondria. These events signal to apoptosis. ROS, reactive oxygen species; ANT, ADP/ATP translocator; cardiolipin-OOH, cardiolipin hydroperoxide; Cytc, cytochrome *c*.

PtdIns are predominantly exposed to the matrix side. The enrichment of cardiolipin in the IM, specifically in the matrix side, is of great significance for the organization and operation of the electron transport chain and oxidative phosphorylation (Figure 5).

Cardiolipin present in prokaryotes and in eukaryotes is enriched in mitochondria. This fact may support the endosymbiotic hypothesis, according to which mitochondria were 'inherited' from prokaryotes living inside eukaryotic cells. On the other hand, cardiolipin function differs from prokaryotes to eukaryotes. In prokaryotes, cardiolipin content increases only in certain conditions, such as environmental stress, whereas in eukaryotes, high amounts of cardiolipin are required for proper mitochondrial function. Consistently with these physiological differences, cardiolipin synthesis in prokaryotes is a near-equilibrium reaction, and in eukaryotes, this reaction is at nonequilibrium with large and negative ΔG.

Cardiolipin (diphosphatidylglycerol) is commonly referred to as the signature phospholipid of mitochondria. In this phospholipid, a glycerol molecule acts as a bridge between the phosphate groups of two phosphatidic acid molecules (Figure 1). As it occurs for PtdIns, phosphatidate is the precursor for cardiolipin synthesis. Biosynthesis of cardiolipin in mammalian cells takes place entirely in the mitochondria. In the OM, phosphatidate is activated to CDP-diacylglycerol by CDP-diacylglycerol synthase. The subsequent steps occur in the matrix side of the IM. The activated phosphatidyl group is transferred to the *sn*-1 hydroxyl group of another glycerol 3-phosphate to yield the formation of the intermediate phosphatidylglycerolphosphate, which in turn is hydrolyzed to phosphatidylglycerol forming premature cardiolipin. Phosphatidylglycerol undergoes a reacylation cycle to obtain its specific acyl composition, receiving a new phosphatidyl group from CDP-diacylglycerol. This reaction is catalyzed by cardiolipin synthase, an integral IM protein exposed to the matrix side.

Phosphatidylglycerol synthesis depends on the fatty acid composition of CDP-diacylglycerol. In general, CDP-diacylglycerols with unsaturated fatty acids as dioleoyl (C18:1) and dilinoleoyl (C18:2) or medium-chain fatty acids as dilauroyl (C12:0) and dimyristoyl (C14:0) are preferred substrates.

Cardiolipin interacts with innumerous molecules of the IM such as the electron transport complex proteins and ADP/ATP translocator. An interesting observation is that cardiolipin is required for the optimal activity of the aforementioned proteins suggesting that it plays an important role in mitochondrial bioenergetics. Indeed, an even increasing number of evidences show that cardiolipin is very susceptible to oxidative damage, with several consequences to mitochondrial and cellular functions. Cardiolipin is enriched in polyunsaturated fatty acids; for instance, in rat heart mitochondria, linoleic acid contents in cardiolipin are approximately 70% of total fatty acids. This high content of polyunsaturates and the fact that cardiolipin is in close contact with electron transport chain complexes, which are sources of reactive oxygen species in either physiological or pathological situations, render this phospholipid very sensitive to oxidation

(Figure 5). Oxidation of cardiolipin promotes destabilization of the IM, which may lead to derangements of mitochondrial electron transfer complexes and to an abrupt increase in the permeability of the IM. These effects have a direct impact in mitochondrial bioenergetics since they promote a decrease in mitochondrial membrane potential. Increased ROS production and oxidation of cardiolipin are also related to an increase in calcium influx to the mitochondria, which aggravates this scenario (Figure 5). Altogether, these events may lead to cytochrome *c* release from the mitochondria to the cytosol, which is a signal for the intrinsic apoptotic cascade pathway and, therefore, cell death. Cytochrome *c* release may occur via permeability transition pore (PTP) or Bax–Bak oligomerization and insertion into mitochondria (Figure 5). It appears that degenerative diseases and heart ischemia/reperfusion are physiopathologic conditions associated with oxidized cardiolipin. Thus, antioxidant compounds targeted to the mitochondria, and able to prevent cardiolipin oxidation, may open new perspectives for the treatment of these disorders.

Phospholipids: Properties and Occurrence

BF Szuhaj, Central Soya Company Inc., Fort Wayne, IN, USA

© 2016 Elsevier Ltd. All rights reserved.

This article is reproduced from the *Encyclopedia of food sciences and nutrition*, vol. 7, pp. 5414–4519, © 2003, Elsevier Science Ltd, with an updated Bibliography section supplied by the Editor.

Introduction

Phospholipids have been scientifically studied since the 1700s and became commercially available as lecithin in the 1930s. Their primary commercial source today is the soya bean, but phospholipids can be found in all living cells as part of the cellular membranes. This article covers the properties and occurrence of phospholipids as commercial lecithins, their chemistry, manufacture, composition, specifications, and their potential use in food systems.

Occurrence

The International Lecithin and Phospholipid Society defines lecithin as 'a complex mixture of glycerophospholipids obtained from animal, vegetable or microbial sources, containing varying amounts of substances such as triglycerides, fatty acids, glycolipids, sterols, and sphingophospholipids.' Lecithins are natural surfactants primarily derived from soya beans and eggs. They are found most abundantly in seeds and nuts, eggs, brains, and cell walls, in a concentration range of 0.5–2%.

Properties of Phospholipids (Lecithins)

There are three types of properties necessary to define phospholipids and lecithins: (1) chemical, (2) physical, and (3) functional.

Chemical Properties

The chemical composition of deoiled and liquid soya bean lecithin is shown in Table 1. There are approximately 17 different compounds in commercial lecithin, including carbohydrates, phytosterols, and minor phytoglycolipids. The three major phospholipids are phosphatidylcholine, phosphatidylethanolamine, and phosphatidylinositol.

Structure of the Major Phospholipids

The chemical backbone of the major phospholipids is a diacylglycerol molecule with the third carbon attached to a phosphate molecule. Choline, ethanolamine, serine, and inositol can be attached to the phosphate group to change the physical and functional properties, leading to the formation of phosphatidylcholine, phosphatidylethanolamine, phosphatidylserine, and phosphatidylinositol, respectively. The groups attached to positions 1 and 2 (α or β) are C_{14}–C_{18} fatty acids with double bonds associated with the lecithin source. The second carbon of the glycerol molecule, the β-position, usually contains linoleic acid.

Physical Properties

There are two major physical classes of lecithins: (1) fluid, and (2) waxy solids.

The fluid lecithins can have viscosities from 5000 to 100 000 cP, depending on processing conditions and diluents. The low-viscosity products are made through the addition of fatty acids and vegetable oil, depending on the function and stability required. Divalent metal ions like calcium can be added during drying to decrease viscosity. The moisture content can also make a difference. Water levels above 1% will increase the viscosity, eventually to a plastic state.

Deoiled lecithins are waxy solids that can be ground to various particle sizes. They are stable, free-flowing granules or powders.

Functional Properties

Lecithins are multifunctional agents. They can be used for many purposes in a food system, as shown in Table 2. The most popular functionalities are discussed below.

Antidusting agents

Lecithins reduce static electricity by wetting dusty particles. They can be used alone or in conjunction with vegetable oils. Oils can be selected for the degree of shelf-life required.

Crystal formation modifier

Lecithins retard nucleation in fats and even monoglycerides, reducing graininess in texture.

Emulsifiers

Lecithins are most often used as amphoteric emulsifiers. They promote stable formation of oil-in-water and water-in-oil emulsions by reducing the interfacial surface tension between immiscible liquids.

Mixing and blending aids

Lecithins decrease time and increase efficiency of mixing of unlike ingredients such as sugar and shortening by providing lubricity as well as viscosity reduction at the contact surfaces of the incompatible solids.

Release agents

Lecithins provide easy release from metallic surfaces by attaching to the metal surface during hot or cold cooking. They assist in the cleaning of hot surfaces where proteins or batters are

applied. They also reduce sticking between frozen food products.

Separating agents

Lecithins prevent the adhesion of products that normally stick when in contact, like cheese slices and caramel confectionery.

Viscosity modifiers

Lecithins reduce viscosity by coating particles to reduce particle–matrix friction such as in chocolates.

Wetting agents

Lecithins provide complete wetting of fatty or hydrophilic powders in aqueous systems. The fatty acids are attracted to the fatty portion and the hydrophilic portions of the molecules actively imbibe water and control the hydration of the powder.

Manufacture

The majority of phospholipids are solvent-extracted from their source. Usually, nonpolar hydrocarbons, like hexane, are used. Soya beans, for example, are cleaned, cracked, and dehulled before flaking and extraction. The hexane is removed from the solvent micelle and the crude soya bean oil is cooled for further refining. Figure 1 shows a flow diagram for the degumming of crude soya bean oil and the production of lecithin. Approximately 2–3% water is added to the crude oil and agitated for at least 30 min. The phosphatides hydrate, swell, and are separated by centrifugation. The wet gums with 50% moisture are dried through a thin-film drier. The important points here are careful drying temperatures and cooling of the product below 20 °C. Lightening the color of the product can be achieved with hydrogen peroxide in the gum stage. The hydrogen peroxide is removed through drying.

Modification

The chemistry and functionality can be altered by simple chemical additions with acids and bases as well as hydrogen peroxide and acetic anhydride. These modifications increase the dispersion and hydration properties of the lecithin. Enzyme modification is also possible with lipases and phospholipases. These changes markedly affect the functionality in emulsification.

Composition of Lecithins

The composition of lecithins and their phospholipids will vary depending on their source: vegetable, animal, or bacterial. There are minor differences within a class but major differences

between the sources. Vegetable lecithins are high in phosphatidylcholine, phosphatidylethanolamine, phosphatidylinositol, and phosphatidic acid, but very low in phosphatidylserine and contain no sphingomyelin. Animal lecithins are high in phosphatidylcholine, phosphatidylethanolamine, phosphatidylserine and sphingomyelin but contain no phosphatidylinositol. Microbes have phospholipids similar to the plant kingdom with high levels of phosphatidylethanolamine and phosphatidylcholine and phosphatidylserine or sphingomyelin.

Specifications of Lecithins

Lecithins may be qualified in several ways, chemically, physically, and functionally, but there are also specifications used to assess quality and purity (Table 3). These include acetone-insolubles (AI), acid value (AV), hexane-insoluble matter (HI), peroxide value (PV), moisture, color, free fatty acids (FFA), divalent metals (DVM), iodine value (IV), and phosphorus. Most of these analytical methods are found in the American Oil Chemists' Society (AOCS) *Official Methods and Recommended Practices*, Section J.

Acetone-Insolubles

Phospholipids are nearly insoluble in cold acetone. This quantitative method should measure the active ingredients in lecithin. Depending on the type of lecithin, the range is 35–98%.

Acid Value

The phosphorus group in lecithins have a titratable acidity that is measured with this volumetric method. FFAs are also measured in this test and should not be confused with phospholipid acidity. The AV range is 20–36 mg of potassium hydroxide per gram.

Hexane-Insolubles

In the processing of soya bean lecithin, particulate matter finds its way through some processes and gives the product a hazy appearance. The HI can be determined by dissolving the product in hexane, centrifuging and gravimetrically measuring the insolubles. The HI range for soya bean lecithins is 0.05–0.3%.

Peroxide Value

The PV is a measure of oxidation in fats and oils. In lecithin, however, the PV usually measures the residual hydrogen peroxide from processing. The range in unbleached products is 0–10 mmol kg^{-1} and in bleached products is 10–75 mmol kg^{-1}.

Moisture

The water content of lecithins is quite low, at 0.1–1.0%. It can be measured by oven drying but is more accurately determined by the Karl–Fischer method. This water content is so low that there is no measurable water activity for microbial growth. Moisture contents above 1% will change the viscosity from a fluid to a plastic state.

Viscosity

The Brookfield viscosity at 25 °C will have a range of 150–20 000 cP. Diluents and divalent metals can alter the viscosity to usable levels.

Free Fatty Acids

This method measures the true fatty acid levels in lecithins which range from 1 to 5 mg of potassium hydroxide per gram. Fatty acids are added as additives to adjust the viscosity.

Iodine Value

The IV is a traditional method for qualifying lecithin sources. The more unsaturated fatty acids are found in soya bean lecithins, which have a range of 95–110 in natural fluid lecithins, to 80–90 in deoiled lecithin.

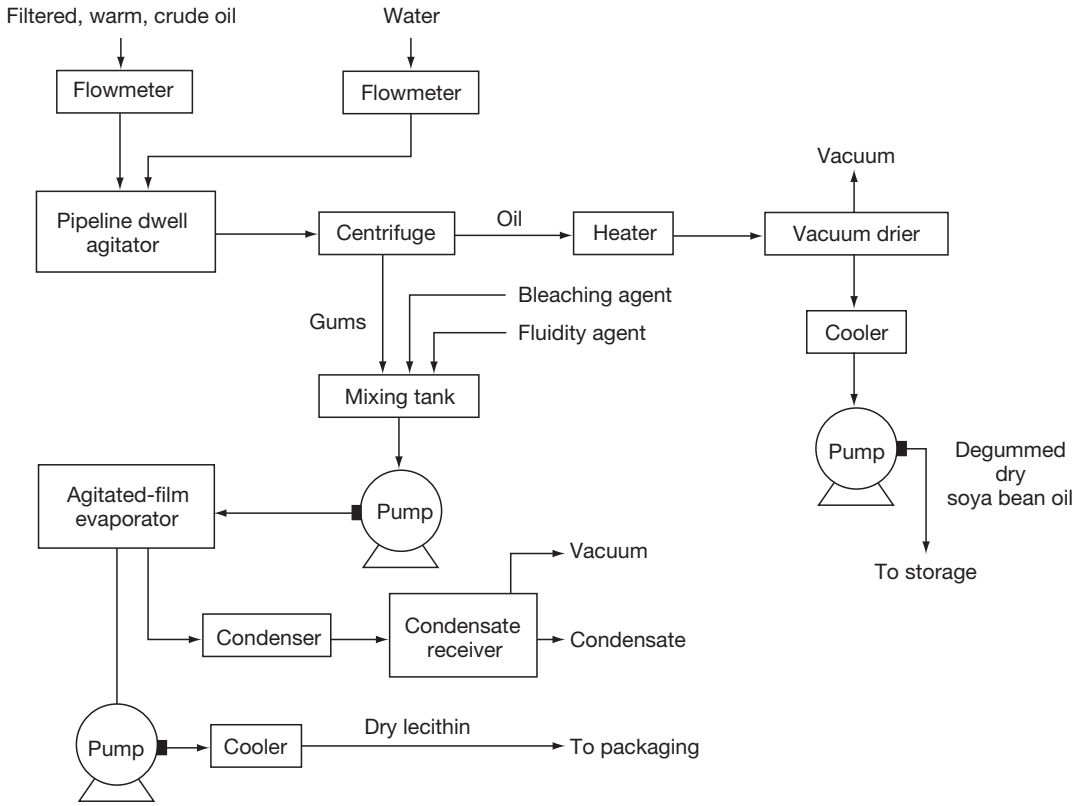

Figure 1 Flowsheet for degumming and crude lecithin production. Reproduced from List GR (1989) In Szuhaj BF (ed.) *Lecithins: Sources, Manufacture and Uses*, p. 149. Champaign: American Oil Chemists' Society, with permission.

Table 3 Specifications range for commercial lecithins

Analysis	*Typical range*
Acetone-insolubles (%)	35–98
Acid value (mg KOH g^{-1})	20–36
Hexane-insolubles (%)	0.05–0.3
Peroxide value (mmol kg^{-1})	
Unbleached	0–10
Bleached	10–75
Moisture (%)	0.1–1.0
Viscosity (Brookfield, 25 °C) (cP)	150–20 000
Free fatty acids (mg KOH (g^{-1})	1–5
Iodine value (cg I g^{-1})	
Natural	95–110
Oil-free	80–90

	Fatty acid composition (%)		
	Soya bean oil	*Natural*	*Oil-free*
$C_{16:0}$	10.3	15.6	20.3
$C_{18:0}$	4.4	4.7	4.6
Total saturates	14.7	20.3	24.9
$C_{18:1}$	24.5	17.9	9.2
$C_{18:2}$	53.8	54.0	58.9
$C_{18:3}$	7.0	6.7	7.0
Total unsaturates	85.3	78.6	75.1
Unsaturated: saturated ratio	5.8:1	3.9:1	3.0:1

Reproduced from Central Soya, Chemurgy Division (1990), with permission.

Phosphorus

This wet chemical method is an indirect way of measuring the phospholipid content. The typical level of phosphorus is 2.0% in fluid lecithin and 3.0% in deoiled products. The AOCS method Ca 12–55 has an approximation for converting percent phosphorus to the phosphatides in soya bean oil. The equivalent phosphatides content is equal to percent phosphorus $\times$ 30.

Uses of Lecithin

There are many uses of phospholipids in the food industry. As seen from the functional properties, there are multiple functions for lecithins. The following is a listing of the major areas of use:

- margarines – emulsifier, stabilizer, and antispatter;
- confectionery and snack foods – crystallization control, viscosity control, antisticking;
- instant foods – wetting and dispersing agent, emulsifier;
- commercial bakery products – crystallization control, emulsifier, wetting agent, release agent;
- cheese products – emulsifier, release agent;
- meat and poultry processing – browning agent, phosphate dispersant;

- dairy and imitation products – emulsifier, wetting and dispersing agent, antispattering and release agent;
- packaging aid – release agent, sealant;
- processing equipment – internal or external release agent, lubricant.

Applications of lecithins in foods are clearly supported by the Food Chemicals Codex, the European E322 regulations, and they are considered as generally regarded as safe substances by the US Food and Drugs Administration.

Storage and Handling

Lecithins are very stable products. They are shipped in drums or in bulk containers. They can be stored at ambient temperatures for up to 2 years without loss of activity or becoming rancid or spoiling. The water activity is so low that no microbial growth can occur. The products may be heated to 25 °C for easier application.

Phytic Acid: Properties, Uses, and Determination

A-S Sandberg and N Scheers, Chalmers University of Technology, Gothenburg, Sweden

© 2016 Elsevier Ltd. All rights reserved.

Sources and Properties

Phytic acid (*myo*-inositol-1,2,3,4,5,6-hexa-dihydrogen phosphate; $InsP_6$; Figure 1) is the major storage form of phosphorous, inositol, and cations in plant foods including cereals, nuts, legumes, and vegetables. Cereals are high in phytate, whole grain products in particular since phytate is abundant in the bran. Due to its acidic properties, phytic acid is only fully protonated at high pH conditions (>12), and therefore, its anionic form, phytate, is the chemical form encountered in plant-based foods. The charged phytate molecule has high affinity for divalent cations such as Fe^{2+}, Zn^{2+}, Ca^{2+}, and Mg^{2+}. This property is important for the ability of plants to store metals and results in that the mineral concentration of plants is directly related to phytate content. This has implications for human nutrition research, in which plants are genetically modified or bred to decrease its phytate content, which also decreases its metal content, and may thus be regarded as a contraproductive strategy to improve mineral absorption from plants. In plants, phytate is almost always found as metal complexes, which have different compositions depending on origin, for example, phytate salts in oats are mostly composed of magnesium and manganese, while in wheat, phytate–calcium complexes are dominating. However, the composition of phytate salts changes during food processing and in the harsh environment of the gastrointestinal tract (pH gradient and enzymatic degradation). At small intestinal pH (6–7), where metal and mineral absorption occurs, phytate carries 8 (out of 12) negative charges and is therefore prone to form insoluble complexes with metals making the cations unavailable for absorption by humans. In addition to the high affinity of phytate to metals, phytate salts easily form insoluble aggregates, which further aggravate their absorption.

During food processing, some of the phytate is degraded into lower inositol phosphates ($InsP_{5-3}$), which also form metal chelates, but to a smaller extent. Since phytate degradation and the formation of inositol phosphate chelates are pH-dependent, the pH during food processing and the digestion in the gastrointestinal tract will determine the extent of metal chelation at the site of nutrient absorption, in the human small intestine.

Determination of Inositol Phosphates

Traditionally nonspecific methods have been used for phytate determination involving extraction of the food/feed by hydrochloric acid (HCL) and subsequent precipitation of ferric iron phytate in dilute acid solution. The content of iron or phosphorus was then determined in the precipitate. In the current AOAC (Association of Analytical Chemists), the extraction by HCl and anion exchange chromatography on AG1 resin for purification and stepwise elution with NaCl was introduced. The phosphate content of this fraction is then used to calculate the phytate content; also, with this AOAC method, there is a lack of specificity. Disadvantage is that this method does not discriminate between inositol phosphates and various organic phosphates. The nutritional and biological significance of phytate ($InsP_6$) and its degradation products have driven the need for the development of specific and reliable analytic methods, which differentiate between the different inositol phosphates. Adequate procedure for sample preparation from different matrices and high sensitivity methods for determination of the low concentrations occurring particularly in cells and tissues are required.

With the development of ion-pair HPLC procedures, quantitative determination of phytate and some of its degradation products ($InsP_6$–$InsP_3$) formed during food/feed processing or digestion in the gut became feasible. Later, isomeric-specific high-performance ion-exchange chromatography (HPIC) methods have been developed using gradient elution and post-column reaction with Fe^{3+} ions and UV detection. This system allows the analysis of isomers of $InsP_2$–$InsP_6$ in the same run (Figures 2–4). These HPLC methods are most commonly used in food and nutrition research. Using HPLC with metal-dye detection, the high sensitivity makes it applicable to biological samples and also the use of HPLC-mass spectrometry (MS), inductively coupled plasma-MS (ICP-MS), or ICP-atomic emission spectrometry (ICP-AES). Reliable determination of inositol phosphates in food can also be performed by 31P-NMR spectroscopy, but the low sensitivity makes it less useful for biological samples.

Availability, Absorption, and Metabolism

Most human cell types contain inositol phosphates ($InsP_{(1-6)}$). Whether phytate ($InsP_6$) is absorbed in the gastrointestinal tract or produced by cells has been debated for years. However, there are now several studies in humans, animals, and cell lines that suggest that inositol phosphates are indeed absorbed. $InsP_6$ has been detected in human urine and plasma in which the levels were correlated with dietary ingestion or deprivation of phytate. In human cells, $InsP_{5-6}$ are present at relatively high levels (10–100 μM), in which they are degraded to lower inositol phosphates, which play roles as second messengers in cellular processes. $InsP_3$ and $InsP_4$ are important for intracellular Ca^{2+} mobilization and sequestration during events such as mitosis. Decreased rates of mitosis lead to a slower rate of cell proliferation. In several cellular processes, Ca^{2+} may be seen as an on switch and $InsP_{3-4}$ as off switches. The mechanism of absorption of inositol phosphates has not yet been established, but there is some evidence suggesting that $InsP_6$ may be internalized into cells by means of pinocytosis. Bioavailability data for inositol phosphates are scarce, but the formation of salts seems to have an impact, for example,

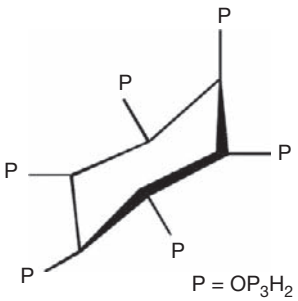

Figure 1 Structure of phytic acid.

Ca^{2+}phytate decreases the availability of phytate in rats and hamsters. This may also be a result of the favorable aggregation of phytate salts, especially calcium phytate.

Health Effects

The most significant effect of phytate in human nutrition is its potential to reduce mineral absorption. This is particularly a problem in low-income countries where the diet is based on staple foods (cereals and legumes). Phytate constitutes typically 1–3% of cereal grains, legumes, oil seeds, and nuts

St. Paul, MN: AACC International.

(Table 1) and occurs also in low concentrations in roots, tubers, and vegetables. The high prevalence of iron and zinc deficiency is a main nutritional issue in these countries especially in women of fertile ages, infants, and adolescents resulting in premature deliveries, morbidity of mother and child, retarded brain development in infants, prevention of normal child growth, and reduced immune and cognitive function. Phytate is the major inhibitor of iron and zinc absorption from food and feed. It has been demonstrated in humans that the inhibition of zinc and iron absorption by phytate is dose-dependent. Also, $InsP_5$ was shown to have an inhibiting effect. Even $InsP_4$ and $InsP_3$ contribute to the negative effect in processed food and feed probably due to binding of minerals between molecules. For this reason, efforts have been made to remove phytate, especially in infant foods. Controlled degradation of $InsP_6$–$InsP_3$ during processing was shown to markedly increase zinc and iron absorption from single meals. This is technically feasible by enzymatic degradation (soaking, germination, fermentation, or addition of phytase), but processing has to be optimized and removal of phytate extensive to improve zinc absorption and virtually complete to improve iron absorption. Combining dephytinization with enrichment strategies (adding meat and ascorbic acid) and breeding/genetic engineering for iron and zinc biofortification can be a means to improve mineral nutrition. Dephytinized cereal–legume-based complementary foods for infants are options to improve iron and zinc nutrition in low-income countries. However, in high-tannin cereals, it is not enough to remove phytate; the phenolic compounds still have a strong inhibiting effect on iron absorption. Also, if milk is added to the infant formulas, as often is the practice in industrialized countries, the iron absorption is markedly reduced.

In animal nutrition, two aspects are of importance: First, phosphates need to be liberated from phytate to meet the

Table 1 Content of phytic acid in selected plant foods

Common name	*Phytic acid (g per 100 g dry weight)*
Cereals

phosphorus requirements of the growing animal, and secondly, the animal needs iron and zinc. Dietary phytate is resistant to degradation in the stomach and small intestine if active dietary phytate-degrading enzymes (phytases) are not present. Monogastric animals and humans have very limited phytase activity in the gastrointestinal tract. Therefore, microbial phytases are often used as additives to animal feed to degrade phytate in the feed or in the gut, thereby increasing mineral absorption. Microbial phytases are more stable to gastric juice than plant phytases and are active in a broader pH area. What is also priority for use in animal nutrition is high specificity for $InsP_6$ and $InsP_5$. The commercial phytases used in animal nutrition are often extracted from molds or produced by genetically engineered organisms. So far, microbial phytases are not used in human nutrition but may have a potential use in the future.

In contrast to its antinutritional properties, dietary phytate has also been suggested to have beneficial properties such as antioxidative and anticancerogenic effects. Although demonstrated antioxidative effects *in vitro*, such as the inhibition of the hydroxyl radical formation by iron binding, it is difficult to show this *in vivo*. Anticancer activity of dietary phytate has so far been demonstrated in carcinogen-induced cancer models and cell line experiments. Thus, there is a need to evaluate the significance of the anticancer activity by phytate in humans.

Introduction

Pickling is the process of preserving edible products in an acid solution, usually vinegar, or in salt solution (brine). In the latter case, the acid that does the preservative action (lactic acid mainly) is produced by fermentation. The process of pickling is also known as brining and the resulting foods as pickles. However, in the United States and Canada, the word 'pickles,' unless otherwise specified, generally means cucumber pickles. Usually, pickles refer to vegetable products, but sometimes, fish, eggs, or meat is also subjected to pickling. The process applied to meats is usually called curing. The focus in this article will be on pickled vegetables.

Most major vegetables can be preserved by pickling, either commercially or in households. Cucumbers, cabbage, and green olives account for the largest volume of vegetables and fruits commercially pickled in Western countries. Capers, garlic, onions, carrots, cauliflower, beans, and other vegetables are also pickled, albeit in lesser quantities. In Asian countries, fermented vegetables are very popular too, scientific research being mainly concentrated on kimchi, which is the general name given to a group of acid-fermented vegetable foods that have a long tradition in Korea. Therefore, the emphasis in this article will be on the following groups of fermented vegetables: fermented cucumbers, cabbage, and green olives, as well as kimchi. Information about two interesting nonfermented pickled vegetables, that is, capers and garlic, is also included.

The History of Pickling

Pickled vegetables were, probably, originally designed to preserve food and especially as a means to preserve surplus agricultural products for winter when supplies were scarce. Vegetable fermentation may have started in China, which can be deduced from references to the mixing of vegetables, which were given as rations to coolies during the construction of the Great China Wall in the third century BC. The origin of pickled cucumbers is unclear, but it is believed that cucumbers were first fermented around 2000 BC in the Middle East. Early written records of pickled cucumbers come from paper fragment remains of a play (*The Taxiarchs*) by the Greek writer Eupolis (429–412 BC), and this product is also mentioned in the Christian Bible (Old Testament books Numbers and Isaiah). Pliny the Elder, in the first century AD, is said to have been the first who described the production of sauerkraut by preservation of the so-called salt cabbage in earthen vessels. The method used today for sauerkraut could have been developed between AD 1550 and AD 1750 in eastern Europe. Korean-style fermented cabbage, kimchi, is thought to have originated in the primitive pottery age from the natural fermentation of withered vegetables stored in seawater. Kimchi is mentioned in the book *Samkuksaki*, published in AD 1145. The oldest written reference to the preparation of pickled green olives dates back to the first century before the Christian era, and different ways of pickling olives were described by Columela in his agriculture treatise *De Re Rustica* (AD 42). The history of the international trade of this product began when olives were sent to America in 1540.

Types of Pickled Vegetables

Pickled vegetables are divided into two types: fermented and nonfermented.

Fermented Vegetables

The general procedure for the preparation of fermented vegetables is shown in Figure 1.

Most, if not all vegetables, may be fermented in brine. The fermentation process for vegetables can result in foods that may be stored for extended periods, that is, 1 year or more, without refrigeration. Vegetables may be treated in various ways before fermentation, depending on the nature of the fresh vegetable and the product desired. Examples of such prebrining treatments include washing, cutting, peeling, blanching, and exposure to NaOH solution. Vegetables may be brined at various salt concentrations by either the dry-salt method (e.g., cabbages) or the brine method (e.g., cucumber, green olives, carrots, and caper berries). When vegetables are brined at salt concentrations of up to about 8% (w/v) and allowed to undergo natural fermentation, the brine solution supports fermentation by a sequence of various types of microorganisms: several gram-negative and gram-positive bacteria, mostly lactic acid bacteria (LAB), and yeasts. After fermentation, vegetables are packed with fresh packing brine in proper containers in order to be consumed or commercialized. Depending on the final conditions of the fermented product, a pasteurization treatment can be applied to further stabilize the packed product. Factors that affect fermentation are acid content, pH value, salt concentration, temperature, natural inhibitory compounds that are present in the vegetable, chemical additives, sugar content, redox potential, and availability of nutrients in the brine. Four species of LAB have historically been associated with the natural fermentation of vegetables: *Leuconostoc mesenteroides*, *Pediococcus pentosaceus*, *Lactobacillus brevis*, and *Lactobacillus plantarum*. Nevertheless, many other LAB (e.g., *Lactobacillus fermentum*, *Lactobacillus pentosus*, and *Weissella* spp.) and yeast species play also important roles. Information about the preparation of the major fermented vegetables is summarized later in the text.

Cucumbers

Cucumbers for pickling are harvested while still immature. Sorting to remove blossoms and broken, defective, and

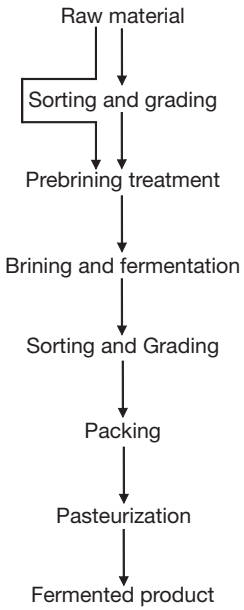

Figure 1 General procedure for the preparation of fermented vegetables. Pasteurization depends on the final conditions prevailing in the fermented vegetable.

distorted cucumbers should be done before brining to minimize spoilage during the fermentation. Sorting is followed by size grading. After that, cucumbers are covered with salt brine. Fermentations are typically carried out in brine equilibrated at about 6% NaCl. Most commercial cucumber fermentations rely upon growth of the LAB that are naturally present on the surface of cucumbers. Cucumber fermentations typically undergo a homolactic fermentation by *Lactobacillus plantarum* and related LAB. Carbon dioxide may be generated from the respiration of cucumbers and by the decarboxylation of malate during the initiation of fermentation. In an effort to prevent bloater formation, cucumber fermentations are purged with air to remove excess carbon dioxide from the tank. In addition to lactic acid, the LAB produce a variety of metabolites (e.g., bacteriocins) that can be inhibitory to other bacteria. At the end of the fermentation, there may be 1.5% lactic acid, a pH of 3.1–3.5, and little or no residual sugar. Prior to sale, cucumbers are washed to remove excess salt and then packed in a variety of containers (plastic pails, pouches, or jars) with appropriate cover liquor. The cover liquor typically contains acetic acid and spices in addition to residual lactic acid. Fermented pickles may be pasteurized to ensure long-term stability.

Sauerkraut

Sauerkraut is the product resulting from the natural lactic acid fermentation of salted, shredded cabbage. The German word literally translated means acid (sauer) cabbage (kraut). The heads of cabbage are trimmed to remove the outer green, broken, or dirty leaves, and the core is bored or partly removed. Subsequently, the cabbage is shredded into 0.7–2 mm wide strips that, in most cases, are salted with 0.7–2.5% salt. The shredded cabbage is placed into fermentation containers. Filling and pressing the cabbage into the fermenters together with added salt lead to an osmotic withdrawal of water out of tissue cells and, as a consequence, brine is formed. Finally, the surface of the filled containers must be covered carefully in order to exclude oxygen and microbial contamination. Usually, a sheet of plastic large enough to cover more than the area of the top of the fermenter is used. Depending on the temperature, a 'spontaneous' fermentation will start within a few hours to 1–2 days and will continue between 7 days and several weeks. The microbial growth sequence of spontaneously fermenting cabbage is invariably initiated by *Leuconostoc mesenteroides*, followed by heterofermentative LAB, and finally homofermentative LAB. A completely fermented sauerkraut contains 1.8–2.3% acid (calculated as lactic acid) giving a pH of 3.5 or less. Lactic and acetic acids are the predominating acids, but other organic acids such as succinic, malic, and propionic acids may also be formed in smaller quantities. Ethanol, mannitol, CO_2, and other compounds are produced in variable amounts as a result of the metabolism of heterofermentative LAB. Sauerkraut may be packaged in cans, glass jars, or plastic bags. Refrigerated sauerkraut, packaged in glass or plastic, is an unpasteurized product to which preservatives (e.g., sodium benzoate or potassium metabisulfite) are added. Pasteurized sauerkraut, packaged in cans or glass jars, can be made by pasteurization at 74–82 °C for 3 min.

Kimchi

The ingredients for kimchi preparation include four major groups: the main vegetable (mostly Chinese cabbage or white radish), spices, seasonings, and additional materials. The spices may include garlic, hot chili, ginger, onion, and others, whereas seasonings form a group of optional ingredients that include salt, pickled seafoods, sesame seed, soy sauce, vinegar, and sugar. Optional ingredients include small amounts of other vegetables, fruits, cereals, nuts, meats, seafoods, and mushroom, which may influence the rate of fermentation, flavor, and nutritional value of kimchi, as well as the fermentation process.

For cabbage kimchi (known as *baechu* kimchi or referred to simply as 'kimchi'), the trimmed Chinese cabbage is cut 3–5 cm in length, washed, mixed with salt (8–15%) for 2–7 h, rinsed with freshwater, and then drained. Sliced radish, onion and bunching onion, chopped garlic, ginger, hot chili, and salt-pickled seafood and dry salt are combined together to make a premixture in an appropriate ratio according to the formula. These minor ingredients are mixed well with the treated cabbage. The final salt concentration of the mixed vegetable fermentation is usually adjusted to ~2–3%. The mixed vegetables are placed in a fermentation vessel with a closed lid and left to ferment for 1–3 weeks at a low temperature (2–10 °C) or for 2–3 days at room temperature (20–25 °C). The microorganisms mainly responsible for the fermentation process are LAB, although fermentation by aerobic bacteria, yeasts, and molds occurs simultaneously. The pH of optimally fermented kimchi is 4.2–4.5 corresponding to organic acid contents of 0.4–0.8% (as lactic acid), respectively. Pasteurization is a successful method in preventing overacidification and can be used to extend the storage period of kimchi. However, possible flavor defects caused by heating may occur.

Green olives

The most common preparation is known as 'treated green olives in brine,' also known as Spanish-style or Sevillian-style green olives. Green olives must be harvested when the fruits have reached their maximum development (size) and prior to color change. The fruits are sorted, partially graded by size, and finally treated with a dilute 2.0–3.5% (w/v) NaOH solution (lye) to chemically remove bitterness by the chemical hydrolysis of the oleuropein. The penetration of the lye into the flesh is considered sufficient when the lye reaches about two-thirds of the distance from the exterior to the pit. After this treatment, olives are washed with tap water several times for variable periods of time, to eliminate the excess of alkali. Later, olives are immersed in a 9–10% (w/v) brine in which olives are maintained during the fermentation and preservation periods. Brine stabilization is fairly rapid, and in a few days, the NaCl concentration stabilizes at a level of 5–6%. *Lactobacillus pentosus* is considered the species mainly responsible for the fermentative process. Former microbiological research on olive fermentation was carried out before this species was finally recognized as a different species from *Lactobacillus plantarum*. Nowadays, most strains isolated from Spanish-style green olive fermentations are allocated to the species *Lactobacillus pentosus*. When the active fermentation has finished, fruits are sorted and graded by size again and, finally, conditioned to be packed as plain (whole), pitted, or stuffed with diverse products. The levels of acidity and salt determine the product stability. Traditionally, this has been obtained by setting high values of acid and salt (0.5–0.7% and 5–7%, respectively) and low pH (<3.5 units). However, the progressive preference of consumers for milder conditions (low salt and acid percentages) has modified such conditions. In these cases, the stability of the product is guaranteed by pasteurization. It has been established that a value of accumulated lethality of 15 pasteurization units (15 min at 62.4 °C) is enough to assure correct pasteurization. Specific heating times depend on the container characteristics and heat penetration curves.

Nonfermented Vegetables

Nonfermented vegetables are prepared according to the procedure outlined in Figure 2.

After preliminary operations (sorting, grading, etc.), vegetables are directly packed or can be preserved in concentrated brine with as high as 20% of salt before packing. At this high salt concentration, virtually no lactic acid fermentation takes place but the occurrence of a film of yeasts is not impossible. In this case, a desalting operation must be carried out prior to packing. Vegetables are packed using acidified brine as packing solution. The microbial inhibitor effect of acid pH is usually complemented, when necessary, by heat treatment (pasteurization) or by refrigeration plus the addition of antimicrobials (sorbates, benzoates, or sulfites). Acetic acid is commonly used as an acidulant at a concentration of 0.5–2%. More details about the preparation of selected pickled vegetables by this procedure are given in the succeeding text.

Cucumbers

Fresh-pack cucumber pickle products typically contain between 0.5% and 1% acetic acid. The salt concentration varies from 0% (in dietetic pickles) up to about 3%. A recommended pasteurization procedure consists of heating to an internal temperature of 74 °C for 15 min. Refrigerated, nonfermented cucumbers are preserved by the addition of low concentrations of vinegar and a chemical preservative (e.g., sodium benzoate), in addition to refrigeration at 1–5 °C.

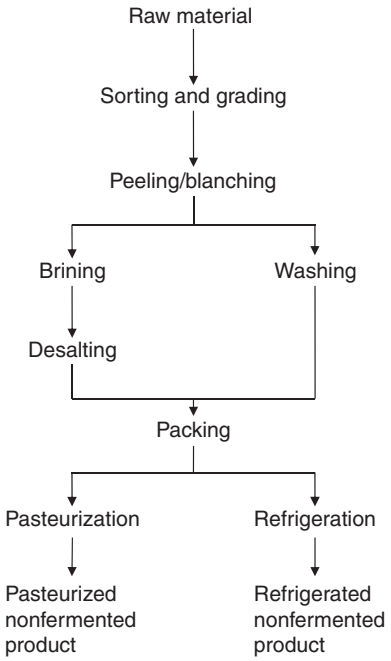

Figure 2 General procedure for the preparation of nonfermented vegetables. Peeling/blanching depends on the type of vegetable.

Capers

Capers are flower buds of the Mediterranean shrub *Capparis spinosa* L. The young buds are harvested when they are still tightly closed. The usual commercial procedure for the manufacture of pickled capers includes a first step of pretreatment of high brine (ca. 16% NaCl w/v, at the equilibrium, increasing 20% after changing the first brine). At the end of the pretreatment stage, capers are desalted and packed into a finished product containing about 6% salt and 1% acid w/v, as acetic acid.

Garlic

After cracking the bulbs to separate the garlic cloves and peeling the outer covering, the defective and smallest cloves are discarded. The peeled cloves are washed, blanched in hot water to eliminate the enzymatic activity responsible for pungent flavor, and then packed. Blanching can be carried out in water at 90 °C for 15 min, but less heating time (4 min) is also effective. Brine acidified with a lactic acid–acetic acid mixture (to give equilibrium values of 1.5% acidity, expressed as lactic acid, and 3% salt) can be used as packing solution. The corresponding packed product can be successfully stored at room temperature, at least for 4 months, without the need for pasteurization or refrigeration.

The Nature of the Preservative Action

Common salt and organic acids are primary preservatives for most types of pickled vegetables.

Common Salt

Common salt (NaCl; solubility in water at 25 °C, 35.7%) lowers the water activity (a_w value) of a system and thus renders conditions less favorable to microbial life. However, since the a_w value of a saturated common salt solution is only in the region of 0.75 and some microorganisms continue to grow below this limit, it is impossible to protect a foodstuff reliably from all microbial deterioration by using common salt alone, apart from the virtually unacceptable restrictions imposed on taste. Common salt also reduces the solubility of oxygen in water, which is of relevance for aerobic microorganisms.

Organic Acids

Organic acids are weak acids naturally found in vegetables, fruits, and fermented foods and have been used for decades as food additives for preservation. Lactic and acetic acids are the most used in pickled vegetables. Acidic pH environments can alter intracellular metabolic activities in bacteria. The diffusion of a protonated organic acid through cell membranes followed by intracellular dissociation of the acid can result in the acidification of the cytoplasm and intracellular acid anion accumulation, with eventual disruption of pH homeostasis and cellular metabolism.

Lactic acid ($pK_a = 3.79$) is a hygroscopic, syrupy liquid having a moderately strong acid taste. In the pickled vegetable industry, lactic acid is widely used to adjust acidity in brines. Lactic acid is produced naturally in fermented foods by LAB. As an end product in natural fermentations, lactic acid is probably one of the oldest known antimicrobial agents. The inhibitory capacity of this acid lies in its reduction of pH to levels below which bacteria cannot initiate growth. In fermented foods, lactic acid coupled with other antimicrobial factors excreted by lactic acid-producing microorganisms inhibits competing microorganisms.

Acetic acid ($pK_a = 4.75$) is used in food preservation in two forms, namely, as 5–10% vinegar and as 25–80% aqueous solutions of synthetic acetic acid. Vinegar is a dilute solution of acetic acid produced by a two-stage fermentation process. Vinegar contains a large number of secondary constituents that contribute to its flavor. As well as the sharpness conferred by acetic acid, individual vinegars each have their own particular flavor. This reflects the process by which it was made and the raw material used. Normally, a vinegar takes its name from the raw material used (malt vinegar, wine vinegar, etc.). The preservation action of vinegar is due to its acetic acid content, but is not simply a pH effect. Activity is associated with the unionized, lipophilic molecule that can penetrate the cell membrane, disrupting membrane transport processes and dissociating within the cell to increase acidity and produce toxic levels of the anion. Besides its preservative action, acetic acid is very important as a flavoring and acidulant.

Effect of Pickling on Sensory Quality and Nutritional Properties

Historically, pickled vegetables have played an important role in providing safe, preserved food commodities. With the introduction of new preservation techniques (freezing, canning, etc.), pickling has become less commonplace. However, pickling remains an important technology because it provides unique, desirable organoleptic traits, requires low energy, and allows the processing of fruits and vegetables to be extended over a longer period of time. Aside from their appreciated organoleptic characteristics, fermented vegetables are nutritious, owing to the presence of the vegetable nutrients and viable LAB, which may in some cases beneficially affect the human intestinal system. The nutritional value of nonfermented vegetables is generally lower than that of the fermented type, since these vegetable products are frequently preserved in high salt brine with exudation of cell contents and then desalted with excessive water leaching and nutrient losses.

The chief nutritive value of vegetables is in their content of vitamins, which may include important amounts of β-carotene, ascorbic acid, and folic acid and less important amounts of riboflavin and some of the other B vitamins. In general, vegetables used for fermentation are an important source of fiber but contain low levels of protein and calories. More specific information regarding the effect of pickling on sensory quality and nutritional properties for specific pickled vegetables is given later in the text.

Cucumbers

In the pickling process, the color of cucumbers changes from bright green to an olive or yellow-green color due to pigment degradation. Chlorophylls are converted to pheophorbides and pheophytins, whereas the carotenoids, consisting principally of β-carotene and the xanthophylls lutein and neoxanthin, undergo some destruction. The tissue changes to translucent from the normal chalky white and opaque due to the expulsion of gas during brine storage. This translucent appearance is not desired in pasteurized or refrigerated pickles since this is associated with a perception of loss in freshness. Retention of firmness is a key quality issue in the fermentation and storage of cucumbers. Calcium chloride (0.1–0.4%, equilibrated) is added to the cover brine to maintain the firm, crisp texture of the fermented cucumbers during fermentation and storage. Apart from acid formation due to sugar metabolism, numerous secondary fermentation reactions also occur in fermenting cucumbers that generate by-products such as fusel oil components, esters, and carbonyl compounds that impart unique flavor attributes to the pickled cucumber. A notable effect of fermentation on cucumber volatiles is the inhibition of the production of (*E*, *Z*)-2,6-nonadienal and 2-nonenal, the two most important odor impact compounds in fresh cucumbers, because the low pH of the brine inactivates lipoxygenase activity. Inactivation of lipoxygenase suppresses the pathway for the biogenesis of cucumber flavor compounds. The most potent odorants that define the typical characteristic brine aroma of pickled cucumbers are *trans*-4-hexenoic acid and *cis*-4-hexenoic acid.

With regard to nutritional aspects, pickling normally results in losses of vitamins. Losses of 86%, 82%, and 28% for ascorbic acid (vitamin C), thiamin, and carotene, respectively, have been reported in the case of desalted salt-stock cucumbers. When cucumbers are not desalted (e.g., fermented product at low salt concentration), 40–67% losses for ascorbic acid have been reported.

Sauerkraut

Acidity and salt levels influence greatly the sensory quality of this product. Ideal ranges for titratable acidity (1.1–1.5%), salt (1.7–2.4%), salt/acid ratio (1.0–1.7), and lactic/acetic acid ratio (3.0–5.0) have been proposed for canned sauerkraut. Textural characteristics of the final product are influenced by the salt concentration. Less than 1.8% (w/w) NaCl produces sauerkraut of soft texture, whereas applications in excess of 2.5% impart fibrous and tough textural properties to the product. It suggests that salt may serve to partially inactivate pectinolytic enzymes inherent in cabbage and/or reduce the pectinase activities of salt-intolerant microorganisms. Volatile sulfur compounds, such as hydrogen sulfide, methanethiol, dimethyl sulfide, carbon disulfide, dimethyl disulfide, allyl isothiocyanate, and dimethyl trisulfide, can be detected in the headspace of sauerkraut, having a great impact on the product flavor.

Sauerkraut is usually considered to be a healthy product. A health-promoting effect of sauerkraut may be linked to the high content of glucosinolates (up to 1% of dry weight) of the white cabbage. These compounds are hydrolyzed by the enzyme myrosinase during fermentation, resulting in the formation of indoles and isothiocyanates. The latter compounds were shown to be powerful inhibitors of carcinogenesis in animals. Ascorbigen, a compound formed from the reaction of a degradation product of indole glucosinolate (glucobrassicin) and ascorbic acid, is the dominant glucosinolate degradation product in sauerkraut, and is considered to be one of the most potent anticarcinogens of the glucosinolates family. Because sauerkraut is not desalted before use, good retention of water-soluble vitamins (especially vitamin C) would be expected. In fact, during the last centuries, sauerkraut was one of the major sources for vitamin C in the diet. The losses of this vitamin from the fresh cabbage to canned and pasteurized sauerkraut have been reported to range from 13% to 53%.

Kimchi

Numerous biochemical changes occur during kimchi fermentation, forming flavor compounds and changing the texture of the vegetables. A firm, crisp texture is highly desired in the vegetable components of kimchi. As can be predicted from the numerous ingredients of kimchi, this product is an important source of vitamins and their precursors, such as certain vitamins from the B group, β-carotene, and ascorbic acid. Kimchi is also a good source of dietary fiber. Kimchi consumption also seems to have hypolipidemic effects in humans. Some of the raw vegetables used for kimchi, such as cabbage, parsley, perilla leaf, green pepper leaf, garlic, and red pepper, have been tested and shown to be antimutagenic with an *in vitro* assay system. Kimchi extracts have shown anticarcinogenic activities in animal studies. This may be due to an enhancement of the immune system of the host or to kimchi's ability to affect the metabolism of mutagens. Further, it has been found that LAB isolated from kimchi block the adherence of *Helicobacter pylori* to a human gastric epithelial cell line and inhibit the growth of *H. pylori in vitro*.

Green Olives

Spanish-style processing of green olives includes several steps (lye treatment, washing, and fermentation in brine) that influence the sensory and nutritional characteristics of the final product. Lye treatment produces a marked loss of texture that persists during washing but recovers partially during fermentation due to the effect of salt and the absorption of divalent cations from the brine. As found in pickled cucumbers, fermentation causes total transformation of the chlorophylls initially present in the fruits and degradation of some carotenoids. As a result, the olives lose their original green color and become pale yellow. The unique and pleasant flavor of this product is probably the most important characteristic that makes Spanish-style green table olives so enjoyable and directly influences consumer acceptability. Flavor compound formation is a dynamic process that develops mainly during fermentation by LAB and yeasts, together with a variety of contaminating microorganisms, which produce volatile compounds from major fruit constituents through various biochemical pathways.

Soluble sugars disappear during the fermentation and are absent from the final product. The same happens to the bitter principle, oleuropein, which is mostly hydrolyzed during the alkaline treatment. The fiber content tends to decrease slightly, while the oil and protein contents do not significantly change during processing. Protein has been found to have a high content of essential amino acids, except for lysine. Contents of water-soluble vitamins such as ascorbic acid are low or negligible due to losses during processing, but green olives can be considered a reasonable source of provitamin A carotenoids (due to their content in β-carotene) and vitamin E (α-tocopherol mainly), which remain practically unaltered during processing.

Although the loss in total polyphenols during Spanish-style processing can reach some 90%, an important content still remains in the final product. This content is similar to the total polyphenol content (about 400 mg kg^{-1}) of commercial virgin olive oils. Phenolic compounds of olives have been shown to possess antioxidative, antimutagenic, anticarcinogenic, and antiglycemic beneficial properties. Because of their natural polyphenolic content, green olives are an important part of the health-promoting Mediterranean diet.

Capers

The color of capers shifts from bright green to a more yellowish color as a consequence of the brining treatment. In addition, the surface of capers is covered by tiny grayish spots, which are typical of pickled capers after a few days in brine. Pickling results in lower contents of fiber, protein, and water-soluble vitamins in pickled capers compared to fresh capers. Pickled

capers are a very rich source of the flavonols quercetin and kaempferol. During brining, some hydrolysis of flavonoids occur releasing quercetin and kaempferol from the original glycosides. Quercetin derivatives have received special attention as dietary constituents, as epidemiological studies point out that they might have a role in preventing cardiovascular diseases and cancer. Similarly to sauerkraut, pickled capers are rich in isothiocyanates, which derive from glucosinolates by enzymatic hydrolysis.

Garlic

Blanching step modifies the color and firmness of garlic. Immediately after this treatment, garlic color is less white than raw garlic. Firmness decreases by 70% compared to raw garlic. The nutrient most affected is ascorbic acid, which is totally lost during processing. It is known that the health properties of garlic depend on its organosulfur compounds, namely, γ-glutamyl peptides, *S*-alk(en)yl-L-cysteine sulfoxides, and *S*-allyl-L-cysteine. In general, the concentration of these compounds decreases significantly during processing, mainly as a result of their solubilization into the packing brine, but a relatively high concentration of each compound still remains in the final product. In the case of the packed product, 65% total identified sulfur compound retention has been found. Therefore, it is reasonable to assume that a large part of the health benefits of garlic is maintained following pickling.

Conclusion

The preservation of vegetables by pickling is one of the earliest and most widespread technologies developed by humans. Both fermented and nonfermented pickled vegetables are produced and consumed in every culture and society around the world, usually based on traditional processing methods. This is because the products produced are safe, due to the presence of inhibitory compounds, primarily NaCl and organic acids, and have appealing sensory characteristics. Aside from these features, there are other reasons nowadays to recommend the consumption of this type of foods, taking into account the growing interest by consumers in healthy foods. Thus, some pickled vegetables such as sauerkraut, kimchi, green olives, capers, and garlic appear to be a rich source of compounds (e.g., polyphenols, glucosinolates, and organosulfur compounds) with beneficial properties. Another health-promoting property may result from the LAB involved in fermentation in case of fermented vegetables, although the probiotic efficacy of these microorganisms still have to be demonstrated in most cases.

Pine Kernels

Pine kernels are the edible seeds of pine trees. Pine kernels are among the most expensive and priced nuts on the market because of its high harvest costs and limited supply. Recently, pine kernels have gained much popularity and attention as health food. Pines are evergreen trees that bear cones. Pine trees belong to the Pinaceae family in the genus *Pinus*. Pine kernels are released by cracking open the seeds of cones from pine trees. Nuts from three types of pines, the stone pine (*P. pinea*), Korean pine (*P. koraiensis*), and chilgoza pine (*P. gerardiana*), have been widely traded internationally for many years. Siberian pine nut (*Pinus sibirica*) is a recent addition to international trade as well. Stone pines traded globally are primarily collected from domesticated trees, while seeds from other species are mostly gathered from the wild. China is the world's largest exporter of pine nuts (mainly Korean pine). However, a major share of China's exports originates from other countries that ship unshelled pine nuts to china where they are processed and exported. In 2011, about 36 080 tonnes of pine kernels were produced globally. China and the Russian Federation contribute 55% and 14%, respectively, to world pine nut production. Spain, Portugal, and Italy also export nuts from stone pine. Prices of pine nuts fluctuate greatly in international markets.

Sources and Production

Most of the marketed pine kernels are collected from the wild forests. Different pine species have seeds of different sizes and with different flavors. Cones are woody and contain numerous seeds. Cones are made up of cone scales arranged in spirals around a central axis. The upper surface of the cone scales bears seeds. Seeds of most of the pine species have membranous wings. Piñon and some other pines lack the wings. Based on the wood and leaf anatomy, pines are classified as soft and hard pines. The wood of soft pine is soft, even-textured, and creamy white, and their summerwood is light in color. Most of the edible nut-bearing pines are soft or haploxylon pines, and some of these are also of the hard or diploxylon group. Being a gymnosperm, pine nuts are not a true nut and they lack a carpel. Approximately 29 species of *Pinus* produce edible seeds. Only a few species produce edible nuts of sufficiently high quality with desirable flavor. The most important sources of pine nuts are *P. sibirica* (Siberian pine), *P. koraiensis* (Korean pine), *P. pinea* (Italian stone pine), *P. gerardiana* (chilgoza pine), *P. monophylla* (single-leaf piñon), *P. edulis* (Colorado piñon), and other piñon species. *P. gerardiana*, *P. koraiensis*, *P. pumila*, and *P. sibirica* are important nut-bearing pine species in Asia. *P. koraiensis* is the most internationally traded species, and they are produced and harvested in China. The seeds of *P. gerardiana* (chilgoza pine) are long and boat-shaped with one sharp end. The Asian pine nuts are shorter and stubbier than the European pine nuts. *P. koraiensis* (Korean pine) is a native of eastern Asia. It is an evergreen monoecious tree growing 40–50 m tall. Needles are dark bluish green and occur in bundles of five. Cones are borne on a short peduncle and are ovoid or cylindrical. Triangular ovoid seeds are 12–16 mm long with a hard seed coat covering a shiny yellowish kernel. A list of edible nut-bearing pine species are presented in Table 1.

The Mediterranean Stone Pine

The most commonly consumed pine nuts are derived from *P. pinea*. *P. pinea* L. is commonly known as the stone pine. The section *Pinea* under the subgenus *Pinus* includes the other true Mediterranean pines (*P. pinaster*, *P. halepensis*, *P. brutia*, and *P. canariensis*). The stone pine (*P. pinea*) has a long history of cultivation and is the most widely used species in Europe and in the Middle East. Italy is the largest producer of stone pine followed by Spain and Portugal. It is often called umbrella pine because of its widespread umbrella-shaped foliage. This evergreen tree can grow to a height of about 80 ft, and its reddish-brown bark is scaly and deeply furrowed. Needles are in twos and round ovoid cones are borne singly or in groups of 2 or 3. These trees are slow-growing and start production in 7–8 years, and it may sometimes take longer (10–12 years) to start bearing under poor conditions. Cones are about 80–150 mm long, up to 110 mm wide and 153 mm in height. The cones of stone pines generally take 3 years from pollination to ripening. Each cone contains 100 s of narrow cylindrical seeds with hard brown covering. Thick-shelled seeds are dull brown with wings. The kernel is whitish yellow and possesses a sweet flavor. Stone pines are propagated from seeds.

Piñon Pines

The piñon pines of northern Mexico and southwestern United States are the largest group of edible nut-bearing pine species. Among the 13 species of known piñon pines, three species (*P. cembroides*, *P. edulis*, and *P. monophylla*) have a widespread distribution, being the largest group. Other piñons are used as food sources locally and have limited distribution. Other edible nut-bearing North American pines include *P. albicaulis*, *P. flexilis*, and *P. strobiformis* of the Rocky Mountains and Great Basin regions and *P. coulteri*, *P. lambertiana*, *P. sabiniana*, and *P. torreyana* of California, the United States, and Baja California del Norte. The single-leaf piñon (*P. monophylla*) has needles arranged singly, and the Colorado piñon (*P. edulis*) has two needles per bundle and produces a hard-shelled pine nut. Some other species of pinion pines are border piñon (*P. discolor*), Texas piñon (*P. remota*), Nelson piñon (*P. nelsonii*

Table 1 Some common edible nut-bearing pine species

Species	*Natural range*	*Uses*
P. pinea (stone pine)	Mediterranean Europe	Global trade
P. coulteri (Coulter pine)	The United States (California)	Traditional food
P. ponderosa (ponderosa pine)	The United States and western Canada	Traditional food
P. sabiniana (gray pine)	The United States (California)	Traditional food
P. roxburghii (chir pine)	India	Traditional food
P. torreyana (Torrey pine)	The United States (California)	Traditional food
P. ayacahuite	Central America, Mexico	Traditional food
P. albicaulis	Western Canada and the United States	Traditional food
P. cembra	Europe	Locally used
P. flexilis	Western Canada and the United States	Traditional food
P. gerardiana	Afghanistan, Pakistan, India	Global trade
P. lambertiana	West United States (California and Oregon)	Traditional food
P. monticola	NW United States and Canada, SW United States	Traditional food
P. koraiensis	Russia, China, Korea, Japan	Global trade
P. sibirica	Russia, Mongolia	Locally and globally used
P. pumila	East Siberia, China, Korea, Japan	Locally used
P. strobiformis	N Mexico, southwestern United States	Locally used
Piñon pines		
P. cembroides (Mexican piñon)	Mexico	Locally used
P. culminicola (Potosí piñon)	Mexico	Locally used
P. edulis (Colorado piñon)	Mexico and the United States	Imp nut producer
P. johannis (Johann's piñon)	Mexico	Locally used
P. monophylla (single-leaf piñon)	Mexico and the United States	Important nut producer
P. orizabensis (Orizaba piñon)	Mexico	Locally used
P. quadrifolia (Parry piñon)	Mexico and the United States	Locally used
P. remota (Texas/papershell piñon)	Mexico and the United States	Locally used
P. catarinae	Mexico	Locally used
P. juarezensis	Mexico and the United States	Locally used
P. maximartinezii	Mexico	Locally used
P. nelsonii (Nelson's piñon)	Mexico	Locally used
P. pinceana (weeping piñon)	Mexico	Locally used
P. remota	Mexico and the United States	Locally used

Shaw), Pince piñon (*P. pinceana* Gord.), Potosí piñon (*P. culminicola* Andresen & Beaman), and Martinez piñon (*P. maximartinezii* Rzedowski).

Collection, Storage, and Processing

Pine nuts are collected in several ways. The majority of pine nuts are picked by hand. Cones are also gathered while they are still green; pickers climb the trees and collect the cones. Pickers also use a long pole with hooks to pull the cones off the tree. Harvesting the green cones is difficult and time-consuming. Dry picking of the brown cones takes place later in the season once the cones have dried. When the cones turn brown, their scales open up and the seeds in the opened cones fall down. The seeds can also be removed from the brown cones by hitting the cones over a blanket to collect the seed. Collections of brown cones are easier but there is a chance of birds and mammals consuming a large portion of the seeds. Collectors also spread sheets, blankets, and tarps under individual trees, and trees are shaken to dislodge seeds or cones. Some commercial pickers also gather seeds directly from the ground beneath the trees particularly in bumper crop years when the seeds are abundant. Pickers rake or sweep up the seeds and then sift the seeds from the litter. Some pickers also collect seeds from the packrat middens, and these seeds are more likely to have fecal matter contamination. There is a great fluctuation in the quality and quantity of pine nut harvests from year to year. Demand for pine nuts often exceeds production, which often leads to high prices and price fluctuation.

Processing of Pine Kernels

Pine kernels need processing before they are ready to be eaten. Processing method depends on the stages of the harvested cones. Green cones are sun-dried or machine-dried prior to processing. Dried green cones and brown cones are shaken to extract the nuts using a tumbling machine. Separated nuts are then sorted to remove empty shells and poor quality seeds. Sorted nuts are again dried to reduce their moisture content to prolong their shelf life. Pine kernels are covered with a hard shell or seed coat when first isolated from the pine cone. This shell has to be removed prior to consumption. Dried nuts are milled to remove the kernel from the outer shell. Seeds collected from ground or rodent caches need to be washed before they are processed further. All nuts are best stored in a cool dry

environment. Fresh unshelled nuts can be stored at temperatures between −5 and +2 °C for a year or more preserving their flavor and texture. Unshelled nuts have a long shelf life under dry and refrigerated conditions. Shelled nuts can turn rancid within a few weeks especially under warm conditions. Nuts of different species vary in size, taste, and nutritional composition. Pine nuts of different species are generally mixed together during marketing and sold generally as pine nuts.

Methods of Consumption

Pine kernels are nutritious healthy snacks and are consumed raw or roasted. The bulk of the piñon nuts is sold as whole nuts for human consumption. Nuts are sold shelled, unshelled, fresh and dried, and raw and roasted. Some vendors soak unshelled nuts in brine giving them a salty taste. Whole nuts and pieces are also included in breads, candies, cookies, cakes, and sauces such as pesto. They are also added to gourmet chocolates. Pine nut flakes are by-products of pine nut oil, and they are used for making granolas, chocolates, and crunch bars. Pine nut flakes are further pressed and crushed to extract oil, and the by-product is pine nut meal or flour that has a variety of uses. It can be used as a substitute for wheat or rye flour and can be used for making pastries and pancakes. A dairy-free milklike drink with a rich nutty flavor is obtained by mixing pine nut meal with water. It can serve as a thickening agent for sauces and also a nutritious soup. Pine nut oil is extracted from pine nuts, which is valued for its many health benefits such as antioxidant and anti-inflammatory properties. Pine nut oil is used as gourmet cooking oil or as a medicine. Oil extracted from *P. sibirica* and low-grade seeds of *P. yunnanensis* and *P. koraiensis* is used as cooking oil, which contains polyunsaturated fatty acids (PUFAs) such as pinolenic, linolenic, and linoleic acids. Pine nut oil is also used in beauty, cosmetic, and spa products.

Nutritional Composition

There is great variation in the nutritional composition of pine nuts with species and subspecies depending on geographic location and climatic conditions. The nutritional profile of some edible pine nuts is presented in Table 2. Pine nuts have a high nutritional value being particularly rich in protein, lipids, and vitamins such as B_1, B_2, K, and E. It also serves as a good source of minerals such as potassium, phosphorus, and magnesium. Zinc, iron, and manganese have also been detected. In *P. pinea* seeds, potassium was identified as the most prominent mineral followed by phosphorus and magnesium. The content of thiamine and riboflavin was high in pine kernels and has only traces of vitamin C. The protein content of some pine nuts (e.g., *P. edulis* and *P. pinea*) exceeds that of all other commercial nuts, except the cashews. Proteins account to about 25% of *P. pinea* seeds on dry weight basis. Among the various edible pine nut species, *P. pinea* seeds have the highest protein content that is comparable to that of beefsteak. Seeds from *P. monophylla*, *P. quadrifolia*, *P. edulis*, and *P. koraiensis* show a protein content of about 9.5, 11.0, 14.3, and 17.0–18.0 g per 100 g dry mass, respectively. Of the piñon pines, *P. cembroides* has the highest protein content and lowest starch content. Protein quality of pine nuts is also high. All 20 of the amino acids are found in the protein of the nuts of both *P. edulis* and *P. monophylla*. Essential amino acids such as lysine, threonine, and tryptophan are also present in the pine nut oil. Carbohydrate content ranges from 2.4 to 5.4% of *P. pinea* seeds. Sucrose (4.3%) is identified as the main sugar component of *P. pinea* seeds.

[a]The USDA National Nutrient Database for Standard Reference Release 27. NUTTAB 2010 Online searchable database http://www.foodstandards.gov.au/science/monitoringnutrients/nutrientables/nuttab/Pages/default.aspx.

Total lipid content of various pine species ranges from 23% to as high as 68% (by weight). Oil comprises about 60% of pine nuts. Korean pine nut oil is composed of more than 92% of PUFAs like pinolenic acid (C18:3) and linoleic acid (C18:2) and monounsaturated fatty acids (MUFAs) like oleic acid (C18:1). Approximately 15% Korean pine nut oil is pinolenic acid (C18:3). According to various studies, oil from *P. pinea* is rich in unsaturated fatty acids. Oleic and linoleic acids account for more than 85% of the total fatty acids of *P. pinea*. Saturated oil constitutes about 13% of total fatty acids of *P. pinea*, and the predominant saturated acids were palmitic, stearic, and lignoceric acids with trace amounts of arachidic, myristic, and behenic acids. Triacylglycerols with chain lengths of 44 and 48 were predominant in the oil. The nuts of *P. sibirica* contained about 65% of oil on a dry weight basis. The unsaturated fatty acids accounted for about 90% of the total lipids of *P. sibirica* nut oil. About 66% of *P. sibirica* oil is PUFAs, and palmitic and stearic acids were the predominant saturated fatty acids. *P. koraiensis* contains oleic and linoleic acids as predominant fatty acids. Seed oil of conifers contains considerable amounts of an unusual group of PUFAs, and these PUFAs contain Δ18 or Δ20 carbon atoms with their first double bond located at Δ5 and the second one at either Δ9 or Δ11. In most pine nut species, pinolenic acid is the most predominant Δ5 polymethylene-interrupted PUFA. Its content varies greatly with pine species. The unique nature of Korean pine nut oil is that it contains approximately 15% of pinolenic acid.

Substantial amounts of tocopherols and triacylglycerols were present in the *P. pinea* seeds. The total tocopherol content of the pressed *P. sibirica* oils was 49.6 mg per 100 g oil. Tocopherols were mostly α- and γ-tocopherols. Tocopherols are powerful antioxidants, which can reduce the risks of cardiovascular diseases (CVDs). Pine nuts are good sources of phytosterols. Among various edible nuts, pine nut has very high total phytosterol content. Beta-sitosterol is identified as the predominant phytosterol in most pine nuts, and the European *P. pinea* contain about 429.8 mg per 100 g oil. Research reports suggest that phytosterols can reduce blood cholesterol and risks of certain types of cancers such as colon, breast, and prostate and enhance immune function. Phytosterols can inhibit intestinal absorption of low density lipoproteins (LDL), thus reducing plasma cholesterols and LDL levels. Studies show that pine nut also contains low amount of squalene of about 400 mg/100 g oil. Squalene acts as a biosynthetic precursor for all steroids in plants and is implicated to have important health benefits such as decreasing serum cholesterol levels and the risks of cancer. The total phenolic acid in defatted pine nut kernel was determined as 0.137 mg gallic acid equivalents (GAEs) per 100 g and reported to contain caffeic acid as the predominant phenolic acid. Among commonly consumed tree nuts and peanut, pine nuts contained the lowest total phenolic content of 0.68 mg of GAE per gram fresh sample, and an antioxidant activity of 7.19 μmol of TE per gram fresh sample. Pine nuts do not contain anthocyanins. Studies showed that pine nuts contain 32 μg isoflavones. Also, pine nuts have no detectable proanthocyanidins.

Health Effects

In general, a large body of research is available on the health benefits of nuts, but there has been little information available on the pine nut specifically. A number of investigations have been carried out to study the effect of intake of pine nut oil on plasma lipoprotein levels, and the biological mechanisms involved were studied using the French maritime pine (*Pinus pinaster*). Some of these studies done using animal systems demonstrated the potential benefits of pine nut and its oil in improving the plasma lipid profiles. In a study conducted in 2008, Pasman and coworkers evaluated the appetite suppressant effects of Korean pine nut free fatty acids (FFAs) and triglycerides (TGs) in STC-1 cell culture for their ability to increase cholecystokinin (CCK-8) secretion against several fatty acids from Italian stone pine nut FA. FFAs from Korean pine nuts had the greatest ability to increase CCK-8 release from the STC-1 cells compared to the other fatty acids tested and the negative control. Korean pine nut FFA showed approximately eightfold potency in releasing CCK-8 than the other fatty acids tested. Evidence from this study suggests that pine nut FFA and TG may act as an appetite suppressant in overweight women. A human intervention study performed in 18 overweight postmenopausal women who consumed Korean pine nut FFA, pine nut TG, or placebo (olive oil) in combination with a light breakfast showed enhanced secretion of CCK-8 after pine nut FFA (after 30 min) and pine nut TG (after 60 min) when compared to placebo.

In animal models, Korean pine nut oil improved the activities of superoxide dismutase (SOD) and glutathione peroxidase activities and reduced the content of malondialdehyde in serum indicating its antioxidant activities. Additionally, studies conducted in animal models showed that supplementation of *P. pinaster* oil reduced the levels of TG and very low density lipoprotein in rats, suggesting the potential of *P. pinaster* in lowering the high blood triglyceride levels. Procyanidins from *P. koraiensis* exhibited antitumor activity in animal models of cancer. PinnoThin is an oil preparation from *Pinus koraiensis* that consists of 66% PUFAs like linoleic and pinolenic acids (C18:3) and 26% MUFAs. A study conducted with PinnoThin™ (pine nut oil with high content of pinolenic acid) showed that it increased the release of satiety hormones CCK and glucagon-like peptide 1 and suppressed appetite. No effect was noticed on hunger-inducing factor ghrelin. Further, toxicity study also showed that pine nut oil was safe to use for obesity treatment and not toxic. Another double-blind placebo-controlled randomized study conducted in 42 overweight female volunteers suggested that Korean pine nut oil, PinnoThin™, may exert satiating effects and no effects of PinnoThin TAG on appetite ratings were found. More human intervention studies are required to investigate into the effects of major pine nut components on CVD risk and health.

Traditional Medicinal Uses

Pine seeds have analgesic, antibacterial, and anti-inflammatory properties. Resin and turpentine are obtained from the trunk of stone pine. Turpentine has a variety of uses such as use in medicinal products and for making varnish. The turpentine is antiseptic, diuretic, rubefacient, and vermifuge. It is used externally as a rub in rheumatic conditions and also for the treatment of a variety of skin complaints such as wounds, sores, burns, and boils.

Pine Mouth/Pine Nut Syndrome

Some individuals experience a bitter, metallic taste disturbance usually lasting a few days after consuming pine nuts, which is exacerbated by the consumption of food and drink. This taste disturbance has become referred to as 'pine mouth' or 'pine nut syndrome'; however, medically, it is known as dysgeusia, metallogeusia, or cacogeusia. The symptoms can last from a few days to 2 weeks and the symptoms decreased over time with no adverse clinical effects. Reports from consumers suggest that the taste disturbance is quite pronounced that it significantly decreases appetite and enjoyment of food causing considerable discomfort to the sufferer. Patients also occasionally complained of abdominal cramp and nausea after eating raw, cooked, or processed pine nuts. While pine nuts are potentially allergenic, as such, pine mouth is not considered a food safety issue. There is an increase in the reports of occurrence of pine mouth worldwide. Although the cause of pine mouth is not exactly known yet, mixing of pine nuts that are regarded as inedible with edible nuts may be a contributing factor. Evidences also show that consumption of *Pinus armandii* nut that is not listed among the edible pine nuts by the FAO may lead to dysgeusia.

Pineapple

S Wilson Wijeratnam, Industrial Technology Institute, Colombo, Sri Lanka

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Pineapple, *Ananas comosus* L., is a monocotyledon, belonging to the large genus *Ananas* of the family Bromeliaceae, which includes many ornamental plants. It is an exotic fruit with origins from South America. It is mentioned in the chronicles of Pedro Martyr d'Anghiera in 1530 as being found in a tiny Indian village on the island of Guadeloupe during the second voyage of Christopher Columbus in 1493. The name pineapple is thought to have originated because of the fruit's resemblance to a pine cone.

The pineapple plant is a drought-tolerant herbaceous perennial plant, with a rosette of waxy leaves and a short stem. The pineapple fruit is a compound fruit that develops through the fusion of many individual fruitlets. These small fleshy fruitlets are fused together around the fibrous central stem referred to as the core. Each fruitlet develops from a hermaphrodite flower, which is self-sterile although it has both male and female parts. Self-sterility is advantageous in terms of fruit quality and palatability. Each fruit is borne on a peduncle, which is an extension of the stem of the pineapple plant. Fruits can vary in size. The flesh of the fruit is juicy, has an exotic sweet flavor, and can be pale cream to yellow in color. The top of the fruit is known as the crown. It is an extension of the apical meristem and can be used as planting material.

Sources and Production

Pineapple is known to have originated in the tropical Americas, where the fruit was a stable component of the Native American diet long before it was discovered by European explorers. It was also used for the production of alcoholic beverages, for medicinal purposes, and for the production of fiber. It was apparent to the explorers that considerable selection had taken place with regard to domesticated pineapples. The American Indians readily distinguished land types from wild types and developed agronomic practices based on the production cycle of the fruit. By the end of the sixteenth century, increasing popularity and interest in this exotic commodity in the West resulted in the introduction of pineapples to many parts of the world including Asia, Africa, and the South Pacific colonies by Spanish and Portuguese explorers.

Commercial production of pineapple began in the nineteenth century in the West Indies, Brazil, and Mexico. Prior to the First World War, pineapples were supplied to North America by Cuba, the Bahamas, Florida, and Puerto Rico, while Europe was supplied by the Azores. However, production shifted to other regions in Africa and Asia after the Second World War. With the development of processing technology, production expanded in Hawaii, Malaysia, Taiwan, the Philippines, Australia, South Africa, the Caribbean, and Kenya. The emergence of improvements in refrigeration in the mid-twentieth century and the launching of refrigerated reefer containers facilitated sea shipment, opened new markets, and created an increased demand for the fresh fruit.

Pineapple contributes to over 20% of the tropical fruit produced in the world. Large-scale production is managed by multinational companies operating in several pineapple-producing countries. As such, it is considered to be the third most important tropical fruit crop after banana and citrus. The total world production of pineapple was estimated as amounting to 23.33 million MT in 2012. While 85 countries are listed in FAO records as pineapple-producing countries, Thailand, Costa Rica, Brazil, the Philippines, and Indonesia together produce over 66% of the total. Thailand, the Philippines, Indonesia, and Malaysia also account for over 75% of canned pineapple exports and 55% of the juice concentrate exports. FAO records indicate that 70% of the global production is consumed in pineapple-producing countries. Costa Rica is the largest exporter of fresh pineapples, while the United States and the European Union (EU) together account for 88% of imports. Supermarkets are the main outlets for pineapple sales, in most importing countries although they are also sold through greengroceries, street markets, and catering outlets. Large supermarkets are supplied by large agro-multinationals. However, many other importers in Europe, North America, Japan, and Singapore are also active in the pineapple trade.

Pineapples are cultivated on a range of different aerated and well-drained soils with soil pH ranging from 4.5 to 5.5. The plant is a xerophyte and is adapted to withstand periods of drought. The leaves of the plant are covered with trichomes and equipped with small stomata situated in furrows under the surface. Leaves also have a highly cutinized upper dermis. However, despite these characteristics, the plant is adversely affected by prolonged periods of drought. On average, pineapple plants need 1–1.5 m of rain per year. The optimum temperature for vegetative growth of the plant is between 28 and 32 °C although varieties are known to differ in response to climatic conditions. Prolonged exposure to low temperatures slows down vegetative growth in most instances.

Mature fruits ready for harvest and fruits reaching maturation develop postharvest physiological disorders when exposed to continuous nighttime temperatures below 18 °C. While exposure to low temperatures induces a high degree of flowering in some varieties, flowering is artificially induced in commercial plantations at an appropriate stage of development to meet quality requirements of respective markets and facilitate harvest and distribution operations (Figure 2). Cultivars such as the Queen-type Mauritius variety respond better to shade and are successfully grown as an intercrop in coconut plantations (Figure 1). Other varieties such as the Cayenne-type Kew pineapples show low Brix values when grown in the shade.

Dry leaves, coir dust, or straw can be used as a mulching material. Mulching with black polythene or saw dust has also

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00547-X

Figure 1 Queen-type Mauritius variety pineapple plantation intercropped with coconut.

Figure 2 Queen-type Mauritius variety pineapple fruit at early stage of development following flower induction.

been found to be very effective. Mulching is practiced in many plantations to prevent the growth of weeds around the plant. Mulching also reduces soil erosion and water loss and helps regulate soil temperature. The maturing fruits may be covered with rice straw or pineapple leaves in order to reduce both sunburn and damage caused by birds.

Pineapples are cultivated as a ratoon crop, where replanting occurs usually after the second ratoon crop is harvested. Crowns, stem shoots or suckers (aerial and terrestrial), and slips from the peduncle are used as planting material. Crowns are used in most commercial plantations where the fruit is grown for processing purposes and harvested 18–24 months after planting. Slips are harvested at 20–22 months and tissue-cultured plants at 15–18 months after planting. Many smallholders prefer to plant ground and stem suckers, which can be harvested between 12 and 14 months and 14–16 months, respectively. Planting material must be selected according to size to ensure uniform development of plants.

Cultivars selected for commercial production may be classified into five distinct groups based on plant characteristics, fruitlets, fruit shape, fruit flesh, number and size of bracts, and leaf morphology. These groups include Cayenne, Spanish, Queen, Abacaxi (Pernambuco), and Maipure (Perolera). The Smooth Cayenne is thought to have originated in India and has smooth leaves with spines limited to the tip of the leaf compared with the Queen types, which have numerous spines distributed along the entire edge of the leaf. Cayenne group cultivars continue to be the most widely grown commercial variety. They are grown for processing purposes as they are cylindrical in shape, juicy, and low in fiber with a sweet to mildly acidic flavor and are less prone to chilling injury. However, the less acidic and sweeter flavored hybrid variety MD2 is also resistant to chilling injury and has become the dominant variety in European markets. Other Queen-type pineapples with sweet flavor are also becoming increasingly popular in the fresh fruit market, despite the latter group being particularly susceptible to a complex physiological disorder referred to as internal brown spot (IBS) or endogenous brown spot.

There are a number of climatic, production, and postharvest conditions that contribute to the development of this disorder. While crops grown under low sunlight conditions and exposed to cool temperatures either in the field or during storage develop the characteristic browning symptoms, pineapple cultivars with high Brix and low titratable acidity are more prone to develop the disorder. Stress conditions also predispose fruit to IBS, for example, where extremes in water availability occur with the commencement of heavy rains following the end of the dry season. Thus, more incidence of the disorder occurs in fruit harvested during the rainy season due to the low sunlight, cool temperatures, and high water availability. Increased incidence of the disorder also occurs when flower induction is practiced during wet periods.

Patterns of Consumption

Fresh and processed pineapples are appreciated and consumed by people of all ages in producing and importing countries alike. Fresh pineapples are a common product in many ethnic and urban supermarkets the world over. Although consumption levels of the fresh fruit continue to be higher in high-income Western markets, consumption trends are expected to grow in low-income European countries as they follow the consumption trends of their more affluent neighbors. Meanwhile, processed pineapples are exported for convenient consumption as canned or frozen concentrates and IQF frozen chunks, rings, or quarters. While pineapple juice is incorporated into tropical juices and concentrate blends, chunks are included in fruit salads. Pineapples are also consumed as dehydrated products and often incorporated into trail mix snacks.

Nearly 80% of the world pineapple production output continues to be utilized by the processing industry, with the bulk of the world production being used by the canning industry. Among canned fruits, pineapples are important next only to peaches. In contrast to the foremost pineapple-producing countries, where over 90% of the production is absorbed by the processing industry, the major portion of the pineapple produced in India and many other developing countries is for consumption in fresh form with less than 10% of the production being used by processing industries.

Major constraints faced by the pineapple-processing industries in these countries include

(a) high cost of canning due to the high cost of raw materials, containers, and overheads;
(b) nonavailability of a continuous supply of fruits throughout the year.

Marketing of fresh pineapple also poses problems due to its highly perishable nature. Mature pineapple fruits cannot be stored for more than 4–5 days after harvest under warm humid ambient environmental conditions.

The international trade in fresh fruits is limited although an increasing demand for fresh fruit has been observed in the major export markets in recent years. The United States is the largest single consumer nation of fresh pineapple, importing over 29% of the world's production with per capita consumption of pineapple estimated at 2.5 kg. In the EU, the market for pineapples is observed to be growing. Germany, Italy, and the United Kingdom are the largest EU markets, with potential for further market growth in the new EU countries. Belgium and the Netherlands are the leading importers for distribution of pineapples in the EU.

There is also an increasing demand for organic pineapples and pineapple products. However, trends in the supply and demand of fresh and processed organic pineapple are difficult to assess due to the lack of official statistics and the resulting reliance on anecdotal information. Organic producers and processors catering to international markets need to obtain certification for their respective products from internationally recognized organic certification bodies and need to meet prescribed standards set by them.

Globalization and the growing consumer quest for a healthier lifestyle are important drivers for exotic fresh fruit consumption and have contributed to the increased demand for pineapple in international markets. While the Cayenne-type pineapples respond better to low-temperature storage and transportation, the current overall preference is for a less acidic, sweet, and juicy fresh pineapple. It is also noted that pineapple is not the most convenient of fruits to handle or to convert into consumable portions. This obstacle to consumer preference is overcome by some retailers who offer precut and ready-to-eat fresh pineapple products. The introduction of the popular baby pineapple into many international markets also meets the demand for smaller portions and single servings. Pineapple juices are subjected to fermentation procedures and used to produce wine or alcohol and are also used to extract citric acid.

Availability Absorption and Metabolism

Fruit crops available for human consumption are estimated in trade and socioeconomic reports as a measure of supplies of the crop moving from production to marketing channels for domestic human consumption. These estimates are often used in food availability databases as a popular proxy for actual fruit consumption. However, information on the availability of beneficial nutrients in individual fruit crops is important to dietitians and nutritionists.

On average, pineapples are estimated to have close to 50 calories per 100 g of weight. The fruit is rich in the essential vitamins A, B, C, E, and K, beta-carotene, folate, and pantothenic acid. One cup (US) of raw pineapple can contain 31% of the daily requirement of vitamin C. It is also a useful source of minerals such as iron, calcium, copper, potassium, and magnesium and an excellent source of manganese as one cup serving (US) of raw pineapple can contain up to 76% of the daily value requirement of this mineral. Pineapples are also rich in dietary fiber and low in calories and contain no saturated fat.

The sugar content changes from 4% to 15% during the final stages of fruit ripening and in some cultivars rise to 18%. The sugar–acid ratio and the ascorbic acid content could also vary with cultivar.

Bromelain present in pineapples is associated with many health benefits and contains a collection of protein-digesting enzymes including proteinases, peroxidase, and acid phosphatase, as well as several protease inhibitors. Bromelain is absorbed in the gastrointestinal tract. Significant amounts of bromelain can be absorbed by the human body without ill effects. Bromelain contains organically bound calcium, which remains stable over a pH range of 2–9 and is considered to be readily absorbed orally. It is used as a phytomedical compound. Though it is present in the fruit, pineapple stems contain higher concentrations of bromelain, and as stems are a waste by product, they prove to be a cheaper source of the substance for commercial extraction. Fruit bromelain and stem bromelain are prepared differently and are of different enzymatic properties.

Pineapples are known to contain bioactive compounds such as alkaloids, flavanoids, and tannins, which are present in both pineapple flesh and skin. Nutrients available in this fruit are listed in Table 1.

Health Effects

Fruits, nuts, and vegetables play an important role in providing the nutrients essential to humans and must be incorporated into the daily diets of men, women, and children. It is currently estimated that over three billion people lack adequate micronutrients in their diets. Lack of these nutrients increases morbidity and mortality rates, results in lower worker productivity, and causes learning disabilities in children. This also results in increased healthcare costs, diminishes human potential, and affects overall national economic development. Among tropical fruits, many health benefits are associated with pineapples. Per the US Food and Drug Administration, the nutrient content descriptors approved for pineapples are fat-free, saturated fat-free, very low sodium, cholesterol-free, and high in vitamin C. The fruit contains calcium, potassium, and magnesium. It is a good source of vitamins B1 and B6, copper, and dietary fibers. Pineapple has an abundance of anti-inflammatory properties. The juice is taken as a diuretic, to expedite labor, and as an antidote for sea sickness.

Pineapples as a Source of Vitamins

Pineapples are a useful source of vitamins. A cup of pineapple chunks can contain up to 28 milligrams of vitamin C, which is

31% of the recommended daily vitamin C intake for men and 38% for women. The water-soluble antioxidant properties of vitamin C help prevent scurvy, increase immunity, and build resistance against infectious disease. Vitamin C is a useful free radical scavenger and helps remove harmful free radicals from the body. Vitamin C is also needed for the production of collagen, which is the major structural protein required in the human body for maintaining the integrity of blood vessels, skin, organs, and bones. Vitamin C present in pineapples also contributes to oral health and helps with the prevention of gum disease. Vitamin C reduces the risk of colon, esophagus, and stomach cancer. Vitamin A and beta-carotene, though present in smaller quantities, also have antioxidant properties and are required for good vision and retarding age-related macular degeneration, healthy skin, and maintaining mucus membranes. Pineapple is also a good source of thiamine. This component of the vitamin B complex acts as a cofactor in enzymatic reactions central to energy production and red blood cell formulation. Antioxidant-rich foods in the diet can improve fertility. The bioavailability of nutrients is the proportion of a nutrient that is absorbed from the diet and used for normal body functions. Both external and internal factors govern the bioavailability of the nutrient. External factors include the food matrix and the chemical form of the nutrient in question, whereas gender, age, nutrient status, and life stage are among the internal factors. Ascorbic acid and S-containing amino acids present in pineapple are agents that promote micronutrient availability in the human body, while polyphenolics and phytates are known to inhibit micronutrient bioavailability.

Bromelain

Bromelain belongs to a group of protein-digesting enzymes that attack the internal peptide bonds of the protein chain. While the fruit bromelain, which is an acidic protein, is present in modest amounts in the fruit, the bromelain widely used as a food supplement is extracted from the pineapple stem. It is a mixture of different thiol endopeptidases and other components such as phosphatase, glucosidase, peroxidase, cellulase, escharase, and several protease inhibitors. Bromelain is readily absorbed by the body in the gastrointestinal tract and remains functionally intact.

Bromelain enhances the absorption of drugs, particularly antibiotics. *In vitro* and *in vivo* studies demonstrate that bromelain exhibits various fibrinolytic, antiedematous, and antithrombotic activities. Bromelain has anti-inflammatory properties and is used to prevent postsurgical inflammation and trauma.

It is used in the treatment of arthritic patients, for pain relief for those suffering from osteoarthritis and joint injury. It is able to dissolve mucus and is used in the treatment of bronchitis and sinusitis. Bromelain supplement is used to reduce the incidence of various cardiovascular disorders as it is an inhibitor of blood platelet aggregation. It prevents the coagulation of blood and is used to combat thrombophlebitis and to minimize the severity of angina pectoris and transient ischemic attack.

It is effective in curing burn wounds where the formation of layers of burned and traumatized tissue if not removed will serve as an infection site and a medium for growth of bacteria. In such instances, bromelain is administered to remove the dead and infected tissue and bring about effective healing of the wounds.

Bromelain contains proteolytic enzymes called cysteine proteinases, which break down proteins and help digest food. It is also used to combat diarrhea and is thought to counteract some of the effects of intestinal pathogens such as *Vibrio cholera* and *Escherichia coli*.

Bromelain also possesses some anticancerous activities and is known to prevent the growth of certain types of tumors as it promotes apoptotic cell death.

Manganese and Copper

One cup of pineapples contains 2.6 mg of manganese, which covers the entire recommended daily intake of this mineral. It is instrumental in the creation and activation of certain enzymes. It activates clotting factors and helps prevent excessive bleeding. This trace mineral is an important cofactor in many enzymes that are involved in energy production. It thus helps the body convert nutrients such as fat and carbohydrates into usable energy. It is also a necessary cofactor in antioxidant defense enzymes as with the oxidative enzyme superoxide dismutase, which disarms harmful free radicals produced within mitochondria. Manganese is also essential for the development of strong bones and connective tissue. Copper present in pineapples helps with absorption of iron and regulates blood pressure and heart rate.

Fiber

A medium-sized pineapple can provide up to 13 g of fiber. Individuals with type 1 diabetes and who consume high-fiber diets have lower blood glucose levels, while type 2 diabetics show improved levels of blood sugar, lipids, and insulin. The fiber present in pineapple is effective in curing constipation and irregular bowel movements. Consumption of the fruit is known to make bowel movements easy and regular. Pineapples can contribute to high-fiber intake, which is associated with a lowered risk of colon cancer. Pineapple fiber has many other uses. It is extracted from leaves and used in the manufacture of thread, fabrics, and fishing nets and for stringing jewels.

In Africa, the dried, powdered root is used to treat edema and the crushed rind is applied on fractures. Corns and calluses on the feet or rough skin on elbows and heels may be treated with the fruit pulp as follows – repeated application of the pulp to the affected area for an hour, followed by rinsing off the pulp and gently scrubbing the affected area.

The flesh of immature fruits is toxic and can cause severe diarrhea and vomiting. Excessive consumption of pineapple could cause swelling and tenderness of lips. Consumption of unripe fruit can cause throat irritation and drastic bowel discharge. In some cultures, the toxic flesh of very young fruits is ingested to expel intestinal worms and achieve abortion. Excessive consumption of pineapple cores can cause fiber balls to develop in the digestive tract.

Pitaya (*Stenocereus* spp.)

C Chuck-Hernández, R Parra-Saldívar, and L Sandate-Flores, Tecnológico de Monterrey, Monterrey, Mexico

© 2016 Elsevier Ltd. All rights reserved.

Definition

Pitaya (*Stenocereus* spp.) (Figure 1) is a fruit that belongs to the Cactaceae family (Table 1). It is a crop of paramount importance for the inhabitants of semiarid zones of Mexico, mainly because of its nutrimental, therapeutic, and decorative value. The columnar cactus producing this fruit, named pitayo, is from the tribe Pachycereae and subfamily Cactoideae, with Stenocereae being the most important subtribe and *Stenocereus* the most relevant genus.

Cactaceae are prosperous crops in arid and semiarid regions due to their low water requirements and the good use of the natural resources. Moreover, the ancient populations of these areas, mainly in Mexico and Southern parts of the United States, have traditionally selected cacti according to their usefulness; that is, it has been used as biomass, as a source of water, as building material, as a source of carbohydrate and as decorative plants. The use of water by pitayos is five to ten times more efficient compared with regular crops. This characteristic is due to its CAM metabolism (*Crassulaceae*-type metabolism), based on the optimal opening of stoma (overnight) for CO_2 fixation when respiration is low. The thickness of the plant skin (14 μm) is another adaptation for pitayo's survival in arid and semiarid regions, allowing the plant to cope with long periods of drought.

In Mexico, the predominant Cactaceae with fruits are garambullo (*Myrtillocactus geometrizans* – Martius Console), nopal (cactus pear, *Opuntia* spp.), and pitayo (*Stenocereus* spp.). The genus *Stenocereus* (from the Greek words 'stenos,' meaning narrow, and 'cereus,' meaning candle) includes a heterogeneous group of cacti found from Southern Arizona, the Baja California peninsula and other parts of Mexico, Costa Rica, Guatemala, to northern Colombia and Venezuela. *Stenocereus* are creeping, group-forming, and treelike cacti. Stems of the *Stenocereus* cacti are cylindrical and often show numerous ribs. This plant yields funnel-shaped flowers, typical from various Cactaceae. *Stenocereus* includes at least 24 species distributed from the southern part of the United States to Peru and Venezuela. In Mexico, at least 19 species are found throughout the country (Figure 2). *S. thurberi* grows in the Baja California peninsula, in Sonora, and in some areas of Sinaloa; *S. montanus* flourishes from Sonora to Nayarit; *S. queretaroensis* is found in Jalisco, Michoacán, Guanajuato, and Queréraro; *S. quevedonis* flourishes from Sinaloa to Guerrero (Pacific coast); *S. griseus* is found not only within the Mixteca region (Oaxaca, Guerrero, and Puebla) but also in the states of Tamaulipas and San Luis Potosí; *S. dumortieri* is found in Hidalgo, Morelos, Puebla, Oaxaca, and Chiapas; *S. weberi* can be found in Puebla, Oaxaca, and Guerrero; *S. stellatus* can be found in Morelos, Puebla, and Oaxaca. In Mexico, the most important cultivated *Stenocereus* species are *S. queretaroensis*, *S. griseus*, *S. stellatus*, and *S. fricii*.

Despite the wide geographic area of pitaya's production, the most important zones for pitaya production are the Sayula Basin (Jalisco, Zacatecas, Guanajuato, Michoacán, and Querétaro) and the Mixteca (between the states of Oaxaca and Puebla) (Figure 2).

The common name for *S. griseus* is pitaya de mayo, while *S. queretaroensis* and *S. stellatus* are known as pitaya de Queretaro and pitaya agria, respectively. Pitaya is known locally by various colorful common names such as amarilla (yellow), espina negra (black spine), cántaro (pitcher), Acateca, borrega (sheep), hormiga (ant), pitaya de flor o chica (flower pitaya or small), agria (sour) or espina amarilla (yellow spine), Copal, Pitaya Señora (Mistress Pitaya), Pitaya Xoconostle, and cantarito (little pitcher).

Sources, Production, and Agronomical Aspects

Pitayo requires few agronomical inputs. In fact, most of the production in America is based on harvesting wild plants (as opposed to an intensive and controlled farming process). *Stenocereus* grows well in slightly acidic and sandy soils, but it can also grow well in stony ground and soils where no other crops can prosper. The optimum temperature for its growth is in a range from 10 to 34 °C, with an average of 22 °C in the Sayula Basin.

The average rainfall in the pitaya production area in Mexico is 700 mm, mostly in summer. The flowers and fruit of pitaya reach their development during late winter and spring, when rains are scarce, and mature from May to August. The production of flowers and fruits starts between the first and third year after plantation, but in order to obtain a large production for commercial viability, the plant requires 10 years of development. Pitayo's lifetime production is from 25 to 30 years, and for *S. stellatus*, there are some documented cases with 100 years of production.

Fertilizers are almost never applied, and although irrigation can increase fruit production, this practice is not used regularly in Mexico. Trimming to control plant height is not practiced either, even when this is recommended to reduce harvesting time.

Most of the pitaya produced in Mexico is wild type, although some varieties are selected and grown in family backyards for decorative purposes, and the practice helps to enhance the genetic diversity.

Compared with other fruits, pitaya is not very productive. The average yield per hectare is 3.44 metric tons (mt), while primary production of fruit worldwide is 27 mt ha^{-1} and 7.23 for prickly pear, the most similar cactus fruit. There is no information available about worldwide pitaya production, but in Mexico, according to SINAREFI, pitaya crop has increased steadily from 448 mt in 2000 to 3428 mt in 2010 (Table 2).

Yield, in terms of number of pitaya fruits per pitayo plant and also average weight, varies widely according to the *Stenocereus* species or variety (Table 3).

The annual harvest for a middle-age pitayo plant ranges from 45 to 98 fruits per plant and their weight from 89 to 165 g. Fruits

Figure 1 Pitaya fruit and pitayo cacti.

Table 1 Classification of *pitaya* (*Stenocereus* spp.)

Kingdom	*Plantae*
Division	Magnoliophyta
Class	Magnoliopsida
Order	Caryophyllales
Family	Cactaceae
Genus	*Stenocereus* (pitaya)
Species	Griseus, queretaroensis, stellatus, and fricii (as the most important species)

Figure 2 Main areas for pitaya production in Mexico. Areas cross hatched are regions with traditional wild fruit harvest and dappled regions are areas with pitaya commercial production. Adapted from Pimienta-Barrios and Nobel (1994).

of *S. griseus* are larger than those of *S. queretaroensis*, generally from 200 to 350 g; nevertheless, this depends on the genetic selection made with traditional propagation.

The yield of pitaya increases with the plant's age, because of the increase in number and length of stems along which fruits are borne. When a pitayo is about 20 years old, the production can reach up to 17 mt ha^{-1}.

Physicochemical Characteristics

The pitaya fruit consists of three main anatomical parts: pulp (in its interior chamber); seeds, located within the pulp; and high-fiber skin or peel (Figure 3). The pulp is very aromatic, juicy, and sugary. Pulp color can be white, pinkish, yellow, red, or purplish. As discussed before, the fruit weight varies widely; in a mature pitaya, it could be anything between 69.3 and 148.3 g (*S. stellatus*), of which 53.9–111.8 g would be pulp, 15.3–36.5 g would be skin, and 1.63–3.42 g would be seeds. Compared with cactus/prickly pears (tuna), a larger fraction of the pitaya fruit is edible. The peel of pitaya represents 18% to 24% of the fruit weight, whereas in the tuna, it is up to 45%. Furthermore, in the case of tuna or cactus pear, the seeds (4%) are usually not eaten, while pitaya seeds (1.6–3.4% of fruit weight) are chewed and digested.

Regarding the geometry of the fruit, pitaya is almost spherical, with transverse and longitudinal diameters of 4.4–6.2 and 4.4–6.8 cm, respectively. Based on our experimental data over *S. griseus* specimens, the ratio for transverse and longitudinal diameters was 0.79–0.81, the volume 97–119 cm^3, and density 1015–1019 kg m^{-3} (Table 4).

Skin or peel texture or resistance (Table 4; Figure 4) and color are also a distinctive trait. Color can range from green to yellow as the fruit develops, and it can be described as reddish when the pitaya matures (Figure 5).

If a color index is calculated with the three parameters of a lab color scale ($color\ index = (a \times 1000) \times (L \times b)^{-1}$), differential values can be obtained, and if a value ranges between +2 and +20, it describes a pitaya from pale yellow to orange, whereas values >+20 are related to intense orange to red.

The chemical characteristics of pitaya are shown in Table 5 for fifteen varieties or species as reported by different authors. Acidity and pH are related traits, ranging from 0.09 to 0.64 for the former and from 3.95 to 5.20 for the latter. This is a very wide range of pH, higher compared with apples (3.3–3.9) and blueberries (3.1–3.4); similar to pear (3.5–4.6), cherries (3.2–4.5), and bananas (4.5–5.2); and lower than watermelon (5.2–5.6). For prickly pear, also a cactus fruit, pH ranges from 5.3 to 7.1, higher than pitaya.

According to this characteristic, some pitaya varieties can be classified as low acidic because their pH is higher than 4.5,

yielding important considerations to make during processing, mainly in thermal-related operations as pasteurization.

Another important characteristic is its sugar concentration. Similar to other fruits, the main sugars in pitaya are fructose and glucose, with a total content of 9.9% on average. Other fruits with similar sugar content are prickly pear fruit, 10%; pear, 10%; apricot, 9.3%; kiwi fruit, 10.5%; and orange, 9.2%. This percentage (almost 10%) of sugars is higher than strawberry (6%), but lower than other fruits as apples (13.3%) and banana (15.6%).

In the case of *S. stellatus*, a total sugar content of up to 15.92% has been reported (Table 6). This species is also one of the most acidic, so as in other fruits, the acidity/sugar ratio is closely related.

Table 6 shows that the sugar content in pitaya *S. stellatus* ranges from 12% to almost 16%. Cultivars of *S. griseus* typically

Table 6 Total sugar content and composition for four pitaya varieties from *S. stellatus* species (common name: xoconostle)

Sugars (%) (moisture basis)	*Variety (*S. stellatus*)*			
	Roja	*Blanca*	*Amarilla*	*Solferina*
Glucose	7.02	6.89	6.93	7.04
Fructose	3.10	4.26	3.29	2.52
Sucrose	2.44	4.76	3.84	3.12
Total reducing sugars	10.13	11.16	10.22	9.56
Total sugars (reducing + nonreducing)	12.58	15.92	14.07	12.68

exhibit contents around 10–11 expressed as percentage of fresh weight. As Table 5 shows, most of the sugars are reducing (glucose and fructose), more readily digested than nonreducing ones. Sugar content of 10–14% is generally considered acceptable for fruits that are eaten raw.

Table 7 shows the approximate composition of different pitaya varieties. Protein ranges from 1.0 to 1.7 and crude fat and fiber from 0.1 to 0.3 and 0.25 to 6.1, respectively. Protein is somehow higher in pitaya compared with fruits as apples, cherries, and prickly pear (0.2, 1.0, and 0.7, respectively), and this can be related to the high content of protein of the pitaya seeds. Regarding fat and fiber, Table 7 shows similar content to other fruits, particularly to prickly pear (0.51 and 3.6 for fat and fiber, respectively).

The moisture content of pitaya is between 85% and 89%, similar to apples and cherries (86%) and prickly pear (88%).

The vitamin C content in pitaya ranges from 8.49 to 17.04 mg/100 g of fresh pulp in *S. stellatus* and up to 21.7 mg for *S. griseus*. Oranges, however, contain approximately 59 mg/100 g fruit. According to the National Nutrient Database for Standard Reference (USDA), the vitamin C concentration in cherries is only 10 mg/100 g, in apples 4.6 mg/100 g, and in prickly pear 14.0 mg/100 g of fruit.

No data regarding concentrations of other vitamins were found in the literature, except for niacin: 0.47 mg/100 g, fairly similar to oranges (0.425 mg/100 g), cherries (0.400 mg), and prickly pears (0.460 mg).

Health-Related Properties: Antioxidant Activity and Nutraceuticals Within Pitaya (*Stenocereus* spp.)

Data available for the phenolic content and antioxidant activity of pitaya's cultivars show the importance of this crop as a

Species	*Variety*	*Antioxidant capacity (mg trolox/g)*[a]
Stenocereus stellatus	Red	2763.2 ± 50.7
	Cherry	3047.1 ± 38.2
	Yellow	4202.1 ± 52.1
	White	4336.8 ± 36.3

[a]Milligram per gram of concentration based upon trolox as standard (Beltrán-Orozco et al., 2009).

potential source of beneficial compounds, in particular for inhabitants of arid regions. Information about the total phenolic content for two different *Stenocereus* species is shown in Table 8. The highest total phenolic content has been reported for yellow and white varieties belonging to the species *S. stellatus:* 2129–2395 gallic acid equivalents (GAE). Red and cherry varieties of the same species of pitaya, on the other hand, have lower amounts of total phenolic compounds: 1384–1552 GAE (Table 8).

The phenolic content in red and cherry varieties of *S. stellatus* and *S. griseus* pitaya is similar to that of apple and strawberry, whereas the yellow, white, and orange varieties show levels similar to cranberries. It is worth mentioning that cranberry is one of the fruits with the highest antioxidant capacity reported worldwide.

Regarding total soluble phenolics, the highest content was found in the red varieties of both *S. pruinosus* and *S. griseus* as compared with orange varieties of the same species (Table 9).

There is conclusive evidence that the antioxidant capacity in pitaya is highly correlated with the level of total phenolic compounds. A higher antioxidant activity for yellow and white *S. stellatus* has been reported (Table 10): expressed in μmol g^{-1}, such activity would be 16.8–17.3 μmol g^{-1} for yellow and white varieties (4202.1 and 4336.8 mg trolox g^{-1}) and 11–12.2 μmol g^{-1} (2763.2–3047.1 mg trolox g^{-1}) for the cherry and red varieties. Reported activity for the genus *Vaccinium* (cranberries) is 17.0 μmol g^{-1} at the lowest end of the range, overlapping somewhat the yellow and white *Stenocereus stellatus* varieties.

The level of polyphenolic compounds in pitaya is so high that 100 g of fresh pulp (14% solids in average) can provide up to 9.3% of the antioxidant levels consumed in a Mediterranean diet (average of 2590–3016 mg/person/day), which is traditionally high in antioxidants. The high antioxidant capacity of pitaya has the potential to suppress the effects of free radicals, providing protection against diseases like colon cancer and cardiovascular problems.

Other compounds of interest present in pitaya are the pigments responsible for the bright color of the pulp. Betalains are water-soluble nitrogenated compounds and are divided in two groups: betacyanins (red tones) and betaxanthins (yellow tones). Five types of betalains have been found in pitaya: two betaxanthins and three betacyanins.

Betalains play an important role in the induction of quinone reductase, an enzyme involved in cancer prevention. The antiproliferative effect of betalains in cells of malign melanoma has been reported, and the highest inhibitory effect is obtained with extracts from pitaya skin. Pitaya red pulp has 347.3 mg of total betalains per 100 g of dry sample, while the orange pulp has 215.0 mg (Table 11). Betacyanin contents for red and orange pulps are 286 mg and 47 mg/100 g of dry sample, respectively; the betaxanthin contents are 321 and 267 mg/100 g for the red and orange pulp, respectively. Total betalain content is higher in the red pulp.

Table 11 Betalains content within different pitaya cultivars (*S. griseus*)

Species	*Variety*	*Total betalains (mg/100 g dry sample)*	*Betacyanin (mg/100 g dry sample)*	*Betaxanthin (mg/100 g dry sample)*
S. griseus[a]	Red	347.3 ± 21	199.6 ± 24.3	147.6 ± 18.2
	Orange	215.0 ± 36.2	37.6 ± 7.5	177.4 ± 30.2
S. pruinosus[b]	Red	610.0 ± 100.0	286.0 ± 38.0	321.0 ± 56.0
	Orange	310.0 ± 40.0	47.0 ± 22.2	267.0 ± 27.0

[a]García-Cruz et al. (2012).
[b]García-Cruz et al. (2013).

The content of betalains in pitaya is significantly lower than in beetroot (*Beta vulgaris*). Total betalains in beetroot are 1227 mg/100 g of dry sample, where 788 mg corresponds to betacyanins and 438 mg to betaxanthins. This represents two to four times higher concentrations of betalains than red and orange pitaya, respectively. Nevertheless, from all cacti, pitaya has the highest betalain concentration. Combined with its agronomic characteristics (efficient land and water use), pitaya is a very advantageous crop for regions with high hydric stress and where arid and semiarid climates are predominant.

In summary, the level of phenolic compounds is highly related to their antioxidant capacity ($R^2 = 0.97$). In the case of pitayas, their content of phenolic compounds puts them on a level similar to some berries from the genus *Vaccinium* and, equally, can be similarly considered as functional foods. In addition to the advantages of pitaya in terms of its nutritional qualities, from the sustainable agriculture perspective, this native crop represents an alternative use of idle land with minimal maintenance and water requirements.

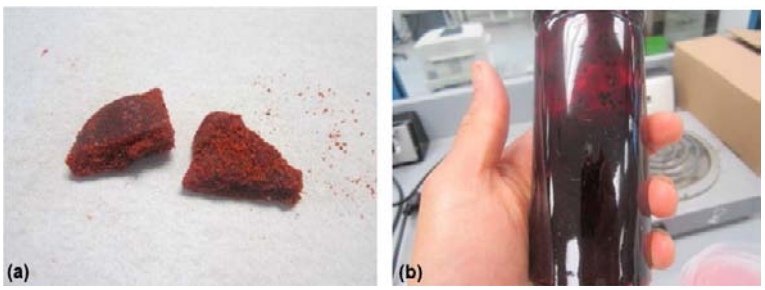

Figure 6 Products obtained from pitaya fruit (*Stenocereus* spp.). (a) A traditional Mexican candy and (b) pitaya jam.

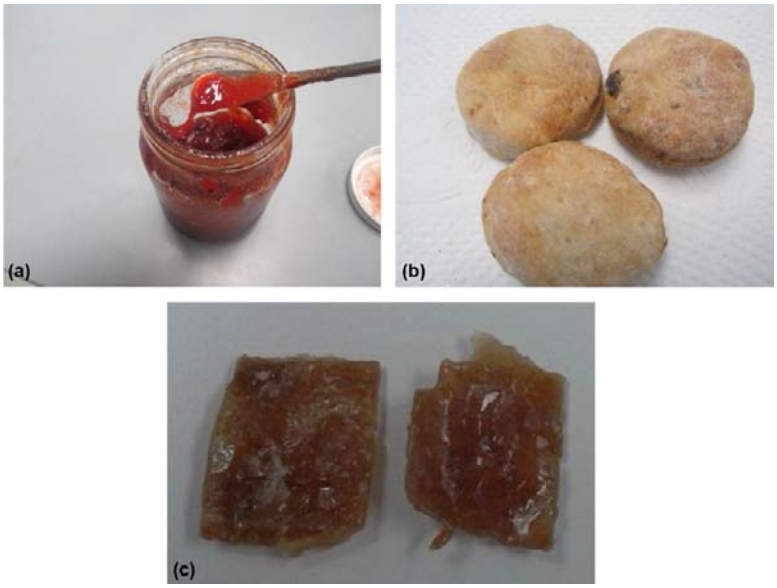

Figure 7 Products obtained with skin or pitaya peels: (a) jam, (b) cookies, and (c) candies, crystallized pitaya skins.

Uses and Commercialization

In some countries like Mexico, pitaya is consumed just as a fresh fruit; however, it can be processed for foods such as jams, frozen pulp, drinks, and ice cream (**Figure 6**). In some areas of Mexico, an alcoholic beverage, called 'ponche,' is traditionally made using underripe fruits mixed with sugar and mezcal.

Fresh pitaya fruit is highly appreciated in exotic fruit markets; however, its short shelf life presents a challenge for postharvest treatments. There are not only proposals for the consumption and industrial utilization of the pulp but also innovative designs to include the pitaya skin or residues in new products, thus supporting local producers (**Figure 7**). Despite the efforts, the pitaya is still mainly commercialized in traditional and local markets only as a fresh fruit, but the antioxidant compounds are an excellent opportunity for its development as a functional food in the international market.

Pituitary Gland: Pituitary Hormones

M Emerald, Phytoceuticals International, London, ON, Canada

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Along with the nervous (central nervous system (CNS)) and circulatory systems, the endocrine system coordinates and integrates a huge variety of vital body functions. The blood circulation is a main carrier for the hormones' distribution to target tissues. The *neurosecretory* cells of the hypothalamus produce and release the *neurohormones* that through the anterior and posterior lobes of the pituitary gland (PG) stimulate the synthesis and secretion of different hormones into the bloodstream, which regulate and maintain the control of the adrenal and thyroid glands and gonads through the cascade of complex neuroendocrine feedback and a number of neuronal peripheral mechanisms. The focus of this article is the organization of the PG, the major elements of the neuroendocrine pathways, and the role of the PG in the control and modulation of a variety of vital body functions.

The Brief History of the PG

The first historical description of the PG (hypothesis) was provided by Galen (AD 150) who proposed the potential role for the found anatomical structure as a draining passage for the phlegm from the brain to the nasopharynx. In 1742, Joseph Lieutaud discovered the pituitary–portal blood system (hypothalamic–hypophyseal axis), and Saucerotte was the first to describe acromegaly in 1772. The gland was for the first time fully described in 1778 by Soemmering and called 'hypophysis cerebri.' The anatomical formation of the PG was described by Rathke in 1838. The posterior part of the PG was investigated by Oliver and Schafer in 1895 and by Dale in 1906, who discovered the vasopressor and oxytocic activities of the posterior pituitary, showing antidiuretic and galactokinetic properties. The first solid description of the clinical symptoms and pathology of the PG was provided by Minkowski in 1887 and Vassale and Sacchi in 1892, who demonstrated that surgically removing the PG (hypophysectomy) causes irreversible change on the water and mineral metabolisms of the body, and it also has been stated that overdevelopment and hyperfunction of the PG cause acromegaly. The first experimental links between the reproductive organs and PG were demonstrated via hypophysectomy leading to dwarfism in growing animals in 1909, by Aschner, and by Cushing in 1910.

Development and Basic Anatomy of the PG

Development

Complex development of the PG is occurring at the early stage of embryogenesis and linked to that of the forebrain. The PG contains three lobes that have dual embryonic origins: *anterior lobe* (*adenohypophysis*), *intermediate lobe* derived from Rathke's pouch (the primitive pharynx), and *posterior lobe*, which develops from the infundibulum (a stalk derived from the region of the ventral diencephalon). The anterior pituitary lobe (adenohypophysis) and posterior pituitary lobe (neurohypophysis) both develop from Rathke's pouch. During the development anterior pituitary loses contact with the oral cavity and the posterior pituitary stays connected with the base of the hypothalamus. Adenohypophys and neurohypophysis basically are joined together in the sella turcica (turkish saddle) at the base of the middle cranial fossa. The forming of the anterior pituitary (*adenohypophysis*) primordium is controlled by a complex signal emanating from the ventral diencephalon/infundibulum and from Rathke's pouch, and after that, Rathke's pouch forms a sac that differentiates and forms the *adenohypophysis*, connecting to the hypothalamus via stalk. The molecular nature of extrinsic signals and especially *transcription factors/morphogenes* that are involved in the patterning of many other organs, lineage specification, and cell type-specific gene expression in pituitary organogenesis has been recently investigated. The *ectodermal primordium* of Rathke's pouch is found to be induced by two major signals emanating from the diencephalon: *BMP4* (bone morphogenetic proteins), inducing the formation of the pouch rudiment, and *FGF8* (fibroblast growth factor), activating the key regulatory gene and development of the rudiment into a Rathke's pouch. Highly regulated gene expression of the controlling processes of cell proliferation and appearance of specific transcription factors allow the formation of gland cell types. A human PG embryogenesis and forming of the neuronal posterior pituitary and nonneuronal anterior pituitary tissues are usually complete at 12 weeks of gestation.

Basic Anatomy of the PG

The PG, which is a relatively small anatomical structure that is situated deep within the head, at the base of the skull, deep in the pit of the sphenoid bone, is surrounded by the optic chiasm, blood vessels, and other important brain structures. It consists of the larger part (80% of the PG size) called *anterior pituitary lobe* (*adenohypophysis*), *intermediate lobe*, and *posterior pituitary lobe* (or neurohypophysis), connected to the hypothalamus by the pituitary stalk. The adenohypophysis is composed of (a) *pars distalis*, containing epithelial cells surrounded by capillaries and fibers, with the cells being divided into *acidophils* (predominantly located in the lateral part of the lobe), *basophils* (concentrated in the central portion of the pars distalis), *chromophils*, and *chromophobes*, (b) *pars intermedia*, and (c) *pars tuberalis*. Acidophils consist of somatotrophs which produce growth hormone (GH), mammotrophs which produce prolactin (PRL), basophils consist of gonadotrophs which produce follicle-stimulating hormone (FSH), thyrotrophs which produce thyrotropin releasing hormone (TSH), and corticotrophs which produce adrenocorticotropic hormone (ACTH). Cromophils consist of cytoplasm

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00548-1

with a large number of secretory granules in difference from chromophobes which consist of cytoplasm with no secretory granules. *Pars intermedia* is located between the *pars distalis* and *pars tuberalis* and contains small basophilic cells. *Pars tuberalis* is a part of the adenohypophysis around the *infundibulum*, composed of basophilic cells that secrete gonadotrophs (luteinizing hormone (LH) and FSH). The adenohypophysis is responsible for the majority of the signaling hormones released into the bloodstream through the well-developed hypothalamic–-hypophyseal portal capillary system that drains into hypothalamic–hypophyseal portal veins (Figure 1(a) and 1(b)). The posterior pituitary lobe (or neurohypophysis, consisting of three distinct regions: *pars nervosa* (posterior lobe, which includes Herring bodies and *pituicytes*), *infundibulum* (pituitary *stalk*, which connects the hypothalamic and hypophyseal systems), and median eminence (ME) (which is included as part of the posterior pituitary). The pituitary stalk contains the fibers of the neurohypophysis connecting the posterior lobe to the supraoptic nucleus (SON) and paraventricular nucleus (PVN) of the hypothalamus and the portal venous system, transmitting hypothalamic peptides that control anterior lobe secretion.

The pathology of the PG leads to the development of symptoms dependent on its change of secretion or symptoms dependent on the new anatomical intracranial relations that arise (lesions, tumors, etc.). It has been found that lack of balanced PG hormonal secretion could lead to *acromegalic gigantism* (first time described by Pierre Marie in 1886), *dwarfism*, Frohlich's disease (dystrophia adiposa genitalis), acute pituitary insufficiency (causes fevers and toxemias), and polyglandular syndrome (autoimmune disease leading to inflammation, lymphocytic infiltration, and partial or complete

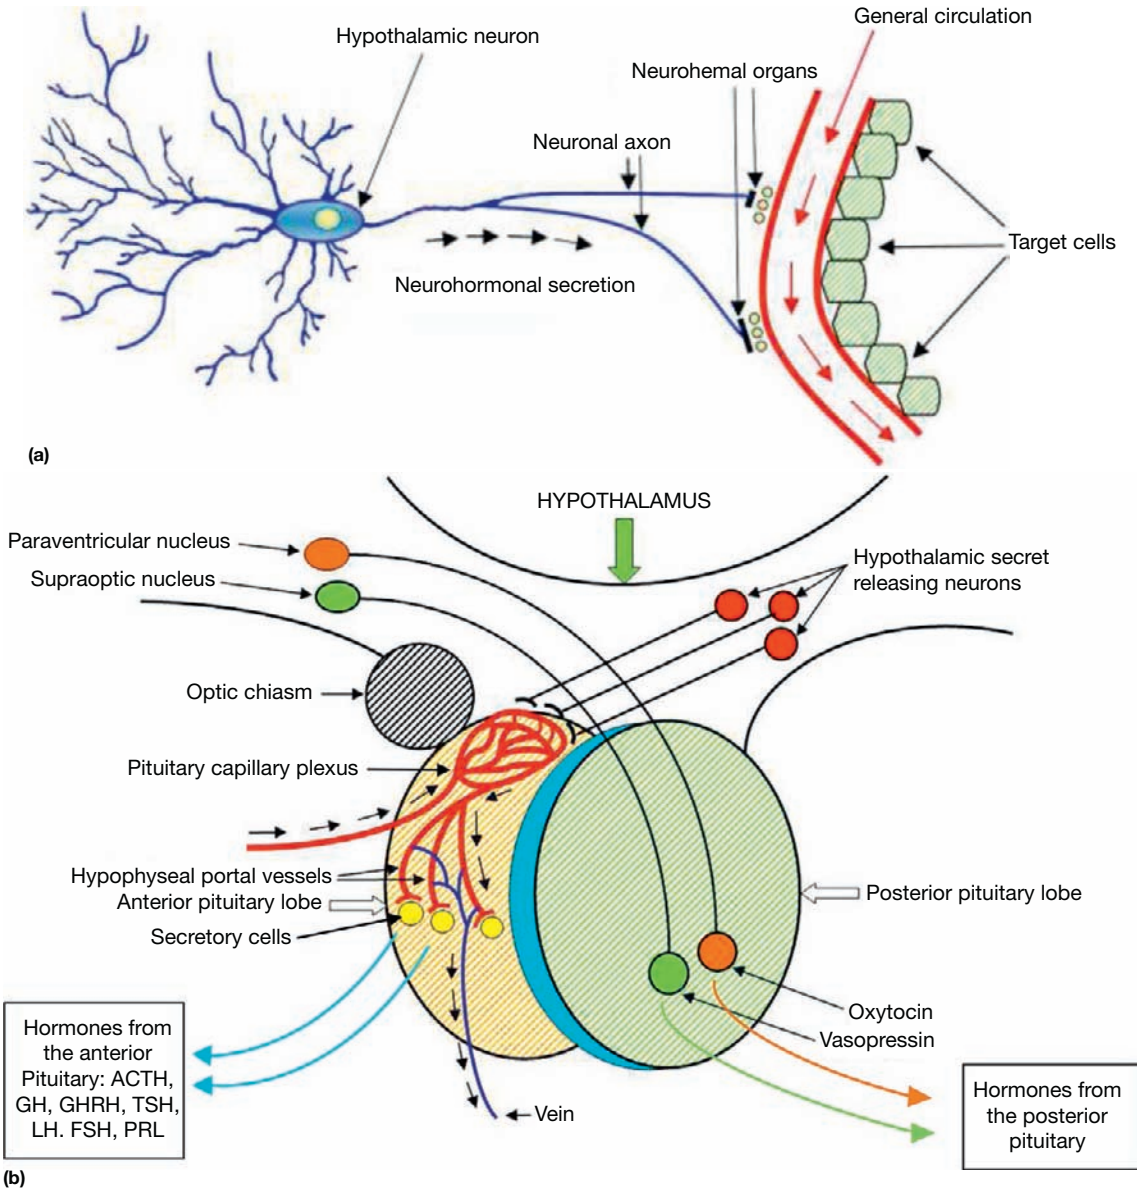

Figure 1 (a) The release of neurohormones from neurosecretory neurons. (b) Hypothalamic–hypophyseal (HPH) axis: hormones of the mammalian pituitary gland. Copyright @ by Dr. M. Emerald, 2015.

gland destruction). The typical anatomical pathology of the PG is a tumor (Cushing's disease) indicative of increased intracranial pressure causing headache, vomiting, vision impairment, nausea, and partial blindness, with main symptoms such as weak immune system, osteoporosis, extreme hair growth on face, fatigue, and cognitive dysfunctions.

Neuroendocrine Pathways

The proper function of the PG is regulated by the hypothalamus releasing *trophic factors* that modulate cell proliferation, hormone synthesis, and secretion. The hypothalamic–pituitary axis represents a complex organization of interactions between the hypothalamus and pituitary and major endocrine glands that regulate a wide variety of the vital body processes via hormones and neurotransmitters. The neuroendocrine pathways are a basic core of the human neuroendocrine system that controls and modulates the adaptation of organisms to changes in the internal or external environment, homeostasis, hormonal and nervous system activities, energy release, mood, the immune and digestive systems, sexual functions, our reaction to stress, etc. The pathology of the neuroendocrine pathways contributes to the manifestation of many chronic diseases. The neuroendocrine pathways are the core part involved in the regulation and control of the (a) hypothalamic–pituitary–adrenal axis (HPA axis, or limbic–hypothalamic–pituitary–adrenal axis), (b) hypothalamic–pituitary–thyroid axis (HPT axis), and (c) hypothalamic–pituitary–gonadal axis (HPG axis, or hypothalamus–pituitary–gonadal–liver axis, typical for females when chorionic proteins such as *vitellogenin* and *choriogenin* synthesized in the liver are vital for the growth and development of *oocytes*).

The HPA axis plays an important role in the regulation of digestion, immune response, response to 'social and physical stress,' mood, energy storage, and the development of anxiety, depression and insomnia, borderline personality disorder, bipolar disorder, posttraumatic stress disorder, Attention-deficit hyperactivity disorder (ADHD), chronic fatigue syndrome (CFS), irritable bowel syndrome (IBS), and other pathological conditions. Produced by the PVN of the hypothalamus, corticotropin-releasing hormone (CRH) and vasopressin (VP) stimulate the release of stored ACTH (from *corticotroph* cells of the *adenohypophysis*) transported by the blood to the adrenal cortex of the adrenal gland, where it stimulates *cortisol* production, which is a main stress hormone.

The HPT axis is responsible for growth, reproduction, intelligence, and regulation of metabolism. The hypothalamus produces and releases thyrotropin-releasing hormone (TRH) in response to low circulating levels of triiodothyronine (T3) and thyroxine (T4) hormones in the blood, which is a part of the negative feedback loop and hypothalamus and anterior lobe of the PG controlling the release of both TRH from the hypothalamus and thyroid-stimulating hormone (TSH) from the adenohypophysis. The HPG axis plays a critical role in the development, regulation, and proper functioning of the reproductive and immune systems and regulation of life cycle, menstrual cycle, behavior, and sexual dimorphism and aging. The importance of the neuroendocrine pathways and hypothalamic control of the endocrine functions is impossible to underestimate, and it has a long history of experimental research. 'Hypothalamic releasing factors' or 'releasing hormones' were introduced to the world in 1905 and in 1936. Marshall proposed an involvement of the brain in controlling pituitary functions, which was proved later using a variety of morphological and functional methods. It has been demonstrated that growth hormone (GH), ACTH, PRL, and TSH were stored in separate special types of cells that actually showed immunoreactivity for both LH and FSH. The classical description of the hormonal function based on their ability to be basically 'chemical messengers' discharged from different glands via endocrine secretion, following release into the bloodstream and targeting specific tissues reacting on their small concentrations, was significantly extended with time. The process of hormonal regulation was suggested to include two main important processes: neuroendocrine regulation, with a control of the hypothalamus over the PG (characterized by quick response, localized effect, and short duration), and endocrine regulation (characterized by slower development but prolonged effect widely distributed through the body). The mechanism of central neuroendocrine regulation is based on neuronal connection between the neurosecretory cells of the hypothalamus, which translate neural signals into chemical stimuli by producing neurohormones that are passed through the neuronal axons and released into the bloodstream at *neurohemal* organs (specific region where axon endings contact with blood capillaries) (**Figure 1(a)**). The *neurohormones* belong to a group of peptide hormones which consist of short or polypeptide chains, such as antidiuretic hormone (ADH) and oxytocin (OT), small proteins such as Growth Hormone (GH), or large glycoproteins, such as follicle stimulation hormone (FSH). The releasing or release-inhibiting hormones synthesized by neurons of the supraoptic, paraventricular, periventricular, and arcuate hypothalamic nuclei projecting their axons into the tuberoinfundibular tract are a major force driving the secretion of anterior pituitary hormones (**Figure 1(b)**). The neurohormones are produced and released by the different hypothalamic nuclei: CRH, prolactin-releasing hormone, and prolactin-inhibiting hormone are synthesized and secreted by PVN neurons of the hypothalamus, somatostatin (GHIH) is synthesized and secreted by cells of the periventricular nucleus (which is a layer of nerve cells adjacent to the third ventricle), growth hormone-releasing hormone (GHRH) is synthesized and secreted by the arcuate nucleus, gonadotropin-releasing hormone (GnRH) is synthesized and secreted by the medial preoptic area and in the arcuate nucleus, and TRH is synthesized and secreted by the neurons of preoptic nucleus and PVN of the hypothalamus (**Figure 2**). Hormones released from the different hypothalamic nuclei cause specific effects on the hormones of the PG and represent the important 'driving part' of the complex neurohormonal 'positive' and 'negative' feedback loops, which regulate multiple endocrine and physiological functions (**Table 1**). The regulatory pathways of the HPA axis are a great example of self-regulating neuroendocrine feedback loops (**Figure 2**). The PVN of the hypothalamus initiates the glucocorticoid secretion of CRH and arginine vasopressin (AVP), which activate the stimulatory circuit. CRH and AVP are released into the anterior pituitary lobe portal circulation at the ME and stimulate the secretion of ACTH (corticotropin), which stimulates the synthesis and secretion of cortisol at the adrenal cortex, which has transsynaptic negative feedback inhibition of the HPA axis at the

Table 1 Hypothalamic releasing factors and their effect on the anterior pituitary hormones

Hypothalamic releasing hormone	*Effect on pituitary gland*
Gonadotropin-releasing hormone (GnRH): Stimulated by estrogen and inhibited by high levels of testosterone and progesterone	Stimulates LH and FSH secretion
Thyrotropin-releasing hormone (TRH): Stimulates to produce and secrete thyroid-stimulating hormone (TSH)	Stimulates TSH, GH, and prolactin secretion
Growth hormone-releasing hormone (GHRH): GHRH inhibited by high levels of somatomedins	Stimulates GH secretion
Corticotropin-releasing hormone (CRH): Stimulated by low levels and inhibited by high levels of glucocorticoids	Stimulates ACTH secretion
Prolactin-releasing hormone (PRH): Inhibited by high levels of prolactin	Stimulates PRL secretion
Prolactin-inhibiting hormone (PIH): Stimulated by high levels of prolactin	Inhibits PRL secretion
Somatostatin (GHIH): GHIH stimulated by high levels of somatomedins	Inhibits GH and TSH secretion

LH, luteinizing hormone; FSH, follicle-stimulating hormone; TSH, thyroid-stimulating hormone (thyrotropin); GH, growth hormone; ACTH, adrenocorticotropic hormone (corticotropin); PRL, prolactin.

different brain levels, and induces epinephrine and norepinephrine from the adrenal medulla. Cortisol, epinephrine, and norepinephrine stimulate immune responses at low concentration and suppress at high concentration. They also found a positive feedback loop between the HPA axis and locus coeruleus norepinephrine cells of the sympathetic nervous system (the brain stem), which is stimulated by stress (Figure 2). One of the examples for other feedback loops is PRL secretion, which is depressed by the adrenal steroids as a result of inhibition of CRH release and a reduction in ACTH secretion by the anterior lobe of the PG and inhibited by dopamine release, which is stimulated by TRH. The direct endocrine regulation is based on the hormone synthesis and release from the adenohypophysis through the portal vascular system. Via 'lock and key' mechanism, hypothalamic hormones can bind to a specific glycoprotein containing receptors on the anterior pituitary cells, which have hundreds of thousands of receptors for one type of hormone. When there is too high level of circulating hormones, cellular receptors reduce their sensitivity ('downregulation'), and if there is too low level of circulating hormones, cellular receptors increase their sensitivity when there is an excess of the specific hormone in the blood ('upregulation'). The hypothalamic secretion is a complex mechanism controlled by multiple stimuli including neural (olfaction, pain, stress, etc.), hormonal feedback, and chemical stimuli (electrolytes, water concentrations in the blood, osmotic pressure, temperature, plasma glucose, etc.). Some of the neurohormones are found not only in the hypothalamus but also in other parts of the body, where they are acting as neurotransmitters and play an important regulatory role. For example, somatostatin (GHIH) is found in the pancreas, where it acts as an inhibitor of the release of insulin and glucagon, and in the gut as well.

Hormones of the Adenohypophysis

The different cells of the adenohypophysis synthesize and release into the bloodstream vital endocrine hormones such as ACTH (secreted by corticotrophs), TSH (secreted by thyrotrophs), FSH (secreted by gonadotrophs), LH (secreted by gonadotrophs) in females also known in males as interstitial cell-stimulating hormone, growth hormone (GH, secreted by somatotrophs), GHRH (secreted by somatotrophs), PRL (secreted by lactotrophs), and melanocyte-stimulating hormone (α-MSH, secreted by melanotrophs). All those hormones can be classified into three major groups: *glycoproteins* (TSH, LH, and FSH composed of a common α-subunit and a hormone-specific β-subunit), growth hormones (GH and GHRH), and *proopiomelanocortins* (α-MSH, regulating the production and distribution of melanin by melanocytes) (Figure 3).

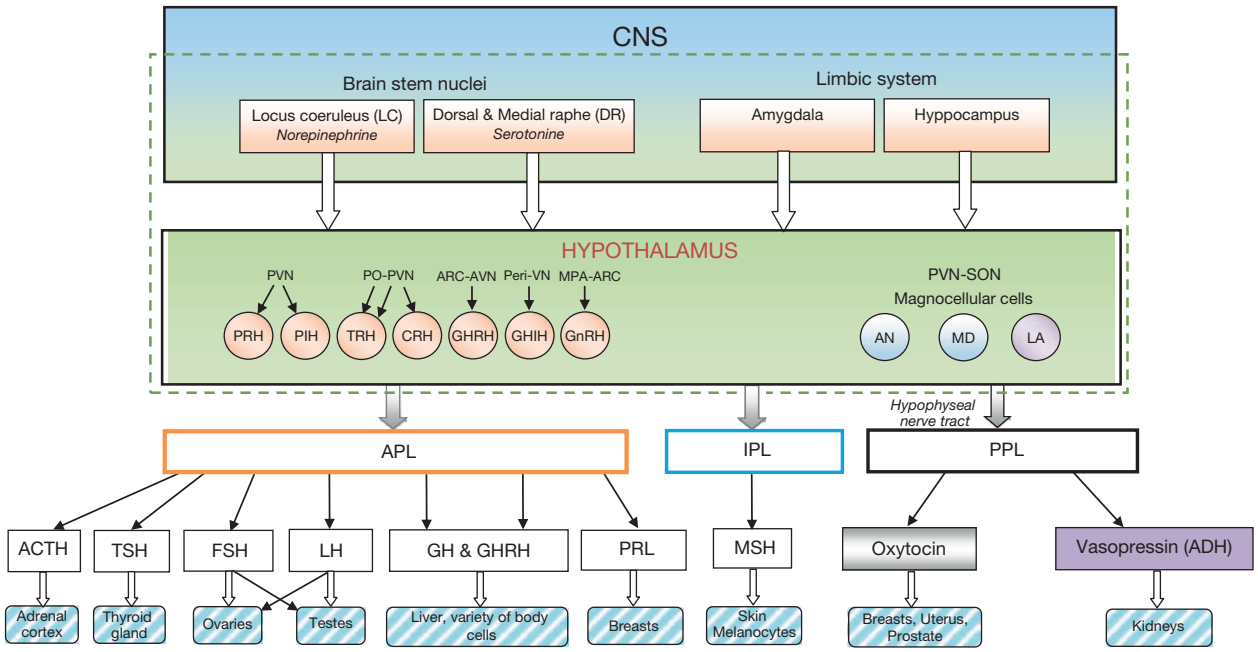

Figure 3 CNS–hypothalamus–pituitary gland diagram. AN, anterior part of the magnocellular division; MD, medial part of the magnocellular division; LA, lateral part of the magnocellular division; CNS, central nervous system; APL, anterior pituitary lobe; IPL, intermediate pituitary lobe; PPL, posterior pituitary lobe; PVN, paraventricular nucleus of hypothalamus; ARC, arcuate nucleus; AVN, adjacent ventromedial nucleus; SON, supra optic nucleus of the hypothalamus; Peri-VN, periventricular nucleus of the hypothalamus; MPA-ARC, medial preoptic nucleus and arcuate nucleus of the hypothalamus; PO, preoptic nucleus of the hypothalamus. Hormones released by the parvocellular neurosecretory cells: PRH, prolactin-releasing hormone; PIH, prolactin-inhibiting hormone (dopamine); TRH, thyrotropin-releasing hormone; CRH, corticotropin-releasing hormone; GHRH, growth hormone-releasing hormone; GHIH, somatostatin (growth hormone-inhibiting hormone); GnRH, gonadotropin-releasing hormone. Hormones released by the anterior part of the pituitary gland: ACTH, adrenocorticotropic hormone (corticotropin); TSH, thyroid-stimulating hormone (thyrotropin); FSH, follicle-stimulating hormone; LH, luteinizing hormone; GH, growth hormone; GHRH, growth hormone-releasing hormone (somatoliberin); PRL, prolactin; MSH, melanocyte-stimulating hormone; ADH, antidiuretic hormone (vasopressin). Adrenocorticotropic Hormone

The properties of ACTH were discovered in 1933 by J. Collip, H. Evans, and B. Houssay. ACTH is based on 241 amino acids and was isolated first in 1943 and synthesized in 1963. The mass production of ACTH for medicinal use and reduction of inflammation and swelling started during World War II. In 1950, Hench and Kendall received the 1950 Nobel Prize in physiology or medicine for their discovery and successful use of ACTH in treating arthritic patients. Presently, ACTH is intensively used for diagnostics of the adrenal gland disorder, and it is sometimes used to treat inflammatory disorders, such as arthritis, ulcerative colitis, and hepatitis. ACTH stimulates the adrenal gland cortex cells to produce (a) *glucocorticoid cortisol* as a response to low blood glucose and stress, which increase blood sugar by stimulating gluconeogenesis; (b) *mineralocorticoids*, which control vascular volume and serum electrolyte (Na^+ and K^+) concentrations; and (c) *aldosterone* and *androgen* (male sex hormones and testosterone). On the adrenocortical cells, ACTH binds to the melanocortin 2 receptor (MC2R) in the middle zone of the adrenal cortex, causing three phases of effects: *immediate effect*, which leads to increase in pregnenolone levels; *chronic effect*, occurring during several hours; and *trophic effect*, occurring during a period of weeks and months. It is well known that cortisol plays an important role in maintaining immune homeostasis; the balance of fat, protein, and carbohydrate metabolisms; increasing bone resorption; decreasing the function of the reproductive axis at the hypothalamic, pituitary, and gonadal levels; inhibiting fibroblast proliferation and collagen formation; increasing the glomerular filtration rate by increasing cardiac output and acting on the kidney; causing muscle weakness and pain due to hypokalemia, which has a trophic effect on the GI mucosa; and stimulating appetite and often causing weight gain. Cortisol also stimulates whole-body lipolysis, an effect that is caused by proportionate stimulation of femoral and abdominal subcutaneous adipose tissues. Through glucagon, cortisol affects liver and muscle glycogenolyses and is usually inactivated in the liver and excreted in the urine. Overproduction of ACTH could be a result of Cushing's disease, which is one of the causes of Cushing's syndrome (characterized by abnormally high levels of the hormone cortisol), which is a result of the excessive production of ACTH by a noncancerous adenoma (tumor) of the anterior lobe of the PG or in the lungs and adrenal gland as well. The overproduction of ACTH stimulates the adrenal glands to produce excessive amounts of cortisol. The genetic mechanism plays an important role in a significant fraction of cases of Cushing's syndrome, which provides a great and reliable diagnostic tool and may also lead to new types of treatment. Underproduction of ACTH leads to a poorly functioning adrenal gland or Addison's disease due to insufficient production of cortisol (*hypocortisolism*). The pseudo-Cushing's disease is usually caused by prolonged taking of steroid medications (such as prednisone) used to treat asthma, lupus, rheumatoid arthritis, alcoholism, and depression.

Melanocyte-Stimulating Hormone

The α-MSH, in which the main functions are mediation of immunity and inflammation, is produced and secreted by the anterior pituitary corticotrophs involved in the synthesis and secretion of ACTH as well, and their chemical structure is similar. In spite of the fact that ACTH demonstrates some MSH-like activity, α-MSH does not share any of the actions of ACTH at all. α-MSH consists of 13 amino acids and can bind with various affinities to five MCRs that are believed to be involved in regulating pigmentation and inflammation, sexual behavior, appetite regulation (appetite suppression), exocrine function and energy homeostasis, and pathogenesis of restless legs syndrome via stimulation of motor activity and increasing body movements in sleep. The main function of the α-MSH (regulating pigment (melanin) production in the skin) is based on binding α-MSH with the MC1Rs on melanocytes and the involvement into the complex signaling cellular pathways through activating adenyl cyclase via G protein signaling, leading to an increase in intracellular cAMP. It stimulates a cascade reaction inducing stimulation tyrosinase synthesis, and increase in the catalytic efficiency of the enzyme. a-MSH triggers the synthesis of cAMP, which initiates the pigmentation process and stimulates the synthesis of melanin granules and their disposal in melanosomes transferred from the dendrites of the melanocytes to nearby keratinocytes. The granules are released and spread to form a protective pigmented barrier over the nucleus to protect the DNA against damage by ultraviolet radiation (UV). α-MSH also plays an important role in enhancing the repair of DNA damage and reducing the generation of free radicals, which both are important in reducing the risk factors for some types of skin cancer. After UV-R exposure, melanocytes increase the proopiomelanocortin (POMC, the precursor of MSH), melanocortin 1 receptor (MC1-R), TYR and TYRP1, protein kinase C (PKC), and other signaling factors' production, as well as endothelin-1 (ET-1) production by keratinocytes. Many factors, including fibroblast growth factor (bFGF), nerve growth factor (NGF), endothelins, hepatocyte growth factor (HGF) and others are involved in iregulating melanogenesis and melanocyte dendrite formation. Keratinocytes produce and release NGF involved in regulating the melanogenesis and dendritogenesis of melanocytes. α-MSH demonstrates a great spectrum of antimicrobial, antipyretic, immunomodulatory, and anti-inflammatory properties. α-MSH was found to be elevated in the plasma of HIV-infected patients, and during sepsis syndrome, the concentrations of α-MSH were reduced. A significant number of independently conducted studies have demonstrated the antimicrobial activity of α-MSH and its C-terminals (containing Lys–Pro–Val) against a wide range of microorganisms including *Candida albicans*, *Candida vaginitis*, *Cryptococcus neoformans*, *Staphylococcus aureus*, and *Escherichia coli* by inhibition of the formation of the germ tube via increasing the level of cAMP (damaging the membrane of the microorganisms) and through anti-inflammatory action of carboxy-terminal tripeptide (KPV). The increase in α-MSH production was reported not only following UV light exposure but also after injury, trauma, and infection and in patients with psoriasis and inflammatory skin conditions. A higher concentration of α-MSH occurred in the synovial fluid of patients with *juvenile arthritis*, acute myocardial infarction, and CFS. α-MSH deficiency is noticed in the early stages of Alzheimer's disease, early-onset obesity, adrenalin sufficiency, and pigmentation alteration, and α-MSH could be used as a potential agent for the treatment of

inflammatory, autoimmune, and allergic diseases, and its analogs could have therapeutic value due to their anti-inflammatory actions in the vasculature in cardiovascular diseases. α-MSH has effects on the MC1R-expressing monocytes, dendritic cells, and macrophages via downregulation of the proinflammatory and immunomodulating cytokine production and demonstrates potent capacity to modulate the function of antigen-presenting cells; α-MSH should be considered and investigated further.

Thyroid-Stimulating Hormone

Thyrotropin, or TSH, is a glycoprotein secreted by the basophilic thyrotrophs of the anterior lobe of the PG, and its secretion is regulated by the negative feedback of thyroid hormones. TSH consists of an *alpha* molecular subunit that is chemically identical to human chorionic gonadotropin hormone (GH), LH, and FSH; the *beta* subunit determines the function of the hormone. TSH is a member of the glycoprotein hormone family, which is structurally classified as a part of the CKGF superfamily of structurally related proteins with very important biological activities. TSH controls the production and secretion of the thyroid hormones, T4 and T3, by the thyroid gland, which are released into the bloodstream and control the body's metabolism, brain development and state (decreased and increased concentrations of thyroid hormones lead to alterations in mental state), bone development, heart (increases heart rate, cardiac contractility, and cardiac output), digestive functions, reproductive system (normal reproductive behavior and physiology are dependent on having essentially normal levels of thyroid hormone), etc. TSH enters the cells through membrane transporter proteins using ATP hydrolysis or other carriers and binds to specific receptors (there are the multiple forms of thyroid hormone receptors). The TSH, which activates the secretion of the hormone T4 via binding to transmembrane G protein-coupled receptors on the surface of the cells of the thyroid gland, is stimulated by TRH but inhibited by somatostatin released from the hypothalamus. The hormone–receptor complex interacts with specific sequences of DNA, which gives an opportunity to modulate gene expression by stimulating or inhibiting the transcription of specific genes. Inappropriate levels of TSH hormone can be caused by problems in the pituitary or thyroid gland itself and can result in different pathological conditions and autoimmune diseases, such as Hashimoto's *thyroiditis* (when the body itself produces antibodies destroying the thyroid gland), which could lead to *vitiligo* (chronic skin disease characterized by part of the skin losing their pigment). More than 2 billion people worldwide suffer from hypothyroidism, which is a result of pituitary and hypothalamus problems and iodine deficiency. Severe hypothyroidism sometimes can develop in people exposed to physical stresses, infections, cold temperatures, and trauma and lead to myxedema coma with loss of consciousness, inhibited breathing, and seizures. Hypothyroidism may be associated with incident coronary heart disease (CHD), especially in men, independently of conventional cardiovascular risk factors. Hyperthyroidism is a main cause of Graves' disease (when the immune system produces an antibody that stimulates the entire thyroid gland) and toxic goiter or toxic thyroid adenoma. It has been shown that higher TSH levels are associated with risks of thyroid tumors (papillary, follicular,anaplastic, and medullary), especially in advanced tumor stage. The ectopic TSH-secreting pituitary adenoma (TSH-oma) has been shown to raise levels of TSH as well as free thyroxine.

Follicle-Stimulating Hormone and Luteinizing Hormone

In females, the FSH assisted by LH stimulates the release of estrogen and is activated by GnRH released by the hypothalamus. In males, the FSH activates *spermatogonia*, which with testosterone input stimulate the production of sperm. In females, LH helps complete meiosis I of the egg and ovulation and stimulates follicles to develop into the *corpus luteum* secreting *progesterone* during the second half of the menstrual cycle. In males, LH stimulates the Leydig cells of the testes to secrete the male sex hormone, testosterone. The release of the regulatory hormones from the hypothalamus to the anterior pituitary lobe and secretion of the anterior pituitary hormones are controlled by negative feedback or classical neuroendocrine loop. When the parvocellular CRH and VP-containing neurons of the PVN of the hypothalamus initiate the glucocorticoid secretion, the anterior pituitary lobe releases ACTH, which promotes the synthesis and secretion of glucocorticoids at the level of the adrenal cortex, which are exerting transsynaptic negative feedback inhibition of the HPA axis at multiple levels in the brain. Low FSH and low LH levels in women are a result of the pituitary or hypothalamic problem leading to ovarian failure. The symptoms of *gonadotropin* deficiency are hot flashes and lack of libido, which cause infertility, amenorrhea (absence of menstruation), or oligomenorrhea (infrequent menstruation) in women and impotence in men, and osteopenia (weak bones), which need hormone replacement therapy (gonadotropin deficiency could be diagnosed in the presence of low or normal LH and FSH). The hypersecretion of LH can lead to polycystic ovary syndrome with typical menstrual irregularities, infertility, acne, and hirsutism.

Prolactin

PRL (luteotropin) is a protein, in which its chemical structure is similar to growth hormone, that is known in three different forms varying in size, and the level of larger ones is higher during early development. PRL is detected in epithelial cells of the mammary gland and in the milk and is produced at the PG, breast, lymphocytes, leukocytes, prostate, and other tissues. In spite of the fact that the main function of PRL is lactation, it also can be an indicator of relaxation and sexual satisfaction. Increased levels of PRL decrease estrogen and testosterone and are responsible for impotence and loss of libido. PRL influences the hypothalamus, decreasing the release of growth hormone-releasing hormone (GnRH) and subsequently LH. PRL stimulates the process of myelin coating formation on axons in the CNS. The role for pituitary and lymphocytic PRL in immune response and in transplant rejection needs further detailed investigation.

Growth Hormone

The main and vital function of the growth hormone (GH) produced by somatotropic cells in the anterior lobe of the PG

is development and growth. The GH synthesis is initiated by the GHRH, secreted by the cellular structure of the hypothalamus called a *porosome*, which induces the production and pulsatile secretion of GH. The GH is traveling via the bloodstream, demonstrates affinity to specific GH receptors on the surface of a large variety of cells, and causes the cellular division of the cartilage, bone, muscles, and other tissues as a result of insulin-like growth factor 1 (IGF-1, somatomedin C) production by the liver. However, the GH production is also inhibited by somatostatin (GHIH) released by the anterior PG, pancreas, and GI tract. The glucocorticoids and IGF-1 are also able to suppress the release of GHRH and diminish the sensitivity of the GHRH receptors. Most of GH's effect occurs through the stimulation of IGF-1 (somatomedin C), primarily by the liver. IGF-1 causes the growth of muscle, bone, and cartilage, protein synthesis, amino acid transportation, DNA and RNA syntheses, and cell proliferation. IGF-1 also suppresses the production of GH as a part of a negative feedback loop. The decreased muscle strength, diminished libido, metabolic disturbances, social isolation, decrease of the bone mineral density (increased total cholesterol, low-density lipoprotein, apolipoprotein B, and triglyceride levels), dwarfism, acromegaly, gigantism, multiple endocrine neoplasia, McCune–Albright syndrome, and neurofibromatosis are the conditions of GH deficiency in adults, often caused by pituitary tumors. The typical symptoms of GH deficiency are carpal tunnel syndrome, weakness, joint pain, fatigue, sleep apnea, enlarged hands and feet, weight loss, etc. The GH deficiency can be evaluated by insulin tolerance and GHRH/arginine test. The growth disorders, which are the result of GH deficiencies, are presently treated by synthetic GH produced by recombinant DNA technology.

Hormones of the Neurohypophysis

The large (magnocellular) neurons located in the SON and PVN of the hypothalamus synthesize and transport along the axons to terminals situated within the posterior lobe of the PG (neurohypophysis) two vital hormones: *oxytocin* and VP (or antidiuretic hormone (ADH)), which are secreted by calcium-dependent exocytosis. The posterior pituitary hormones are transported in association with specific proteins, the *neurophysins*, via the 'unmyelinated' nerve fibers that extend through the infundibulum along with small cells called *pituicytes* to end in nerve terminals that lie within the posterior lobe; prior to secretion, they are stored in secretory granules in the Herring bodies. The oxytocin stimulates contraction of the uterus during labor, prevents posttraumatic hemorrhage, and is involved in lactation and milk ejection from the nipples, sexual arousal, suppressing appetite, etc. Oxytocin is also called the 'love and bonding hormone' that plays an important role in social recognition (especially in trust, empathy, rejection, and suspicions in the group), increasing positive attitudes, the formation and realization of maternal instinct, orgasm, depression and anxiety, wound healing, and soothing inflammation. Oxytocin receptors are expressed by neurons not only in the neurohypophysis but also in the septum, nucleus accumbens, brain stem, amygdala, and other parts of the brain and body. The chemical structure of VP (ADH) is very similar to oxytocin, and this is why oxytocin has mild diuretic properties, and high levels of ADH can cause uterine contractions. The main functions of the ADH are water retention and maintaining normal body fluid volume via specific renal (V2) and vascular (V1) receptors, regulation of body temperature, initiation of aggressive behavior, and male pair-bonding behavior. ADH produces vasodilation in the renal, pulmonary, cerebral, and mesenteric vascular beds by stimulating endothelial nitric oxide (NO) release and increases the systemic blood pressure. ADH is also involved in the modulation of the corticosteroid release from the adrenal gland in response to stress during pregnancy and lactation and also may cause an analgetic (nociceptive) effect during sex and stress. ADH demonstrates anti-inflammatory properties via inhibition of the inflammatory cytokine interleukin-1 released in response to trauma or infection. ADH deficiency, as a result of the hypothalamic–neurohypophyseal lesions or insensitivity of the kidney to ADH in nephrogenic diabetes insipidus, leads to dehydration, diarrhea, hyperosmolality, and eventual death. ADH overproduction promotes excessive water retention and hyponatremia, which may cause convulsions and coma. ADH could be effective in reversing hypotension produced by septic shock and could be a useful therapy for hypovolemic cardiac arrest.

Pineal Gland and Biological Clocks

The human primary circadian 'clock' is located in the hypothalamic pacemaker suprachiasmatic nucleus (SCN), where the information on the lengths of the day and night is passed from the retina to the pineal gland, where the hormone melatonin is secreted with peaks at night and ebbs during the day. The pineal melatonin is rhythmically released onto the SCN, which helps modulate circadian patterns of activity and other vital processes throughout the body. Disruption to rhythms usually has a negative effect and significant adverse health consequences on peripheral organs especially in the development or exacerbation of cardiovascular diseases and greater risks of metabolic syndrome, hypertension, and gastrointestinal disturbances.

Conclusion

Recent advances using a wide range of methodologies provide more detailed knowledge and generate new valuable insights about the cellular, molecular, and genetic mechanisms involved in the anatomy, organization, development, and function of the human PG. The recognition of the fascinating role of the PG and its sophisticated hormonal system, which is a retrograde regulator of hypothalamic and peripheral endocrine functions, raises important questions regarding the extraordinary complexity and vital role of the PG in neuroendocrine regulation of a huge variety of human physiological functions on molecular, organic, and systemic levels that remain virtually not fully explored.

Plums and Related Fruits

S Jayasankar, C Dowling, and DK Selvaraj, University of Guelph-Vineland, Vineland, ON, Canada

Introduction

Plums are one of the ancient and long cultivated fruits and belong to the 'stone fruit' family, which includes peach, nectarine, cherry, and apricots as well. They come in a variety of colors, although red and black are the most common ones seen in the market. Most plums ripen in the summer/fall months due to their production cycle; however, we are currently seeing plums in the market almost year round due to modern storage and shipping worldwide. In addition to being a delicious and juicy dessert fruit, a number of products, both homemade and industrial, are made out of plums, and thus, they find a way in our food system. Information from recent research on their health benefits helps in increasing the consumer interests in plums.

Origin and History of *Prunus* Species

The family Rosaceae includes a number of fruits, including plum and prune, in addition to cherry, apple, nectarine, peach, pear, and several berry crops. In Rosaceae, the genus *Prunus* is an important member to which all the true plums belong. It is estimated that around 200 species of *Prunus* are found predominantly in the northern temperate regions of the world. There are a number of plums, among which European plums (*Prunus domestica* L.) and Japanese plums (*Prunus salicina* Lindl) are the most important. In addition, there are also American plums, damsons, mirabelle plums, myrobalan plums, etc. More recently, there are also a few 'interspecific hybrids,' by crossing plums with apricots or sweet cherries often marketed as Pluots™, Apriums™, or plumcots. The basic chromosome number of *Prunus* species is $x = 8$. While a number of them are true diploids, European plums are hexaploid. The polyploidy species emerged from two more ancient wild plums, which were the diploid cherry plum, *Prunus cerasifera* Ehrh, and the tetraploid blackthorn *Prunus spinosa* L. The product of this crossbreeding was cultivated and propagated and carried westward to Europe and later to other continents by the immigration of Europeans to other countries, including the Americas. Although several opinions are aired regarding the classification and the relationship between various plums, recent molecular evidences suggest that *Prunus* is monophyletic and descended from some Eurasian ancestor. The fruits of this family are rich in polyphenolic components, including anthocyanins, vitamin C, and fiber, which has led to increasing research into the functional properties of these widely consumed stone fruits and berries.

Plums and the related *Prunus* species are important international commodities due to their broad consumer acceptance and a number of value added preparations including canned, dried, and processed for cooking use or occasionally distilled into brandy. Similar to the other stone fruits, the history of prunes dates back thousands of years since prunes were used as a ready snack for centuries. Some varieties of the numerous cultivars were dried and preserved by desiccation in the sun or warm oven for continuous consumption after the harvest season. The virtues of prunes were extolled for its use in aiding digestion and curing mouth ulcers. European plums were introduced only relatively into North America when French horticulturist, Louis Pellier, brought European plums to California in the mid-to-late nineteenth century, resulting in the first-known prune production in North America.

Botany and Horticulture of Plums

Plums are deciduous temperate species and can tolerate zone 2 temperatures. In cultivation, they are grown in subtropic climates and also in higher elevations in the tropics where the temperature goes to near-zero temperatures, required for dormancy of these species. Most of the plums in nature are about 8–10 m tall with occasional spiny stems, although no spines or thorns are usually left in cultivation. The leaves are simple, alternate, elliptic to lanceolate, unlobed with a serrated margin, and often with nectaries on the leaf stalk. The color, size, and texture of the leaves vary slightly between cultivars. Leaves range from light green to dark green when mature and are quite tough and leathery. Young leaves are relatively soft and are often bronze or pale green in color. There are a few genotypes that produce dark, wine red leaves, which are often used as ornamentals. The flowers are mostly white and rarely light pink with five petals and five sepals. There are numerous stamens. Flowers are usually in umbels of two to six or sometimes more on racemes. While the flowers are generally perfect with functional stamen and pistil, incompatibility is very common among plums. The fruit is a fleshy drupe with a single hard-coated seed, often referred to as the stone. The fruit skin colors among Japanese plums are yellow, red, and black with various shades in between. Mostly, they exhibit solid color with some varieties showing mottled or freckled skin. The flesh is usually golden yellow to amber. There are some varieties with dark red flesh as well. Although they are known as 'Japanese plums,' they originated in China, but due to its popularization through Japan, they got the name.

The European plums are native to Eastern Europe around the Caspian Sea area. They are often blue black in color with a strong ashy coating and hence they are referred as 'blue plums.' Some varieties also exhibit green, yellow, and occasionally pink to purple colorations in skin. The flesh of European plums may be green, yellow, to amber brown. Plum fruit is about 5–6 cm in diameter and weighs 70–80 g at maturity. Externally, a central depression is often found at the stem end of the fruit. The fruit pulp is juicy with a sweet, tarty taste and a pleasant aroma. European plums are prone to lower incidences

of frost damage as they bloom later than in the spring than the Japanese plums.

Plums generally propagated by grafting as seedlings are not true to type. Most of the plums are grafted to another plum or a closely related species that provides the root system, called the rootstocks. Traditionally plums have been grafted on another species called myrobalan plums. However, modern plum growing involves a number of other rootstocks developed by breeders to address the industry demands. Japanese plums require a well-drained soil, while European plums can be grown even in fairly heavy soils. Typically, grafted trees are planted in the beginning of spring. Care must be taken to have the graft union at least an inch above the soil. It is important to take the wind direction into consideration as it will greatly aid in pollination as well as tree architecture. As the young trees grow into their second or third year, they are carefully thinned by selectively removing some branches to encourage proper passage of sunlight as the trees get older. This process is called training. The most common method of training for plums is 'open center' where three to four scaffolds are allowed to grow around leaving the central area for smaller branches to fill in. Another method that is popular is the 'central leader,' where a main scaffold grows in the center allowing branches to spread around it. Modern plum cultivation is gearing towards mechanization to facilitate ease of harvest and maintenance, although it tends to be expensive and is not practiced by small growers. Since plums produce copious amounts of branches every year, unwanted branches that would otherwise hinder cultivation practices are often removed in a systematic manner called pruning. Pruning is an annual event that helps to keep the growth to crop load ratio balanced. Pruning is mostly done just at the beginning of spring or in some cases at flowering. Proper training and pruning are the key to maintain the health, productivity, and longevity of the plum trees. It is very important to plant more than one variety of plum as plums are often cross-pollinated and requires a pollenizer. When choosing the pollenizer, only compatible cultivars should be chosen. Compatibility of any plum cultivar should be readily available with the nursery or any regional extension agents.

Production of Plums and Prunes

Although plums are primarily cultivated in the subtropic and temperate regions, there are producer countries across the world. The major prune producers in the world include the United States and France following the predominant production in China, as seen in Table 1. Asia is the largest producer of plums worldwide; North American producers contribute close to 5% of the worldwide average and the United States alone is the second highest exporter of plums and the top exporter of prunes internationally with 28% and 32% of the worldwide average, respectively. In particular, California has become the top producer over the past decade, producing about 67% of the world's dried prune supply, 178 million kilograms of prunes per year (Table 1).

Food and Nutritional Attributes of Plums

Both Japanese and European plums are largely consumed as a fresh fruit, either as a healthy snack or as a dessert. Since they come in a range of vibrant colors, both inside and out, they are preferred in fruit salads and bowls. The sweet and tangy taste of the plums coupled with their unique flavor adds to their food value. Both types of plums are processed into jams, spread, and chutney that are often classified as low-sugar products. Sliced Japanese plums go well in a number of entrées as they add their unique flavor and color to the food. Dried European plums constitute the prunes and hence people refer them as 'prune plums.' Not all varieties of European plums are good for drying and only a few varieties do well for prune making. The term prune is being phased out in favor of 'dried plums,' especially in California, where a study revealed that more than 80% of the respondents in the 25–54 age group preferred the term 'dried plum.' This is largely due to the perception that 'prunes' or prune products such as prune juice are associated with bowel movement and other health issues.

Current consumer appeal of plums is largely attributed to taste, texture, and soluble sugar content. However, plums also have low caloric content and relatively high nutritive value. These fruits contain carbohydrates, including sucrose, glucose, fructose, sorbitol, and isatin, as well as organic acids such as citric and malic acids, in addition to soluble fibers (pectins), tannins, aromatic substances, and enzymes. These substances contribute to nutritive value and taste of plums. The fruits are also high in health-promoting antioxidants such as flavonoids, polyphenols such as anthocyanins, and carotenoids such as cryptoxanthin, lutein, and zeaxanthin. These compounds are known scavengers of oxygen-derived free radicals and reactive oxygen species that are associated with aging and chronic diseases. Zeaxanthin is an important dietary carotenoid that is selectively absorbed into the retina and is considered to provide antioxidant and UV light-filtering properties. Their dried counterparts, prunes, contain significant quantities of soluble fiber in the form of pectin with at least 3 g per 100 g of fruit in a serving, which has been shown to decrease plasma concentrations of cholesterol, possibly through increased bile acid excretion in the feces. Plums are also rich in a variety of mineral and vitamins, including vitamins C, B1, B2, A, and PP, that are essential for certain functions in the human body. The minerals with known recommendations that are present in physiologically significant amounts include iron, magnesium, copper, zinc, manganese, and potassium. Specifically, the amount of iron that is bioavailable is also among the top in fruits and vegetables, which is attributed to the ascorbic acid content in prunes. Although some vitamins are degraded during the dehydration process at high temperatures, such as vitamin C, others may be concentrated by dehydration, resulting in more nutrient density in prunes than plums and other fresh fruits. In addition to vitamin C, a significant contribution may be made by riboflavin, niacin, and pyridoxine, which are present at levels of 10% of the recommended daily intake per serving of prunes. Prunes are one of the richest sources of antioxidants and soluble fibers and hence could qualify very well as a 'super food.'

Table 1 Production of plum crops worldwide in 2011

Country	*Production (tonnes)*	*Area harvested (Ha)*
Africa	324 342	49 751
Asia	7 090 653	1 820 729
Australia and New Zealand	17 686	3361
Europe	2 817 981	526 843
Northern America	562 288	35 491
Oceania	17 686	3361
South America	475 369	44 004
Canada	2464	401

Breeding and Improvement of Plums

Plum breeding or improvement is done largely by publicly funded academic or research institutes in several parts of the world. However, there are a few private breeders who have been successful in developing new and improved varieties as well. Being a perennial crop, breeding and improvement take a long time with much less success rate than other horticultural crops. Unlike several other fruits, a successful pollination can at best result in only one seed in *Prunus*. Hybridization is also dependent on a number of intrinsic factors such as compatibility and extrinsic factors among which weather is a major player. Published records show that plum breeding has been done for at least 150 years now. Among the major countries that are involved in plum improvement are Japan and China in Asia, Eastern European countries, England and Germany in Europe, South Africa and Canada, and the United States in North America. In Australia and South America, plum breeding is more recent and is very limited. It is safe to say that Japanese plum breeding is performed in more places than the European plums, which are currently performed only in a few places.

The general objective of any plum breeding program is to develop a variety that can be successfully grown for that specific locality with good marketability. As for Japanese plums, the focus largely is on fruit quality and their capacity for shipping since most of the Japanese plums are consumed as fresh fruit or in desserts. Since most of the Japanese plums are grown in relatively warmer regions, breeding programs aim for lower chilling requirements for a good production, while varieties developed for the northern latitudes should exhibit sufficient cold hardiness. In regions where several varieties are grown and there is a need to maximize the market potential, breeding cultivars to fit the gaps in the marketing window is often a priority. In addition to these, there are niche markets for certain types of plums that are also addressed in the breeding program. For instance, yellow-skinned Japanese plums such as Shiro and Early Golden or the red-fleshed varieties such as Red Heart and Vampire are preferred in certain local markets, and hence, breeding complementary varieties to these is addressed.

European plum breeding is often oriented towards the end use. Fresh market European plums are often bred with size, shape, and color of both skin and flesh in mind. Uniform-looking plums are preferred by retail markets so that they can be sold as 'club packs.' Often, three to four varieties that look extremely similar but ripen at different times are promoted in a particular region so that the consumers get similar fruits for an extended period. These varieties should be 'free stone' where the seeds (or pit) separate from the flesh easily. Further, such free stone varieties are also preferred for baking purposes where plum halves are often used and also for jam making. A large amount of European plums however goes for prune making and 'prune' cultivars should have a fairly high degree of sugars, have less water at ripening, and be easy to pit. Self-fertility is another factor that is increasingly important that precludes the planting of multiple varieties in a region or that of pollenizer.

Just like any other crop, both types of plums are affected by a number of diseases. Thus, resistance to these diseases is a common thread in any breeding program. Brown rot, a fungal disease caused by *Monilinia fructicola* that can cause serious economic losses, and bacterial spot caused by *Xanthomonas campestris* pv *pruni* are two important diseases for which field tolerance is needed in a good variety. With mechanization on the rise, breeding for tree architecture with smaller, compact trees with less pruning requirements is currently explored. Value addition is an important area that is being addressed in breeding as well. As mentioned earlier, plums are a rich source of beneficial phytochemicals. Tapping into these for marketing purposes is a good strategy in plum breeding, and thus, antioxidant- or nutrient-rich plum varieties can be expected in the market soon.

Related Fruits

A number of other fruits that are closely related to plums are grown and available in the market for various reasons. Some of them are just interesting variants of either Japanese or European plums or some are hybrids – mostly man-made. Among these, the most noteworthy are damsons, plum hybrids, and 'yellow European plums' (or YEPs) (Figure 1). Further, there are several other species of *Prunus* that are closely related to cultivated plums (Table 2).

Damsons

Damsons are often thought as a subspecies of *P. domestica* var. *insititia* or a species itself *P. insititia*. It is thought to have been in cultivation for much longer and is believed to have been brought from Syria to Britain where it gained most popularity

Figure 1 Plums related fruits. Top left – red Japanese plum, top right – yellow Japanese plum, middle left – European plum or blue plum, middle right – yellow European plum (YEP), bottom left – damson, bottom right – interspecific hybrid plumcot.

Table 2 Classification of cultivated plum species based on geographic distributions

Class	Prunus *species*	*Pomological*	*Cultivar*
European/Asian	*P. domestica* L.	Lombards Prunes	Victoria, Pond, Bradshaw D'Agen, Hungarian
	P. domestica var. *italica*	Greengages	Reine claude, Jefferson
	P. domestica var. *intermedia*	Yellow egg	Monroe, Golden Drop
	P. domestica var. insititia	Damsons	Shropshire, Crittenden
	P. domestica var. *syriaca*	Mirabelles St. Julians	Late Mirabelle, Drap d'Or
	P. cerasifera	Myrobalans (cherry plums)	Marianna, Lindsayae
American	*P. americana*	Common wild	
	P. nigra	Wild goose (Chickasaw)	Golden Queen, Cherokee
	P. angustifolia		Crimson, Oxford, Aitkin
	P. munsoniana		Caddo chief, Ogeechee
	P. hortulana		Jewel, Osage
	P. maritime	Beach plums	Golden beauty, Cumberland, Bassett's American, Sisson
	P. subcordata	Pacific Coast plums	
Oriental/Japanese	*P. salicina*	Japanese plums	Early Golden, Shiro
	P. simonii	Apricot plums	Wickson, Climax

in middle age. Stones of damsons have been found in excavation sites in and around Britain confirming its presence in the eleventh to thirteenth centuries. Other than Britain, it is grown sparingly throughout Europe and more so in Eastern European countries and Germany. It is not as popular in other continents including North America, although one can see small stands in these places, often sold in local markets as a niche product. Damsons were grown for their heavy cropping and small fruits with a rich color that were used in a number of ways. Other than the usual jam, jelly, and spreads that can be made out of these sugar-rich fruits, they were extremely coveted for dyeing clothes in those days. Further, the somewhat short and sharp branches made them ideal candidates for hedges and they were also very good as wind breaks. A number of varieties were grown, but Shropshire and Westmorland damsons were among the popular varieties. The damson fruits are quite small −10–15 g and 2.5–3.5 cm long. They are mostly oval with occasional round types in cultivation. There are also other 'fruits' often mixed up with damsons. 'Bullace' and sloe are commonly mixed with damsons. It is accepted that both are *P. insititia*. However, 'bullace' is considered as the wild form and the 'damson' refers to the cultivated form. If the fruits are small and roundish, it is likely to be the wild form as most of the cultivated forms are oval or elliptic. Sloe is another species, *P. spinosa*, and their fruits are probably the smallest of the group. It is very likely that 'sloe' and 'bullace' were hybridized to get some of the modern damsons.

Hybrid Plums

It is not uncommon to see a variety of Japanese plums in the market, especially in the slightly warmer growing regions such as California or eastern United States. Although they are mostly listed as 'plums,' in reality, many tend to be interspecific hybrids. Quite often, such varieties are the result of a cross between *P. salicina* and *P. americana* or *P. simonii*. More recently, there are a lot of hybrids between plum and apricot, originally called as plumcots by Luther Burbank, a renowned breeder of horticultural crops. In the current market, we see a number of hard plums in very unique colors both inside and out, often referred as Pluots® or Apriums® – hybrids between plum and apricots (*P. armeniaca*). Pluots® are more plum than apricot, while Apriums® are more apricots than plums. These were developed in the 1970s and still being continued by a private breeding firm, Zaiger Genetics in California, who have trademarked both the names. More recently, they have also developed NectaPlums, which are hybrids between plums and nectarines (*P. persica*). Most of these have a firm flesh and are fairly large in size and there are several varieties of these in the market.

Yellow European Plums

As mentioned earlier, European plums are generally blue black in color with rare variants of yellow or green color. Some of the earlier off-color varieties include 'greengage' and 'yellow gage,' which are not cultivated extensively. Recently, the plum breeding program in Canada has identified a number of such off types that range widely in color from yellow to green with intermittent pink blush and started calling them YEPs, an acronym for yellow European plums. These types are preferred by consumers as fresh fruit since they are quite sweet and do not have the slightly bitter aftertaste that typical blue plums exhibit due to the presence of phenolics. It was hypothesized that the phenolics may be less in these YEPs, thus making them less bitter. While the blue-black plums are rich in anthocyanins, YEPs may lack the anthocyanins and associated phenolic compounds. However, these YEPs may have more of other flavonoids and thus compensate for the lack of phenolics, and thus, their antioxidant potential is quite comparable to that of regular European plums. It is anticipated that using suitable preservation methods, prunes that are different in color and taste will be developed from these YEPs in addition to being a good fresh fruit.

Future of Plum Cultivation

As consumer awareness toward healthy eating is on the rise, it can be safely said that plum cultivation and availability will be steady in the market. However, changes are bound to happen as the improvement programs are always looking to meet the consumer and marketing demands. Thus, there will be an emphasis on breeding plums that have higher nutritional and health-promoting benefits as well as improved postharvest shelf life, which will help in shipping. With the world looking for continuous changes, newer products such as the interspecific hybrids and YEPs will find a place in the market shelf, while the traditional varieties will still be cultivated and eventually getting 'premium' status. The global push for 'local' foods will help the expansion of plums in wherever possible to attract the local food market. The postharvest treatment and processing of plums is also a critical factor that can help to optimize the quality of the fresh and dried plums. The storage conditions of the fresh fruit are imperative to preserve quality, including optimal temperature and light conditions. The typically cooler temperatures and reduced light conditions favor extended shelf life for both the fresh and dried fruit but may adversely affect the retention of natural phenolic compounds present. Modified atmospheric packaging, which has produced very good effects on retaining heath compounds in a number of fruits and vegetables, may be another area that will boost plums and prunes.

Polycyclic Aromatic Hydrocarbons

G Purcaro, S Moret, and LS Conte, Department of Food Science, Udine, Italy

© 2016 Elsevier Ltd. All rights reserved.

General Overview

Polycyclic aromatic hydrocarbons (PAHs) are a large group of carcinogenic organic compounds, which originated from incomplete combustion or pyrolysis of organic matter. They are formed by two to six fused aromatic rings (linear, cluster, or angular arrangement), and they solely consist of carbon and hydrogen. They can present alkyl substituents, depending on the generating process.

Although the International Union of Pure and Applied Chemistry defined a systematic nomenclature for these compounds, many of them have maintained their common name, reflecting the initial isolation from coal tar (e.g., naphthalene and pyrene), their color (e.g., fluoranthene and chrysene; the latter erroneously, because contaminated with naphthacene, which is orange, when first isolated), and their shape (e.g., coronene and ovalene).

The numbering and naming of PAHs are based on a few basic rules: Rings are drawn with two vertical sides (when possible), with as many rings as possible in a line and the rest of the structure sitting in the top right quadrant; the numbering starts from the first carbon atom not engaged in ring fusion in the right-hand ring and proceeds clockwise; the name of a fused-ring system is made up of a prefix of the fixed part (e.g., benzo) followed by an italic letter denoting the bond of the base (e.g., *a* refer to the 1,2-bond) and the name of the parent compound follows (e.g., benzo[*a*]anthracene reported in Figure 1). A list of the most analyzed ones is reported in Table 1, along with their chemical structure, molecular formula, molecular weight (mw), solubility in water at 25 °C, partition coefficient octanol–water (log K_{ow}), and abbreviation (that will be used all over the chapter).

PAHs are solid at ambient temperature and are the least volatile of the hydrocarbons (the boiling points of the PAH are markedly higher than those of the *n*-alkanes of the same carbon number). Nonetheless, light PAHs (2–3 rings) are present in the environment mainly in the vapor form, while heavier PAHs (more than five rings) are predominantly adsorbed on organic particulate matter, usually on small particles (<2.5 μm); four-ring compounds have an intermediate behavior. The high mw and the absence of polar substituent groups make these compounds very insoluble in water, but the presence of detergent or organic matter causing emulsions in water, or PAHs adsorbed on suspended particles, can increase the content of PAHs in wastewater or in natural waters.

Although PAHs are chemically stable and poorly degraded by hydrolysis, they are susceptible to oxidation and photodegradation, and this behavior is particularly relevant to possible losses during analysis.

Legislation

In the European Union, the necessity of a harmonized European legislation appeared evident after 2001, when a batch of pomace oil entering the Czech Republic was found highly contaminated. Following this event, some states fixed their own limits for PAH contamination in edible oil, mainly considering the 16 PAHs highlighted by the US Environmental Protection Agency (EPA) (called 16 EPA PAHs). These different limits among the European Member states caused several commercial problems.

In 2002, the Scientific Committee on Food (SCF) published an opinion where 15 PAHs, over 33 assessed for toxicity information, were identified as both genotoxic and carcinogenic. Furthermore, BaP was pinpointed as a suitable marker for PAH contamination in food. Subsequent to the opinion, the European Commission (EC) introduced a new regulation (Reg. 208/2005, shortly followed by Reg. 1881/2006) harmonizing the PAH legislation among all the member states and fixing a limit for the presence of BaP only, used as a marker of PAH contamination. The EC also published a recommendation (Rec. 2005/108/EC), requiring all the member states to investigate the presence of the 15 PAHs highlighted by the SCF plus the one (BcF) considered by the Joint FAO/WHO Expert Committee on Food Additives (JECFA) (called the 16 EU PAHs) to review the limits already set and to add new food classes by 1 April 2007. No new limits were set in 2007, but the European Food Safety Authority (EFSA) raised doubts on the suitability of BaP as a marker. In 2008, it was definitely concluded that BaP was not appropriate, while the sum of eight heavy PAHs (PAH8) (BaA, Ch, BbF, BkF, BaP, DBahA, BghiP, and IP) or of a subgroup of four (PAH4) (BaA, Ch, BbF, and BaP) was suggested. Following the EFSA opinion, the EC enacted a new regulation in 2011 (Reg 835/2011) fixing new limits considering both the BaP only and the PAH4. Additional food classes compared to the previous legislation were added, but the limits for these newly introduced classes came into force later than the previously regulated classes, giving more time to adapt the production technologies. The complete overview of the considered food classes and respective limits are shown in Table 2.

Meanwhile, the EC, not dictating any official method, fixed the performance criteria required by any analytic method applied for PAH analysis (Reg. 836/2011), extending the parameters set only for BaP in previous regulations (Reg. 333/2007 and Dir. 2005/10/EC), to all the analytes included in the PAH4 sum (Table 3). Finally, if any of the four PAHs is at the limit of quantification (LOQ), it would be considered as zero in the summing of the four PAHs.

Outside Europe, regulations are much less restrictive. In the United States, even though EPA has always paid a great attention to PAHs as environmental pollutants, no standards governing the PAH content of foodstuffs have been established by the US Food and Drug Administration (FDA). The only exception regards the level of PAHs in seafoods after the Deepwater Horizon oil spill, which occurred in the Gulf of Mexico in 2010. In response to this event, the FDA developed risk criteria and established threshold for allowable levels (levels of concern) for

Table 1 (Continued)

Compounds (abbreviation)	*Molecular formula (mw)*	*Solubility at 25 °C ($\mu g\, l^{-1}$)*	*Log K_{ow}*	*Structure*
Benzo[*a*]anthracene (BaA)	$C_{18}H_{12}$ (228)	11.0	5.63	Chrysene (Ch)	$C_{18}H_{12}$ (228)	1.9	5.63	5-Methylchrysene (5MeCh)	$C_{19}H_{14}$ (242)	65	6.07	Benzo[*j*]fluoranthene (BjF)	$C_{20}H_{12}$ (252)	2.4	6.21	Benzo[*b*]fluoranthene (BbF)	$C_{20}H_{12}$ (252)	2.4	6.04	Benzo[*k*]fluoranthene (BkF)	$C_{20}H_{12}$ (252)	0.8	6.11	Benzo[*a*]pyrene (BaP)	$C_{20}H_{12}$ (252)	3.8	6.06	Dibenzo[*a,h*]anthracene (DBahA)	$C_{22}H_{14}$ (278)	0.4	6.86	Benzo[*g,h,i*]perylene (BghiP)	$C_{22}H_{12}$ (276)	0.3	6.78	Indeno[*1,2,3-cd*]pyrene (IP)	$C_{22}H_{12}$ (276)	-	6.58	
(*Continued*)

Table 1 (Continued)

Compounds (abbreviation)	*Molecular formula (mw)*	*Solubility at 25 °C (μg l^{-1})*	*Log K_{ow}*	*Structure*
Dibenzo[*a,l*]pyrene (DBalP)	$C_{24}H_{14}$ (302)	0.24	7.71	Dibenzo[*a,e*]pyrene (DBaeP)	$C_{24}H_{14}$ (302)	0.24	7.71	Dibenzo[*a,i*]pyrene (DBaiP)	$C_{24}H_{14}$ (302)	0.5	7.28	Dibenzo[*a,h*]pyrene (DBahP)	$C_{24}H_{14}$ (302)	-	6.26	
Table 2 Limits fixed by EC Regulation 835/2011 for BaP and the sum of PAH4 (BaA, Ch, BbF, and BaP)

	Maximum levels (μg kg^{-1})	
Foodstuffs	*BaP*	*Sum of PAH4*
Oils and fats intended for direct human consumption or use as ingredient in food (excluded cocoa butter and coconut oil)	2	10
Coconut oil for direct human consumption or use as ingredient in food	2	20
Cocoa beans and derived products	5	35[a] 30[b]
Processed cereal-based foods and baby foods for infants and young children Infant and follow-on formulae, including infant and follow-on milk Dietary foods for special medical purposes, intended specifically for infants	1	1
Smoked sprats and canned smoked sprats Bivalve mollusks (fresh, chilled, or frozen) Heat treated meat and meat products sold to the final consumer	5	30
Smoked bivalve mollusks	6	35
Muscle meat of smoked fish and smoked meat and meat products	5[c] 2[d]	30[c] 12[d]

[a]Until 31/3/2015.
[b]From 1/4/2015.
[c]Until 31/8/2014.
[d]From 1/9/2014.
Adapted from EC Regulation n 835/2011.

Table 3 Performance criteria required for analytic methods by the EC Regulation 836/2011

Parameter	*Value*
Applicability	Foodstuffs listed in Reg 1881/2006
Specificity	Free from matrix or spectral interferences, verification of positive detection
LOD	$\leq 0.3\ \mu g\ kg^{-1}$ for each PAH
LOQ	$\leq 0.9\ \mu g\ kg^{-1}$ for each PAH
