Table beet was domesticated in the Mediterranean and originally used as a leaf crop. In its earliest forms, the crop did not have a swollen root and was only consumed for its leaves and petioles. Swiss chard most likely resembles this early form of the crop. As beet moved throughout the Mediterranean region and spread north, selection occurred for a swollen root that could be stored throughout the winter. This process of selection resulted in swollen rooted forms that became the modern, pigmented table beet. Selection among the swollen rooted forms also resulted in two additional crops: fodder beet and sugar beet; the former is used for livestock and the latter as an industrial source of sucrose. Sugar beet was developed in the eighteenth century from white fodder beets. A sugar beet is about 30 cm (12 in.) long and weighs 1–2 kg (2–5 pounds) at harvest.

Patterns of Consumption

Carrots, parsnips, and beets, like other root vegetables, store well and can be eaten throughout the winter when many other vegetables are out of season. They will keep best when stored in the refrigerator, in the crisper drawer, or in plastic bags and will last for 1 month or more.

Carrots are a popular vegetable, especially in Europe and the United States, and fresh-market carrot consumption in the United States has increased recently due in part to the introduction of 'cut-and-peel' carrots. Cut-and-peeled carrots offer a convenience to consumers in their ready-to-eat form that comes in a variety of package sizes. In the United States, ~4 kg (9 pounds) are available per capita each year (Figure 3 (a)). Orange carrots are likely the highest source of α- and β-carotene in the diet of many people in the United States, and thus, modern orange carrots are a significant source of vitamin A.

Carrot leaves are consumed in parts of Asia, used either fresh in a salad or cooked in other dishes. The young tender leaves are occasionally used as a stir-fried herb in China and Japan. Carrot leaves have a similar appearance to some of its wild relatives that are not carrots, and some of these wild relatives, such as hogweed or cow parsnip, have toxic compounds in their leaves. Carrot top consumers should avoid leaves from these wild plants. In the leaves, the carotenoids are located in the photosystems of the inner chloroplast membrane usually associated with lipids. Carrot leaves have a different carotenoid profile than the roots.

Parsnips can be eaten raw but are usually cooked. Taproots of parsnips have a mild and very pleasant flavor and are prized as an ingredient in soups and stews because of their rich flavor.

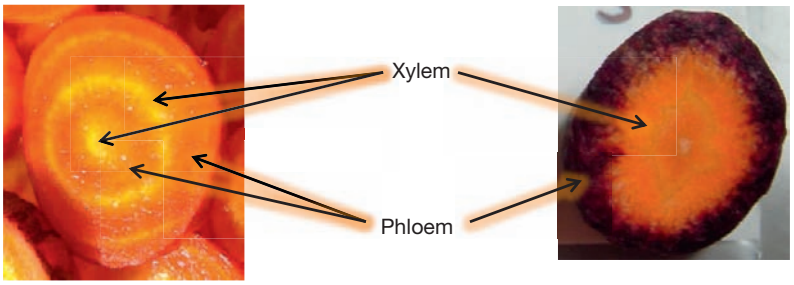

Table beet with red and yellow cambial rings

Carrot with purple phloem and orange-red/yellow xylem

Figure 1 The accumulation of pigments in beet and carrot storage roots often varies across root tissues, and as a consequence, nutritional value varies. Beetroots have multiple cambia and, with that, concentric rings of xylem and phloem tissue, while carrot roots have one cambium that separates the xylem (core) and phloem (cortex).

Table 1 World carrot production and availability, 1965–2011

Continent	*Variable*	*1965*	*1975*	*1985*	*1995*	*2005*	*2011*
Africa	Area (% world)	8	5	6	8	8	9

They contain more sugar and starch than other vegetable members of the *Apiaceae* family, such as carrot, and appear to have been used as a source of both of these compounds prior to the introduction of the potato. Parsnips are sweeter than typical carrots, especially when cooked. Parsnips have sugar content comparable to fruits, such as bananas and grapes. They can be baked, boiled, pureed, and roasted and are sometimes fried to make chips. It is interesting to note that the starch in parsnips converts to sugar when exposed to cold and thus winter parsnips are sweeter than autumn parsnips. Refrigeration will also cause them to develop more sweetness.

The table beet is consumed in a variety of ways. Compared with carrots, however, availability per capita in the United States has tended to decrease over the past few decades (Figure 3(b)). Leaves, particularly small leaves known as 'baby leaves,' are consumed as a salad crop. Roots are eaten in salads, placed on sandwiches, pickled, roasted, boiled, or used in soup. A substantial portion of the United States crop is canned. Beet root can be eaten raw and will maintain more of its folate content if not cooked. When table beet roots are consumed, the hypocotyl tissue is also consumed as it is a transitional zone between the root and stem. The root/hypocotyl is actually composed of supernumerary cambia, or zones of xylem and phloem tissue, that increase in size during growth. The root/hypocotyl region also contains storage parenchyma cells, where sucrose is stored. Table beet has long been known as a sweetener and was likely used in Roman times for this purpose.

The sugar beet was developed following the Napoleonic wars when Europe needed a domestic source of sugar that did not depend on the West Indies sugar trade. Sugar beet is a natural source of sucrose, which is not different from cane sugar. Sugar beets contain about 18% sucrose, which is about two to three times higher than table beets. Sugar beet must be processed quickly because it is perishable. Beet sugar represents about 50% of domestically produced sugar in the United States.

Availability, Absorption, and Metabolism

In general, phytochemicals found in vegetables have putative mechanisms of action in the body including antioxidant effects, modulation of detoxifying enzymes, stimulation of the immune system, modulation of hormone metabolism, and antibacterial and antiviral effects. Brightly colored

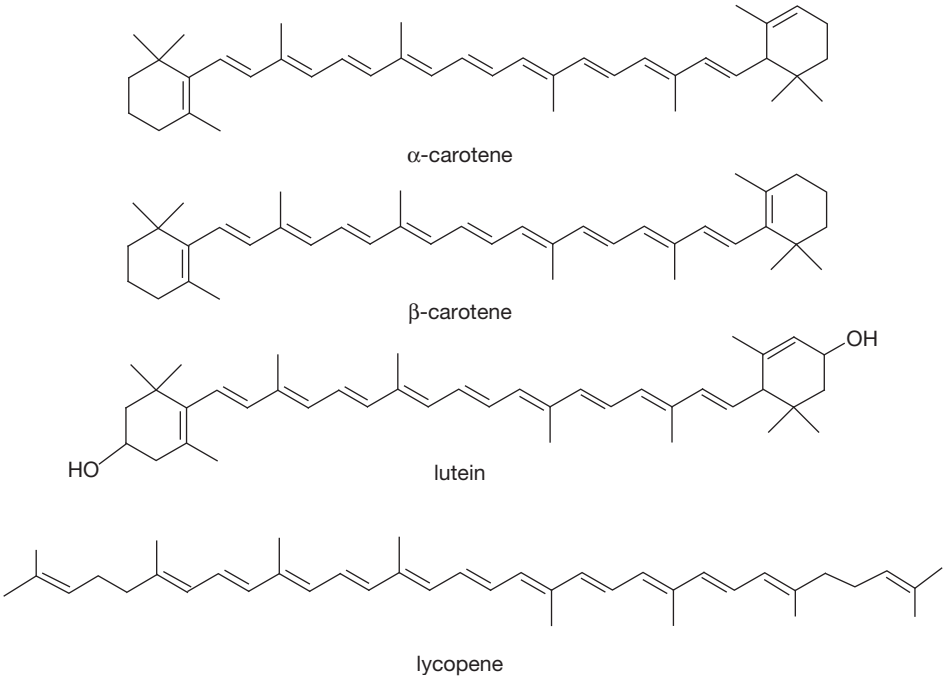

Figure 2 The four main carotenoids that are found in carrots. α- and β-carotene predominate in orange carrots. Lutein is relatively high in yellow carrots compared with β-carotene. Lycopene is high in red carrots in addition to high levels of β-carotene.

vegetables, such as carrots and beets, generally contain high amounts of phytochemicals and nutrients.

In addition to being a significant source of β-carotene, orange carrots are likely the highest source of α-carotene among all vegetables. Both of these orange compounds from carrots provide vitamin A upon central cleavage. Most mammals, including humans, are able to cleave α- and β-carotene to vitamin A. α-Carotene provides one molecule of vitamin A and one molecule of a compound commonly called α-retinol, while β-carotene can provide two molecules of vitamin A due to its symmetrical structure (Figure 2). Thus, orange, red, and some purple carrots are great sources of vitamin A. Vitamin A is essential for healthy eyes, cell growth, and reproduction. It is also important in strengthening the immune system by keeping the skin, lungs, and intestinal tract mucosa healthy. When carrots are eaten, not only do they provide vitamin A, but also the excess carotenoids can be absorbed and circulated intact in the human body. In circulation, α-carotene and β-carotene are predominantly associated with low-density lipoproteins. Therefore, some animals that have higher-density lipoproteins, such as gerbils and chickens, may not circulate much β-carotene in the blood.

Carrots of other colors have a different carotenoid profile. Yellow carrots contain lutein, which is bioavailable to humans, in addition to small amounts of β-carotene. Lutein is a xanthophyll carotenoid, which means it is partially oxygenated. Because it contains hydroxyl groups on both sides of the molecule (Figure 2), lutein cannot be cleaved by mammals to form molecules of vitamin A. A human study demonstrated that lutein from yellow carrots was 65% as bioavailable as that from a lutein supplement dissolved in oil.

Red carrots accumulate lycopene, a common pigment in red tomatoes, in addition to high amounts of β-carotene. Like α- and β-carotene, lycopene is a hydrocarbon carotenoid, but it does not have any cyclic rings, making it quite different structurally from the other well-known carotenoids in carrots (Figure 2). Lycopene from red carrots is about 40% as bioavailable as that from tomato paste. For consumers who do not like tomatoes, red carrots are another food source of lycopene. Consumers in India actually prefer red-pigmented carrots to orange ones.

Other phytochemicals present in purple carrots include flavonoids, such as red or blue anthocyanins (Figure 4), and purple carrots may, or may not, contain carotenoids. Anthocyanin pigmentation develops independently of carotenoid colors, so some purple carrots contain α- and β-carotene. Purple color may mask the appearance of carotenoids. The purple anthocyanins found in carrots are sometimes used as food colorants. Some of the carrot anthocyanins have an acyl chemical group, while some do not. The acylated anthocyanins of carrot are more stable when used as a food colorant, but the nonacylated anthocyanins are more bioavailable. Some strains of purple carrot are sometimes referred to as 'black' carrot because the anthocyanins are so concentrated that they have deep purple color in the phloem and xylem. Efforts to breed carrots of several colors have been on the rise, and within the past decade, purple-orange-red carrots have been bred for increased red color. These particular carrots would have anthocyanins, α- and β-carotene, in addition to lycopene (Figure 1). A common name for these types of carrots is 'rainbow carrots.' Through outreach efforts, rainbow carrot seeds have been distributed to community and youth gardeners to build awareness and to use the harvested carrots to demonstrate the diversity of pigments in vegetables.

Lastly, carrots also contain phenolic acids that have a single aromatic ring. The main phenolic acids are chlorogenic acids

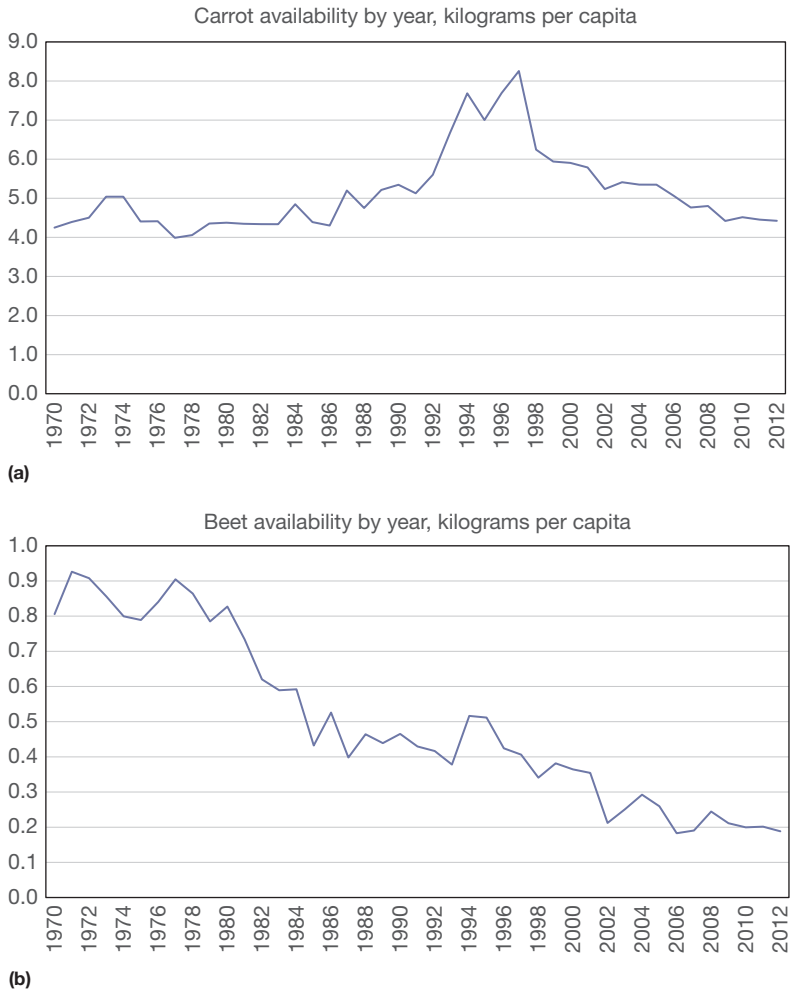

Figure 3 Carrot and beet availability in the United States over the past few decades expressed in kilograms.

(Figure 4), which are hydroxycinnamic acid derivatives formed by the esterification of cinnamic acids with quinic acid. These compounds contribute to the organoleptic properties of fresh and processed carrots. Approximately 30% of chlorogenic acids are absorbed by the intestine and the remainder is extensively metabolized by colonic microflora.

Although typical parsnips are white, they contain compounds known as polyacetylenes, which may impart beneficial properties to this vegetable. Plants synthesize polyacetylenes to protect them against pathogens and pests. They are derived from unsaturated fatty acids. One type of polyacetylene called falcarinol is highly bioavailable in humans, being rapidly absorbed after ingestion (Figure 4). Interestingly, falcarinol was viewed as a potentially undesirable component of food in the 1980s, and now, it is viewed by some as desirable.

Table beet is colored by betalain pigments (Figure 5). The betalains are a unique class of alkaloid pigments found in plant species in the order *Caryophyllales* and in some fungi. Tyrosine is converted to L-DOPA via hydroxylation and subsequently to betalamic acids via the extradiol ring cleavage reaction. Betalains are ultimately formed via spontaneous chemical conversion. Recently, the *R* locus that controls betalain pigment production in table beet was identified as a novel cytochrome P450. This protein provides the cyclo-DOPA moiety that is required for all red betacyanin pigments. Selection has been effective at increasing betalain concentration in table beet. Betalains are water-soluble, fairly easy to extract, and a commonly used source of natural colorants. After ingestion, betalains are thought to be degraded in the stomach and absorbed in the gut, possibly through passive diffusion. An estimated 50% of betalain is lost during digestion, and urinary betalain ranges between 0.3% and 1% after consumption of beet juice or extract, which may reflect low absorption. Food processing also affects betalain absorption, with lower bioavailability from the whole beet matrix compared with purified beet juice or extract.

Health Effects

Root vegetables provide energy through their carbohydrate content and are naturally low in fat. Root vegetables are a good source of fiber, ranging from 3 g fiber in 100 g of raw carrots and beets to 5 g in 100 g of parsnips. Cooking tends to lower the fiber content in beets and parsnips. Carrot fiber is highly regarded and has become of interest to food processers

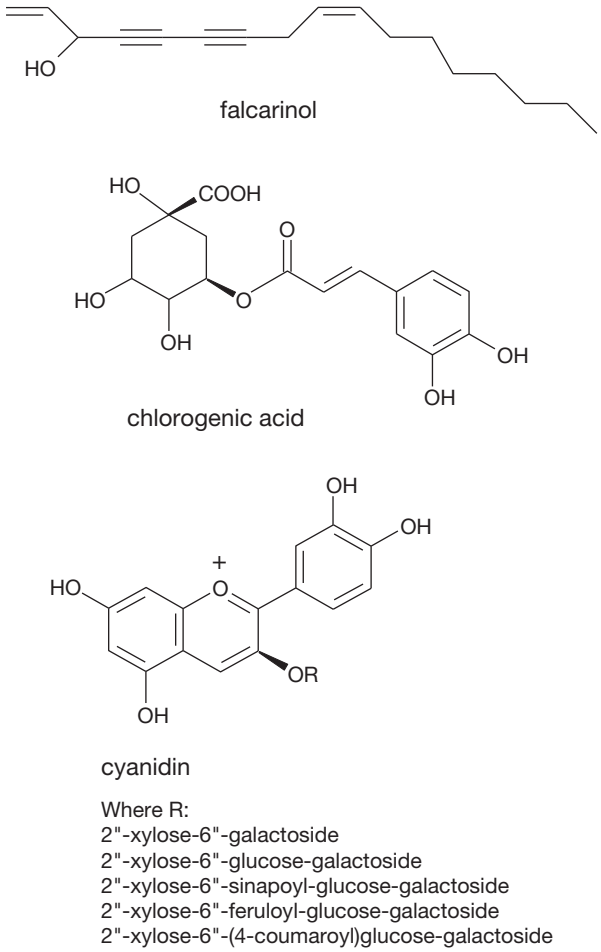

Figure 4 Carrots contain many phytochemicals. Falcarinol contributes to carrot sensory characteristics and is also found in parsnips. Chlorogenic acid is a common phenolic acid found in carrots. Anthocyanins are the red and blue compounds that give purple carrots their hue and contribute to their high antioxidant capacity.

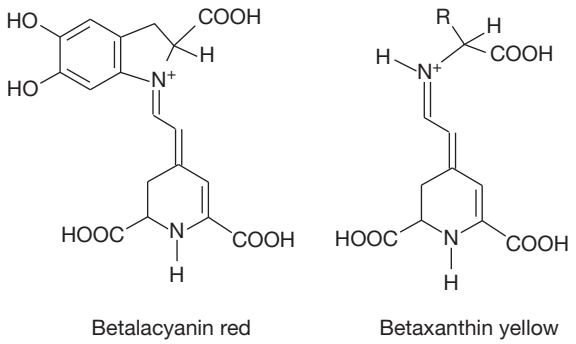

Figure 5 Betalains are the primary pigments in red and yellow beets. These water-soluble pigments are unique to the order *Caryophyllales*, of which the *Amaranthaceae* family, and the table beet in particular, is a member. The betalains are used as a natural alternative to synthetic food dyes in certain food products. They show considerable antioxidant activity and may have potential in improving the health functionality of foods.

due to the large quantities of carrot waste, known as pomace, created in the cut-and-peel and juice industries. The insoluble fibers, primarily cellulose and hemicellulose, constitute the greatest portion of the total dietary fiber with small amounts of lignin. The soluble fibers include fermentable hemicellulose and pectin. The fiber composition of dried carrot pomace differs from whole carrot and depends on the processing method.

Raw root vegetables are also a good source of water ranging from 80% in parsnips to 88% in carrots and beets. Boiling the vegetables does not appreciably change the water content (<2%) when based on a 100 g serving. While cooking breaks down some nutrients, both carotenoids and anthocyanins of carrot are quite stable with light cooking. Root vegetables are also a good source of potassium providing ~350 mg in 100 g.

Research has focused on the numerous health benefits of phytochemicals, including those that are found in the root vegetables. Carrots, in particular, have been studied for nutritive benefits and color components and are widely considered a 'functional food.' The pigments in carrots serve an important role because they have been associated with reduced risks of atherosclerosis, cancer, and inflammation. Carrots have antioxidant capacity because both α-carotene and β-carotene are antioxidants, which are important to trap free radicals and fight against heart disease. Both carotenoids have been reported to have anticancer potential. Yellow carrots contain lutein, which has been implicated in improved eye health. Specifically, lutein and zeaxanthin are concentrated in the macula of the eye and may be important in preventing macular degeneration. Lutein has also been implemented in preventing some forms of cancers and reducing the risk of atherosclerosis. Intake of dietary lycopene, as found in red and some purple carrots, has been associated with a reduced incidence of some forms of cancer. Lycopene, which has much higher antioxidant potential than β-carotene, is also associated with a reduced risk of serum lipid oxidation and heart disease.

When carrots or carrot juice are consumed at a high level in the diet, a condition known as hypercarotenemia can occur. This is due in part to the downregulation of bioconversion of the provitamin A carotenoids to vitamin A as a way to protect the human body from hypervitaminosis A due to high vegetable intake. The carotenoids will accumulate in the adipose tissue and the yellow pigmentation of the palms is usually first noticeable. This is thought to be a benign condition.

Eleven different phenolic acids in orange, purple, yellow, and white carrots have been identified. Total concentration of all identified phenolic acids is greatest in the purple carrots followed by orange, white, and yellow. In particular, chlorogenic acid consumption has been associated with reductions in several chronic diseases.

Anthocyanins in purple and black carrots act as powerful antioxidants to sequester harmful free radicals in the body; however, human data are lacking. Anthocyanins may prevent heart disease by acting as anti-inflammatory agents and reducing lipid oxidation. Solid-colored purple carrots contain the most phenolic compounds and therefore may have higher antioxidant capacity in the human body.

Parsnips are a better source of vitamin C than carrots and beets. Parsnips and beets provide more folate than carrots. Falcarinol may be involved in carrot and parsnip beneficial

health effects including anti-inflammatory, antiplatelet aggregation, and potential anticancer activity. While falcarinol can cause allergic skin reactions, contact dermatitis from *Apiaceae* family vegetables is rare, likely due to the relatively low concentrations of falcarinol in the species commonly consumed or sensitization from oral intake.

Parsnip leaves also contain furanocoumarins, which can cause photodermatitis if they are touched or brush up against the skin in the presence of light. Burns caused by these compounds can be serious and can leave scars that do not easily disappear. Parsnips are therefore difficult to handle and individuals handling the crop require substantial protection during production. Parsnip root contains photocarcinogenic psoralens, which are not destroyed by cooking. However, the effect and potential toxicity of these chemicals from normal human consumption are not known.

Beet greens by weight have even more micronutrients than beetroot, including vitamin A as β-carotene, vitamin C, vitamin K, calcium, iron, magnesium, potassium, copper, and manganese. Beet leaves also contain a substantial amount of lutein and zeaxanthin and thus have health benefits associated with those carotenoids as detailed earlier for carrots.

Beets are among the vegetables with the highest antioxidant content. Betalain pigments are among the antioxidants in beets and may be associated with cancer prevention. Betalains in beet extract reduced tumors associated with skin and lung cancer in mice, but no human studies have been done to date that demonstrate substantial health benefits. Betalains have a large nonpolar surface area that allows them to interact with lipid membranes and low-density lipoprotein particles in the blood reducing oxidation.

Oxalic acid is related to the formation of kidney stones and has other antinutritive properties. Table beet is considered a high oxalate food, and therefore, breeding to decrease oxalic acid levels is an area of interest. In a collection of table beet cultivars, mean values were from 722 to 1909 mg in 100 g of leaf tissue and 553 to 1679 mg in 100 g leaf tissue for total and soluble oxalate levels, respectively. Root-soluble oxalate values ranged from 103 to 171 mg in 100 g of root tissue, and total values ranged from 95 to 142 mg in 100 g of root tissue. These findings confirm relatively high levels of oxalate in table beet.

Many people are familiar with 'beeturia,' or the excretion of red urine following beet consumption. This occurs in 10–14% of the population and seems to be a harmless idiosyncratic reaction relating to digestion of the beet pigments. The occurrence of beeturia is probably related more to an individual's physiological conditions (such as stomach acidity), nutritional status, type of beet, and amount consumed, rather than genetics as previously thought.

Summary

Root vegetables are a source of energy in the form of carbohydrates and a good fiber source. They contain essential nutrients as well as a variety of classes of phytochemicals associated with optimal health.

Vegetables of Temperate Climates: Leafy Vegetables

A Alvino, Università del Molise, Campobasso, Italy
G Barbieri, Università Federico II di Napoli, Naples, Italy

© 2016 Elsevier Ltd. All rights reserved.

Definition of Vegetables

The term vegetable, appearing in the fifteenth century, recorded for the first time the adjective use of the word familiar to us as 'having to do with plants.' Vegetable comes from the Medieval Latin term 'vegetabilis' meaning vegetative; the Latin word 'vegetare' means grow.

Taso and Lo define a vegetable as "an edible, usually succulent plant or portion of it eaten with staples as main course or as supplementary food in cooked or raw form."

Vegetables are commonly grouped according to the edible part: root, stem, leaf, immature flower bud, fruit, and sprout. As a general rule, the edible parts of leafy vegetables are the leaves and the immature flower buds for cauliflower, broccoli, and artichoke.

Among all vegetable species, the leafy vegetable groups show the highest rate of respiration, which has the function of releasing energy from stored chemical compounds in the plant. The depletion of energy reserves leads to the reduction of shelf life of the product. During the shelf life, the fresh product loses water continuously (transpiration), which causes a moisture reduction of tissues and thus an irreversible loss of turgor. Water loss is the major cause of postharvest losses in leafy vegetables. Leafy vegetables are perishable because senescence starts very soon in detached vegetables. Senescence is characterized by the appearance of undesirable symptoms: reduction of greenness and appearance of yellowed leaf areas and loss of flavor and aroma. With ongoing senescence, the nutrition value of the vegetable is corrupted. For this reason, the quality of leafy vegetables is strongly dependent on freshness, such as the time elapsed from cutting (in the field or in a controlled environment) and the cold storage chain (from field to shelf).

Types of Leafy Vegetables

Leafy vegetables are a wide group of horticultural plants that roughly can be defined as "vegetables cultivated for the edible part constituted of foliar structures, comprising lamina, petiole, midrib and veins." A list of the most common species of temperate climate vegetables is presented in Table 1.

Leafy vegetables may be cool-season or warm-season crops and thrive in areas where the mean temperatures range between 15 and 18 °C. These vegetables can be grown as annuals or as biennials or perennials. Leafy vegetables such as lettuce and spinach are most tolerant of shade.

Many leafy vegetables have shallow root systems and cultivation should be done carefully: sandy loam soils are best for growing these vegetables. All leafy vegetables grow best in soils with a pH of 6.0–6.8 except lettuce which grows best at a pH of 6.5–7.0.

Leafy vegetables are defined as 'green' when cooked before consumption (mature leaves of many Brassicaceae and Chenopodiaceae), and 'raw' when consumed fresh (e.g., salads). This latter group includes different lettuces of the botanical genus Lactuca and chicory, escarole, endive, and radicchio are classified as *Cichorium intybus* L. and include minor species such as valerian or lamb's lettuce (*Valerianella locusta* (L.) Laterr.), rocket or arugula (*Eruca vesicaria* (L.) Cav., Diplotaxis spp.), cress (*Lepidium sativum* (L.)), etc.

Consumption of salads is particularly high in the Mediterranean countries where the cultivation of these species has ancient traditions linked to the hot weather and refreshing, thirst quenching, digestive, and diuretic properties of these products. The salad leaves can be eaten by themselves or, according to tradition, served with salt, oil, and different types of vinegar or lemon. Today, they are offered as a side dish or, in the low-calorie diets, as an appetizer or as a main dish topped with a variety of ingredients.

Fresh-Cut or Minimally Processed Leaf Vegetables

The consumption of vegetables with a high content of service – such as fresh salads ready for use – has undergone significant increases in recent times; and high prices, compared to the corresponding unprocessed products, do not seem to be an obstacle to the development of the sector. The high request for the service and the good quality and availability are causing the demand for pre-made salads to grow, even in countries with a strong culture of fresh and loose products, which is still considered safer and more natural.

The most important requirements for fresh-cut or minimally processed products are qualities related to consumer preferences, such as color, brightness, and maintenance over time; high resistance to oxidation processes after cutting; the absence of soil or other solid material, residues of pesticides, and nitrates within the limits of tolerance; limited microbial load; high dry-matter content; and long shelf life.

This category includes all those vegetable crops cultivated with very high plant densities (number of plants per square meter), which are eaten as fresh salad leaves, harvested young – the so-called 'baby leaf vegetables,' The maturity of the plants is defined by their height, which, at harvest, may range from 50–70 mm up to 80–120 mm, depending on the species and the customer demands. At harvest, which is defined as marketable maturation, smart growers apply a cutting height that excludes most of the petiole and includes the major part of lamina.

This group of salad-leaf plants includes chard, chicory, lettuce, rocket, spinach, lamb's lettuce, and other species that are of lesser importance, but which are often used in order to vary the appearance and taste, especially in mixtures (e.g.,

Table 1 The most common cultivated species of temperate climate vegetables

Common name	*Edible part*	*Botanical name*	*Family*
Endive, Escarole	Leaf	*Cichorium endivia* L.	Asteraceae

Quality of Leafy Vegetables

The concept of vegetable quality is dynamic, always evolving and strongly influenced by lifestyle, tastes, religion, culture, and tradition. At the time of the 'green revolution,' science was mainly oriented toward solving problems linked to malnutrition and starvation; genetic studies were performed essentially to enhance productivity and to primarily safeguard the commercial (size and uniformity of size, weight, texture) and organoleptic (taste, crunchiness, color) qualities of the product. At the end of the 1960s, and in the following decade, due to the chemistry boom that had spread the use of synthetic

fertilizers and pesticides in agriculture, the public started to have serious doubts about the indiscriminate use of these substances, especially on horticultural products for fresh consumption, and the problem of the accumulation of nitrates had already begun to be felt.

In those years, the legislator increasingly issued rules regarding safety times, residues of the active ingredients, doses, and sale and use of synthetic chemicals in agriculture. The insufficient dissemination of the culture of hygiene and the use of wastewater (a bad habit not entirely lost even today in many countries) caused salads to be at the center of scandals about the spread of epidemic diseases transmitted via the fecal–oral route, such as hepatitis A, cholera (*Vibrio cholera*), typhoid (*Salmonella typhi*), salmonellosis (*Salmonella* spp.), and bacterial enteritis (*Campylobacter jejuni*).

In the 1960s and 1970s, early alarms about dietary excesses were sounded because of the prevailing presence of high-energy foods in the diet. Therefore, the need to define the criteria for a healthy and balanced diet was born (dietetics science emerged), and vegetables for fresh consumption were highly valued for their contributions of nutritional minerals, vitamins, fiber, and low energy supply. Thus, although it started with traditional commercial and organoleptic characteristics, the concept of the quality of leafy vegetables has been enriched with new attributes related to nutritional and hygienic characteristics. In subsequent years, the rapid development of large and multinational food companies, the increase in the standard of living, and the consequent greater purchasing power have increased the importance of quality, in a broad sense, as a deciding factor in consumer choices.

The cultural level, sensibility, and income growth of communities put consumers in a position to appreciate the quality parameters of the vegetables as they would the health properties, which went beyond the traditional and widely accepted approach to determining product value. These properties are essentially linked to the capabilities of specific substances contained in vegetables, such as vitamins (A, B, C, E, etc.), polyphenols, carotenoids, and other substances, to prevent the onset of serious human pathologies.

Moreover, additional services related to preparing leafy vegetables for fresh consumption (washing, cutting, mixing, and packaging) are increasingly appreciated, perfectly matching the new ways of living and the changes in modern society. Recently, there has been a tendency to broaden the concept of food quality and safety beyond the simple intrinsic characteristics of the products, increasing the quality of the production process. In terms of consumer preferences, the sense of taste and nutritional requirements are combined with and compared to consumer expectations regarding the environment, the biosphere, and perceptions of the guarantees offered by the manufacturers. These new aspects of quality fundamentally linked to the production process call to mind subjects of popular concern, such as environmental pollution, the efficient use of natural resources, and the consequent sustainability of agricultural and job activities, as well as the traceability of food chain and product.

Biologically Active Constituents and Health Properties

Although energy poor, vegetables are rich sources of minerals, fiber, vitamins, and, most of all, many phytochemicals belonging to four main classes: polyphenols, terpenoids, sulfur compounds, and alkaloids. Polyphenols and, to a certain extent, carotenoids and sulfur-containing compounds have been shown through epidemiological cohort studies or through mechanistic *in vitro* or animal studies to prevent coronary heart diseases, chronic inflammatory diseases, obesity, diabetes, neurodegenerative diseases, cancer, macular degeneration, and many others. Owing to their chemical structures, these phytochemicals by-and-large display strong antioxidant capacity *in vitro*.

These horticultural products add diversity, stimulate our senses by having organoleptic properties such as color, flavor, and texture, and contribute to our appetite. Fruits and vegetables have long been recognized for their nutritive value. They are excellent sources of minerals, essential fatty acids, and fibers, but also unique sources of vitamins (C, E, B, and folic acid). Most of all, they are rich sources of bioactive phytochemicals. They contribute, through their high content in non-digestible fibers, to the feeling of satiety. For these reasons, fruits and vegetables, and plants in general, are the base of most of food pyramids.

Where Beneficial Compounds Come From

Desjardins provides an exhaustive essay on the origin of secondary metabolites produced by plants to cope with stress. Because plants cannot move away from stress or danger, they produce molecules to palliate stress. In particular, vascular plants accumulate several thousand secondary metabolites in response to a variety of biotic stresses, such as insects and pathogens, and abiotic stresses, such as phosphorus deficiency, cold temperatures, high light or ultraviolet radiation, and low nitrogen. These secondary metabolites can be grouped in four main classes: polyphenols, terpenoids, sulfur-containing compounds, and alkaloids. Unexpectedly, even if plant secondary metabolites are toxic against pathogens and herbivores and protect against abiotic stress, many of these compounds also show health benefits against many human chronic diseases.

Astorg reports that almost 600 carotenoids from natural sources have been characterized. Green leafy vegetables are considered to be rich in carotenoids. Flavonoids are one of the largest groups of secondary plant metabolites: over 4000 compounds have been identified.

The values shown in Table 2 reveal that the leafy vegetables are generally characterized by a good number of vitamins and minerals, low dry-matter content that at most reaches 10% (spinach and lamb's lettuce), and reduced contents of proteins, carbohydrates, and fats. Consequently, these foods have modest caloric power between 15 and 31 cal per 100 g of fresh product. A summary of the contents of Table 2 follows.

- Amaranth leaves have very low values for thiamine and pantothenic acid. Many values are ranked medium and high, and the leaves have very high contents of Ca, Zn, Mg, and vitamin K.
- Arugula is very low in α-carotene and β-cryptoxanthin, low in Se and β-carotene, and medium-high in lipids, Ca, and fat poly, while no parameter is classified very high.

Within each parameter, values are presented according to a scale of ten colors, with a gradient from dark red (the lowest value) to dark green (the highest value).
Source: USDA National Nutrient Database for Standard References, Release 27, 2014. Cholesterol is not reported since all species show null values.

- Beets are low in vitamin C, Ca, vitamin A, α-carotene, β-carotene, β-cryptoxanthin, lutein + zeazanthin, vitamin E, and vitamin K.
- Beet greens show values higher than those for beet roots.
- For broccoli, most parameters are classified medium–high; selenium is very high, and vitamin A, β-carotene, and fat poly are low.
- Chicory (witloof) has very low contents for most substances, and only its fiber levels are appreciable.
- Chicory greens show values higher than witloof. It is rich in fiber and pantothenic acid.
- Chives are low in Na, α-carotene, β-cryptoxanthin, lutein + zeazanthin, and vitamin E.
- Collards show many medium and medium-high parameters. No parameters are very low.
- Coriander leaves score medium-high for the majority of parameters, but their low levels of fats, both polyunsaturated and total, make them favorable for human health.
- For dandelion greens, many parameters are ranked high: energy, protein, lipids, carbohydrates, fiber, Fe, thiamin, riboflavin, vitamin a, α-carotene, β-carotene, lutein + zeazanthin, vitamin e, and total fats.
- For endive, many parameters are classified medium-low; vitamin B, α-carotene, β-cryptoxanthin, lutein + zeazanthin, vitamin C, selenium, and sugar are very low.
- Kale shows all values high or very high, with pantothenic acid excluded.
- Lettuce (butterhead) has many parameters classified as very low and low. Thiamin and sugar are medium. Other lettuces (red leaf, green leaf, and cos) show high values for vitamin A. Cos and romaine show many very low values for substances such as Cu, Mg, Se, riboflavin, and β-cryptoxanthin. Iceberg lettuce, including crisp head types, shows low values for all parameters (sugar excluded); the levels of copper, vitamin c, α-carotene, and β-cryptoxanthin are very low.
- Spinach shows many parameters ranked as medium-high, while Mg, folate, β-carotene, and lutein + zeazanthin are very high.
- For radicchio, many parameters are ranked medium and low; Ca, vitamin A, α-carotene, β -carotene, and β-cryptoxanthin are very low. Only a few substances are classified as high and very high, such as Mg, folate, vitamin A, lutein + zeazanthin, and vitamin K.
- Watercress is very low in energy, lipids, carbohydrates, fiber, sugar, Fe, Zn, P, vitamin A, α-carotene, β-cryptoxanthin, and polyunsaturated fats. Very few substances in watercress are medium-high.

The leafy vegetables in salads, as with most foods of plant origin, are an important source of minerals, such as potassium, calcium, and iron, even if the absorption of these substances is, in some cases, lower than that resulting from the meat). Leafy vegetables are also excellent sources of vitamins. The fiber in them helps to regulate intestinal peristalsis and to control the levels of sugar and cholesterol in the blood, and studies have shown a relationship between a lack of fiber in the diet and a high incidence of some intestinal diseases with a chronic course, including constipation, diverticulosis, and colon cancer.

In addition to these aspects more traditionally known, nutritionists are focusing on the specific health properties of vegetables, that is, their health-protective properties. A number of epidemiological studies have shown that a diet rich in fruits and vegetables is associated with a reduced incidence of many chronic diseases widespread in advanced countries, in particular various forms of cancer and cardiovascular diseases. These beneficial effects have been attributed to different antioxidant components whose protective effects are associated with the inhibition of free radicals.

Among the different classes of antioxidants present in leafy fresh vegetables, the most common are ascorbic acid carotenoids, phenolic compounds, and tocopherols. A range of factors influences the content of these molecules in vegetables: soil and climate conditions, genotype, cultivation technique, stage of maturity at harvest, and methods of storage and transportation of fresh produce. Thus, defining the pre- and postharvest conditions that maximize the accumulation and storage of these components can help to enhance these products.

During their evolution, plants have developed strategic solutions that allow them to balance growth (mainly due to primary metabolism involving sugars, proteins, and lipids) with needs related to survival (defense against parasites, herbivores, and toxic agents; attraction of pollinators; stress resistance) that are connected to the so-called secondary metabolism. Plants experiencing suboptimal environments tend to strengthen the secondary metabolism and produce food with higher nutritional value. This has significant implications for the production of vegetables in relation to the use, development, and management of agronomic factors of production.

Ultimately, therefore, climatic factors such as temperature, light radiation, relative humidity, soil factors, and water shortages, which characterize the environments of cultivation of leafy vegetables, play crucial roles in the stimulation of secondary metabolism and thus, in the last analysis, the biosynthesis of all biologically active substances.

In recent studies, total phenolic content (TP), a complex of plant secondary metabolites known to possess a wide range of therapeutic uses, ranged from 21.7 to 82.3 mg gallic-acid equivalents per 100 g of dry weight, with the highest value recorded in red lettuce harvested at high light intensity. Among species studied, the red-fleshed leafy vegetable was richer in phenolic content than green leafy vegetables due to the presence of anthocyanins. TP content fluctuated over the two sampling dates, and the variations were highly correlated to the changes in light intensity, with the effect being species-dependent. In fact, the TP content in chicory, green lettuce, lamb's lettuce, mizuna, red chard, and red lettuce were significantly higher by 48.8%, 46.9%, 96.3%, 12.7%, 100.5%, and 68%, respectively, when plants were harvested at high light intensity, whereas no significant differences among treatments were recorded in rocket, spinach, Swiss chard, and tatsoi.

Mineral Content

The increase in the amount of bioavailable micronutrients in vegetables is a particularly important challenge for developing countries, but it could also represent an added value for the same vegetables in the more economically developed societies.

The theme should, therefore, carefully be explored as a function of the possibility of producing vegetables that satisfy specific requirements for chemical composition and nutritional characteristics. This possibility appears to be important for building popular interest, because plant products with tailored compositions and nutritional values could be marketed to categories of consumers who express special dietary needs. For example, baby foods require ingredients with very low nitrate levels and or with high vitamin and mineral contents, and people with special metabolic diseases also require foods with certain compositions. The pursuit of these objectives seems particularly connected to breeding, biotechnology, and cultivation techniques. The use of nutrient solutions at known concentrations and the control of the quantity and quality of the water supply make the soilless system of cultivation potentially interesting for the mineral enrichment of leafy vegetables.

Accumulation of Nitrates

The nitrate content of leafy vegetables was discussed extensively in recent reviews. Here it is worth recalling, briefly, that the intake of water and vegetables with a high concentrations of nitrates is always considered potentially dangerous to human health. From a toxicological point of view, the nitrate has an extremely low acute toxicity, but the product of its reduction, nitrite, and the N-nitrous compounds formed by the reaction between nitrite and other substances are responsible for methemoglobinemia in children and stomach cancer in adults, respectively. Some epidemiological researchers have critically reviewed the potential risks to health caused by the absorption of nitrate in the diet. In addition, the acidic conditions in the stomach lead to the formation of nitric oxide, which is considered essential in the human body's defense against bacterial pathogens.

Leafy vegetables are among the vegetable species most sensitive to nitrate accumulation, thus contributing greatly to the total intake of nitrates in the diet. A high level of nitrates in leafy vegetables is considered undesirable because of the possible implications for health; however, due to the lack of substantial epidemiological studies, many researches have not found a direct correlation between nitrate concentration in food and incidence of cancer. Despite the debate about the positive or negative effects of nitrates on human health, the production and commercialization of leafy vegetables (spinach, lettuce, and rocket) in Europe is subjected to rigorous limitations (Table 3). This is because some groups of the human population could be at higher risk of developing cancer when subjected to elevated levels of dietary nitrate intakes. Therefore, the World Health Organization (WHO) has set an acceptable daily intake for nitrates of 3.7 mg kg^{-1} body weight.

Several factors can significantly influence the level of nitrates in various raw leafy vegetables, including genetic, agronomic (e.g., amount, timing, and form of nitrogen fertilizer), and environmental factors (e.g., temperature, light exposure, photoperiod, and carbon-dioxide concentration). Beyond that, within species and cultivars, the nitrate content also varies in relation to different parts of the plant. According to several authors, the nitrate concentration, although it is generally higher in older tissues, is generally distributed in plants as follows: petioles > leaves > stems > roots > inflorescences > tubers > bulbs > fruits and seeds. This shows that the organs used for the transport of nutrients, unprocessed and therefore richer in xylem, are those with the highest concentrations.

Genetic background, nitrate supply, harvesting time, and light intensity are predominant. For instance, the relationship between light levels and nitrate concentration has been demonstrated in a number of studies. Recently, research was carried out, in the field and in growth chambers, on changes in nitrate concentrations over a 24 h period for spinach, sweet basil, and scallions. The nitrate content fluctuated over the 24 h period, and these species-dependent variations were strongly correlated to changes in light intensity over the same period: the reduction of nitrate content could be possible by harvesting the vegetables at the right time during the day.

Low levels of light radiation on spinach, in addition to promoting the accumulation of nitrate in the leaves, lead to an increase in the content of oxalic acid (antinutritional factor that limits the bioavailability of Ca in the human body) and a decrease in vitamin C, resulting in the further deterioration of the nutritional quality of the product.

There is a lack of information on the effect of the quality of light radiation on the qualitative characteristics of the product,

Table 3 Maximum levels for nitrates in foodstuffs

Foodstuffs	*Maximum levels (mg NO_3 kg^{-1})*	
Fresh spinach (*Spinacia oleracea* L.)		3500
Preserved, deep-frozen, or frozen spinach		2000
Fresh Lettuce (*Lactuca sativa* L.)	Harvested 1 October to 31 March:	
Protected and open-grown lettuce excluding iceburg lettuce	Lettuce grown under cover	4000
	Lettuce grown in the open air	5000

with particular reference to its nutraceutical value. In rocket, altering the ratio between red and far-red wavelengths increases the content of nitrates and antioxidants in the leaves. Moreover, recent studies have shown a positive role of blue light on the biosynthesis of compounds with antioxidant action in lettuce. With respect to nitrates, high temperatures induce a greater accumulation of such compounds in lettuce.

Cultivation Environment: Greenhouse Versus Open Field

In general, the quality of vegetables is favored by conditions of cultivation in the greenhouse compared to those in the open field. In a protected environment, it is possible to more accurately control microclimatic parameters (light, temperature, humidity, and CO_2) and to employ radical environments (e.g., soilless cultivation). However, the greenhouse environment may negatively affect the quality of vegetables. Some declines are related to the light radiation, both from the point of view of quantity and quality. The reduction of light intensity due to the covering material can, in fact, contribute to, in some areas and times of the year, a higher concentration of nitrate in leaves and a resulting deterioration in the nutritional quality, as observed in lettuce. In addition, the interiors of glasshouses have an almost complete absence of UVB radiation (280–320 nm), with negative effects on the biosynthesis of polyphenols. Similarly, the content of flavonoids in the leafy vegetable *Gynura bicolor* DC has been much higher when the plants were grown in an open field as opposed to a greenhouse. In addition, the content of glucosinolates in different *Brassicaceae* species was lower in plants grown in the greenhouse compared to those grown in an open field, with a consequent decay in the quality and nutritional alteration of the organoleptic quality of the product. Moreover, some greenhouse vegetables are more sensitive to the appearance of physiological disorders that involve a strong deterioration of the commercial quality of the product. For example, the high growth rates in lettuce grown in the greenhouse predispose the plants to the appearance of marginal necrosis of the leaves (tipburn).

Soilless Cultivation Systems

Soilless cultivation systems are the best means of intensive vegetable production. The use of solutions with known concentrations and composition allows the precise control of the water and mineral nutrition of plants, with important consequences on the raw quality. Several studies have shown the possibility of enhancing the nutritional value of the product by changing the content of specific compounds beneficial for human health in the nutrient solution, in order to obtain functional vegetables. For example, in lettuce and spinach, it was found that increasing the concentration of iron in the nutrient solution near harvest time increases the content of this nutrient in the leaves. The systems of soilless cultivation allow for the improvement of product quality, even through the reduction of compounds potentially dangerous to human health. In this regard, the replacement of the nutrient solution with water, a few days before the harvest, has reduced to one-third the concentration of nitrate in the leaves of endive and celery, and up to one-third in lettuce.

Irrigation and Water Quality

Most vegetable crops are localized in ho, arid environments (e.g., Mediterranean countries), where the scarcity of good quality water severely limits productivity and causes a deterioration of some qualitative characteristics of the product.

Irrigation with saline water often determines a yield reduction and an improved product quality. The use of water with high electrical conductivity leads to an increase in the dry mass and a relative increase in nutraceutical substances. That is a consequence of the water-content reduction of organs and the activation of the secondary metabolism in an accumulation of antioxidant compounds. However, the stimulus on the biosynthesis of antioxidant compounds is often found only in conditions of moderate salt stress. The salinity level beyond which the biosynthesis is reduced varies depending on the cultivar, the growing conditions, and the type of bioactive molecule. Salinity also changes the mineral composition of plant tissue. For example, increasing the salinity through the addition of NaCl reduces the concentrations of P, K, Mg, and Zn, due to antagonism by Na and Cl, with a consequent decline in the nutritional quality of the product.

Differently from other vegetable species, leafy vegetables show the most sensitive period for water deficit during the the vegetative period of cultivation. A water deficit during this period has a high effect on the yield. Because their root systems are shallow (max 30 cm), frequent and light irrigations are necessary when about 20% of available water has been depleted by the crop. In general, excellent irrigation systems have to be properly managed to avoid under- and over-irrigation. Overirrigation may cause disease-spreading.

Anyway, incorrect irrigation-scheduling may negatively affect vegetable performance, with yield quality being impaired. All leafy vegetables are irrigated with localized systems. Heavy rainfall and heavy irrigation may cause severe damage to the leaf surface, with a sensitive reduction of the commercial value of product.

Fertilization

The effects of fertilization on the quality of the vegetables may vary depending on the element and its chemical form, genotype, environmental conditions, and cultivation techniques. The form of nitrogen affects the nutritional quality of the vegetables through variation in the mineral composition. The use of nitrogen as ammonium may cause the acidification of the rhizosphere, with increased absorption of Fe, Zn, and Ca; the opposite effects are induced by the use of nitrogen in the nitrate form. The increase in phosphorus availability often impacts phytochemicals such as ascorbic acid, anthocyanins, and flavonoids. Regarding the method of application for fertilizers, the foliar fertilization appears to be more effective in some cases than applying fertilizer to the substrate, especially in the presence of factors limiting the functionality of the root system (e.g., salinity).

Although there is much debate about the quality of organic vegetables in comparison to conventional ones, the availability of a limited number of rigorous studies on the subject does not

allow an objective comparison between the two types of product. Among the distinctive features of organic farming, there is certainly fertilization. In this respect, research has shown a direct influence of organic fertilization on the content of nitrates in a number of leafy vegetables, with levels almost always lower in organic products than in conventional products; this would seem to result from the gradual availability of nitrogen during the crop cycle. However, repeated organic fertilization may provide abundant levels of N, resulting in nitrate concentrations in the leaves of chard and spinach, especially in hot weather.

The relationship between organic fertilization and the content of vitamins, minerals, and secondary metabolites does not always appear clear. Although the supply of fertilizers in organic form has increased the content of phenolic compounds in tomato fruits (but not in pepper fruits), there were no observed differences in the content of phenolic compounds in lettuce raised using conventional and organic systems. The variability of the results may be related to the lack of a direct relationship of cause and effect between organic fertilization and quality of vegetables. However, excessive fertilizer application, especially with N fertilizer, can result in undesirable changes, such as increases in nitrate, titratable acidity, and acid:sugar ratio, while decreasing the concentration of vitamin C, soluble sugar, soluble solids, and Mg and Ca in some crops.

Conventional and Organic Farming

Given that organic farming has the potential to produce healthy foods and to protect the agroecosystem, its use is growing rapidly in a wide range of climate and soil types. The perception among consumers is that organically produced crops possess higher nutritional quality, because organic farmers are committed to excluding synthetic fertilizers, pesticides, herbicides, plant growth regulators, livestock additives, and genetically modified organisms, and they follow a natural way of farming.

Nevertheless, variability in cultivation factors (soil fertility, effectiveness of different types of amendments, planting and harvest dates, irrigation and tillage intensity in each crop cycle, etc.) and unpredictable and uncontrollable production variables (year-to-year weather variation, plant disease, etc.) can produce data variability that can lead to contradictory results. Some detractors claim that organic farming could be unsafe because of the risk of exposure to biological contaminants and foodborne diseases coming from manure, which is known for carrying human and animal pathogens and mycotoxins from molds. Therefore, the large number of variables involved in the vegetable cultivation make it very difficult to draw any general conclusions on the effect of agricultural practices on these parameters of food quality. Our point of view is that differences among cropping systems, presented here as conventional versus organic, may be only evaluated on a case-by-case basis.

Conclusions

There is sound scientific evidence suggesting that the regular consumption of fruits and vegetables is negatively associated with a reduced risk of developing chronic diseases. Unfortunately, the specific contributions of individual nutrients and phytochemicals to health are yet to be fully explained. Further studies are needed to identify the specific combinations of foods, within and across nutrient categories, that exhibit positive synergetic interactions. Consumers should obtain nutrients and bioactive phytochemicals from a wide variety of whole foods for optimal nutrition and healthy well-being.

Vegetarian Diets

N Burkholder, S Rajaram, and J Sabaté, Loma Linda University, Loma Linda, CA, USA

© 2016 Elsevier Ltd. All rights reserved.

Introduction: History, Description, and Trends

Historical Context

The term 'vegetarian' was established by the Vegetarian Society of the United Kingdom in 1847. The origins of vegetarianism, however, date back to at least 600 BC in ancient India and Greece. Religious groups and philosophers promoted a vegetarian diet based on the idea of nonviolence toward animals. Vegetarianism was almost nonexistent in Europe after Christianity reached the Roman Empire and then reemerged to some extent during the Renaissance. Until the last century, vegetarianism was primarily limited to religious units, but in recent decades, the health benefits of such a dietary pattern have become widely recognized.

Definitions of Vegetarian Diets and Rationale for Vegetarianism

There is no consensus concerning the definition of a vegetarian diet. The Vegetarian Society defines a vegetarian as "someone who lives on a diet of grains, pulses, nuts, seeds, vegetables, and fruits with, or without, the use of dairy products and eggs. A vegetarian does not eat any meat, poultry, game, fish, shellfish, or by-products of slaughter." Vegetarian diets encompass all meatless diets and are usually further categorized as lacto vegetarian (i.e., milk and dairy included), ovo vegetarian (i.e., eggs included), or lacto-ovo vegetarian (LOV) (i.e., dairy and/or eggs included). About 90–95% of North American vegetarians include dairy and/or eggs. Strict vegetarian or vegans exclude all meat, poultry, fish, seafood, and animal products, and some vegans also exclude honey. Semivegetarians are occasional meat eaters who predominantly practice vegetarianism, qualified as pescovegetarians (i.e., those who include fish) and pollovegetarians (i.e., those who include chicken). Typical reasons for vegetarianism include health concerns, religious or ethical beliefs, and political, metaphysical, and ecological reasons.

Trends in Vegetarian Dietary Practices: Shift in Logic behind Vegetarian Diets

About 7% of the US and UK population is vegetarian, and approximately 1% of US adults are vegan. The vegetarian population in Asia is large and ranges from approximately 25 to 40%. More females are vegetarian than males, and vegetarians tend to be slightly more educated than the general US population; however, no differences in socioeconomic status have been observed. A large proportion of the vegetarian population is over 40 years of age, but an even greater percentage is composed of young families.

The concentration of vegetarian nutrition research has changed over time. While earlier research focused mainly on nutritional adequacy of vegetarian diets, present knowledge supports vegetarianism as a viable choice for optimum health and the environment. The main theme in 40% of all vegetarian nutrition articles published in 1986–95 was preventive and therapeutic applications of vegetarian diets. The shift in coverage indicates the growing awareness that vegetarian diets, despite marginal intake of a few nutrients (e.g., iron and B_{12}), can provide ample health benefits to humans. The new paradigm suggests that nutrients present in plant foods may prevent chronic disease (e.g., cardiovascular disease (CVD) and some cancers) and promote longevity. Additionally, there is an increased awareness of the environmental impact of meat consumption, which may further promote a vegetarian lifestyle.

Vegetarian Consumption Patterns

Results from the National Health and Nutrition Examination Survey (NHANES) show that vegetarians consume more total grain, legumes, fruit, soy, and dairy compared with nonvegetarians. Vegetarians consume fewer discretionary calories from fat than nonvegetarians. According to the Continuing Survey of Food Intake by Individuals (CSFII) from 1994 to 1996 and 1998, there were 0.9% self-defined vegetarians who reported no meat intake within the nationally represented sample of US adults. According to 24 h recalls, not all self-reported vegetarians avoid red meat, poultry, or fish. However, the dietary intake of self-defined vegetarians, regardless of whether meat intake was reported or not, was lower in fat, saturated fat, and cholesterol and higher in fiber compared with nonvegetarians who ate meat. Self-defined vegetarians who ate no meat had greater intake of grains, legumes, green leafy and yellow vegetables, fruit, and wine than nonvegetarians. Intake of soy among vegetarians is higher than nonvegetarians, but the amount and type of soy consumed are variable. It is estimated that Western vegetarians consume about 5–6 g and vegans consume about 10–12 g of soy per day. Nuts are commonly consumed by vegetarians as snacks or part of a meal and are eaten whole, in spreads, or as oils or contained in commercial products.

Nutritional Status of Vegetarians

NHANES results from 1999 to 2004 revealed that for vegetarian adults over 19 years of age, adjusted means for fiber; vitamins E, A, and C; thiamin; riboflavin; folate; calcium; magnesium; iron; potassium; and phytochemicals were greater than for nonvegetarians. Protein, total fat, cholesterol, sodium, niacin, vitamin B_{12}, and zinc intake was reduced in vegetarians; however, only zinc status was below the recommended dietary allowance (RDA). A study on older adult vegetarians in Taiwan demonstrated that vegetarians consumed less total calories and cholesterol and consumed a greater proportion of fat as polyunsaturated, higher calcium, and more fiber than omnivores. Compared with vegan, ovo or lacto vegetarian diets contain more vitamin K, calcium, magnesium, and fiber. Recent literature has revealed that vegetarians consume a more nutrient-

dense diet, lower in protein and total fat, and higher carbohydrate and fiber intake compared with nonvegetarians. Additionally, data on Flemish vegetarians from show that nutritional intake of lifelong vegetarians is close to the Belgian RDA.

Health Benefits of Vegetarian Diets

It is apparent that vegetarians worldwide display low rates of a variety of health problems, including overweight and obesity, CVD, hypertension, certain cancers, T2D, kidney stones, constipation, gallstones, and diverticular disease, as well as increased longevity. The observed health benefits result from the independent influence of the absence of meat and the presence of a variety of plant foods. A vegetarian diet pattern, with lower intakes of total calories, animal protein, cholesterol, and saturated fat but greater intakes of dietary fiber, complex carbohydrates, vitamins C and E, carotenoids, magnesium, folic acid, and other phytochemicals, has been associated with reduced risk of numerous chronic diseases and overall mortality. Although uncertainty remains regarding whether the observed benefits of a vegetarian diet are due to the presence of plant foods or the absence of meat, it is important to note that epidemiological studies of diet and health among vegetarian and omnivorous populations have recorded more correlations between the protective effect of plant foods and the detrimental impact of animal foods (e.g., meat and dairy). A balanced plant-based diet that includes fish, dairy, and small amounts of red meat has also produced positive health improvements.

Longevity

Cohort studies indicate that those who follow a diet devoid of or very low in meat experience longevity, whereas high meat intake has been associated with increases in total mortality. In contrast, a large European study showed no significant differences in longevity of vegetarian compared with nonvegetarians. The inconsistent findings may be due to the minimal differences in nutrient intake between British vegetarians and nonvegetarians in the European study. The most recent report on vegetarian diets and longevity examined health records of 73 308 people for an average of almost 6 years, and researchers uncovered significant reductions in total mortality, cardiovascular mortality, noncardiovascular noncancer mortality, renal mortality, and endocrine mortality for vegetarians; associations were greater and more significant in men compared with women (Table 1).

Cardiovascular Health

Established risk factors for coronary heart disease (CHD) include lipids and lipoproteins, hypertension, hemostatic factors, glucose intolerance, obesity, smoking, alcohol, and exercise, as well as possibly homocysteine, antioxidant, and $n-3$ fatty acid levels. Numerous studies have demonstrated consistent evidence for the benefit of a vegetarian diet on reducing risk of CHD. A recent meta-analysis concluded that vegetarians have 29% lower heart disease mortality than nonvegetarians. Vegetarians usually have a more favorable lipid profile than nonvegetarians, including lower total and low-density lipoprotein (LDL) cholesterol, reduced susceptibility to LDL oxidation, lower body weight, and reduced incidence of diabetes and hypertension. Research has linked red meat intake to CHD risk, particularly processed meat intake. Many studies have shown that a primarily plant-based diet decreases risk of CHD and reduces rate of ischemic heart disease mortality, possibly due to vegetarians' higher antioxidant intake, reduced total serum cholesterol, and lower prevalence of obesity.

Overall, vegetarian diets appear to have a protective effect against CHD and are considered a strategy for primary prevention of heart disease. The observed cardiovascular benefits of a vegetarian diet are probably due to specific aspects of a vegetarian diet, particularly low intake of saturated fat, high intake of soluble fiber, and higher intake of whole grains, soy protein, legumes, and nuts. Whole grain intake and reduced CVD risk have been consistently supported by research. A recent meta-analysis concluded that intake of at least 2.5 versus 0.2 servings per day of whole grains reduced risk of CVD events by 21%. There is also evidence that the dietary fiber in whole grains reduces CHD risk through lipid reduction, blood pressure control, body weight regulation, and decreased chronic inflammation. The Japanese Collaborative Cohort Study found an inverse relationship between bean intake, including soy, and risk of CVD. Reductions in LDL attributable to intake of 25 g of soy protein per day have been observed in a recent meta-analysis of 30 studies. Both epidemiological studies and clinical trials have shown that nuts may protect against CHD, possibly through action on inflammation, vascular reactivity, lipids, and lipid oxidation. While individual components of a vegetarian diet may reduce CVD risk, the synergistic effect of these plant foods will probably deliver the maximum effect. As an example, a vegetarian diet that includes soluble fiber, soy protein, almonds, and plant sterols has been shown to reduce LDL to a similar extent as 20 g of lovastatin, a cholesterol-reducing statin drug (Table 2).

Hypertension

There is evidence that a vegetarian diet may prevent and reduce hypertension. The Adventist Health Study-2 (AHS-2) showed that vegetarians, particularly vegans, with otherwise diverse characteristics, have lower systolic and diastolic blood pressure and less hypertension than meat eaters. This is only partly due to their lower body mass index (BMI). A significant ranked relationship between meat intake and blood pressure was also observed. Compared with nonvegetarians, vegans were 75%, LOV 65%, pescovegetarians 38%, and semivegetarians 23% less likely to be treated for hypertension. In AHS-2, differences in BMI between groups only explained part of the observed relationship. The European Prospective Investigation into Cancer and Nutrition (EPIC) – Oxford study showed that those who do not eat meat had a lower prevalence of hypertension and lower systolic and diastolic blood pressures than meat eaters, but this was largely a result of differences in BMI. After adjustment for age, self-reported hypertension prevalence was 15% in male meat eaters, 5.8% in male vegans, 12.1% in female meat eaters, and 7.7% in female vegans. Fish eaters and vegetarians had a comparable intermediate prevalence of hypertension.

Randomized clinical trials have shown that components of a vegetarian diet can lower blood pressure in both normotensive and hypertensive individuals. Although it is well accepted that both weight loss and reducing sodium intake can lower blood pressure, the effect of a vegetarian diet on blood pressure appears to be independent of these, suggesting that other components of the diet are responsible. These results are consistent with previous findings that concluded that diets high in fruit, vegetables, whole grains, and low-fat dairy significantly reduced blood pressure in those with mild hypertension or normal blood pressure (Table 3).

Diabetes

Vegetarian diets are associated with a decreased risk of type II diabetes (T2D). Data from large prospective cohort studies (e.g., Women's Health Study, Nurses' Health Study, Health Professionals Follow-Up Study, and Multi-Ethnic Study of Atherosclerosis) found that men and women with the highest meat consumption had the highest risk of T2D. Intakes of red meat and processed meat were associated with a 21% and a 41% increased risk of T2D, respectively. In AHS-2, vegans were one-third less likely to have diabetes compared with nonvegetarians, with prevalence of 2.9% and 7.6%, respectively. LOV, pescovegetarians, and semivegetarians had an intermediate diabetes prevalence of 3.2%, 4.8%, and 6.1%, respectively. After adjusting for confounding factors, vegans had an almost 50% reduction in the risk of developing T2D, compared with nonvegetarians. A graded risk reduction was observed based on meat consumption, where LOV had a reduction of 46%, pescovegetarians 30%, and semivegetarians 24% in T2D risk (Table 4).

Cancer

Vegetarians tend to have reduced risk of overall cancer when compared with nonvegetarians of the same demographic. A recent meta-analysis showed that overall cancer incidence was 18% lower in vegetarians compared with nonvegetarians, where males possess a stronger degree of protection than females, perhaps due to lifestyle habits.

For specific cancers, results are inconclusive. Despite convincing evidence that red meat and processed meat consumption increases colorectal cancer risk, AHS-2 studies determined that vegetarians have a reduced risk of colon cancer, whereas results from EPIC-Oxford demonstrated that vegetarians and nonvegetarians had similar rates of colon cancer. When comparing vegetarians in different countries, it is important to recognize that the definition of vegetarian may differ between studies; some self-defining vegetarians still consume white meat or seafood regularly. Research suggests that lifelong vegetarianism may be associated with decreased risk of breast cancer due to a higher intake of vegetables, fruit, soy, and legumes and the avoidance of red meat. The lower incidence of breast cancer observed in vegetarians might be attributable to their reduced exposure to estrogen caused by lower blood estrogen levels, longer menstrual cycles, and a later onset of menstruation. Furthermore, red and processed meat intake has been positively associated with certain cancers. Additional research has not supported these findings, and further studies on the prevention of breast cancer by a plant-based diet are necessary (Table 5).

Osteoporosis

Recent cross-sectional and longitudinal population-based studies suggest little or no difference in bone mineral density (BMD) between omnivores and vegetarians. Current research demonstrates that BMD is not statistically different between

Table 2 Observational studies and intervention trials on vegetarian diets and cardiovascular disease, 2002–12

vegetarian and nonvegetarian women. The EPIC-Oxford study found that the fracture risk was similar in vegetarians and in meat and fish eaters, but there was an increased risk for vegans. However, the increased risk of fracture among vegans did not remain in those consuming at least 525 mg per day of calcium, which implies that the lower calcium intake of vegan subjects was the plausible cause for the increased fracture risk. Cross-sectional studies have shown that increased intake of major micronutrients in fruits and vegetables such as potassium, magnesium, vitamin C, vitamin K, and carotenoids is associated with higher BMD, reduced bone loss with aging, and decreased risk of fracture. Plausible mechanisms of this association include the reduced dietary acid load of plant-based diets and the promotion of positive calcium balance due to high potassium and magnesium intake. In contrast, quality and quantity of protein in animal products have been suggested

to increase acid load, which is suggested to have detrimental health effects (Table 6).

Obesity

Obesity is less prevalent among vegetarians compared with omnivores, and meat consumption is positively associated with obesity. This may be attributed to a lower caloric intake in a vegetarian (i.e., about 460 kcal) than a nonvegetarian diet pattern. Vegans weigh about 10 kg less than nonvegetarians; the mean weight was 7.6 kg less and 3.3 kg less in male and female vegetarians, respectively. The AHS revealed 21% of meat eaters versus 10% of vegetarians among men and 13% versus 8% among women were overweight or obese. Data from the CSFII 1994–96 and EPIC-Oxford studies showed that vegetarian men and women had lower BMI than nonvegetarians. A vegetarian diet may be a reasonable strategy for weight management without diminishing diet quality, as a vegetarian diet is higher in vitamins and minerals, overall fiber, and complex carbohydrates, yet lower in total calories, protein, and fat. Nuts and legumes contain slowly digestible carbohydrates, high fiber and protein contents, and moderate energy density, features known to promote weight control. Additionally, vegetarian diets are typically low in saturated fat and high in *n*-6 polyunsaturated fatty acids, and a vegetarian diet has been shown to increase levels of phospholipid linoleic acid (Table 7).

Aspects of Vegetarian Diet Responsible for Health Benefits

Lifestyle factors associated with vegetarians

It is important to note that vegetarianism is associated with nondietary lifestyle factors known to benefit health. Vegetarians tend to exercise more, smoke less, and consume less alcohol and are generally thinner compared with omnivores. It appears that vegetarians are inclined to be more health-conscious than nonvegetarians; however, observed health benefits persist even when these characteristics are controlled.

Presence of plants

There is a protective effect of plant-based dietary patterns that include whole grains, legumes and soy, nuts, fruits, and vegetables. Plant foods are rich in antioxidant nutrients including vitamins A, C, and E and the minerals zinc and copper and also contain many phytochemicals such as carotenoids, phytosterols, tocotrienols, organosulfur compounds, phenolic compounds (e.g., flavonoids, phytoestrogens, and phenolic acids), and nondigestible carbohydrates (e.g., prebiotics and dietary fiber). Phytochemicals are biologically active nonnutrients found almost exclusively in plant foods and are thought to carry antioxidant, antimutagenic, and antiproliferative properties. These plant-derived components have the ability to inhibit synthesis and activities of proinflammatory mediators (e.g., eicosanoids, cytokines, adhesion molecules, and C-reactive protein); decrease blood cholesterol, LDL oxidation, and blood pressure; and

can act as antioxidants to protect against some cancers, CVD, and T2D.

Fruits and vegetables are known to have antioxidant effects through phytochemicals lycopene, carotenoids, anthocyanins, catechins, and flavonols and vitamins A, C, and E. These components may have a synergistic effect on cells to protect from free radicals and lower chronic inflammatory signals that can increase risk of CVD, select cancers, and insulin resistance. Anticancer activity has been observed with intake of carotenoids, flavonoids, isoprenoids, phenolics, and isothiocyanates found in fruits and vegetables. Carotenoids in green leafy vegetables and fruits, vitamin C found in citrus fruits and vegetables, and lycopene abundant in tomatoes can protect against CVD by inhibiting LDL oxidation. The fiber found in fruits and vegetables aids in lowing blood cholesterol. Grape polyphenols, quercetin found in onions and garlic, and vitamin C in citrus fruits have been shown to decrease blood pressure. Grape polyphenols may also improve endothelial function and platelet aggregation and have anti-inflammatory activity.

Isoflavones in soy may inhibit cancer metastasis, have effects on lipid levels, and reduce bone loss after menopause. Soy intake is associated with significant reduction in CVD risk as it provides protein and has favorable fatty acid content with primarily linoleic and oleic acid and a smaller proportion of α-linolenic acid. Genistein and daidzein from soy appear to be protective against CVD by reducing blood pressure and lowering LDL-C. Legumes (e.g., dry beans, peas, chickpeas, and lentils) have nutritional qualities that are known to aid in weight control, including high fiber and protein contents, slowly digestible carbohydrates, and moderate energy density. Randomized controlled trials show a general benefit of legume consumption combined with calorie restriction on weight loss. Observational studies demonstrate a consistent inverse relationship between legume intake and BMI or obesity risk. Results from a recent meta-analysis show that a diet high in legumes other than soy reduces total and LDL cholesterol. The fiber and polyphenols in legumes protect against CVD by lowering blood cholesterol.

The greater fiber intakes of vegetarians may have significant effects in reducing colon cancer risk. The bulking ability of fiber may reduce the transit time of carcinogens through the bowel and decrease the surface contact exposure of the bowel wall to carcinogenic compounds. Additionally, fiber intake is independently associated with reduced weight gain and obesity risk. Fiber forms in whole grains increase intraluminal viscosity, which is associated with reduced obesity risk, but the physiological mechanism behind protective effects is unclear. Whole grain consumption is associated with reduced risk CVD, likely due to the action of fiber and phytochemicals in lowering blood cholesterol, reducing blood homocysteine, and decreasing blood pressure. Benefits of fibers found in whole grains have been demonstrated in glucose metabolism, but results are variable.

Tree nuts and peanuts contain ample nutrients, including unsaturated fatty acids, fiber, high-quality vegetable protein, tocopherols, minerals, phytosterols, and phenolic compounds. Epidemiological studies have consistently shown an association between nut consumption and a reduced risk of CVD, possibly due to the presence of unsaturated fatty acids, tocopherols, and fiber. Recent evidence suggests health-protective benefits of nuts beyond CVD. It is likely that regular consumption of nuts reduces risk of diabetes and cancer in women, and protective

benefits of frequent nut consumption on gallstone diseases have been observed in both sexes. Additionally, long-term nut consumption is linked with lower body weight and lower risk of obesity and weight gain.

Absence of meat

Dietary meat contains several components that may increase the risk of developing cancer and CVD. These food components include saturated fat, protein, iron, phosphorus, exogenous hormones, antibiotics, feed composition, preservatives and bacterial toxins, and by-products of cooking. There are several studies that relate low meat intake to longevity, including the EPIC-Oxford Health Food Shoppers, OXCHECK, German Vegetarians, and AHS. There is general agreement that red meat consumption increases the risk of colon and bladder cancer. This was the only food association with cancer labeled 'convincing' in the recent report from the World Cancer Research Fund and American Institute for Cancer Research.

Meat is twice as calorically dense as plant-based protein foods. Caloric restriction is linked to increased life span and higher cognitive function in a variety of species possibly due to reduced production of free radicals and oxidative stress. A meat-containing diet is higher in saturated fat and cholesterol and lower in essential fatty acids leading to a low polyunsaturated–saturated fatty acid ratio, which increases oxidative stress and inflammation and contributes to insulin

resistance and increased risk of T2D, CHD, and some cancers. Protein, though necessary for proper physiological function, can be detrimental in excess. Disproportionate intake of protein increases fecal nitrates, and colonic flora forms carcinogenic N-nitroso compounds, the heterocyclic amines formed during cooking of meat and fish associated with the risk of colon cancer and CVD. Excess iron from the highly absorbable heme iron in meat promotes oxidation, resulting in an increase in free radicals known to promote CVD. Furthermore, unabsorbed iron increases fecal concentration, which has a hyperproliferative effect on the colonic epithelium. Meat is also abundant in phosphorous; high phosphorus intake in the context of low calcium intake contributes to secondary hyperparathyroidism causing loss of bone mass and increased risk of osteoporosis.

Red meat, particularly high-fat processed meats, may lead to development of carcinogens (i.e., precursors to cancer) when cooked at a high temperature. Additionally, there are components of meat formed or added during processing or storage that may have detrimental health effects, including growth hormones, antibiotics, and contaminated feed from rendered scraps that can transmit various diseases to humans (e.g., mad cow). Preservatives added to meat, such as nitrates and nitrites, are implicated in colon and gastric cancer (i.e., endogenous formation of N-nitroso compounds), and salting and curing of meats irritate gastric epithelium and may increase risk of gastric cancer. Finally, improper handling of uncooked ground meat can lead to outbreaks of *E. coli* and *Salmonella*.

Potential Concerns of Vegetarian Diets

Protein

Vegetarians generally consume less protein than omnivores; however, they typically have adequate protein intake, assuming a variety of plant protein sources with adequate calories are eaten. Plant sources of protein include soy products (e.g., soy milk, soy yogurt, tofu, and tempeh), nuts, and legumes; small amounts of protein also exist in vegetables and grain products. In general, plant protein sources contain limited amounts of one or more essential amino acids; however, the protein found in soy has a protein digestibility-corrected amino acid score that is analogous to meat. It is currently recognized that strict protein combining is not necessary, assuming a variety of plant foods are eaten daily.

Vitamin B_{12}

Vegetarians consume few and vegans do not consume any vitamin B_{12} food sources. Vitamin B_{12} is essential for homocysteine metabolism, and low intake is associated with elevated plasma homocysteine. Although hyper-homocysteinemia has been observed in vegetarians of various races and genders, the total cardiovascular risk profile of vegetarians remains favorable compared with omnivores, and the role of homocysteine in CVD is inconclusive. Additionally, B_{12} supplements are readily available for vegans and vegetarians who do not consume adequate amounts of this nutrient from foods. For LOV, dairy products and eggs can supply significant amounts of B_{12}; vegans should obtain dietary B_{12} from fortified foods, such as cereals and fortified yeast, soy, or meat analogues.

Calcium and vitamin D

Research demonstrates that calcium intake is similar between vegetarians and omnivores, with vegans usually having lower intake. Some studies have shown that vegetarians, and predominantly vegans, have lower intakes of vitamin D compared with omnivores. However, data from the AHS-2 found no relationship between serum vitamin D concentrations and dietary pattern, suggesting that factors other than diet (e.g., sun exposure) have a greater influence on vitamin D status.

A vegetarian diet can easily meet the daily requirements assuming adequate calorie intake and regular consumption of dairy or soy fortified with vitamin D and calcium. Dairy products provide adequate calcium for LOV, and vegans consume calcium in fortified soy products and other calcium-rich plants. Vegans and vegetarians should select an appropriate milk or milk alternative with 5–7 g protein per serving, calcium fortified with 250–300 mg per serving, and added vitamins A and D. Calcium bioavailability in plant foods varies, but low-oxalate greens have a high bioavailability of 50–60%, and fortified soymilk, sesame seeds, and almonds are approximately 21–24% bioavailable; in comparison, cow's milk is 32% bioavailable. Additionally, a diet rich in fruit and vegetables that is typical of a vegan diet has a positive effect on calcium status and markers of bone metabolism in men and women, due to the effect of high magnesium and potassium intake.

Zinc

Zinc is present in plant foods, but is less bioavailable from plants compared to animal sources. The low absorbability is in part due to phytate content in plants, which binds minerals and hinders their absorption. Vegetarians frequently consume nuts, seeds, and whole grains, which are high in zinc and likely contribute to the observed satisfactory status in vegetarians.

Iron

Despite the lower bioavailability of nonheme iron found in plant foods, iron deficiency anemia occurrence is similar in vegetarians and nonvegetarians. Vegetarian diets are typically high in vitamin C, which enhances iron absorption. Vegetarians tend to have reduced iron stores and serum ferritin levels; however, research indicates that hemoglobin levels of vegetarians are similar to nonvegetarians. Plant sources of iron include cashews, raisins, spinach, soybeans, kidney beans, black beans, cabbage, and tomato juice.

Essential fatty acids

Although intakes of the essential *n*-3 α-linoleic acid (ALA) are similar in vegetarians and meat eaters, intakes of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) are reduced in vegetarians and nonexistent in vegans. Due to a lack of direct plant sources of *n*-3 fatty acids and limited efficiency of conversion of ALA to EPA and DHA, experts advise vegetarians to consume twice the current adequate intake of ALA. A recent study demonstrated small differences in plasma *n*-3 PUFA status in fish eaters compared with non-fish eaters; an explanation for this result may be greater conversion of ALA to EPA and DHA in non-fish eaters. To promote optimal *n*-3 fatty acid status in vegetarians, it is recommended that intake of saturated and *trans* fats be minimized and monounsaturated rather

than *n*-6 fats be consumed. Rich sources of ALA include walnuts, soy products, flaxseed, and chia seed; smaller amounts exist in green leafy vegetables; *n*-3-enriched eggs or foods fortified with DHA from algae are direct sources of DHA for vegetarians.

Practical Applications

Dietary Guidelines for Vegetarians

When counseling vegetarians, guidelines similar to the US Dietary Guidelines for Americans are applicable. These guidelines encourage whole, plant-based foods including grains, legumes, vegetables, fruits, nuts, and seeds and discourage meats, full-fat dairy, and eggs as well as all refined and processed foods. It is also recommended that vegetarians include a range of healthy fats (e.g., nuts, seeds, and avocado), consume 25–30 g of fiber per day, and possibly incorporate vitamin and mineral supplements (e.g., B_{12}, vitamin D, and calcium). Additionally, adequate calories and protein are needed to spare lean body tissue and meet nutrient needs. The vegetarian dietary guide specifies that a one ounce-equivalent serving of protein is one egg, 0.25 cup cooked dry beans or tofu, 1 tablespoon peanut butter, or 0.5 oz nuts or seeds as acceptable alternatives to meat products. Numerous foods that usually contain meat or poultry can be made vegetarian (e.g., veggie burgers, soy-based sausage, wheat gluten, and texturized vegetable protein).

Vegetarian Food Guides

A vegetarian food guide pyramid developed by Loma Linda University includes recommended servings of relevant food groups based on energy needs for both vegans and LOV. USDA's MyPlate provides resources for vegetarians, including alternative protein sources, tips for vegetarians, and the Vegetarian Nutrition Resource List. Additionally, the General Conference of Seventh-Day Adventists established the vegetarian MyPlate, a vegetarian version of the USDA MyPyramid; a vegan MyPlate is also available from the Vegetarian Resource Group. A Japanese vegetarian food guide has also been created for both the general public and the health professionals to promote adequate intakes of all nutrients (Figure 1).

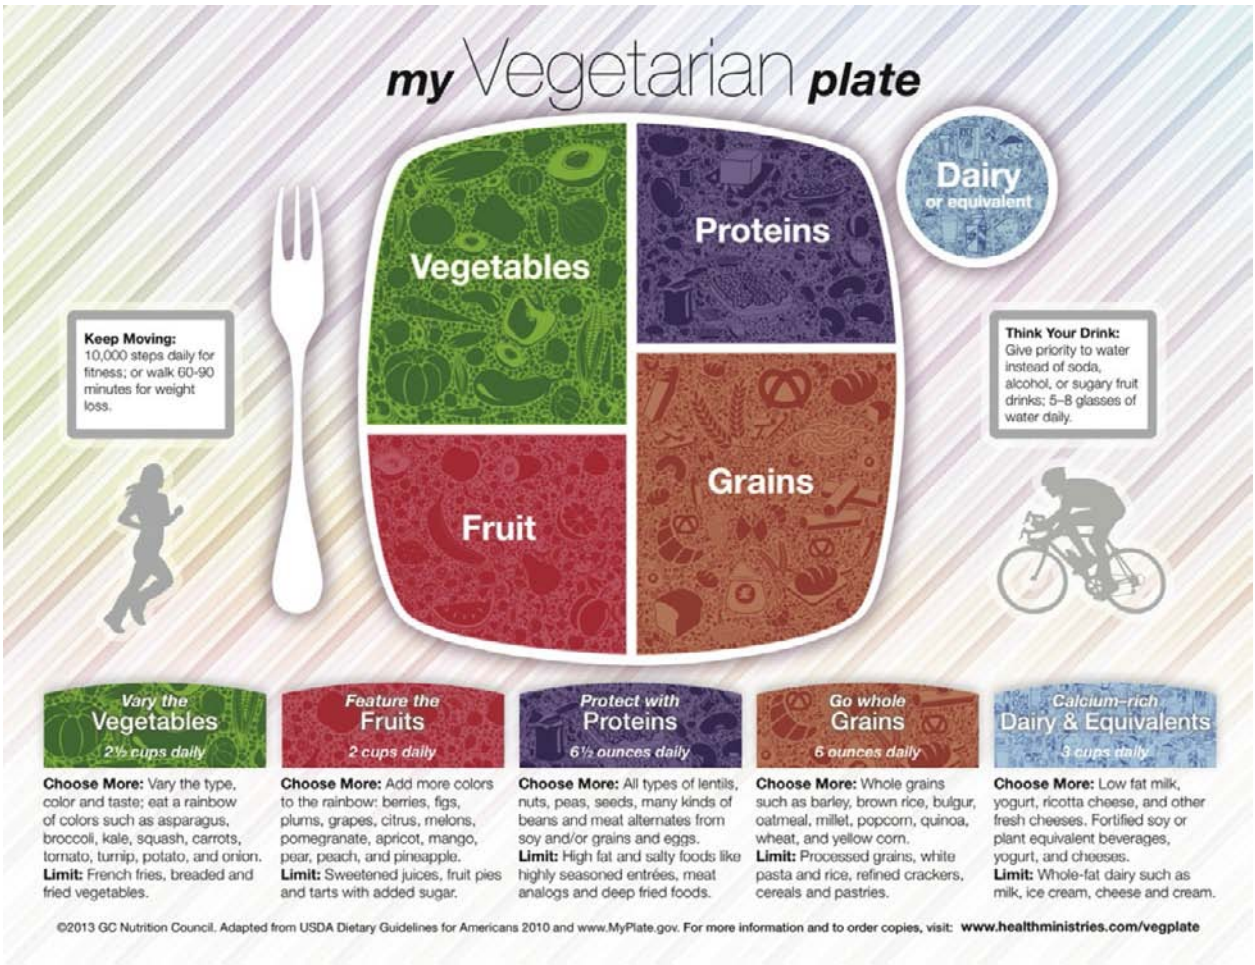

Figure 1

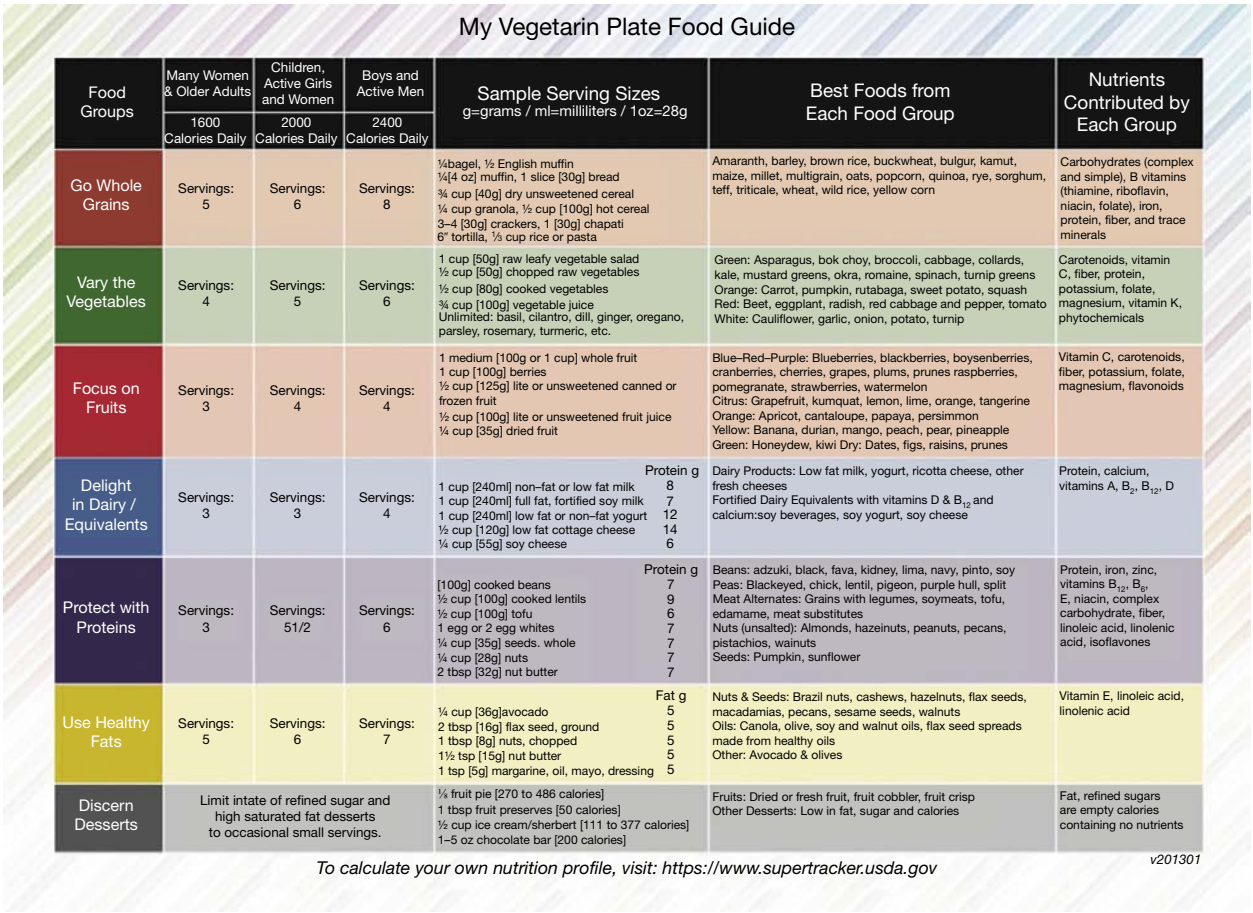

My Vegetarin Plate Food Guide

Food Groups	Many Women & Older Adults 1600 Calories Daily	Children, Active Girls and Women 2000 Calories Daily	Boys and Active Men 2400 Calories Daily	Sample Serving Sizes g=grams / ml=milliliters / 1oz=28g	Best Foods from Each Food Group	Nutrients Contributed by Each Group
Go Whole Grains	Servings: 5	Servings: 6	Servings: 8	¼bagel, ½ English muffin ¼[4 oz] muffin, 1 slice [30g] bread ¾ cup [40g] dry unsweetened cereal ¼ cup granola, ½ cup [100g] hot cereal 3–4 [30g] crackers, 1 [30g] chapati 6" tortilla, ⅓ cup rice or pasta	Amaranth, barley, brown rice, buckwheat, bulgur, kamut, maize, millet, multigrain, oats, popcorn, quinoa, rye, sorghum, teff, triticale, wheat, wild rice, yellow corn	Carbohydrates (complex and simple), B vitamins (thiamine, riboflavin, niacin, folate), iron, protein, fiber, and trace minerals
Vary the Vegetables	Servings: 4	Servings: 5	Servings: 6	1 cup [50g] raw leafy vegetable salad ½ cup [50g] chopped raw vegetables ½ cup [80g] cooked vegetables ¾ cup [100g] vegetable juice Unlimited: basil, cilantro, dill, ginger, oregano, parsley, rosemary, turmeric, etc.	Green: Asparagus, bok choy, broccoli, cabbage, collards, kale, mustard greens, okra, romaine, spinach, turnip greens Orange: Carrot, pumpkin, rutabaga, sweet potato, squash Red: Beet, eggplant, radish, red cabbage and pepper, tomato White: Cauliflower, garlic, onion, potato, turnip	Carotenoids, vitamin C, fiber, protein, potassium, folate, magnesium, vitamin K, phytochemicals
Focus on Fruits	Servings: 3	Servings: 4	Servings: 4	1 medium [100g or 1 cup] whole fruit 1 cup [100g] berries ½ cup [125g] lite or unsweetened canned or frozen fruit ½ cup [100g] lite or unsweetened fruit juice ¼ cup [35g] dried fruit	Blue–Red–Purple: Blueberries, blackberries, boysenberries, cranberries, cherries, grapes, plums, prunes raspberries, pomegranate, strawberries, watermelon Citrus: Grapefruit, kumquat, lemon, lime, orange, tangerine Orange: Apricot, cantaloupe, papaya, persimmon Yellow: Banana, durian, mango, peach, pear, pineapple Green: Honeydew, kiwi Dry: Dates, figs, raisins, prunes	Vitamin C, carotenoids, fiber, potassium, folate, magnesium, flavonoids
Delight in Dairy / Equivalents	Servings: 3	Servings: 3	Servings: 4	Protein g 1 cup [240ml] non–fat or low fat milk 8 1 cup [240ml] full fat, fortified soy milk 7 1 cup [240ml] low fat or non–fat yogurt 12 ½ cup [120g] low fat cottage cheese 14 ¼ cup [55g] soy cheese 6	Dairy Products: Low fat milk, yogurt, ricotta cheese, other fresh cheeses Fortified Dairy Equivalents with vitamins D & B_{12} and calcium:soy beverages, soy yogurt, soy cheese	Protein, calcium, vitamins A, B_2, B_{12}, D
Protect with Proteins	Servings: 3	Servings: 51/2	Servings: 6	Protein g [100g] cooked beans 7 ½ cup [100g] cooked lentils 9 ½ cup [100g] tofu 6 1 egg or 2 egg whites 7 ¼ cup [35g] seeds. whole 7 ¼ cup [28g] nuts 7 2 tbsp [32g] nut butter 7	Beans: adzuki, black, fava, kidney, lima, navy, pinto, soy Peas: Blackeyed, chick, lentil, pigeon, purple hull, split Meat Alternates: Grains with legumes, soymeats, tofu, edamame, meat substitutes Nuts (unsalted): Almonds, hazeinuts, peanuts, pecans, pistachios, wainuts Seeds: Pumpkin, sunflower	Protein, iron, zinc, vitamins B_{12}, B_6, E, niacin, complex carbohydrate, fiber, linoleic acid, linolenic acid, isoflavones
Use Healthy Fats	Servings: 5	Servings: 6	Servings: 7	Fat g ¼ cup [36g]avocado 5 2 tbsp [16g] flax seed, ground 5 1 tbsp [8g] nuts, chopped 5 1½ tsp [15g] nut butter 5 1 tsp [5g] margarine, oil, mayo, dressing 5	Nuts & Seeds: Brazil nuts, cashews, hazelnuts, flax seeds, macadamias, pecans, sesame seeds, walnuts Oils: Canola, olive, soy and walnut oils, flax seed spreads made from healthy oils Other: Avocado & olives	Vitamin E, linoleic acid, linolenic acid
Discern Desserts	Limit intate of refined sugar and high saturated fat desserts to occasional small servings.			⅛ fruit pie [270 to 486 calories] 1 tbsp fruit preserves [50 calories] ½ cup ice cream/sherbert [111 to 377 calories] 1–5 oz chocolate bar [200 calories]	Fruits: Dried or fresh fruit, fruit cobbler, fruit crisp Other Desserts: Low in fat, sugar and calories	Fat, refined sugars are empty calories containing no nutrients

Figure 1 (Continued) Vegetarian MyPlate.

Conclusion

A vegetarian diet could present a marked advantage over meat-based diets, and ample research has demonstrated increased longevity and several chronic diseases in vegetarians. A vegetarian diet is lower in total fat, saturated fat, cholesterol, and animal protein but higher in complex carbohydrates, fiber, antioxidants, and unsaturated fats and thus provides a potential dietary option for preventing diabetes, CVD, obesity, and select cancers. Despite lower intakes of certain nutrients for strict vegetarians, careful dietary planning can ensure that current recommended intakes for essential nutrients are met. Additionally, a plant-based diet is abundant protective food components that benefit health. The reported health benefits of a vegetarian diet as well as the economic and environmental ramifications of meat consumption should be considered when assessing the health effects of a vegetarian diet.

Vibrio Types and Properties

Vibrio Genus

The genus *Vibrio* belongs to the Vibrionaceae family and includes bacteria autochthonous of the marine environment. To date, the genus includes more than 90 species and its taxonomy is continuously updated due to the addition of new species. Morphologically, vibrios are Gram-negative straight or curved rods, with a size between 0.5 and 0.8 μm in width and 2–3 μm in length; they are motile by means of a single polar flagellum and display both respiratory metabolism and fermentative metabolism. Vibrios are nonsporogenous microorganisms, but survival in the environment is facilitated by resistance forms as the viable but nonculturable state (VBNC), a dormant state characterized by a reduction of cells size, and a shift to alternative metabolic pathways. The genus *Vibrio* includes both halotolerant and halophilic bacteria: halotolerant vibrios are capable of growth in the absence of salt (NaCl), whereas halophilic vibrios are dependent on the presence of NaCl for multiplication. Due to their flexible physiology, vibrios are one of the most common microorganisms in marine and estuarine waters throughout the world, and they can persist in a variety of aquatic ecosystems, including freshwater habitats (*V. cholerae* and *V. mimicus*) and seawater, both as free-living cells and in association with aquatic animals and plants.

Several *Vibrio* species are known to be associated with outbreaks and sporadic cases due to the consumption of contaminated water, food manipulated in inadequate hygiene conditions, seafood (raw fish and shellfish), or the exposure of skin lesion (cuts, open wounds, or abrasions) to aquatic environments and marine animals (Table 1). Pathogenicity toward humans is commonly associated with the presence of specific genetic features (e.g. toxin-coding genes and virulence factors) whose variable distribution among the strains often results in the coexistence of pathogenic and nonpathogenic populations in the same species. The most commonly known pathogen is *V. cholerae*, the etiologic agent of cholera, one of the few foodborne illnesses with pandemic potential. Other relevant species that may cause disease, mainly by seafood ingestion, are *V. parahaemolyticus* and *V. vulnificus*, which are normal inhabitants of marine environments and are isolated from seawater and seafood with frequencies varying, according to the studies, from less than 10% up to 36% for finfish samples and 100% for shellfish. Variations in *Vibrio* prevalence and levels are indeed expected, in relation to the food type (with higher presence in filter-feeding animals as shellfish), the geographic origin of the seafood product, and the sampling period. *Vibrio* levels in the aquatic environment, in fact, are known to correlate with water temperatures, and detection is therefore more likely in warm months than in winter periods. Unfortunately, because vibrios are part of the normal marine microflora and, with the exception of *V. cholerae*, are not associated with fecal pollution or anthropic impact on seafood production or harvesting areas, control measures can only rely on adequate manipulation of the products (rapid refrigeration, uninterrupted cold chain, and proper cooking) and on the monitoring of the environmental conditions that may favor the increase of *Vibrio* levels.

Further to the three major human pathogens (*V. cholerae*, *V. parahaemolyticus*, and *V. vulnificus*) and to the other species (*V. alginolyticus*, *V. fluvialis*, *V. furnissi*, *V. metschnikovii*, etc.) that are occasionally responsible for disease in susceptible individuals, several *Vibrio* species (e.g., *V. anguillarum*, *V. harveyi*, and *V. salmonicida*) express pathogenicity toward marine animals (fish, shellfish, or mammals) with considerable economic loss in the aquaculture sector due to large mortality episodes or to prolonged decrease of production. Significantly, some *Vibrio* species display potential for both severe diseases in humans and in aquatic animals, as is the case of *V. vulnificus*, which causes mortality in eels and deadly wound infections in aquaculture professionals (fishermen, processors, etc.), or of *V. parahaemolyticus*, causative agent of gastroenteritis in seafood consumers and responsible for the early mortality syndrome in shrimps.

Vibrio cholerae

V. cholerae is the etiologic agent of cholera, an infectious disease responsible, in areas endemic for this microorganism, for large epidemics and for a high number of deaths, especially in the presence of inadequate hygiene standards and improper treatment of wastewaters. The first description of a '*Vibrio*-like' microorganism from patients affected by cholera dates back to 1854 with Filippo Pacini and first isolation of *V. cholerae* was achieved in 1884 by Robert Koch. The modern history of cholera is marked by seven pandemics, during which the disease spread at a global level with reiterated and geographically shifting epidemic peaks.

V. cholerae includes more than 200 hundred serogroups according to somatic antigen O, a thermostable polysaccharide of the cellular wall. Serotypes O1 and O139 are associated with cholera epidemics, whereas the other serotypes, generally defined as '*V. cholerae* non-O1/non-O139,' are occasionally responsible for sporadic cases of gastroenteritis, mild forms of disease similar to cholera, or extraintestinal infections. Serogroup O1 can be further divided in two serotypes (Ogawa and Inaba) and two distinct biotypes: the biotype Classic, deemed responsible for the first six pandemics (1817–1923), and the biotype El Tor, so called by the name of the quarantine center where it was first isolated, responsible for the seventh ongoing pandemic (1961). Biotype differentiation was based initially on the characteristic hemolytic effect of El Tor variant on sheep erythrocytes, but this feature became progressively less discriminating during the seventh pandemics as the nonhemolytic

Table 1 Most relevant *Vibrio* species associated with human diseases

Species	*Source*	*Disease*
V. alginolyticus	Seafood, seawater	Wound infection, ear infections, gastroenteritis
V. cholerae O1-O139	Water or food	Gastroenteritis
V. cholerae non-O1/non-O139	Water or food	Gastroenteritis, wound infection, ear infection
V. fluvialis	Seafood	Gastroenteritis
V. furnissii	Seafood	Gastroenteritis
V. hollisae	Shellfish	Gastroenteritis, ear infection
V. metschnikovii	Shellfish, seawater	Primary septicemia, gastroenteritis
V. mimicus	Shellfish, seawater	Gastroenteritis, ear infection, wound infection
V. parahaemolyticus	Shellfish	Gastroenteritis
V. vulnificus	Shellfish, seawater	Primary septicemia, wound infection, bacteremia, gastroenteritis

strains overcame the hemolytic ones. The distinction, however, maintained an epidemiological convenience, as the different biotypes seem to correlate with the clinical severity of the disease, being the El Tor type less aggressive (only 2% of patients develop severe disease, compared to 11% of the classical infection). Until 1992, the distinction between *V. cholerae* O1 and non-O1 (also described as NAG, nonagglutinable *V. cholerae*) was considered pivotal to differentiate between strains with potential for epidemic cholera and nonpathogenic *V. cholerae* isolates. In early 1993, however, reports appeared in India and Bangladesh of a severe cholera-like disease associated with a new serogroup, O139, sometimes referred to as '*V. cholerae* Bengal,' for the origin of the strain. Since its first appearance, this serogroup, characterized by hybrid features of O1 and non-O1 strains, has spread to other countries (China, Thailand, Pakistan, Nepal, and Malaysia) and, although remaining geographically confined to Southeast Asia, has compelled a global revision of serological testing.

As other *Vibrio* species, *V. cholerae* is part of the autochthonous bacterial flora of estuarine areas, and its growth may occur in variable temperature conditions (from 10 to 43 °C) and in NaCl concentrations ranging from 0.1% to 4.0%. Halotolerance of *V. cholerae* is a key feature of its transmission, especially in developing countries, where ingestion of contaminated water is probably the most important vehicle. Free in the drinkable water, *V. cholerae* can, in fact, survive for several days (up to 13) and can contribute to persistence of the infection also via food prepared with contaminated water, as in the case of some outbreaks generated by rice dishes or fruit juices, or with the use of contaminated water for the irrigation of vegetables. It is also demonstrated that *V. cholerae* can persist in the environment in the absence of human disease, possibly through the colonization of the surface of zooplankton (e.g., copepods) and aquatic plants. Another relevant feature for *V. cholerae* transmission is related to its pH tolerance. *V. cholerae* may grow in a pH range between 5.0 and 9.6 with pH 7.6 being the optimum pH and displays sensitivity to acidic environment (which, in the form of gastric acids, provides the major human defense barrier to *Vibrio* infection). Foods involved in *V. cholerae* transmission (crustaceans, shellfish, cooked meat and rice dishes, nonalcoholic and noncarbonated drinks, and raw vegetables and fruits) usually display neutral or nearly neutral pH, and thus, this aspect can be taken into account to orientate the investigations in outbreak settings.

The main virulence factor of *V. cholerae* is represented by the cholera toxin (CT), a typical AB subunit toxin encoded by the *ctx* gene (*ctxA* and *ctxB*), which is present on a horizontally transmissible filamentous bacteriophage (CTXΦ). CT is responsible for the osmotic disequilibrium in intestinal lumen at the origin of the massive water flows ('rice water feces') characteristic of cholera disease. CT, however, is not the only pathogenicity determinant of *V. cholerae*, as multiple systems are involved in regulation of virulence. Among these, the ToxR regulon controls the expression of several (at least 17) genes involved in the pathogenic mechanism of *V. cholerae*, and therefore, *toxR* gene is often used as a molecular marker in *V. cholerae* analysis. Further to CT, other factors are expressed in virulent strains: the zonula occludens toxin (*zot*), which affects the structure of tight junction and increases the permeability of the intestinal mucosa; the accessory CT (*ace*), which acts on fluid accumulation; and the toxin-coregulated pilus (TCP), long filaments on the surface of the microorganism with an important role in adherence and colonization of intestinal mucosa. Also, non-O1/non-O139 *V. cholerae* strains may occasionally encode for some of these genes, as well as for other specific virulence factors as a heat-stable toxin (codified by the *st* gene), thermostable direct hemolysins, or shigella-like toxins.

Vibrio parahaemolyticus

V. parahaemolyticus was first described as the etiologic agent of the 'shirasu food poisoning' in Japan. Late in 1950, a severe foodborne outbreak (272 cases and 20 fatalities) was reported in Osaka, with patients suffering from acute gastroenteritis, severe abdominal pain, vomiting, and diarrhea. Epidemiological investigation led to identify the source of the outbreak to a small, semidried fish ('shirasu') and to the isolation by Dr. Tsunesaburo Fujino of a new microorganism, *Pasteurella parahaemolytica*, later renamed *Vibrio parahaemolyticus*.

Since then, *V. parahaemolyticus* outbreaks have been repeatedly reported in the world, and at present, *V. parahaemolyticus* is considered the first cause of the nonviral infections related to shellfish consumption in the United States, Japan, and Southeast Asia. This microorganism, in fact, displays the features common to *Vibrio* genus, as the natural occurrence in the marine environment and the correlation with water temperature and salinity, and is therefore commonly present in seafood products, with densities usually lower than 10^3 cfu g^{-1}, although such levels may be exceeded in products harvested from warmer seawaters. In addition, *V. parahaemolyticus* is also characterized by a remarkable replication time (as short as 8–9 min in optimal conditions and in the range of 12–18 min in seafood) that allows multiplication of the microorganism and rapid reaching of the estimated infectious dose (10^5–10^7 cfu for pathogenic strains) in raw, undercooked, or cross contaminated seafood products that are incorrectly stored.

As for *V. cholerae*, not all *V. parahaemolyticus* strains are pathogenic. A strong correlation between human disease and

production of two toxins (the thermostable direct hemolysin (TDH) and the TDH-related hemolysin (TRH)) has been demonstrated. TDH production, which induces beta-hemolytic activity in human erythrocytes on Wagatsuma agar (a process designated as Kanagawa phenomenon), is dependent upon the presence and expression of one or more nonidentical copies of the *tdh* gene (five variants have been reported), while TRH is encoded by the *trh* gene, in which at least two major subgroups (*trh1* and *trh2*) can be defined. Besides these hemolysins, other putative virulence factors are currently under investigation, as it has been shown that about 10% of clinical strains contain neither *tdh* nor *trh*. In particular, the role of the type III secretion systems (T3SSs) detected in *V. parahaemolyticus* (T3SS2-α and T3SS2-β) and of its genomic islands (*Vibrio* pathogenicity islands (VPaIs)) has been scrutinized since the emergence in early 1996 of a O3:K6 strain, whose diffusion, first in Asia (India, Bangladesh, Indonesia, Thailand, Laos, Taiwan, Korea, and Japan) and then in Europe, Mozambique, the United States, Mexico, and South American countries, has given rise to the first *V. parahaemolyticus* pandemic. Serotyping of *V. parahaemolyticus* is based on both somatic O (13 antigens) and capsular polysaccharide K antigens (65), but up to the description of the pandemic strain, there was no correlation between serotype and virulence and, until now, factors providing advantage to O3:K6 over other strains remain unclear.

Vibrio vulnificus

V. vulnificus is the most clinically serious *Vibrio* infection in developed countries, accounting in the United States for almost the totality (95%) of the deaths associated with seafood consumption. *V. vulnificus* is responsible, in fact, for severe infections in susceptible individuals, with two distinct disease syndromes, primary septicemia (with a case-fatality rate of approximately 50%) and necrotizing wound infections.

Based upon the variation of their biochemical profiles, three *V. vulnificus* biotypes can be distinguished. Strains belonging to biotype 1 are most commonly associated with human disease and can be isolated from seafood products (finfish and bivalve mollusks), biotype 2 is usually considered as an eel pathogen, while strains belonging to biotype 3, isolated in Israel in 1996, affect humans through wound infection and bacteremia. *V. vulnificus* is a widespread inhabitant of estuarine environments; its presence has been reported in seawater, shellfish, crabs, etc., and a strong correlation has been detected between water temperature and its isolation.

Infections are usually sporadic, and in almost all of them, the patient has an underlying chronic disease (e.g., cirrhosis or liver- or blood-related disorders) leading to elevated serum iron levels; other cases are reported in the presence of pathologies as chronic renal or gastric diseases, immunosuppression, and diabetes. Many studies have attempted discrimination of virulent and avirulent strains by comparison of clinical and environmental strains, but due to the high degree of genetic diversity, a definitive indicator has yet to be identified. *V. vulnificus* invasivity is related to the high variety of virulence factors expressed by this species: the polysaccharide capsule, which is produced by nearly all strains and confers an opaque aspect to *V. vulnificus* colonies, is essential for infection as it protects the microorganism from phagocytosis and from the activity of the complement system; the endotoxic lipopolysaccharides is responsible for the typical symptoms (fever, hemorrhage, hypotension, etc.) of *V. vulnificus* septicemia; siderophore production allows iron uptake from host serum; and a large number of extracellular enzymes, including proteases, elastase, and a hemolysin/cytotoxin with strong cytolytic activity, support the tissue disruption activity during the infection.

Other *Vibrio* Species

Besides the three species previously described, other vibrios have been recognized as potential pathogens for humans. *V. alginolyticus* is one of the *Vibrio* species most commonly detected in seawater and in seafood products; infections (otitis and wound infections) are mostly related to contact with the marine environment and few reports of its implication as a foodborne pathogen are available, even though severe cases have been described in patients with underlying medical conditions. *V. mimicus*, formerly known as 'sucrose-negative *V. cholerae* non-O1' for its similarity to the more renowned species, is causative agent of sporadic cases of gastroenteritis, mainly in relation to consumption of raw shellfish and crustaceans. Most of the virulence factors expressed by *V. mimicus* are toxins described in other species, including CT, TDH, zot, and st of non-O1/non-O139 *V. cholerae* strains. Finally, two closely related species, *V. fluvialis* and *V. furnissi*, have also been implicated in gastroenteritis episodes or outbreaks; *V. fluvialis*, in particular, has been reported in a large number of pediatric patients in India, and in surveillance data from the Center for Disease Control and Prevention, it represents approximately 5% of the vibriosis in the United States.

Vibrio Detection

Cultural Methods

In routine analysis of food products, the detection of pathogenic vibrios mostly relies on conventional cultural methods, followed by biochemical and, for *V. cholerae*, serological testing. Such approach, applied in internationally recognized methods as ISO/TS 21872 and the FDA Bacteriological Analytical Manual, includes a preenrichment step in a nonselective medium (usually alkaline peptone water with an appropriate concentration of NaCl) and provides resuscitation of bacteria, including cells in a VBNC state and cells stressed due to product refrigeration or freezing. Enrichment is then followed by isolation of colonies on selective agar media, with thiosulfate citrate bile salt agar (TCBS) being the most commonly used. Random selection of colonies with characteristic features represents a critical point of the procedure, as species of interest in food analysis (*V. cholerae*, *V. parahaemolyticus*, and *V. vulnificus*) may be overgrown both during enrichment and on agar plates by other vibrios as *V. alginolyticus* or by other genera, therefore making isolation of relevant colonies less efficient. In this context, the formulation of new selective and differential media (e.g., chromogenic media) to use in association with TCBS has progressively improved the chance to differentiate the species targeted by the analysis. The isolation of colonies is critical also under another prospective: as pathogenic strains of *Vibrio* species often represent a small minority of the microbial flora, the number and the proportion of characteristic colonies

selected for further testing may significantly affect the probability of detecting the pathogenic strains of a species (e.g., isolates belonging to the serogroups O1/O139 of *V. cholerae* or *tdh*-positive/*trh*-positive *V. parahaemolyticus* strains). Further to the isolation step, the total performance of the cultural methods may be challenged also by the identification of the isolates; the variability of the biochemical profiles of *Vibrio* environmental strains, in fact, may negatively affect the accuracy of the biochemical identification by conventional tests, dichotomous keys, or miniaturized tests, leading to inconclusive results or to misidentifications.

Conventional cultural methods for *Vibrio* analysis show, overall, important characteristics that encourage their routine adoption, including technical easiness, relatively low costs, and integration with laboratory's workflows. On the other hand, however, the cultural analytic process is time-consuming (4–5 days to obtain the identification of the microorganisms), labor-intensive, and, lastly, unable to provide a characterization of the virulence factors associated with human illness. To this aim, a progressive integration of the cultural and molecular analytic methods for *Vibrio* analysis has been pursued, as testified by the introduction, also in the aforementioned methods for official controls, of polymerase chain reaction (PCR) protocols for sample screening, improvement of species identification, and characterization of pathogenicity factors.

Molecular Methods

During the past years, nucleic acid detection and amplification methods have significantly broadened the spectrum of diagnostic tools for the analysis of *Vibrio* species, and to date, a large number of both conventional and real-time PCR protocols, isothermal amplification (LAMP) procedures, and some hybridization methods have been published for the detection, identification, characterization, or enumeration of potentially pathogenic species. One of the major advantages accorded by nucleic acid-based techniques is related to the fact that, by targeting directly genetic sequences responsible for or associated with virulence of defined *Vibrio* species, they provide more reliable information on the risk associated with the presence of pathogenic vibrios in a product. A second advantage is given by the substantial reduction of the time required for the analysis, with detection of potentially pathogenic species completed, for certain protocols, in 24 h or less. In this sense, the molecular techniques represent the most suitable analytic approach for industries and food producers to prevent release on the market of products containing pathogenic *Vibrio* species, as well as for control authorities to provide timely results, therefore ensuring food safety and preventing outbreaks.

Molecular detection methods for *Vibrio* have been directed, depending on the scope of the analysis, to either conserved region of the genome (species detection or isolates identification) or genes encoding or associated with virulence (detection of potentially pathogenic strains). PCR targeting total *V. cholerae*, for example, has largely relied on the detection of conserved and widespread genes as *toxR*, which is involved in the regulation cascade of virulence-associated genes; *ompW* gene, which encodes an outer membrane protein and is conserved in both clinical and environmental isolates; and *hlyA* gene, a nonclassical fragment of the hemolysin gene present in O1, O139, and non-O1/non-O139 *V. cholerae* strains. Identification of pathogenic strains has, on the other hand, mainly targeted genes associated with the CT production, including *ctxA* and *ctxB*, or codifying for other virulence factors as *zot*, *ace*, *tcp*, or *st* genes. PCR protocols, however, have also been successfully developed for rapid characterization of strains, for example, with the identification of *V. cholerae* O1 epidemic strains through *ctxB* allelic discrimination or by using *rfb* gene for the molecular differentiation of O1 and O139 isolates.

Compared to *V. cholerae*, a multiplicity of sequences has been proposed in the last years for the detection of *V. parahaemolyticus* in food samples and seawater or for the identification of isolates. The 16S ribosomal RNA gene, for example, was repeatedly evaluated as a possible target for molecular analysis, but high sequence homology with other species (e.g., 99.7% with *V. alginolyticus*) and the presence of intrastrain polymorphisms have hampered its use. *GyrB* gene, encoding the B subunit of DNA gyrase, and fragments of the *hsp* (heat shock protein) gene, being characterized by a lower sequence homology with other *Vibrio* species, were also suggested as possible targets for differentiation of *V. parahaemolyticus*. Three other targets, however, have been extensively used and compared, especially for the application in food analysis: the *tlh* gene, codifying for a thermolabile hemolysin (TLH) in *V. parahaemolyticus* and, at present, widely used in the United States and Japan; the *toxR* gene, homologous to the regulator gene of *V. cholerae* and conserved with low sequence identity in the whole Vibrionaceae family, whose application is common in Southeast Asia and Europe; and the pR72H sequence, a restriction fragment generated by HindIII enzyme that includes a coding (phosphatidylserine synthase gene) region and a noncoding region and that appears to be conserved in *V. parahaemolyticus* strains. In contrast to methods for *V. parahaemolyticus* identification, protocols aiming at the detection of potentially enteropathogenic strains have unequivocally targeted the *tdh* and *trh* genes, often in multiplex format with each other or with one of the aforementioned sequences for species identification.

For *V. vulnificus*, identification has been mainly based on the cytotoxin–hemolysin gene (*vvh*), thought to be common to all biotypes, although potential problems of gene loss associated with the use of this target have been reported. Alternative genomic loci, as the 16S rRNA gene, have been therefore investigated, both for identification purposes and to achieve differentiation between clinical and environmental strains; a 17-base sequence variation in the 16S rRNA gene, in fact, was shown to have a statistically significant correlation with clinical isolates. Other genes and sequences, including the virulence-correlated gene (*vcg*), a siderophore-encoding gene (*viuB*), and the capsular polysaccharide operon, have demonstrated, however, comparable or higher discriminative power and have been widely applied for *V. vulnificus* characterization.

In the analysis of foods in which *Vibrio* species may be present, nucleic acid amplification-based methods usually provide results with high specificity and information relevant for the characterization of pathogenicity potential of microorganisms. Nonetheless, a major drawback of these methods is that, due to the low concentration of the targets and the high inhibitory effect of food matrices on PCR amplification, sensitivity levels compatible with food analysis can be achieved only on

preenriched samples. As a consequence, even though several real-time qPCR protocols have been developed for analysis of vibrios in foods, quantification by molecular methods has in the end settled for the use of MPN-PCR formats that, although sensitive, call for a considerable increase of analytic work and costs. An alternative approach for *Vibrio* enumeration is granted by colony hybridization techniques, which combine growth on nonselective agar media with molecular identification/characterization using specific probes, and a few hybridization protocols have been described, especially for quantitative analysis of *V. parahaemolyticus* and *V. vulnificus*.

Sources and Production

Despite some small local differences, in general, food regulations consider vinegar to be the result of a double fermentation (alcoholic and acetic fermentation or acetification) of any sugary substrate. European countries have specific rules for vinegars sold in different regions. In the European Union, the established limits for acidity and residual ethanol content are strictly set. Therefore, the acidity of wine vinegar (acetification obtained exclusively from wine) must be at least 6% (m/v) of acetic acid, and the maximum residual ethanol allowed is 1.5% (v/v). However, the variety of raw materials used in the production of vinegar is very broad, ranging from by-products and agricultural surpluses to high-quality substrates for the most unique and prized vinegars, such as sherry vinegar (Spain) and Aceto Balsamico Tradizionale (ABT) (Italy). Chemically, the main component of vinegar is acetic acid. Although most of the acetic acid produced in the world is the result of chemical synthesis, only the acetic acid obtained from double fermentation is accepted for the food industry in general.

Vinegars can be classified by their substrates of origin or by their systems of production (Figure 1). According to the origin-derived classification, vinegars can be fruit vinegars (the most common types, especially from grapes, mostly called wine vinegars), grain vinegars (originating from several cereals, such as malt or rice vinegars), alcohol vinegars (mostly derived from pure alcohol obtained by distilling different by-products of the beverage industry: grape or other fruit pomace, corn, etc.), or even vinegars from products of animal origin (such as honey or milk serum). It is necessary to differentiate between those products derived from the double fermentation of a single fruit (most often grapes or apples) and those that are 'flavored' vinegars, that is, vinegars of various origin with fragrances or concentrates of different fruits, flowers, or spices. Although these 'flavored' vinegars are not considered vinegars in some countries, lax regulations in other countries allow these products or condiments to be sold as 'vinegars.'

The first fermentation is an alcoholic fermentation and transforms sugars or processed starches into ethanol. This process is performed by yeast, mostly from the species *Saccharomyces cerevisiae*, although some other species can also perform the alcoholic fermentation in part or in total. The final result is considered the substrate of the second transformation, that is, from ethanol to acetic acid. Although this second process is often referred as 'acetic' or 'oxidative' fermentation, it is not biochemically a fermentation but an oxidation. The proper term is thus 'acetification.' This process involves a two-step oxidation, from ethanol to acetaldehyde and further from acetaldehyde to acetic acid, whereby the end of this process requires an electron acceptor, with molecular oxygen being the most common. The microorganisms responsible for this process are acetic acid bacteria.

Acetic acid bacteria are Gram-negative or Gram-variable, either ellipsoidal or cylindrical, and can be observed under a microscope alone, in pairs, or in aggregates and chains. They have aerobic respiratory metabolism because oxygen is the final electron acceptor, although other compounds may occasionally act as final electron acceptors. As a result, acetic acid bacteria can survive under nearly anaerobic conditions albeit by displaying severely limited growth. These bacteria are found on substrates containing sugars and/or alcohol, such as fruit juice, wine, cider, and beer. On these substrates, the sugars and alcohols are incompletely oxidized, leading to the accumulation of organic acids, such as the production of acetic acid from ethanol or gluconic acid from glucose. Some of the transformations performed by acetic acid bacteria are of great interest to the biotechnology industry. During acetification, these bacteria can also produce ethyl acetate and other esters that are characteristic of their metabolism. Although more than 60 species have been described as acetic acid bacteria, only a limited number of them are involved in the production of vinegar. Most of the species involved in vinegar production were initially classified within the genus *Acetobacter*, but some of them have been reclassified to the genus *Gluconacetobacter* and, more recently, to *Komagataeibacter*. For instance, *Komagataeibacter europaeus*, a common species in high-acetic acid content vinegars, can be found in the literature described as *Gluconacetobacter europaeus* or *Acetobacter europaeus*. The species most commonly found in the production of vinegar are *Acetobacter pasteurianus*, *Komagataeibacter europaeus*, and *Komagataeibacter xylinus*.

Apart from their different substrates, vinegars can also be differentiated by their production systems. In traditional vinegars, the transformation of ethanol into acetic acid is performed by a static culture of acetic acid bacteria at the interface between the liquid and air. Barrels are filled to 2/3 of their capacity, as to leave an air chamber that is kept in contact with the outside air using one opening or various types of openings. This production system, which is considered to be the traditional method, is called 'surface culture.' A more standardized version of this method, the 'Orleans method,' includes side holes for air circulation and adds a funnel with an extension to the base of the barrel to allow wine to be added at the bottom of the barrel, preventing the alteration of the 'mother of vinegar.' This mother of vinegar is the biofilm formed by the transforming microorganisms, that is, the acetic acid bacteria, which develops on the surface due to the need for oxygen (Figures 2 and 3). The vinegars produced by this traditional system are generally considered of high quality because of their organoleptic complexity, which is mainly due to the metabolism of the acetic acid bacteria and the overlapping vinegar production with aging. However, this process is very slow, and the production of vinegar can take from months to years.

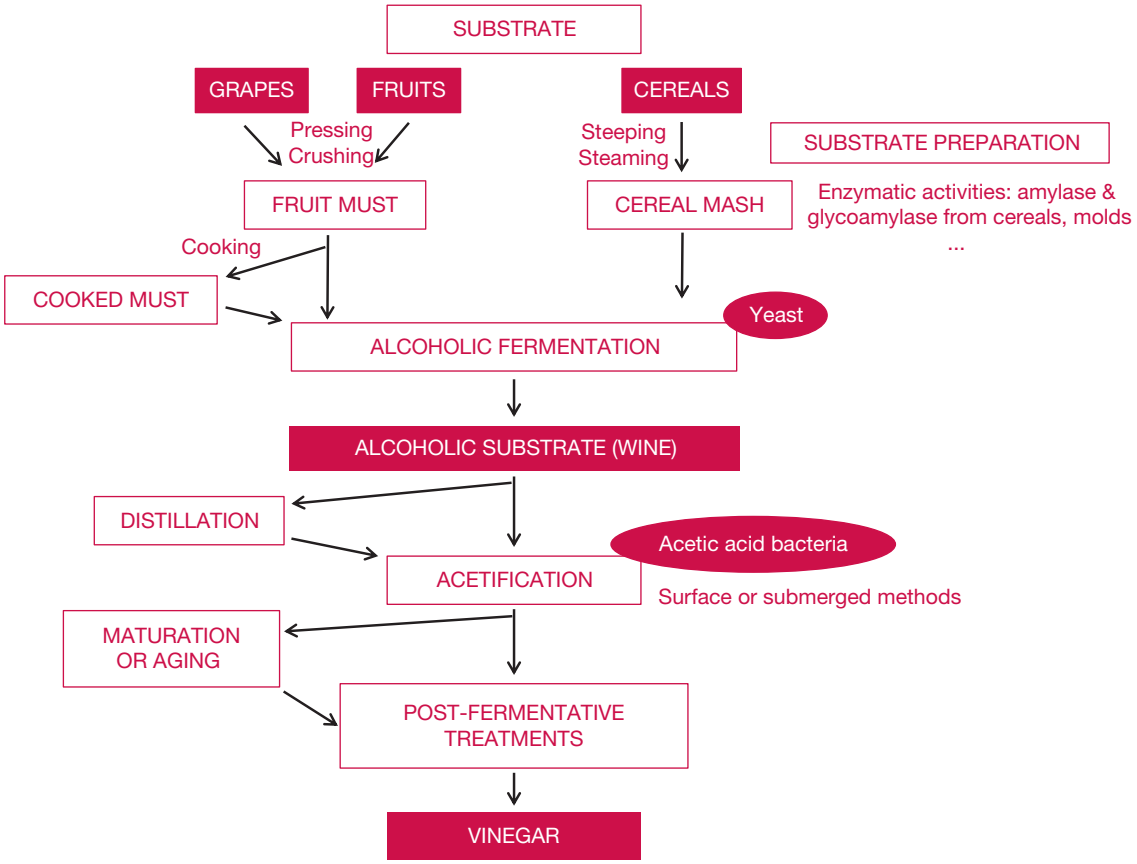

Figure 1 Schematic representation of vinegar production from different substrates using different elaboration systems.

Figure 2 'Mother of vinegar' formed at the liquid–gas interface of a wooden barrel in traditional vinegar production.

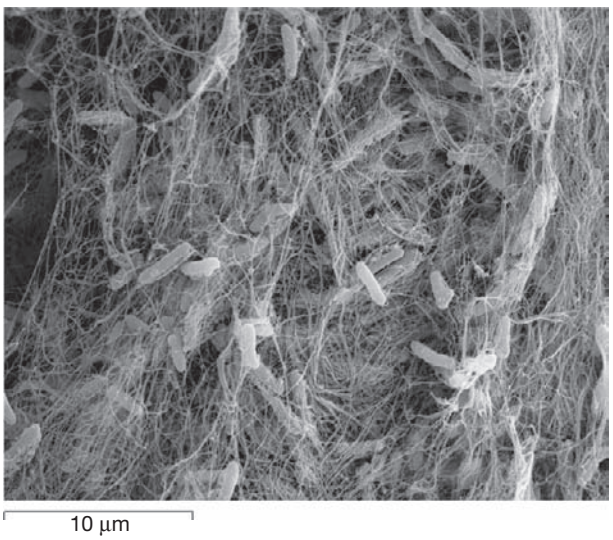

Figure 3 Electron microscopy image of acetic acid bacteria cells embedded in a biofilm that constitutes the 'mother of vinegar.'

To reduce the acetification time, other methods, such as the Schützenbach system or systems with submerged cultures, have been developed. In the former, bacteria are immobilized on wood chips or charcoal, forming a solid bed on which the vinegar spreads. After passing through the bed of chips, the vinegar is collected in a container at the bottom and pumped back to the same fixed bed. The acidity successively increases, and it is possible to obtain vinegar of reasonable quality within a week.

Submerged culture systems provide a much faster alternative. These systems rely on suitable turbines to generate a flow of air bubbles into the wine or alcoholic solution. The oxidative process occurs in the air–liquid interfaces of the air bubbles. Improvements to this process generally involve engineering (improving the maintenance and persistence of the bubbles in the liquid, the uniformity of the bubble size, the recovery of lost aromas, etc.). In this type of vinegar produced

at a significantly lower cost, the bacteria act as bioreactors for the transformation of alcohol into acetic acid, with only very limited production of other metabolites. The airflow also contributes to a considerable loss of the volatile compounds present in the original alcoholic solution, resulting in a less complex product from a sensory point of view. Although early containers for submerged culture processing were made of wood, the usual containers are stainless steel, which is more hygienic and resistant to acidic conditions. Despite the fact that wood containers were meant to provide some organoleptic complexity, there was hardly any transfer of flavor compounds from the wood to the vinegar because of the imbalance between the contact surface and volume and the speed of the process. This limitation can be compensated by subsequent aging in barrels or by submerging wood fragments or wood chips, which may contribute to the recovery of some missing organoleptic character. Despite the loss in product quality, this methodology has two important advantages: speed (the vinegar can be produced in cycles of 24 h or even shorter) and acidity (the product can reach concentrations of acetic acid of up to 23–25%, compared with the 6–13% achieved with other systems). Higher acidity helps to reduce transportation costs by reducing water transport.

Patterns of Consumption

Vinegar consumption dates at least from 5000 BC, when Babylonians used it as a condiment and as a preservative. Its acidic character (until the description of sulfuric acid, it was the strongest known acid) facilitated its use as a preservative due to its antimicrobial activity. This antimicrobial activity was used to heal wounds and as a general antiseptic by 2000 BC, and vinegar was even used for treating wounds during World War I. This preserving use initiated the development of the pickling industry that became extensive with the Greeks. However, in the production of different fermented beverages (such as wine and beer), vinegar became a by-product. The Romans also used it as a drink, as some wines were partially converted into vinegar. In fact, the name 'vinegar' derives from the term 'sour wine' in French ('vin aigre').

As for fermented foods and beverages in general, the consumption of vinegar is a cultural trait. Although the use of some type of acid in the food industry is widespread in every culture, this acidity is achieved by acetic acid or vinegar in some cultures, whereas in others, citric acid (e.g., lemon juice) is used. The use of some types of high-quality vinegars is very common in Europe and Asia and has become fashionable in North America. Wine vinegar is the most common type in Mediterranean countries, although the latest gastronomic trends have led to a considerable expansion of the varieties available in recent years. In Asia, rice vinegar is the most common type, although other types are also found, many of them following very traditional systems of production. In Northern Europe and in the United States, most of the vinegar produced is 'white' vinegar, that is, vinegar produced directly from diluted alcohol. These differences also determine their pattern of consumption, which in turn affects the concept of 'quality.' In Mediterranean countries, most vinegar is used directly or added to salads or to raw or cooked vegetables; thus, the appreciation of the organoleptic characteristics is straightforward. Therefore, 'quality' vinegars are closely associated with these patterns of consumption. In contrast, in other countries, most vinegar is used for pickling or as part of sauces, and the impact of the organoleptic quality, although possibly relevant for the final product, is less evident. However, this trend of consumption is changing, and some premium vinegars are being commercialized worldwide. A typical example of this trend is the increased consumption and trade of Balsamic Vinegar of Modena (Aceto Balsamico di Modena, ABM). In fact, Italy is the country that exports the most vinegar, providing twice the quantities of the other main exporters, Germany, Spain, and France. Moreover, in terms of revenues, Italian vinegars are exported at much higher values than Spanish or German vinegars. The situation in Germany is different, considering that most German vinegar is sold for the pickling or sauce industry, whereas the Spanish exports include also some premium vinegars such as sherry vinegars.

Sherry vinegars that are included in the European Union's protected designation of origin (PDO) framework derive from sherry wines and are necessarily aged in wood barrels for at least 6 months. This aging can be performed by a dynamic system (i.e., passage through different barrels known as 'solera' and 'criaderas' containing vinegar from different vintages or different ages) or a static system (i.e., always in the same barrel). A more complex example is aceto balsamico, which is either ABT, regulated by two different PDO labels (ABT di Modena or ABT di Reggio Emilia), or ABM, which has a protected geographical indication status. The production of ABT is a long process that starts with the cooking of the grape must, which increases the sugar concentration to 400–500 g l^{-1}. Next, a partial alcoholic fermentation, which is initiated by osmophilic yeasts, produces a 'sweet wine' of approximately 7% (v/v) ethanol concentration and over 200 g l^{-1} of residual sugars. Then, some mother of vinegar is added to this 'sweet wine,' and it is left to be acetified. Once acetified, the vinegar is placed in a 'bateria' formed by five to seven barrels of different woods (oak, mulberry, chestnut, cherry, juniper, ash, and acacia) and decreasing volumes (from 60 to 15 l), which are filled up to 2/3 of their total volume. This 'bateria' is kept for at least 12 years with a yearly refilling from the previous barrel in a dynamic aging process. During this aging process, two phenomena occur: the transfer of components from the wood to the ABT and, more importantly, the concentration of the product and the integration of its components. The final product can have up to 500 g of sugar per kg of product, 7% acetic acid (v/v), and 20 g of gluconic acid per kg. The oxidation of glucose by acetic acid bacteria yields gluconic acid. The result is a dark, concentrated, and thick product sold in 100 ml bottles and with a market value that can easily reach 100 euros. In contrast, ABM is a mixture of vinegar, caramel, and cooked or concentrated must that is aged at least 2 months, not necessarily in barrels. However, some of these ABM can be aged for more than three years and are labeled 'invecchiato' (aged). Overall, ABM is a cheaper version of ABT that has been popularized all over the world.

Some Asian vinegars, such as black vinegars from China or 'kurosu' from Japan, are produced from rice and other cereals (including sorghum, wheat, and others) with a very important aging process in which concentration and thickening occur in a similar manner to ABT. These vinegars can even be consumed

as a beverage in small volumes, as is sometimes claimed for ABT (used as a dessert wine). However, the direct use of vinegar as a drink is rare. In fact, despite some exceptions, the individual consumption of vinegar is very limited, whether directly (as an addition to salads or raw vegetables) or indirectly (through its presence in dressings, of which salad dressings as vinaigrette, mayonnaise, or mustard sauce are the most popular). This limitation is mostly due to the pungency of the main component of vinegar, acetic acid. The direct use of vinegar as a drink can produce throat and esophagus wounds due to the caustic character of acetic acid. However, this aspect can be reduced by the composition of the vinegars, especially due to the complexity of different compounds present that, although in low concentrations, can compensate for the acidity. In particular, the sour taste and pungency are mitigated well by the quality of the substrate (wine, for instance) and by combination with some tastes, such as sweetness or umami. This mitigation is the main reason why the direct consumption of small quantities of beverages containing up to 8% (v/v) of acetic acid is possible, while consuming the same amount of acetic acid diluted in water would be impossible.

Composition

Depending on the type of vinegar, its composition may be the result of (i) the raw material (wine or other substrate), (ii) the metabolism of the acetic acid bacteria, which accomplish some additional transformations (mostly oxidations and also other reactions, such as ester formation) in addition to the basic transformation (ethanol to acetic acid), (iii) the interaction between the vinegar and the wood from the barrels, and (iv) the aging process, which integrates all the previously mentioned characteristics.

The main and characteristic compound in vinegars is acetic acid, which is found in concentrations higher than $50\,g\,l^{-1}$, usually expressed as a volume percentage (5% (v/v) of acetic acid or 5 acetic degrees). Acetic acid is essentially the only component in vinegars produced from distilled alcohol. Normally, most vinegars contain residual ethanol in their compositions, mainly to prevent the complete oxidation (or respiration) of acetic acid to oxygen dioxide and water by the acetic acid bacteria, a reaction that is strongly inhibited by the presence of small amounts of ethanol.

Fruit vinegars, especially wine vinegars, are considered to be more complex due to the presence of polyphenols, aromas, etc. that are characteristic of the raw material. In general, it is relatively easy to appreciate the sensory differences between vinegars made by traditional methods and those manufactured at the industrial scale, as submerged culture acetification results in a substantial loss of volatile compounds. In fact, the vinegar aroma is of complex composition, containing many compounds with a wide range of volatilities and polarities and with concentrations ranging from several $mg\,l^{-1}$ to $ng\,l^{-1}$. To date, more than 100 different chemical compounds have been identified in the aroma of wine vinegar, including carbonyl compounds, ethers, acetals, lactones, acids, alcohols, phenols, and volatile esters, all of which are involved to different extents in the final flavor. However, not all of the volatile compounds are responsible for the aroma of the product. These volatile components must not only reach odorant receptors but also interact with them in the olfactory epithelium, and not all volatile compounds are active odorants. The use of techniques based on gas chromatography coupled with olfactometry has allowed to pinpoint the contribution of each volatile compound to the final vinegar flavor. For example, it has been determined that the characteristic aroma of sherry vinegar involves several volatile compounds, such as diacetyl, isoamyl acetate, isovaleric acid, ethyl acetate, and sotolon.

Esters are a significant part of the vinegar aroma and a main element of the quality of vinegars. Of special interest is the production of ethyl acetate, which as a pure compound would smell like glue or nail polish remover but adds some sweet character to vinegar. Interestingly, noticeable concentrations of this ester (in the order of grams per liter) are considered to be defects in wine (as is the presence of acetic acid), yet in vinegar, ethyl acetate compensates for the pungency of acetic acid, and it can thus be appreciated in moderate amounts. Traditional methods of production favor the formation of esters due to not only the metabolism of the bacteria but also the process duration, which allows condensation between acids and the residual alcohol.

In some premium vinegars, residual sugars are also a main component, and they particularly help to reduce the pungency of acetic acid by their sweet taste. In ABT, kurosu, and black rice vinegar, these residual sugars, together with amino acids or peptides, can undergo Maillard reactions due to heating and/or aging, which results in the formation of some melanoidins and their polymerization, yielding a dark color. Furthermore, glucose, which is one of the most characteristic residual sugars in vinegars, can be partially converted to gluconic acid by acetic acid bacteria. Due to its molecular weight and structure, gluconic acid is much less pungent than acetic acid, and it provides a mouth-filling sensation. Other organic acids that are often found in vinegars include citric, malic, and lactic acids; these acids can add some sour flavor, yet they are less pungent than acetic acid.

Polyphenolic compounds, which are ubiquitous in plant products, are of great interest as quality determinants because, in addition to their antioxidant activity, they are responsible for the color and astringency of vinegar and are a useful tool for the purposes of determining authenticity. The reactivity of phenolic compounds with oxygen is specifically analyzed in wine making for its relationship to the browning of white wines and with respect to the reactions of anthocyanins in red wines. These anthocyanin reactions dramatically decrease after the submerged acetification process because the anthocyanins are extensively oxidized. It should be emphasized that submerged systems use excess oxygen to secure and accelerate the process, whereas the oxygen availability is limited in superficial cultures. Additionally, oxygen affects different classes of polyphenolic compounds to different degrees. For example, the flavonol content of vinegars is largely influenced by the oxygen availability during submerged fermentation. Aging in wood strongly determines the phenolic composition, as phenolic aldehydes are released from wooden barrels into the product. The substances provided by the wood depend on the type of wood and roasting, the ratio of the contact surface to the liquid volume, and the aging time. Specifically, oak releases mainly vanillin, syringaldehyde, coniferyl aldehyde,

and cinnamic acid after 90 days of aging. Furthermore, certain flavonoids are chemical markers of the wood that the vinegar has been in contact with; (+)-dihydrorobinetin is a characteristic compound released from nontoasted acacia wood, while (−)-taxifolin is typically released from cherry wood. Chestnut provides remarkable concentrations of gallic acid. Wood toasting can degrade thermolabile compounds such as (+)-dihydrorobinetin or increase the rupture of lignin into phenolic aldehydes of small molecular weight. Therefore, aging is a fundamental aspect of the integration of the different compounds in vinegars. The increase in organoleptic quality after aging is remarkable; in addition to interactions with the wood, a series of chemical reactions, such as the production of esters and reactions between acids and residual alcohols; evaporation; and other processes result in better integration of aromas and metabolites and a reduction in the pungency of acetic acid. The aging process involves the reaction of compounds over time, including both the polymerization and release of compounds from the wood and the losses through evaporation.

Thorough characterization and quality evaluation require both the determination of the content of a number of compounds and sensory analysis. In recent years, there have been significant advances in the elucidation of the compounds responsible for the sensory quality of the products, and production methods have changed to obtain vinegars with high acceptance at very competitive prices. The consumer perception of the product is the most important factor. Vinegar is a difficult product to taste due to the intense sensations it provokes. The pungency of the high acetic acid content masks other flavors, and some familiarity with the product is required to proceed with a tasting. In fact, there is no consensus on how vinegar should be tasted. A vinegar sensory analysis panel requires well-trained tasters, and specific attributes that are useful for differentiating among samples must be chosen. To train a vinegar panel, solutions used are prepared with different concentrations of the compounds most typically found in vinegar, such as acetic acid, ethyl acetate, and wood extract obtained by maceration. The last two should also be prepared in 7% acetic acid to provoke a sensation similar to that of vinegar. The aggressiveness of acetic acid determines the number of samples that can be examined in each session, and each sample is tasted several times. These replicate samples should be tasted on different days to avoid sensorial saturation among the tasters. A descriptive analysis of the samples is prepared based on previously selected attributes that can be evaluated by the panel. For instance, the main attributes used to describe wine vinegar samples are color, aromatic intensity, woody scent, herbaceous smell, fruity odor of ethyl acetate, wine smell, and pungent feeling. As expected, higher sensory thresholds for most compounds are obtained in an acetic acid matrix compared with water solutions. Conversely, high-quality vinegars contain a large number of these compounds at concentrations higher than their threshold limits, including vanillin, eugenol, and benzaldehyde, which could be selected as attributes of high-quality vinegars. Additionally, adequate training and a standardized tasting protocol contribute to the reliability of the descriptive sensory analyses of vinegar and of ascertaining the aging period and wood used in its development.

Bioavailability, Absorption, and Metabolism

The main component of vinegar, acetic acid, is rarely absorbed in the stomach; most of it is absorbed in the small intestine. After its absorption, acetic acid is mostly transferred to the liver through the portal vein. Once in the liver, it is transformed into acetyl coenzyme A and used for lipogenesis. Some amounts of acetic acid that might be left in the circulation are taken up by the peripheral tissues, activated to acetyl coenzyme A, and metabolized through the Krebs cycle. However, not all of the acetic acid in the body is derived from the ingestion of vinegar (whether directly or as an ingredient in sauces): a considerable amount is produced in the large intestine as a main by-product of the fermentation of nondigested saccharides (disaccharides or oligosaccharides) by the gut microbiota, next to lactic acid. Other acids, such as propionic and butyric acids, are also formed, yet they are formed in lower concentrations and depend on the fermented saccharide and the individual microbiota. The acetic acid is absorbed in the large intestine, transferred to portal circulation, and further metabolized as explained in the preceding text.

Health Effects

Although many health effects have been claimed as a result of vinegar consumption, only a few of these effects are based on clear evidence. Certain studies show reductions in hyperglycemia, hyperinsulinemia, hyperlipidemia, and obesity. Therefore, the consumption of acetic acid from vinegar has been related to an antiglycemic effect because acetic acid has an effect on enterocytes, reducing the activity of the disaccharidases and thus decreasing the digestion of di- and oligosaccharides. Indeed, if vinegar is consumed with a high-carbohydrate meal, the glycemic index of that meal decreases. This effect has been observed in both patients with type 2 diabetes and in healthy people, with a notable reduction of insulin resistance in the diabetic patients. This reduction could be one of the reasons for claims that the direct consumption of vinegar can result in weight loss. However, it is important to emphasize the high risk of the direct consumption of vinegar as a drink due to the caustic effects on the pharynx and esophagus and the inflammation of the intestines.

Another health effect is the increased absorption of calcium ions. It is well known that the reduction of calcium absorption can be a problem, especially in the elderly, and many components of the diet result in a reduced absorption. The combination of calcium ions with acetate in the intestine is facilitated by the change of pH between the stomach and intestine, and thus, the formed compound, calcium acetate, is easily absorbed, resulting in an increased absorption of calcium.

Moreover, vinegar has antioxidant activity related to its phenolic composition described in the preceding text. However, the consumption of vinegar may be too low to expect a significant effect on health.

Other claimed activities of acetic acid (or vinegar) on health effects have been less clearly demonstrated, as for its antitumor or hypocholesterolemic activities, among others. However, further research in this field is required. Some of these effects are considered to be related to other components of vinegar. To

that end, it is important to consider the reduced individual consumption of vinegar and the low concentration of those compounds in vinegar.

Conclusion

Vinegar is a food condiment and preservative that has been used for centuries but is still widely used today. Several qualities are available, yet the indirect use through sauces and pickles remains the most common one. The health effects are still under investigation, yet some observations indicate positive effects that could help to increase the overall consumption of vinegar.

This article is reproduced from the *Encyclopedia of Food Sciences and Nutrition*, volume 9, pp. 6039–6045, © 2003, Elsevier Science Ltd., with an updated Further Reading section supplied by the editor.

Background

From the 1930s until the 1970s, the only known role of vitamin K was as an essential antihemorrhagic factor, which initially had been shown to promote the synthesis of active prothrombin (factor II), but later also of factors VII, IX, and X. Collectively, these four factors, all synthesized in the liver and then released into the circulation, became known as the classical vitamin K-dependent coagulation factors. In 1974, it was shown that vitamin K was required as a cofactor for the enzymatic conversion of specific glutamate residues in the prothrombin molecule to γ-carboxyglutamate (Gla) residues. The elucidation of this biochemical pathway leading to the synthesis of a new amino acid was the impetus that led to the discovery of many more vitamin K-dependent proteins. These proteins, also known as Gla proteins, are now known to have a widespread tissue distribution. They include further coagulation proteins (proteins C, S, and Z) and others with putative roles in the regulation of bone turnover (osteocalcin) and bone calcification (matrix Gla protein (MGP)). New evidence suggests that MGP is also a powerful inhibitor of vascular calcification. Other suspected functions of Gla proteins are in vascular repair processes (protein S), cell cycle regulation, cell–cell adhesion (Gas6), and signal transduction (Gas6 and proline-rich Gla proteins). For the most part, the precise physiological function of these new Gla proteins is poorly understood. However, nutritional and epidemiological studies in humans suggest that optimal intakes of vitamin K are necessary to maintain skeletal and cardiovascular health. Despite the possibility of these new health roles, the only clearly defined deficiency syndrome is bleeding due to a lack of functional molecules of the vitamin K-dependent coagulation factors II, VII, IX, and X. Bleeding due to vitamin K deficiency is rare in adults but is more common in infants during the first 6 months of life. The potential risk of serious life-threatening bleeding in infancy means that most countries recommend that all newborns should receive vitamin K prophylaxis.

Intestinal Absorption and Bioavailability

Dietary vitamin K, mainly as phylloquinone, is absorbed chemically unchanged from the proximal intestine after solubilization into mixed micelles composed of bile salts and the products of pancreatic lipolysis. In healthy adults, the efficiency of absorption of phylloquinone in its free-form is about 80%. The bioavailability of vitamin K from foods varies according to food type and the associated matrix. Thus, the efficiency of absorption of phylloquinone may be as low as 10% from green leafy vegetables (e.g., spinach) in which the vitamin is tightly associated with chloroplast membranes. Less is known about the absorption of dietary menaquinones (MKs), but the efficiency of absorption decreases with increasing length of the side chain.

MKs are also synthesized by the intestinal microflora, predominately in the colon. Major forms are MK-10 and MK-11 synthesized by *Bacteroides* species, MK-8 by *Enterobacteria*, MK-7 by *Veillonella*, and MK-6 by *Eubacterium lentum*. It is commonly held that microfloral synthesis provides an important nutritional source of vitamin K for humans, but direct evidence is lacking. A microfloral contribution of vitamin K is supported by the findings that very-long-chain MKs 10–13 are rare in foods but make up the majority of hepatic stores. However, all experimental evidence suggests that the absorption of MKs from the large intestine is an extremely inefficient process.

Transport in Plasma and Tissue Distribution

After intestinal absorption, vitamin K is incorporated into chylomicrons, is secreted into the lymph, and enters the blood via the lacteals. Once in the circulation, phylloquinone is rapidly cleared at a rate consistent with its continuing association with chylomicrons and the chylomicron remnants that are produced by lipoprotein lipase hydrolysis at the surface of capillary endothelial cells. After an overnight fast, more than half of the circulating phylloquinone is still associated with triglyceride-rich lipoproteins, with the remainder being equally distributed between low-density and high-density lipoproteins. Phylloquinone is the major circulating form of vitamin K, but MKs MK-7 and MK-8 have been detected at lower concentrations.

Dietary vitamin K is delivered to the liver and possibly other tissues, including bone marrow, in the form of chylomicron remnants. The cellular uptake of vitamin K is mediated by apolipoprotein E in the chylomicron remnants and heparin sulfate proteoglycans on the cell surface. The liver, the site of synthesis of the vitamin K-dependent coagulation proteins, has a limited capacity for storing phylloquinone. Thus, the hepatic reserves of phylloquinone are several thousandfold lower than those of vitamin A, despite the fact that dietary intakes of phylloquinone are only about tenfold lower. The distribution of molecular forms of vitamin K in the liver is quite different from that in plasma in that the major transport form, phylloquinone, represents only about 10% of total stores; the remainder comprise bacterial MKs, mainly MKs 7–13. Long-chain MKs are also present in other nonhepatic tissues but at lower concentrations than the liver. Some tissues such as the brain and pancreas seem to have the capacity to selectively convert phylloquinone to MK-4, but little is known about the biochemistry or physiological significance of this enrichment.

Catabolism and Turnover

The metabolic transformations leading to the elimination of vitamin K from the body occur exclusively in the liver.

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00729-7

Phylloquinone is rapidly degraded with about 20% of a single dose being excreted in the urine within 3 days and about 40–50% excreted in the feces via the bile. The hepatic reserves of individuals on a low-phylloquinone diet decline rapidly. The overall picture is that phylloquinone has a fast turnover time, suggesting that the body stores are being constantly replenished.

The route of hepatic catabolism leading to the urinary excretion of vitamin K proceeds by oxidative degradation of the phytyl side chain, probably involving the same enzymes used for the ω-methyl and β-oxidation of fatty acids, steroids, and prostaglandins. The end products of this pathway are shown in Figure 1. Two major aglycone metabolites have been identified; they are carboxylic acids with five- and seven-carbon atom side chains that are excreted in the urine as glucuronide conjugates. The biliary metabolites have not been clearly identified but are initially excreted as water-soluble conjugates and become lipid-soluble during their passage through the gut, probably through deconjugation by the intestinal microflora. There is no evidence that body stores of vitamin K can be conserved by an enterohepatic circulation, since vitamin K itself is not excreted in bile and the side chain-shortened carboxylic acid metabolites are not biologically active.

Cofactor Role of Vitamin K

Vitamin K-Dependent Carboxylation of Glutamate Residues

The only unequivocal biochemical role for vitamin K is as a cofactor for a unique posttranslational chemical modification confined to a small group of unusual calcium-binding proteins. The vitamin K-dependent step is a carboxylation reaction that transforms selective glutamic (Glu) residues in the protein precursor into Gla. The reaction shown in Figure 2 is catalyzed by a microsomal enzyme called vitamin K-dependent (γ-glutamyl) carboxylase and requires molecular oxygen and carbon dioxide. The form of vitamin K required as the cofactor is not the stable quinone structure found in the diet but the reduced quinol (or hydroquinone) structure (KH_2). The subsequent oxidation of vitamin KH_2 to vitamin K 2,3 epoxide is coupled to the abstraction of a proton from the γ-carbon of the Glu residue to generate a carbanion that reacts with CO_2 to yield the final Gla product. The biological relevance of the Gla structure is that it forms a cage structure to which divalent metal ions such as calcium may be bound. In the case of the vitamin K-dependent procoagulants, this induces the conformational change and membrane-binding properties that are essential for their biological activity.

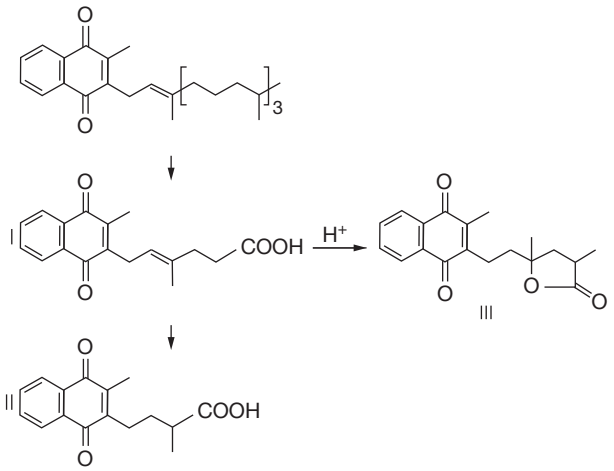

Figure 1 Simplified pathway and chemical structures of the two major urinary metabolites of phylloquinone in their aglycone forms (structures I and II). In acidic conditions, metabolite I may cyclize to produce phylloquinone γ-lactone (structure III). (I) 2-Methyl-3-(5′-carboxy-3′-methyl-2′-pentenyl)-1,4-naphthoquinone; (II) 2-methyl-3-(3′-carboxy-3′-methylpropyl)-1,4-naphthoquinone; (III) 2-methyl-3-(5′-carboxy-3′-hydroxy-3′-methylpentyl)-1,4-naphthoquinone lactone.

Vitamin K Epoxide Cycle

In all tissues and cells that synthesize Gla proteins, vitamin K-dependent carboxylation is intimately linked to a metabolic sequence known as the vitamin K epoxide cycle. This cycle and the associated enzyme activities are shown in Figure 3. During γ-glutamyl carboxylation, vitamin KH_2 is transformed to

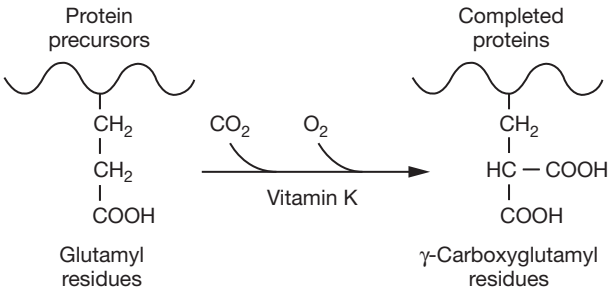

Figure 2 Posttranslational vitamin K-dependent carboxylation reaction showing the conversion of protein-bound glutamyl residues (Glu) to γ-carboxyglutamate (Gla) residues.

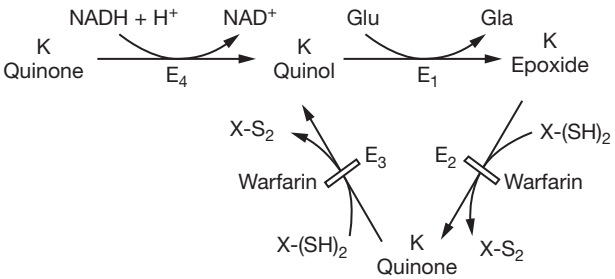

Figure 3 Scheme showing the reactions and enzyme activities (denoted by E_1, E_2, E_3, and E_4) of the vitamin K epoxide cycle. The active form of vitamin K needed for the conversion of glutamate residues (Glu) to γ-carboxyglutamate (Gla) residues is the reduced form, vitamin K quinol (K quinol). The carboxylation reaction is driven by a vitamin K-dependent carboxylase activity (E_1), which simultaneously converts K quinol to vitamin K 2,3-epoxide (K epoxide). K epoxide is reduced back to the quinone (K quinone) by vitamin K epoxide reductase (E_2). The cycle is completed by the reduction of recycled K quinone by a vitamin K reductase activity (E_3). Both E_2 and E_3 reductase activities are dithiol-dependent (X-(SH_2) and X-S_2 denote reduced and oxidized dithiols) and are inhibited by coumarin anticoagulants such as warfarin. Dietary vitamin K (K quinone) may enter the cycle via an NAD(P)H-dependent vitamin K reductase activity (E_4), which is not inhibited by warfarin.

vitamin K epoxide (enzyme activity E_1). The epoxide product is recycled in two steps: first by a vitamin K epoxide reductase activity (E_2) to produce vitamin K quinone and second by a quinone reductase activity (E_3) to produce the coenzyme vitamin KH_2. Both these activities are thiol-dependent and are probably effected by the same enzyme.

An important property of the dithiol-dependent epoxide and quinone reductase activities is their sensitivity to certain antagonists, especially those based on 4-hydroxycoumarin (e.g., warfarin) or indandione structures. Drugs based on these structures have long been used as oral anticoagulants, and it is now clear that their anticoagulant action is based on their ability to inhibit the epoxide reductase activity (E_2) and block the recycling of the vitamin. The dithiol-dependent quinone reductase (E_3) is also sensitive to warfarin, but there is a second quinone reductase activity catalyzed by an NAD(P)H-dependent enzyme activity (E_4) that is less sensitive to warfarin inhibition, and this provides an alternative pathway for the reduction of vitamin K to KH_2 in the presence of warfarin or other oral anticoagulant drugs. Therapeutic anticoagulation is dependent on a balance being achieved between the inhibition of the recycling enzymes and the amount of dietary vitamin K that can enter the cycle to support carboxylation at a reduced efficiency.

Vitamin K-Dependent (Gla) Proteins

Distribution and Structure

γ-Glutamyl carboxylase activity is present in a wide variety of extrahepatic tissues such as bone, kidney, placenta, pancreas, skin, spleen, lung, testis, and vessel wall tissues. New Gla proteins continue to be discovered; the present list together with their tissue distribution is shown in Table 1. Some of these Gla proteins are found in only one major tissue (e.g., procoagulant factors in liver and osteocalcin in bone), while others (e.g., MGP and protein S) are more widely distributed.

All Gla-containing proteins are secretory proteins and are characterized by an intracellular precursor form possessing a leader sequence that facilitates specific posttranslational events and is then normally cleaved before secretion. Within the leader sequence, a hydrophobic presequence facilitates the translocation of the precursor Gla proteins across the endoplasmic reticulum, while a second prosequence serves as a recognition signal for the vitamin K-dependent carboxylase. With the exception of matrix Gla protein, the prosequence of currently characterized Gla proteins is located immediately before the N-terminal of the mature protein. In matrix Gla protein, the carboxylation recognition site is internal and is retained in the mature protein. The number of Gla residues varies: the four classical vitamin K-dependent clotting factors contain 10–12 Gla residues, whereas the much smaller MGP and osteocalcin contain five and three Gla residues, respectively.

Role of Gla Proteins

Hemostasis (procoagulants and anticoagulants)

The vitamin K-dependent coagulation proteins comprise four plasma procoagulants (factors II, VII, IX, and X) and two feedback anticoagulants (proteins C and S). The physiological function of a seventh plasma protein (protein Z) is less established but seems to play a role in dampening coagulation by acting as a cofactor for the inhibition of factor Xa. The four vitamin K-dependent procoagulants have long been known to play a central role in the blood-clotting cascade leading to the formation of a fibrin clot. Circulating as inactive forms (or zymogens) of serine proteases, their biological activity is dependent on their ability to bind to anionic phospholipid surfaces where cleavage of the zymogens yields the active protease clotting factors. The Gla residues of these clotting factors provide an efficient chelating site for calcium ions that enables ion bridges to be made between the factor and the surface phospholipids of platelets and endothelial cells where, together with other cofactors, they form membrane-bound enzyme complexes. The intricate control of coagulation is illustrated by the fact that another Gla protein (protein C), once activated, performs an anticoagulant role by specifically degrading phospholipid-bound activated factors V and VIII in the presence of calcium. This anticoagulant activity of activated protein C is dependent on yet another Gla protein (protein S) that acts as a synergistic cofactor by enhancing the binding of activated protein C to negatively charged phospholipids.

Bone metabolism

The discovery in 1975 that bone tissue contains a Gla protein, which is also one of the most abundant proteins in the body, has revolutionized earlier thinking that vitamin K is only needed for coagulation. This protein, called osteocalcin or bone Gla protein, accounts for about 15% of the

Table 1 Distribution and roles of vitamin K-dependent (Gla) proteins

Gla protein	*Tissue*	*Role*
Prothrombin (factor II), factors VII, IX, and X	Liver (then plasma)	Blood clotting (procoagulants)
Protein C	Liver (then plasma)	Blood clotting (anticoagulant)
Protein S	Liver (then plasma), endothelium, bone	Anticoagulant role (cofactor for protein C); role in bone unknown
Osteocalcin (or bone Gla protein)	Bone	Implicated in bone remodeling
Matrix Gla protein	Most tissues	Inhibits calcification of arteries and cartilage
Gas 6	Most tissues	Implicated in cell cycle regulation, cell survival, cell proliferation, cell adhesion, platelet signaling
Proline-rich Gla proteins	Most tissues	Unknown, but protein structures suggest roles as cell-surface receptors

noncollagenous proteins in the bone of most vertebrate species, although this proportion is less in humans. The three Gla residues of osteocalcin project away from the Gla helix, and their periodic spacing complements the interatomic spacing of the calcium ions of the hydroxyapatite lattice; this is thought to account for the strong mineral-binding characteristics of the fully carboxylated form of osteocalcin. The adsorption affinity of osteocalcin for hydroxyapatite and other features such as its high degree of conservation throughout evolution, its regulation by vitamin D, and its chemoattractant properties suggest an important role for osteocalcin in bone metabolism, although the nature of this role still remains unknown. Osteocalcin is specifically synthesized by osteoblasts, and since its concentration in blood reflects osteoblastic activity, measurements of total osteocalcin have become clinically important in the diagnosis of bone disease.

Besides osteocalcin, bone tissue contains lower concentrations of other Gla proteins: MGP, protein S, and Gas6 (Table 1). MGP is a 10 kDa secretory protein, with five residues of Gla. It was first isolated from demineralized extracts of bone by Price in 1983 but is expressed by a wide variety of tissues and cell types. Its function in bone is unclear but is probably related to its capacity to inhibit localized calcification as recently shown for arteries. Transgenic MGP-deficient mice show inappropriate calcification of the cartilage, including the growth plate, and a phenotype characterized by short stature, osteopenia, and fractures. This function is consistent with the effects of the vitamin K antagonist warfarin, which, when given *in utero* or to young animals, results in excessive mineralization and premature closure of the epiphyseal growth plate. An important role for Gla proteins during human fetal bone development is suggested by the bone defects often seen in infants born to mothers who had received vitamin K antagonists such as warfarin during the first trimester of pregnancy. Evidence that warfarin embryopathy is mediated by a dysfunctional MGP comes from the demonstration that mutations encoding MGP are responsible for a rare inherited disorder called Keutal syndrome, which is characterized by a similar abnormal calcification of cartilage. The functions of protein S and Gas6 in bone are presently unknown.

Vascular calcification

A series of remarkable studies since 1997 have firmly established MGP as a potent inhibitor of calcification of arteries and cartilage. Thus, targeted deletion of the *MGP* gene in mice resulted in rapid focal calcification of the elastic lamellae of the arterial media but not of the arterioles, capillaries, or veins. This process begins at birth and by 3–6 weeks is sufficiently severe to cause the arteries to become rigid tubes that fracture, causing death from bleeding. Most of the phenotypic features of arterial calcification seen in MGP-deficient mice can be mimicked, albeit to a somewhat muted degree, by the vitamin K antagonist warfarin. This effect of warfarin points to the need for Gla residues, and hence vitamin K, to the function of MGP. Overall, the dramatic features of both genetic and biochemical models of MGP depletion strongly suggest that MGP is central to the process by which calcification of arteries is normally inhibited *in vivo* and that there is no effective alternative inhibitor at aortal sites.

Assessment of Vitamin K Status

The traditional criterion for vitamin K sufficiency is the maintenance of normal plasma concentrations of fully γ-carboxylated vitamin K-dependent procoagulants II, VII, IX, and X. The presence of a clinically significant vitamin K-deficient state is usually investigated by global coagulation assays such as the one-stage prothrombin time. Such assays are insensitive to small changes in γ-carboxylation of the vitamin K-dependent coagulants and, while appropriate for detecting overt vitamin K deficiency, are not useful for picking up suboptimal states of vitamin K deficiency.

Modern assessments of vitamin K status need to take into account both coagulation and noncoagulation roles of Gla proteins and their different sites of synthesis. When vitamin K is in short supply, or its action is blocked by an oral anticoagulant such as warfarin, undercarboxylated (des-γ-carboxy) species of Gla proteins are produced at the tissue site of synthesis and, in some species, including humans, are secreted into the circulation. Collectively, these undercarboxylated species are known as proteins induced by vitamin K absence or antagonism (PIVKA). In the case of the coagulation protein prothrombin, specific and sensitive immunoassays for undercarboxylated prothrombin (PIVKA-II) provide a powerful marker of the coagulation status of vitamin K because they can detect small decreases in the Gla content of prothrombin well before any changes occur in conventional coagulation tests. Similarly, the assay of circulating undercarboxylated species of osteocalcin provides a specific functional marker to assess the sufficiency of vitamin K for the carboxylation of bone Gla proteins. Since prothrombin and osteocalcin are synthesized in the liver and bone, respectively, the detection of their respective undercarboxylated species allows the vitamin K status of these tissues to be assessed independently. Such studies have shown that the carboxylation of osteocalcin in bone is more susceptible to reduced dietary intakes of vitamin K than the carboxylation of the classical coagulation proteins. Measurements of undercarboxylated osteocalcin are being increasingly used to assess the importance of optimal vitamin K intakes with respect to bone health. The excretion of free Gla in urine represents the final catabolic product of all Gla proteins, and its measurement has also been shown to reflect dietary intakes and status. Another method for assessing vitamin K status is from direct serum assays of phylloquinone, the predominant transport form of vitamin K. A low serum phylloquinone is a good indicator of a poor overall vitamin K status.

Vitamin K and Health

Role in Hemostasis

Overt vitamin K deficiency in adults, resulting in clinical bleeding, is almost unknown except as a consequence of underlying disease, most commonly resulting from hepatointestinal disorders that disturb the absorption or utilization of the vitamin. However, oral coumarin anticoagulant drugs, such as warfarin, are widely used in the prevention and management of thromboembolic disease. These vitamin K antagonists are used to induce an artificial but controlled state of vitamin K deficiency,

the aim being to reduce the circulating levels of the vitamin K-dependent clotting factors to within a predetermined target range depending on the clinical condition.

In contrast to adults, bleeding due to vitamin K deficiency may occur spontaneously in the first few months of life. The resulting bleeding syndrome is traditionally known as hemorrhagic disease of the newborn, in recognition of the Boston physician Townsend, who is credited with the first description of the syndrome in 1894. The modern name is vitamin K deficiency bleeding (VKDB) of early infancy. Until the late 1960s, VKDB was considered to be solely a problem of the first week of life (classical VKDB), but two other forms (early and late VKDB) have now been recognized (Table 2). Late VKDB, peaking between the third and sixth weeks of life, is the most common syndrome and is still a significant worldwide cause of infant morbidity and mortality. In different parts of the world, some 2–100 cases per 100 000 births of late VKDB have been reported, with a particularly high incidence in the Far East. Unlike the classical form, late VKDB has a high incidence of intracranial hemorrhage, resulting in death or severe and permanent brain damage in around 50% of cases. One major risk factor, exclusive breast-feeding, is common to both classical and late syndromes and is probably related to the relatively low concentrations of vitamin K in breast milk (1–2 $\mu g\,l^{-1}$) compared to about 50 $\mu g\,l^{-1}$ in formula feeds. Another probable etiologic factor is the precarious hepatic stores of vitamin K in newborns because of poor placental transfer of phylloquinone and the lack of neonatal stores of bacterial MKs, which only build up slowly after bacterial colonization of the intestine. Some infants who develop late VKDB have abnormalities of liver function, leading to cholestasis, and an impaired absorption efficiency of vitamin K.

By the early 1980s, reports in the literature were suggesting a worldwide rise in the incidence of late VKDB. This resurgence may have been related to both a decline in routine vitamin K prophylaxis and the promotion of exclusive breast-feeding. In recent years, many countries have reemphasized the need to give all babies extra vitamin K as a public health measure. Often, this was given as a single intramuscular dose at birth, but since 1992, concerns about an epidemiological association between the intramuscular route and later childhood cancer have seen a shift in some countries towards oral prophylaxis. However, there is evidence that even multidose oral regimens fail to give full protection against late VKDB and that this is because there is an underlying reservoir of infants who have a reduced efficiency of absorption due to underlying and unrecognized cholestasis. Several epidemiological studies conducted since 1992 have not substantiated the link between vitamin K prophylaxis and cancer.

Role in Bone Health

Despite mechanistic gaps in our knowledge, a picture is emerging that a suboptimal vitamin K status may play a role in the pathogenesis of osteoporosis. Much of this evidence is still circumstantial, being based on associations of fracture risk and bone mineral density with indices of poor vitamin K status and low dietary intakes. Of particular note is that undercarboxylated osteocalcin is an independent risk factor of both hip fracture risk and bone mineral density. However, osteoporosis is a complex disease, and without a fuller understanding of the biological function of osteocalcin, the interpretation of these associations with vitamin K status remains uncertain.

In the near future, the results from a number of long-term intervention studies on the effects of vitamin K supplementation on bone health will become available. These may help to answer the question of whether extra intakes of vitamin K can influence bone mineral density and bone turnover. Most of these studies have used phylloquinone because this is the major dietary form, but in Japan, the effects of very large doses of MK-4 (menatetrenone) on bone health are being studied. Both phylloquinone and MK-4 are known to promote the γ-carboxylation of osteocalcin, but these forms differ in other important respects. Thus, there is evidence that tissues can convert phylloquinone into MK-4 *in vivo* (but not vice versa) and that MK-4 may have a direct inhibitory effect on bone resorption. In an intervention study in which Japanese women with osteoporosis were treated with a high-dose MK-4 regimen, the incidence of fractures was significantly reduced, and the rate of bone loss was decreased.

Dietary Intakes and Requirements

The major dietary source of vitamin K is phylloquinone. In Western societies, the majority of phylloquinone intakes (up to 50%) come from green leafy vegetables followed by certain vegetable oils such as soybean, canola (rapeseed), and olive oils. Mixed dishes and meals contribute about 15% of total phylloquinone intake, largely because of their oil content. The wide range of the vitamin K content of different food items means that individual daily intakes may vary widely but average adult intakes mostly range from 60 to 120 μg per day. Intakes of this order are more than sufficient to maintain

Table 2 Classification of vitamin K deficiency in the newborn (VKDB)

VKDB syndrome	*Time of presentation*	*Common bleeding sites*	*Etiologic factors*
Early	0–24 h	Cephalohematoma, intracranial, intrathoracic, intraabdominal	Maternal drugs (e.g., warfarin and anticonvulsants)
Classical	1–7 days	Gastrointestinal, skin, nasal, circumcision	Mainly idiopathic, breast-feeding (may be related to low milk intakes)
Late	2–26 weeks	Intracranial, skin, gastrointestinal	Mainly idiopathic, breast-feeding, some degree of cholestasis often present; may reflect underlying disease (e.g., biliary atresia, α-1-antitrypsin deficiency, cystic fibrosis)

normal hemostasis, and even intakes as low as 10 μg per day for a few weeks have no effect on global coagulation assays. However, more sensitive measures of vitamin K status (e.g., undercarboxylation of Gla proteins, urinary Gla excretion, and serum phylloquinone) respond readily to moderate changes in dietary intakes. One conclusion from nutritional depletion/repletion studies is that the daily intakes of vitamin K needed to sustain the posttranslational γ-carboxylation of extrahepatic Gla proteins such as osteocalcin are higher than those needed for the coagulation Gla proteins synthesized in the liver. Therefore, previous recommendations of a daily intake of 1 μg kg^{-1} of body weight, which have been based on the coagulation role of vitamin K, may need to be revised upward if evidence continues to harden on other potential health benefits such as the amelioration of osteoporosis and arterial calcification. Studies in the United Kingdom and the United States already suggest that a substantial proportion of their populations have intakes below 1 μg kg^{-1} of body weight. What this optimal intake should be must await further research on the physiological function of Gla proteins, the further delineation of functional markers of vitamin K status, and studies of the health consequences of different intakes.

Background

Vitamin K is a fat-soluble vitamin widely distributed in nature and comprises several molecular forms. It was discovered as an essential antihemorrhagic factor in the 1930s by the Danish scientist Henrik Dam, who named it *koagulations vitamin*. This article reviews the properties and analysis of vitamin K, with special reference to its measurement in foods. Such measurements have proved difficult, and reliable methods have only become available since the 1980s with the development of physicochemical assays based on high-performance liquid chromatography (HPLC). According to recent evidence, in addition to its well-defined role in blood coagulation, vitamin K is needed for a variety of physiological processes related to a number of extrahepatic vitamin K-dependent proteins.

Chemical Structures and Nomenclature

Naturally occurring compounds with vitamin K activity possess a common 2-methyl-1,4-naphthoquinone nucleus but differ in the structures of the side chain at the 3 position (Figure 1).

In traditional nomenclature (Table 1), the vitamin K found in plants (of which there is only one major chemical form) is known as vitamin K_1 and the multiple forms synthesized by bacteria are known as vitamin K_2, where the number of carbon atoms (n) in the side chain is indicated as vitamin $K_{2(n)}$. This nomenclature was revised by the International Union of Pure and Applied Chemistry–International Union of Biochemistry (IUPAC–IUB) Subcommittee on Nomenclature of Quinones, who recommended that vitamins K_1 and K_2 be called phylloquinone and menaquinones, respectively. Recommended current abbreviations are K_1 for phylloquinone and MK-n for menaquinones. Table 1 also shows a nomenclature that the International Union of Nutritional Sciences recommended should replace the IUPAC system. This new system, however, has not found favor among most workers in this field. Consequently, the IUPAC–IUB nomenclature is still the one most generally accepted at the present time and will be used throughout this article.

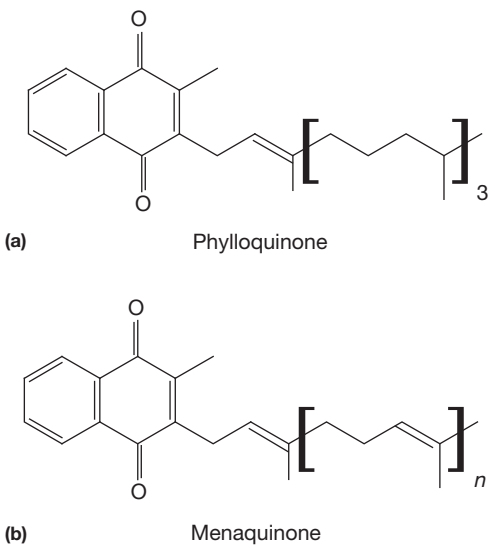

Figure 1 Chemical structures of naturally occurring K vitamins: (a) phylloquinone (vitamin K_1) and (b) menaquinones (vitamin K_2).

The parent compound of the vitamin K group of vitamers is 2-methyl-1,4-naphthoquinone. This structure is not found in nature but, because of its historical use as a synthetic derivative, was originally designated vitamin K_3. Under the IUPAC system, this artificial vitamin K is called menadione.

Phylloquinone, which has the same phytyl side chain as chlorophyll, is found throughout the plant kingdom and in cyanobacteria (blue-green algae). In higher plants, the synthesis of phylloquinone is associated with the chloroplast, while the unusual finding of phylloquinone in cyanobacteria has been cited as supportive evidence for the possible bacterial origin of the chloroplast in evolution.

The menaquinones represent a highly diverse family of compounds all synthesized by bacteria. The side chain of menaquinones is based on a number of repeating unsaturated five-carbon (prenyl) units. The major forms are designated menaquinone-n (MK-n), with n denoting the number of prenyl units. Some bacteria also synthesize menaquinones in which one or more of the multiprenyl side-chain double bonds are saturated. In such cases, the additional hydrogen atoms are indicated by the prefixes dihydro, tetrahydro, hexahydro, etc., and these may be abbreviated to MK-$n(H_2)$, MK-$n(H_4)$, MK-$n(H_6)$, etc. The division between the plant-form phylloquinone and the bacterial menaquinones is somewhat artificial, since phylloquinone may be regarded as a partially saturated form of menaquinone-4, namely, MK-4(H_6), but the distinction serves to emphasize their different origins.

Carbon atoms in the side chain are designated C1′, etc., and the presence of double bonds at C2′ in phylloquinone and at C2′, 6′, 10′, etc., in menaquinones indicates that *cis–trans* isomerism is possible. Natural forms of phylloquinone and menaquinones exist as *trans* isomers, but synthetic forms contain both *trans* and *cis* isomers.

Biological Activities

The biological activity of different vitamin K compounds has been assessed in whole animal systems (*in vivo*) or as a cofactor to the

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00728-5

Table 1 Nomenclature of K vitamins

Chemical name	*Old name*	*IUPAC–IUB (abbreviation)*	*IUNS (abbreviation)*
2-Methyl-1,4-naphthoquinone	Vitamin K_3	Menadione	Menaquinone
2-Methyl-3-phytyl-1,4-naphthoquinone	Vitamin K_1	Phylloquinone (K)	Phytylmenaquinone (PMQ)
2-Methyl-3-multiprenyl-1,4-naphthoquinone (class)	Vitamin K_2	Menaquinone-*n* (MK-*n*)	Prenylmenaquinone-*n* (MQ-*n*)
2-Methyl-3-farnesyl-farnesyl-1,4-naphthoquinone	Vitamin $K_{2(30)}$	Menaquinone-6 (MK-6)	Prenylmenaquinone-6 (MQ-7)

vitamin K-dependent γ-glutamyl carboxylase in isolated enzyme systems (*in vitro*). γ-Glutamyl carboxylase is an integral membrane glycoprotein that requires vitamin K to activate posttranslational modification of glutamate (Glu) to γ-carboxyl glutamate (Gla) in specific vitamin K-dependent proteins. The *in vivo* systems are normally based on the correction of blood clotting time in chicks induced by vitamin K deficiency or through measurement of undercarboxylated vitamin K-dependent proteins, and their interpretation needs to take account of the route of administration and other metabolic considerations, such as absorption and interconversion to other chemical forms.

It has been established that besides the 1,4-naphthoquinone nucleus, a methyl group at the C2 position is essential for both *in vivo* and *in vitro* activities. The activity of menadione *in vivo* is due to the presence of tissue alkylating enzymes that can transform this compound to MK-4. Recent evidence is accumulating that suggests an alternative *in vivo* route to MK-4 via tissue-mediated conversion of phylloquinone. The essential requirement for *in vitro* activity is for a 2-methyl-3-phytyl (or polyisoprenyl)-1,4-naphthoquinone structure, which can be reduced to the corresponding hydroquinone. The biological activity of K_1 is reduced by saturation of the phytyl double bond (2′,3′-dihydrophylloquinone), whereas the desmethyl or *cis* isomers have no appreciable activity *in vitro*, although some conversion of the *cis* form to the active *trans* form may occur *in vivo*.

Physicochemical Properties

Appearance, Solubility, and Stability

Phylloquinone and menaquinones are golden yellow oils at ambient temperature, though the higher menaquinones may also be obtained as fine, yellow crystals.

All K vitamins are insoluble in water but are soluble in normal lipid solvents such as hexane, chloroform, diethyl ether, and acetone, but are less soluble in ethanol. They are only sparingly soluble in methanol, and the degree of solubility depends on their hydrophobicity (i.e., menaquinones with long side chains are less soluble than those with short side chains).

Vitamin K compounds are reasonably stable towards heat, oxygen, and mild acidic conditions but are degraded by UV light, alkalis, and strong acids.

Spectroscopy

The spectroscopic properties of K vitamins are important for their detection, identification, and quantification in assays. All vitamin K compounds possess the same characteristic ultraviolet spectrum, which is a summation of the benzenoid and 1,4-quinone components. Naturally occurring phylloquinone and menaquinones exhibit typical benzenoid bands with maxima at 242, 248, and 238 nm (shoulder), whereas the quinone contributions appear as distinct bands with absorption maxima at 260 and 269 nm and a higher-wavelength maximum at 326 nm. Ultraviolet spectroscopy is particularly useful for the quantification of standard solutions; the molar absorption coefficient (ϵ) is the same for both phylloquinone and menaquinones and, at 248 nm (the wavelength of highest absorption), has a value of 18 900.

Vitamin K compounds, in their stable quinone forms, do not possess native fluorescence, but they can be readily reduced to the corresponding quinols, whose fluorescent properties have been exploited for the assay of K vitamins in foods and other biological tissues.

The K vitamers also exhibit infrared and nuclear magnetic resonance absorption spectra distinctive of the naphthoquinone nucleus and may be further characterized by mass spectroscopy.

Occurrence and Forms in Foods

Vitamin K is largely found in the membranous fractions of cells. Thus, in plants, phylloquinone is concentrated in the chloroplast lamellae, and in bacteria, menaquinones are located in the plasma membrane. In animals, the vitamin is found in various cellular membranes, especially those of the microsomes and mitochondria.

Recent progress in analytic techniques for this vitamin, as well as increased emphasis on its nutritional significance, is responsible for the current development of a comprehensive database of the vitamin K content of foods. Whereas, before 1980, most published values for the vitamin K content of foods originated from bioassays, contemporary data derive from the highly specific and accurate HPLC methods. These techniques have focussed predominantly on phylloquinone ubiquitously distributed in foods, although more recently, increasing amounts of data are becoming available for the menaquinones.

Table 2 lists some values of the phylloquinone content of various foods arranged into four concentration ranges to illustrate the wide distribution of the vitamin in the diet.

In general, the relative values confirm the known association of phylloquinone with photosynthetic tissues, with the highest values (400–600 μg per 100 g) being found in green, leafy vegetables. Nutritionally significant amounts of phylloquinone are, however, present in many nonleafy vegetables, as well as in fruits, oils, dairy products, eggs, and some meat products. With modern HPLC techniques, naturally occurring phylloquinone can be detected in most foods. Vegetable oils show a high degree of variability, ranging from <5 μg per 100 g in coconut, corn, groundnut, and safflower oils to 100–200 μg per 100 g in soybean and rapeseed oils. This leads to a similar

Table 2 Vitamin K_1 content of common foods determined by HPLC (μg per 100 g)[a]

0.1–1.0	*1–10*	*10–100*	*100–1000*
Bananas	Apples	Avocado	Broccoli tops
Beef, steak	Aubergines	Beans, runner	Brussels sprouts
Bread, white	Baked beans	Beans, French	Cabbage, green
Chicken, thigh	Barley	Beans, broad	Kale
Coconut oil	Beef, minced (1–30)	Cabbage, red	Lettuce
Cod, fillet (0.1–2)	Bilberries	Cauliflower	Margarine
Cornflakes	Bran, wheat	Chick peas	Parsley
Flour, white	Bread, wholemeal	Cucumber	Rapeseed oil
Grapefruit	Butter	Greengages	Soybean oil
Ham, tinned	Carrots	Kiwi fruit	Spinach
Ice cream	Celery	Margarine	Water cress
Maize	Cheeses (1–80)	Mustard cress	
Mangoes	Chocolate, plain	Natto (900–1200)	
Melon, yellow	Corn oil	Olive oil, ex. virgin	
Melon, water	Courgettes	Peas	
Milk, cows	Cranberries		
Mushrooms	Cream, double		
Onion	Dates, fresh		
Oranges	Eggs (10–25)		
Parsnips	Figs, fresh		
Peanuts, roast	Grapes, black		
Pilchards, brine (0.1–2)	Grapes, green		
Pineapple	Infant formula		
Pork chop, lean	Leeks		
Potatoes	Liver, lamb		
Rice white	Liver, ox (10–20)		
Rice brown	Nectarines		
Salmon, brine	Oats		
Sausages, pork/beef	Palm oil		
Spaghetti	Peaches, fresh		
Trout, rainbow (0.1–3)	Pears		
Tuna, brine	Peppers, green		
Turnips	Peppers, red		
Yogurt (0.1–0.4)	Plums, red		
	Raisins		
	Rhubarb		

[a]MK-*n* ranges are shown in parentheses.

variation in the phylloquinone content of margarines according to the oil base. The phylloquinone content of lean meat and fish is generally low (<1 μg per 100 g), but higher amounts are found in animal livers; this organ acts as a storage site of the vitamin. Please refer to individual foods.

There is less information on the menaquinone content of foods. It is known that animal liver contains substantial concentrations of menaquinones, which normally greatly exceed the phylloquinone content. The livers of ruminants contain particularly large concentrations of long-chain menaquinones (MK-6–13), which derive from bacterial fermentation in the rumen. The only other known sources of significant amounts of menaquinones in the Western diet are fermented foods, such as cheese and yogurt. All cheeses contain relatively high concentrations (≤20 μg per 100 g) of MK-8 and MK-9, with the latter predominating. Natto, the Japanese fermented soybean food, contains substantial amounts of MK-7. Whereas menaquinones are detectable in cow's milk at much lower concentrations than phylloquinone, MK-4 has been confirmed to be present at comparable, or higher, levels than phylloquinone in the milk of several mammalian species.

Foods containing hydrogenated vitamin K-rich oils will also include a contribution from 2′,3′-dihydrophylloquinone. The biological activity of this K vitamer is currently under investigation, and hence, its abundance in the diet is of uncertain nutritional significance.

The processing of foods can have a variable effect on retention of vitamin K, with conventional cooking, canning, γ-irradiation, and freezing practices having a relatively minor influence, whereas significant and rapid loss occurs on exposure to UV light.

Use in Food Fortification

Since the requirements for vitamin K are low, fortification of foods with vitamin K is not common, with the exception of infant formula feeds to which synthetic preparations of

phylloquinone are invariably added. Depending on the method of chemical synthesis, the ratio of the natural *trans* to the inactive *cis* form will vary but is typically *c.*7:1.

Although national guidelines for the fortification of infant formulas differ, their common aim is to protect against rare, but life-threatening, bleeding due to deficiency of vitamin K in early life. It is now known that the typical fortification levels of *c.* 50 μg l^{-1} (as fed) are several times higher than human breast milk concentrations of phylloquinone, which average *c.* 2 μg l^{-1}. Although the reasons for adopting such high levels of fortification are somewhat empirical and based on the erroneously high estimates of vitamin K in breast milk by early bioassays, there has been little impetus for change because the low concentrations in breast milk are an established risk factor for neonatal vitamin K deficiency.

The synthetic vitamin K derivative menadione is no longer used to fortify infant formulae because of its association with neonatal hemolytic anemia and liver damage. In fact, the vitamin K activity of menadione is dependent on its *in vivo* conversion to biologically active MK-4. Nevertheless, because menadione is much cheaper to manufacture than phylloquinone, menadione derivatives are widely used in animal husbandry, particularly in poultry feeds, since poultry are very prone to bleeding due to dietary deficiency of vitamin K. In the poultry industry, the birds' dietary requirements may be further increased by the use of antibiotics, the effect of which may be either to inhibit the growth of intestinal microorganisms that synthesize menaquinones or to interfere directly with vitamin K metabolism. Consequently, stabilized water-soluble derivatives of menadione, such as crystalline menadione sodium bisulfite complex, are used universally as poultry feed supplements.

Measurement of Vitamin K in Food

In the 1930s, shortly after the discovery of vitamin K, Dam and colleagues developed a curative bioassay that involved the feeding of substances to vitamin K-deficient chicks and measuring the response on blood clotting. Although values that have been derived from this early work are often given in textbooks and handbooks of nutrition, a closer evaluation of the methodology shows that attempts to use these results as the basis for absolute food values are unjustified. Although such bioassays were greatly improved in the 1960s, little further work has emerged on their routine use and validation for food analysis.

The introduction of modern HPLC techniques has revolutionized the measurement of vitamin K in tissues. This powerful technique has met the criteria of high selectivity and sensitivity, which are also necessary for the measurement of the low concentrations in most foods. Although several diverse protocols have been developed for phylloquinone, only one procedure has been validated by collaborative study. A range of sample extract purification strategies may be implemented prior to the final chromatographic analysis, which is usually accomplished by analytic reversed-phase HPLC. Due to the instability of vitamin K at high pH, saponification techniques commonly utilized for other fat-soluble vitamins are inappropriate for vitamin K analysis. The need for preliminary enhancement techniques is dependent principally on food type, analyte level, and final detection mode and may incorporate one or more techniques including (1) lipid extraction, (2) enzymatic lipid digestion, (3) solid-phase extraction (SPE), and (4) semipreparative normal-phase HPLC.

Extraction and Cleanup

No universal extraction and purification procedure exists for vitamin K analysis in all foods. Nonpolar lipid solvents including hexane, isopropanol, dichloromethane, acetone, diethyl ether, and methanol, used either singly or in combination, have been used for initial total lipid extraction depending on the food type. For certain high-fat foods (fats, oils, and milk), bulk lipid may be effectively removed with enzymatic digestion prior to hexane extraction of triglyceride-depleted lipid. For low-fat foods (vegetables, fruit, cereals, meats, and fish), acetone is an effective solvent, whereby, after the addition of water and hexane, the K vitamins partition entirely in the upper hexane phase, leaving polar lipids in the acetone–water phase. Alternatively, hexane/isopropanol or chloroform/methanol binary solvents are commonly used.

For protocols relying on a preliminary total lipid extraction, further purification is required in view of the overwhelming proportion of triglycerides and their incompatibility with reversed-phase HPLC. Various combinations of lipase digestion, SPE, and semipreparative normal-phase HPLC techniques are commonly recommended.

The extraction stage may also incorporate the addition of an internal standard, which, in general terms, compensates for procedural losses of the target analyte. This technique is essential when multidimensional protocols for vitamin K are implemented. The internal standard is chosen on the basis of several criteria that include its similar physical, chemical, and chromatographic properties to the analyte. Depending on the sample matrix, several vitamin K compounds and analogs (including radiolabeled compounds) have been found to be suitable internal standards for vitamin K assays.

A general scheme outlining commonly applied extraction and cleanup options is illustrated in Figure 2. Purification techniques usually comprise two successive stages based on the principles of adsorption chromatography, which facilitate the separation of K vitamers from most other potentially interfering lipid classes (e.g., hydrocarbons, sterols, and fatty acids). If required, semipreparative normal-phase HPLC can also be used to isolate both K_1 and MK fractions and to separate the *cis* and *trans* isomers of phylloquinone.

The fraction(s) collected at the semipreparative HPLC stage may then be analyzed by reversed-phase HPLC using a variety of detection methods. For certain foods, a lipase digestion and hexane extraction scheme has been found to be sufficient to facilitate a direct analytic HPLC quantitation, without the need for additional purification steps.

Detection and Quantification

The final analytic stage of HPLC is almost exclusively based on the principles of partition chromatography in the reversed-phase mode. This robust mode of liquid chromatography resolves the individual K vitamins from each other while supporting the mobile-phase additives necessary for the most

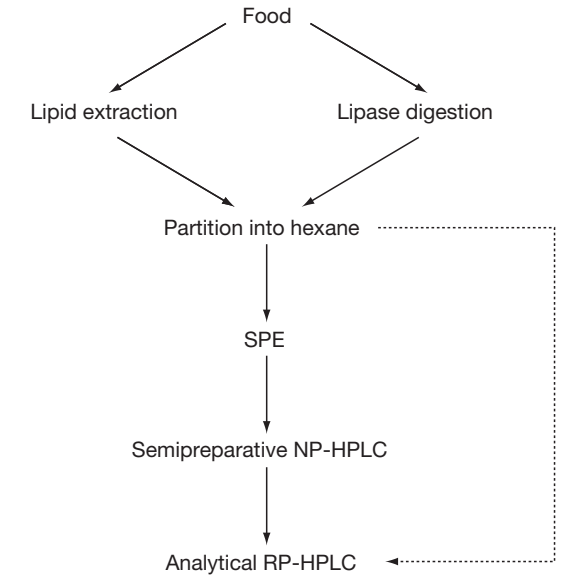

Figure 2 Flowchart summarizing extraction and purification of vitamin K from foods.

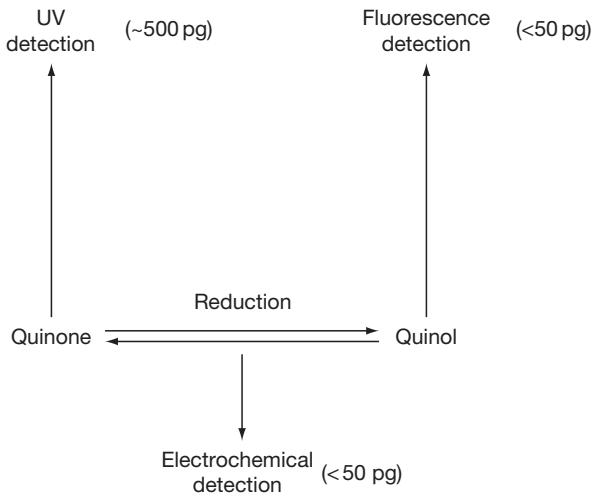

Figure 3 Detection options for vitamin K.

sensitive detection techniques currently utilized. Whereas isocratic systems are generally used for the analysis of vitamin K_1, gradient elution is preferable when profiling the menaquinones, in view of their very wide hydrophobic range. The C18 functionality has most commonly been employed, although the recently developed C30 phase has been shown to allow resolution of the *cis* and *trans* isomers of phylloquinone, previously only accomplished under normal-phase conditions.

The properties of K vitamins offer several avenues of approach to their detection by HPLC, and the most common options are summarized in Figure 3. The parent quinone form, in which the vitamin is isolated, may be detected with reasonable sensitivity (*c.* 500 pg) by ultraviolet absorbance detection, but this lacks selectivity and may be subject to interferences from other lipids. This detection method does, however, give reliable results for green vegetables but is less satisfactory for animal tissues.

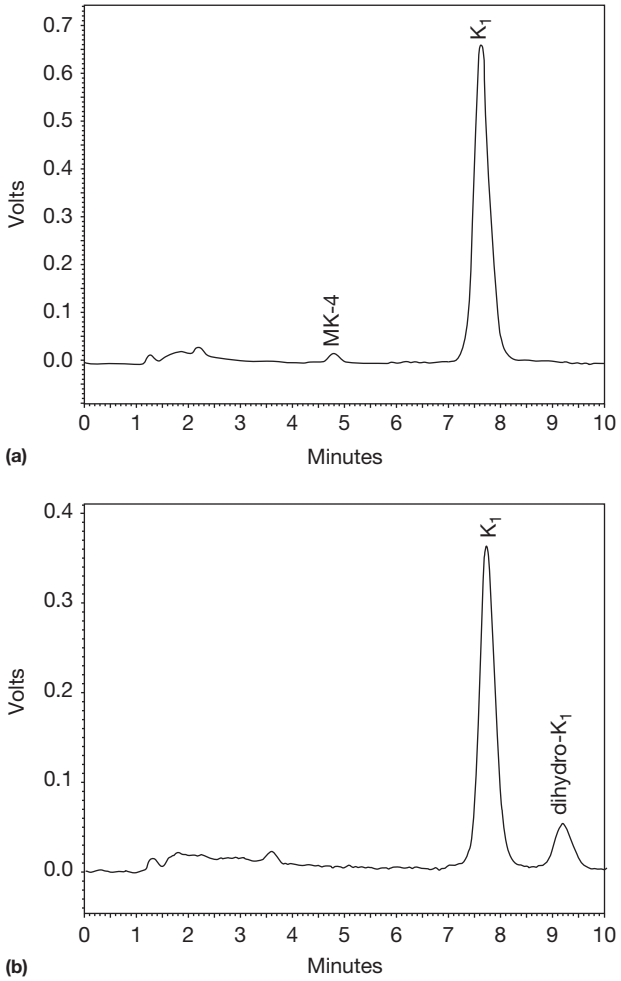

Figure 4 Liquid chromatography obtained for (a) infant formula and (b) margarine. C18 column, isocratic elution, postcolumn reduction, and fluorescence detection.

Alternatively, the more recently developed strategies exploit the reversible reduction of the quinone to the quinol, which may then be detected by either electrochemical or fluorescent techniques. For electrochemical detection, the greatest sensitivity and selectivity are obtained by employing a redox technique in which the detector has a dual-electrode cell with the electrodes arranged in series. Vitamin K is first reduced at the upstream (or generator) electrode to the quinol, which is then reoxidized at the downstream (or detector) electrode: the current generated in the second reoxidation step is measured by the detector and is proportional to the amount of vitamin K passing through the electrochemical cell. This method is capable of detecting 50 pg or less of phylloquinone. Fluorescence detection again requires the postcolumn generation of the quinols after the chromatographic separation of their respective quinones. Reduction can be achieved by chemical, photochemical, or electrochemical techniques, with fluorescence detection providing similar sensitivity to redox electrochemical detection (*c.* 25–50 pg). Currently, the most commonly employed reduction technique involves a short dry-packed zinc or platinum oxide column, configured between the separation column and detector. Examples of chromatography achieved for a representative infant formula and

margarine are illustrated in Figure 4, utilizing a C18 column and fluorescence detection.

Further theoretical and practical details are provided in the methodological references listed in 'Further Reading' section.

Vitamins: Overview

PM Finglas, Institute of Food Research, Norwich, UK

© 2016 Elsevier Ltd. All rights reserved.

Overview

This article covers the vitamins' definition, brief historical account of the discovery, classification and nutritional role, forms found in food, and effects of processing on vitamin stability.

Vitamins are defined as a group of complex organic micronutrients present in small amounts in food or nutritional supplements that the body requires for its normal metabolism and function. They cannot be synthesized by humans in sufficient quantity for normal metabolic requirements. Certain substances that are considered vitamins can be synthesized in small amounts by gastrointestinal tract bacteria (e.g., B-groups). Each vitamin consists of a mixed group of compounds, which may not be related to each other chemically and are therefore classified by function.

History

It was not until the early 1900s that the existence of the 'accessory food factors' was recognized. Indeed, the term 'vitamine' was first used by a Polish biochemist named Funk to describe an 'accessory food factor.' However, deficiency diseases were well known many centuries earlier, the earliest documented disease being beriberi, which was recorded in China around 2600 BC. Yet, it was not until the end of the eighteenth century that the nutritional etiology of the disease was established. In 1885, a Japanese physician named Takaki succeeded in reducing the effect of beriberi among Japanese sailors by feeding them a diet containing more meat and vegetables and less rice. Then, in 1890, a Dutch doctor named Eijkman reproduced symptoms of the disease in chickens fed exclusively with shelled rice. His collaborator, Grijns, showed that these symptoms disappeared by adding rice husks to the chicken diet. Finally, in 1912, Funk isolated the antiberiberi factor from the cuticle of the rice and named it 'vitamine,' the 'life-essential amine.' This term was adopted to name all the nutritional factors responsible for deficiency diseases.

Similarly, scurvy and night blindness were described in ancient Egypt around 1500 BC. During the period AD 1400–1600, the explorers Vasco da Gama and Magellan described in detail the scurvy and night blindness that had devastated their ships' crew. A century earlier, Jacques Cartier had succeeded in saving a good many sailors thanks to an Indian medicine based on pine needles. Finally, in 1747, James Lind found the preventive effect of citrus fruit using controlled experiments at sea, and this was shortly followed by the demonstration, during the voyages of Captain Cook in the period 1768–71, that prolonged sea voyages were possible without the ravages of scurvy.

Thirteen vitamins were isolated, identified, and synthesized between 1929 and 1975. The last vitamin to be discovered was vitamin B_{12} in 1948. Many researchers who contributed to the fundamental discoveries have been honored by the Nobel Prizes Committee, such as Szent-Gyorgyi and King for the simultaneous discovery of ascorbic acid in 1928, Karrer for his work on vitamin A and β-carotene between 1928 and 1933, Dam and Doisy for the discovery and chemical nature of vitamin K in 1943, and Hodgkin for the structural determination of vitamin B_{12} in 1964.

Nowadays, vitamin research is still very active. The understanding of the precise, complex role of vitamins has made remarkable progress owing to the study of vitamin-dependent metabolite diseases of genetic origin. More recently, because of their antioxidant properties, some fat-soluble vitamins, notably vitamins A, E, and C and provitamin A compounds (carotenoids; including β-carotene, lutein, and lycopene), are also considered to play an important role in the prevention against chronic degenerative diseases and cancers. Also, it has been shown that folic acid can reduce significantly the incidence of neural tube defects (such as spina bifida) and folates, in general, may protect against vascular diseases and some cancers, notably colonic cancer.

Classification and Properties

A number of factors can make the identification and classification of vitamins difficult: (1) A vitamin can exist in a number of different structures with similar, or different, biological activities; (2) the biological activity is organism-dependent; (3) the physiologically or metabolically active form of a vitamin *in vivo* may be different from that found in food (e.g., B vitamins are active in coenzyme forms; 1,25-dihydroxycholecalciferol is the active form of vitamin D_3); (4) several forms of the same vitamin can interconvert during extraction (e.g., pyridoxine, pyridoxamine, pyridoxal, and their phosphorylated derivatives); and (5) synthetic forms of a vitamin are often available commercially in a more stable form, for example, α-tocopherol acetate and retinol acetate are more stable compared with the free vitamins and are converted to the letter in the body.

Vitamins are generally classified by their solubility characteristics into fat-soluble and water-soluble groups. A full list of vitamins, forms, functions, and health benefits is given in Table 1. The fat-soluble vitamins (A, E, D_3, and K and carotenoids) are derived from the isoprenoid pathway, whereas the synthesis of the water-soluble vitamins (B_1, B_2, B_6, B_{12}, C, biotin, niacin, and pantothenic acid) is much less connected, and several of them have multiple biosynthetic pathways. Other 'vitamin-like' compounds are sometimes associated with the classical vitamin compounds. These include vitamins F (essential fatty acids), L (*o*-aminobenzoic acid), P (bioflavonoids), U (*S*-methylmethionine sulfonium chloride), and B_{13} (orotic acid); choline; α-lipoic acid; myoinositol; plastoquinone; pyrroloquinoline quinone; and ubiquinones.

Table 1 Fat- and water-soluble vitamins: forms, function, and potential health benefits

Vitamin	*Vitamers and related forms*	*Functions*	*Potential health benefits*
Fat-soluble vitamins			
A	Retinal, retinoic acid, retinol *cis*-isomers, β-carotene, other carotenoids	Needed for normal vision, reproduction, and various tissues; immune function	Protection against various cancers
D	Cholecalciferol (D_3), ergocalciferol (D_2), 1-α-25-dihydroxycholecalciferol	Enhances calcium absorption; regulates calcium/phosphate metabolism; promotes bone mineralization	Reduces risk of osteoporosis
E	All-rac-α-tocopherol, β-tocopherol, δ-tocopherol, γ-tocopherol, various tocotrienols	Prevents lipid oxidation of membranes and PUFAs from autoxidation; essential for normal immune function and healthy tissues	Reduces risk of cardiovascular disease, precancerous lesions, and cancer
K	Phylloquinone (K_1), menaquinone (K_2), menadione (K_3)	Essential for normal blood clotting, formation/maintenance of healthy bones	Reduces risk of blood clotting and osteoporosis
Water-soluble vitamins			
B_1	Thiamine, thiamine monophosphate (TMP), thiamine pyrophosphate (cocarboxylase, TTP) complexed to proteins	Helps convert carbohydrates into energy metabolism; required by the brain, nervous system, and heart	Important role in energy metabolism
B_2	Flavin mononucleotide (FMN), flavin adenine dinucleotide (FAD)	Involved in carbohydrate, protein, and fat metabolism; helps release energy into cells	Important role in energy metabolism; healthy skin
Niacin	Nicotinic acid, niacinamide (nicotinamide), nicotinamide adenine dinucleotide (NAD), and nicotinamide adenine dinucleotide diphosphate (NADP)	Involved in carbohydrate, protein, and fat metabolism	Reduces risk of arteriosclerosis
B_6	Pyridoxine, pyridoxal, pyridoxamine, and related phosphorylated forms	Essential for proper protein utilization; involved in homocysteine metabolism	Reduces risk of cardiovascular disease (with folate and B_{12}) and osteoporosis
B_{12}	Cyanocobalamin, methyl- and hydroxycobalamins, adenosylcobalamin (coenzyme B_{12})	Needed for red blood cell formation and DNA and RNA syntheses; involved in homocysteine metabolism	Prevents certain anemias and reduces risk of cardiovascular disease
Folic acid (folacin)	Pteroylmonoglutamic acid, 5-methyl-tetrahydrofolic acid and 10-formyltetrahydrofolic acid, tetrahydrofolic acid as both mono- and polyglutamates	Involved in amino acid interconversions and methylation reactions, needed for red blood cell formation and DNA and RNA syntheses, involved in homocysteine metabolism and protection against neural tube defects	Prevents certain anemias and birth defects, reduces risk of cardiovascular disease (with B_6 and B_{12}) and certain cancers
Pantothenic acid	Coenzyme A, pantetheine, and acyl carrier protein (ACP)	Active in protein, carbohydrate, and fat metabolism, formation for certain nerve regulators	General health and well-being
Biotin	Biotin, desthiobiotin	Active in protein, carbohydrate, and fat metabolism	Helps develop healthy nails
C	Ascorbic and dehydroascorbic acids, isoascorbic acid	Helps form/maintain collagen; important for healthy tissues and wound healing; enhances iron absorption; protects against free-radical damage and infection	Protects against cancer and cardiovascular and eye diseases; reduces symptoms of colds and flu and risks of osteoporosis

Source: Francis, F. J. (ed.) (2000). Vitamins: survey. In: *Encyclopedia of food science and technology* (2nd ed.), vol. 4, pp. 2440–2449. New York: Wiley.

During the early years of vitamin discovery, their chemical composition was largely unknown and vitamins were each assigned a letter of the alphabet for convenience. This was further complicated when it was found that the activity attributed to a single vitamin was, in some instances, the result of a combination of several vitamins, for example, vitamin B complex. Once a vitamin had been isolated from a food and its chemical structure determined, variations in the structure were found within compounds having the same vitamin activity but in different species. A system of numerical subscripts was therefore adopted to overcome this problem, for example, D_2 and D_3.

In order to simplify the system, letters were sometimes replaced with names, for example, thiamine (vitamin B_1), riboflavin (B_2), pantothenic acid (B_5), and biotin (vitamin H), based on the chemical structure of a specific function or source. 'Thiamine' contains the prefix 'thi,' which is derived from the Greek word for sulfur and refers to its sulfur content. 'Riboflavin' indicates the chemical structure and is derived from the chemical names 'ribose' (a pentose sugar) and 'flavin' (a heterocyclic ketone). 'Pantothenic acid' is derived from the Greek word *pantos*, meaning 'found everywhere.' 'Biotin' originates from the German word *haut*, meaning skin, as this vitamin protects the skin.

Occurrence in Food

One of the main differences between fat- and water-soluble vitamins is their distribution in biological tissues.

The water-soluble vitamins are found in all living tissues, whereas the fat-soluble vitamins are completely absent from some tissues. Vitamins A and D occur widely in plant tissues in the form of a provitamin. Similarly, the amino acid tryptophan can be converted into nicotinic acid in the body. Although it is generally assumed that sufficient amounts of vitamins can be absorbed from a balanced diet for normal requirements, the use of vitamin supplements, either as single compounds or in multivitamin products, is widely consumed. The major vitamin forms found in foods, some commercial forms, and some examples of rich food sources are given in Table 2.

Nutritional Aspects

Vitamins are required in trace amounts in the diet for the maintenance of optimal health, growth, and reproduction. Deficiency symptoms will occur if a single vitamin is omitted from a diet of a species that requires it. Many of the vitamins act as coenzymes, whereas others have no single role but perform certain essential functions. A list of known functions for each vitamin is given in Table 1. Vitamin requirements based on metabolic needs are similar for animals and humans, but dietary needs vary widely among species.

The recommended intakes of nutrients, including vitamins, are intended as daily intake guidelines for preventing deficiencies and maintaining body reserves among healthy individuals. The values are derived from studies on volunteers on nutrient balance studies, measures of tissue saturation, normal vitamin intakes in the general population, and extrapolation from animal studies and are generally revised every 5–10 years by panels of expert scientists. The recommended intakes can vary from country to country owing to a number of factors such as different interpretations of investigations into the determination of requirements, the level of the safety margin needed, and the amounts needed to allow for individual variation in the general, healthy population. The recommended dietary allowances (RDAs) and recommended nutrient intakes used in the United States and the United Kingdom, respectively, are given in Table 3 for adult males and females.

It is also becoming evident that some vitamins have additional health benefits when given, via diet or by supplementation, at levels above those required for eliminating classical deficiency states. Although, for most vitamins, the optimal levels are not yet established, for some vitamins such as folic

Table 2 Vitamins: commercial forms, food forms, and rich dietary sources

Vitamin	*Major commercial forms*	*Main food forms*	*Rich dietary sources*
Fat-soluble vitamins			
A	Retinol acetate and palmitate, β-carotene	Retinyl esters, carotenes (provitamin A compounds)	Fatty fish, butter, margarines, and liver
D	Cholecalciferol, ergocalciferol	Cholecalciferol	Fatty fish, eggs, and margarines
E	(*RRR*)-α-tocopherol, (*RRR*)-α-tocopherol acetate, all-*rac*-α-tocopherol, all-*rac*-α-tocopherol succinate	Tocopherols (α-, β-, and γ-forms) and tocotrienols (α- and β-forms)	Vegetable oils
K	2-(*R*,*S*-)-vitamin K_1 (*cis*/*trans* mixture), menadione sodium bisulfite	Phylloquinone (K_1), menaquinones (K_2)	Green leafy vegetables, beef, and liver
Water-soluble vitamins			
B_1	Thiamine chloride HCl, thiamine mononitrate, and thiamine diphosphate	Thiamine; thiamine monophosphate and thiamine pyrophosphate complexed to proteins	Cereals, potatoes, liver, and yeast extract
B_2	Riboflavin, riboflavin sodium phosphate	Riboflavin; riboflavin mononucleotide, flavin adenine dinucleotide complexed to proteins	Liver, milk, eggs, and green vegetables
Niacin	Niacin, niacinamide	Nicotinic acid; nicotinamide adenine dinucleotide (NAD) and its phosphate form (NADPH) complexed to proteins	Meat and meat products, cereals
B_6	Pyridoxine hydrochloride, pyridoxal-5′-phosphate	Pyridoxine, pyridoxal, and pyridoxamine and their phosphorylated forms bound to proteins	Meat and meat products, eggs, cereals
B_{12}	Cyanocobalamin, hydroxycobalamin	Methyl-, adenosyl-, hydroxy-, and sulfitocobalamins	Kidneys, eggs, milk, and cheese
Folic acid (folacin)	Folic acid	Folic acid; 5-methyltetrahydrofolate, 10-formyltetrahydrofolate, tetrahydrofolate as mono- and polyglutamates	Green leafy vegetables, cereals, yeast, and vegetable extracts
Pantothenic acid	Calcium pantothenate, d-panthenol	Pantothenic acid, coenzyme A, and acyl carrier protein (ACP)	Liver, kidney, yeast, wheat germ, and egg yolk
Biotin	D-biotin	Biotin and biotin bound to lysine and proteins	Widely distributed especially liver, kidney, yeast, and eggs
C	Ascorbic acid, ascorbyl palmitate, and sodium ascorbate	Ascorbic acid, dehydroascorbic acid, and isoascorbic acid	Citrus fruits and vegetables

acid, the health benefits have been clearly demonstrated for taking higher intakes to protect against spina bifida or other neural tube defects.

Availability

The way in which vitamins are absorbed and utilized in the body can be affected by a number of factors that can be broadly divided into dietary-related factors and physiological factors related to the host. The vitamin may not be in a form that can be readily absorbed by the body. For example, nicotinic acid occurs in cereals in a form that is not absorbed from the gut. Other components in the diet may also interact with the vitamin, causing an enhancement, or depression, of absorption. Thus, the nutritive value of a diet for a given vitamin may be somewhat different from the amount actually analyzed chemically. Thiamine requirements are higher when the diet contains large amounts of carbohydrate or alcohol. Similarly, when the intake of polyunsaturated fat is high, vitamin E requirements are also raised.

In general, for food tables, allowances are normally made for reduced biological activities of different forms of three vitamins: 13-*cis*-retinol and retinaldehyde (vitamin A), carotenes other than β-carotene (provitamin A compounds), and tocopherols and tocotrienols other than α-tocopherol (vitamin E).

Adverse Effects

Along with increasing evidence of health benefits from consumption of diets containing vitamins at levels much higher than the RDAs, there is concern over potential adverse effects and even toxicity. Vitamins can be generally divided into two groups: first, those vitamins with a safety level of 100 times or more the RDA for that vitamin for which there is no clear indication of any adverse effects, including most of the water-soluble vitamins and the tocopherols, and, second, those vitamins with a safety level of about ten times the RDA, above which serious adverse reactions can occur. These vitamins include retinol, calciferols, phylloquinone, and pyridoxine.

In particular, chronic intakes of vitamins A and D are to be avoided. For example, an excessive intake of vitamin D can lead to vitamin D intoxication, which is characterized by an increase in serum 25-OH-D and is associated with hypercalciuria and hypercalcemia. The safe upper limit for vitamin D is 25–50 μg day^{-1} (1000–2000 IU day^{-1}). Pregnant women should avoid large doses of vitamin A, either by avoiding foods, such as liver, that contain high concentrations of vitamin A or by avoiding multivitamin supplements that contain doses of vitamin A > 5000 IU.

As for the water-soluble vitamins, there has been some concern about excessive intakes for nicotinic acid and pyridoxine. Vitamin B_6 intakes as low as 50 mg day^{-1} can be associated with possible neurological damage in patients. Similarly, the potential benefits of lipid-lowering effects of high nicotinic acid intakes (2–6 g day^{-1}) have to be considered alongside the possible toxic effects, particularly for the liver. One of the main concerns of folic acid fortification is its potential to mask the diagnosis of pernicious anemia, which is caused by vitamin B_{12} malabsorption, at intakes of ≥ 1 mg day^{-1}, causing progressive and irreversible nerve damage.

Effects of Processing on Vitamin Stability

Vitamin stability varies greatly and depends on a number of factors such as temperature, oxygen, and acid or alkali strength. Table 4 provides general information on stability (S) or instability (U) under several conditions. Several processes have been developed to produce stabilized forms of the vitamin, including spray drying in a suitable matrix (e.g., gelatin) and encapsulation.

Consumer interest over recent years in the nutritional labeling of foods, and the increased awareness in health benefits of vitamins, has focussed attention on the effects of food processing on vitamin stability. It should be remembered also that one of the major benefits of processing is that it has a marked

effect on preserving vitamin concentrations by inactivating food enzymes despite any immediate loss.

The content of vitamins in processed foods is determined initially by the content of the raw materials used. There is a wide variability in vitamin concentrations of commercially grown foods. For example, carrots may vary in their carotene concentration 100-fold, and vitamin C can vary by as much as 35-fold. This can be due to a number of factors, including variety differences, climate and growing conditions, maturity at harvest, and postharvest storage conditions. Thus, the vitamin content of raw materials for processing can vary enormously, in many cases exceeding that found in normal processed food.

The different chemical and physical properties of the vitamins mean that they vary widely in their degree of stability. In the pure crystalline form, they retain their activity for long periods of time. However, when foods are processed, vitamins are subjected to a range of conditions that can be detrimental to their stability such as light, moisture, oxygen, heat, and pH, these being typical environmental factors to which the food will be subjected in the food chain (see Table 4). The most labile vitamins are retinol, ascorbate, folate, and riboflavin. Niacin and biotin are the most stable, but information on some of the vitamins, especially vitamin D, is incomplete.

Domestic Cooking

Typical percentage losses of vitamins on cooking for selected food groups are given in Table 5.

Vitamin C is one of the most labile of all the vitamins and is readily leached into water on boiling, particularly when the surface of the food has been cut or damaged. Vegetables are an important source of vitamins in the diet, and typical losses on boiling vegetables are quite variable. The use of microwaving can reduce vitamin losses for cooked vegetables (see in the succeeding text).

Meat is also an important source of several vitamins. A considerable amount of B-group vitamins, especially thiamine, can be lost when meat is grilled or fried (up to 40%). Losses are less when pot roasting and braising are used. Some vitamins that leach into the meat juices during cooking will not be lost if the sauce or the gravy is eaten as part of the actual dish. This means that average losses in meat dishes are not higher than for grilled or fried meat, even though the cooking times are longer. Similarly, when bread is baked, 30% of the thiamine content can be destroyed, and this can increase to as much as 80% if alkaline baking powders are employed.

Microwave cooking can result in retention of vitamins equal to, or greater than, conventionally cooked vegetables. However, a number of studies have shown that cooking time, water volume used, etc. affect considerably vitamin retention with microwave cooking, as with other cooking procedures. For meat and meat products, the effect of microwave versus conventional cooking on vitamin retention seems to be less pronounced. A higher degree of riboflavin retention and a lower degree of thiamine retention have been found, but there is no difference in niacin concentrations.

Other Processing Methods

There has been only limited work reported on the effects of extrusion cooking on vitamin retention. In one of the few studies, the retention of B-group vitamins was investigated during crispbread production. The destruction of the more labile vitamins (thiamine, folate, B_6, and B_{12}) was directly proportional to the energy input, although other factors, such as moisture content, mass temperature, screw geometry, and rate of throughput, are also thought to influence retention. It appears that retention can be improved by increasing both the rate of throughout and moisture content. However, carotenoids in corn starch are fairly stable to extrusion, although some of the forms can be oxidized further. Losses of vitamin C during extrusion of 25–40% have been found.

Radiation-induced changes in vitamin concentrations in foods during irradiation have been reviewed extensively in the literature. At low irradiation doses (<1 kGy) used for

disinfectant treatment, losses are negligible compared with the larger variations in the vitamin content of the raw materials. The most thermolabile vitamins are thiamine, tocopherols, and ascorbate, but, with the medium-dose range (1–10 kGy) used to control microbial contamination, losses can be minimized.

It is well known that fermentation can increase the B-vitamin content (e.g., folates) of some foods, such as cheese, milks, yogurts, and other dairy foods, and this is a potential area for production of foods with enhanced health benefits. There does appear to be some potential for producing significant amounts of vitamins with various fermentation conditions and organisms.

Vodka

RI Aylott, Aylott Scientific, Dunblane, UK

© 2016 Elsevier Ltd. All rights reserved.

Vodka is a distilled alcoholic beverage. The word vodka comes from the Slavic word for water (voda). Vodka was first produced in Russia and Poland, but it is now produced globally.

Vodka is made from neutral spirits; high-strength alcohol is fermented from a carbohydrate source and concentrated by distillation so that the organoleptic characteristics of the raw materials and by-products of fermentation are selectively reduced. Neutral spirit is very pure alcohol with low concentrations of associated compounds (known in the industry as congeners). This is then subject to further processing and reduction in alcoholic strength with water to give vodka (Figure 1). Unlike whisky, brandy, and other 'brown spirits,' vodka does not undergo maturation in wooden barrels.

Neutral Spirit Production

'Neutral spirits' or 'neutral alcohols' as defined in the US Code of Federal Regulations (Title 27, Part 5.22) are distilled spirits produced from any material at or above 190° proof (95 vol.%). The equivalent term in European Union Regulation 110/2008 (Annex I) is 'ethyl alcohol of agricultural origin.' This regulation requires distillation at or above 96 vol.% alcoholic strength from a material of agricultural origin and defines specific analytic parameters (Table 1). Elsewhere, the term 'rectified alcohol' may be used along with 'ENA' (for 'extra neutral alcohol' in India) and 'GNS' (for 'grain neutral spirits,' as appropriate).

The production of neutral spirits (like all alcoholic beverages) starts with fermentation of sugars derived from a carbohydrate feedstock into ethanol by the action of yeast. The choice of carbohydrate feedstock is normally based on cost and availability. Neutral spirits may be made from various raw materials such as potatoes, cereals, molasses, and grapes and perishable materials such as sugar cane juice or cheese whey. The start of the process depends upon the ease by which the fermentable sugar, glucose, is extracted from the raw material. For example, cereals are first ground down to small particle sizes in a mill, mixed with water, and cooked under pressure. This process creates a 'mash' by breaking down the granular structure of the starch and causing it to gelatinize (i.e., absorb water and become a viscous liquid gel). Malt or added enzymes then hydrolyze the starch into dextrins (oligosaccharides), which are further broken down into a solution of fermentable sugars known as 'wort.' On the other hand, fermentation from molasses is much simpler as the carbohydrate is present as sugars that are ready for fermentation.

A distiller's yeast (such as *Saccharomyces cerevisiae*) is added to the 'wort' in vats and batch fermentation begins. The process typically takes about 40 h and produces a 'beer' (or 'fermented wash') with an alcoholic strength between 6 and 10 vol.% and a range of trace congeners that include trace methanol, higher alcohols, aldehydes, acids, and esters. The amount of congeners formed is dependent upon the composition of the raw material.

The 'beer' is converted into neutral spirits by distillation in a still that comprises a series of columns that operate continuously and is capable of concentrating alcohol from <10% up to over 95% alcoholic strength. Distillation is the process by which the components of a mixture are separated by differences in their boiling points. Temperatures are highest at the base of the still and decrease to the top of the columns. Vapor rises up the columns through internal components known as 'trays' and liquid flows down. The trays increase contact between vapor and liquid. The various congeners in the liquid boil and recondense according to the temperature at different points on the still. Although there is diversity in the designs of distillation columns found throughout the industry, the objective is to recover pure alcohol and eliminate water and congeners.

Steam is introduced into the first column (known as the 'beer stripper' or 'analyzer') and this separates alcohol and other volatile congeners from residual fermentation solids. Solids are usually recovered as by-products and used as animal feeds or biomass; some producers remove protein and fiber from the initial raw materials as useful by-products.

Subsequent distillation columns concentrate and purify the alcohol through a process of rectification so that the neutral spirit collected at the top of the last distillation column is very pure, has no discernible organoleptic character, and contains only trace congener concentrations. Trace congeners can be further removed using the technique of 'extractive distillation' (otherwise known as 'hydroselection'), a process that separates congeners of different volatility. Some raw materials such as potatoes and grapes yield relatively more methanol than molasses and cereals. Methanol concentrations can then be further reduced on a 'demethylizing' column.

Vodka Production

Vodka, along with other distilled spirits, is subject to definition in the regulations of most countries. The United States defines vodka and flavored vodka in the Code of Federal Regulations (Title 27, Part 5.22), European Union Regulation 110/2008 defines vodka and flavored vodka processes, while Russia (GOST R51355-99), China (GB/T 11858-2008), and India (IS 5286: 2005) each have very detailed and analytical vodka definitions. Neutral spirits/ethyl alcohol of agricultural origin provides the alcohol base from which not only vodka but also wide ranges of other distilled spirits, such as gin, pastis, ouzo, and aquavit, are made.

Although neutral spirits for vodka can be fermented from any carbohydrate source, cereals or potatoes are required raw materials for vodka producers in Baltic countries. Producers in other countries also use molasses (from cane and sugar beet), grapes, and rice depending on cost and market requirements. Indeed, the Canadian regulations (B.02.080.) require vodka to be made from cereals or potatoes, while European Union

Source: Regulation (EC) No 110/2008 of the European Parliament and of the Council of 15 January 2008 on the definition, description, presentation, labelling and the protection of geographical indications of spirit drinks and repealing Council Regulation (EEC) No 1576/89.

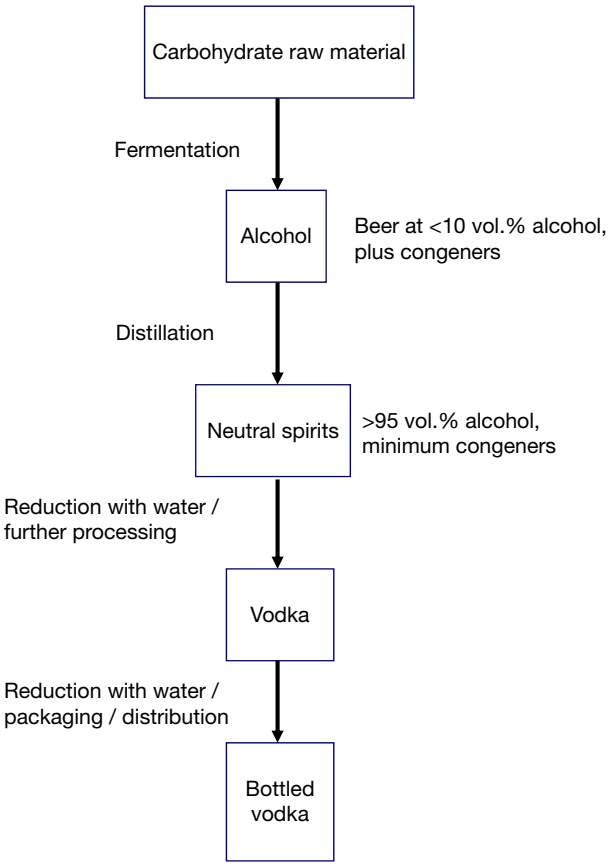

Figure 1 Key stages in vodka production process.

regulations require vodkas that are made from materials other than cereals and potatoes to be labeled as such.

The vodka process utilizes neutral spirits that are normally first reduced in alcoholic strength with pure water before undergoing various processes such as filtration through activated carbon and other media (to further reduce trace congeners). The quality of the reducing water is very important. This water is usually made using a town water supply but further treated by demineralization to reduce trace anions and cations and then passed through activated carbon and ultraviolet light treatment processes to eliminate the risk of foreign off-odors.

Some producers pass their vodka through a series of large columns containing activated charcoal, while others employ simpler systems. Trace additives may be used including sugars, glycerol, propylene glycol, and fermentation products depending on style and local regulations. Some additives were first introduced to create a smoother taste and mouthfeel for a particular brand, while others were designed to make their brand more distinctive. Some government excise agencies once required the use of additives as 'obscurants' to demonstrate that the neutral spirits had undergone further treatments to create vodka.

Finally, more pure water is added to reduce the alcoholic strength down to that required for bottling. If the additives give the product a predominant flavor, then the product is designated as 'flavored vodka' with the name of the flavor included. Minimum bottling strengths are set in different markets ranging from 37.5 vol.% in the EU to 40 vol.% (80° proof) in the United States.

Packaging and Distribution

Vodka is most commonly packaged in 70 and 75 cl glass bottles; lightweight PET (polyethylene terephthalate) bottles are often used in the duty-free trade. Bottle closures are made from aluminum and plastics; some bottle closures are designed to include one-way valves for added packaging security and thus reduce the risk of refilling.

Although alcoholic beverages are generally exempt from nutrition labeling, consumers may require specific information. The energy value of vodka is derived from its alcohol component at 91 kJ/222 kcal per 100 ml; there is zero carbohydrate, zero fat, and zero protein present unless additives are present in specific brands, in which case the energy associated with the additives must be taken into account.

The European Union's allergen labeling regulations include ingredients described as 'cereals that contain gluten' (Annex IIIa in Directive 2003/89/EC, 2003). However, distilled spirits made from cereals do not contain allergenic material as it is involatile and eliminated during distillation. Therefore, cereals used for making distillates (among others) are exempt from allergen labeling (EU COMMISSION DIRECTIVE 2007/68/EC, 2007).

Vodka is generally available for purchase in all countries where alcohol is consumed. It is also manufactured in many countries; the choice of raw material is usually dependent upon its availability and cost in the place of production. Some global brands are produced in one country and then exported, while other brands may be produced and bottled at numerous locations. Global brands usually have consistent compositions in all their markets, the only exception being for those markets where additives are not permitted (such as Canada). Regional vodka brands tend to be consumed in their country of production. Labeling regulations require that the product's label should define its producer, its country of origin, and, if exported, the name and address of the local distributor.

Producers often apply 'track and trace' markings to their bottles and labels. These codes can be interpreted to provide considerable detail on the product's supply chain. 'Track and trace' markings are designed to be compliant with food traceability requirements of modern food law such as Article 18 of European Union Regulation 178/2002. The markings are usually in the form of letters and numbers and are printed behind the front label, on the rear of a label, and on the bottle itself or are applied by a laser that marks the glass. Information such as brand name, batch number, production date, line number, and even details of the first customer can be determined from the code (working in conjunction with the manufacturer's database).

Quality Assurance

Bottled vodka, essentially being 40% ethanol and 60% water with only negligible congeners, is very stable and requires no shelf life/expiry date on the package. It is normally a clear liquid, although some brands may contain additives and other materials that make the liquid opaque. Flavored vodkas on the other hand may be sweetened, blended, flavored, matured, and colored. Check the product's label for more information.

The trace congeners found in vodka are normally those compounds with a similar volatility to ethanol that are not completely removed during distillation. It is normal to detect very low levels of methanol (typically <10 g/100 l absolute alcohol) and occasionally trace acetaldehyde, ethyl acetate, *n*-propanol, and fusel oils. Such congeners are normal in vodka at trace concentrations and have negligible impact on sensory properties.

Sensory assessment and alcoholic strength measurement are applied during the production process. Producers have skilled panelists to conduct sensory tests. Alcoholic strength is defined as the volume of ethyl alcohol at a set temperature and is expressed as a percentage or degrees proof where 100 vol.% is equal to 200° US proof. Its measurement is normally based on the density of the test liquid and various methods and instruments are available.

In addition, gas chromatographic (GC) techniques are used to determine trace congeners. This analysis can give useful information on the efficiency of the distillation/rectification process, on the raw materials employed (as different plants lead to different methanol concentrations), and on contaminants or adulterants. Such analyses usually employ a capillary column GC with flame ionization or mass spectrometric detection. Other chromatographic separations may be used to detect additives.

Patterns of Consumption

Vodka is the most popular global distilled spirit category by volume produced, considerably ahead of rum, Scotch whisky, gin, and tequila. Total global consumption in 2012 was reported by The Economist to be nearly 4.44 billion liters. Russia consumed nearly 2 billion liters corresponding to

Table 2 Major vodka brands in 2012 and their ranking order in the top 100 global and regional distilled spirits

Ranking order	*Brand*	*Brand owner*	*Sales in 2012 (million 9 l cases)*	*Status*
3	Smirnoff	Diageo	25.8	Global
17	Absolute	Pernod Ricard	11.4	Global
24	Khlibniy Dar	Bayadera Group	8.0	Regional
27	Khortytsa	Khortytsa Distillery	7.7	Regional
28	Belenkaya	Synergy	7.3	Regional
30	Pyat Ozer	Alcohol Siberian Group	7.0	Regional
36	Kristall	Minsk Kristall RUP	5.5	Regional
39	Medoff	Eastern Beverage Company	5.4	Regional
43	Krupnik	Belvédère	5.1	Regional
54	Czysta de Luxe (ZG)	Stock Spirits Group	4.3	Regional
66	Svedka	Constellation Brands	3.9	Regional
67	Grey Goose	Bacardi	3.8	Global
69	Skyy	Gruppo Campari	3.7	Global
73	Stolichnaya	SPI Group	3.4	Global
79	Finlandia	Brown-Forman	3.1	Global
82	Russian Standard	Roust	2.9	Global
96	Magic Moments vodka	Radico Khaitan	2.5	Regional
100	Sobieski	Belvédère	2.3	Global

annual per capita consumption at nearly 14 liters. Other major vodka markets, although well behind Russia, were Ukraine, the United States, Poland, Uzbekistan, Belarus, Kazakhstan, Britain, Brazil, and Germany.

Vodka brands are numerous and tend to be either global or regional in their sales profile (**Table 2**). The high vodka consumption in Russia and associated countries is reflected in the number of regional vodka brands that sell in large volumes in these areas.

Vodka is consumed in various ways depending on the drinking culture of the country: on its own neat in Russia and in 'cocktails' and with mixers in the West. As vodka is essentially alcohol, without the sensory impact of congeners present in other spirits, it is readily consumed. It is absorbed and metabolized like other alcoholic beverages. Excess consumption can lead to the same health issues as other alcoholic beverages.

The counterfeiting of alcoholic beverages is an issue in some markets as prices are relatively high with heavy tax duties applied to distilled spirits. Vodka is an easy target as it is relatively easy to imitate, by counterfeiters. Sometimes, empty bottles from genuine brands are refilled with illicit liquor in bars and sold as the real liquid; sometimes, the entire package is counterfeited resulting in consumers being deceived; tax revenue lost and brand owners losing business.

Health issues have been reported when counterfeiters use potentially dangerous liquids such as industrial alcohol and methanol. Owners of genuine brands often have the capabilities to confirm the authenticity of their packaging and their liquids. The additives present in certain brands can act as useful authenticity indicators when analyzing suspect samples.

Wastage of Food

Introduction

The Food and Agriculture Organization of the United Nations (FAO) definition of food loss and waste considers that it is food intended for human consumption but not consumed as such. This definition encompasses landfilled food fit for human consumption (food waste), anaerobic digestion (AD) incineration, and any edible food mass used as animal feed, plowed back, or sent to be composted (food loss).

With global population recently reaching 7 billion, there are growing concerns with regard to medium-term food sustainability. With such risk being introduced into the food supply chain (FSC), fundamental food security questions are being raised in addition to the need to feed an ever-growing number of mouths; estimated to increase to 9 billion by 2050, such population growth suggests that food demand will increase by 50% and that the agricultural and power generation demand for water will outstrip supply by 2030. A 2011 study by the FAO estimated that global food wastage stood at around 1.3 billion tonnes (1.3×10^{12} kg) p.a. In terms of feeding a growing population, it is important to consider this in terms of calories and can crudely be calculated at 6.825×10^{12} kcal. It is also pertinent to draw attention to the additional losses that occur alongside all wasted food, which is the sum total of the resource and energy input to produce that food throughout its life.

The issue of food waste is not however new, and while postwar food shortages were the primary concern of the FAO at its inception in 1945, by 1954, there had been a significant shift in its focus with the Consultative Subcommittee on Surplus Disposal being established within the 1949 established Committee on Commodity Problems. This was necessary as not only had food supply been reestablished in the war-affected areas, but also many surpluses were now being seen.

More recent efforts have been driven by nongovernment organizations (NGOs) such as the Waste & Resources Action Programme (WRAP). Notable activity by WRAP in the United Kingdom has seen the introduction of the Courtauld Commitment in 2005, now in its 3rd phase, through which retailers representing 92% of the UK grocery market, brand owners, and manufacturers publically committed to a series of targets to reduce food waste, packaging waste, and carbon dioxide emissions.

To date, the Courtauld Commitment has demonstrated significant success in the delivery of effective food waste reduction strategies with the first phase reporting reductions of 670 000 tonnes of food waste between 2005 and 2009 and the second phase boasting a reduction of 270 000 tonnes per year between 2010 and 2012, saving the UK consumer an estimated £700m a year.

Societal Contribution

Sociologically, it is disappointing that such external action is required to reduce the ever-growing issue of food wastage, with estimates that up to 1/3 of all food produced goes to waste. What's more, it is estimated that a large proportion of this is avoidable waste driven by consumer preference trends, legislative restrictions, and a fear over perceived health risks.

What is apparent however is that while globally 1/3 of produced food goes to waste and is fairly static worldwide, the categorization and origin of that waste vary significantly. Such disparity across the FSC reflects the maturity of the retail market, the controlled supply chain it demands, the overall wealth of the nations, and the length of supply chain.

The European and North American markets show that of the 900 kg of human food produced per capita, up to 20% is wasted in the FSC and a further 10–15% is wasted by the consumer. A similar pattern is apparent in industrial Asia. However, consideration of developing territories shows a slightly different picture; the actual per capita loss is less (<150 kg per capita in South and Southeast Asia), yet it still represents 1/3 of the total food production. However, only 5–10% of that wasted is at the consumer level. This clearly demonstrates the impact that societal wealth, a mature retail environment, and heavily controlled supply chain can have. The impact of household waste is exacerbated by the fact that for a product to have been a consumer product, it should have achieved its maximum cost and value through its consumption (depletion) of the resources required to create it.

It is also worth taking into consideration that the more developed nations are producing much more edible human food per capita and, in some cases, double; this is resulting in considerably more consumer wastage in societies that are increasingly obese and suffering from many more dietary related diseases such as diabetes and heart disease. For example, in the period between 1993 and 2013, obesity increased in the United Kingdom from around 15% of the population to nearer 25% in a society that disposes of almost 100 kg of edible food per capita per year.

The end of postwar rationing period saw a generation rewarded by better food quality, innovative food processing, and improved supply chains and a generation wanting their

progeny to have everything they did not – and food was an important element of that. This is shift was seen, and perhaps predicted, by the FAO in their 1954 restructure as previously discussed. As highlighted by Helena Semedo, FAO Deputy Director-General at the 2014 Green Week: "*Food production has tripled since 1945 and average food availability per person has risen by 40%.*" This has resulted around 1.5 billion of the global population being overweight or obese with a further 2.8 billion suffering the effect of malnutrition and hunger. This disparity in distribution and availability of excess underpin the root cause of avoidable food wastage. It has been suggested that the US obesity epidemic is in fact a push effect resulting from the availability and oversupply of cheap calories; therefore, actually addressing this surplus would reduce food waste.

It is also important to consider that a number of conflicts exist that also contribute to food wastage that is 'mega trends.' These may include the demand for 'fresh' fruit and vegetables throughout the year, and the demand for more natural and additive free products was in fact counter to efforts to reduce waste by increasing product shelf life.

Increase in Food Waste

By comparison of Europe and North America to less developed economies, it suggests that the hallmark of a developing economy is an increase in waste. This can be seen further in consideration of the US food waste trends, which has seen an increase of around 50% per capita between 1970 and 2005. This growth has been widely acknowledged and resulted in many countries initiating nationwide schemes to engage with manufacturers, retailers, and consumers, such as WRAP in the United Kingdom, in order to ultimately change behavior. The catastrophic impact on the rising population in terms of calorie distribution and potentially food security that continued food wastage growth would have should not be underestimated.

Supply Chain Waste

Within the FAO definition of 'food wastage,' food loss incorporates all agricultural and processing loss and food waste is focussed on consumer and household waste. However, it is distinguished from the EU's Waste Framework Directive (2008/98/EC) 'waste' definition by virtue of the fact that it only includes edible food mass suitable for human consumption and excludes inedible crop by-products, residues, and animal parts. This definition does have limitations due to cultural differences of what may or may not be considered edible.

The FSC can be long, complex, and varied, and from its agricultural origins, whether it is livestock or crops, there are numerous interconnecting component elements of selecting, processing, and packing to name few. As we have seen already, the supply chain element waste is a significant contributory factor in the overall wastage picture.

At the earliest stages, good farming practices should be in place to minimize this. However, efforts to drive quality and homogeneity saw the introduction of EC 730/1999 EC 85/2004 and (EEC) 1677/88, which controlled the sale and classification of fruit and vegetable based largely on their aesthetic appearance rather than their nutritive value. Such control measures will have undoubtedly contributed to the increase in food wastage seen in recent decades. These were largely repealed in 2009, but EU Regulation 543/2011 makes thorough specifications regarding fruit and vegetable quality and classification. Such controls will undoubtedly result in unwarranted wastage of food fit for human consumption based on appearance. It is also unlikely that such losses are quantifiable since products may be selectively harvested, a process by which produce failing to meet the exacting standards are simply left and replowed to enrich the soil rather than incurring the costs of downstream preparation and ultimately a low market value.

Processing Waste

The majority of food materials are processed once harvested, whether that is a simple washing and freezing process as would be seen for vegetable products or a more complex multilayered industrial process such as refined sugar production from sugar beet. During such processes, there are inevitable losses and clear waste minimization strategies need to be employed within a manufacturing environment. The joint food wastage declaration 'Every Crumb Counts' laid out a clear framework and philosophy to be adopted by its signatories to in order to change behavior throughout the supply chain.

The first point of note is the headline 'Every Crumb Counts,' clearly demonstrating the starting philosophy to always 'not waste anything.' In a manufacturing or processing environment, an aggregation of such marginal gains can certainly prove to be of commercial importance. The principle is that macro gains are almost always catered for through efficiency data, preventative maintenance and output data, etc. However, to gain the incremental advantage that takes the process efficiency to a higher level, attention to the minutiae is required as is the need to leave no stone unturned; therefore, each slight improvement builds into a quantifiable gain. It is this approach that many manufacturers, even those who consider themselves efficient, need to take to achieve even further waste reduction benefits. While there are many continuous improvement models and lean manufacturing techniques being used to great effect, the next generation of waste reduction is only likely to be achieved by an even more critical look at the process.

Further part of the toolkit recommendations include partnerships where waste streams could be integrated and utilized; such collaborative and open innovation could be highly beneficial and create value for both parties. This approach is not a new one; after all, yeast extracts are essentially by-products of other processes, but it is a potential avenue that may have been overlooked during times when, as a society, we considered ourselves 'resource-rich.' An analytic (chemical, nutritional, and functional) screen of waste materials is an essential step to understand the nutritional value of what is being discarded, and with knowledge of the nutritive waste, collaborative partners could be more easily identified.

A third key element is the need to drive 'innovation' and develop new products from food and ingredients that would normally be thrown away. Within the confectionery industry,

for example, the idea of reworking or inventing new products from waste is not a new one especially since many well-known products have origins as a by-product, for example, Cadbury Flake. There are many processes that produce what is considered to be unusable waste that may not be reworked into an existing product, but could be valorized through development of something new. However, the success of a new product may result in there being insufficient waste from the primary process to fulfill demand; however, this would be a 'nice' problem to have. More radical waste reduction innovation may be to increase the by-product of a process in order to enhance its value.

A key part of sustainability is to facilitate the move from a linear economy in which waste is an output to a more circular paradigm, where waste and recyclables become an input of design and manufacture; essentially, waste streams become a value to themselves. To achieve this, process waste reviews will look at all of the components of waste material from a manufacturing process from a quality angle and then assess them based on ingredient value and manufacturing input. Systematic analysis of these elements can then identify functionality and start to build a picture of potential utilization of the material as an input into alternative products, either as an internal reformulation or through external partnerships. Open innovation is a paradigm for identification and deployment of new technology, and this provides the perfect model to valorize waste streams through external partnerships. An evocative way of thinking about this is by using a 'farm-to-farm' concept, so that the provenance no longer ends at the fork but considers every element of waste that a product creates and how it will be recycled or reprocessed in such a way that it contributes to long-term ecological stability.

Sustainable innovation is becoming increasingly essential in product and packaging development projects. In many ways, the focus that this brings is resulting in a step change in some of the key thought processes in the innovation life cycle.

Each of these elements is going to require a 'step back' approach, but if waste reduction targets are to be achieved, serious reflection of what was previously considered acceptable and efficient is required. This process will also require a greater degree of collaborative and open innovation of food and drink products to achieve an even more sustainable food chain.

Retail Waste

In the developed nations with mature retail markets, the supply management system tightly controls many aspects such as production planning, distribution, temperature control, and delivery schedules in order to achieve an as efficient as possible integrated system. Such mechanisms are increasingly important in densely populated urban environments, where on-site and local retail storage may be at a premium. The success of such systems, and the overall impact that they have on waste, is apparent as supply chain waste becomes a less significant factor in territories where developed logistics exists, namely, Europe and North America, although it could be equally argued that this significance is somewhat distorted by the excessive consumer waste of such developed societies.

It is estimated that 3.5 billion people live in urban environment and this is expected to increase to 6.3 billion by 2050 due to a combination of population growth and social change. This shift will only further impact on the need for retail-driven supply chains.

In the developed world, retail giants have driven quality and safety across the supply chain and, supported by strong legislation, have without doubt enhanced the standard of food on the shelves and consumer confidence. However, they have also been a contributory factor in the increase in avoidable food wastage. Retailer standards are generally more exacting and less forgiving than legislative requirements. In addition to such high expectations and unforgiving relationships with suppliers, food wastage and its impact were placed on a much lower standing than ensuring continuous supply of homogenous product to the consumer. In more recent years, however, through engagement with organizations such as WRAP, the awareness of their role in the production of waste has been acknowledged. Among the criticism levied at the retail trade and areas that could be addressed to reduce food wastage were inconsistent forecasting and promotion management. Such promotional activity, in particular 'buy one, get one free (BOGOFs),' is considered to be counterproductive in the war on waste as they encourage overpurchase of short shelf life products that then often are disposed of as they exceed their product life.

Household Waste

In industrialized societies, food waste in households is increasingly an issue. The WRAP estimates that in 2012, 7 million tonnes of household waste was produced in the United Kingdom. This does include 1.6 million tonnes as food waste classed as unavoidable, so for consistency within this text, this represents 5.4 million tonnes of food wastage composed of 4.2 m tonnes of avoidable waste and 1.2 million tonnes of possibly avoidable waste such as peeling. This was a considerable reduction when compared to 2007, which showed an avoidable wastage level of 5.3 million tonnes. Almost half of this was cited as 'not used in time.' This links strongly to consumption trends and parallels can be drawn to an earlier suggestion that obesity was a result of availability of excess.

Contributory Factors

There are many deep-seated reasons behind the increase in food waste, and the real action to address it on a global level has occurred since 2000. While these efforts are starting to pay dividend, the changing nature of the growing population provides an ongoing challenge. Among the key activities has been the recognition and challenge to many of the contributory factors.

Quality Standards

The introduction of safety, quality, and legal standards such as the British Retail Consortium Global Standard for Food Safety within the context of the Global Food Safety Initiative has been a positive step. These have been applied rigorously by the major retail chains, in order to deliver consistent, reliable, and transparent supply chains in efforts to instill confidence

in their consumers. They have however introduced exacting standards, as discussed previously that have contributed to food wastage issue. Not only has fruit and vegetable classification and marketing standards led to the devaluing of the so-called ugly fruit, forked carrots, and curved cucumbers for purely aesthetic reasons, it has also driven a general expectation for homogeneity. This has also driven scenarios in industrialized nations where it is not economically viable to harvest lower-class produce and edible food mass is diverted to animal feed, fertilizer, or compost so as not to incur further processing time and expense. Many such cases including the rejection of up to four slices of bread per loaf during pre-prepared sandwich manufacture have been exposed, as it is suggested that the consumer was not accepting of crusts and misshapen slices. The expectation of homogenous food products is then perpetuated by consumers in their selection and/or rejection of product at point of purchase.

An artifact of the drive to improve the overall integrity of food products is the need for tight product specifications and comprehensive traceability of ingredients used. As such, the use of manufacturing by-products, that is, the concept of rework, is not widely supported in standard and premium range products, thus creating a market for 'value' tier products, ultimately devaluing the input of the edible food mass, which has already absorbed the full cost of processing. Such costs are unlikely to be fully recovered, and unless waste reuse is culturally significant within the organization, they will be balanced on a purely financial basis against the alternative of landfill or other nonfood chain waste stream outlets such as AD or incineration.

Legislation

Alongside thorough quality and safety standards, legislative restrictions are in place that have a direct impact on the production of and handling of waste. The discovery of bovine spongiform encephalopathy (BSE) in cattle led to the introduction and subsequent evolution of various controls over the handling of animal by-products, namely, EC 1069/2009 and 142/2011. Much of the components affected by such legislation are not considered to be food wastage since it is most likely by-products not considered fit for human consumption, although the lowest-risk categories refer to by-products fit for, but not intended for human consumption, which should by rights be considered as food wastage.

In 2001, the foot-and-mouth disease in pigs outbreak, in Northumberland, the United Kingdom, was traced to the mishandling and contamination of the pig 'swill' feed; this led to the introduction of the ban on pig swill feeding across the United Kingdom, which was subsequently adopted across Europe, in some US states, and in Australia. This has resulted in food manufacturing and catering waste in particular diverted away from the food chain to AD or incineration. Such waste would not be considered as food wastage since it would not be considered fit for human consumption.

Value

Much has already been discussed regarding the differing split of food wastage across the world and the primary sources of waste. The developing world clearly demonstrates though minimal consumer waste that the food on the plate is valued. The industrialized nations however are failing to recognize this and place less value to their meals. Conversely, the supply chain wastage of wealthier nations demonstrates that wastage can be controlled and to some degree minimized. Regions that rely on local supply chain and subsistence farming however are comparatively more wasteful at the front end of the chain. This is likely to be a result of less well-developed farming techniques; less use of fertilizers, pesticides, antibiotics, etc.; and less controlled or robust transportation networks.

Urbanized societies therefore lose the connection with food and agriculture and hence fail to recognize its wider value, aside from the nutrition and retail cost.

Of particular importance is consideration of Engel's law, introduced by German statistician Ernst Engel in 1857 who observed proportion of income spent or food purchases decreased as income rises and likewise lower-income cohorts spent a greater percentage, which is compounded as food prices increase. This is of particular interest as is widely reported food prices have been exhibiting a general upward trend for many years, influenced by a number of external factors such as fuel prices, crop yields, and political events. Aside from specific spikes, such as in 2008, they have in fact more than doubled since 2000. The corresponding aggregated global wealth is also seen to exhibit similar growth over the same period.

This trend is significant when correlated with the increase in food waste and the shift to a greater proportion of household waste in the so-called richer states. It is therefore suggestive that a lower value is generally assigned to food normalizing household food wastage. In economies where wealth is less and food constitutes a higher proportion of income, household waste is significantly reduced.

Shelf Life

The role of durability coding has been considered a key factor in household food wastage behavior.

In Europe, according to Article 24 and Annex X to Regulation (EU) 1169/2011, the date code is in the form of either a date of minimum durability ('best before' date) or a 'use by' date, when a product is, from a microbiological point of view, highly perishable. In this context exceeding by a products' 'use by' date, a food shall be deemed to be unsafe in accordance with Article 14(2) to (5) of Regulation (EC) No 178/2002. Best before dates are applied when a product simply drops below an acceptable organoleptic standard (i.e., it does not taste very nice or the mouthfeel is not what is expected) after a period of time.

Durability coding is essential in assuring the quality and safety of food and is fundamental in communication to the consumer. They do however contribute to food wastage. The household food and drink waste in the UK 2012 report indicated that almost half (2.0 m tonnes) were wasted as they were 'not used in time,' half of which had not been opened. This results from a disconnection with food to such a degree that consumers are failing to interact with the food and have no confidence in their own judgment; their ability to taste and smell 'off' food; and an overreliance on the retailer, packaging

format, integrity, and a general devaluing of purchased food products. 'Use by' dates are in fact underestimated by manufacturers in order to protect brand values. This would therefore suggest that much of the products disposed off by the consumers were in fact safe and fit for human consumption.

In addition to such legal requirements, there had been an increasing trend in retailers applying 'display until' and 'sell by' dates, which had no legal standing but were in fact stock rotation tools. These were found to be counterproductive and contributed to waste-level increases through confusion of the meaning of dual-coded products. This is now actively discouraged in the United Kingdom through clear government-led guidance.

Significant dietary changes also occur within wealthier nations. Bennett's law shows that as a nation increases its overall wealth, there is a corresponding shift to less starch-based staples and an increase in shorter shelf life products such as meat, fish, and dairy. Such products are more susceptible to storage deterioration and in societies where less value is placed on food household waste increases. Thus, Bennett's law and Engel's law must be considered in parallel.

Solutions

There are no immediate solutions to food wastage; however, increasing awareness of the impact throughout the supply chain is essential. Food wastage has become normalized with developed worlds, and this needs to be challenged. Consumer engagement models exist throughout the world with campaigns such as Love Food Hate Waste (the United Kingdom), Stop Spild Af Mad (Stop Wasting Food) (*Denmark*), *Every Crumb Counts* (*Europe*), Save Food from the Fridge (*the Netherlands*), Food Use for Social Innovation by Optimising Waste Prevention Strategies (FUSIONS) (*European Union*), *and the* Food Waste Reduction Alliance Project (the *United States*). *Such mechanisms are successful and are essential in engaging with the consumers and ultimately changing behavior.*

A key basic philosophy to reduce waste is outlined in EU Waste Framework Directive, which showcases the common waste prioritization pyramid and encourages a hierarchical approach to waste reduction strategies. In effect, this directive made the application of the hierarchy a legal requirement (Figure 1).

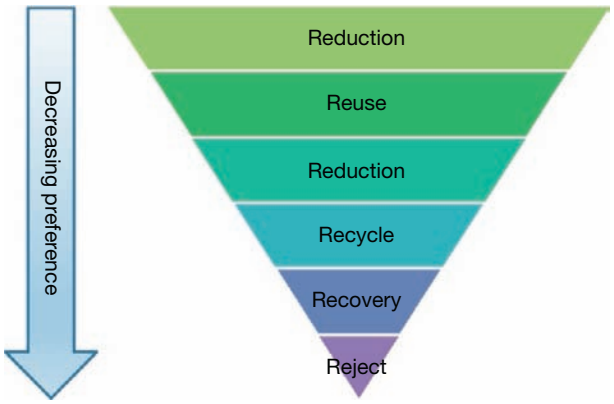

Figure 1 Waste prioritization/hierarchy pyramid.

A key component of this is to ensure that no waste is sent to landfill, and while this does not prevent waste per se, it does as a bare minimum encourage composting of food waste or incineration from which some energy is recovered.

Likely Future Trends

With growing populations, food wastage is going to remain high on the agenda of all nations, and with the impact of food wastage on food supply, it is hoped that the seriousness of the issue will be acknowledged by the comparatively more affluent consumer. As FSC systems develop in poorer regions, it will then be important to ensure that food wastage and surplus is not seen as an aspirational mark of affluence. The potential exists to combine the ideals of both industrial and subsistence regions, so that while some food wastage is inevitable, it is valued throughout the supply chain. The primary ideal in this scenario is to achieve a developing world supply chain waste of less than 20% of total food production and educate the developed world consumer to achieve household waste levels of nearer 5%. This will then go hand in hand with developing an overall healthier dietary landscape as the current levels of excess and overconsumption will be realized.

Sources of Further Information and Advice

With the public need for action on waste, numerous resources are available that provide data, trends, and action. The Waste & Resource Action Programme in the United Kingdom are very much leading the way in engaging with the consumer and industry to address the wasteful cultures that exist. Also in the United Kingdom, the Institute of Grocery Distribution (IGD) started working on a waste initiative in late 2014 to engage with food and grocery companies across the United Kingdom. On a wider European base, FoodDrinkEurope's 'Every Crumb Counts' campaign is designed to engage industry and develop toolkits to target a more sustainable manufacturing base. Further key initiatives aim to drive change of behavior and legislation through more specific activities such as 'The Pig Idea,' a campaign group trying to reverse legislation preventing food waste being returned to the food chain through pig swill and being diverted to nonfood chain routes. The zero waste to landfill agenda is championed in the United Kingdom by Vision 2020.

Water Use in Food

Food industries use water in several different functions. There are food industries that add water to the food or drink in order to produce their final product. Other food industries sell water or associated products. Most food industries use water for cooling and cleaning.

During the Production of Raw Materials

The production of food raw material requires the use of water. Vegetables and animals require watering. Depending on the cultivation practices and the laws for irrigation water and animal consumption water, there are different requirements for both the quantity and quality of water used. Fish and seafood do not need watering, but they live inside freshwater, sometimes even springwater, or saltwater.

Inside the Food Final Product

Some processed foods such as canned soups require water to be prepared. In this case, water is used to prepare the food, and this water is also included in the final product. If water is used untreated from a spring, from a well, or from the municipality supply, it is thought to provide a special character to the food taste. If it is undesirable for water to add any taste to the final product, then the local water is treated. For example, water hardness (that occurs mainly due to the presence of calcium and magnesium ions) or conductivity (that occurs mainly due to the presence of dissolved ions in water) can add taste (e.g., salty) to the final product. Water pH, that is, a measure of acid or base in water, can also make the final product taste sour (low pH) or bitter (high pH). Some minerals such as calcium can interact with some of the ingredients found in food, such as proteins, phosphate, and enzymes, with both desirable (stable) and undesirable (less bioavailable) results.

Dilution Water

Some drinks require the addition of water in order to achieve the required alcohol degrees appropriate for consumption or in order to meet legislation rules. Again, based on taste requirements, producers treat (or not) the water available. For example, expensive vodka production involves the mixing of distilled alcohol with ultrapure most commonly deionized water. Ouzo (the Greek distilled anise drink) producers advertise the use of water originating from a local river or mountain spring in order to emphasize the local identity of their product. Beer and whiskey producers achieve the special local flavor of their products by using local water.

For example, in beer, there are four anions found in water that are particularly significant. Calcium is the most important and has three major effects. It stabilizes the enzyme α-amylase and helps the breakdown of starch. It precipitates phosphate and thus increases the acidity that affects the fermentation and the microbiological stability of the enzyme processes. It also promotes flocculation of the yeast during fermentation. Magnesium produces a sour to bitter taste and reduces acidity. Sodium in small amounts gives a salty to sour taste. Potassium also gives a salty flavor and can be particularly laxative above a certain concentration. Modern breweries treat the water to remove the native minerals and then reconstitute it to a given composition for a particular brew. This practice ensures the continuity of the supply quality.

Bottled Water

The bottled water industry uses water as their final product either by bottling the water as it comes from its source or by treating it according to certain regulations in order to be suitable for human consumption. 'Mineral water' comes from a mineral spring when it is bottled at the source and has undergone no or minimal treatment. 'Table water' is a mixture of drinking water and mineral water and can contain added mineral salts and carbonic acid. 'Table water' may be produced and bottled anywhere.

Ice Industry

The ice industry also uses water after it is turned into ice cubes for human consumption or for preservation of sensitive food such as fresh fish.

Wash Water

Many food industries use water in order to wash the raw materials before using them for the production of the final product.

Cooling Water

Some food industries use water to cool their engines and return the water back to its source without having it involved in the food production but having increased its temperature by several degrees.

Deicing Water

Food industries that receive their raw materials as frozen use water to deice them so that they can use them in the production phase undistracted.

Cleaning Water

All food industries use water for cleaning purposes. For example, water can be used to clean the dishes and pots used for

food production and clean and maintain production equipment that sometimes come into direct contact with food products, but it can also be used to clean the floor. This water does not require any special quality, but it has to be free of pathogen microorganisms.

Personnel Water

Food industry personnel use water for drinking and for their personal hygiene. They consume drinking water while they are working their shift at the industry. They also use water to clean their hands while they are working or when they are using the industry toilets or to clean their dishes. Some industries have certain rules for toilet use or lunch breaks and thus of the water consumption of the personnel.

Water Management in Food Industries

There are at least four questions that each food industry manager has to ask himself or herself. Where should the water come from? How much water is needed for each application of the industry? How much water is needed every day, every season, and each year? What kind of water is needed for each application?

Water Supplies

Depending on the location of the food industry, the available water sources of the industry, and the legislation of each country, water in food can originate from several different sources. They can be divided into two main categories: (1) surface water and (2) groundwater. Surface water includes river, lake, dam, and seawater. Groundwater includes springwater and well water.

Water Quantities

Depending on the use of water in each production step, water requirements in terms of quantity have to be determined and recorded along the operation life of the farm or industry. In most cases, the water needed to cultivate the food of an individual is several times more than the water needed by the same individual as drinking water or for any other domestic use. So one cannot compare the water quantities needed for farming or meat production with water needed for food manufacturing. Nowadays, globally, irrigation consumes 70%, industry 22%, and domestic use 8% of freshwater. The increasing use of water due to increasing meat consumption can be demonstrated by the following examples: 1 kg of rice requires 1000–3000 l of water, whereas 1 kg of grain-fed beef requires 13 000–15 000 l of water.

Two terms have emerged in order to describe the water needed for the production of food and the actual water in the food: water footprint and virtual water. The water footprint of a product is the volume of freshwater appropriated to produce the product, taking into account the volumes of water consumed and polluted in the different steps of the supply chain. For example, the water footprint of a potato is 25 l of water, whereas the footprint for a bag of potato chips is 184 l of water. For the production of one glass of milk, 200 l of water is spent. The 'virtual water' contained in a product is the volume of water consumed or polluted for producing the product, measured over its full production chain, and it is considered that if one country exports a water-intensive product to another country, it exports water in virtual form. For some countries, it could be attractive to import water-intensive products instead of producing all water-demanding products themselves. The highest contributions to virtual water trade are from oil and oil crops (28%), meat and animal (26%), cereal (20%), and fish and seafood (14%).

Water Quality

There are certain laws that regulate the water quality depending on each use. There are certain requirements for water to be used for the irrigation of food and different ones for human consumption. According to the European Drinking Water Directive, water intended for human consumption includes

> (a) all water either in its original state or after treatment, intended for drinking, cooking, food preparation or other domestic purposes, regardless of its origin and whether it is supplied from a distribution network, from a tanker, or in bottles or containers.
>
> (b) all water used in any food-production undertaking for the manufacture, processing, preservation or marketing of products or substances intended for human consumption unless the competent national authorities are satisfied that the quality of the water cannot affect the wholesomeness of the foodstuff in its finished form.

The parametric values set in accordance with this regulation shall be complied with not only in the case of water supplied from a distribution network but also in the case of water used in a food-production undertaking, at the point where the water is used in the undertaking.

Generally, water has to be as pure as possible with low calcium and magnesium content (low hardness), low metal content, low nutrient content, and no pollutants. It should also be clear without having any color or any particulate matter. For example, in the preparation of spirit drinks, the addition of water shall be authorized, provided that the quality of the water is in conformity with EU directives and that the water added does not change the nature of the product. This water may be distilled, demineralized, permuted, or softened.

Impact on Water Supplies from Water Usage by Food Producers

Regular Consumption

The establishment of a new farm or new food industry in an area has to take into consideration the availability of water resources. Such activities could highly impact the water resources of a small community with limited access to clean water for regular consumption.

Water Mining

In some cases that the farm or industry has its own water resource, it may divert from sustainable use of water. It may decide to use the available water based on its needs until the

available resource is depleted. This practice is called water mining and it is not advisable since it destroys a nonrenewable source. Some countries that do not have high rainfall allow this practice.

Water Reuse

During the last years, in order to save water, water reuse has been proposed as a promising practice. Some of the activities related to food production do not contaminate the water as much as others. Water involved in such activities could be saved and used again in other activities that do not necessarily require the use of ultraclean water (e.g., for flushing toilets). Even the treated effluent of a wastewater treatment plant can be used for watering plants, if the necessary precautions set by the regulations are met. This is very critical because there are several episodes reported in the newspapers throughout the world that resulted in the death of the consumers of raw products. If there are pathogens in the effluent and irrigation is not performed appropriately, it is possible that the produce is contaminated with pathogens. However, if the appropriate microbe concentration levels have been reached and the appropriate irrigation technique is followed, then the products are considered safe. The consumers are not necessarily positive to such produce, but considering that in arid areas wastewater recycling is a common practice for many years (in some cases and in space exploration, it is even used as a drinking water source), this attitude should eventually change.

Another idea that is very popular is to save water from the different processes. Some industries monitor the water needed for each production step and then test the possibility of reducing the amount of water used. This way, less water is consumed, less wastewater is produced, and less water and wastewater treatment are needed.

Water Treatment

Common Practice

Water treatment is performed in order to improve water quality. The processes employed for water treatment depend on the quality of the water supply. In all cases, water has to be disinfected in order to deactivate any existing microorganisms present in water. So far, this technique was proved to be the most important for the protection of human life. It is commonly done using chlorine or chlorine dioxide, and in many cases, other processes are also used such as ozonation and ultraviolet irradiation. If the water originates from a surface water supply such as a river, lake, or dam, then the suspended particles are the most important problem. Different techniques to remove suspended particles include the addition of coagulants and the use of membranes. If the water originates from groundwater through mountain springs, usually, the water quality is good, and in most cases, only disinfection is required. However, if the water originates from groundwater wells, it may be rich in metals that need to be removed through chemical precipitation. Softening is another technique commonly used to remove hardness in case water is hard, which is performed by the addition of lime and subsequent precipitation of calcium as calcium carbonate and magnesium as magnesium hydroxide.

A common water treatment plant involves the following processes: (1) pretreatment to remove big objects that can be found in the pipelines that transport water from the supply to the treatment plant, (2) softening and/or coagulation for the removal of hardness and/or suspended particles, (3) filtering through sand beds to remove any fine particles that are left in the water stream, (4) activated carbon filter or air/water jet to sorb or oxidize any dissolved organic matter, (5) disinfection for the removal of any pathogens left, and (6) storage of the disinfected water before distribution to the consumers.

Wastewater from Food Production

Production

The regular everyday cycle of water includes clean water acquisition, water use, wastewater production, wastewater treatment, and treated wastewater discharge to an aqueous system.

Characteristics

The main difference between municipal wastewater and food industry wastewater is the high organic loading. The organic loading is measured with different indirect methods that commonly measure the oxygen required by the wastewater to oxidize the organic compounds either by chemical or by biochemical methods. So, there are two wastewater characteristics related to the oxygen consumption of the wastewater during organic compound degradation: chemical oxygen demand (COD) and biochemical oxygen demand (BOD). The higher the values of the COD and BOD are, the higher the difficulty to treat the wastewater. Also, the higher the difference between COD and BOD is, the more toxic the wastewater is, suggesting that a big fraction of the organic compounds is not biodegradable, and thus, it is persistent. The average municipal wastewater demonstrates values of COD from 300 to 500 mg l^{-1} and BOD of 200–300 mg l^{-1}, whereas food industry wastewater demonstrates COD and BOD values from 1000 to several 100 000 mg l^{-1}. The meat, cheese, olive oil, and fish industries produce wastewater with really high organic loadings. In some cases, these wastewaters are nutrient-deficient, and in other cases, they contain toxic compounds that are not biodegradable. For example, whey wastewater demonstrates a deficiency in nitrogen that is a nutrient required for the biological treatment of wastewater. Olive oil wastewater contains a high amount of polyphenols that are disinfectants and thus prohibit the biological treatment of wastewater.

Treatment

The most common method to treat wastewater and lower its organic loading is biological treatment. Wastewater comes in contact with microorganisms and oxygen at the same time. The presence of nutrients is essential for the successful degradation of organic compounds. This combination can successfully remove more than 90% of BOD in most wastewaters. Some food industry effluents are deficient in nutrients, but some others have high amounts of nutrients that require special

Figure 1 A typical municipal wastewater treatment plant. The main components include (1) primary sedimentation tanks, (2) aeration tanks, and (3) secondary sedimentation tanks.

attention. In this case, tertiary treatment is required employing both aerobic and anaerobic biological treatment of wastewater.

A typical wastewater treatment plant (Figure 1) includes the following processes:

(1) Pretreatment that is a mechanical process and is used to remove any big objects that can end up in the wastewater pipes.
(2) Primary sedimentation that is a physical or physicochemical process; the water passes through or stays in a tank and through gravity (sometimes after the addition of coagulants); the suspended solids are separated from wastewater resulting in the primary sludge and the wastewater stream flowing to the next tank.
(3) Secondary or biological treatment that is a biological process taking place in an aeration tank as described in the preceding text; activated sludge that is a mixture of microorganisms is suspended in an aerated tank and degrades the dissolved organic matter that is left in the wastewater stream after the primary treatment.
(4) Secondary sedimentation that separates the microbial mass that overflows from the previous tank from the treated wastewater; the sludge can be recycled by sending it back to the aeration tank or can be removed and further treated.
(5) Disinfection (if it is required by the regulation) to remove any remaining microbes left in the treated wastewater.

Other advanced technologies that can be used in addition to traditional wastewater treatment include the use of activated carbon filters to remove micropollutants or oils, the use of advanced oxidation techniques such as Fenton or catalysis or ultrasound to remove organic micropollutants, ultrafiltration and nanofiltration for further removal of colloids or microbes or decrease of conductivity, and chemical precipitation for the removal of heavy metals.

Facilities

Most of the food industries have their own wastewater treatment facilities that are specifically designed for their specific needs (Figure 2). As mentioned in the preceding text, most of the food industry wastewater facilities do not require all the steps that have been described in the previous section. It is common to use an aeration tank and either add nutrients for the biodegradation to take place (Figure 3) or add another tank that will facilitate the removal of nutrients. However, there are cases where some of the industries lower their BOD to a certain level, and then, they send their wastewater to a central wastewater treatment facility.

Figure 2 Removal of fats from wastewater in a cheese factory. Air blowers in the base of the tank help recover the fat as a froth, and mechanical skimmers on the top collect this froth in this stainless steel device that throws them on the cement ground. The fat is given away as feedstock.

Figure 3 Addition of urea in the biological treatment tank in a cheese wastewater treatment plant.

Impact on Water Quality from Food Industry Wastewater

Legislation

In most countries, legislation exists that regulates the characteristics of wastewater treatment facility effluents. These

characteristics are basically the BOD, COD, and suspended solids (SS). Each wastewater plant needs an environmental impact assessment report that determines the site of the plant, the additional regulations that are needed based on the specific site, and the receiver of the treated effluent.

Receivers

The receiver of the treatment plant effluent is either a nearby river or stream or the nearest sea. Extra treatment, such as disinfection, is required in case that the river or stream is used downstream as a drinking water source. Also, if there is a swimming beach at the sea where the effluent will be discharged, then the pipeline has to be far and deep and the effluent also requires disinfection. If the receiver is a closed gulf or a sensitive wetland, then the effluent is additionally regulated for nutrient concentrations to avoid the occurrence of eutrophication. This is a phenomenon that can be observed once high amounts of nutrients are added to an aquatic system in equilibrium. If these nutrients were the regulating factors for this system to reach equilibrium, the excessive addition results in an enormously high increase of algae production. Then, there is a cycle of events that results in the increased degradation of the aquatic systems. Due to the increased algae production, the light cannot penetrate into the lower levels of the water column, creating the death of organisms living there. Due to the death of organisms, there is an increase in the demand for oxygen needed for their biodegradation and especially during the night as oxygen levels become lower and lower. Anaerobic conditions result in the death of higher organisms, the occurrence of anaerobic microbes, and the production of methane, hydrogen sulfide, and ammonia.

Lack of Adequate Technologies and Improper Discharge

Although legislation does not allow untreated wastewater to be discharged to the environment, there are certain cases that this is happening. As mentioned in the preceding text, some of the food industry wastewater contains toxic compounds that are difficult to treat. In such cases, there is not any available effective technology. Some industries keep their waste in constructed wetlands and discharge them periodically and illegally to nearby streams, or they illegally discharge them to the municipal sewage pipes. This illegal discharge to nearby streams can result in gradual degradation of the environment and the alteration of the stream ecosystem.

Accidents

The occurrence of an accidental release of untreated wastewater to the environment is also possible. In this case, the concentration of the toxic compounds will be too high, and the effects will be visible. Initially, the higher organisms of the aquatic systems die, the drinking water supplies can be affected, bad smell will occur, and a lot of money needs to be spent in order to clean up the mess. Even if such a system is cleaned up, the residual concentrations of the toxic can remain in the system for several years resulting in chronic effects on the organisms of the aquatic system.

Background and History

The first documented record that related contaminated drinking water supply to a disease dates back to mid-nineteenth-century London, when Dr. John Snow linked the spread of the cholera epidemic to drinking water polluted by human sewage. In 1883, Robert Koch introduced the concept of testing source water as well as drinking water at the point of use for all microorganisms, which became a precursor to heterotrophic plate counts, widely used today. In 1914, the US Public Health Service (USPHS) recommended the use of total coliforms as the first standard for drinking water quality and safety, beginning the era of using coliform bacteria as indicators of human fecal pollution.

The legislative acts in the United States that recognized the need for monitoring and improving water quality started with the passage of the Clean Water Act (CWA) by the Congress in 1972. The intention of the CWA was to regulate pollutant discharges to surface waters, with the broader scope of attempting to restore the nation's waterways to their designated use (e.g., fishing and primary body contact recreational use). In 1974, the Safe Drinking Water Act (SDWA) was passed with the intent to protect public health by regulating the nation's drinking water supply.

The Revised Total Coliform Rule and Long Term 2 Enhanced Surface Water Treatment Rule and the EU Drinking Water Directive are guidance documents in the United States and European Union, respectively, that govern the quality of finished drinking water (please see 'Further Reading' and 'Relevant Websites' for additional material). These documents specify two general types of testing practices. For drinking water systems that do not use surface water and are not under the direct influence of the surface water, guidelines recommend the use of various bacterial indicator organisms (e.g., total coliforms, fecal coliforms, *Escherichia coli*, and enterococci). For drinking water systems that utilize surface water and/or are directly influenced by it, testing for bacterial indicator organisms is augmented by tests for various pathogens and/or additional indicator organisms (e.g., *Cryptosporidium* spp., *Giardia* spp., enteric viruses, and *Clostridium perfringens* and heterotrophic plate counts). The purpose of this article is to provide an overview of the methodological approaches employed to enumerate indicator organisms, which are discussed in more detail in the section in the succeeding text.

Bacterial Indicator Organisms

Human and animal waste, particularly feces, is fertile ground for human pathogens. These pathogens are numerous and highly diverse, comprising thousands of bacteria, viruses, protozoa, and worms. However, because only a fraction of any given population is generally infected, pathogen levels in water tend to be low. The great diversity of potential pathogens that can be found in water, coupled with their low levels, makes direct testing for pathogens impractical. Ubiquitous fecal microorganisms known as indicator organisms are therefore used as warnings of increased risk of pathogen presence. Ideally, indicator organisms should be confined to gastrointestinal (GI) tracts of humans and animals that carry human pathogens. They should have similar survival times and transport characteristics in the environment compared to those of pathogens, whose behavior they are intended to mimic. Furthermore, their response to treatment strategies such as disinfection should be similar to that of pathogens. The most important criterion for the use of indicator organisms to assess drinking water is that their concentrations are correlated with the presence of pathogens, whether those pathogens are viruses, bacteria, protozoa, or other eukaryotic parasites such as worms.

Indicator organisms are generally commensal inhabitants of human and animal GI tracts and assays used to detect them are, by practical necessity, relatively simple and inexpensive. These idealized criteria described earlier are deceptively simplistic; decades of research have suggested that the ideal indicator organism is an unattainable goal, as none of the organisms used for that purpose to date can meet all of the criteria. For example, in addition to being found in the human GI tracts, bacterial indicator organisms are also commensal inhabitants of the GI tract of other mammals, birds, and various insects. Because the fecal flora of various animal species is more or less likely to include specific waterborne pathogens, the broad distribution of indicator organisms across animal phyla contributes to great uncertainty about the risk associated with the presence of indicator organisms in drinking water. The imperfect fecal source association is further confounded by close association of indicator organisms with sediments, soils, and aquatic vegetation, which not only extends their persistence in the environment but, in some instances, also facilitates extraintestinal growth. Lastly, human pathogens are not necessarily of fecal origin (e.g., *Legionella* spp. and *Vibrio* spp.), span a broad phylogenetic range (e.g., viruses, bacteria, and protozoa), and have equally variable physiology and susceptibility to environmental stressors, making it exceedingly difficult to select a single organism (or groups of organisms) that are likely to reflect the fate of all waterborne pathogens.

Coliform bacteria (comprised of facultatively anaerobic, Gram-negative, non-spore-forming, rod-shaped, lactose-fermenting organisms) have a long history of employment as indices of drinking water quality. Members of the total

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00741-8

coliform group are further defined as organisms that produce gas from lactose fermentation at 35 °C and include the genera *Escherichia*, *Klebsiella*, *Enterobacter*, and *Citrobacter* spp.

Fecal coliforms are a thermotolerant subgroup of the coliforms, growing well at 44.5 °C. Fecal coliforms include most *E. coli* strains and certain strains of *Klebsiella* spp. and *Citrobacter* spp. The ability of *E. coli* to hydrolyze 4-methylumbelliferyl-β-D-glucuronide (MUG) to yield a fluorogenic product via the enzyme β-glucuronidase is an important phenotypic trait used to differentiate it from *Klebsiella* spp. and other thermotolerant coliforms and is frequently used to identify *E. coli* in enzyme substrate tests (see succeeding text).

Enterococci are Gram-positive cocci arranged in pairs or chains that are catalase-negative, strictly fermentative organisms capable of growth over wide pH (4.5–10) and temperature (10–45 °C) ranges and elevated salt concentrations (10% NaCl). Enterococci were formerly classified as Lancefield group D streptococci based on the serology of cell wall antigens, until phylogenetic analysis placed these organisms into a separate genus. The ability to grow in 6.5% NaCl and the hydrolysis of esculin in the presence of bile are two important phenotypic characteristics that are used to distinguish *Enterococcus* spp. from *Streptococcus* spp.

Analytic Methods

The International Organization for Standardization (ISO) and a publication by the American Public Health Association, American Water Works Association, and Water Environment Federation, 'Standard Methods for the Examination of Water and Wastewater,' describe testing procedures for the analysis of microbiological quality of drinking water. From the methodological standpoint, the analysis can be accomplished in three ways: (1) multiple-tube fermentation method, (2) membrane filtration method, and (3) enzyme substrate test.

Multiple-Tube Fermentation

The multiple-tube fermentation method consists of three phases, presumptive, confirmed, and complete, and is used to enumerate total coliforms, fecal coliforms, and *E. coli*. Presumptive and confirmatory stages involve successive inoculation of broth tubes in order to detect the acid and or/gas production that is characteristic of total coliforms. The third phase of testing, which constitutes a 'completed' test, determines the presence of fecal coliforms and/or *E. coli* and is performed on at least 10% of positive samples from the confirmed phase. The multiple-tube fermentation method requires setting up the testing for the most probable number (MPN) technique where analysts need to use either (1) ten replicate tubes each containing 10 ml of sample or (2) five replicate tubes with 20 ml of sample each containing several dilutions of the sample or (3) a single bottle containing 100 ml of sample (for the presence/absence coliform test when qualitative information is satisfactory). Based on the combination of positive/negative tubes for each dilution, MPN tables provide an estimate of bacterial concentrations, reported as MPN per 100 ml. It is noteworthy that the precision of MPN is rather low and caution should be exercised when examining the results.

Membrane Filtration

The membrane filtration method is less labor-intensive and requires fewer days to complete than multiple-tube fermentation. Rather than inoculating broth tubes, drinking water samples are passed through a membrane filter with pore sizes sufficiently small to trap bacteria on the surface (e.g., 0.45 μm). The membrane filter is aseptically transferred to a petri dish containing selective-differential media for incubation. This method does not involve MPN to enumerate the bacteria; instead, colony-forming units (CFU) are counted and reported per 100 ml of sample filtered. Of note, this particular method is also used in the assessment of sanitary quality of surface waters used for recreation and fishing/shellfishing, although growth media and the incubation temperatures are different than those described in the succeeding text.

Enzyme Substrate

This technique can be used for the simultaneous detection of total coliforms and *E. coli*, and it capitalizes on the ability of each to hydrolyze different compounds (i.e., the entire coliform group possesses β-D-galactosidase, which hydrolyzes lactose, while only *E. coli* has β-glucuronidase). Furthermore, the enzyme substrate test can also be used for the detection of enterococci whereby 4-methylumbelliferyl-β-D-glucoside becomes hydrolyzed by enterococcus β-glucosidase releasing a fluorescent intermediate. The enzyme substrate test is similar to the multiple-tube fermentation technique as it also relies on enumeration by MPN, rather than on counting CFU, and commercially available tests can considerably simplify the procedure. Testing can be performed as a multiple-tube or multiwell setup, where various amounts or dilutions of the sample are prepared and incubated as specified by the manufacturer. In addition, enzyme substrate tests are also commercially available in a plate format, thus allowing the data to be gathered in the CFU format as well. Similar to the membrane filtration method, enzyme substrate is not limited to the assessment of the drinking water samples but is also utilized for testing the sanitary quality of recreational waters.

Specific Analytes

Sections in the succeeding text detail the application of multiple-tube fermentation, membrane filtration, and enzyme substrate methods for detection of total and fecal coliforms, *E. coli*, and enterococci, which are summarized in Table 1.

Total Coliforms

All three methods described earlier can be used to enumerate total coliforms. In the multiple-tube fermentation method, the presumptive phase tests for the ability of organisms to ferment lactose with gas production after incubation at 35 °C for 24 h in lauryl tryptose broth. Testing for gas production necessitates addition of inverted (Durham) tube, while testing for acid production calls for addition of bromocresol purple, a pH indicator. Production of either acidic reaction (manifested by the presence of yellow color) or gas (in the form of bubble trapped in the inverted tube) constitutes a presumptive

Table 1 Characteristics of methods used for enumeration of indicator organisms

Indicator organism	*Medium*	*Incubation temperature*	*Selective components*	*Differential components*
Total coliform				
	Lauryl tryptose broth	35 °C	Growth with development of yellow color and/or gas production; sodium lauryl sulfate is inhibitory to many Gram-positive and Gram-negative organisms	Lactose, bromocresol purple
	Brilliant green lactose broth	35 °C	Growth with gas production; bile and brilliant green are inhibitory to many Gram-positive and Gram-negative organisms	Lactose
	Endo-type agar	35 °C	Red colonies with metallic sheen; sodium deoxycholate and sodium lauryl sulfate are inhibitory to many Gram-positive and Gram-negative organisms	Lactose, basic fuchsin
	Lactose TTC agar with oxidase test	35 °C	Yellow colonies; sodium heptadecyl sulfate is inhibitory to many Gram-positive and some Gram-negative organisms	Lactose, bromothymol blue, TTC, cytochrome oxidase
	Enzyme substrate	36 °C	Presence of β-D-galactosidase and development of red or yellow color	Ortho-nitrophenyl-β-D-galactopyranoside (ONPG, yellow), chlorophenol-red-β-D-galactopyranoside
Fecal coliform				
	EC broth	35 °C	Growth with gas production; bile are inhibitory to many Gram-positive and Gram-negative organisms	Lactose
	MacConkey agar	44.5 °C	Temperature, red/pink colonies; bile salts and crystal violet are inhibitory to many Gram-positive and Gram-negative organisms	Lactose, neutral red
E. coli	Enzyme substrate (also EC MUG)	44.5 °C	Temperature, the presence of β-glucuronidase	4-Methylumbelliferyl-D-glucuronide (MUG)/blue fluorescence
	Lactose TTC agar with indole test	35 °C, 44.5 °C	Temperature, yellow colonies; sodium heptadecyl sulfate is inhibitory to many Gram-positive and some Gram-negative organisms	Lactose, bromothymol blue, TTC, tryptophan deamination/indole production
Enterococci	Slanetz–Bartley TTC	36 °C	Red/maroon/pink colonies; sodium azide inhibits many Gram-negative organisms	TTC
	Bile esculin azide agar	44 °C	Temperature, tan/black colonies; bile salts inhibit many Gram-positive organisms and sodium azide inhibits many Gram-negative organisms	Esculin, ferric citrate
	Enzyme substrate	41 °C	Temperature, the presence of β-glucosidase	4-Methylumbelliferyl-β-D-glucoside/blue halo

positive result for total coliforms. Those tubes that show growth but no gas or acid production require additional 48 h incubation at the same temperature. Samples with presumptive positive reactions are subjected to the confirmatory test in the second phase. The growth medium utilized is brilliant green lactose bile broth containing lactose, oxgall, and brilliant green. Growth with any amount of gas production after up to 48 h incubation at 35 °C is considered to be a confirmed positive result. The completed phase of the multiple-tube fermentation test requires identification of the organisms from confirmed phase as either fecal coliforms or *E. coli* using methods described in the sections in the succeeding text.

The membrane filtration method for the detection of total coliforms utilizes either endo-type medium or lactose 2,3,5-triphenyltetrazolium chloride (TTC) agar, followed by 24 h incubation at 35–36 °C depending on the specific methodology used. Endo-type medium (e.g., LES Endo or M-Endo) contains lactose and basic fuchsin with typical total coliform colonies being red with a metallic or golden sheen. Typical total coliform colonies on lactose TTC agar produce yellow color in the medium under the membrane. Irrespective of the media used, membrane filtration methods for total coliforms necessitate verification of the negative cytochrome oxidase test.

Enzyme substrate test does not require additional confirmatory steps, and a positive result for total coliforms is the development of either yellow or red color, depending whether test uses ortho-nitrophenyl-β-D-galactopyranoside (ONPG, yellow) or chlorophenol-red-β-D-galactopyranoside (CPRG, red) following 24 h incubation at 36 °C or a temperature recommended by the manufacturer.

Fecal Coliforms

Testing for fecal coliforms directly is not a part of methods for the assessment of drinking water quality, but fecal coliform (or *E. coli*) identification of confirmed total coliforms is necessary as a part of the completed phase of multiple-tube fermentation method. Testing for fecal coliforms involves inoculation of

either EC broth containing an inverted tube or MacConkey agar followed by incubation at 35 °C and 44.5 °C for 24 h, respectively. In addition to lactose and bile salts, which are common to both MacConkey agar and EC broth, the former also contains a pH indicator, neutral red. Growth accompanied by gas production and development of red colonies are considered to be positive results for the EC broth and MacConkey agar, respectively.

Escherichia coli

Testing for *E. coli* is a part of the completed phase of the multiple-tube fermentation method, as well as independent test of the drinking water quality via enzyme substrate and membrane filtration methods. Both completed phases of the multiple-tube fermentation method and the enzyme substrate utilize the same test, inoculation into EC-4-MUG broth containing lactose and bile salts. Following 24 h incubation at 44.5 °C, all tubes fluorescing bright blue after exposure to long wavelength UV source are considered to be positive for *E. coli*.

Testing for *E. coli* in the drinking water via membrane filtration method is a two-step procedure, and it initially requires incubation on lactose TTC agar under the conditions described earlier for total coliforms. The second step involves testing either all or at least 10% of colonies for indole production. This involves inoculation of L-tryptophan broth and incubation at 44.5 °C for 24 h, followed by the addition of Kovac's reagent. The development of red color is considered to be a positive result.

Enterococci

Testing for enterococci in drinking water is accomplished by a two-step membrane filtration procedure. The culture medium used in presumptive phase is TTC amended Slanetz and Bartley agar also containing sodium azide. Agar plates are incubated at 36 °C for up to 48 h, and typical positive colonies are red, maroon, or pink. Confirmatory test is accomplished by transferring the membrane onto bile esculin azide agar preheated to 44 °C, followed by 2 h incubation at 44 °C. Bile esculin azide agar, as the name implies, contains dehydrated ox-bile, esculin, ammonium iron (III) citrate, and sodium azide, and confirmed enterococci colonies are those that develop tan to black color in the surrounding medium. Another possibility for the enumeration of enterococci is the use of a commercially available enzyme substrate test, although at the present time, this particular technique is more commonly used for the assessment of the sanitary quality of recreational waters. Briefly, this particular test involves inoculation into media containing 4-methylumbelliferyl-β-D-glucoside followed by 24 h incubation at 41 °C. All tubes/wells fluorescing blue after exposure to UV light are considered to be positive result for enterococci.

Regulatory Uses and Limits

Since 1990, federal regulations for drinking water quality in the United States have been mandated by the Total Coliform Rule. This rule was revised in 2013 (Revised Total Coliform Rule), and compliance is mandated by 2016. The distribution system of public water systems (PWS) must be tested for total coliforms at a frequency that is proportional to the size of the population served, for example, PWS serving at least 50 000 individuals must test a minimum of 60 times per month, while those serving at least 2 500 000 must test a minimum of 420 times per month. The maximum contaminant level (MCL) for total coliforms specifies that the indicator organisms cannot be detected in more than 5% of the 100 ml samples analyzed. A positive total coliform test requires repeat sampling within 24 h, and all positive tests are further analyzed for fecal coliforms or *E. coli*. The Revised Total Coliform Rule removes the MCL for total coliforms and replaces it with an MCL for *E. coli* in recognition of the many possible nonfecal sources of total coliforms. In addition to testing for *E. coli* (and optionally for total coliforms), the EU Drinking Water Directive specifies testing the drinking water for enterococci. The frequency of monitoring is dependent on the volume of water distributed or produced within the supply zone (in m^3 per day). For instance, if the volume of water produced is between 100 and 1000 m^3 per day, the directive recommends testing four times a year, whereas volumes between 1000 and 10 000 m^3 per day call for three additional samples for each 1000 m^3. For volumes below 100 m^3, the frequency of sampling is determined by the individual member states. The allowable limit is zero CFU and any positive samples trigger immediate action to identify and remove the contamination source.

Summary

Routinely testing drinking water directly for pathogens is not practical due to the broad diversity of potential pathogens encompassing viruses, bacteria, and protozoa. Instead, the quality of potable water is assessed by testing for bacterial indicator organisms, including total coliforms, *E. coli*, and enterococci. Methods used to detect bacterial indicator organisms can be broadly divided into multiple-tube fermentation, membrane filtration, and enzyme substrate test, and appropriate media and incubation conditions are used to select for and differentiate specific groups of indicators. Microbial analysis of drinking water is an evolving science, as evidenced by recent changes to the Total Coliform Rule in the United States.

Water Supplies: Water Analysis

K Katsanou and HK Karapanagioti, University of Patras, Patras, Greece

© 2016 Elsevier Ltd. All rights reserved.

Water Supplies for Food Industries

Water supply systems obtain water from a variety of sources, mainly including groundwater (aquifers) and surface water (lakes and rivers). In certain cases, seawater can also be used through the process of desalination. Freshwater is not evenly distributed across the world. The availability of freshwater varies both spatially (geographic region) and temporally (seasonally and annually). The renewable fraction of the Earth water is usually found in the form of surface water (rivers, lakes, streams, etc.) and displays an uneven distribution. Although groundwater is more evenly distributed in comparison with surface water, much of it is nonrenewable (fossil water).

The water use in a particular region is determined by a number of factors. Among them, not only the natural groundwater availability but also the population, the land use (agricultural, residential, or industrial) of an area, and economical factors play a key role. The wealth of a community determines attitudes and funding toward water development and treatment as well as environmental issues. For example, in the developed countries, high-quality water is supplied by the municipality to the consumers' tap, and this is required by law. In the developing countries, safe water supply by the municipality is not necessarily provided. Some of the food industries treat the supplied water anyway to make sure that the industrial water meets their needs. The local climate also plays a significant role due to influences on evaporation rates as well as practices such as lawn watering and cooling requirements. Additionally, cultural values, actions, policies, and laws of national governments also have an impact on water use. Finally, the issue of ownership of the resource that is linked to government influences can be an important factor.

Tap Water: Municipal Water Supply

Freshwater

Approximately 97% of the global water supply comprises the saline water of the oceans. On the other hand, a very limited amount of saline water is also located onshore in saline lakes. The remaining 3% of water is fresh. Out of this percentage of the total freshwater supply, nearly 69% is captured in glaciers, accounting for about 2% of the total global resources. Freshwater is also found beneath the Earth's surface as groundwater (approximately 30% of the total freshwater supply) and in surface water reservoirs such as lakes, streams, swamps, and marshes. Finally, limited amounts of freshwater are also stored in the soil, the atmosphere, and biological organisms.

It is widely accepted that water is the basic substance of life on earth and is increasingly in short supply. Water scarcity affects 88 developing countries that are home to half the world's population.

Groundwater

Groundwater is hosted in aquifers. An aquifer is called any saturated (in water) underground layer of rock or sediment that can store and transmit water. Formations that do not conduct water (are well-cemented, unfractured, etc.) are called confining or impermeable layers.

Although globally groundwater is not very significant in volume, it is a critical source of water that can cover the human needs, because it is part of the limited budget of freshwater. From the perspective of long-term sustainability, it is the renewable resource that is most critical. However, it can also be viewed as a nonrenewable resource because the rate that may be withdrawn can be higher than the rate that it replenishes.

Springs

The physical outlets of an aquifer are known as springs. Springs occur mainly in mountainous or hilly terrains, in locations where the water table meets the ground surface (Figure 1). In the past, the community water supplies were often based on springs, and they still comprise a source of water, because springwater usually has a high natural quality and intake arrangements are relatively easy. Springs can be classified in artesian, gravity, perennial, intermittent, tubular, seepage, and thermal springs.

Description of sources of groundwater

The only naturally renewable source of freshwater globally is precipitation (about 110 000 km^3 per year). It occurs in different forms, including rain, snow, and hail. The first rain wets vegetation and other surfaces and then infiltrates into the ground. Out of the precipitation occurring over land, a large fraction (70 000 km^3 per year) moves back to the atmosphere through evaporation and transpiration from plants. Infiltration rates vary depending on land use, the character, and moisture content of the soil, as well as the intensity and duration of precipitation.

In case that the rate of precipitation exceeds the rate of infiltration, overland flow occurs. About 26% of this part of the cycle (18 000 km^3 per year) can be used by humans, for example, for agriculture.

Worldwide, the total annual runoff (including soil infiltration and groundwater replenishment) is estimated to be 41 000 km^3 per year. Geographic remoteness and seasonal issues (e.g., floods) limit the accessibility of water and drop the total annual accessible runoff to 12 500 km^3 per year.

Therefore, it is estimated that about 54% of the accessible runoff and 23% of the total renewable resource (precipitation over land) are currently appropriated for human use in some form.

Characteristics of groundwater

Groundwater within an unconsolidated rock moves only a few centimeters a day, that is, about 10 m per year. Its velocity

Figure 1 Springs.

depends largely on the steepness of the aquifer slopes and the permeability of the rocks. However, in consolidated rocks, the water velocity can be many times higher. A typical example is the karst formations.

Groundwater occurs in aquifers under two different conditions, the unconfined and the confined. In an unconfined aquifer, the water only fills the aquifer partly and its upper surface of the saturated zone may rise and decline. On the other hand, in a confined aquifer, the water completely fills the aquifer that is overlain by a confining bed. The recharge of the saturated zone occurs by percolation of water from the land surface through the unsaturated zone.

Groundwater can be obtained from an aquifer by drilling a well or a borehole below the water table. The water level in wells drilled into unconfined aquifers stands in the same position as the water table in the surrounding aquifer.

The water level in wells drilled into confined aquifers stands at some height above the top of the aquifer but not necessarily above the land surface. If the water level in an artesian well stands above the land surface, the well displays artesian flow, where water rises to the surface without pumping. Pumping water out of an aquifer lowers the water level near the well.

The 'safe yield' of an aquifer is the volume of water that can be withdrawn without depleting the aquifer, that is, the water that is renewable. In case that a higher volume is withdrawn, a number of undesirable effects can occur. In addition to the risk of completely draining an aquifer, seawater intrusion or land subsidence may commonly occur.

The chemical composition of groundwater reflects the geology of the area that has been in contact. If the groundwater is in contact with limestone, then it can be considered as hard water since it is expected to contain high concentrations of calcium and carbonates. In general though, the water quality is not differentiated significantly enough to be a concern to humans, wildlife, aquatic organisms, or vegetation. The human impact is mainly responsible for groundwater quality degradation. There are cases though where pollution sources are absent, while groundwater does not lie within the potable regulations. These waters are usually found in areas with recent volcanic activity. Groundwater displays higher temperatures than the groundwater that is hosted in the surrounding watershed area; it has higher residence time in the aquifer and displays higher salt content than freshwater. Moreover, natural seawater intrusion into the aquifers may exist in many coastal areas worldwide and particularly in karst areas.

Groundwater pollution most often results from overuse of fertilizers and pesticides, improper disposal of wastes on land, industrial and household chemicals and garbage landfills, industrial waste ponds, tailings and processed wastewater from mines, oil field brine pits, leaking underground oil storage tanks and pipelines, leaky underground gas tanks, sewage sludge and septic systems, etc. Groundwater can be also contaminated by overpumping in coastal regions that triggers seawater intrusion. Seawater intrusion in coastal aquifers is a widespread and serious problem in many parts of the world, especially in the Mediterranean region.

Deterioration in water quality may result from either changes in the quality of water in the aquifer or changes in the well. These changes may affect the biological, the chemical, or the physical quality. Both the biological quality and the chemical quality of water from new public-supply wells must be analyzed before the wells are placed in use to determine if the water meets water-supply standards and, if it does not, what treatment is required. A good practice is to monitor the biological and chemical quality of water from all wells, especially those that supply domestic needs, in order to determine if changes in quality occur. Deterioration in biological quality, associated with human or animal wastes, leads to the appearance of bacteria and/or viruses in water.

The most vulnerable water supplies are those hosted in unconfined and karst aquifers, where pollutants can readily diffuse into groundwater supplies. Moreover, in case of water supply through springs, the variation of their water temperature during the day and coloration of their water shortly after rain are indications that the water-bearing soil layer is not deep enough or that there is rapid infiltration of surface water through the topsoil.

Common treatment of groundwater

The most common treatment for groundwater (well water) is a combination of softening, aeration, and disinfection. The only treatment that is used for springwater is disinfection. Sometimes, this is also not necessary but is done anyway to keep the water safe throughout the supply pipelines. Softening is used for the removal of hardness, and most industries do it in order to avoid scaling in the pipelines or the machines that heat water. Aeration is used for oxidation and thus precipitation of iron and manganese. It is also possible to use an oxidation medium such as potassium manganate (VII) or chlorine to help metal precipitation. Disinfection is used to deactivate microorganisms in water and keep the water supply safe throughout the pipelines of the municipality. The most common disinfection method is chlorination that requires the mixing of water with chlorine gas or with sodium hypochlorite. Chlorine is effective for the disinfection from bacteria and is also persistent in the supply pipeline without requiring the addition of another disinfectant. On the contrary, ozone and UV, which are also effective disinfectants, require the addition of chlorine before water supply through pipelines. The use of chlorine as a disinfectant could be a problem for food industries since chlorine has strong taste and odor. Most food

industries use activated carbon filters to remove the taste and odor of chlorine.

Other methods to get water free from salts are distillation, ion exchange, and membrane filtration. Conventional distillation requires high amounts of power and a lot of water for cooling. Solar distillation is friendlier to the environment but requires space and good weather. Ion exchange requires the use of specific resins that remove both anions and cations, but they still require water softening beforehand to avoid excessive cost by the fast consumption of the resins by hardness. Membrane filtration requires high pressure to push water through the membrane.

Contaminated water may require additional treatment before it can be consumed. Toxic metals present in groundwater due to pollution or to natural minerals can be removed by sorbent materials that will strongly bind them. However, in many countries, it is considered preferable to change water supply than try to treat a contaminated one. In places where water supplies are scarce, in-house water filters are commonly used employing ceramic pots and sorbent filtering media (e.g., activated carbon, zeolites, biosorbents, and bone chars).

Surface water

Water in aquifers is brought to the surface naturally through a spring or can be discharged into lakes and streams. Water in the saturated zone moves downward and laterally to sites of groundwater discharge such as springs on hillsides or seeps in the bottoms of streams and lakes or beneath the ocean.

Lakes

Lakes have numerous features, such as catchment area, inflow and outflow, nutrient content, dissolved oxygen, pollutants, pH, sedimentation, and type. Most lakes have at least one natural outflow in the form of a river or stream, which maintains the lake average level by allowing the excess water to be drained. However, there are lakes that do not have any natural outflow and lose water solely by evaporation and/or underground seepage. There are also many artificial lakes that are constructed for power generation, aesthetic or recreational purposes, or agricultural use (e.g., see Figure 2).

Description of sources of lake water

The total land area that contributes surface runoff to a lake or river is called a catchment area. The volume of water depends not only mostly on the amount of rainfall but also on the size of the watershed, the slope of the ground, the soil type and vegetation, and the land use. Any changes in the water level of a lake are controlled by the difference between the input and the output compared to the total volume of the lake. The most significant inputs are precipitation onto the lake surface, the runoff carried by streams from the lake catchment area, the aquifers, and artificial sources from outside the catchment area. The most significant outputs are evaporation from the lake surface, surface and groundwater flows, and any water extraction for human activities. The water level of a lake displays fluctuations related to climate and water abstraction variations.

Figure 2 Lake water.

Characteristics of lake water

The majority of lakes globally contain freshwater. The lake water composition varies depending on many factors. One of the most important is the lake type. Lakes can be classified into tectonic, landslide, saline, volcanic, glacial, and others such as karst lakes.

Based on their nutrients content, lakes can be also classified into oligotrophic, mesotrophic, eutrophic, and hypertrophic. The first category is characterized by clear waters that display low concentrations of plant life, while the last one is characterized by waters excessively enriched with nutrients and poor clarity and is subject to devastating algal blooms caused by human activities, such as heavy use of fertilizers in its catchment area. Such lakes are of little use to humans and have a poor ecosystem due to decreased dissolved oxygen. Water in lakes, bogs, and swamps may gain color, taste, and odor from decaying vegetation and other natural organic matter.

Water in lakes form layers called thermoclines, due to differences in its temperature and its density. When the water at the surface of a lake reaches the same temperature as deeper water, the water in the lake can be mixed, bringing oxygen-depleted water up from the depths and bringing oxygen down to decomposing sediments.

Lake water can be polluted by (i) runoff of soils and farm chemicals from agricultural lands, (ii) waste from cities, (iii) discharges from industrial areas, (iv) leachate from disposal sites, and (v) direct atmospheric pollutants such as rain, snow, and dust.

Common treatment of lake water

The most common treatment for lake or dam water is a combination of coagulation, flocculation, sedimentation, sand filtration, and disinfection (e.g., see Figure 3). Coagulation, flocculation, and sedimentation are needed for the removal of colloid particles that will take a long time to settle due to gravity only. However, in case these suspended solids are microalgae, then more sophisticated treatment is necessary, and then, expensive membranes are employed. Coagulation requires the addition of chemicals called coagulants that are used to neutralize the surface of colloids and allow their flocculation. Colloids repulse each other due to common surface charge. Once their surface charge is neutralized then, they flocculate due to gravity forces. Heavier particles settle much faster by gravity. Sand filtration follows the sedimentation tank and removes the finer flocs that did not settle. Disinfection is used to deactivate microorganisms in water and keep the water supply safe throughout the pipelines of the municipality. In some countries for surface water, sand filtration is mandatory

Figure 3 An aerial view of a surface water treatment plant.

Figure 4 River water.

before disinfection since attached microbes to suspended particles are more persistent than suspended microbes, and thus, disinfection is not as effective.

Some industries use pressure filters, ion exchange, and ultraviolet radiation to remove solids and alkalinity and to disinfect. This way they avoid the addition of any chemicals that could create a taste and odor problem.

Rivers and streams

Rivers are part of the hydrologic cycle. Water generally assembles in a river from precipitation through a catchment area from surface runoff and other sources such as groundwater recharge and springs and in some cases due to the release of stored water, for example, snow and glaciers (Figure 4). The water that reaches the rivers or streams, both by overland flow and from groundwater discharge, moves to the sea, where it evaporates again to perpetuate the cycle.

Description of sources of river water

A river begins at a spring's outlet or at a springs' front and ends at a mouth. The water in a river is usually flowing within a channel formed between its banks. In larger rivers, there is also a wider floodplain shaped by floodwaters, which may be far wider than the size of the river channel.

The discharge of a river varies with time. Higher flow rates typically occur in the spring, and lower flow rates occur in the winter. When the average discharge of a river cannot serve the water supply throughout the year, then a dam is built to block the flow of water. In this place behind the dam, an artificial lake is formed.

Characteristics of river water

Flow in rivers is a function of many factors including precipitation, runoff, interflow, groundwater flow, and pumped inflow and outflow. These factors vary seasonally highly affecting the river discharge and thus the pollutants concentrations.

The chemical composition of the river water is complex and depends on the inputs from the atmosphere, the geology of the catchment area, and the human activities. It has a large effect on the ecology (both plants and animals), and it also affects the uses of the river water. In order to understand and characterize the river water chemistry, a well-designed sampling and analysis is required.

Rivers in higher topographical areas can greatly reflect the local geology. In the absence of any pollution, river water is similar to the rainwater and springwater quality. In case that the local geology is deleterious, the water quality can be poor. The volume of the water is relatively smaller and its chemical composition is affected by fewer rock types. However, as a river flows to lower topographical areas, its water gathers fine soil particles, microbes, organic material, and soluble minerals. Surface runoff acquires usually less dissolved minerals than groundwater, because of its longer direct contact with soil and rock. In populated areas, the quality of surface water as well as groundwater is directly influenced by land use and by human activities. Finally, there are rivers that generate brackish water by having their river mouth in the ocean or sea.

Common treatment of river water

River water follows similar treatment schemes as lake water for the removal of suspended solids and for disinfection.

Seawater

From the perspective of growing the global supply, the most practical way of increasing the renewable water supply is to build new dams and reservoirs. The process of desalination can also have an impact on the increase of the local water supplies. Globally, there are more than 12 000 desalination plants, mainly located in wealthy and energy-rich nations. Unfortunately, many at-risk developing nations do not possess the wealth or energy resources required to install and operate large desalination plants.

Description of sources

Both surface water and groundwater eventually return to the ocean, where evaporation replenishes the supply of atmospheric water vapor.

Characteristics

Seawater cannot be used for drinking or irrigation purposes unless it is first treated.

It displays high salt content ($\sim$35 g l^{-1} of dissolved solids), while its salinity can vary spatially, due to many factors such as

incoming freshwater from rivers, precipitation, evaporation, and in some cases the formation and melting of sea ice. The dissolved substances in ocean water come both from inflowing river water and from the ocean floor.

The sea temperature varies depending on the solar radiation enhancing the continuous circulation of water through the sea. Globally, deep seawater has a temperature varying between −2 and 5 °C. The major ions of seawater are sodium and chloride, which constitute 85% of its total ion composition. The remaining 15% comprises magnesium, calcium, sulfate, bromides, etc.

Besides the natural composition of seawater, in many areas, there are substances derived by human activities that enter the seawater not only through river, aquifer, and spring underflow discharge but also through air and rain. Agricultural, industrial, and sewage outflows contribute heavy metals (such as copper, lead, mercury, cadmium, and zinc), pesticides, PCBs, disinfectants, and other synthetic products such as cleaning products. The same applies with the combustion products (ash) transported through the air and deposited through precipitation. Nuclear facilities and nuclear accidents sometimes cause radioactive material to seep into the sea.

The excess of nutrients (e.g., nitrogen), due to fertilizer or sewage discharge into the sea, can lead to excessive plant growth and in some cases in algal blooms, which lead to the depletion of oxygen in the water and have a severe impact on the ecosystems.

Common treatment

The most common treatment for seawater is a combination of coagulation, filtration, reverse osmosis, and disinfection. Desalination is a process that requires high amounts of energy to create pressure that will facilitate reverse osmosis through expensive membranes. Water molecules are pushed through a semipermeable membrane that separates seawater from clean water.

Private Wells or Springs

Many food industries try to valorize their private water resources and use them in their production. This is done either for saving money or for commercial purposes. If water resources are considered of high quality, they are used to promote the products. Usually, this is done for springwater (e.g., soft drinks made with crystal clear water originating from a famous mountain). If the industry has its own water resource, usually, it needs to provide local agencies with the water analysis requested by law and then obtain a permission to use this water supply in the food manufacturing. Then, there needs to be a periodic monitoring of the water supply to assure that the water is safe for human consumption or the necessary treatment needs to be applied.

Water Analysis

Water analysis is necessary to assure that water used is of the desired quality and does not affect food quality. Some of water characteristics could affect the quality of the final product. If water contains undesired taste, color, or odor, then the final product will be affected. However, if water contains contaminants such as pathogens, heavy metals, pesticides, or other toxic micropollutants, then the final product could be characterized as unsuitable for human consumption and then it has to be returned back to the producer.

Legislation

There are certain laws governing water quality indented for human consumption. Usually, drinking water quality standards are stricter than water quality standards set for industrial water use. However, according to the EU legislation, if the water is in contact with food, the water quality has to be the same as that of drinking water. There are certain recommendations provided by World Health Organization (WHO) and USEPA or EU also set legislation that is then followed by each government or state laws. Legislation sets standards based on epidemiological studies related to compounds that can be found in water and affect human health. Both microbiological and physicochemical water characteristics are regulated. Aesthetics related to the appearance of water are also mentioned. For microbiological parameters, EU laws provide lists of parameters, their desired values, their limits, and corresponding exact methods for their analysis. For chemical parameters, the specified performance characteristics is that the method of analysis used must, as a minimum, be capable of measuring concentrations equal to the parametric value with a trueness, precision, and limit of detection specified. Whatever the sensitivity of the method of analysis used, the result must be expressed using at least the same number of decimals as for the parametric value provided by the regulation. For example, drinking water iron should be lower than 200 $\mu g\, l^{-1}$, and the method of analysis used must be capable of measuring concentrations equal to the parametric value with trueness, precision, and limit of detection equal to 10% of the parametric value.

Water Sampling

Water sampling is very important for the correct outcome of water analysis. Using the correct technique and the appropriate glassware or plasticware is essential for the correct outcome. For example, metals react with glass and can be adsorbed on the glass; for this reason, water sampling for metal analysis is performed in plastic (usually polyethylene) containers. Another important factor is the correct lifetime of the parameters to be used and the preservation method. Some parameters such as metals require immediate pretreatment such as the addition of acid in the sample, and then, storage and other parameters require immediate analysis (e.g., nutrients).

Common Practice

There are standard methods for water analysis and most of the water analysis laboratories use these methods. Commonly, the standard methods are aiming to measure one parameter at the time.

In Situ Monitoring Methods

The unstable parameters of groundwater and surface water are determined on site during the sampling run. More specifically, the water temperature, pH, dissolved oxygen, electric conductivity, and redox potential are measured *in situ* using different electrodes or a multiparameter portable equipment. The color can also be determined on site. Additionally, alkalinity and CO_2 are measured using the titration method. In cases that H_2S is present, for example, when thermal water is present in a watershed, then H_2S is also measured on site using either an electrode or a portable spectrophotometer. The water samples for chemical analyses are collected in acid-washed, well-rinsed polyethylene bottles after pumping when the quality of a borehole is checked. The bottles must be made of materials with minimal reactivity with substances to be measured.

Normally, two to three bottles are collected for subsequent analysis for each sampling site. One bottle of bulk water (1 l) is intended for the anion concentration. One of 0.1 l volume water sample filtered through a 0.45 μm membrane filter and acidified with 0.5 ml ultrapure HNO_3 for the determination of metals. The third bottle of bulk water is used for biological oxygen demand (BOD) and chemical oxygen demand (COD) analyses. Nitrate, NO_2^-, and NH_3 concentrations are easily determined on site or soon after the sampling by a spectrophotometer. Additional water samples are collected in case that biological analyses will be carried out. For microbe analyses, glass bottles that are firstly sterilized are required.

Advanced Methods

Advanced methods require the use of analytic instruments that can measure several parameters at the same time such as gas (GC) and liquid (LC) chromatographies with different detectors such as flame ionization detector (FID), electron capture detector (ECD), mass spectrometry (MS), and ultraviolet detector (UV). They are used to analyze water for specialized chemicals such as pesticides, perfluorinated organic compounds (PFCs), and polychlorinated biphenyls (PCBs). These chemicals are usually present at low concentrations in water and they are usually toxic. Special pretreatment is usually needed for concentrating these chemicals in an organic solvent or on a solid phase that can be used to thermally release the chemicals in the injection port of the analytic instrument. In case the analysis is performed to identify unknown organic compounds in water, more specialized techniques are needed such as GC MS/MS and LC MS/MS. There are also advanced techniques that allow simultaneous analysis of several metals (inductively coupled plasma mass spectrometry, ICP-MS, and inductively coupled plasma optical emission spectrometry, ICP-OES) or ions (ion chromatography, IC) at rather low concentrations.

Certified Laboratories

There are certified laboratories that can undertake water analysis and provide the necessary paperwork for food industries to get permission to use their own water supply. It is possible to find laboratories that are specialized in water analysis and perform both microbiological and chemical analyses or to find specialized only microbiological or only chemical analysis laboratories. Usually, such laboratories attain certification for the analyses of the parameters regulated by law (laboratory that performs certified analysis). However, it is possible to certify the whole laboratory (certified laboratory).

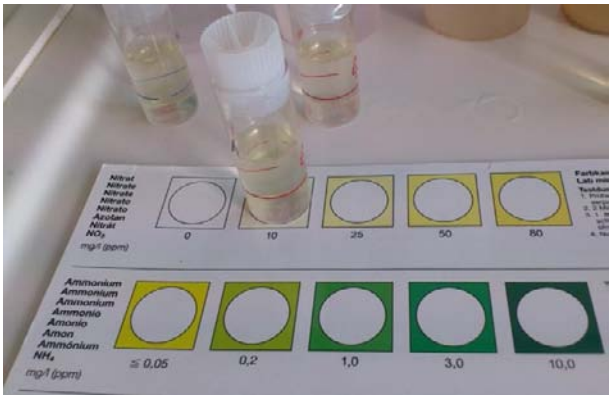

Figure 5 Standardized water analysis kit.

Food Industry: In-House Laboratories

Some food industries have their own laboratories for quality control, and at the same time, they check water parameters. This is most commonly done using automated kits (**Figure 5**) based on standard methods that are routinely used to check the quality of incoming water.

Wheat

Wheat, barley, rye, and triticale are part of the grass family (Poaceae) in the *Triticeae* group. The cultivation of *Triticeae* was evident 10 000 years ago in Egypt, the Middle East, and Turkey. The genus *Triticum* includes common wheat (*Triticum aestivum* L.), club wheat (*Triticum compactum* Host), spelt (*Triticum spelta* L.), and pasta wheat (*Triticum durum* Desf.). According to the FAO, world cereal production in 2014 reached a new record of nearly 2534 million tonnes, which included 725 million tonnes of wheat, with a similar amount predicted for 2015. World cereal production in 2014 reached a new record of nearly 2534 million tonnes, which included 725 million tonnes of wheat, with a similar amount predicted for 2015.

Grains and grain foods have been a staple since ancient times with Hippocrates 400 years BC recommending whole wheat meal or flour for bowel health. In relation to human nutrition, wheat-based foods provide about 20% of the world's energy intake. Wheat-based foods are a good source of essential nutrients such as carbohydrates and proteins; however, most food applications use milled wheat in the form of white or refined flour and some of the most beneficial components of the grain are often lost. While carbohydrates should be the body's major source of energy, diets rich in whole grain are recommended for the prevention of cardiovascular disease and type 2 diabetes. This protective aspect of whole grain and the importance of whole grain food must be highlighted to minimize loss of essential components from the diet. Dietary guidelines around the world recommend that about 30% of food consumption should be grain-based foods and that the consumption of grain (cereal) foods should be mostly whole grain. Whole grain cereals are rich in B vitamins and fiber.

There is an increased demand by consumers for healthy convenient food but consumers also expect food to taste and look good. In these respects, whole meal wheat products meet the requirements of a large range of attractive, tasty, and nutritious convenience foods. However, a limitation is in the use of higher extraction flour streams, which may detract from product appearance, particularly color, and processing ability of the higher fiber and ash flours. Color is particularly important for some Asian products, including steamed buns, noodles, and dumplings. Flours used in the manufacture of these products must meet stringent standards in flour ash levels, to reflect low levels of bran contamination that would otherwise lead to a lack of brightness and the appearance of dark specks in the final product. Nevertheless, there is growing interest in research to raise fiber levels in some of these products by incorporating nutritious high fiber-containing raw materials of plant origin that would cause minimal change in appearance and processing ability.

The Structure and Composition of Wheat Grains

The nature of wheat grain in its native state is important in the understanding of the changes that occur due to processing wheat-based products and health aspects of wheat-based products. A whole grain product would include all components of the grain including the outer pericarp (Figure 1).

Starchy Endosperm and Aleurone

Cereal grains are mainly starchy endosperm (around 80%), which contains the protein component (between 7% and 15%) with associated vitamins and minerals and a diverse range of lipids. The endosperm consists of cells packed with starch granules embedded in a protein matrix. The protein, vitamin, and mineral contents are highest in the outer layers of the endosperm but decrease toward the center. Wheat starch is made up of amylose and amylopectin. Starch is uniquely organized and contains mainly branched amylopectin ($1\rightarrow4$-α-D-glucan with frequent $1\rightarrow6$ branches) and varying amounts of mostly straight-chained amylose ($1\rightarrow4$-α-D-glucan with few $1\rightarrow6$ branches). Waxy grain contains almost all amylopectin. The starchy endosperm also contains nonstarch polysaccharides and phenolic compounds or pigments, but most of the pigments are contained in the bran.

The ratio of amylose/amylopectin has a critical effect on the texture of starchy foods, such as noodles, and this is largely due to the higher swelling ability or water uptake of the amylopectin component upon gelatinization. The ratio is closely linked

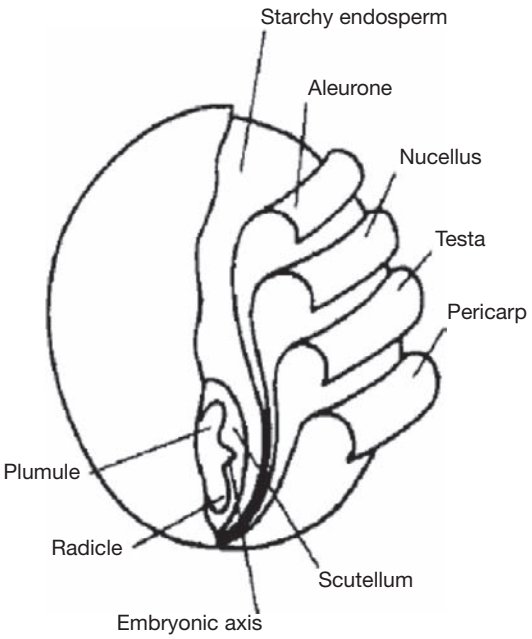

Figure 1 The generalized structure of whole grain wheat caryopsis. Source: Evers, T. and Millar, S. (2002). Cereal grain structure and development: some implications for quality. *Journal of Cereal Science* **36**, 261–284, with permission.

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00746-7

to the biosynthesis of amylose, which is controlled by granule-bound starch synthase (GBSSI). GBSSI is normally present in three isoforms or isozymes – these are referred to as Wx-A1, Wx-B1, and Wx-D1. These isozymes can be present in eight possible combinations, allowing wheat genotypes to be classified as wild-type (all three isozymes present), single-null (any one isozyme absent), double-null (any two isozymes absent), and triple-null (all three isozymes absent). The lowest degree of swelling occurs with wild types, while highest swelling occurs with triple-null types, also known as full waxy wheats. Wheat varieties developed in Western Australia for the manufacture of Japanese udon noodles are single-null types or partial waxy wheats, which have been determined to give the preferred texture required by the Japanese market.

The single layer of square, thick-walled aleurone cells is part of the endosperm and lies next to the bran layers. The aleurone is not crushed during milling and hence is treated by the miller as part of the bran. The aleurone is a concentrated source of vitamins and minerals, which are often lost during milling (with the bran), unless included as whole grain or whole meal (e.g., whole grain bread). The vitamins and minerals are contained in an indigestible fibrous layer, which is difficult to access from a nutritional aspect.

The major storage proteins gliadin and glutenin make up 80% of the total grain protein. The combination of gliadin and glutenin when mixed with water results in a viscoelastic structure called gluten. Glutenins are multichain linear polymeric proteins and include low-molecular-weight (<90 000) and high-molecular-weight glutenins (>90 000). Gliadins (α, β, γ, and ω) are single-chain globular proteins with low molecular weight (30 000–80 000). Structural and metabolic proteins such as the amylases are also present in wheat.

Bran and Germ

The outer bran layer includes aleurone (because most of the aleurone is removed during milling) and constitutes 14% of the grain. The germ (3–4%) makes up the remainder of the grain. The bran layer is a good source of fiber, mainly arabinoxylans (up to 3% of flour and up to 7% of the whole grain), minerals, and phenolic compounds, such as alkylresorcinols and phenolic acids.

Bran consists of several distinct layers that surround the endosperm, including pericarp and testa: It constitutes the main fiber component of grains, and it is relatively high in lipid.

The outer pericarp and inner pericarp (cross cells and tube cells) lie outside the seed coat. The testa is the seed coat. The nucellus or nucellar epidermis surrounds the endosperm and embryo.

The germ or embryo includes the embryonic axis or sprouting section of the seed and the scutellum. At germination, the scutellum becomes the organ for the plant to digest starch and protein from the endosperm and to transfer it to the growing plant. The plumule becomes the rudimentary shoot and the radicle the rudimentary root. The germ is high in ferulic acid, phenolic compounds, and lipids. Wheat germ has a high proportion of unsaturated fatty acids and is a rich source of vitamin E (α-tocopherol).

Wheat-Based Products

Figure 2 indicates the protein content and grain hardness requirements of wheat-based products. Wheat is labeled hard or soft according to its grain hardness and this is genetically

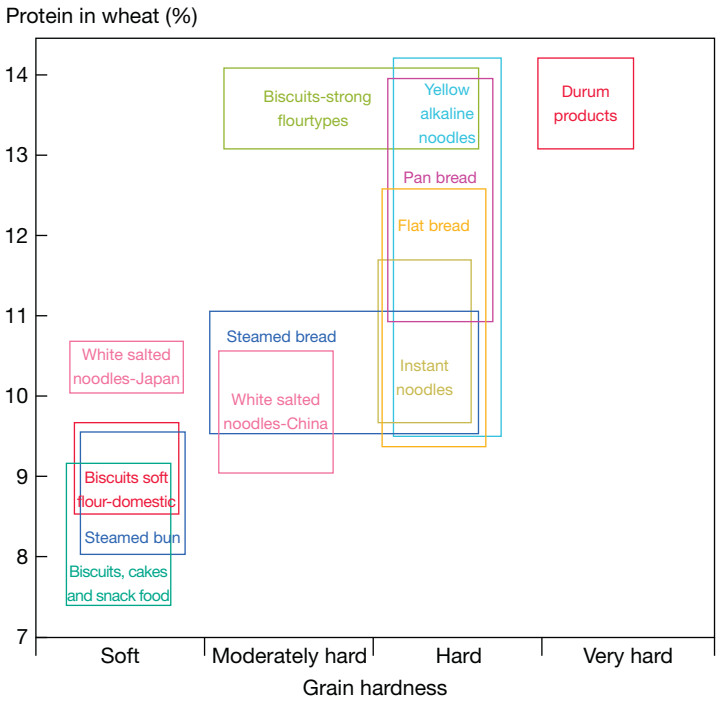

Figure 2 Grain hardness and protein content requirements of wheat-based products. Source: Blakeney, A. B., Cracknell, R. L., Crosbie, G. B., et al. (2009). *Understanding Australian wheat quality*. Kingston, ACT: Wheat Quality Objectives Group and Grain Research and Development Corporation.

controlled. Gluten strength is also largely genetically controlled, and hard wheats are generally bred with stronger gluten, while soft wheats are bred to have weaker gluten – again, this is to conform to the requirements of various end products and markets. Hard wheat is usually grown in higher protein situations, so it is 'fit for purpose,' for example, to bake bread, while soft wheat is grown in lower protein situations for products such as udon noodles, biscuits, and cakes. Protein content is influenced mainly by environmental conditions, particularly rainfall, and also soil type and soil fertility, fertilizer use, and cropping history.

Wheat Protein in Food

The wheat gluten proteins are the main storage proteins found in the endosperm cells and form a continuous viscoelastic network when flour is mixed with water to form dough. Gluten proteins form heat-set gels. When combined with starch, as in noodles, the protein concentration will affect firmness/hardness of the gel. Flour proteins as gluten, the hydrated form of the gliadins and glutenins, provides the structure of bread and noodles. Protein content in the flour and gluten strength affects noodle elasticity and hardness.

The protein content of bread wheat is on average 11–14% and the performance of that wheat in bread making relates mainly to the properties of the gliadin and glutenin proteins. Protein strongly influences the texture of wheat-based food, but it can also influence the color of foods, due to difference in inherent color or contribution to enzymatic reactions or its association with lipids. The Maillard reaction is important for the formation of the brown bread crust color and delicious aroma of the bread. Nonenzymatic chemical reactions between the reducing sugars from the carbohydrate and amino acids, amines, and small peptides from the proteins are involved in the Maillard reaction.

Wheat Starch in Food

In grain-based foods, the starch contributes in complex ways to the final food characteristics. The major component in wheat starch is amylopectin but amylose varies from 0% to 28%. Amylopectin usually makes up over 75% and amylose less than 25% of the starch granule. When amylose increases to 28% or more, the grain is described as high amylose, even though the starch is still mainly amylopectin.

When foods such as noodles are made, it is the swelling and gelatinization of starch and the amount and quality of the protein and subsequent gel formation that determine appearance and texture. The type of gel formed depends on amylose to amylopectin ratio, granular size, branch chain length, and crystallinity. The higher the amylopectin content, the more a starch will swell and the softer the starch gel.

Caramelization is also important for the formation of the bread crust color and delicious aroma of the bread. The high temperatures used in baking result in caramelization of sugars in the bread.

Whole Grain Wheat

In order to meet the whole grain definition for AACCI, the whole grain product must be an intact grain kernel or 'ground, cracked or flaked caryopsis, whose principal anatomical components (the starchy endosperm, germ, and bran) are present in the same relative proportions as they exist in the intact caryopsis.' The HEALTHGRAIN project defines whole grain as having the starchy endosperm, germ, and bran present in the same relative proportions as they exist in the intact kernel. Polishing or milling resulting in small losses of less than 2% of the grain and less than 10% of the bran still allows a whole grain label. Examples of whole grain include wheat flakes, wheat flake biscuits, and bulgur. Whole grain foods include breakfast cereals, pasta, and breads made with whole grains and whole grain flours. Whole grain foods must have a whole grain content of 27% or more to meet the AACCI definition.

Regular consumption of whole grain reduces the rate of coronary heart disease, cancer, and type 2 diabetes. The reduction in the risk of cardiovascular disease provided by a diet rich in whole grain is a result of the high dietary fiber and bioactive compounds, especially those in the bran and germ. Arabinoxylan, a viscous dietary fiber found in cell wall material, provides health benefits such as greater satiety or a feeling of fullness after eating. Whole grain wheat food provides satiety as a result of the high viscous fiber content, resistant starch, energy density, macronutrient composition, particle size, and palatability of food. The larger particle size and resistant starch result in slower digestion of the grain resulting in a greater satiety or feeling of fullness over a longer period. Raw whole grains are not eaten unless they are processed by at least heating because of the lack of palatability and digestibility.

Whole Grain and Whole Grain Foods

Products that meet whole grain definition include wheat flakes, wheat flake biscuits, bulgur, freekeh (firik), and chapatti. Whole grains have a dietary fiber content of 9–12%, but if grain has been processed to remove additional bran, this dietary fiber content will be lower. Whole grain foods include breakfast cereal, pasta, noodles, and breads made with whole grains and whole grain flours.

Wheat Flakes

Wheat flakes are a toasted breakfast cereal made preferably from hard-grained wheat.

The main quality characteristic of wheat for flaking is consistency for size, moisture content, and protein content (11–12%).

Whole wheat grains, often malted, are used for the manufacture of wheat flakes. The grain is tempered; bumped (slightly flattened between rollers); cooked under pressure with water, sugar, malt, and salt; and then passed through flaking rolls and toasted and dried to a very low moisture content of 2–4%, to ensure a long shelf life and a reasonable time before they go soggy after milk addition. Wheat flakes are a good source of dietary fiber (~12%).

Wheat Flake Biscuits

Wheat flake biscuits are eaten as a breakfast cereal, with milk, or as dry biscuits with a topping.

The main quality characteristic for wheat for flaked biscuits is consistency for size, moisture content, and protein (11–12%).

Flaked Wheat biscuits (photo V.Solah)

As with wheat flakes, the whole wheat grain is tempered, bumped, and then cooked under pressure with water, sugar, malt, and salt and sometimes vitamins and minerals. After passing through flaking rolls, the flakes are layered in a mold and baked and then decanted and dried to a very low moisture content of 2–4% to ensure eating quality. They soften on the addition of milk but keep their shape.

Wheat flakes biscuits are a good source of dietary fiber (~12%).

Bulgur (Burghul)

Bulgur is a minimally processed whole grain wheat product and the final product is harder than pasta.

Bulgur (photo V.Solah)

Durum wheat (*Triticum durum*) is the preferred raw material for making bulgur, due to its natural properties of yellow color, hardness, low-swelling (high-amylose) starch, and high protein content (>13%), but bulgur can be made from hard wheat and soft wheat.

Bulgur (bulgor, boulgur, burgul, broughoul, and burghoul) has been a staple whole grain cereal in the Middle Eastern diet for many centuries, and bulgur is popular as a health food in Western Europe especially Germany. Bulgur was referred to as 'arisah' in the Old Testament. Bulgur is extremely popular in Turkey where it is seen as a traditional health food and is used in many dishes including tabouleh, kofta, or kibbeh.

Bulgur is made from intact whole grain wheat and processed by the following basic, traditional steps of soaking or tempering to 20–24% moisture, cooking by boiling for 1–3 h until tender, drying, and polishing. Wheat is then milled into coarse to fine particles and classified by size (3.5–2.0 mm for coarse, 2.0–1.6 mm for middle, 1.6–0.5 mm for fine, and <0.5 mm for flour). Bulgur is traditionally sun-dried in the open air, or commercially, it is hot air-dried.

Quality bulgur should be yellow and hard and have high protein content. The high protein, high amylose, and hardness of the bulgur, due to the boiling and drying process, all contribute to the high resistant starch and high satiety characteristics. The polishing step removes about 6–10% bran so it is considered a whole grain food. Bulgur is high in dietary fiber (~12%) and is a good source of vitamins and minerals.

Freekeh

Freekeh (firik) is a whole grain product produced from green immature durum wheat. The green wheat plants are cut and roasted on flames and then threshed to provide grain that is processed in a similar way to bulgur. Freekeh is a good source of dietary fiber (~12%) and minerals.

Chapatti

Chapatti, chapati, or chapathi is a type of flat unleavened bread, which is a traditional and staple food for the people of India and the Indian subcontinent. Chapatti is made from whole wheat flour called atta and water. Atta is traditionally stone-milled whole grain wheat flour. Initially, there can be a pearling stage prior to milling to remove up to 10% of the bran or the atta is sieved afterward to remove coarse bran particles.

Chapatti (photo H.Fenton)

Quality characteristics of atta for good chapatti making include medium-hard grain with a protein content of 10–12% and medium dough strength, which aids in having a dough that is easy to knead and sheet. Atta with high damaged starch and high water absorption is also important and helps

contribute toward a softer textured product and chapattis that puff easily.

Traditionally, the process to make chapatti involves mixing atta and water to form a dough, resting and then sheeting the dough to a thickness of 1.5–3.0 mm that is typically circular in shape and 150 mm in diameter. A cast iron griddle pan or gas-heated griddle, referred to as a tawa or tava, is used to cook the chapatti. The chapatti is cooked for a short time on one side and flipped and baked on the other side. The water remaining in the chapatti converts to steam and temporarily puffs the chapatti to create two layers. Chapattis are traditionally prepared fresh at meal times as they are preferred to be consumed while still warm.

Quality chapattis are ideally creamy in color with a scattering of light brown spots over the surface. Full puffing of chapatti is important so that two distinct layers are formed. The texture of chapatti is soft and pliable, and it is important that chapattis can tear and fold easily. A slight soft chewy texture in the mouth, a sweet wheatish taste, and a pleasant wheaty aroma are also characteristics of quality chapatti. Chapatti are a good source of dietary fiber (~9%).

Whole Grain or Whole Meal Pan Bread and Hearth Bread

Pan and hearth bread are made from wheat flour (11–14% protein), water, yeast, and salt but often include fat, gluten-modifying chemicals or enzymes, and sugar. Pan bread is oven-baked in a baking tin or pan, using hot air, and direct heat from contact with a hot surface or using steam. Hearth bread is leavened bread that is baked without a tin, directly on the hearth of the oven widely used in small bakeries around the world. The main flour type used for bread is from hard-grained, medium- to high-protein wheat (Figure 2). Pan bread should have a soft crumb, even cell size, high volume, and a brown crust. Hearth breads should have a crisp crust, white soft crumb, and a coarse open texture and is usually eaten on the day of baking.

Hearth bread – Pan de sal (photo Blanca Villarino)

Whole grain or whole meal bread can be found in every country of the world. Whole meal flour is called 100% extraction flour meaning 100% of the grain has been utilized in the flour. More often, whole meal flour is white flour with the bran fraction (which has been removed during milling) added back to the flour. Stone-milled whole meal flour is 100% extraction flour as the flour components are not separated, and it includes the bran and the germ. Bread made with whole grain or whole meal flour or mixed grain bread includes whole grains mixed into the dough and baked or pressed into the surface and baked. Bulgur and kibbled wheat (whole wheat that has been milled into smaller particles and steamed and dried) are added to mixed grain bread with other grain types such as kibbled rye and triticale. Spelt (*Triticum spelta* L.) is high protein (>14%) and used in spelt bread and pasta.

The quality for whole grain, whole meal, or multigrain pan bread is the same as for white bread. Quality requirements are more difficult to achieve with the additional fiber (bran and germ) interfering with gluten development, therefore impacting on bread loaf volume and density. The protein content is usually higher due to added gluten (14.0%). The fat content is about 1.8%. The process for making whole grain or whole meal bread is similar to white bread, but there is a higher water requirement and dough mixing time and resting times are longer. Whole meal and mixed grain bread are an important source of dietary fiber (9–12%).

Refined Wheat Foods

Traditional products from refined white flour or semolina such as noodles, pasta, bread, and couscous have a place in a healthy diet. Four to six serves of grain-based foods, including bread, pasta, and noodles, should be consumed each day depending on age and gender and should be processed and eaten without fats and sugars.

Dietary and functional fibers include naturally occurring edible carbohydrate polymers, nonstarch polysaccharides (arabinoxylan and β-glucan), and resistant starch and have a physiological effect that plays a key a role in weight regulation and the reduced risk of disease. Satiety is the sensation of fullness after eating that deters the desire to eat more. Foods that contain carbohydrates that digest more slowly and release glucose gradually provide a prolonged feeling of fullness (satiety) and may lead to increased time between eating occasions and reduced food intake. Slower metabolism of the carbohydrate, lower glycemic index, and higher satiety are a result of higher dietary fiber, higher amylose to amylopectin ratio, larger particle size, and increased hardness, and they are also influenced by the cooking method. High amylose content, in the food consumed, is correlated with increased resistant starch. The high-protein and hard, vitreous, coarse character of the semolina, which remains intact in pasta, makes pasta slower to digest and more satiating compared to noodles. In uncooked pasta, the protein is not denatured and the starch is ungelatinized. In addition, cooked noodles and pasta contain water (75%) and this contributes to a lower energy density.

Bread

Bread is only briefly covered in this article because there are articles on bread specifically by Cauvain, Collar, and Rosell in this encyclopedia. Bread is the most common wheat-based staple food consumed in many forms worldwide. There are four main types of bread: pan bread (baked in tins), hearth bread, flat bread, and Chinese steamed bread. There are numerous differences in bread types and quality around the world, and consumers prefer the bread they are used to. Baguette, also known as French bread or Vienna bread, has a thick hard crust due to steam injection into the oven during

baking. Pan de sal is a small traditional Philippines bread roll with a crisp thin crust, soft white crumb, and sweet taste due to added sugar. Sliced pan bread has a thin, soft crust. All leavened bread types undergo four steps: mixing of the dry ingredients with water, fermentation, proofing, and baking. Important parts of bread making are the formation of the gluten network and the formation of air and carbon dioxide bubbles during fermentation, which allows dough expansion and the setting of this matrix during cooking.

Flat bread

In addition to whole grain chapatti, there are flat breads that are popular in the Middle East, North Africa, India, Turkey, and Central and South America and around the world. Diets of the world's population are now more diverse due to immigrants bringing their traditional foods to their new homes. Flat breads vary in size and thickness and are made from whole meal flour or white flour (9.5–12.5% protein) and sometimes a mix of whole meal and white flour, water, salt, yeast, and soda or baking powder. Leavened breads include lavash, naan, and English muffins, and unleavened bread includes wheat tortilla or chapatti and paratha and puri that is made from whole meal atta. In single-layered flat breads, the dough is baked immediately after sheeting, and for Arabic and Turkish flat breads, the two layers that form during baking are a result of docking of the dough (perforating the surface). Flat breads are usually baked at very high temperatures 300–600 °C (572–1112 °F) for a very short time (seconds) in clay ovens (such as tandoors) or hot presses.

Turkish bread (photo V.Solah)

Flat bread must be soft and pliable and are traditionally usually eaten the day they are made.

Steamed bread or steamed bun

Steamed bread is a staple food of China and there are many types, but these can be broadly classified into three styles northern-style, southern-style, and Guangdong-style. Steamed bread is made from flour with low to medium protein (9.5–11%) in northern China and low protein (8–10%) in southern China. Part of the flour is mixed with water, dry yeast, and lactic acid to start the sour-dough fermentation, which is used in the production of most Chinese steamed bread, which can be unfilled or filled. Mantou is a type of fermented bread with no filling and has smooth white skin and a compact crumb structure. Bao or pao has a sweet or savory filling. The northern-style steamed bread is made from hard wheat flour with high protein level and medium to strong dough strength and has a firm, cohesive, and chewy texture. The southern-style steamed bread is softer and less chewy and made from wheat flour with medium dough strength and protein content. Guangdong-style steamed breads/buns such as char siew bao are typically made from soft wheat with low protein (7.5–8%) and weak dough strength, water, dry yeast, lactic acid, and sugar (20%). Important quality attributes of steamed bread include a white-colored skin and crumb, a smooth, glossy thin skin, and a fine uniform cohesive crumb structure.

Steamed buns (photo V.Solah)

Noodles

There is a vast range of types of wheat-based Asian noodles that vary with respect to formulation, size and shape, and processing method. White salted noodles, prepared from a simple mixture of flour, water, and salt, are popular in China, Japan, and Korea and are growing in popularity worldwide. In Japan, popular types include very thin somen, thin hiya-mugi, and flat wide kishi-men or hira-min and thick and square (sharp-edged) udon. In China, there is very thin long xu mian, thin xi mian, and flat wide dai mian or cu mian. Another major category of Asian noodles is broadly referred to as yellow alkaline noodles, and these incorporate alkaline salts, particularly sodium and potassium carbonates. Instant noodles, which are popular throughout Asia, also fall into the category of alkaline noodles because of the incorporation of a small addition of alkali in their formulation.

Noodle appearance, texture, and taste are strongly influenced by the characteristics of the wheat flour, other ingredients, and how the noodles are processed. Protein, fat, and salt contents and energy density and how they are eaten (in soup or stir-fried) are important considerations in determining the role of noodles in the diet.

White salted noodles: udon (Japan)

Japanese white salted noodles are known as udon. Udon noodles are made from flour, water, and salt, and

sometimes starch, such as tapioca, is added. Ingredients are made into a crumbly dough and sheeted through sheeting rolls and then made into strands by passing through cutting rolls.

Soft wheat flour is recommended with protein 8.0–10.0% with high-swelling starch (Figure 2), but medium-hard wheat with similar protein content and high-swelling starch is also suitable. Low extraction flour (60%) is needed to provide the low ash and bright creamy white color, speck-free high-quality noodles. Fresh or dried udon is boiled in water and eaten in soup or mixed with vegetables, seafood, or meat. Udon noodles should be soft but not excessively soft, elastic, or springy and have a smooth mouthfeel, with slight stickiness.

White salted noodles (China)

Chinese white salted noodles are made from hard wheat flour, water, and salt. The ingredients are usually made into crumbly dough and sheeted through sheeting rolls and then cut into strands. The flour protein content ranges from 9.5% to 11.0%. Fresh or dried noodles are boiled in water and often eaten in soup. The noodle color should be bright white and the surface visually smooth, and when eaten, noodles should be medium-firm, elastic, and smooth, with no stickiness, and have a fragrant wheat smell.

Dried Chines noodles (photo V.Solah)

Yellow alkaline noodles

Yellow alkaline noodles are consumed in most Asian countries. The ingredients typically consist of flour, water, salt, and kansui (alkaline solution), which are mixed to form a crumbly dough sheeted through sheeting rolls and then cut into strands. The flour protein content (Figure 2) and kansui used vary for the many various types of noodles. Ramen (Japan) is 10.5–12% protein and uses sodium and potassium carbonate as the alkali, and Hokkien (Southeast Asia) is 10.0–11.5% protein and uses sodium hydroxide as the alkali. Sometimes, additives such as eggs or yellow coloring are added.

Cooked noodles colored with β-carotene (photo V.Solah)

The noodles should be bright, yellow, and glossy with no specks and the texture should be firm and elastic.

Durum

Durum wheat, *Triticum durum*, is harder than other wheat and grown at a higher protein content (13–14%; Figure 2). Semolina is coarsely reduced endosperm. Semolina is used for traditional pasta, couscous, and semolina pudding such as halva.

Pasta

Pasta is produced from a mixture of durum semolina at 13–14% protein and water, sometimes with the addition of eggs. Pasta is mixed into a slightly dry dough and sheeted through sheeting rolls and then cut into sheets as for lasagna or strands as in fettuccine or extruded under pressure through a die into vermicelli, spaghetti, penne, or macaroni or stamped into shapes such as farfalloni (bow tie) or rotelle (wagon wheel).

Cooked pasta should be firm (al dente), with a creamy yellow color, and have a rough surface due to the effect of coarse semolina. Pasta can be made from a mix of durum and hard wheat semolina or hard wheat semolina alone but the eating and nutritional quality would decrease.

Pasta can be made with whole meal flour but this has a large impact on texture, especially in thin pasta. Pasta is digested more slowly than bread and other foods, and it is more satiating due to the hard, vitreous, coarse character of the semolina, which remains essentially intact in the final product.

Couscous

Couscous is rolled granules of durum semolina (10–12% protein) originating from northern Africa. Couscous is popular in Morocco, Algeria, Libya, France, and Egypt and around the world. Couscous is produced by mixing durum semolina and water into a crumbly dough. The dough is then rolled by hand or rotated in a drum or sieved to form small round particles. The raw couscous is then steamed and dried in the sun or using

a commercial rotary drier. Couscous should have an even creamy yellow color, and the granules should have an even size and should remain in their granule form and not be sticky when cooked. The hard, vitreous, coarse character of the semolina, which remains partially intact in cooked couscous, makes it slower to digest and more satiating.

Limitation

Instant noodles, cakes, and biscuits are allowed as 'sometimes food,' that is, eaten only sometimes, that are not recommended to be consumed every day and therefore are not included in this article.

Conclusion

The composition, structure, and special properties of the wheat grain have allowed the evolution of many unique food products worldwide. The understanding of the development of the gluten and starch gel matrix has grown in recent times but much more research is needed into wheat quality for specific end uses. In ancient times, methods were developed to process wheat into bulgur, chapatti, bread, noodles, pasta, and couscous. In modern times, industrialization and mechanization have meant new equipment and methods to mix, sheet, cut, shape, and bake. The consumer interest in healthier wheat products that taste great will mean new methods and equipment in the future.

Wheat Production and Consumption

Wheat is one of the world's major staple food grains with over 700 million tonnes (Mt) produced annually. It is the primary food grain for human consumption and in terms of total grain production is ranked 2nd only to corn, with >975 Mt produced annually, much of which is used for animal feeding purposes, and well ahead of rice, wheat is the other major human food grain (~475 Mt annually).

Table 1 lists the countries with an annual wheat production of over 8 million tonnes. The European Union (EU-27) is now the world's largest wheat-producing region, with France, Germany, the United Kingdom, Poland, Spain, and Italy being the leading contributors. Table 1 also lists the total cereal grain production for some countries, highlighting the relative importance of wheat compared with the other grains, in particular rice and corn. The reasons for this are twofold, the adaptability of the wheat plant and the unique nature of wheat storage proteins enabling the production of a plethora of food types. These will be covered in more detail later in this article.

Some countries both consume and produce substantial quantities of wheat so that they are approaching self-sufficiency. These include China, the European Union, India, Iran, and Pakistan. However, depending upon seasonal production and other conditions, countries such as these might be a net importer or exporter. In contrast, other countries with large wheat consumption do not produce wheat sufficient for their needs, so are regular major importers such as Algeria, Brazil, Egypt, Indonesia, and Japan. Finally, there are other countries like Argentina, Australia, and Kazakhstan that are large producers of wheat but are relatively minor consumers, resulting in significant surpluses that they routinely export.

Wheat-Growing Conditions

The wheat plant is extraordinarily adaptable, and as exemplified by the countries listed in Tables 1 and 2, it can be grown in a wide range of environments stretching from the dryland conditions of Australia and Mexico where yields of as little as 1 tonne ha^{-1} can be experienced due to poor soil types or limited rainfall, to the ideal wheat-growing conditions of the southern United Kingdom and northeastern France where 10 tonnes ha^{-1} of crops is commonplace, to the extreme winter temperatures experienced in the northern parts of the United States, Canada, and Russia.

In order to survive and flourish in these vastly disparate climates, the wheat plant has adapted remarkably. Much of the Northern Hemisphere wheat crop has a 'winter' habit, being sown in autumn or 'fall,' laying relatively dormant under the snow that provides both protection from freezing air temperatures and water for ongoing development once warmer spring temperatures arrive and the snow melts. This process is known as vernalization and is the trigger for the plant to continue its development through to grain development and maturity. In some temperate climates, this can result in a very long growing period between sowing and harvest, putting additional pressure on the farming practices being employed.

Conversely, the extreme winter conditions that are typical of the Prairie Provinces of Canada and the Great Plains of the Northern United States are way too severe for winter wheat to survive. In their place, 'spring' wheat are typically grown, sown in spring once the land has thawed and can be worked, and these tend to be fast-growing and gradually overhaul the 'winter' types grown further south to be ready for harvesting before winter returns. This provides the additional challenge of falling temperatures, which can prevent the grain from drying down to a level where it can be stripped from the stem and safely stored. This has required the development of a process called 'swathing' where the crop is cut and pushed up into 'windrows' where the grain dries down to a manageable moisture level prior to threshing to separate the grain from the straw, rachis, and glumes. There is an added complication that as this final drying stage extends into winter, there is an

increasing chance of early snowfall, further compromising grain moisture levels.

In Southern Hemisphere environments on the other hand, the problems are the complete reverse; with, depending on the latitude and altitude of the region, and without the fear of extreme winter conditions, sowing normally takes place in autumn from April to June and the plant develops through the southern winter months of July, August, September, and October and then matures with the onset of summer. This usually concludes with hot, dry, harvesting conditions that produce grain of less than 12% moisture content, making it ideal for long-term storage. There are however still danger periods, as a result of either early flowering where an untimely frost can kill developing florets or, at the other end of the spectrum, late flowering where high temperatures can have an adverse effect on protein development leading to weak dough properties. In really extreme arid climates such as those experienced in Saudi Arabia where wheat is grown under irrigation, grain moisture levels as low as 6% can result. This then provides further but potentially profitable challenges for the miller when the grain has to be 'conditioned' by water addition to toughen the outer bran layers and bring it up to the

optimum moisture content of from, say, 13% to 16.0% before being milled into flour.

Another interesting phenomenon is seen in temperate climates where the so-called 'dual-purpose' wheat can be employed. They are sown very early as soon as there is sufficient moisture to do so, and they can then be used for grazing livestock, following which the plants recover and go on to produce a grain crop in the conventional manner. Even then, the farmer has the flexibility of cutting and baling the entire crop for feed purposes, or if the grain is of marketable quality, it can be harvested and marketed in a conventional manner. These are usually very late-maturing, long-season varieties that can take up to 11 months from the time of sowing to harvest.

The Green Revolution

Wheat varieties developed for broad-acre agriculture were traditionally tall plants with a long straw that was also used extensively for animal feeding or thatching. However, with that came the downside of the plants being unstable, particularly in dry, sandy soils, and subject to 'lodging' where in windy conditions, whole sections of the crop would lay down, making it difficult to harvest. The problem was largely solved by the introduction of semidwarfing genes into wheat genomes. A Japanese dwarf wheat cultivar 'Norin 10' was the primary source and the resultant short-strawed and much more stable varieties contributed to improved wheat yields worldwide. These have been credited with being one of the main factors in the 'Green Revolution,' the phenomenon whereby cereal production more than doubled in many developing countries between the years 1961 and 1985. These production increases can be attributed roughly equally to irrigation, fertilizer, and seed improvements, and the overall impact of the Green Revolution on global food security is the subject of much debate.

The world population has grown by about 4 billion since the beginning of the Green Revolution, and India saw an annual wheat production rise from 10 million tonnes in the 1960s to 73 million in 2006. Between 1950 and 1984, as the Green Revolution transformed agriculture around the globe, world grain production increased by over 250%, and these production increases are often credited with having helped to avoid widespread famine and feeding billions of people.

Conversely, there are also claims that as well as saving many lives, the Green Revolution has decreased food security in many developing countries by encouraging a shift from subsistence agriculture to cropping aimed at producing grain for export or stockfeed.

Origins of Wheat and Its Products

Most authorities agree that the cultivation of wild grass species first took place around 10 000 BC in the area now bounded by parts of Israel, Palestine, Jordan, western Syria, southeast Turkey, and northern Iraq, commonly referred to as the Fertile Crescent, and the early forbearers of modern wheat can still be found in this region, providing valuable sources of new genes for wheat breeders (Figure 1).

The bread, durum, and spelt wheat that we know today are all the result of natural hybridization between wild grass species. These are mostly diploids containing one set of seven pairs of chromosomes. Two diploid grasses with different genomes (chromosome complements) naturally hybridized to produce new plant types with 14 pairs of chromosomes. Tetraploids like the wild emmer wheat (*Triticum turgidum*) were the origins of modern durum or pasta wheat (*Triticum turgidum* ssp. *durum*). Further natural hybridization events occurred between domesticated emmer and another diploid grass (*Aegilops tauschii*) to produce plants with 21 pairs of chromosomes (hexaploids), giving rise to the bread (*Triticum aestivum*) and spelt (*Triticum aestivum* ssp. *spelta*) wheat.

This cultivation of wild grasses for food purposes and the associated establishment of semipermanent settlements of individuals who sowed, tended, harvested, and stored these early food crops are now linked to what is loosely termed 'civilization.' The cultivation and utilization of temperate cereal grains as a staple source of food then spread throughout the Mediterranean and parts of what is now Europe and Central Asia, and while the chronology of these movements is uncertain, there is archaeological evidence of emmer being cultivated in Iraq as early as 10 000 BC.

The Etruscans developed handmade pasta, and this manufacture is depicted in tombs near Rome built in the fourth century BC and was eventually handed down to the Romans and still exists today. The Etruscans seemed to have sourced their grain locally, but the Romans brought their wheat mostly from Egypt and Sicily where durum wheat appears to have been cultivated. Drawings from Egyptian tombs from about 2500 BC show farm activities indicating that emmer was grown and harvested in ancient Egypt.

By 1700 BC, wheat had a role in the Chinese diet. The ancient Chinese ground wheat in a stone mortar to make flour. There is evidence that noodles were made during the Han dynasty, 206 BC to AD 220, and were extremely popular in the Ming dynasty, AD 1368–1644, when they were first called *miàn*. Noodles have continued to evolve since that time and many types exist today. The Chinese also developed steamed breads, steamed buns, and dumplings (Figures 2 and 3).

The origins of bread follow closely on those of the organized cultivation of grains. Initially, grains would have been consumed fresh from harvesting; however, it was discovered that the caryopses of cereal species are extremely robust and can be stored for lengthy periods without any significant loss of functionality or palatability. This was a massive breakthrough in early food technology and provided these early civilizations with the ability to store a staple food and in so doing provide insurance against future periods of acute food shortage.

Grains would have been ground into a rough wholemeal between heavy stones, mixed with water to form a dough and baked on hot stones either around or dragged from within an open fire, into primitive flatbreads.

Some of these doughs would have been left exposed to natural yeast and allowed to ferment under the high ambient temperature conditions common to the region, prior to the final baking stage. The bread produced in this way would have been immediately recognized for its more appealing flavor, texture, and appearance, and this simple and most likely

Figure 1 The Fertile Crescent.

Figure 2 Various types of dried noodles.

Figure 3 Fried and steamed Chinese dumplings.

accidental process would have been the precursor for the art of baking as we know it today.

Over the following millennia, with the constant migration of conquering armies and civilizations, the cultivation of cereals and the consumption of bread as a staple food spread throughout what we now know as Western and Eastern Europe, with the common bread wheat, *Triticum aestivum*, largely replacing the primitive einkorn (*T. monococcum*) and emmer (*T. dicoccum*) species that had gone before.

Bread was initially baked in the home using simple home-ground wholemeal flours, and the styles of bread and the methods used to make them evolved to satisfy local tastes and eating habits. Flour milling emerged as a local business where, for a fee, farmers could have their grain milled into flour for

Figure 4 Traditional-style Arabic pocket bread.

Figure 5 Traditional Arabic flatbread.

their own use or to sell in the marketplace. Subsequently, bread making on a commercial scale emerged as a vital component of local society, and as will be outlined later in this article, wheat-based foods evolved into the myriad styles that we know today.

Today, in the Middle East, traditional flatbreads are fast-baked in very hot ovens; however, they were originally baked on hot stones around open fires. Similar techniques were used in Central Asia and the Indian subcontinent (Figures 4 and 5).

In Europe, the use of yeast-fermented loaf-type breads has predominated, resulting in the myriad of styles seen today throughout the entire region (Figure 6).

In Eastern Europe and Scandinavia, many types of bread, with or without the inclusion of rye flour in the formulation, are produced by the sourdough process where the leavening agents are naturally occurring wild yeast and bacteria. The bread has a characteristic 'sour' flavor and is as old as the history of leavened bread itself. Most of the bread is produced as small loaves or rolls, which all have extended shelf lives. In Italy, rather robust and chewy breads, *pane di casa*, are baked in wood-fired ovens from flour often milled from a grist including durum wheat.

The development of pan breads occurred in Britain. Yeasted doughs were baked in an open metal tin, which determined the shape of the loaf. This eventually led to the development of lidded tins and the popular 'sandwich loaf' that we know today.

Figure 6 Various types of hearth or artisan bread.

European Colonization

From the fifteenth to the eighteenth centuries, European explorers, and in particular the Portuguese, Spanish, British, and French, sailed the globe in search of land to claim for their own. The early colonizers took their staple foods and domestic animals with them, and in so doing, wheat, wheat flour, and bread spread to the Americas, the Indian subcontinent, Southern and Western Africa, and Australasia, becoming the staple food of the then New World, now known as the Western world.

Much more recently, these 'Western-style' foods have become popular in many regions around the world, in particular Central, Southeast, and North Asia. This is in much the same way that Asian foods are now an integral component of the menu in most Western countries.

Interestingly, however, the Western foods that have gained popularity throughout Asia have often been modified to suit local tastes. In particular, the volume, appearance, and sugar content of popular bread types have emerged into styles that are more akin to confectionery than plain bread, reflecting the higher status that bread often holds in these societies than in the West.

Why Wheat Is So Different

The processing quality of wheat is arguably more complex than that of any of the popular food grains, with numerous genetically determined quality traits interacting with each other, in ways that can have a profound influence on the quality of the finished product and the profitability of commercial milling and baking operations. The situation can be further influenced by environmental factors – the conditions under which the crop was grown – which can also have a significant impact on the processing performance, product quality, and hence market value of the grain.

When wheat flour and water are mixed, the inherent water-insoluble proteins known as 'gluten' combine to form a continuous matrix referred to as a 'dough,' and of all of the many quality traits of wheat, it is the unique viscoelastic properties of wheat flour dough that set it apart from the other food grains.

The inherent strength, resistance to extension, and extensibility of wheat flour doughs can vary enormously between

wheat varieties. By careful management of the variety and the environmental conditions under which it is grown, protein content and quality can be controlled to produce dough properties that suit particular food products and manufacturing processes. It is this unique capability to produce viscoelastic doughs of vastly differing physical characters that provides the key to the extraordinary range of wheat-based foods consumed worldwide.

As a consequence, wheat tends to command a premium in the marketplace above prices obtained for most other food grains, and the protein content and inherent protein quality of wheat have a significant impact on its market value.

Dough Processing

Once one has produced a wheat flour dough of the desired quality, it may be manipulated in a variety of ways to generate foods of vastly different appearances, tastes, and characters.

Doughs may be leavened, the process by which gas is introduced into the dough by yeast fermentation or chemical addition, to produce an attractive light open-textured structure in the finished baked product.

Before baking, dough pieces may be shaped into an endless array of styles of breads, buns, and rolls, which are often a characteristic of the cultures that have developed them.

Doughs may be rolled into sheets and baked in that form into flatbreads and tortillas, which for convenience are then used to wrap other foods prior to eating. Dough sheets may be cut into shapes and baked into biscuits and are used to encase fillings such as with Chinese dim sum and Italian-style filled pasta, prior to cooking.

After sheeting, doughs may be cut into strips before further processing, as is the case with the seemingly limitless styles of noodles produced and consumed throughout Asia and now spreading to the rest of the world.

Doughs may also be extruded through dies, which is the popular means of producing pasta products in an endless array of shapes, lengths, and thicknesses and most snack foods.

Food Preparation

Once a dough piece has been produced and leavened, sheeted, cut, stamped, or extruded, it may be dried for preservation as it happens in dry pasta and then cooked, or it can be cooked straight away by a variety of means.

The earliest and arguably most common form of wheat-based food preparation is baking to produce foods such as pan and hearth breads, buns, cookies, biscuits and cakes, and pastries.

However, processed doughs may be cooked in many other ways in order to produce foods with different flavors, textures, and appearances, with the most common being steaming, boiling, frying, or freezing.

Steaming is a very common practice in many parts of North Asia where steamed bread in a range of forms; steamed buns, both plain and filled with sweet or savory fillings; and steamed dumplings are an integral part of the daily diet.

Boiling is the standard method of preparation for most noodle types and for all forms of pasta products, whether they be short (e.g., penne and macaroni) or long (spaghetti and fettuccine) extruded goods or filled types like ravioli and cannelloni.

Frying has been the traditional form of processing for most types of instant noodles. The finished product is deep-fried prior to packaging in order to pregelatinize the starch and introduce flavor and texture, which may then be reconstituted into a ready-made meal simply by adding boiling water. However, rising concerns about the deleterious effects of fried food consumption have seen a swing to steaming for the final processing stage prior to packaging.

Finally, freezing is now a very common form of wheat-based food processing, where the product is taken to a very late stage in its preparation and then frozen prior to packaging, distribution, and marketing. The product, which can be safely stored for extended periods, is thawed prior to the final step in its preparation whether it is by steaming, boiling, or baking.

Similarity of Products Around the World

As a result of the unique properties of wheat flour doughs, distant populations independently developed similar wheat-based foods.

Dumplings that use thin dough sheets to enclose fillings are quite popular in China. Similar types of dumplings are also consumed in Japan and Korea.

Other types of dumplings are also popular in many Eastern European countries. Various types (*pelmeni*, *pierogi*, *knödel*, and *kalduny*) exist in Russia and countries from the former Soviet Union, Hungary, Poland, and Germany. *Kreplach* are the Jewish version of these Eastern European dumplings.

The Italians use sheeted doughs to make *lasagna*, *ravioli*, *and cannelloni*.

In the north of China, thin-sheeted flatbreads called *bing* are popular. Peking duck pancakes are a type of bing, and *shaobing* is a thin-pocketed bread that can be stuffed with savory fillings. These breads are similar to some Middle Eastern flatbreads and Mexican tortillas.

Chinese steamed breads (*mantou*) and filled steamed buns (*bao*) are quite similar to the boiled dumplings made in some European countries.

Some European pasta products bear a striking similarity to the texture and appearance of white salted noodles.

White- Versus Red-Grained Wheat

Wheat is categorized in the international grain trade by its seed coat color. There are two distinct types, red-grained wheat and white-grained wheat, and they are genetically very similar.

Both red and white wheat have advantages and disadvantages. Red wheat are in widespread production in the Northern Hemisphere where the harvest period is in late autumn and early winter. Rain events often interrupt harvest, so grain dormancy becomes an important attribute conferring sprouting tolerance. White wheat do not possess the same tolerance

to preharvest sprouting and tend to be grown in regions where the likelihood of rain at harvest is lower.

Australia is unique among international wheat exporters in that it only produces white-grained wheat for milling purposes. As a result, Australian wheat is preferred in certain markets ahead of the red wheat mostly grown by the other major wheat exporters. This strong customer preference has seen Australia's major competitors like Canada and the United States attempt to develop sufficient quantities of white wheat to compete in the highly demanding markets of Asia. However, to date, North American hard white wheat varieties have failed to show any yield advantage over comparable red-grained varieties, which, together with reduced sprout tolerance and limited storage options, has resulted in much of the hard white crop being absorbed by the US domestic market for products like pizza bases.

Red wheat produce dark and quite bitter bran that limits their use for whole wheat products and for products using flour that requires a bright and white appearance, like noodles, dumplings, and steamed breads.

The bran from white wheat does not impart a bitter flavor to grain products, and any bran specks that get into the flour are less noticeable. Thus, white wheat can be milled to higher flour extractions without the deleterious effects of bran contamination. Flours produced from Australian white wheat are ideal for producing Asian products such as noodles, dumplings, and steamed breads where a bright, clean external appearance of the final product is paramount.

Wheat and Health Issues

As outlined earlier, wheat is one of the major sources of nutrition worldwide, and in many countries and cultures, it is a major source of energy, protein, essential amino acids, essential fatty acids, vitamins, minerals, and fiber. Traditionally, wheat and other cereal grains have been one of the key components in all scientifically based healthy food diets, but for a number of reasons, those recommendations are now being called into question.

In the past decade, the cereal industry has witnessed the emergence of a new food phenomenon variously described as wheat allergies and gluten intolerance. In the popular press, this has been sensationalized, raising concerns among consumers, many of whom, without any formal diagnosis, declare themselves to be intolerant to wheat-based foods and seek a gluten-free diet. The gluten-free food explosion is massive with anecdotal evidence in many Western countries, suggesting an annual increase of around 20%. This is providing a challenge to the wheat-based food industries with concerns about reduced consumption rates and the need to produce alternative food products that address the demand for 'gluten-free' products, whether it is clinically based or not.

For a small proportion of individuals in many countries, gluten intolerance is very real with potentially very serious consequences. For around 1% of the population, wheat and other cereals including rye, barley, oats, and triticale are poisons, not foods.

Celiac disease (CD) is not an allergy but is an immune-mediated condition triggered in genetically susceptible individuals by the ingestion of grains containing gluten. Once expressed, the condition is lifelong, causing damage to the small intestine, which prevents efficient absorption of nutrients, bowel upset, and an increase in the risk of intestinal cancers, osteoporosis, chronic fatigue, and infertility and a doubling of the overall risk of death. There is no known cure and the only treatment is lifelong avoidance of gluten. In Australia, only about 20% of cases are currently diagnosed. The percentage is significantly lower in most other countries of the world.

Many patients presenting with symptoms of allergy (including asthma, eczema, migraine, Ménière's disease, irritable bowel syndrome, brain fog, nasal polyps, and some mental disorders such as depression) are found to have elevated antibodies to gluten, yet they are negative for other markers of CD such as tissue transglutaminase and are normal on small intestinal biopsy. Removal of all gluten-containing foods from the diet has been shown to have significant beneficial effects. At this time, it is unclear what role, if any, gliadin-specific IgA and IgG play in this condition.

Gluten intolerance (nonceliac gluten sensitivity) is more prevalent than CD worldwide, with up to 12% of the population affected. In a recently published book, *The Gluten Syndrome*, Dr. Rodney Ford, a pediatric allergist in New Zealand, provides compelling evidence from a 1000-patient cohort that 10% of the population may be sensitive to gluten but are not celiac. Typically, these patients experienced a range of different symptoms including gut disorders, behavior problems, allergy/immune issues (e.g., eczema), and growth problems.

Clearly, there is growing clinical evidence that health problems associated with dietary gluten aside from CD are real and far more prevalent than might be expected and are going to lead to major threats and opportunities for the food industry.

The growing number of wheat-related food disorders draws attention to this serious health concern. In addition to the obvious detrimental effects of health and daily diet, there are potentially long-term medical, psychological, and social effects. Correctly diagnosing wheat- and gluten-related disorders is often challenging, especially given the limitations of current diagnostic testing. However, it is important to prevent children from unnecessary invasive treatments and potentially unhealthy dietary restrictions. Therefore, research is needed to determine the precise prevalence of different wheat- and gluten-related disorders, to discover more accurate and less invasive procedures for the identification of the mechanisms that lead to adverse reactions against wheat and related cereals and find suitable source materials with low or no allergenic effects.

Whey and Whey Powders: Fermentation of Whey

Whey as a Fermentative Source

Whey is a by-product of cheese; ~85% of the total milk used for manufacturing cheese is discarded as whey. Most milk plants do not have proper treatment systems for dealing with this amount of whey; it is completely prohibitive to divert whey in waterways or even in municipal sewage systems. Thus, disposal of whey becomes a big problem – not only because of the environmental, economic, and human health problems, but also for the significant loss of food and energy potential. Whey retains about 55% of milk nutrients. During the last 50 years, to overcome this problem, the research community has made efforts to develop new biotechnological processes in order to suggest ways of exploiting cheese whey to decrease the whole production cost. Those new processes could be based on the application of valorization technologies – recover proteins and lactose or produce subproducts obtained by hydrolyses – and another choice could be the application of biological and/or physicochemical treatments without valorization, aiming for the legal discarding of whey. Nevertheless, the richness of whey composition leads us to consider it as a resource and not only as a waste effluent, in view of the large potential of new added-value products production, which may contribute wholly or partially to the disposal costs.

Even so, nowadays, only 50% of world cheese whey is treated, from which 50% is used in liquid form, 30% as whey powder, 15% as lactose and its by-products, and the remaining 5% in the form of whey protein concentrates. The costs associated with valorization technologies are normally intolerable by medium and small producers, so they are forced to choose the cheapest solution.

As previously referenced, there are two options regarding the enhancement of whey. The first one – more commonly used when whey powder is produced in excess – is based on the application of technology in order to recover the added-value compounds (proteins by membrane filtration systems and/or chromatography techniques and lactose by crystallization). The second one is applying the fermentation process to obtain whey by-products. Sometimes there is a combination of both, using whey permeate obtained from the whey protein concentrate production as the fermentation medium, which is rich in lactose (~80%). When it is desirable to concentrate this solution, nanofiltration and reverse osmosis processes can be used.

Lactose is the carbohydrate reservoir of whey (70% of total whey solids), being largely responsible for the whey-polluting load. Per year in the European Union, there is a surplus of ~620 000 tons of lactose, which is not used in the production of lactose and its by-products, thus representing a serious environmental problem.

This carbohydrate is a disaccharide formed by galactose and glucose. Its solubility and sweetness is low when compared with other sugars, even its hydrolysis products (glucose, galactose, fructose, and sucrose). Lactose can be used as a food ingredient in infant formula, the confectionary industry, baker's yeast, meat products, and kefir-like whey drinks. It can also be applied in the pharmaceutical industry as an excipient for most table drugs because of its characteristics (innocuous, nonhygroscopic, inert). When submitted to fermentation coupled with other essential nutrients for microbial growth, lactose presents a wide range of possibilities, making the whey permeate a suitable raw material for the production of several by-products, such as organic acids (e.g., lactic, succinic, and propionic); single cell protein (SCP) and single cell oils (SCO); biopolymers (enzymes, bioplastics, and exopolysaccharides (EPS)); bacteriocins; and biofuels (potable or bioethanol, biogas, biohydrogen), with lactose providing the carbon source.

Lactose-Consuming Microorganisms

There are different types of microorganisms that use lactose as a carbon source and as energy, among which are bacteria, yeast, and filamentous fungi.

Bacteria have different strategies in order to hydrolyze lactose. The most common involves phosphorylation and sugar transport into the cell, which can be done through two mechanisms: lactose-proton symporter and lactose–galactose antiporter. Once inside the cell, if phosphorylated, lactose is broken by phospho-β-galactosidase if not by β-galactosidase.

The lactic acid bacteria (LAB) are Gram-positive, usually catalase-negative, anaerobic facultative, nonmotile, nonspore forming, devoid of cytochromes, fastidiously acid tolerant, and strictly fermentative. They comprise several genera; the most usual are *Lactobacillus*, *Lactococcus*, *Leuconostoc*, *Pediococcus*, and *Streptococcus*. Due to their low toxicity, LAB are usually known as GRAS (generally regarded as safe) bacteria, so they are commonly used in the food industry, being the most significant lactose-consuming microorganisms with an important role in lactic acid production. The essential feature of LAB metabolism is the efficient carbohydrate fermentation, coupled with substrate level phosphorylation. Basically, there are two major pathways for hexose fermentation in LAB: homolactic and heterolactic (facultative or obligate). Homolactic fermentation is the process where lactic acid is the unique product of glucose fermentation. Through the Embden–Meyerhof glycolytic pathway, homolactic bacteria can extract twice the energy from a defined amount of glucose than heterolactic fermentation. Homofermentative behavior is observed when the glucose is metabolized, but not necessarily when pentoses or gluconate are, because some homolactic bacteria produce acetic and lactic acid when using pentoses. Theoretically, through homolactic fermentation, one molecule of glucose produces two molecules of lactic acid and a net gain of two ATP molecules per molecule of glucose.

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00749-2

The homofermentative character of some strains can be changed by changing the growth conditions (glucose concentration, pH, and nutrient limitation).

In the heterolactic fermentation process, the production of lactate, carbon dioxide, acetic acid, and ethanol from hexose occurs. In the facultatively heterolactic fermentative process, hexoses are metabolized through the Embden–Meyerhof glycolytic pathway, but pentoses and some other substances are metabolized via a phosphoketolase-dependent pathway to produce lactic acid and other products (typically acetic acid and ethanol). On the other hand, the obligate heterolactic fermentative species use only the phosphoketolase-dependent pathway for sugar metabolism. So in addition to lactic acid, they produce significant quantities of acetic acid and/or ethanol with the generation of carbon dioxide. The presence of oxygen may also significantly affect the metabolism. The heterolactic bacteria are more important than the homolactic in the production of aroma and flavor components such as acetaldehyde and diacetyl. The process of the formation of diacetyl from citrate in the food industry is essential for the formation of odor, for example in the manufacture of butter.

Different factors affect the growth of LAB in fermentation media, such as temperature, hydrogen ion concentration, and pH.

The second most commonly used microorganisms in the lactose fermentation process are yeasts; the ones that assimilate lactose aerobically are widespread, whereas the ones that ferment lactose are rare (*Kluyveromyces lactis*, *K. marxianus*, and *Candida pseudotropicalis*).

Filamentous fungi utilize lactose, but at a very low rate. In fungi, the lactose break can be done in two ways: one by an extracellular hydrolysis and a catchment of lactose monomers (*Hypocrea jecorina* and *Aspergillus niger*), and the other by lactose molecule uptake as a disaccharide and then hydrolysis inside the cell (*Aspegillus nidulans*, *Neuspora crassa*, and *Fusarium graminearum*).

Whey Fermentation Products

Organic Acids

Although acetic, propionic, lactic, lactobionic, citric, gluconic, and itaconic acids can be obtained from lactose/whey fermentation, from an economical point of view, lactic acid is the most important.

Lactic acid

Lactic acid or α-hydroxypropionic acid is widely used in the food, chemical, textile, and pharmaceutical industries. As previously mentioned, a process for the recovery of whey lactose is through LAB fermentation, in order to produce lactic acid as the major metabolic end-product of sugar fermentation. Ultrafiltration is one of the processes used to get raw lactose from cheese whey. The resulting permeate of this method presents a low protein content but is high in lactose and minerals; these factors are favorable for lactic acid production.

The industrial demand for lactic acid by fermentative production (~90%, ~72 000 tons worldwide per year) has been increasing considerably, owing to its use in an expanding range. For example, in the food industry, besides being used as a natural preservative and acidulant, it is used in novel foods and products designed to have specific nutritional or other health-enhancing benefits (nutraceuticals, prebiotics, probiotics, etc.). However, it has been mainly used as a raw material in the promising applications in food packaging, and one of the widest fields of the plastics market.

In recent years, several studies aimed at optimizing the production of the lactic acid process have been performed. Thus, among LAB, *Lactobacillus helveticus* appears to be the most effective, followed by *Streptococcus*, which also shows satisfactory results with respect to lactic acid productivity. The search for satisfactory and efficient LAB strains for cheese whey fermentation has been carried out by genetic engineering approaches.

When cheese whey or its permeate is used to obtain lactic acid through LAB, the addition of supplements is very important. Otherwise, at the industrial scale, productivity is drastically affected, as nutrient supplementation is a key factor limiting process efficiency. Accordingly, supplementation of manganese, yeast extract, peptones, molasses, corn-steep molasses, malt combing nuts, soya flour, lactose, glucose medium, vitamins, minerals, amino acids, hydrolyzed whey, and inorganic supplements ($MgSO_4$, $MnSO_4$, and $(NH_4)_2SO_4$) to the whey is useful for increasing the lactic acid yield. This production could double if proteolytic enzymes or proteolytic microorganisms are used instead of these supplements. In the same way that supplementation with nutrients is important for good growth of the microorganisms with the concomitant high production of lactic acid, also the temperature or use of mixed cultures affects the production of lactic acid.

Immobilization technology applied to whey fermentation processes (bio-film, membrane-based cell recycle reactors, fibrous-bed) is identified as a good solution to improve the economics of the process, allowing cells reutilization, higher cell densities in bioreactors, long-term stability, and easier purification and productivity of lactic acid. However, it also presents some limitations. The continuous fermentation process presents the main problem, with the biggest difficulty being the complete conversion of sugar, exhibiting limited production of lactic acid due to the lack of pH stability, clogging of the column reactor, destabilization of the gel used for immobilization/entrapment by chelating calcium lactate, diffusion limitations of substrate and product, and loss of stability of the biocatalyst activity. LAB have been immobilized by several methods on different supports (calcium alginate, k-carrageenan, agar, and polyacrylamide gels); however, more studies must be undertaken to try to eliminate the less positive aspects and improve the performance of the reactors to achieve high stability, high productivity, and low operating and capital costs.

Biofuels

Nowadays, biofuels can be produced by fermentation of sugars, followed by distillation and drying. The most widely produced are bioethanol and biogas (methane); however, biohydrogen can also be produced. The ability to produce biofuels from raw material, such as whey permeate disposal, shows low

environmental effects. That will be the key to making it competitive with other fuels, such as gasoline.

Biogas

Nowadays, the world markets for biogas are booming. Biogas is produced by anaerobic microorganisms and can be used to produce thermal energy (heating); electricity; or if compressed, fuel vehicles. It is a gas comprising methane (CH_4 – 50–70%), responsible for determine the biogas properties, and carbon dioxide (CO_2 – 50–30%), being produced by a wide variety of available waste organic materials through anaerobic fermentation, leading to a safer disposal of effluents. One cubic meter of biogas has an average calorific value of about 6.5 kWh. Advances in biotechnology, high tech, molecular science, and microbiology have contributed to enhancements in biogas yield production. As a result, biogas competes with petroleum-based fuels in terms of performance, cost, and additional benefits such as reducing greenhouse gas emissions. Innovations are still necessary to support research and development in the field of renewable energy. In that order, renewable biomass feedstock is needed.

Although microorganisms involved in anaerobic digestion are not fully identified, at least four groups of microorganisms are involved in this process. Hydrolytic bacteria degrade organic molecules into simpler compounds (CO_2, hydrogen, alcohols, and organic acids); acetogenic bacteria convert organic acids and alcohols into acetate and hydrogen; homoacetogenic bacteria form only acetate from hydrogen, CO_2, organic acids, alcohols, and carbohydrates; and methanogenic bacteria produce methane from acetate, CO_2, and hydrogen. All of these microorganisms play an equally important role in methane production. The accumulation of intermediate compounds led to a methanogen inhibition and concomitant microorganism imbalance, decrease in methane production, or process failure. The two main steps (acidogenesis and methanogenesis) are normally out of balance even at low digester feed rates. The usual fermentative bacteria are *Lactobacillus*, *Eubacterium*, *Clostridium*, *Escherichia coli*, *Fusobacterium*, *Bacteroides*, *Leuconostoc*, and *Klebsiella*. Examples of acetogens are *Acetobacterium*, *Clostridium*, and *Desulfovibrio*. Methane-producing organisms are classified under domain Archaea, phylum AII, Euryarchaeota. Archaea is a group of prokaryotes that differ from bacteria.

Concerning biogas production by anaerobic digestion of whey, some studies have shown a decrease of chemical oxygen demand, which is intensified with the use of two reactors in series. Increasing methane production results when an anaerobic sludge blanket reactor is used and with anaerobic treatment of diluted and undiluted cheese whey supplemented with trace metal, in contrast with the presence of copper chloride, zinc chloride, or nickel chloride presenting a significant inhibition of methane production, which could be reverted with the addition of sulfide.

When two-phase processes are used, such as anaerobic digestion with acidogenic and methanogenic reactors coupled to a membrane filtration system, a thermophilic process with partial acidification followed by a methanation step and a continuous process enables the removal of the soluble effluent while retaining solids, an increase in methane production, and an increase in hydrogen and methane production, respectively. A mathematical model was applied to determine the optimum physiological conditions during acidogenesis of cheese-whey wastewater.

Bioethanol

Bioethanol is an alcohol made by fermentation, mostly from carbohydrates produced in sugar or starch crops such as corn, sugarcane, cereal, sugar beet, or sweet sorghum. It has a number of advantages over conventional fuels, being biodegradable and far less toxic than fossil fuels. It is generally CO_2 neutral, and it can help reduce the amount of CO_2 as well as other poisonous gases produced during fuel combustion. Bioethanol can be used as a fuel for vehicles in its pure form, but it is usually used as a gasoline additive to increase octane and improve vehicle emissions. Nowadays, the bioethanol market continues to grow rapidly.

Whey could be a suitable and less expensive substrate for bioethanol production. All over the world, there are several industrial-scale whey-ethanol plants. Fermentation could be done in batch cultures or in a semicontinuous process, for which a kinetic model was developed.

Yeasts are usually the microorganisms used in the fermentation of lactose from ultrafiltered whey permeate to bioethanol production. The potential applications of yeast strains are focussed on *Kluyveromyces* sp. Though it has a great advantage because of the use of lactose as a direct substrate, it is very sensitive to ethanol concentration (inhibiting the process at very low concentrations). In addition, it presents a low conversion yield (~40%). Thus, *Saccharomyces cerevisiae* can be used, presenting a fermentation yield of 50% and a fourfold ethanol tolerance. Notwithstanding, the fermentation performed by this yeast is an indirect one, not having the ability to hydrolyze lactose directly. Although the yeasts that assimilate lactose aerobically are widespread, those that ferment lactose are rare. In the last decades, researchers have been studying ways to overcome this problem. Genetic engineering is used in order to achieve the optimal yeast strain. Other efforts have been made, aiming to facilitate the process with a simultaneous lactose hydrolysis, for example by coimmobilization of yeast cells with the enzyme.

The development of yeasts' biotechnology processes and engineering techniques leads to the application of different stimulation processes that improve the biological activity of yeasts, achieving new ways to produce higher ethanol amounts. It has been seen that proper ultrasonic stimulation has the function of promoting the activity of enzymes, cell growth, and cell membrane permeability.

Biohydrogen

Biohydrogen is commonly used for heating, lighting, and as a motor fuel. Its production has grown over the years; it has been increasingly used as alternative energy, with the great advantage of the absence of polluting emissions, where the only product of combustion is pure water. Nowadays, most hydrogen is obtained from fossil fuels that generate gases, contributing to global warming due to the greenhouse effect.

On a laboratorial scale, there are different ways to obtain biohydrogen through fermentation (photofermentation, dark fermentation, and both combined); however, information given on an industrial scale is rare.

Fermentative hydrogen production could be coupled with the anaerobic process of acidogenic bacteria of biogas production. This fermentation is usually called dark fermentation and leads to the formation of organic acids from organic material degradation. A two-stage fermentation process, in which acidogenesis and methanogenesis occur in the separate reactors, may offer several advantages, such as improved total wastewater degradation and enhanced biohydrogen and methane production. Studies pertaining to the use of carbohydrate-rich wastewaters as fermentation substrate in order to obtain biofuel on an industrial scale are still very embryonic. Although there are preliminary studies that indicate great potential for the use of raw materials in biohydrogen production, details with respect to the optimization of process and operating parameters are needed, whether on an industrial or laboratory level in some cases. The scale-up of industrial production is a key point.

Single Cell Protein and Single Cell Oil

The production of SCP or SCO can be performed by algae, actinomycetes, bacteria, yeast, molds, or higher fungi, and its dried cells can be obtained by large-scale culture systems, which can be used as a protein or lipid source. In the case of whey fermentation, lactose is usually converted in biomass by yeasts, usually GRAS. Lactose can be directly used by yeasts, hydrolyzed into glucose and galactose, or fermented by LAB into lactic acid and galactose. The use of whey derived or even lactose as a carbon source for producing yeast biomass leads to increased harnessing of industrial by-products, normally used as feed or baker's yeast.

Depending on the type of yeast, it is not always necessary to add vitamin supplements to achieve a high fermentation yield. However, the specific growth rate usually increases with the addition of yeast extract and corn-steep liquor. It is also necessary to add a nitrogen source; in this case, ammonium salts are enough. If the pH and temperature optima of microorganisms cannot match the optimum conditions for production of single cells, there must be a compromise.

The most common processes applied on SCP are the Vienna process, which entails only a single species *Candida intermedia*, with an exclusive oxidative metabolism; and the Bel process, which presents a balance between three species: *Kluyveromyces marxianus* var. *marxianus* (metabolizes lactose), *K. marxianus* var. *lactis* (metabolizes lactic acid), and *Candida pintolopepsii* (metabolizes ethanol). The Bel is a continuous aerobic process, where deproteinated whey is used as substrate and cannot be supplemented with nitrogen, phosphorus, and trace elements, depending on the type of whey.

When biomass is produced from whey with a high amount of lactose hydrolyzed, it is possible to choose strains that do not metabolize lactose, so the first sugar to be metabolized is glucose. The process for the production of baker's yeast involves whey as substrate and an immobilized enzyme (lactase) followed by glucose–galactose fermentation.

Kluyveromyces and Candida are the most commonly used strains in SCP production from whey. Some studies have been done in order to achieve the optimal conditions of the processes. Thus, different fermentation modes, temperatures, substrates, supplements, and concentrations have been tested:

- *K. fragilis* is used in bath production using whey as substrate.
- Yeast biomass with an improved nutritional profile is produced by methionine-enriched *K. lactis* mutants in whey permeate.
- Production of SCP uses *K. marxianus* CBS6556; in deproteinized sweet whey supplemented with trace elements, ammonium and calcium, and sour cheese whey concentrates supplemented with ammonium, trace elements and vitamins.
- Considering the economic factor, studies with several batch reactors in series were done, having seen a drastic decline in energy costs.
- Mathematical models have been developed so that experimental data is described.

Other yeasts and microorganisms are also been explored:

- Increased SCP production of *Wingea robertsii* using cheese whey as substrate supplemented with minerals and yeast extract
- Development of a fed-batch system for scale-up kefir biomass production using whey
- Use of whey or buttermilk supplemented with yeast extract for the growth of thermophilic LAB
- Probiotic biomass from deproteinized and non-supplemented milk whey
- Batch, continuous, and fed-batch *Lactobacillus casei* in deproteinized goat milk whey

For SCO production, oleaginous microorganisms (*Zygomycetes*, *Mortierella isabellina*, *Thamnidium elegans*, and *Mucor* sp.) were tested with the aim of discovering their ability to produce biomass with specialty lipids, lipid-containing g-linolenic acid (GLA), and polyunsaturated fatty acids from whey. An appreciable microbial growth and a variation of GLA concentration depending on strains and fermentation time can be seen.

Biopolymers

Enzymes

Whey or whey derivates in the form of lactose have also been used as substrates for the production of different enzymes, with β-galactosidase (β-D-galactoside galactohydrolase), commonly known as lactase, as one of the most important enzymes produced due to its important role in the lactose enzymatic hydrolysis, catalyzing the break of the β1–4′ linkage in lactose to yield glucose and galactose. This enzyme plays a key role in food processing.

β-galactosidase can be isolated and purified from a wide range of microorganisms. Notwithstanding the fact that bacteria *Streptococcus thermophilus* and *Bacillus stearothermophilus* can be used to produce lactase, yeasts and fungal sources are mainly responsible for the production of this enzyme. *Kluyveromyces* spp. *K. marxianus*, *K. lactis*, and *K. fragilis* are the strains normally responsible for production in a lactose-rich medium. In most cases, this medium requires the addition of supplements in order to optimize production of the enzyme.

The optimum conditions for enzyme production and extraction vary according to yeast strains. However, the improvement

of new technologies can help optimize the feeding rate in fed-batch cultures and overcome the extraction problem. Genetic engineering can also improve β-galactosidase enzymatic activity at different temperatures, fostering its use in the hydrolysis of lactose in milk and other dairy products.

Lactose-rich products have been also employed on the production of other enzymes, such as protease, amylase, and polygalacturonase, though different microorganisms viz. fungus, bacteria, and yeast, respectively, although for supplementation with different nutrients such as yeast extract, gelatin, peptone, aspartic acid, casein, or acetamide, dried sweet whey is required in all cases.

Bioplastic synthesis

Polylactic acid

As previously mentioned, lactic acid could be used as a raw material in the plastics market. Namely lactic acid polymer, the polylactic acid (PLA), is an environmentally friendly biodegradable plastic (if disposed in landfills, it will last in the environment for years). Not only is it used as a specialty medical material, but it also has other industrial applications as an alternative to plastics derived from petrochemicals. Also, it has applications as a biodegradable plastic component (polylactide, polymers, polyhydroxybutyrate).

The physical properties of PLA depend on the enantiomeric composition of lactic acid, where an optically pure lactic acid (one enantiomer) is desirable and extremely important. Once the type of fermentation and the optical configuration of lactic acid are dependent on the genera of LAB, a fermentative means of lactic acid production has an advantage over chemical synthesis. Thus, it is possible to choose the specific LAB strain that will degrade cheese whey, in order to produce the desired lactic acid.

Polyhydroxyalcanoate

Polyhydroxyalkanoates (PHAs) are aerobic bacterial polyesters that have received interest in recent years, as they can replace common plastic materials. As a surplus product with environmental impact, whey lactose can be applied for the production of these future-oriented biopolyesters, thus providing a promising approach to solving prevailing economic problems.

Among biodegradable plastics, PHAs have been considered good substitutes for petroleum-derived synthetic plastics (polyethylene and polypropylene). Though they possess similar chemical, physical, and mechanical properties, PHAs are distinguished by their degradability after disposal, UV resistance, oxygen impermeability (fundamental property for food packaging), and biocompatibility (essential property for medical and surgery applications). PHA biosynthesis occurs via condensation of acetyl-CoA units. They are synthesized using expensive synthetic substrates, so it is necessary to search for a cheap alternative. Usually when a nutritional factor is limited (e.g., nitrogen, phosphorus, potassium, oxygen, sulfur, or magnesium), in the presence of an excess carbon source, several microorganisms redirect the carbon flux from biomass formation toward accumulation of PHAs. The optimum strategy of applying whey for PHA production depends mainly on the selected production strain. Bacteria that have a GRAS status for PHA production, such as LAB and bacilli belonging to probiotic species, might constitute an added value to these biotechnological processes.

Several studies were related to the production of PHAs from whey and its derivates using pure cultures of wild-type microorganisms or recombinant ones. In several of these works, whey lactose was hydrolyzed by lactase.

There are different ways to convert whey lactose to PHAs. Only a restricted number of microorganisms directly convert lactose to PHAs, for example the wild-type stains of *Hydrogenophaga pseudoflava* DSM 1034 and *Sinorhibium melitoti*. This can be overcome when whey lactose is hydrolyzed enzymatically or chemically to glucose and galactose; these monosaccharides are converted by a broader number of organisms. Poly-β-hydroxybutyrate (PHB) was produced with *Ralstonia eutropha* DSM545 on whey permeate and inverted sugars. *Pseudomonas hydrogenovora* DSM 1749, *Hydrogenophaga pseudoflava*, and *Haloferax mediterranei* are able to cometabolize glucose and galactose from lactose-hydrolyzed whey permeate supplied with sodium valerate to produce PHB. A pH-stat fed-batch fermentation and supplemented whey powder has been used for PHB production using a recombinant *E. coli* strain GCSC 6576 and strain K24K harboring the PHA biosynthesis genes of other species. PHB production was also described in LAB belonging to *Lactococcus*, *Lactobacillus*, *Pediococcus*, and *Streptococcus* genera. PHB was also produced on whey and lactose by *Methylobacterium* sp. ZP24.

A third possibility arises from the anaerobic conversion of lactose in a first-step fermentation by LAB such as *Lactobacillus lactis*, *Propionibacterium*, *Lactobacillus delbrueckii* toward lactic acid with high yields; lactic acid can serve as substrate for PHA production. These strains could act as a coculture fermentation system, where lactic acid produced by LAB is taken up by *Cupriavidus necator* to produce PHAs, resulting in an increased yield, as well as the possibility of utilizing substrates cheaper than glucose for production of PHAs. Thermus species have been found to utilize disaccharides such as lactose.

Exopolysaccharides

These molecules are polysaccharides with diverse high molecular weights (10–1000 kDa). They may be homopolymeric, when composed of either D-glucose (glucans) or D-fructose (fructans) residues, with different types of linkage and branching degree; or heteropolymeric, constructed from multiple copies of an oligosaccharide (the most common) and showing little structural similarity to one another: glucose, galactose, xylose, mannose, arabinose, and rhamnose.

The interest in EPS has increased in recent years because of their potential properties, having revolutionized the industrial and medical sectors. They can be added to food products (ensuring safety qualification) or produced in situ during dairy product fermentation, acting as natural thickeners, giving the product a suitable consistency, and acting as emulsifiers and gelling agents, improving viscosity and reducing syneresis. Some of them may have beneficial effects on human health, being related with microbial cell protection from toxic compounds, phagocytosis, osmotic stress, antibiotics, prebiotics, anticoagulants, antithrombotics, immunomodulation, and anticancer effects. That way, LAB-synthesized EPS have been implicated as antitumor agents, immunostimulators, and blood cholesterol lowering agents. The increasing demand by consumers for novel dairy products requires a better understanding of the effect of EPS on existing products and, at the same time, a search for new EPS-producing strains with

desirable properties. The use of genetically modified organisms capable of producing high levels of EPS or newly designed biopolymers is still very limited.

The ability to produce EPS is widespread among LAB, although they can be produced by microalgae, too. The GRAS and probiotic status of some lactobacilli give them more preference for consumable EPS production; the best known are *L. casei*, *L. acidophilus*, *L. brevis*, *L. curvatus*, *L. delbrueckii bulgaricus*, *L. helveticus*, *L. rhamnosus*, and *L. plantarum*. Nevertheless, *Lactobacillus* sp. are not the best polysaccharide producers; there are other bacteria offering a great yield. For EPS production, there are Gram-negative bacteria *Xanthomonas campestris*, *Acetobacter xylinum*, and *Sphingomonas paucimovilis*; for xanthan, acetan, and gellan production, respectively, or even for dextran production by strains of the LAB *Leuconostoc mesenteroides*.

As expected, due to high lactose content, whey and its derivates are great substrates for EPS production by fermentation; some practical examples are presented in Table 1. All of the studies related to EPS production and optimization point to a strict relationship among the effects of temperature, whey permeate concentration, type and level of supplementation, dilution rate, and interactions on biomass with the yield. Furthermore, the functional properties of the EPS could be modified by the influence of growth conditions. Studies pertaining to immobilized cell technology for production of EPS as a functional food ingredient clearly show its high potential. Immobilization and culture time-induced cell aggregation could be used to produce new symbiotic products with very high viable cell and EPS concentrations.

Bacteriocins

Bacteriocins have been claimed to be valuable tools in improving food safety, namely in dairy, bakery, meat, and fishing products, as well as in fruits, vegetables, and beverages. Besides the food industry, they can be applied in medical, pharmaceutical, and veterinary fields. The term bacteriocin means a protein/peptide antibiotic of relative high molecular weight, which is active mainly against the same or closely related species via adsorption to receptors on the target cells. Bacteriocins are synthesized, at the ribosomal level, through fermentation by various Gram-positive and Gram-negative bacteria, acting toward strictly correlated bacteria (growth inhibition or kill) – they are an antibacterial substance. LABs are able to synthesize different classes of bacteriocins, including antagonistic molecules. Generally, bacteriocins are produced at the end of the exponential growth phase, and their spectrum of action can vary depending on the producing species. Nysin is the only bacteriocin that is industrially gaining widespread permission and authorization in commercial food application. Several studies have been done in the last few decades in order to achieve potential production and application of bacteriocins, once they present important features inhibiting the growth of foodborne bacterial pathogens and demonstrating biopreservative action in food.

Bacteriocins are divided into three classes: antibiotics, small hydrophobic heat-stable peptides, and large heat-labile proteins. Such compounds can be incorporated in food in a variety of ways: using a preparation of semipurified or purified bacteriocins as an ingredient (e.g., nisin); incorporating a previously fermented culture containing bacteriocin; using a substitute for the bacterial culture; or as part of the culture itself, which can release bacteriocin in situ (which is the approach closest to the concept of bioconservation).

Although bacteriocins can be produced in the food matrix during food fermentation (in situ), bacteriocins by LAB can be produced in much higher amounts during fermentations under optimal physical and chemical conditions. Bacteriocin production depends on pH, temperature, media composition, agitation, and aeration.

Bacteriocin production by whey or its derivates' fermentation is summarized in Table 2. Nisin can be produced in batch cultures during the bacteria exponential growth phase, using filtered or unfiltered skim milk, whey, sweet whey, or pasteurized whey as substrate. Higher nisin concentration obtained in whey filtered, or in some cases diluted, was probably related to insoluble proteins released into the media; higher nisin production was observed in diluted whey than in concentrated whey.

Table 1 Exopolysaccharide production by whey or its derivates' fermentation

Microorganism	*Fermentation mode*	*Substrate*	*Supplement*
Lactobacillus bulgaricus LB3 and LBs	Batch fermentation	Whey	1% peptone
Lactobacillus rhamnosus RW-9595-M	Batch fermentation	Whey permeate	Yeast nitrogen base
Lactobacillus rhamnosus RW-9595-M	Repeated fermentation with immobilized cells	Whey permeate	$MgSO_4{\cdot}7H_2O$, $MnSO_4{\cdot}7H_2O$, Tween 80 and yeast extract
Lactobacillus rhamnosus RW-9595-M	Continuous fermentation with free and immobilized cell chemostat culture	Whey permeate	Yeast extract
Lactobacillus delbrueckii subsp. *bulgaricus*	Continuous fermentation	Deproteinized whey	Peptone, $MgSO_4{\cdot}7H_2O$, $MnSO_4{\cdot}7H_2O$, Tween 80 and yeast extract
Aureobasidium pullulans P56	Batch fermentation	Deproteinized whey + enzyme-hydrolyzed whey	K_2HPO_4, L-glutamic acid, olive oil, and Tween 80
Xanthomonas cucurbitae PCSIR B-52	Batch fermentation	Partially deproteinized whey	Corn-steep liquor and penicillin waste mycelium
X. campestris pv mangiferaeindicae 1230 and pv manihotis 1182	Batch fermentation	Whey	$MgSO_4{\cdot}7H_2O$ and K_2HPO_4
Streptococcus thermophilus ST 111	Batch fermentation	Milk + whey protein hydrolyzate	Nitrogen source

Table 2 Bacteriocin production by whey or its derivates' fermentation

Bacteriocin	*Microorganism*	*Fermentation mode*	*Substrate*	*Supplement*
Nisin	*Lactococcus lactis* UQ2	Bioreactor (controlled pH 6.5)	Sweet whey	Soybean peptone
	Lactococcus lactis subsp. *lactis*	Batch fermentation (extremely low-frequency magnetic field)	Whey permeate	
	Lactococcus lactis subsp. *lactis* CECT 539	Batch fermentation	Diluted whey	
	Lactococcus lactis	Batch fermentation	Skim milk or whey	
	Lactococcus lactis ATCC 11454	Batch fermentation	Pasteurized whey (filtered)	
	Lactococcus lactis subsp. *lactis* ATCC 11454	Continuous fermentation with immobilized cells (packed-bed bioreactor)	Whey permeate	Casein-hydrolyzate
Nisin-Z	*Lactococcus lactis* subsp. *lactis* biovar *diacetylactis* UL719	Repeated fermentation with immobilized cells (controlled pH 6.5)	Whey permeate	
Pediocin	*Pediococcus acidilactici* NRRL B-5627	Fed-batch fermentation (re-alkalized)	Diluted whey	2% yeast extract
	Recombinant strains *Lactococcus lactis* ssp. *lactis*, *Streptococcus thermophilus*, and *Enterococcus faecalis*	Batch fermentation	Skim milk or whey	0.5% yeast extract
Enterocin AS-48	*Enterococcus faecalis* A-48-32	Batch fermentation	Whey derived – Esprion-300	1% glucose

The same result could be achieved for pediocin production obtained in diluted whey supplemented with yeast extract.

Studies encompassing the immobilization of strains in the presence of supplemented supplemented media showed an increase in production, emphasizing the case of nisin continuous production through *Lactococcus lactis* subsp. *lactis* ATCC 11454 in a whey permeate supplemented with casein hydrolyzate, where the bioreactor was operated continuously for 6 months and submitted to the optimal conditions, without encountering any clogging, degeneration, or contamination problems.

In recent years, special attention has been given to the study of bacteriocins derived from *Bacillus*, because they present a broader spectrum of inhibition compared to LAB, leading to an increase in potential applications.

Membrane Protein Separation

One booming market is that of health-promoting foods – foods that are able to promote health and reduce the risk of diseases if regularly included in balanced diets. Over the years, whey has gained a strong position as a valuable source for dairy-based ingredients with applications within a wide range of physiological roles (namely related to the immune, cardiovascular, nervous, and gastrointestinal systems), being able to respond to demand by specific consumer groups. Thus, the dairy industry has been searching for nonconventional conversion of effluents into added-value products, following economically feasible routes. Consequently, whey begins to no longer be a disposal problem; it is now a profit center. The value of whey products and their individual components increases significantly when the components are separated and purified. Because of this, a great number of techniques have been developed, namely centrifugation and membrane technologies.

Membrane separation processes are used to fractionate and/or concentrate a liquid by passing it through a semipermeable membrane, which allows differential concentration of a liquid provided that the solute at stake is larger in diameter than the membrane pore (cannot cross membrane – retentate or concentrate). The liquid that percolates the membrane (permeate or filtrate) has in its composition components smaller than the membrane pore diameter. Thus, the separation process is based on the selective permeability of the initial different liquid compounds. The selective permeation is the result of a driving force; the application of hydrostatic pressure; or in a few cases, electric potential, depending on the type of separation. The mechanisms that mediate the mass transport in different membrane processes vary, depending on the type of membrane, process conditions, and equipment configuration. Usually, the different types of membranes are described with reference to pore size and the cutting point regarding molecular weight.

During the classic filtration process, the suspension to be filtered is poured perpendicular to the filter media. Under these conditions, it produces an accumulation of material, forming a layer that decreases the porosity and, consequently, the flow rate of filtration. So, this kind of filtration does not allow an acceptable duration of time when applied to the industrial scale. The frontal filtration processes are improved by introducing a third component, in the form of a speed gradient parallel to the membrane surface. This new process vector acts at the side of fluid to concentrate. Thus, the tangential filtration is a membrane process under the action of a pressure gradient in which the membrane is filled by a liquid-containing substance, which will be separated. This liquid must be pushed by enough gradient pressure in order to allow passage of filtrate or permeate through the membrane, created by a pump or an electric current. The concentrate or retentate corresponds to the part of the liquid that does not pass through the membrane, in which one or more compounds present in the initial feed liquid are concentrated. The filtration flow rate corresponds to the flow rate of permeate that passes through a given membrane surface and is usually expressed in $l\ h^{-1}\ m^{-2}$.

In the last 40 years, the development of membrane techniques for food industry applications has been intrinsically related to the membrane evolution. From the earliest membranes made of cellulose acetate to the third generation of mineral membranes, important advances have been made. Changes that allow the expansion of filtration technologies include the improvement of their selective permeability, high resistance to temperature and extreme pH values, greater mechanical strength, dead volume decrease, replacement facility, and reduction of cost per square meters. Market membranes can be classified according to different criteria, such as selectivity, chemical nature, structure, mode of operation, and geometric configuration.

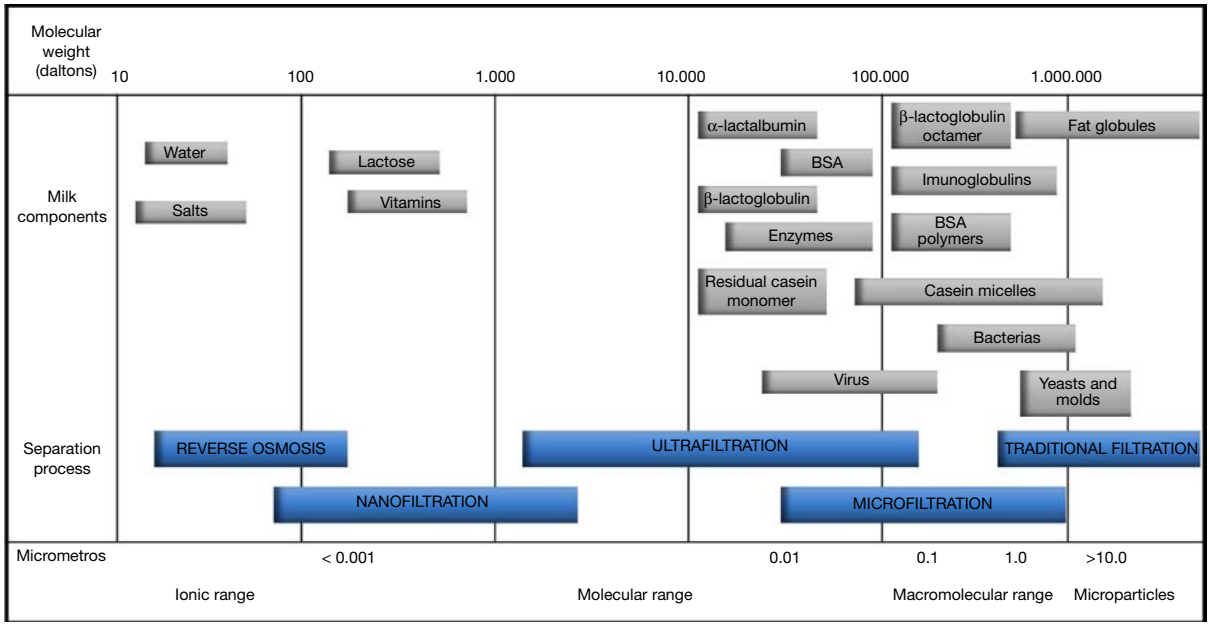
So, membrane technology presents important features such as its straightforward scale-up and relatively low cost when compared with alternative separation/concentration methods, as well as elimination of heat treatment that allows the maintenance of nutritional and physiological properties of whey components.

Membrane Selectivity and Process Type

The food industry, especially the dairy field, has been a pioneer in developing equipment and techniques of membrane filtration. Whey proteins can be recovered in a nondenatured state through filtration processes already implemented on an industrial scale, as well as fractionation of whey proteins that allows studies of the biological properties of some high-purity whey components, with the prospect of possible industrial and biomedical applications. With water content in the raw material of about 94%, there are numerous possibilities for water recovery in whey processing.

One of the most relevant barriers to the widespread use of whey for food is its high relative ash, two times higher than for milk. The mineral salts affect the flavor, functionality, quality, and value of whey products. This problem is solved by whey demineralization, aimed at removing divalent metals and reducing active acidity, leading to expand the scope of whey use in the food industry. In the same way, the large-scale reduction of microbial loads could be performed.

According to their selectivity, one can distinguish membranes and processes that can be applied to whey. Figure 1 shows the spectrum of separation of milk components that can be obtained by different membrane processes, according to the size of the molecules and the pore diameter of the used membranes. Typically, the procedures include basic membrane



Process:	Reverse osmosis (RO)	Nanofiltration (NF)	Ultrafiltration (UF)	Microfiltration (MF)
Applied pression:	200 – 1.200 psig	150 – 400 psig	30 – 150 psig	20 – 100 psig
Retentate:	Total solids	Total solids except monovalent ions	Proteins and fats	fats, large proteins and particles
Filtrate:	only water	monovalent ions	salts, non-protein nitrogen and lactose	Lactose and salts
Separation method:	ability organization of the compounds into tetrahedral structures determine the permeation capacity	diffusion and flow through the pores controlled by mass transfer, characteristics of diffusion and charges	shape, charge, flexibility, MW determines the ability to cross the membrane	size determines the ability to cross the membrane

Figure 1 Relationship between membrane filtration techniques (membrane pore size range) and relative size of various components of milk retained. Adapted from Alfa Laval/Tetra Pak, 1995.

separation, for example, reverse osmosis (RO), ultrafiltration (UF), and diafiltration (DF), which permit fractionation of proteins, as well as concentration and purification thereof; nanofiltration (NF) and electrodialysis (ED), which allow removal of salts or low-molecular weight contaminants; and microfiltration (MF) to remove suspended solid particles or microorganisms. Sometimes it is necessary to use a combination of membranes in order to get the desired effect.

MF is a process that uses membranes with internal pore diameter of 0.1–20 μm separating particles bigger than 200 kDa molecular weight. Depending on the pore size, one may separate whey components with remains of caseins, phosphoproteins, or skimmed milk components such as somatic cells, bacteria, and spores. The working pressures used are less than 0.2 MPa.

UF is a membrane process that separates components based on a molecular filter. Membranes have a pore size of between 0.015 and 0.1 μm, allowing the separation of molecules within a molecular weight of 1–200 kDa. In the case of cheese whey UF, lactose, nonprotein nitrogen, water-soluble vitamins, and salts pass through the membrane, though protein and fat are retained. The choice of the pore diameter depends on the molecular mass and conformation of molecules that are intended to be separated (more specifically, its Stokes radius). The working pressures used are smaller than 1 MPa.

DF is employed to increase the recovery of solutes across the permeable membrane during the UF or MF processes. The DF process consists in diluting the concentrate, usually with water, and then continuing the separation until a satisfactory degree of solute is removed. It allows, for example, the obtainment of a protein concentrate with low lactose and minerals content.

NF is a membrane process under high pressure, which is able (as RO) to reverse the effects of osmotic liquids. The NF is processed by mass transfer phenomena, consisting of diffusion and flow through the pores; it can also use membranes that are electrically charged, so that they can select which ions can pass through. In addition, it can be used to concentrate. NF membranes are partially permeable to ions, minerals, and other low molecular weight components (they let in compounds with a molecular weight cutoff between 200 and 1000 Da); being employed to demineralize. The monovalent ions normally pass through the permeate while the divalent ions are concentrated in the retentate. The diameters of the pores are between 0.001 and 0.015 μm, to working pressures of 0.7–3.5 MPa. This process began to be applied in the dairy industry in order to obtain concentrates with low concentrations of salts, although in some cases it also reduces the lactose content.

RO is a process in which the membrane separates the solvent (usually water) and solutes with molecular weights below 150 Da of the remaining components of the solution. This separation is achieved by applying external pressure that exceeds the osmotic pressure, so it gets water flow through a membrane, contrary to what would be produced naturally. It is a process of solute concentration. The pore diameter is less

than 0.001 μm, and the working pressures used are between 4 and 8 MPa. One of their applications is in the concentration of whey by eliminating ionized water and minerals.

Electrodialysis

ED principle

ED belongs to the group of membrane-based separation processes. It is a combination of two phenomena: a membrane phenomenon, which implies multimembrane cells responsible for the dilution/concentration and water dissociation applications (dialysis method); and an electrode phenomenon with electrolysis cells for redox reactions (electrolysis method). So, ED is an electrochemical separation process where small electrically charged ions are transported through one or more selective permeable membranes (electrically charged) from a desalted stream (permeate) to a stream with a higher concentration of salts (concentrate), under the influence of an electrical potential (Figure 2). This phenomenon leads to the separation of salts from the electrically uncharged compounds. Therefore, it is a method based on the selective movement of ions in solution, contrary to other membrane technologies that separate particles based on their molecular weight.

ED takes place in an electrodialyzer, an equipment with a stack that consists of a series of anion and cation exchange membranes (AEM and CEM) arranged in an alternating pattern between two electrodes (anode and cathode) to form individual cells and spacers. Worldwide, ED dominates as a desalting process, exceeding RO, and distillation applications. It is used in the pharmaceutical, chemical, and food industries, namely in the separation and purification of inorganic and organic solutions, water treatment (ultrapure, waste, sea, brackish, salty mine, and industrial waters), recycling of chemical substances, wine stabilization, desalination of fruit juices, whey demineralization, and others.

Ion-exchange membrane

Ion-exchange membranes are made of molecular material containing fixed ions immobilized in the membrane. These could be positively charged with alkyl ammonium groups in the case of anionic membranes, or negatively charged with sulfonic, carboxylic, arsenic, or phosphoric groups in the case of cationic membranes. Both of these membranes are monopolar, being permeable to only one type of ion. Therefore, the transport of an ionic species through the membrane depends on the nature of the ion. Membranes are electronically neutralized by counterions (mobile ions with opposite sign charges), which carry current in the membrane, exchanging by diffusion between membranes and the surrounding solution.

ED membranes present selectivity in the result of an electrostatic repulsion. That way, they may be permeable to cations (in the case of a CEM), where anions are repulsed, or anions (in the case of an AEM), where cations are repulsed, and do not allow the passage of water back into whey because of the chemistry of the porous membranes used. Thus, the process leads to separation of electrolytes from nonelectrolytes, concentration or reduction of electrolytes in solution, and the exchange of ions between solutions.

ED types and applications in the dairy industry

There are two types of ED, the most common use being monopolar membranes. The principle of the method has already been described. In the case of dairy products, it is responsible for demineralization of milk whey, protein separation and purification, acid caseinate production, and organic acid. The main application of this technique in food technology is whey demineralization, with the aims of producing whey concentrate with low ash content. This is necessary for further whey use as a raw material for other valuable products such as infant formula and animal feed, or for the recovery of proteins. These applications use the sole property of dilution-concentration of the monopolar ion-exchange membrane.

In addition to this conventional method, there is a newer one that is performed with bipolar membranes, presenting the same support principle as monopolar ED, although carrying out the dissociation of water molecules. Besides AEM and CEM, bipolar membranes possess a hydrophilic transition layer at their junctions. It is not yet well known the explication

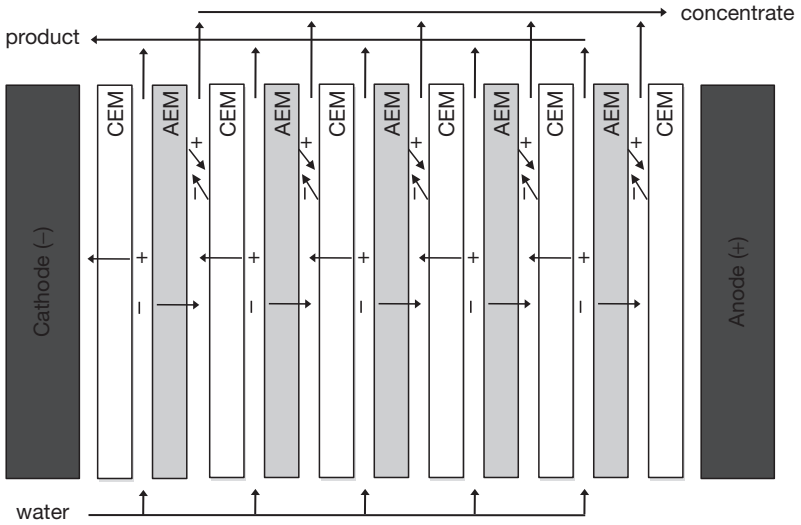


Figure 2 Principles of electrodialysis.

of the magnitude of the electric current and changes of pH value observed near the membrane with this method. In the case of the dairy industry, it is applied in the purification of fermented solution – lactic acid production from whey, production of caseinates, and fractionation of whey proteins.

Whey ED

Nowadays in the dairy industry, the ED is successfully applied, in order to obtain a whey raw material without mineral ions (ca. 6–15% in a solid base), keeping the microbiological quality, the native protein content, and key properties.

Whey and water are pumped through the track. The first is pumped in the interspace of adjacent sheets of membrane, while the second is pumped through the flat spaces between those interspaces (see Figure 2). The applied voltage encourages cations to move through the porous membranes from the whey into the water toward the cathode. Negatively charged, cation-selective membranes reject ions with the same charge, letting positively charged ions pass. The same happens with anions moving to the anode. Ions can be removed from whey by placing multiple membranes in a row, which alternately allow positively or negatively charged ions to flow through. In some columns concentration of ions will take place, and in other columns ions will be removed. The concentrated saltwater flow is circulated until it has reached a value that enables precipitation. At this point, the flow is discharged. Particles that do not carry an electrical charge are not removed.

All types of whey can be demineralized by ED. In order to minimize fouling and microbial contamination, some care must be taken. Operation conditions (flow rate, type of spacer, spacer thickness, etc.) and membrane type should be appropriated; in some cases, pretreatment is necessary before the ED can take place and do regular regeneration cycles. Suspended large particles (e.g., casein) and fat need to be removed, or else they will plug the membrane pores. For industrial applications, pretreatment methods should be performed in order to concentrate whey, leading to an increase of the efficiency of ED. Evaporation, NF, or RO are usually used. These complementary methods, namely the membrane ones, simultaneously demineralize whey at the time of concentration, helping in terms of cost, time, and water disposal. Whey preconcentration leads to a conductivity increase, with a large-scale migration of ions resulting in low electrical resistance, which is desirable in order to reduce energy losses and consequently intensify the process efficiency. Although when these complementary methods are used alone, they are suitable only for partial demineralization of whey, which is the same as what happens with DF. Beyond ED, high levels of desalting degrees could be achieved with an ion-exchange column. This technology presents some limitations, the major one being the need for lots of water and chemicals for the regeneration of resins. When ion-exchange and ED methods are compared, it can be verified that the ion-exchange column produces three times more waste water and chemical oxygen demand, four times more salt (expressed in mass), and higher cumulative energy demand than ED does.

Whey ED parameters

ED can be performed in continuous, feed-and-bleed (continuous with recycle), and batch recirculation processes; however, the last one is the most efficient and used mode for obtaining desalted whey because it leads to high levels of demineralization (90–95%). To obtain the same yield level in a feed-and-bleed system, several ED stacks in series are needed; in continuous mode, low demineralization levels are achieved during one pass through an ED unit.

Several actual studies deal with ED for whey demineralization parameters, among which can be highlighted ash, protein and lactose content, pH, titratable acidity, type of membranes and spacers, operating conditions (voltage, linear velocity, temperature), and others. Only pH can be continuously monitored during the process, and the maximum demineralization rate is obtained near the whey protein isoelectric point at pH 4.6, where the neutral global net charge is not involved in ion membrane cross. Conductivity is an important parameter to control during the process because it is intrinsically related to ash content. It can be measured online but requires calibration for different kinds of whey.

When referring to the ED unit, it can be seen that spacer thickness does not affect total demineralization time and energy consumption. The selectivity of transport of inorganic ions is observed; monovalent ions are transported preferably. It is unlikely that the voltage has a strong influence on demineralization time and energy consumption, with the application of higher voltage resulting in shorter demineralization time and higher energy consumption.

Whey ED advantages

The main advantages of membrane-based processes are feasibility of a substance separation without phase changes and additional chemicals, and energetically advantageous separation (low energy consumption), allowing high capacity of industrial units. Other advantages include easy operation of ED equipment, presenting a modular design, usually processed at ambient temperature, and also the chance for automation and continuing of these processes. Finally, membrane-based processes enable the demineralization of biological solutions with minimal losses of valuable compounds (proteins, lactose, etc.), without affecting their quality.

In the dairy industry, ED has great potential as an economical and efficient method.

Whey

Whey is the liquid remaining from the precipitation and curd removal during cheese manufacture. Like milk, whey may have different origins (e.g., goat, sheep, and buffalo), but the most relevant in terms of production volume and economical value is that obtained from cow milk processing; this will be the main focus of this text. Whey generally represents a volume fraction of 90% in milk and is classified in two different types: sweet whey, resulting from rennet-coagulated cheese with a pH of at least 5.6; and acid whey, obtained from acid-coagulated cheese with a pH below 5.1.

Up until very recently, whey resulting from the curd during manufacture of cheese was regarded as a polluting effluent from the dairy industry, being commonly discarded in rivers or lands (without any treatment), thus resulting in a serious environmental problem due to its high production volumes and organic content. This paradigm has been changed due to the combination of three critical driving forces: (i) legislation, (ii) potential of whey proteins, and (iii) evolution of technology. In short, legislative regulations, together with the growing consumer concern regarding environmental problems and incentives to recycle whenever possible, forced the dairy industry to explore other approaches to managing whey as a waste. Since Ancient Greece, whey has been claimed to be a cure for many illnesses, used as a medicine or as skin balm. Nowadays, the potential of a vast range of whey proteins and their peptides with great potential health benefits is well known. Despite these, application of whey or whey powder in human food products was always very limited due to the uneven composition of whey solids. However, the developments of separation technologies relying on selective porous membranes are allowing superior isolation and fractionation of whey components, which are undoubtedly becoming one of the most widespread additives in food. Consequently, over the last 40 years, the number of commercial and technological applications using whey has increased considerably. Digestion processes were applied as an important step to minimize the pollution problem caused by the deposition of this by-product through the use of enzymes and microorganisms, resulting in the production of commodities for other industries, such as monosaccharides and amino acids. Recently, whey gained interest as a food ingredient, coming into use as a technological agent particularly through whey proteins, achieving a unique blend between nutritional and functional properties with applications both in food and health.

Whey is a turbid yellowish liquid, consisting in its majority (90–94%) of water, while also having a high and diverse organic content. Its composition and characteristics may vary according to origin and producing method. Lactose is the major organic fraction present in whey, followed by proteins, minerals, lactic acid, and lipids. The general whey composition and its major applications are summarized in Table 1. Other minor components encompass citric acid, nonprotein nitrogen compounds (urea and uric acid), and vitamins of the B-complex.

Whey Proteins

Whey proteins are the most economically and technologically interesting fraction in whey. These proteins are globular molecules with a substantial content of α-helix motifs, in which the acidic/basic and hydrophobic/hydrophilic amino acids are distributed in a fairly balanced way along their polypeptide chains.

Whey protein fraction is mainly constituted by β-lactoglobulin (β-Lg), α-lactalbumin (α-La), immunoglobulins (IGs), bovine serum albumin (BSA), lactoferrin (LF), and lactoperoxidase (LP), representing at least 50%, 20%, 10%, 10%, 3%, and 0.3%, respectively. The general physiochemical properties of whey proteins are listed in Table 2.

Whey Protein System

Since the 1920s, efforts have been made to concentrate whey, essentially using heat-drying methods. However, these efforts never resulted in commercial and technological interest once the characteristics of the obtained product (i.e., yellow-brownish colour) and their composition (i.e., high content of lactose and denatured protein), coupled with the high costs of the process, limited their use. Later, with the implementation of an innovative process (i.e., spray drying), the thermal degradation of whey components, as well as the cost associated to its concentration reduced significantly. Nevertheless, not until the 1970s, with the utilization of membrane filtration, was it possible to achieve an efficient separation and concentration of whey protein fractions while preserving their integrity. This technique employs semipermeable surfaces (membranes) with specific pore sizes, where the permeate flows though while the retentate is blocked based on size/molecular weight. Throughout the combination of successive filtrations steps, it is possible to produce protein fractions with different compositions and degrees of purity. These fractions can then result in a dry product if followed by a spray-drying process. This technology leads to a selective concentration of proteins, which after drying is called whey protein concentrate (WPC). This whey product contains different protein concentrations (usually ranging from 35% to 80%) and appreciable amounts of lactose and minerals, thus fitting several applications. Further purification, often conjugating other techniques as

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00747-9

ion-exchange chromatography, allows the achievement of higher degrees of purity with residual or no lactose content and higher desalination, resulting in whey protein isolate (WPI) containing at least 90% protein. With the application of more advanced techniques, such as chromatography, partial hydrolyses, and selective precipitation combined with centrifugation and dialysis, it is yet possible to obtain pure whey protein fractions. Figure 1 shows the main whey protein processing approaches to obtain different whey protein subproducts and products, and purer fractions.

Nowadays, whey protein fractions have a vast range of applications in several areas. Nutrition is by far the most important, although there is growing interest in the pharmaceutical field, particularly regarding enriched whey protein ingredients, essentially due to their biological activities.

Concentrated whey is typically incorporated in animal feed or used as a component in growing media for bacteria, yeast, and algae. Small quantities may also be incorporated in human food, although its high salt and lactose contents, together with low protein composition (~10%), do not make it attractive for this purpose.

Among concentrated whey products, WPI followed by WPC gather suitable characteristics for food applications such as higher protein and amino acid contents; low calorie, fat, and sodium contents; absence of pathogens and toxic compounds; biocompatibility and generally recognized as safe status; ready availability; and inexpensive products. Some of these potential food applications will be discussed below in a critical manner.

Table 1 Whey composition profile, their relative concentration, and main applications

Whey component	*Concentration ($g\ l^{-1}$)*	*Applications*
Lactose	45–60	Browning agent, sweet syrups, fermentation substrate
Proteins	6–11	Nutrition, technological agents, bioactive compounds
Minerals	8–10	Nutrition, fertilizers, growing medium
Lactic acid	0.5–9	Food preservative, acidulant, biodegradable plastic component
Lipids	0.6–5	Nutrition

Table 2 Composition of major proteins in bovine whey, their relative concentration, molecular weight (Mw), and number of amino acid residues

Whey protein	*Concentration ($g\ l^{-1}$)*	*Mw (kDa)*	*Amino acid residues*
Total	7.0	–	–
β-Lactoglobulin	3.5	18.3	162
α-Lactalbumin	1.2	14.2	123
Immunoglobulins	0.7	150–900	[a]
Bovine serum albumin	0.4	66.4	583
Lactoferrin	0.02–0.35	80.0	700
Lactoperoxidase	0.01–0.03	78.5	612

Whey Protein Biological Properties

The development of new processing technologies and more sophisticated analytical methods has allowed better insight into the nutritional and biological properties of whey proteins and whey-derived products and their role in human health, including prevention of diseases and health conditions. Whey proteins exhibit a range of biological activities that influence digestion, metabolic responses to absorbed nutrients, growth and development of specific organs, and resistance to disease. Other biological activities of the individual whey proteins, and

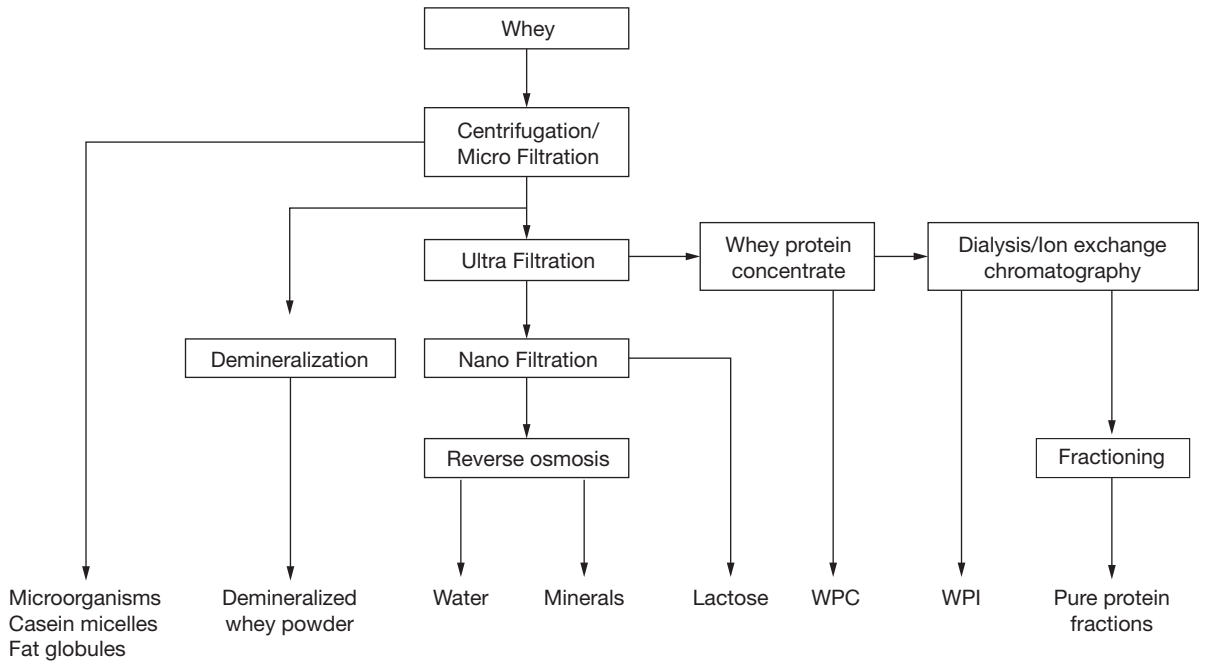

Figure 1 Liquid whey processing strategies to obtain protein-based ingredients.

of their fragments obtained by hydrolysis (termed bioactive peptides), include antihypertensive, antimicrobial, opioid, antioxidant, antiviral, immunomodulant, anticarcinogenic, or mineral binding. The main biological activities of whey proteins are summarized in Table 3.

The physiological effect of whey proteins can be attributed to their fast digestion, which leads to a rapid increase in serum amino acids after ingestion. After exercising, people enter in a form of metabolic stress that requires immediate availability of usable energy, which can be gathered by the consumption of essential amino acids (e.g., leucine, isoleucine, and valine). Therefore, whey proteins, via their composite amino acid residues and/or associated compounds, can provide substrates and bioactive components that permit extending the overall benefits of regular physical activity. Thus, whey proteins have been the protein source choice by elite athletes, in addition to those people whose health is compromised. Moreover, these proteins can contribute to improving muscle strength and reducing the tendency for bone breaking. These features are once again directly related to the unique amino acid sequences. Furthermore, whey protein dairy consumption has been shown to play an important role as a metabolic regulator in protein and glucose homoeostasis and in lipid metabolism; this allows better weight control, lower plasma and liver cholesterol, and lower plasma triacylglycerol levels, and helps to reduce fat deposition and improve insulin sensitivity.

Table 3 Biological activities and potential health benefits of whey protein consumption

Protein	*Biological activity*
Whole whey protein	Prevention of cancer (e.g., breast and intestinal cancer) Increment of gluthatione levels Increase of tumor cell vulnerability HIV treatment Antimicrobial activities Increment of satiety response Increment in plasma amino acids, cholecystokinin, and glucagon-like peptide
β-Lactoglobulin	Transporter of retinol, palmitate, vitamin D, cholesterol, fatty acids, and triglycerides Protection during passage through the stomach conditions Development and transfer of passive immunity Regulation of mammary gland metabolism Anticarcinogenic activity Immunomodulatory activity
α-Lactalbumin	Anticarcinogenic activity Lactose synthesis Treatment of chronic stress-induced disease
Bovine serum albumin	Synthesis of lipids Antimutagenic activity Antioxidant activity Anticarcinogenic activity
Immunoglobulins	Immunomodulatory activity Growth and development Disease protection through passive immunity Antibacterial activity Antifungal activity Opioid activity HIV treatment
Lactoferrin	Antimicrobial activity Antifungal activity Antiviral activity Antithrombotic activity Immunomodulatory activity Antiproliferative activity
Lactoperoxidase	Antimicrobial activity Antifungal activity Immunomodulatory activity

β-Lactoglobumin

β-Lg is a small, soluble, and globular protein. Its actual biological functions are still unclear; however, it can bind to small hydrophobic ligands acting as carrier systems of these compounds, for example, retinol, fatty acids, triacylglycerols, aromatic compounds, vitamin D, cholesterol, palmitic acid, and calcium. Reported biological activities for β-Lg are summarized in Table 3. The homology of β-Lg tertiary structure with the plasma retinol-binding protein, as well as its high stability to proteolytic activity of digestive enzymes, has suggested that this protein can act as a resistant carrier of retinol. Moreover, its high stability at low pH protects hydrophobic molecules during passage through the stomach, in order to permit a specified delivery of such compounds to receptors located in the intestine, thus facilitating the digestion of milk lipids.

β-Lg plays also an important role in developing passive immunity with immunoglobulin G and in its transference to the newborn, and in regulation of phosphorus metabolism at the mammary gland. The amino acid content of this protein is rather important because, besides stimulating muscle growth, it is a rich source of cysteine, which is essential for synthesis of glutathione, an anticarcinogenic tripeptide produced by the liver for protection against intestinal tumors.

The high nutritional and functional value of β-Lg is now widely recognized and has made of this protein an ingredient of high quality in the formulation of modern foods and beverages.

α-Lactalbumin

α-La is a small and globular protein rich in cysteine, essential as a coenzyme for the biosynthesis of lactose – an important source of energy. Some important bioactivities have been reported for α-La (see Table 3).

α-La contributes to reducing the risk of incidence of some cancers (e.g., breast and colon cancer), as it constrains cell division when present in intestinal cell lines. This whey protein has also been associated with the treatment of chronic stress-induced cognitive decline due to its high tryptophan content (~6%); tryptophan (as a precursor of serotonin) is important for maintaining the essential levels of serotonin in the brain for good cognitive performance.

Bovine serum albumin

BSA is not synthesized in the mammary gland; it appears in milk through passage from the blood stream. Due to its size and structure, BSA can bind to fatty acids, which are stored in the human body as fat, or to free fatty acids and flavor compounds, hence participating in synthesis of lipids (which are a part of all outer and inner cell membranes) and in energy production. Moreover, this whey protein has revealed antioxidant activity, thus protecting lipids against phenolic oxidation, and potent inhibitory activity against breast cancer cell proliferation through modulation of activities of the autocrine growth regulatory factors (see Table 3).

Immunoglobulins

IGs represent the most abundant of the established bioactive proteins found in whey. IGs constitute a complex group of globular proteins produced by B-lymphocytes, making a significant contribution to the whey protein content, besides exerting an important immunological role. IGs are present in the serum and physiological fluids of all mammals; some of them attach to surfaces where they behave as receptors, whereas others function as antibodies that are released in the blood and lymph. These whey proteins protect the gut mucosa against pathogenic microorganisms; impart passive immunity; combat infections, providing protection against diseases, particularly in a neonate until its own immune system is developed; improve physical performance and recovery times in athletes; and allow faster recuperation of immunocompromised persons. Important biological properties of IGs are summarized in Table 3.

Lactoferrin

Lactoferrin, also known as lactotransferrin, is a globular multifunctional protein that binds, transports, and supplies the organism with iron. It is present in the human body as a secretor protein and is synthesized by glandular epithelial cells and mature neutrophils. LF possesses antimicrobial activity attributed to the aforementioned iron-binding property, as it makes such cation unavailable to the (otherwise active) microorganisms, or by direct binding to their microbial membrane. The antimicrobial activity of this protein is not restricted to bacteria, but is available also to a wide range of other microorganisms, including fungi and some viruses (Table 3).

LF plays a relevant role upon stimulation of the immune system, owing to the increase of macrophage activity mediated thereby, as well as upon induction of inflammatory cytokines, stimulation of proliferation of lymphocytes, and activation of monocyte (natural killer) and neutrophil cells. This whey protein also stimulates humoral immune response to sheep red blood cells, promotes appropriate intestinal and peripheral specific antibody response, and modulates production of lymphokines. Moreover, LF has been shown to potentiate bone growth enhancement properties manifested through stimulation of growth of osteoblasts and inhibition of osteoclasts (Table 3).

Lactoperoxidase

LP is a member of the family of mammalian peroxidases, and is an important part of the natural host defense system in mammals, which provides protection against invading microorganisms. This protein, combined with LF, displays suppressive effects on mitogen-activated lymphocyte proliferation. LP also regulates expression of genes involved in the metabolism, immunity, apoptosis, and cell cycle of epithelial intestinal cells, while also displaying an important role in controlling microorganism growth in milk from lactating animals, and in cell-mediated pathogen killing. Additionally, this whey protein plays a significant function in oral health care, promoting the inhibition of harmful microorganisms associated with gingivitis and oral irritation, and combating both the causes and effects of halitosis. Biological activities for LP are summarized in Table 3.

Other Bioactive Components in Whey

Lactose and oligosaccharides

Lactose is the major carbohydrate in whey and is a valuable nutrient because it favors the intestinal absorption of essential minerals such as calcium (Ca), magnesium (Mg), and phosphorous (P), and the use of vitamin C. On the other hand, whey oligosaccharides possess prebiotic and anti-infective properties. Many of these oligosaccharides contain sialic acid; this compound present in whey seems to promote several positive effects in the human body, with particular relevance during the development of the infant's brain.

Minerals

Many major and trace minerals play an important role in the physiology and metabolism of the human body. The most abundant elements are Ca, sodium (Na), P, Mg, and potassium (K), while those present in minor amounts encompass zinc (Zn), iron (Fe), copper (Cu), and manganese (Mn). The levels of Ca, P, Mg, Zn, Fe, and Cu are higher in sheep than in cow whey; the opposite appears to be the case for K and Na. Goat whey contains about 134 mg of Ca and 121 mg of P per 100 g. Na and K are almost entirely soluble and fully available in whey, whereas Ca, Mg, and P are associated in different proportions to the colloidal suspension of casein micelles and, therefore, are partly retained in the curd during cheese-making. The presence and concentration of these minerals, essential for the proper functioning of the human body, varies depending on the element and on the needs of each person.

Vitamins

Vitamins are physiological, biochemical, and metabolical bioactive molecules of small dimension and low molecular weight, being divided into liposoluble and water-soluble vitamins according to their solubility. They are essential for the growth, development, and normal maintenance of human organisms. However, humans do not have the capacity to synthesize vitamins, except vitamins D and B_3, meaning that they must obtain them through external sources. Therefore, whey appears as a suitable source of these compounds, as it is extremely rich in vitamins. However, part of the liposoluble vitamins remain in the curd during cheese-making, whereas water-soluble vitamins go into the whey. In the literature, it is described that sheep whey is richer than cow whey for most of the vitamins. For instance, goat and sheep whey have higher amounts of vitamin A than do their cow counterparts. However, goat whey has a significant dearth of folic acid and vitamin B_{12} compared to cow whey.

Applications

Industrial Applications – Overview

Whey ingredients are an excellent way to increase the overall nutritional value of foods. For example, whey ingredients with low protein content, such as WPC, are frequently used in low-value products such as dairy and bakery. More purified products such as WPI are used in high-value products such as meat, seafood, confectionaries, health foods, infant formula, and sports supplements. Besides nutritional aspects, these ingredients have found several applications as technological agents regarding gelation, thermal stability, foam formation, or emulsification. Additionally, pure fractions of whey proteins have the potential to enable the development of novel food products with improved functionalities, as well as new applications in nutrition, cosmetic, and pharmaceutical industries.

Figure 2 summarizes some of the most relevant industrial applications of whey components in food. In particular, functional properties of WPC and WPI are very interesting and render these two whey protein ingredients extremely versatile. They support the development of food products, as follows:

- Improve aeration in bakery and confectionary products.
- Improve color and taste by interaction between proteins and lactose during thermal processing (Maillard reactions) in candy products (e.g., toffees, caramels, and cooked syrups).
- Replace skim milk powder in dairy product formulations (e.g., yogurt, ice cream, and milk chocolate drinks).
- Improve quality of meat and fish due to emulsion, gelation, and hydrophilic attributes.
- Develop infant formula with nutritional benefits by adapting infant formula to that of human milk.
- Increase bioavailability of salts such as Ca and Zn in elderly foods.
- Develop dietetic foods with high satiety value – low fat and high protein content, with an excellent amino acid composition.
- Develop nutraceuticals due to the presence of important bioactive proteins (e.g., LF and LP).

Together with the applications listed above, whey proteins are being successfully used in the production of edible films and coatings, with the purpose of improving the shelf life of perishable food products. In addition, the by-products of whey protein concentration (i.e., lactose and Ca-rich milk) are also valuable, as previously shown. They are becoming increasingly useful in pharmaceutical and dietary supplement food markets. Lactose is mainly used as an excipient in tablet processing, and the milk minerals are used for the fortification of various foods and beverages with Ca. In the following subsections, the use of whey components for the development of both bioactive packaging systems and functional foods will be pointed out.

Bioactive Packaging

Food packaging has evolved considerably during the last decades to have new functionalities and to assist in meeting the demands of extremely stringent markets that constantly trigger the development of stable and fresh food products. Depending on the type of food, packaging materials need to fulfill different requirements in terms of light, moisture, water vapor, and gas (i.e., oxygen and carbon dioxide) barriers in order to avoid color or taste deterioration, loss of nutritional value, and eventually growth of potential pathogens. To fulfill these requirements, there is an ongoing interest in sustainable packaging materials throughout the use of renewable/biodegradable and edible biopolymers (e.g., proteins, polysaccharides, and lipids), in an attempt to replace environmentally unfriendly petroleum-based plastic films, which are still widely used in the packaging industry. Whey is one of the most promising biopolymers in the field of packaging. Currently, the best potential applications of whey protein-based edible films lie in protective coatings for foods. When applied on surfaces of food as a coating, these films can protect food from chemical or microbial degradation, thus lengthening product shelf life and maintaining high product quality. Further, edible films and coatings manufactured from whey proteins have demonstrated mechanical and barrier properties better than competitive protein-based (e.g., corn zein, wheat

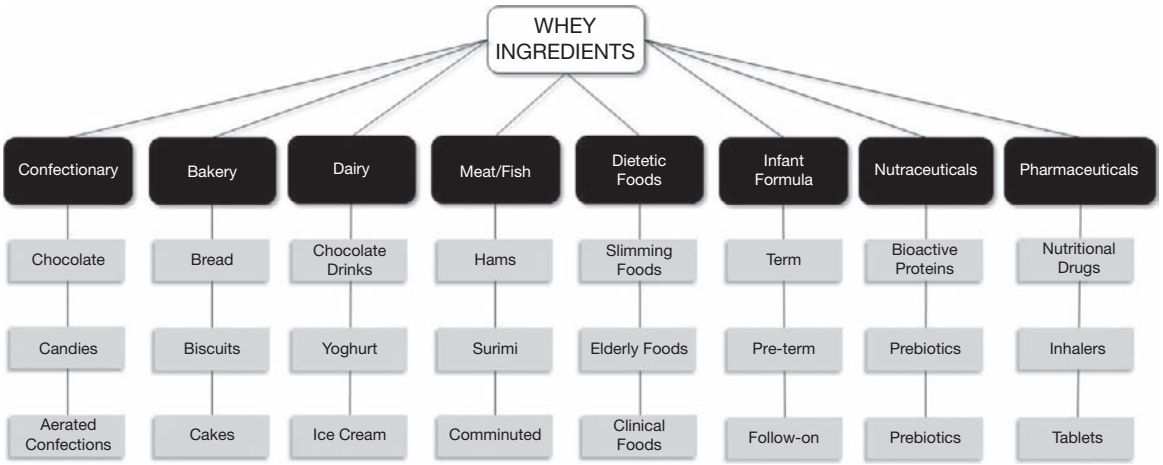

Figure 2 Various industrial applications of whey ingredients. Adapted from de Wit, J. N. (2001). *Lecturer's handbook on whey and whey products*. Brussels: European Whey Products Association.

gluten, and soy protein isolate) or polysaccharide-based (e.g., starch, cellulose, carrageenan, and pectin) films.

Whey protein films and coatings have already been applied in several food products such as peanuts, walnuts, frozen salmon, fruits, and breakfast cereals, aiming for good aroma, fat, moisture, and gas oxygen barriers. They also have the potential to improve the appearance of food products by adding gloss. Several examples of whey protein-based coating and film applications are described. In particular, these have the potential to increase the shelf life of roasted peanuts by reducing lipid oxidation and avoiding the appearance of rancid off-flavors. Fresh-cut fruits and vegetables can also be better preserved due to the minimization of both moisture loss and oxidative browning. These coatings also provide an efficient protection of frozen salmon against lipid oxidation and water loss. In addition to the aforementioned features, those edible films can be the vectors of various bioactive agents, such as antimicrobials, antioxidants, nutraceuticals, or even flavors and colorants, enhancing not only food quality and safety, but also functionality while providing some health benefits for the consumer. Films or coatings carrying antioxidants in their composition have shown promise for minimizing rancidity in meat products. Active antimicrobials approved for use in contact with foods (e.g., nisin, sorbic acid, and potassium sorbate) can be incorporated in whey protein film matrices protecting food from microbial spoilage. Current research on antimicrobial packaging and coatings is being directed toward the surface protection of cheese, meat, and fruit products. In fact, antimicrobial food packaging using edible whey protein films is starting to be envisioned as a part of the hurdle technology, thus reducing the risk of pathogen contamination and extending the shelf life of perishable food products, when in combination with other processes. In addition, whey protein edible films can be employed to carry flavor compounds, thus providing a way to minimize the deleterious effects of aroma loss. Flavor and aroma can be incorporated into a coating for delayed release in order to improve the flavor profile of the food. This release can occur during the intermediate steps of food preparation (heating or rehydration), or even in the mouth by mastication.

Development of Functional Foods

Food and pharmaceutical industries are constantly triggering the development of novel products with a strong nutraceutical function using whey or whey-derived ingredients (e.g., WPC and WPI) as a valuable source. The list of nutraceutical compounds associated to whey-derived products includes vitamins, probiotic cultures, and bioactive peptides, and the scientific evidence to support health benefits, either by prevention or treatment of some diseases, is steadily growing. As previously shown, a diverse group of bioactive proteins with antimicrobial activity can be obtained from whey, such as in the case of LP, lysozyme, and LF.

However, whey proteins and their properties have been extensively studied not only due to their importance as food ingredients, but also due to their ability to serve as vehicles for bioactive compounds. Gelation properties of globular proteins such as β-Lg allow the development of micro- and nanostructures such as microgels, nanohydrogels, nanofibrils, and nanotubes. Figure 3 illustrates the wide range of structures (macro, micro, and nano) that can be developed for the

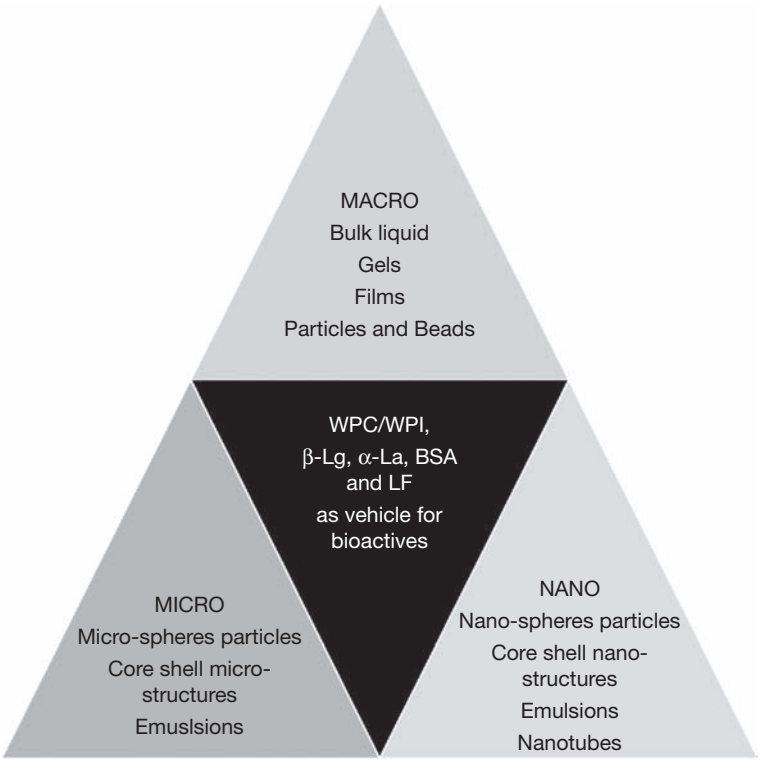

Figure 3 Globular whey protein systems used as vehicles of bioactive compounds in foods.

encapsulation and controlled release of bioactive compounds using whey proteins as a carrier system. Microgels have been specifically targeted for two main functions: (1) as a means to tune more precisely the texture and mouthfeel of food, especially as a replacement for fat; and (2) to encapsulate functional food ingredients or other nutraceuticals that have potential health benefits (e.g., vitamins, flavor volatiles, antioxidants, omega-3 fatty acids, phytosterols, flavonoids, and folic acid). Regarding nanostructures, the swelling capability is the most important characteristic feature and is attributed to the presence of hydrophilic moieties such as hydroxyl, amino, and carboxyl groups in the protein structure. These structures, known as nanohydrogels, can absorb or expel water in response to several stimuli as small changes in pH or temperature. This capability is responsible for their soft and elastic properties, but more important, it makes protein nanohydrogels an ideal structure for use in the encapsulation and controlled release of bioactive compounds in specified sites of the gastrointestinal (GI) tract. Further, the ability of globular whey proteins to form gel networks under cold conditions is also attracting attention due to the possibility of applicating these structures in novel food and nonfood areas. The formation of cold-set gels opens interesting opportunities for food proteins as carriers of heat-sensitive nutraceutical compounds.

Whey proteins can be used in clinical foods aiming at providing supplemented nutritional support to persons/patients who are incapable of digesting adequate amounts of conventional food products or who have special nutritional needs. After a starting stage of digestion and absorption in the stomach (under acidic conditions and pepsin), dietary whey proteins can be further hydrolyzed by pancreatic enzymes (chymosin and chymotrypsin), resulting in a combination of unique amino acids and small peptides with remarkable physiological functions (e.g., stimulation of growth factor and blood flood regulation). *In vitro* hydrolyzed whey proteins can also be used on patients with deficient enzymatic digestion or with specific diseases, having the need of parenteral diets (i.e., small amino acids and peptides injected directly into the blood stream) and enteral diets (i.e., oral diets containing larger peptides that can be further digested in the GI tract). However, in this case, food formulae demand high levels of purity and low allergenicity, thus entering in the category of hypoallergenic foods. Lactose, also a major component of whey, can be used as an excipient in the formulation of pharmaceuticals such as tablets, capsules, and inhalers. Lactose has a wide range of derivatives, including lactobionic acid (produced by oxidation), lactulose (produced by isomerization), lactitol (produced by hydrogenation), galactooligosacccharides (produced by hydrolysis and chain extension), galactose, and glucose (produced by hydrolysis). This range of derivatives has great versatility acting as nutritional supplements, as carriers of antibiotics and protection against diseases (e.g., colon cancer).

Concluding Remarks

There is now increasing evidence that many whey components, particularly proteins and their factions (peptides), are effective in reducing the risk of developing some diet-related chronic diseases. As a result, there is growing interest by the dairy, food, and pharmaceutical industries to design and formulate products (e.g., functional foods) that incorporate bioactive components of whey proteins, nutraceuticals, or active medicinal agents in an effort to meet consumer trends for health and well-being. In fact, the dairy industry has achieved a leading role in the development of functional foods and has already commercialized several products that boost the immune system, kill pathogenic microorganisms, or reduce blood pressure. Also, fractionation and marketing of bioactive whey ingredients has emerged as a lucrative new sector for dairy industries and specialized bio-industries. In leading dairy countries, this industrial sector is moving from commodity marketing to the ingredient marketing business, which entails good prospects for adding more value to the products. Current challenges in the exploitation of bioactive components are their maximal recovery from milk, colostrum, whey, and milk fat; their stability in different food matrices; and their optimal bioavailability in the body in order to deliver expected health effects. To meet these challenges, it is crucial to develop appropriate technologies and product concepts, as well as to verify their bioavailability not only upon ingestion, but also through the digestive tract, and after absorption through the intestinal walls into the blood circulation system using *in vivo* tests.

Cheese Whey

Health is one of the major reasons that determine consumer's choices of food; following and maintaining a healthy diet is crucial. However, the difficulty in having consumers change radically their eating habits has led to the emergence of a number of foods that have the same appearance as the conventional ones but that contain certain functional ingredients able to bring health benefits in addition to responding to the nutrition issue.

The liquid portion obtained during the coagulation and syneresis process in a cheese production is a by-product called whey (the water-soluble fragment). That can be found in different sources, depending on which milk it arises, although the majority is derived from cows. The worldwide production of bovine whey is estimated as ca. 10^8 tons per year. Unfortunately, all over the world, a great part of whey does not undergo those downstream processing routes, so a significant portion is (1) sprayed onto fields while the resulting smell and salt levels often prove troublesome; (2) discharged into rivers, lakes, or seas, although the very high polluting power usually precludes other species to survive therein; (3) or discharged into municipal sewage systems. These discharges cause serious environmental problems, because whey is a strong organic pollutant – with particularly high biological oxygen demand (40–60 g l^{-1}) and chemical oxygen demand (50–80 g l^{-1}).

An increased interest in whey protein products, owing to their nutritional role and their role upon human health, has been seen in the last decades. There are two categories of food uses for whey: as raw material for fermentation (due to its high lactose content) aiming at the production of bioproducts or through its protein components as whey protein isolates, whey protein concentrates, whey fractions, and heat-stable whey proteins to bioactive peptide production derived therefrom. These science-based nutritional solutions are perfectly formulated for the production of functional ingredients showing a variety of functional, physiological, and nutritional properties that make them potentially useful in a wide range of applications, such as healthy beverages, nutrition bars and supplements, and pharmaceutical preparations – thus providing a promising alternative for whey upgrade.

Whey Protein Composition

Whey retains c.50% of the total milk nutrients; the most important components of whey are soluble proteins (0.6–0.8%, w/v) that represent 20% of total milk proteins, namely, β-lactoglobulin (β-Lg), α-lactalbumin (α-La), immunoglobulins (Igs), bovine serum albumin (BSA), lactoferrin and lactoperoxidase enzymes and caseinomacropeptide, lactose (4.5–5%, w/v), lipids (0.4–0.5%, w/v), and mineral salts (8–10%, w/w using a dry extract basis). The concentration of whey protein could vary depending on the source of milk, time of the year, type of feed, stage of lactation, quality of the cheese manufacture process, and the type of whey (acid or sweet). Whey proteins have unique characteristics. Beyond their great importance in nutrition (supply energy and essential amino acids), they exhibit chemical, physical (gel formation, foam stability, and water retention), physiological (useful in therapies, including antimicrobial and antiviral actions, immune system stimulation, and anticarcinogenic activity), functional (growth and cellular repair), and technological features. Based on these properties, individual proteins and protein concentrates of whey have been incorporated in food formulation by industry. The most relevant whey proteins are briefly characterized in Table 1.

Key components of whey

What makes the whey proteins being so high quality in what concerns to biological activities? The amino acid content of each protein influences whey protein products' bioactivities, being one of the reasons for such success. Whey proteins are rich in sulfur-containing amino acids (i.e., cysteine and methionine); therefore, they are susceptible to intramolecular bond formation via disulfide bridges.

The high content of cysteine leads to achieve whey as an important and cheap container of dietary L-cysteine. Although this amino acid is not an essential one (can be synthesized from methionine), it appears to have some manner of deficiency syndrome associated with it, at least indirectly via glutathione. Glutathione, tripeptide in which cysteine is the limiting substrate, is an antioxidant molecule responsible for several functions, including immune-modulation mechanism, cellular defense against oxidative stress, and detoxification. Aging, cancer, and HIV patients are supplemented with whey protein in order to increase glutathione levels. A lack in glutathione is a common problem in HIV-infected individuals. Cysteine could be itself an adjuvant in diabetes type II therapy. As mentioned before, theoretically, an increase in cysteine leads to an increase of glutathione production that can relieve the risk of diabetes when this is caused by oxidative stress. Otherwise healthy persons can also benefit when taking a whey protein supplement. The increase of glutathione levels leads to the increase of resistance training.

In addition to the glutathione production and its role in the defense against oxidative stress and detoxification, cysteine might also have an important role on hydrogen sulfide (H_2S) cardioprotective control. H_2S is produced and transported by the enzyme action, acting as a signaling molecule, promoting vasorelaxation of blood vessels. It is also characterized by antioxidative capabilities. Low levels of H_2S increase homocysteine levels, which is an indicative of heart and neurovascular diseases. H_2S is derived from a circulating cysteine pool that remains in storage in the body and fit to buffer a pool of H_2S that preserves physiological functions.

Table 1 Whey protein characterization

Proteins	*Concentration (% whey dry bases)*	*MW (kDa)*	*Solubility*	*Structure*	*Source of*	*Properties*
β-Lactoglobulin	50	18.4	Solubility depends on pH and ionic charge pI: 5.2 Temp. >65 °C, pH 6.5 Denature and aggregate formation Temp. < 65 °C pH 5.2–7.2 – stable dimmer pH 3.2–5.2 – octamer formation pH 3.0 and 8.0 – monomer Do not precipitate during milk acidification	Globular protein with rigid spatial structure Composed mainly of β-sheet motifs Monomer: 1. Free thiol group 2. Disulfide bridges	BCAAs (25.1%) Leucine (13.5%) Cysteine	Gelling capacity Structuring and stabilizer agent Resistant to gastric digestion Binds small hydrophobic molecules assuming their transport Stimulates glutathione synthesis (Cys content) High nutritional value (high sulfur content) – sport supplements
α-Lactalbumin	20–25	14.2	pI: 4.7–5.1 Low pH, high temperature, or moderate concentrations of denaturants – 'molten globule' Neutral pH the 'apo' state (partially unfolded state) pH > 6.7 Irreversible denaturation/ aggregation Temp. <75 °C *R*eversible denaturation	Compact globular protein – highly heterogeneous, 26% α-helix, 14% β-sheet (significantly unfolded), and 60% of other motifs 4 Disulfide bonds make this protein relatively heat-stable The 'molten globule' presents a balance between native and unfolded states Ca^{2+} stabilizes the conformation of chiefly the β-sheet domain	Essential amino acids BCAAs Leucine (10.6%) Isoleucine Valine Aspartic acid (10.6%) Cysteine	Structure and composition with 72% homology to human α-lactalbumin – supplements for infant formula High nutritional value (amino acid content) – sport supplements Lactose biosynthesis – acting as a coenzyme

(*Continued*)

Table 1 (Continued)

Proteins	*Concentration (% whey dry bases)*	*MW (kDa)*	*Solubility*	*Structure*	*Source of*	*Properties*
					(6.5%) Tryptophan	
Immunoglobulins	10–15	150–1000	pI: 5.5–8.3	Small Y-shaped proteins (4 polypeptide chains) 2 Light 2 Heavy Bond by disulfide bonds	Cysteine	Not inactivated by gastric acids Partially resistant to proteolytic enzymes
Caseinomacropeptide	10–15	8	pI: 4.0–5.0 pH 1–10 – soluble Temp. 80–95 °C, pH 4 and 7, 15 min – soluble pH 1–5 – minimum solubility (88%) Emulsifying activity – minimum near pI Decrease in pH – decrease in CMP volume	Glycosylates through *O*-glycoside bridge Phosphorylates by phosphorylation of a Ser residue (conditions without post-transcriptional modifications)	BCAAs Acidic and hydroxyl amino acids	Increases absorption of Zn^{2+} Interactions with cellular components, for example enterotoxins, bacteria, and viruses Ingredient in diets, patients with liver diseases and phenylketonuria (amino acid content) Interactions with hormone cholecystokinin Sialic acid – regular functioning of cell membranes and membrane receptors Lactose synthesis
Bovine serum albumin	5–10	69	pI: 4.7–4.9 Heat-induced gelation at pH 6.5 pH 4.5–8.0 – forms a heart-shaped molecule	Globular protein 17 Intrachain disulfide bonds 1 Free sulfhydryl group	Essential amino acids	Binds small hydrophobic molecules – assuming their transport
Lactoferrin	1–2	78	pI: 8.0–8.5	Monomeric glycoprotein 1–4 Glycans (depending on the species)	BCAAs Leucine (9.58%) Alanine (9.72%)	Iron-binding glycoprotein Iron transport and absorption in the gut
Lactoperoxidase	0.5	89	pI: 9.6 Acidic pH – more active			Catalyzes oxidation of thiocyanate (SCN^-)

They also present a high concentration of branched-chain amino acids (BCAAs) (in some cases higher than 26%) – leucine, isoleucine, and valine, being important factors in tissue growth and repair. Leucine has been identified as the key amino acid in protein metabolism during the translation–initiation pathway of protein synthesis. In that order, leucine-rich proteins are efficient in improving muscle protein synthesis. It has been speculated that the quality of a particular protein for enhancing muscle hypertrophy and stretch is related with the content of leucine. Thus, nutritional supplements containing these proteins may be efficient in preventing sarcopenia in the elderly and would represent a safe and convenient nutritional strategy. In addition, a high leucine concentration leads to enhance the immune function through intracellular conversion to glutathione.

Tryptophan is the precursor of niacin, serotonin neurotransmitter, and melatonin hormone; the last two regulate many neurobehavioral effects, for example, appetite, satiety, mood, airway sensory perception, pain sensation, and rhythm of sleep and wake.

Zinc is an essential mineral involved in bone, hormone, and enzyme metabolism.

Variants of Whey

The emergence of new processing technologies and more sophisticated analytical methods has permitted the production of a number of whey protein components already available in the market and used as additives. Those products comprise whey protein isolate (90–95% protein), almost pure protein; whey protein concentrate (ranging from 25 to 89% protein), most commonly available as 80%, with reduced lactose, fat, and mineral contents (as protein concentration increases, fat, lactose, and mineral contents decrease); hydrolyzed whey protein, presenting a variable protein concentration in which fat, lactose, and mineral contents also vary with protein concentration (hydrolysis used to obtain smaller peptide fractions, with an increase of bioactive peptides, reduces allergic potential and a theoretical improvement of solubility and digestibility when compared with nonhydrolyzed whey protein); and, finally, undenatured whey concentrate, presenting a variable protein concentration that usually ranges from 25 to 89%, processed to preserve native protein structures, and typically has higher amounts of immunoglobulins and lactoferrin. This variability is important when choosing whey fractions for specific nutritional applications.

Whey and Whey Protein Features

Whey protein is classified as high-quality protein based on human amino acid requirements, digestibility, and their bioavailability. Besides being susceptible to catalysis, they can be hydrolyzed via gastric, pancreatic, and microbial proteases, thus generating peptides that may present biological activity. Nevertheless, advances in nutritional biochemistry and biomedical research have undergone a notable intensification in search of peptides obtained via controlled *in vitro* hydrolyses in order to better understand the complex relationship between nutrition and prevention and/or treatment of diseases. Accordingly, scientific evidences have shown a wide range of peptides playing crucial physiological functions and modulating some regulatory processes. However, only some of such health effects, found *in vitro*, have eventually been confirmed in studies encompassing human volunteers.

Studies showed that whey proteins appear to be resistant to gastric digestion and pass quickly to the intestinal tract. Due to the lack of hydrolysis in the stomach, there is no apparent difference between the time of digestion and absorption and subsequent plasma amino acid profile of a whey isolate and a whey hydrolyzate. It was also found that whey protein takes ca. 40–60 min to reach the blood plasma after ingestion.

A number of favorable health effects have indeed been claimed for some whey protein concentrate, isolate, or its hydrolyzate. They truly open up a wide range of possibilities, within the market, for functional foods. They are able to affect the cardiovascular, nervous, digestive, or immune systems, including antimicrobial properties, and being implicated in diseases such as cancer, diabetes, osteoporosis, stress, obesity, or cardiovascular complications. The main biological activities of whey proteins related with specific diseases and its respective studies are listed in Table 2.

In terms of whey powders, biological function of their proteins is not fully known. Nevertheless, there has been an effort to enhance and justify the market product claims.

Whey proteins have been shown to lower plasma and liver cholesterol, as well as plasma triacylglycerol levels in model animals fed with cholesterol-containing diets. High-protein dairy products, and in particular those that contain whey proteins, may reduce fat deposition and improve insulin sensitivity.

Whey hydrolyzates are characterized by a low degree of allergenicity and very rarely cause adverse reactions. Currently, a hypoallergenic, hydrolyzed formula is recommended to children nonbreast-fed or partially breast-fed with a high allergy risk. The risk for atopic dermatitis in high-risk infants can be reduced with certain whey milk hydrolyzates when breastfeeding is insufficient.

β-Lactoglobulin animal studies suggest reduction of blood pressure by inhibition of angiotensin-converting enzyme and exhibition of immune-enhancing activity. *In vitro* studies reveal that β-lactoglobulin, chemically modified by 3-hydroxyphthalic anhydride, shows antiviral activity against human herpes simplex virus type 1 (HSV-1) and its hydrolyzate antimicrobial activity against several gram-positive bacteria and bactericidal activity.

α-Lactalbumin contributes to reduce the incidence risk of some cancers, and its hydrolyzate reduces the blood pressure. This whey protein has also been associated with treatment of chronic stress-induced cognitive decline. It presents bactericidal activity against *Streptococcus pneumonia* and its hydrolyzate antimicrobial activity against several gram-positive bacteria.

BSA has been shown *in vitro* to protect lipids against phenolic-induced oxidation. One important property that has been associated with this protein is the ability to inhibit breast cancer growth *in vitro*. β-lactoglobulin and α-lactalbumin show antiviral activity against HSV-1, when chemically modified.

Lactoferrin is a bioactive protein with an ability to bind iron. In opposition to anticancer feature, the antibacterial activity has been attributed to the iron-binding property.

Table 2 Specific diseases/whey protein biological functions

Clinical diagnosis	*Type of study*	*Sources*	*Results/advantages*
Cardiovascular disease	*In vitro*	Hydrolyzed: whey protein concentrate, α-lactalbumin, and bovine serum albumin	Angiotensin-converting enzyme (ACE) inhibition
		Caseinomacropeptide	ACE-inhibition activity
	Animal	Hydrolyzed whey protein (peptide concentrate), β-lactoglobulin, and α-lactalbumin	Reduced blood pressure (ACE-inhibiting peptides)
	Human trial	Whey protein concentrate	Hypertensive and obese persons (with resistance exercise):
			Increase of HDL and total antioxidant capacity
			Decrease of triglycerides, systolic blood pressure, and total cholesterol
			Atherosclerosis patients:
			Decrease in CCL5 (atherosclerosis biomarker) levels
Immunologic disease	*In vitro*	α-Lactalbumin	Macrophages enhance function via a tripeptide of glycine–leucine–phenylalanine
		Caseinomacropeptide	
		β-Lactoglobulin	Macrophages enhance function by low concentrations of caseinomacropeptide (CMP)
		Lactoperoxidase and lactoferrin	
		Whey protein isolated	Enhanced production of spleen and lamina propria lymphocytes
			Suppressive actions on lymphocyte proliferation
			Stimulation in the proliferation of murine spleen lymphocytes
	Animal	Caseinomacropeptide	Exertion of anti-inflammatory effects in a rat model of colitis
	Clinical trial	Whey protein concentrate	Increased lymphocyte and glutathione levels in patients with lung inflammation and cystic fibrosis
		Protectamin®	
			Increased glutathione levels (human immunodeficiency virus (HIV))
Gastrointestinal disease	Animal	Whey protein concentrate	41% Reduction in ulcerative lesions and 73% with repeated doses
		Hydrolyzed whey protein (peptide concentrate)	Reduction of gastric injuries to 68.5% (sulfhydryl-containing moieties)
		α-Lactalbumin	Reduction in ulcerative lesions (prostaglandin production)
	Clinical trial	Lactoferrin (infant formula)	Increased bifidobacteria proportion
		Hydrolyzed whey protein (infant formula)	Increased bifidobacteria proportion improving gastrointestinal immunity
			Decreased potential for developing atopic diseases
		Hydrolyzed whey protein (infant formula)	Decreased incidence of infantile colic
		Hydrolyzed whey protein	Bowel resection and protective effect on the gastric mucosa (sulfhydryl component – glutathione production)
Neurological disease	Animal	α-Lactalbumin	Protective effects and better seizure control as assessed by myoclonus (involuntary muscle twitch)
	Clinical trial	α-Lactalbumin	Increased plasma tryptophan (a precursor of serotonin – key for the treatment of stress-induced cognitive decline)
			Improved seizure control in persons with drug-resistant epilepsy; antidepressive effects and sleep quality
Microbial disease	*In vitro*	Whey protein concentrate (enriched with *Helicobacter pylori* – antibodies)	Prevention of infections
		Hydrolyzed β-lactoglobulin	Antimicrobial against several gram-positive bacteria and bactericidal activity
		α-Lactalbumin	Bactericidal activity (*S. pneumonia*)
		Hydrolyzed α-lactalbumin	Antimicrobial against several gram-positive bacteria
		Caseinomacropeptide	Antimicrobial activity
		β-Lactoglobulin, α-lactalbumin, and bovine serum albumin (chemically modified by 3-hydroxyphthalic anhydride)	Exhibition of antiviral activity against human herpes simplex virus type 1 (HSV-1)
	Clinical trial	Lactoferrin	Bacteriostatic and bactericidal activity against *Escherichia coli*, *Salmonella typhimurium*, *Shigella dysenteriae*, *Listeria monocytogenes*, *Bacillus stearothermophilus*, *B. subtilis*, and *Micrococcus luteus*
			Antifungal activity against *Candida albicans*
			In combination with lysozyme, immunoglobulins, or antibodies – more potent bacteriostatic agent against *Pseudomonas aeruginosa*, *L. monocytogenes*, and *E. coli*
			Decreased intracellular group A streptococci in chronic pharyngitis patients
			100% Eradication of *Helicobacter pylori*

Table 2 (Continued)

Clinical diagnosis	*Type of study*	*Sources*	*Results/advantages*
Cancer	*In vitro*	Whey protein concentrate	Increment of glutathione levels; stimulation of immunity; detoxification of potential carcinogens
			Mutagenic agent causing oxidative damage to tissues (iron-binding capacity)
		Whey protein isolate	Increased glutathione levels; protection of human prostate cells against oxidant-induced cell death
		Whey protein isolate (with coadjuvant baicalein)	Protection of human hepatoma cell line
		α-Lactalbumin	Antiproliferative effects in mammalian, colon adenocarcinoma, and intestinal cell lines; delaying initiation of cell apoptosis
		Bovine serum albumin	Inhibition of growth in human breast cancer cells
		Lactoferrin	Induced cell death in tumor cells and exertion of cancer-protective mechanisms in melanoma cells, breast cancer cells, stomach cancer cells, lung cancer cells, lymphoma cells, colorectal cancer cells, and polyps
		Immunocal®	Enhanced cytotoxicity – high rate of apoptosis
	Animal	Whey protein concentrate	Lower incidence of colon and mammary tumors and fewer aberrant crypts (colon cancer)
			Prevention of breast and intestinal cancers in female rats
			Increased glutathione concentration, leading to stimulation of immunity
			Depletion of tumor cells (glutathione concentration higher than normal cells)
		Hydrolyzed whey protein	Prevention and treatment of 5-fluorouracil chemotherapy-induced oral mucositis
		β-Lactoglobulin	Immune-enhancing
		Lactoferrin	Inhibition of metastasis of primary tumors
	Clinical trial	Nondenatured whey protein concentrate	16/20 Survivors at 6 months
			Increased NK cell function, glutathione levels, hemoglobin, and hematocrit
			Improved quality of live
		Lactoferrin	Reduced risk of colon carcinogenesis
		Immunocal® (with coadjuvant baicalein)	2/7 Patients had tumor regression after 6 months
			Increase in glutathione levels in healthy cells and decrease in glutathione levels in cancer cells
Diabetes	Animal	Whey protein concentrate and α-Lactalbumin	Improved postprandial glucose tolerance and long-term glucose control
			Anti-inflammatory effect
			Protection against endothelial dysfunction, lowering of HbA1c, and insulin resistance
			Cellular glucose toxicity
			Reduction in parameters of oxidative stress
	Clinical trial	Whey protein concentrate	Decrease in triglycerides and the exposure to glucose (AUC) by up to 44%
			Increased insulin secretion and reduced postprandial (after meal) exposure to glucose by 21%
Hepatitis	*In vitro*	Lactoferrin	Prevention of hepatitis C virus infection in a human hepatocyte line
		Whey protein concentrate	Reduced inflammatory markers and improved liver enzymes (hepatitis C patients)
	Clinical trial	Immunocal®	Decreased serum lipid peroxidase levels and serum alanine transferase activity (hepatitis B patients)
			Increased IL-2, NK activity, and plasma glutathione levels
Osteoporosis	*In vitro*	Milk basic protein (lactoferrin, lactoperoxidase, and minor components)	Stimulation in the proliferation and differentiation of osteoblastic cells and suppression of bone resorption
	Animal	Whey protein concentrate and hydrolyzed whey protein	Increased femoral bone strength in young ovariectomized rats
	Clinical trial	Milk basic protein	Increased bone formation (osteocalcin and procollagen I carboxy-terminal propeptide levels increase), bone mineral, and radial density
			Inhibition of osteoclast-mediated bone resorption

(*Continued*)

Table 2 (Continued)

Clinical diagnosis	*Type of study*	*Sources*	*Results/advantages*
Exercise	Clinical trial	Nondenatured whey protein concentrate	Increase in body mass composition and improved quality of life on HIV-positive women
		Whey protein concentrate	Improvement in one of the four muscles, lean tissues mass, and strength
			Significant improvements in peak power and increase of 30 s work capacity
			Increased lymphocyte glutathione levels
			Decrease in percent body fat improving body mass index
Obesity	*In vitro*	Whey protein concentrate	Prevention and/or attenuation
	Clinical trial	Whey protein concentrate	Reduced fat buildup in obese women with high liver fat content and reduced triglycerides and total cholesterol

Lactoferrin develops a direct role in defending the body against pathogens. This protein possesses bactericidal power against a wide range of microorganisms. The antimicrobial effect can be taken advantage of in the treatment of enteric infections. Recent studies have demonstrated that iron-unsaturated lactoferrin is active against the fungi – which are responsible for dermatophytosis. Lactoferrin possesses antiviral effects too and plays an important role upon stimulation of the immune system.

Whey Proteins, Interaction with Different Organs

Whey proteins are beneficial to the intestinal lining, especially in clinical situations where gut function is impaired. A study in rats showed that whey promotes neutrophil chemokines – GCP-2 activity in the intestines and subsequent intestinal cell growth. In a clinical study, it was found that the outcome provided by a whey protein concentrate administered to a person with Crohn's disease was very close to the behavior of glutamine, reducing intestinal permeability.

In the liver, whey proteins exhibited an important role in studies with nonalcoholic fatty liver, showing the ability to reduce liver enzyme (ALT, alanine transaminase; AST, aspartate aminotransferase; and GGT, gamma-glutamyl transpeptidase) levels and fat deposits, enhancing glutathione (due to cysteine). A reduction in weight and waist circumference has also been verified. Another study showed that high-dose supplementation in obese women with high fat content in the liver was able to reduce the accumulation of fat in the liver, reducing triglycerides and total cholesterol.

Whey Powder and Exercise

After performing exercise, subjects enter into metabolic stress, requiring consumption of essential amino acids, whey proteins, minerals, or other serum-derived compounds (usable energy). From the mechanistic point of view, due to their composition in amino acids, whey proteins can provide substrates and bioactive components that are capable of extending the overall benefits of regular physical activity. Accordingly, they have been chosen by bodybuilders and elite athletes, in addition to people whose health is compromised. Whey protein can help to improve muscle strength and reduce the likelihood of bone fracture; these characteristics are directly related to their unique amino acid composition, as mentioned earlier, which are quite similar to those of skeletal muscle proteins. However, the improvement seen in increased skeletal muscle protein occurs through mechanisms that are definitely beyond those assigned to the said content of essential amino acids. When it comes to a moderate exercise, there is an improvement in immunity. On the other hand, when the training is heavy, there is stress in the immune system, leading to the production of free radicals and increased inflammatory activity. It is thought that those factors can harm the immunobiological activity of athletes who train heavily, in which muscle performance and recovery may be affected by oxidative stress. The availability of glutathione can be used to combat this problem. Other studies have shown that whey proteins have helped to achieve more easily the desirable weight and shape body, being more effective than caseins in what concerns to satiety.

Whisky, Whiskey and Bourbon: Composition and Analysis of Whisky

Sensory Assessment

Whisky has traditionally been assessed by expert blenders with many years of experience and training within the industry. An experienced blender knows what flavors of distillate a still can produce, which are desirable, and how a whisky is likely to develop during maturation. The blender's task is then to identify faults and deviations from the expected path of maturation and to select a specific maturation point at which a whisky can contribute to the blend. Blenders use a system of flavor description to assist their work, but their method of working is largely by comparison of samples with experience or a reference. Each sample is evaluated in terms of its similarity to an expected or acceptable product.

Scotch grain whiskies are light-bodied continuous still spirits, largely regarded as providing a background for a blend. Malt whiskies provide the majority of the character of a particular blend and, though the distilleries all produce slightly different whiskies, for convenience, they are divided into groups sharing common characteristics. The Highland malts, the most numerous, are further divided into first, second, and third classes. These are not intended to be quality evaluations, but are simply descriptive classes. The Lowland malts are not regarded as having a distinctive character and thus can be used in relatively large quantities in blends. There are three remaining Campbeltown distilleries and this group has, as a result, declined in importance. The Islay whiskies tend to be full-flavored and are usually heavily peated and thus have a significant impact on a blend even when used in small proportions. The Highland group contains most of the great whiskies that have established reputations as single malts and for their value in blending. A wide range of flavors is available and a skilled blender can make use of them to create a distinctive blend.

Formal methods of laboratory sensory analysis have also been used. Many companies use difference tests for quality control monitoring, and the whisky industry seems to have been one of the first to adopt the duo–trio and triangle tests for such purposes. Over recent years, there has also been an increasing interest in the assessment of whiskies by profiling or descriptive methods, largely for research into the origins and development of flavor in whiskies. Several broadly similar vocabularies of descriptive terms have been used. These vary mainly in the number of terms they include and therefore in the detail with which they attempt to describe flavor. They have often been presented in the form of a 'flavor wheel,' with varying numbers of concentric tiers, which while having no particular theoretical significance provide a framework for communication and training (Figure 1).

The Chemistry of Flavor Compounds

With the advancement in chromatographic techniques and, in particular, their coupling with mass spectrometry, the number of compounds identified from whisky has increased dramatically. Particular use is made of gas chromatography with a number of detectors for the measurement of volatile organic compounds. Nonvolatile constituents may be measured as a whole spectrophotometrically or individually by high-performance liquid chromatography. Problems arise as compounds of sensory importance may be present at very low concentrations (nanograms per gram). Major volatile congeners in a range of whiskies are shown in Table 1, and the major categories of compounds thought to be important in the development of flavor are discussed in the succeeding text.

Alcohols, Carboxylic Acids, and Esters

Aliphatic alcohols, acids, and esters are produced by the yeast (*Saccharomyces cerevisiae*) during fermentation, though ester formation may also occur during distillation and maturation. Saturated and unsaturated chains are found, ranging from 1 to 16 carbon atoms. Short-chain alcohols such as propanols, butanols, and pentanols are the most abundant. Nonaliphatic alcohols include 2-phenylethanol and 2,3-butanediol. The principal organic acid is acetic acid, accounting for between 50% and 90% of the total content of volatile acids. Octanoic, decanoic, and dodecanoic acids are quantitatively important, though lower-molecular-weight acids such as butanoic and pentanoic acids may have more sensory impact. The most abundant esters are the ethyl esters of the acids named, their concentrations reflecting the relative abundance of the acid. Any other combination of the acids and alcohols present may occur. After ethyl esters, the most abundant are acetate esters such as isoamyl acetate and phenylethyl acetate. The esters of hydroxy acids, such as lactic acid, and of dicarboxylic acids, such as succinic acid, can be distilled along with alcohol and steam and so occur in whisky.

Aliphatic Carbonyl Compounds

The majority of carbonyl compounds are produced by the metabolic actions of the yeast during the fermentation. However, their formation by oxidation of unsaturated fatty acids or Strecker degradations has been shown to occur at almost any stage of production. Acetaldehyde is the most common and is often used to determine total aldehydic content. Many other aldehydes, ketones, and acetals have also been identified. For aldehydes and ketones, aliphatic chain lengths, both saturated and unsaturated, range from 2 to 14 carbon atoms. Due to the high alcoholic strengths of the distillate, aldehydes exist in equilibrium with the corresponding acetal and hemiacetal. The most frequently reported acetal is 1,1-diethoxyethane, though a range of aldehydes up to six carbon atoms have been shown to form acetals.

Sulfur and Nitrogen Compounds

Yeasts have the ability to utilize inorganic sulfur, sulfur-containing amino acids and vitamins, and from these sources, volatile sulfur-containing compounds are produced. The range of compounds detected include heterocycles, such as thiazoles and thiophenes, and aliphatic mono-, di-, and trisulfides. The formation of sulfur compounds has also been shown to occur during distillation and concentrations are highest in new spirit. Cask char, wood extractives, and traces of elemental copper are important in the degradation of such compounds during maturation (Table 2). Heterocyclic nitrogen compounds such as pyrazines, pyrroles, and pyridines are formed via the Maillard reaction during cooking, mashing, distillation, and barrel charring. As they have relatively low odor thresholds, they may well make a contribution to the aroma of whisky.

Phenols

A wide range of phenolic compounds are found in whisky. Simple phenols such as phenol, the isomeric cresols, xylenols, ethyl phenols, and guaiacols arise through the thermal degradation of benzoic acid derivatives from malt and from peat smoke. Phenolic aldehydes such as vanillin, syringaldehyde, coniferaldehyde, and sinapaldehyde are formed from the breakdown of wood lignin during cask charring and maturation. Their corresponding acids and ethyl esters have also been detected. Polyphenols extracted from the wood include ethanol-soluble lignin and tannins derived from both gallic and ellagic acids.

Heterocyclic Oxygen Compounds

The main types of these compounds found in whisky are furaldehydes and lactones. Furfural (2-furaldehyde) is formed from pentoses and 5-hydroxymethyl-2-furaldehyde from hexoses via the Maillard reaction during mashing, distillation, and cask charring. Lactones are formed by the dehydration of aliphatic hydroxy acids and most are derivatives of 2(3H)-furanones. The most abundant of these are the cis and trans isomers of 5-butyl-4-methyldihydro-2(3H)-furanone, the oak or whisky lactones, which are formed and extracted from oak casks during maturation.

Variations with Processing

Though there are only four basic processes in whisky production, local, regional, and national variations in these processes are responsible for the large number of whiskies available. Each stage of production, from the production of a fermentable extract, to fermentation, to distillation, to maturation, can affect the character of the final product. However, each stage is interlinked and identifying one, as the most important for a particular type of whisky, is often impossible.

The Production of a Fermentable Extract

The cereal grains in common use are wheat, corn (maize), rye, and barley, though the choice of cereal is often legally restricted. Flavor differences between cereals arise from two quite separate sources: the composition of the extract and the levels of precursors present. The choice of cereal can also indirectly affect the flavor of the final product. The composition of the fermentable extract varies with cereal used and can influence the metabolism of the yeast. Factors such as pH, amino acid concentration, and levels of insoluble material are known to affect the levels of fusel alcohols, acids, and esters produced, which may influence the flavor of the final product. Between cereals, differences also exist in the levels of precursors for a number of classes of flavor compounds. Examples are compounds formed by the chemical and enzymatic oxidation of fatty acids, the reaction of free amino acids and reducing sugars (Maillard reaction), and the thermal degradation of biosynthesized precursors like *S*-methylmethionine and benzoic acid derivatives. However, the breakdown of these compounds frequently occurs during fermentation and distillation and is affected by variations in these processes. Consequently, no flavors in the final product have been unequivocally linked to components of the original cereal.

Fermentation

Fermentation is responsible for the primary production of a large number of flavor compounds in whiskies. Factors that are known to alter the production of these compounds are the strain or mix of yeasts used, design and level of aeration in the fermenter, the duration of the fermentation, and the presence of contaminating bacteria. These factors alter according to distillery design and the raw materials employed and so may be important in producing regional and national differences in whiskies.

Distillation

In batch distillation using pot stills, the selection of the cut points in the still run has a marked influence on the flavor of the product. Generally, aldehyde and short-chain ester concentrations are determined by the primary cut from foreshots to spirit, while the concentration of fusel alcohols and acids is determined by the cut from spirit to feints. Other factors, which affect the physical process of separation during distillation, are still design parameters such as the still height, the angle, and length of the lyne arm and the type of condenser used. In addition, a number of chemical reactions can occur when the wash or low wines are heated for distillation. This is particularly true for batch distillation in pot stills where the heat impact is greater. Examples include the formation of sulfur compounds from sulfur-containing amino acids, the breakdown of unsaturated fatty acids to carbonyl compounds, and the dehydration of β-hydroxypropionaldehyde to acrolein. Copper catalyzes many of these reactions.

In continuous stills, congener concentrations are determined by the design, operation, and efficiency of the still. The range of reactions described for pot stills can still occur but become progressively less important as distillate strength increases. Collection of spirit at high ethanol concentrations (>90%) results in low levels of congeners in the spirit.

Maturation

During the maturation period, the new distillate becomes highly modified as a result of its contact with the cask (Figure 2). The composition of the cask wood has a major effect on the extent of this modification and varies with the species of oak used, the pretreatment applied to the wood, and the previous use of the cask. In general, American oak (*Quercus alba*) yields higher concentrations of vanillin and *cis* oak lactone, while Spanish oak (*Quercus robur*) gives higher concentrations of tannins. Charring increases the levels of lignin breakdown products and lactones extracted during maturation, whereas previous use of a cask greatly reduces the amount of extractable lignin breakdown products and lactones. The use of sherry casks results in raised levels of tannins and sugars. The cask is the major determinant of mature quality, but other factors such as filling proof, climate, and warehouse conditions also affect the course of maturation. Higher temperatures produce greater evaporation rates and also increase extract levels and some reaction rates, but do not necessarily produce a more mature product.

Correlation of Chemical Composition with Sensory Data

The flavor of whisky is dependent upon a complex mixture of components that originate from and are modified by different stages of production. While improved analytical methods have revealed much about the chemistry of whisky, this has not resulted in a better understanding of the chemical basis of whisky flavor and quality. Frequently, chemical differences can be related to variation in production processes, but identifying the actual compounds responsible for the flavor differences has been much more elusive.

The extent to which volatile compounds from cereals survive fermentation, distillation, and maturation is the hardest to establish. Whisky prepared from heavily peated malt retains a characteristic medicinal, smoky flavor that is strongly correlated with the total phenols content of the malt and of the whisky. However, the range and concentration of phenols present are greatly altered by mashing, fermentation, and distillation and whether the phenols fully explain the 'peated' flavor is still uncertain. Likewise, some whiskies (especially Canadian) have a characteristic 'spicy' or 'minty' flavor, which is possibly related to the use of rye in the mash, but no compound has been identified as responsible.

Various flavors in new distillates have been correlated with sulfur compounds. Polysulfides are present in whisky at levels around and above their sensory thresholds (3–6 ng g^{-1} for dimethyl trisulfide), and the data available suggest that these compounds are correlated with 'sulfury' and 'heavy' characters in fresh distillates. Other sulfur-containing compounds are thought to be important contributors to flavor, and their formation is dependent on the levels of precursors present in different cereals/cultivars. However, such compounds are

frequently formed during fermentation and distillation and then degraded during maturation. Each stage has its own impact on the concentration in the final product making it harder to establish their role in whisky flavor.

The products of fermentation and distillation make a substantial contribution to whisky flavor. However, these compounds, except when present in excess, appear to form what has been described as the 'integrated whisky complex,' and their individual contributions have not been determined. It does appear that relatively constant proportions of some of these compounds must be present for a recognizable 'whisky' character, though substantial changes can occur with only minor changes in flavor.

Compounds considered to be important in maturation are vanillin, eugenol, and *cis* oak lactone. These have been correlated to 'vanilla' and 'clove-like' flavors in some whiskies matured in new casks. However, cask reuse causes a general decrease in wood extractives and their importance in whisky matured in refill casks is still uncertain.

Attempts to create a model of whisky flavor have been largely unsuccessful. Attempts were based on compositional analyses of the liquid. Research has since shown that there are complex relationships governing the release of flavor compounds from whiskies. Major factors identified include alcoholic strength and the nonvolatile content of the whisky matrix. Dilution of spirits for sensory assessment, to reduce the pungency of ethanol, can greatly alter the release of aroma compounds more soluble in ethanol than in water. Dilution also increases the capacity for matrix effects that suppress the release of ethyl esters and other aroma compounds. Matrix effects may occur through competition for release at the liquid surface or changes in solubility of flavor components. Changes in solubility can be related to the physical structuring of the ethanol–water mixture. Differential scanning calorimetry, light scattering, and mass spectrometry have all demonstrated that physical changes occur during maturation, adding another layer of complexity to whisky flavor and reinforcing the uniqueness of each individual product.

Health Effects

Apart from the well-known benefits of light to moderate alcohol consumption, whisky, in common with some wines and other wood-matured spirits, contains phytochemicals with potentially beneficial effects. Most attention has been given to antioxidants, but wood and spirit matured in it contain a range of other components with possible effects, such as amelioration of allergic reactions. Phytophenols may also reduce the rate of alcohol metabolism, thereby reducing blood acetaldehyde level and prolonging exposure to alcohol. In animal models, whisky has also been found to have a less damaging effect on the stomach compared with aqueous ethanol. The highest antioxidant activity has been found in red wines, followed by Armagnac, Cognac, whiskies, and some wood-aged rums, with white spirits showing no activity. The extent of the activity varies with the maturation time, older spirits showing greater activity, and with the wood and its heat treatment before use. Oak, the species used most commonly for spirit maturation, is among the most active. Activity is correlated with the total phenolic content and with ellagic acid, a major component of the wood-derived materials present in matured spirits. In some studies, flavonoids have been found to be most important for the antioxidative capacity of spirits, whereas in other cases, nonflavonoids appear to be important. Consumption of alcoholic beverages containing phenolic compounds transiently raises plasma phenol concentrations and antioxidant capacity in humans, but as yet, there is little evidence of any real benefit in terms of chronic disease risk.

Whisky, Whiskey, and Bourbon: Products and Manufacture

JR Piggott, Universidade Estadual Paulista, Araraquara, Brazil

Types of Product

Whiskeys are distilled beverages that have been produced by the distillation of fermented cereals and have been matured in oak casks. They can be classified on the basis of the nature of the cereal; the manner in which the product is blended, if at all; and the country of origin. Although there is some evidence for a distillation-type process in ancient Egypt, the first reports of whiskey production arise in Ireland in the twelfth century, and the first description of a whiskey production process is found in Scottish records dating from 1494. The term 'whiskey' was derived from the Gaelic *uisge beathe*, which means 'water of life.' Major countries of production are Scotland, the United States, Ireland, Canada, and Japan, while similar products are produced in many other countries.

Regulations in the European Union (EU) define whiskey as a spirit produced by the distillation of a mash of cereals and matured for at least 3 years in wooden casks. There are limitations on the enzymes that can be used to hydrolyze starch to fermentable sugars and on the distillation strength, and yeast must be used for the fermentation. Within this definition, Scotch and Irish whiskeys are further restricted. In practice, this provides for three distinct products: malt whiskey, produced from 100% malted barley; grain whiskey, produced from unmalted cereal grains; and the bulk of the whiskey produced in Scotland, which is blended from 60 to 70% grain whiskey and 30 to 40% malt whiskeys. This blended whiskey usually contains up to 40 individual malts, which are blended to produce a consistent brand flavor, and every component of the blend must be matured for the minimum period or the age specified on the bottle. Malt whiskeys may contain either a blend of malt whiskeys of a given minimum age or malt whiskey from a single distillery. Scottish malts have a different character depending upon whether they are from the west coast, such as Campbeltown and the Islay region, which produce highly peated malts, or from the highlands or the lowlands. Irish whiskeys have a similar flavor to Scotch but do not have a peaty character.

Whiskey produced in the United States has evolved in a different legislative framework, allowing for a greater variety of distinctive products. The basic definition of US whiskey is that it is distilled from a fermented grain mash at less than 95% alcohol (190° US proof). Within this broad definition, there are two special categories that are bottled as such or provide flavoring whiskeys for blending. In the first group, the cereal content of the mash is restricted to not less than 51% of the named cereal (e.g., rye for rye whiskey and maize for bourbon), the distillation must be at less than 80% alcohol, and maturation must be in new charred oak. Bourbon takes its name from Bourbon County in Kentucky. Corn whiskey must be from a mash of 80% maize and matured in new uncharred or used oak. If matured for 2 or more years, these are 'straight whiskeys.' They are to the blender the equivalent of the Scotch malts and provide the majority of the flavor in a blend with lighter flavored grain spirits. US blenders are also permitted to use 'blending materials,' such as sherry or blending wine, at up to 2.5%.

Canadian whiskey production follows the same general practice as in Scotland and the United States. Canadian blends are light column still whiskeys with normally 10–15% of heavier-bodied flavoring whiskeys. Up to 9.09% (on the basis of absolute alcohol content) of 'flavorings' is permitted, which may include wines and sherries, rum, brandy, bourbon, or malt whiskey. Maturation must be for not less than 3 years, and oak casks of 182 l (40 imperial gallons) are commonly used. The range in flavor required by the blender cannot be achieved by using the products of many different distilleries, but techniques such as variation of the composition of the mash (corn, wheat, rye, or barley), cooking procedures, yeast strain, distillation procedure, barrel type, and maturation period can be used. Traditionally, pot stills were used but these have largely been phased out.

Similar products are produced in many other countries and are subject to local regulations, which, while generally similar in principle to the EU definition, allow different extents of variation. In Brazil, regulations permit the addition of a proportion of agricultural alcohol to blended whiskey, and in Japan, the locally produced spirit is frequently blended with imported Scottish malts. Spain is a substantial producer of whiskey, which must meet the EU requirements. EU and US regulations also include provision for grain spirits or grain brandies, which are essentially similar to whiskeys but not matured. In other parts of Europe (e.g., Poland), 'whiskeys' are produced that are essentially vodkas, matured briefly, and flavored with wood extracts or other materials and that may or may not meet regulations commonly accepted for whiskeys.

Raw Materials

The major grains used in whiskey production are maize (*Zea mays*), barley (*Hordeum vulgare*), wheat (*Triticum vulgare*), and rye (*Secale montanum*). These are the grains traditionally used for whiskey, on the basis of a high fermentable starch content providing a good yield of alcohol. A typical composition of these grains is shown in Table 1. In Scotland and Ireland, all the amylase activity required for starch breakdown is obtained from malted barley, in the form of either a kilned malt, which is stored at a moisture content of 5%, or a green malt, which is prepared specifically on-site as a source of enzyme activity for the production of grain whiskey. Some regulations also permit the use of other (normally microbial) enzymes during wort production. Cultivars are normally selected on the basis of extract and fermentability, corresponding to spirit yield, or enzyme activity in the case of malt for grain distilling. Enzyme activity should be considered under process conditions, as this

Table 1 Composition of cereals used in the production of whiskey worts

	Corn	*Rye*	*Barley*	*Wheat*
Percentage of total

will not be the same as activity measured under optimum laboratory conditions. Ethyl carbamate is an undesirable trace component in distilled beverages, and its content in malt whiskey is largely determined by the cyanogenic precursor, epiheterodendrin, in malt. Barley cultivars that do not contain the precursor are used. The gene responsible for its production has been identified, and differences in the DNA sequence between producers and nonproducers (i.e., different alleles) have been used to develop a simple diagnostic assay that discriminates between them. This can be used as a screening test to eliminate experimental varieties, which are producers.

Water is required for mashing, cooling during distillation, dilution of the spirit before maturation, and blending. The quality of the product may be influenced by the nature of the water supplied, and many distilleries take their water supply from individual water courses or special wells. Soft water is normally used for malt distilleries, but some degree of hardness is preferred in grain distilleries since this has a stabilizing effect on the amylase enzymes. The water should be monitored for chemical and microbiological contamination and be free of decaying vegetable matter. The water used for dilution of the spirit must have a low calcium and iron content and is normally demineralized, to minimize the risk of discoloration or precipitation occurring in the final product.

The yeast used for fermentation is normally a specially grown distilling yeast, which has good physiological and microbiological properties for producing alcohol. However, some recycled brewer's yeast may be used in Scotland, and yeasts from previous distillery fermentations may be used in some bourbon processes; both influence the range of flavor products in the wash. The main criterion for yeast strain selection is normally efficiency in converting fermentable sugars to ethanol. To a limited extent, strains may be selected to provide the required composition and flavor characteristics in the distillate, particularly the ester content, and yeast cultivation and storage conditions also affect its performance. Yeasts expressing glucoamylase activity have been developed.

Barrels used in whiskey production are produced from either American white oak, *Quercus alba*, and related species or the Spanish oak, *Quercus robur*. Scotch whiskey is traditionally matured in barrels that have previously been used for bourbon maturation or sherry production. Spanish sherry production is carried out in barrels constructed from either Spanish or American white oak. Except where the regulations provide otherwise, barrels are commonly reused until they fail to provide a satisfactory maturation. Such barrels may be regenerated by scraping out the inner surface and charring the inside of the barrel, but this does not produce performance equivalent to a new barrel. During periods when sherry casks have been in short supply, barrels have also been wine-treated or wine-seasoned (filled with sherry for up to 6 months), and Madeira, port, or ale casks are also occasionally used.

Method of Manufacture

Malting and Mashing

The traditional method of production involves the production of wort from cereal grains using amylases from barley. These α- and β-amylases are produced by the barley during the malting process. Malting of barley is carried out by steeping the grain in water for 2–3 days and permitting the grain to germinate until the root is approximately one-third the length of the grain. When this stage is reached, the grain is dried down to a moisture level of 5% by kilning. The grain is then stored until immediately prior to use when it is milled before being transferred to a mash tun. In Scotch whiskey production, peated malt is prepared by drying the malt in the presence of smoke from a peat fire and is an important source of flavor compounds, normally assessed on the basis of the total phenols content of the malt (up to 50 ppm), although other components may contribute to flavor. Nitrosamine contamination of malt could arise from the use of natural gas in directly fired kilns but is controlled by the use of burners designed to reduce nitrogen oxides, by burning sulfur to add sulfur dioxide to the air stream, or by indirect firing. Most of the breakdown of the starch occurs during the process of mashing, which is carried out in a mash tun. Barley grist can be mashed directly since it has a high-amylase activity, whereas worts produced from maize and other cereals require the addition of malted barley as a source of enzymes. The process of mashing may be a simple batch process similar to the infusion mashing techniques used in brewing beer, in which the grist is mixed with water at 63–68 °C for 0.5–1.5 h before the wort is filtered off. However, in the production of grain whiskey, an initial cooking stage, to gelatinize the starch of the nonbarley cereals, is required. The cooking may be carried out as a batch process at 120 °C for 1.5 h or, as is more usual in North America, as a continuous process. In either case, the mash is cooled to 60–65 °C before the addition of the malted barley. Careful control is required at this stage to prevent the solidification of the gelatinized starch. When a cooking stage is used, amylase activity is normally provided by adding 10–15% freshly malted barley (green malt) after the cooking stage (Figure 1).

During the malting stage, β-glucanase enzymes are also produced; these facilitate the breakdown of the endosperm cell walls and the release of starch and proteases. The latter are involved in the breakdown of some of the barley grain

proteins to amino acids and peptides. These amino acids are an essential nitrogen source for the growth of the yeast.

The mash is usually filtered prior to the fermentation to give a clear wort, but in some processes, a higher yield is obtained by fermenting the whole mash directly. The composition of a typical Scotch grain whiskey wort is shown in Table 2.

Fermentation

The wort, which is produced when the contents of the mash tun have been filtered, is then transferred to a fermentation vessel and fermented using one or more strains of the yeast *Saccharomyces cerevisiae*. When the wort is not boiled (as is the case in malt whiskey production), it contains microorganisms and active amylases. It is cooled to 20–25 °C before inoculation with a strain of distilling yeast and, in some processes, secondary yeasts. Yeast growth occurs rapidly and is completed in the first 8–12 h. Ethanol production follows growth initially and then continues in a linear manner until the metabolizable sugars have been consumed. The resulting solution contains approximately 7% ethanol and a large number of flavor compounds. During the growth period, wort sugars are rapidly metabolized and the temperature may rise to 33 °C if it is not controlled. The pH drops from an initial value of 5.0–5.5 to 4.2–4.5 as a result of the production of organic acids, such as acetate, succinate, and pyruvate. A wide range of flavor compounds, such as higher alcohols, fatty acids, esters, and carbonyl compounds, are also produced throughout the fermentation; they pass through into the distillate and constitute an important part of the product. In contrast, glycerol, which is also produced, is nonvolatile and does not pass into the distillate; this represents an important loss of yield. At the end of the fermentation, usually between 48 and 72 h, death and autolysis of the yeast may occur. The fermentation is not a sterile process, so bacterial contamination can occur. Most of the bacteria that are introduced from the raw materials die during the early stages of the fermentation. However, lactobacilli can survive and grow with a concurrent formation of lactic acid during the later stages of the fermentation. Limited growth of lactic acid bacteria may be beneficial in flavor terms, but to prevent excessive growth and resulting yield losses, fermentation is normally completed in 40–48 h, rather than the longer times traditionally used. Heavy contamination by lactic acid bacteria can also result in a loss of ethanol yield and the production of acrid off-flavors.

Distillation

The fermented wash (wort after fermentation) is then distilled either in a series of two or three pot stills (Figure 2) or in a

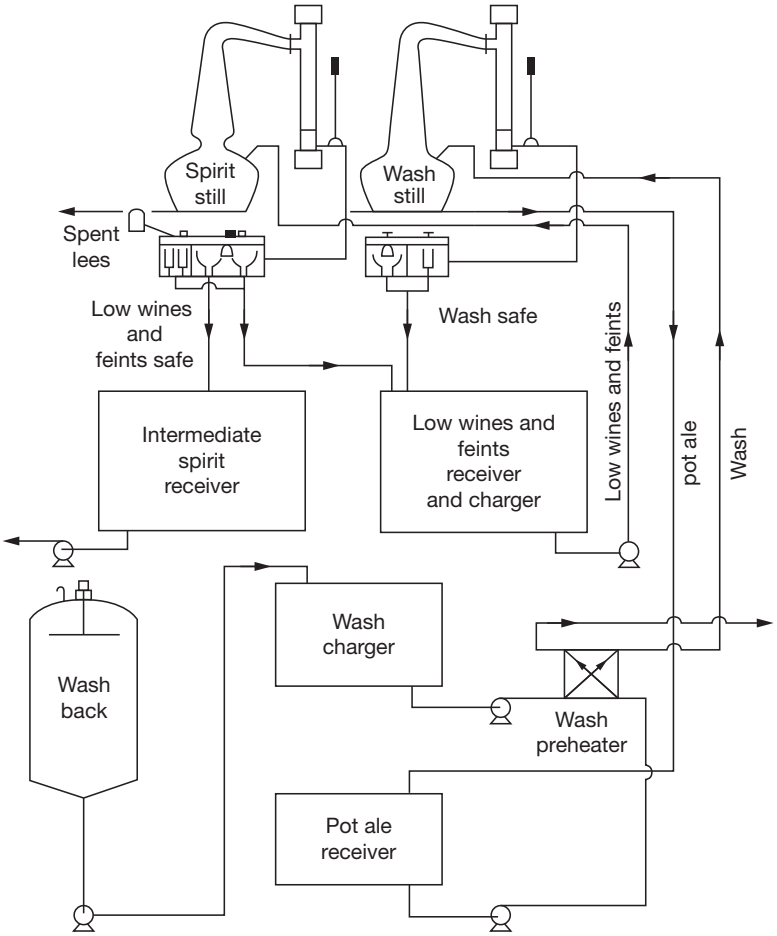

Figure 2 Typical malt distillery flow diagram. Reproduced with permission from Piggott, J. R., Sharpe, R., and Duncan, R. E. B. (Eds.), 1989. *The science and technology of whiskies*, Pearson Education Limited, © Longman Group UK Ltd 1989.

series of column stills. The distillation process varies with the type of product and the country of origin. Historically, the first whiskey processes used copper pot stills and this type of process is still used for the production of malt whiskey in Scotland, where two stills – the wash still and the spirit still – are used. In Ireland, a three-still process is typical. Pot stills have also been used in the United States and Canada, but grain spirit is normally produced by continuous distillation in column stills. The first continuous process was associated with Scotch whiskey production and the development of the Coffey or patent still by Aeneas Coffey in 1830. The ethanol concentration of the distillate determines the extent of impurities (congeners) present, a higher strength distillate being purer aqueous ethanol with a less intense flavor.

In batch distillation processes, all the contents of the fermenter are transferred to the large wash still and boiled for 5–6 h until all the ethanol has been recovered, to produce a distillate, known as low wines, which contains 20–25% (v/v) ethanol. This is transferred to the low wines or spirit still where it is distilled to give a spirit containing around 70% (v/v) ethanol (Figure 3). In Scotch malt whiskey production, the first fraction of the distillate and the third fraction (after collection of the spirit) are recycled for redistillation with a subsequent batch of low wines. The Coffey still consists of two columns, referred to as the analyzer or beer column and the rectifier column. Wash is fed toward the top of the first column and alcohol-free stillage is withdrawn at the bottom of the column; vapors are fed from the top to the base of the rectifying column (Figure 4). It produces a 190° US proof spirit and is still used for the production of grain spirit in Scotland. In the United States, whiskey production employs more complex distillation processes involving the use of up to five columns. The heat for most distillation processes is supplied as steam at the present time, although pot stills directly fired by solid fuel or gas are also in use. In addition to producing spirit, distillation processes produce a large quantity of stillage, which is processed into various by-products, such as dark grains and distiller's solubles, for animal feed.

Maturation

All whiskeys are matured and most legal definitions of whiskey incorporate a minimum maturation period. The legal minimum varies from 1 year for some American grain whiskeys to 3 years for Scotch, Irish, and Canadian whiskeys. In effect, these are the minimum requirements and most spirits are matured for longer periods. Branded products are generally matured for between 4

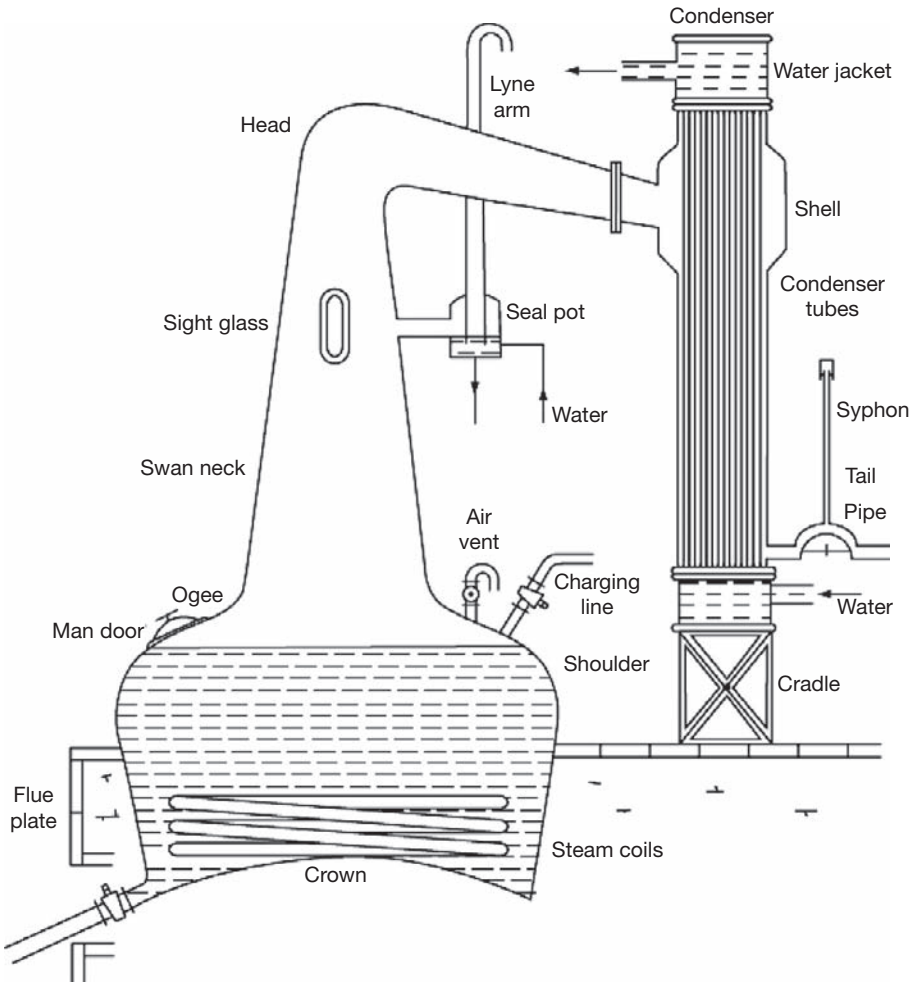

Figure 3 Plain wash still. Reproduced with permission from Piggott, J. R., Sharpe, R., and Duncan, R. E. B. (Eds.), 1989. *The science and technology of whiskies*, Pearson Education Limited, © Longman Group UK Ltd 1989.

and 8 years, while single malts and premium straight whiskeys are matured for 8 to more than 18 years. The process of maturation involves storing the raw spirit from the still, diluted to 50–80% ethanol, in barrels made from a limited range of oak woods. The type of cask used greatly affects the properties of the mature spirit. American straight whiskeys (e.g., straight bourbon whiskey, but excluding straight corn whiskey) are matured in new charred American oak barrels that by law cannot be reused. Maturation in new charred casks is associated with an increase in color, solids, acids, esters, aldehydes, and tannins, together with increases in sugars, such as arabinose, glucose, and xylose. New charred casks give a strong sweet, wood-derived flavor to the final product. The casks used for straight whiskey maturation are American standard barrels (180–200 l) made from American white oak, charred where required by regulation. 'White oak' is a cooperage trade classification used for at least 10 oak species, the principal being *Quercus alba*.

Most other types of whiskey are matured either in barrels previously used for maturation of bourbon or in sherry production. Bourbon barrels may be used 'as is' or reassembled as hogsheads, with additional staves and new ends to increase capacity (250 l). Reuse of casks decreases the levels of wood components extracted during maturation and gives a much less intense wood-derived flavor. Sherry casks used for the maturation of some whiskeys are generally butts or puncheons (480–5201), which have been used for the fermentation and/or aging of various styles of sherry. Sherry casks can be either American or Spanish oak casks (predominantly *Quercus alba* and *Quercus robur*). American oak is generally used for fino and amontillado sherries, while Spanish oak is used for oloroso sherry. For sherry casks, distillers will specify the species of oak, whether the cask is used for fermentation or the contact time with maturing sherry, as all affect the final properties of the mature spirit. In all but bourbon production, casks are reused until they are exhausted, that is, they fail to produce a satisfactory change in the spirit over an economical maturation period. The life of a cask can be extended by the removal of the old char layer and refiring the cask. This regeneration increases the levels of wood polymer breakdown products extracted during subsequent maturation, but does not regenerate all wood constituents and such casks give different sensory properties when compared with a new cask.

Maturing whiskey was traditionally stored in stone-built warehouses located beside the distillery. Casks were stored in

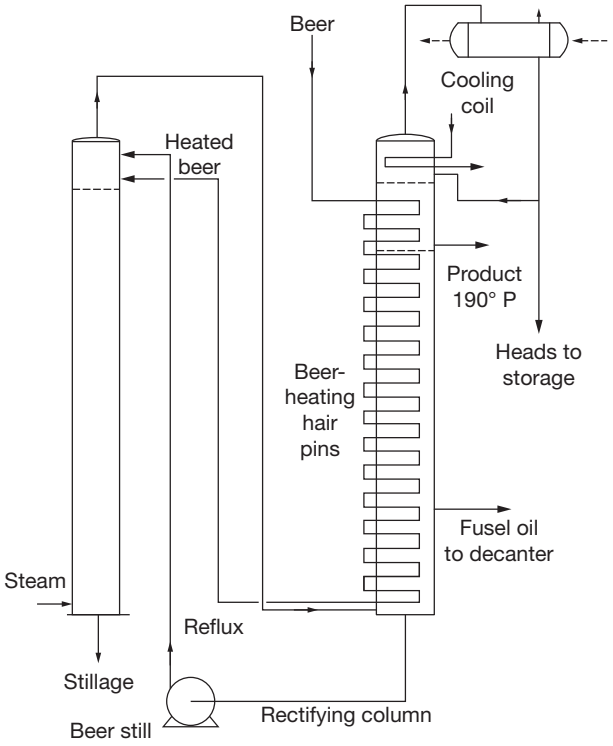

Figure 4 Coffey still. Reproduced with permission from Piggott, J. R., Sharpe, R. and Duncan, R. E. B. (Eds.), 1989. *The science and technology of whiskies*. Pearson Education Limited, © Longman Group UK Ltd 1989.

racks or in 'stows,' two or three high on the earth floor. Expansion in production resulted in much larger warehouses with steel racking, which allowed casks to be stored up to 12 high. The temperature and humidity within warehouses vary between different countries, and this can affect the way in which a spirit matures. In cool damp climates, such as Scotland and Ireland, more ethanol than water evaporates from the cask, and consequently, strength decreases during the maturation period. In warm dry climates, such as the United States, more water than ethanol evaporates and strength increases. During maturation, many of the chemical changes that occur are influenced by the storage conditions, particularly temperature. However, though higher maturation temperatures have been shown to increase the rate of extraction of wood components, this does not generally correlate with improvements in sensory quality.

Blending to Bottling

With the exception of occasional 'single cask' bottlings, all whiskeys are to some extent blended. Even in the most tightly controlled environments, batch-to-batch variations can occur at any stage in the production process. Blending is used to produce a consistent product that has the distinctive flavors of that particular brand. For bourbon and single malt production, variations are evened out to create the recognized brand from different batches of whiskey. True blended whiskeys consist of light-bodied spirits mixed with a number of heavier-bodied spirits in a wide range of proportions. 'Light-bodied spirits' are those distilled to high ethanol concentrations using continuous column stills and include Scotch grain and American light whiskeys. 'Heavier-bodied' whiskeys are either batch pot still products or column still products distilled to lower ethanol concentrations. The nature and components of blends are determined by the traditions and regulations of the country of origin. In Scotland, there are a large number of distilleries and blend recipes are complex with as many as 50 malt whiskeys used. Purchasing or exchanging new whiskeys by producers maintains the complexity of these blends. In North America, where there are fewer distilleries and trading between competitors is uncommon, the variety of whiskeys for blending can be increased by variations in mash bills, fermentation conditions, distillation parameters, maturation periods, and cask types.

The physical process of blending is, however, very similar. Approved whiskeys are drained from casks into passivated steel troughs, which convey the whiskey to a blending vat. Mixing uses mechanical agitators and compressed air. When the blend is correct, deproofing water is added to reduce the alcohol content to bottle strength. In Scotland, blending is sometimes followed by a further maturation or marrying period to allow integration of the individual components into the final product. An additional maturation or finishing period is also used for some single malts. This frequently employs a distinctive wood type, such as port casks, and is used to add complexity to a whiskey or to increase the number of styles available from a single distillery.

Most whiskeys are filtered prior to bottling to reduce the risk of haze formation during storage. In heavier-bodied older whiskeys and whiskeys matured at high strengths, high-molecular-weight lipids and wood components slowly flocculate when the whiskey is reduced to bottling strength. This is controlled by chill filtration, where whiskey is cooled to between -10 and 10 °C for a specified period of time and the problem compounds are removed by physical separation and adsorption by a filter. The conventional filter is a plate and frame filter with preformed pads of cellulose or cellulose impregnated or precoated with diatomaceous earth. Operational parameters depend on batch size, the nature of the product, and the filtration rate required.

Patterns of Consumption

The top ten whiskey markets by volume are India, the United States, France, Japan, the United Kingdom, Spain, Canada, Brazil, South Africa, and Germany. Most of these are also major producing countries, but small amounts of whiskey are distilled in many other countries. Some imported whiskey is sold in India, but the majority is 'Indian-made foreign liquor.' These include whiskey, rum, and brandy, but Indian-made foreign liquors are generally manufactured from molasses and therefore do not meet the standards commonly accepted for whiskeys. The total market for whiskey in the United States in 2012 was 50 million 9 l cases (12 bottles of 75 cl), of which the main varieties were bourbon and Tennessee (17 million cases) and Canadian (16 million cases). After a peak in 1983, Japanese whiskey production steadily declined until a small

rise in 2009 to around 100 million liters (11 million cases). A small but increasing volume is exported. Scotch whiskey production in 2011 was 518 million LPA (liters pure alcohol) (approx. 144 million cases). UK sales have been steadily declining for many years and amounted to 25 million LPA (approx. 6.9 million cases), with exports steadily increasing to 354 million LPA (approx. 98 million cases). Major export markets are France, the United States, and Spain, which together accounted for 114 million LPA (approx. 32 million cases). Small amounts of other whiskeys are also consumed in the United Kingdom, mostly North American. Consumption in Canada in 2012 was 4.7 million cases, of which Canadian whiskey accounted for 72%. The market in Brazil in 2009 was 4.2 million cases, of which 1.3 million cases were locally produced blended whiskey (malt whiskey blended with local agricultural alcohol). The remainder was mostly North American and Scotch.

Wines: Champagne and Sparkling Wines – Production and Effervescence

G Liger-Belair, UFR Sciences Exactes et Naturelles, Reims, France

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Since the time of the Benedictine monk Dom Pierre Pérignon, cellar master of the Abbey of Hautvillers from 1668 to his death in 1715, champagne has been a worldwide renowned French sparkling wine. From a strictly physicochemical point of view, champagne is a multicomponent hydroalcoholic systems, with a density close to unity and a viscosity about 50% greater than that of pure water (mainly due to the presence of 12.5% v/v ethanol). Champagne is also supersaturated with dissolved CO_2 formed together with ethanol during the second fermentation process (called *prise de mousse* and induced by adding yeasts and a certain amount of sugar to bottles filled with a base wine and sealed with a cap). Champagne therefore possesses a concentration of dissolved CO_2 proportional to the level of sugar added to permit the second fermentation. A standard 750 ml bottle typically contains about 9 g of dissolved CO_2, which corresponds to a volume close to 5 l of gaseous CO_2 under standard conditions for temperature and pressure. It is no wonder that tasting champagne and sparkling wines differs so much from still wines. The effervescence and dissolved CO_2 impact the terms used in tasting relative to the following: (i) visual perception (the presence of rising bubbles in the glass), (ii) taste and mouthfeel (the fizzy and chemosensory excitation of nociceptors in the oral cavity, as dissolved CO_2 converts to carbonic acid), and (iii) aromatic perception (as bursting bubbles release both gaseous CO_2 and volatile aromatic compounds above the wine's surface).

The modern production of champagne is not far removed from that empirically developed by Dom Pierre Pérignon in the late seventeenth century. The method is also used outside the Champagne region. Sparkling wines produced as such are labeled *méthode traditionnelle* (*méthode champenoise*). Indeed, most American and Australian sparkling winemakers use this method to elaborate their sparkling wines. This method involves several distinct key steps described hereafter. In this article, particular focus is given to the importance of dissolved CO_2 in champagne and sparkling wine tasting. Infrared imaging techniques were recently applied to visualize the cloud of gaseous CO_2 escaping the bottleneck during uncorking, as well as the cloud of gaseous CO_2 desorbing from the wine during pouring.A brief overview of these two steps (short in duration, but highly important in terms of dissolved CO_2 loss) preceding sampling is presented.

From Grape Must to the Bottle: *Méthode Traditionnelle* in a Few Key Steps

A First Alcoholic Fermentation

Three grape cultivars are grown in the 75 000 acres of Champagne vineyards: Chardonnay (a white grape), Pinot Meunier, and Pinot noir (both dark grapes). Usually, around mid-September, the grapes harvested from these vineyards are pressed to release the juice, called 'grape must.' After pressing, the must is transferred into open vats where yeast (*Saccharomyces cerevisiae*) is added. In the Champagne region, the must typically possesses about 150 g l^{-1} of sugars. Generally speaking, the key metabolic process during winemaking is alcoholic fermentation: the conversion of sugars into ethanol and carbon dioxide by yeast. The process of fermentation was first scientifically described by Joseph Louis Gay-Lussac in 1810, when he demonstrated that glucose was the basic starting block for producing ethanol:

$$C_6H_{12}O_6 \rightarrow 2CH_3CH_2OH + 2CO_2 \qquad [1]$$

The manner yeasts contributed to the fermentation process was not clearly understood until 1857, when Louis Pasteur discovered that not only does yeast fermentation not require oxygen, but also alcohol yield is reduced in the presence of oxygen.

The amount of sugar found in grape juice determines the final ethanol level during fermentation. In cool climates, such as Champagne, Alsace, and Germany, where the vines 'struggle' to ripen their grapes, sugar levels are relatively low. Consequently, following eqn [1], such wines often only reach 8–9% (vol/vol) ethanol after the initial alcoholic fermentation. This value is insufficient to produce fine sparkling wines, as those elaborated in the Champagne area (the natural sugar content of the grapes is too low). Winemakers add sugar to the juice in a process called 'chaptalization' (after Jean-Antoine Chaptal (1756–1832) who suggested the process). He contributed significantly to the development of modern winemaking by applying advances in chemistry to agriculture (see **Figure 1**).

Chaptalization involves adding pure cane or beet sugar to the juice extracted from the grapes. Ideally, the first alcoholic fermentation will produce a wine with between 10.5% alcohol and 11.5% alcohol. This percentage must not be exceeded as the law prohibits the sale of champagne with an ethanol content higher than 13% (a subsequent, second, carbon dioxide-trapping fermentation adds between 1.2% and 1.5% of ethanol to the wine). It is important to reach but not exceed levels of ethanol that help the development of important flavors and secondary aromas in the wine. However, during exceptionally sunny years, the grapes reach sugar contents high enough to reach the desired level of ethanol after the first alcoholic fermentation. Under such conditions, chaptalization may be unnecessary.

The Art of Blending

Because it is rare that a single wine from a single vintage, vineyard, and grape variety will provide the perfect balance of flavor, sugar content, and acidity necessary for making a fine champagne or sparkling wine, winemakers often combine several different still (base) wines. This is called the *assemblage* (or

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00755-8

Figure 1 Jean-Antoine Chaptal (1756–1832) contributed to the development of the modern wine industry by attempting to apply to traditional agriculture, the huge advances in modern chemistry done in the early nineteenth century.

Figure 2 A cellar master (Thierry Gasco, from Champagne Pommery) will blend several different still wines from various grape varieties, vineyards, and vintages to produce one champagne. Alain Cornu/ Collection CIVC.

blending) step. It is carried out shortly after the first alcoholic fermentation is complete. Blending is considered a key step in the art of champagne making. A cellar master will sometimes blend up to 80 different wines from various grape varieties, vineyards, and vintages to produce a single champagne or sparkling wine (see Figure 2). The blending of still wines in champagne can come from three grape cultivars. The blend then undergoes a second fermentation – the key step in producing the 'sparkle' in champagne and other sparkling wines.

The *Prise de Mousse*: A Second Alcoholic Fermentation in a Sealed Bottle

Once the blend of base wines is created, sugar (about 24 g l^{-1}) and yeast are added. The entire concoction is put in thick-walled glass bottles and sealed with caps. The bottles are then placed in a cool cellar (12–14 °C), and the wine is allowed to slowly ferment for a second time, producing alcohol and carbon dioxide again. Following eqn [1], the added sugar promotes a second alcoholic fermentation that produces about 11.8 g of CO_2 and 12.3 g of ethanol (per liter) within each bottle. This gain of ethanol increases the ethanol content to about 12.5%. Moreover, the production of gaseous CO_2 is roughly equivalent to half of the concentration of sugar added into the base wine. Thus, a typical 750 ml bottle will contain about 9 g of gaseous CO_2. Due to the molar mass of CO_2 (44 g mol^{-1}) and the molar volume of an ideal gas (~24 l mol^{-1} at 12 °C), it can be deduced that about 5 l of gaseous CO_2 is trapped into a single 750 ml bottle (i.e., six times its own volume).

During the second fermentation process, the CO_2 released cannot escape and progressively dissolves into the wine. Therefore, CO_2 in the wine and headspace under the cork progressively establish equilibrium – following Henry's law. It states that the partial pressure of a given gas above a solution is proportional to the concentration of the gas dissolved into the solution. This is expressed by the following relation:

$$c = k_H P_{CO_2} \quad [2]$$

where c is the concentration of dissolved CO_2 molecules, P_{CO_2} is the partial pressure of CO_2 in the vapor phase, and k_H is its Henry's law constant (i.e., its solubility in wine).

The solubility of gas in a solution is strongly temperature-dependent (the lower the temperature, the higher the solubility). In champagne and other sparkling wines, Agabaliantz examined the solubility of dissolved CO_2 as a function of both temperature and wine parameters. For a typical sparkling wine, Agabaliantz established the temperature dependence of the Henry's law constant. Thermodynamically speaking, the behavior of the constant as a function of temperature can be conveniently expressed with a van't Hoff-like equation as follows:

$$k_H(T) = k_{298\,K} \exp\left[-\frac{\Delta H_{diss}}{R}\left(\frac{1}{T} - \frac{1}{298}\right)\right] \quad [3]$$

where k_{298K} is the Henry's law constant of dissolved CO_2 at 298 K (≈1.21 g l^{-1} bar^{-1}), ΔH_{diss} is the dissolution enthalpy of CO_2 molecules in a liquid medium (in J mol^{-1}), R is the ideal gas constant (8.31 J K^{-1} mol^{-1}), and T is the absolute temperature (in K). By fitting Agabaliantz data with the latter equation, the dissolution enthalpy of CO_2 in champagne was estimated at $\Delta H_{diss} \approx 24\,800$ J mol^{-1} (see Figure 3).

Disgorging and Cork Insertion

The second fermentation is followed by a minimum aging period of 15 months in contact with dead yeast cells (termed *sur lie* aging). The yeasts undergo autolysis during this aging period. During autolysis, the yeasts release a range of compounds that modify the wine's organoleptic properties, donating roundness and its characteristic aroma and flavor. More details about chemical and biochemical features involved in sparkling wine production (from a traditional to an improved winemaking technology) can be found in the 'Further Reading' section at the end of the article.

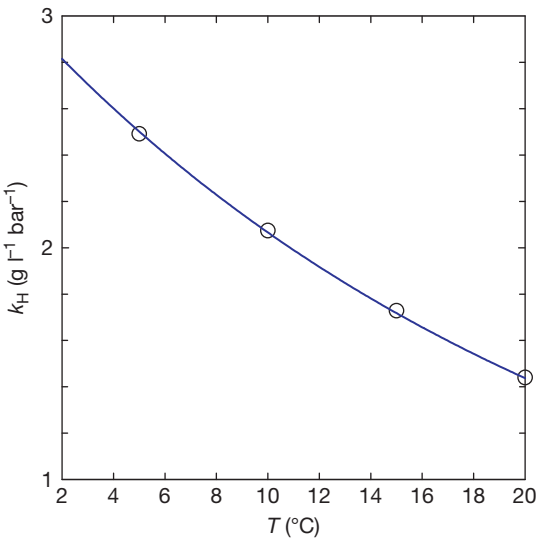

Figure 3 Temperature dependence of dissolved CO_2 solubility in wine (i.e., Henry's law constant) (○), redrawn from Agabaliantz data; the solid line is the best fit to Agabaliantz data, drawn with the van't Hoff-like eqn [2] and with $\Delta H_{diss} \approx 24\,800\,J\,mol^{-1}$.

After aging, the bottles are disgorged. The caps are removed and the plug of dead yeast cells next to the cap is ejected (see Figure 4). A specific dosage, consisting of a mixture of sugar and aged wine, is then added to replace the wine lost during disgorging. A small amount of dissolved CO_2 is also inevitably lost at this step, but rapid resealing with a traditional or technical cork prevents a significant loss of CO_2. After corking, dissolved and gaseous CO_2 in the wine quickly reestablish their equilibrium. Dissolved CO_2 progressively desorb from the liquid raising the gas pressure under the cork. Nevertheless, because the solubility of CO_2 is strongly influenced by temperature, the pressure under the cork also strongly depends on the wine's temperature. As noted earlier, this equilibrium is designated by both Henry's law (for dissolved CO_2) and the ideal gas law (for gaseous CO_2 in the headspace under the cork). Moreover, the total mass of CO_2 is maintained as the wine in the bottle is sealed. Therefore, by combining the two aforementioned laws with mass conservation, the following relationship can easily be determined, linking the pressure P of gaseous CO_2 under the cork (in bars) with both temperature and bottle's parameters as

$$P \approx \frac{mRT}{4.4 \times 10^3 v + (k_H RT)V} \qquad [4]$$

where m is the total mass of CO_2 within the bottle (in grams); k_H is the Henry's law constant, given in eqn [3] (in g l^{-1} bar^{-1}); V is volume of wine within the bottle (in liter); and v is the volume of gas under the cork (in liter).

Typically, champagne and other sparkling wines are available in three bottle sizes, namely, the standard (750 ml), the magnum (1500 ml), and the half bottle (375 ml). Despite their different capacities, each has the same headspace volume ($v \approx 25$ ml), as well as similar cork stoppers (in terms of length and cross section).

The effect of temperature on pressure under the cork in the three bottle sizes is demonstrated in Figure 5. At a temperature typical for tasting champagne (8–10 °C), the pressure within the bottle is close to 5 bars (i.e., $5 \times 10^5\,N\,m^{-2}$), independent of bottle volume. Thus, bottle size has little influence on the internal pressure.

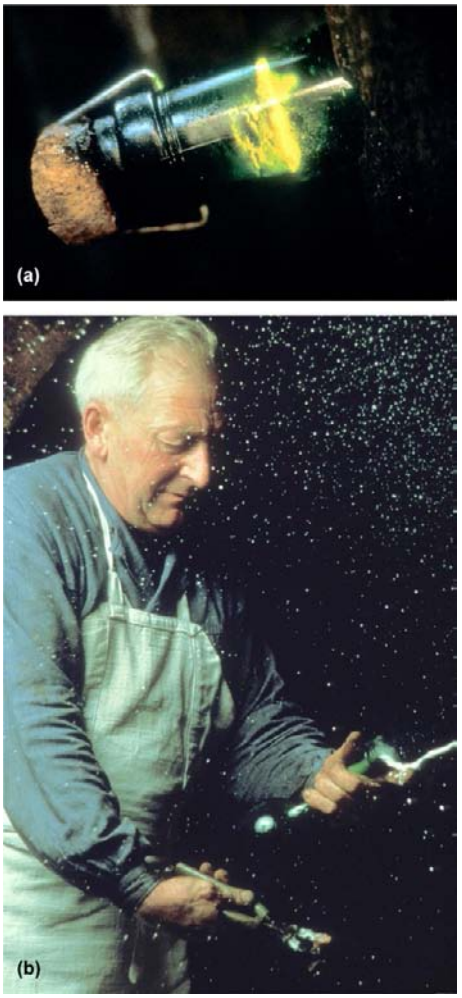

Figure 4 During disgorging, the necks of the bottles are frozen, creating a small ice plug that traps the sediment of dead yeast cells in the bottleneck (a). Traditional cork (illustrated) or bottle cap is removed, and the CO_2 pressure that is released shoots the ice out of the bottleneck, along with all the yeast sediment. Bottles are then corked with traditional cork stoppers (b). Kumesawaga/Collection CIVC.

Moreover, since dissolved and gaseous CO_2 exist in equilibrium in the bottle, the concentration (c) of CO_2 dissolved in sparkling wine can be expressed as follows:

$$c = k_H P \approx \frac{k_H mRT}{4.4 \times 10^3 v + (k_H RT)V} \qquad [5]$$

The relationship between temperature and CO_2 concentration for the three standard bottle sizes is demonstrated in Figure 6. It shows that the smaller the volume, the lower the dissolved CO_2 concentration. Note also that the concentration of dissolved CO_2 is only moderately temperature-dependent (despite the pressure within the bottle being strongly temperature-dependent; see Figure 5).

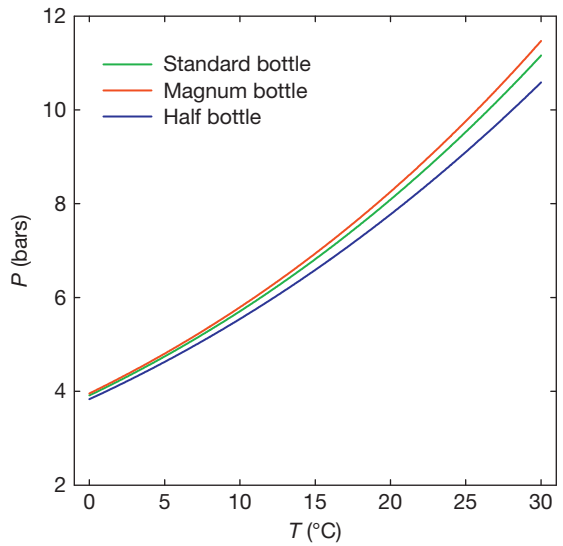

Figure 5 Temperature dependence of the pressure P under the cork, within the three most common champagne bottle types, namely, the standard bottle, the magnum bottle, and the half bottle.

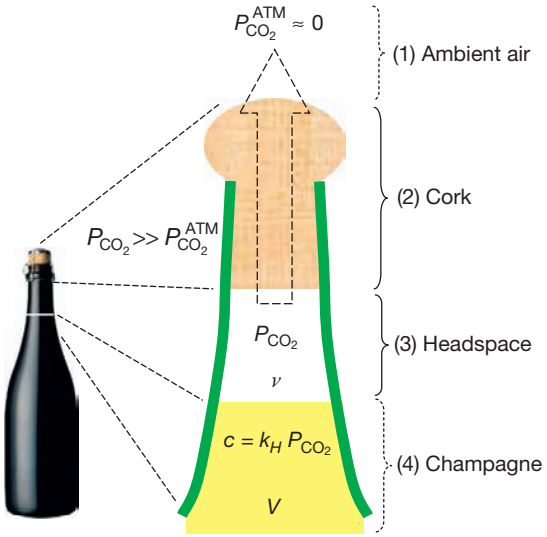

Figure 7 Scheme of the bottleneck and compilation of the various cork, bottle, and wine parameters.

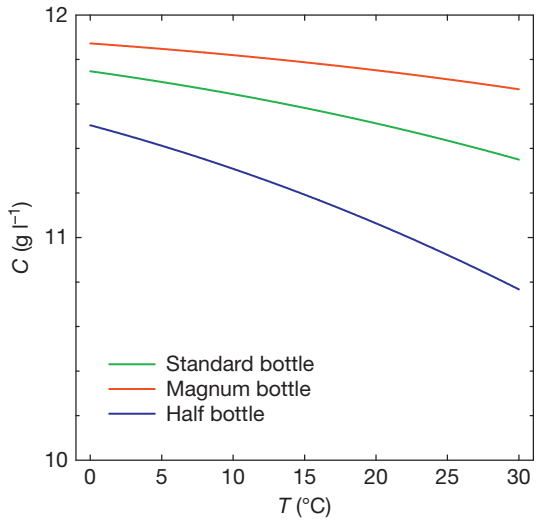

Figure 6 Temperature dependence of the dissolved CO_2 concentration within champagne, within the three most common champagne bottle types.

Concentrations of dissolved CO_2 are easily accessed using carbonic anhydrase, the official method recommended by the OIV (Office Internationale de la Vigne et du Vin) for measuring CO_2 content in champagne and sparkling wines. Numerous experiments with early disgorged champagne samples demonstrated that dissolved CO_2 contents inside freshly opened 750 ml bottles are in the order of 11.5 g l^{-1}, in good accordance with eqn [5].

The Impact of Aging

Cork stoppers used to seal bottles of sparkling wine are far from completely hermetic in terms of gas exchange. Cork is a porous material. Thus, gas species are able to slowly diffuse through the cork, along their associated inverse partial pressure gradients (see Figure 7). In case of corked champagne bottles, the huge difference in CO_2 partial pressure between the headspace (close to 6 bars at 12 °C) and the ambient air (in the order of 0.0004 bar) forces CO_2 molecules to slowly diffuse through the cork. Therefore, during storage, a corked bottle progressively loses both its gaseous and dissolved CO_2 contents.

As noted earlier, early disgorged champagnes possess about $c \approx 11.5\,g\,l^{-1}$ CO_2. Recently, the concentration of dissolved CO_2 in older champagne (bottled in the late 1900s and subsequently stored in a cool cellar) was measured. As expected, the approximately 10-year-old champagne contained substantially less dissolved CO_2 ($c \approx 8\,g\,l^{-1}$) than young versions. This significant loss is interpreted as a consequence of the continuous diffusion of gaseous CO_2 through the pore structure of the cork. By combining diffusion through a porous medium with Henry's law, a multiparameter model was built that shows the dissolved CO_2 content found in champagne across the whole aging period. Both champagne temperature and bottle volume are key parameters concerning the kinetics of CO_2 loss through cork. Nevertheless, additional investigations concerning how cork properties alter over time in the bottle are needed to better understand how their porosity and permeability affect gas transfer.

Chemical Composition

From the chemical point of view, all sparkling wines can be viewed as multicomponent hydroalcoholic solutions, supersaturated with dissolved CO_2. The chemical composition of a typical champagne is given in Table 1.

Typically, gases like CO_2 undergo specific reactions with water. Equilibrium develops between the dissolved $(CO_2)_{aq}$ and H_2CO_3 (carbonic acid):

$$(CO_2)_{aq} + H_2O \leftrightarrow H_2CO_3 \quad [6]$$

Table 1 Average composition of a typical champagne

Compound	*Quantity*
Ethanol	≈12.5% v/v
Dissolved CO_2	11–12 g l^{-1}
Glycerol	≈5 g l^{-1}
Tartaric acid	≈2.5–4 g l^{-1}
Lactic acid	≈4 g l^{-1}
Sugars	10–50 g l^{-1}
Proteins	5–10 mg l^{-1}
Polysaccharides	≈200 mg l^{-1}
Polyphenols	≈100 mg l^{-1}
Amino acids	0.8–2 mg l^{-1}
Volatile organic compounds (VOCs)	≈700 mg l^{-1}
Lipids	≈10 mg l^{-1}
K^+	200–450 mg l^{-1}
Ca^{2+}	60–120 mg l^{-1}
Mg^{2+}	50–90 mg l^{-1}
SO_4^{2-}	≈200 mg l^{-1}
Cl^-	≈10 mg l^{-1}

Typically, pH ≈ 3.2 and the ionic strength is 0.02 M.
Source: Dussaud, A. (1993). *Etude des propriétés de surface statiques et dynamiques de solutions alcooliques de protéines: Application à la stabilité des mousses de boissons alcoolisées*. PhD Thesis, ENSIAA, Massy, France.

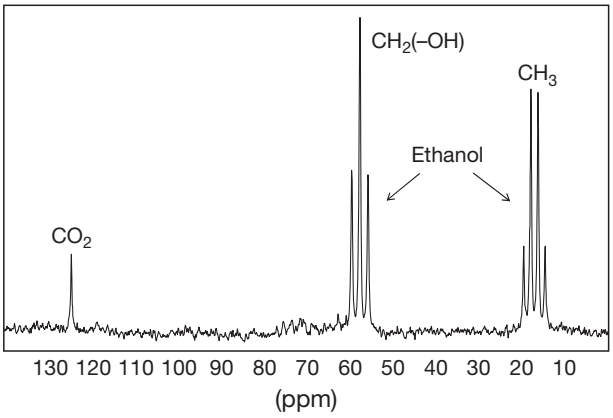

Figure 8 ^{13}C spectrum recorded to measure the CO_2 concentration in champagne; it is clear that no carbonated species (CO_3^{2-} and HCO_3^-) coexist with dissolved CO_2.

Moreover, carbonic acid is a weak acid that dissociates in two steps:

$$H_2CO_3 + H_2O \leftrightarrow H_3O^+ + HCO_3^- \quad pK_{a1}\ (\text{at } 25\,^\circ\text{C}) = 6.37 \qquad [7]$$

$$HCO_3^- + H_2O \leftrightarrow H_3O^+ + CO_3^{2-} \quad pK_{a2}\ (\text{at } 25\,^\circ\text{C}) = 10.25 \qquad [8]$$

However, as the pH of most sparkling wines is relatively low (about 3.2), no carbonated species (CO_3^{2-} and HCO_3^-) should coexist. ^{13}C Magnetic resonance spectroscopy is a nonintrusive, nondestructive method able to determine the amount of CO_2 dissolved in closed bottles of champagne and other sparkling wines. Different well-separated peaks in the ^{13}C spectrum can be seen in the Figure 8: (i) The quadruplet of CH_3 group of ethanol appears at 17.9 ppm, (ii) the triplet of $CH_2(-OH)$ group of ethanol appears at 57.3 ppm, and (iii) the singlet of CO_2 appears at 124.4 ppm, thus confirming the absence of other carbonated species (CO_3^{2-} and HCO_3^-) in the liquid matrix (contrary to fizzy waters, e.g., where pH values near neutrality enable the aforementioned carbonated species to cohabit with CO_2 dissolved gas molecules).

Uncorking and Pouring

Uncorking the Bottle

In order to visualize the cloud of gaseous CO_2 escaping and expanding when the cork is removed from a bottle (invisible in the visible light spectrum), a technique based on infrared imaging has been used. Time sequences displayed in Figure 9 illustrate the uncorking of two champagne bottles, stored at 4 and 18 °C.

As seen in Figure 9, the volume of gaseous CO_2 under pressure in the headspace suddenly expands and gushes out of the bottle. It varies considerably depending on the wine's temperature (mainly due to temperature's influence on headspace gas pressure before uncorking).

After uncorking, the pressure experienced by gaseous CO_2 inside the bottle suddenly falls. Consequently, the thermodynamic equilibrium shifts, and dissolved CO_2 in the wine must inevitably escape to reestablish its equilibrium (fulfilling Henry's law). After removing the cork, the bottle is generally inclined to pour champagne into a flute or coupe. The following paragraph closely examines how dissolved CO_2 progressively escapes from the wine into the headspace of the flute or coupe.

Pouring

Until recently, the impact of pouring on the loss of dissolved CO_2 has remained purely speculation. During pouring, the free air/champagne interface considerably increases. Moreover, pouring causes considerable turbulence, including entrapping air bubbles inside the wine. This also contributes to the diffusion of dissolved CO_2 from the wine to the ambient air. Besides mixing the wine during pouring, eddies of various sizes form in the liquid matrix. These also undoubtedly contribute to a significant loss of dissolved CO_2. The impact of pouring on CO_2 loss was studied at three temperatures (4, 12, and 18 °C) and whether it was poured vertically or on a tilt into a flute (see Figure 10).

Concentrations of dissolved CO_2 (c_L), measured immediately after pouring, are displayed in Figure 11. It clearly shows a correlation between higher temperatures and lower dissolved CO_2 concentrations after pouring. Moreover, it also demonstrates that pouring on a tilt (as beer tends to be poured) has less impact on the concentration of dissolved CO_2 in champagne after pouring.

Visualization, based on infrared imaging, has also been used to film the gaseous CO_2 fluxes outgassing from champagne. Figure 12 illustrates how outgassing is affected as pouring progresses at both 4 and 18 °C. The higher the temperature, the more easily dissolved CO_2 escapes during pouring, confirming the tendency noted in chemical measurements. Note

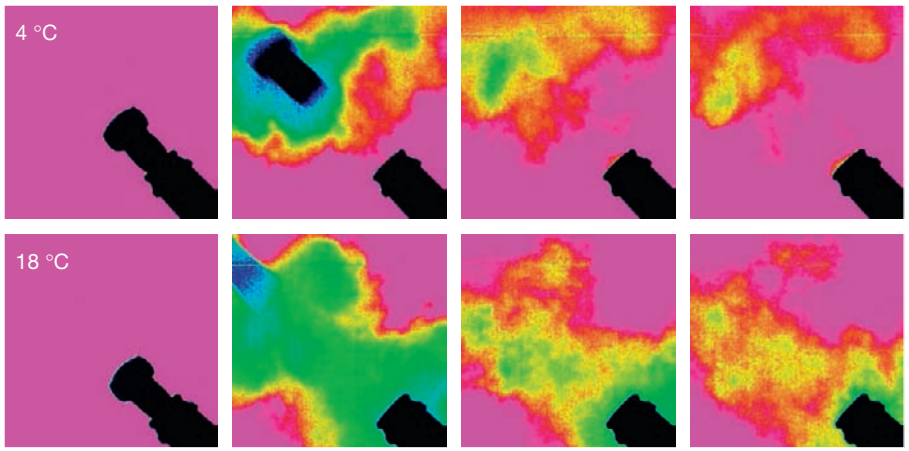

Figure 9 Time sequence illustrating the uncorking of a champagne bottle as seen through high-speed infrared imaging; the time interval between successive frames is 100 ms. The color is an indirect estimation of gaseous CO_2 content (CO_2 molecules absorb some IR wavelengths). High levels show dark blue, while lower levels are in pink/red.

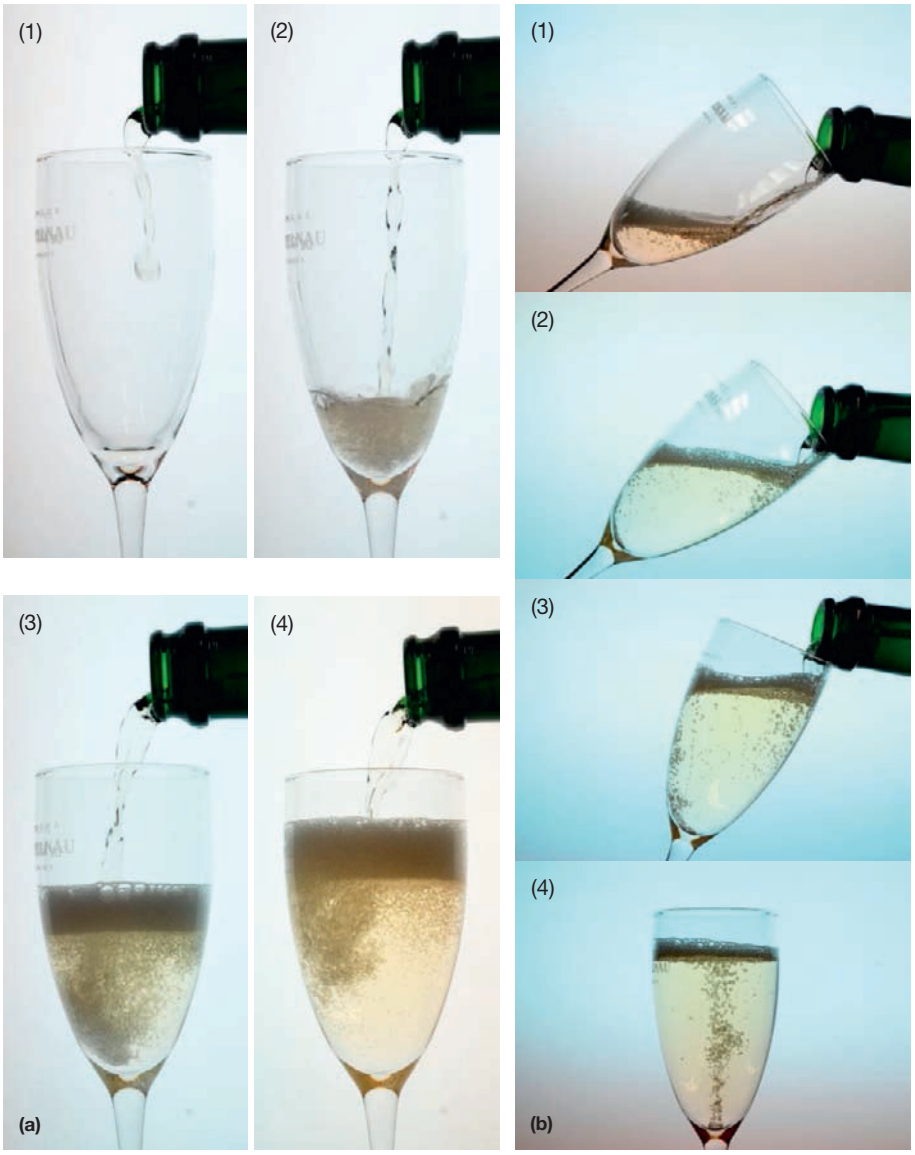

Figure 10 Champagne can be poured straight down the middle of a vertically oriented flute (a) or down the side of a tilted flute (b), with significant differences in the concentration of dissolved CO_2 found within champagne after serving it.

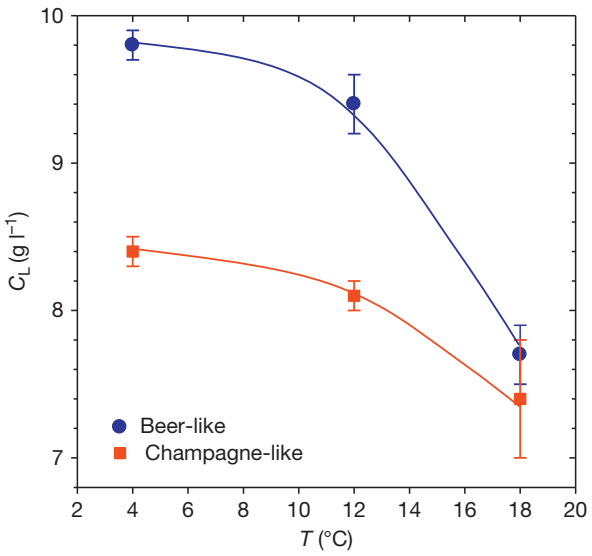

Figure 11 Concentrations of dissolved CO_2, as chemically measured once champagne was poured into the flute, for both ways of serving champagne and for each champagne temperature; each dot is the arithmetic average of four successive values provided from four successive pouring (for both ways of serving champagne); standard deviations correspond to the root-mean-square deviations of the values provided by the four successive data recordings.

that the flow of escaping CO_2 during champagne pouring appears to flow down from the opening of the flute, as if 'licking' the glass walls, rather than diffusing isotropically around it. This observation demonstrates the fact that gaseous CO_2 is approximately 1.5 times more dense ($\rho_{CO_2} = 1.87\,g\,l^{-1}$ at 20 °C) than dry air ($\rho_{air} = 1.20\,g\,l^{-1}$ at 20 °C). Thus, it tends to flow down.

It is worth noting that the surrounding air acts like a huge thermal blanket, quickly warming the outgassing CO_2 during pouring. By considering the gaseous flux of CO_2 discharging from champagne as an ideal gas, the volume of gaseous CO_2 discharging during pouring, denoted $V_{20°C}$, can be expressed as follows:

$$V_{20\,°C} = \frac{\Delta c v_f RT}{M_{CO_2} P_0} \qquad [9]$$

with Δc being the loss in dissolved-CO_2 concentration during pouring (i.e., $\Delta c = c_i - c_L$, expressed in g l^{-1}), v_f being the volume of champagne poured into the flute (in liters, namely, 0.1 l in the present case), T being the ambient temperature (namely, 293 K in the present case), M_{CO_2} being the molar mass of CO_2 (44 g mol^{-1}), and P_0 being the atmospheric pressure (close to 10^5 Pa).

Table 2 compares the losses of dissolved CO_2 (with regard to the initial concentration c_i before pouring of $c_i \approx 11.5\,g\,l^{-1}$)

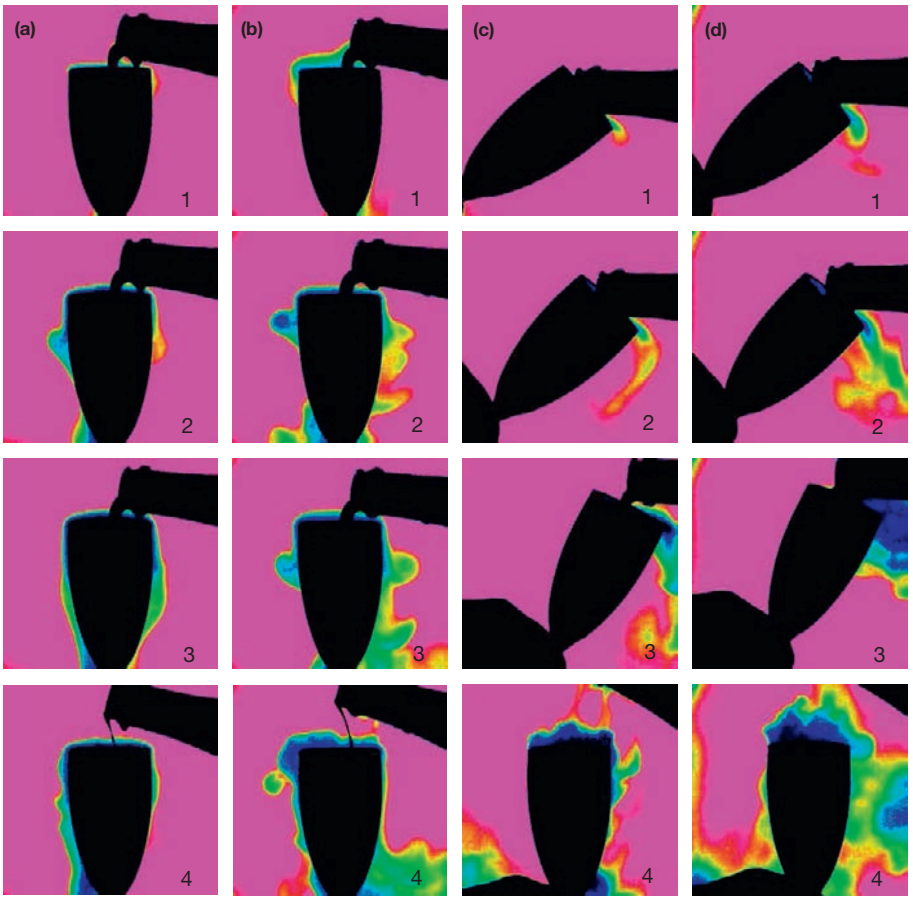

Figure 12 Snapshots illustrating both ways of serving champagne, as seen through infrared imaging – for a bottle stored at 4 °C (a) and (b) and for a bottle stored at 18 °C (c) and (d). The color is an indirect estimation of gaseous CO_2 content (CO_2 molecules absorb some IR wavelengths). High levels show dark blue, while lower levels are in pink/red.

Table 2 Losses of dissolved CO_2 concentrations in champagne during pouring (in g l^{-1}) and corresponding volumes of gaseous CO_2 discharged from champagne (converted in cm^3), for both ways of serving and at three champagne temperatures

	Champagne-like		*Beer-like*	
Temperature (°C)	$\Delta c \left(g\,l^{-1}\right)$	V_{CO_2} (cm^3)	$\Delta c \left(g\,l^{-1}\right)$	V_{CO_2} (cm^3)
4	3.0 ± 0.2	166 ± 11	1.6 ± 0.2	88 ± 11
12	3.3 ± 0.2	182 ± 11	2.0 ± 0.3	110 ± 17
18	4.0 ± 0.5	221 ± 28	3.7 ± 0.3	204 ± 17

and the corresponding volume of gaseous CO_2 escaping during pouring. During the few second it takes to pour champagne into a glass vertically (as typical for sparkling wines), champagne loses approximately as much dissolved CO_2 as during the subsequent 10 min in the glass. To prolong the wine's coolness and to help champagne retain its dissolved CO_2 (and effervescence), the champagne-like manner of serving it is certainly not the most appropriate.

Acknowledgments

Gérard Liger-Belair expresses his gratitude to his colleagues and usual coauthors from and outside the University of Reims. Thanks are also due to the CNRS and the Association Recherche Oenologie Champagne et Université (Reims, France) for the financial support and to the Région Champagne-Ardenne, the Ville de Reims, and the Conseil Général de la Marne for supporting our research. Moreover, special thanks are due to Thierry Gasco, the cellar master from Champagne Pommery, for regularly supplying us with wine samples.

Part I. Madeira, Port, and Sherry Fortified Wines: The *Sui Generis* and Notable Peculiarities, the History, Grapes Used, and Winemaking Process

Introduction

Wine is an alcoholic beverage consumed all over the world. Over the centuries, its production has grown both in popularity and in sophistication. Using a wide range of grape varieties, fortified wines derive their distinctive attributes from the specific and unique winemaking and aging processes employed in their production.

The most well-known fortified wines include *madeira* and *port*, both produced in Portugal, and *sherry* produced in Spain. All three involve the addition of alcohol (fortification with brandy or spirits), with the aim of increasing the total alcohol content up to 18–20%. This procedure may be used to stop fermentation, generating wines with different degrees of sweetness.

Traditional fortified wines are generally associated with areas where the climate and soil conditions do not favor the production of high-quality grapes. In fact, the warm and hotter climates of the *sherry* wine region produce bland, white table wines, the red wines from Douro region are astringent, and the cool, damp summers of the island of Madeira produce wines with acidic characters. However, the application of fortification, maturation, and blending techniques produces wines of great typicity and style. In the succeeding text, we will discuss the technologies used to produce *madeira*, port, and *sherry* wines. In addition to describing historical and traditional practices, their evolution and the chemical characteristics of wines are highlighted.

History

Each wine type has its own history and winemaking characteristics. *Madeira* wine is produced in a variety of styles, ranging from dry (consumed as an aperitif) to sweet (usually consumed with desserts). Historical records show that only 25 years after colonization had begun, the island was already exporting a *madeira*-produced wine. By the middle of the seventeenth century, most producers already fortified their wines. At that time, the West Indies were the main market for *Madeira* wines. Their transportation in the hold of ships exposed the wines to very high temperatures during their passage through the tropics. Eventually, part of the wine returned to Europe, where it was discovered that its quality was greatly enhanced. This induced the intentional transport of barrels of *madeiras* to the West Indies to improve its quality. The eighteenth century was particularly important to *Madeira* wine improvement, which benefited from the general adoption of fortification and *estufagem* (heating process) in its production. *Madeira* wine notoriety in North America is illustrated by its use in toasting of the America Declaration of Independence, in 1776. The commitment to improving the quality of *madeira* continues to be an important concern of producers and trade companies. IVBAM (Madeira Wine, Embroidery and Handicraft Institute) is the organization that regulates *madeira* production and commercialization.

Port has a long history dating back to 1756, when the DDR (Douro Demarcated Region) was declared the third protected wine region in the world, after Chianti (1716) and Tokaj-Hegyalja (1730). Its name comes from the name of O*porto* (*Porto*), the second largest city in Portugal. *Port* is produced in the Douro valley of northern Portugal, in wineries called *quintas*. The vineyards line terraced hills rising up from the Douro river to the east of Oporto, almost reaching the Spanish border. This fortified wine became popular in England during the peninsular campaigns against France. Following the conflict, French wines were banned from England, benefiting Portuguese wines, and *port* in particular.

Port production is tightly regulated by the IVDP (Port and Douro Wines Institute) that limits wine production in the DDR. This region incorporates the subregions of the Lower Corgo, Upper Corgo, and Upper Douro. The first is the oldest and most westerly viticultural area, being simultaneously the least mountainous and most cultivated region (37%). The Lower Corgo favors higher production, generating less concentrated, complex wines. The central subregion, the Upper Corgo, occurs upstream from the previous, covering steep slopes along the Douro. *Port* wines of higher quality are produced in this region that features schistose soils and a more hostile climate. These conditions produce vine stress that lowers yield but enhances grape quality. The last of the three DDR subregions, the Upper Douro, is positioned further eastward and is the largest region (47% of the surface area) but paradoxically is the least productive (7.5% of total production).

Sherry is the most famous fortified Spanish wine. It comes from the southern regions of Jerez de la Frontera and Montilla-Moriles. These include vineyards located within the municipal

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00758-3

boundaries of Jerez de la Frontera, El Puerto de Santa María, Sanlúcar de Barrameda, Trebujena, Chipiona, Rota, Puerto Real, Chiclana de la Frontera, and Lebrija.

Sherry wine is produced in a variety of dry styles, made primarily from the Palomino grape. These styles range from light versions, similar to white table wines (Manzanilla and fino), to darker versions aged in barrels (amontillado and oloroso). In Spain, *sherry* is referred to as *vino de Jerez*. Its earliest records date back to the eighth century, when Moorish Muslims controlled Spain. Over a thousand years earlier, the Phoenicians occupied this area and are believed to have exported wine. It is unknown if the Phoenicians produced wines similar to *sherry*. By the sixteenth century, the wines of Jerez began to resemble contemporary *sherry* and were regularly exported throughout Europe, particularly to England. At this time, *sherry* was widely regarded as one of the finest wines in the world.

Terroir

Grapevines, like other plants, show differences in morphological and physiological phenotype. The relationship between varietal instability and environmental conditions is regulated by hereditary traits influencing phenotypic malleability and selection. The vineyard environment influences all aspects of vine metabolism, growth, and development. Many studies have investigated these relationships, which define the *terroir*, and their effects on wine quality. Overall, the *terroir* involves not only the climate, geology, topography, and soil but also the viticultural ecosystem, grape handling, vinification, and cultural and socioeconomic factors (Figure 1).

Madeira is a volcanic island in the Atlantic Ocean, ~970 km southwest of Lisbon and 600 km northwest of the West African coast. Its total surface area is about 73 200 ha, but its <2% grows *Vitis vinifera* L. grapes. The main viticulture districts are Câmara de Lobos, São Vicente, and Santana (Figure 2).

Madeira has a climate with some tropical influences, with high rainfall and an average mean temperature of 19 °C. Threats from fungal diseases, such as *Botrytis cinerea*, are a constant viticultural hazard as they often inhibit fermentation, resulting in a lower alcohol production. To combat these threats, vineyards are often trained on low trellises, known as *latada* (Figure 3(b)), to raise the canopy off the ground.

The mountainous terrains of the island are difficult to cultivate, so vineyards are planted on man-made terraces of red and basaltic bedrock. These terraces, known as *poios* (Figure 3(a)), are very similar to the DDR terraces where *port* wine grapes are cultivated. The topography does not allow the use of mechanical harvesting or vineyard equipment, making grape growing a costly endeavor.

Regarding *port*, its distinctive qualities are certainly influenced by the unique climatic conditions, topography, and soils of the DDR. The climatic conditions are characterized by a mean annual precipitation between 400 and 900 mm but with only about 30% falling from April to September. The monthly average temperatures range from 5–8 °C to 21–24 °C. The topography involves severe landscape orientations with reliefs unsuitable to mechanization. The soils are schistose, with slatelike metamorphic rock rich in nutrients. They are low in organic content (0.6–1.6%), acidic pH (4.6–5.5), and potassium and phosphorus levels. The surface rock formation has excellent viticultural properties, such as water retention. This enables the roots to penetrate deeply into the subsoil, as well as resisting erosion. In addition, the soil retains heat during the day, transmitting it back to the vines at night. One of the most important factors is the region's

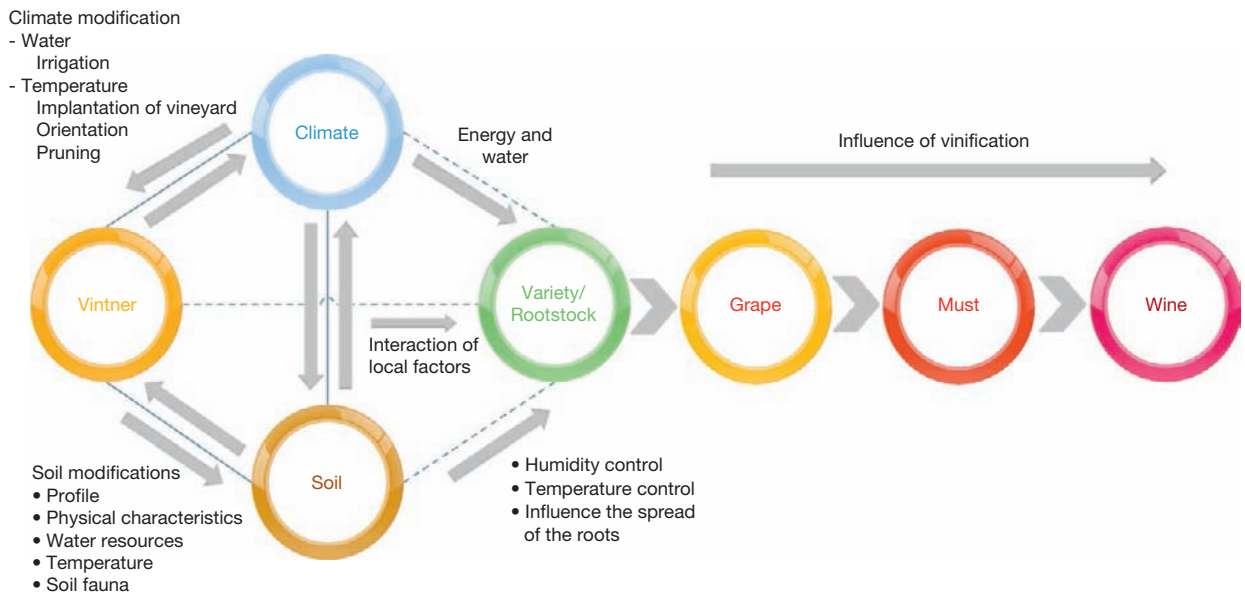

Figure 1 Factors related to *terroir* definition. Adapted from Circle, V. t. W. (2013). http://www.vinetowinecircle.com/en/terroir-2/terroir-and-viticulture (retrieved October 2013).

Figure 2 Main viticultural regions of Madeira island.

(a) (b)

Figure 3 Vineyards traditional systems called *poios* (a) and *latada* (b).

natural climatic variability along its length. However, current accelerated human-induced climate changes are already affecting *port* production. This is mainly because highly variable climatic fluctuations result in marked influences on vineyard management and varietal adaptation. Therefore, much effort will be needed to keep viticulture and winemaking viable and profitable in the region. Possibly, the climate variations will drive shifts in suitable viticultural zones, with some traditional regions becoming too hot while others becoming more viable.

In Jerez, where *sherry* wines are produced, the climate is relatively stable, with a yearly average temperature of 18 °C. The soils are very absorbent and compact, retaining and optimizing the limited rainfall that the region receives. Nevertheless, *albariza*, *barros*, and *arenas* typologies can be distinguished. The *albariza* is a light soil, blending limestone, clay, and sand, and rich in calcium carbonate, being more suitable for Palomino grapes growing. Additionally, these soils reflect sunlight up into the vineyard, thus increasing vine photosynthesis. In turn, *barros* is a dark soil with high clay content and *arenas* is a yellowish soil with high sand content. Both of them are more appropriate for Pedro Ximénez and Moscatel (Muscat) grapes.

Vitis Vinifera L. Grapes

Grapes Used in *Madeira* Production

The *V. vinifera* L. grapes used to produce *madeira* are mainly Bual, Malvasia, Sercial, Verdelho (white varieties, termed 'noble' varieties), and Tinta Negra (a red variety). Unlike the first varieties, Tinta Negra is very resistant to disease (namely, odium and phylloxera). For this reason, it is considered the 'workhorse' variety for *madeira* production. Terrantez and Bastardo are rarely used, although they produce wines of excellent and unique quality. Bastardo, Tinta, and Verdelho Tinto are still recommended, whereas Complexa, Deliciosa, and Listrão can be used, but are not recommended.

Grapes Used *in Port* Production

The number of grape varieties existent in Douro is remarkable, with more than 150 varieties described, most of them of autochthonous origin. This diversity was potentially problematic to *port* wine commercialization and guarantee of authenticity. Thus, since 1985, a list of varieties and respective representativeness in *port* production has been drawn up.

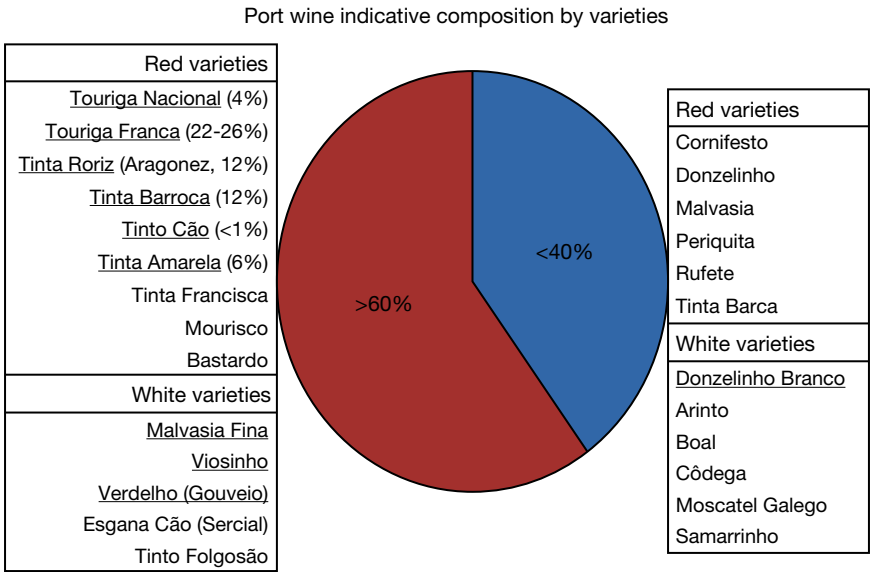

Figure 4 Most common grape varieties used in port production. The underlined grape varieties are the most popular and important varieties used. The vine coverage data available are indicated in brackets.

Table 1 Main grape varieties used in port wine

Grape varieties	*Vineyard coverage (%)*	*Characterization*
Touriga Nacional	4	Its blue-black grapes are small, deep in color, and rich in tannic compounds, being one of the most aromatic of the region (De Pinho et al., 2007). These grapes confer a deep coloration (ruby to violaceous) and a complex and intense aroma (containing essences of red fruits (raspberry and cherry), jammy black fruits (plum), berries (blackberry), raisin, and floral due to its high terpenoid content (α-terpineol, nerol, geraniol, and β-ionone)). In the mouth, these wines are well balanced and structured, with rounded tannins (De Pinho et al., 2007)
Touriga Franca	22–26	Confers to wine an intense color (ruby to violaceous) and a complex, fine, and fruity aroma, containing red fruits (such as raspberry and cherry), berries (blackberry), and floral notes, with high terpenoid concentration, although lower than Touriga Nacional wines (Oliveira et al., 2006). The wines also possess a light herbaceous taste combined with a full-bodied structure. These wines have fine sensory qualities, being a very important component in Port blends
Tinta Roriz	12	It is very resistant to hot weather, giving two to three times higher yields than Touriga Nacional, although intolerant to high mineral content soils and sensitive to mildew and fungal diseases. Produces wines well structured, possessing flavors and tannins of similar quality to Touriga Nacional, mainly when the vine carries few grapes and they are harvested with no rain (Guichard et al., 2003)
Tinta Barroca	11.6	Originates a robust wine with a flowery aroma that contrasts with the fruity aroma of other varieties. In fact, it is often mixed with other varieties to improve the quality of grapes ripened at low elevations (Moreira and de Pinho 2011)
Tinto Cão	<1	Produces small and loose grapes with high sugar contents, being its high natural acidity very important to the quality of port blends with extended aging
Tinta Amarela	6	Its utilization, however, is decreasing due to the high susceptibility of its thin skin to *Botrytis cinerea* vine disease (Moreira and de Pinho 2011)

Nevertheless, the number of grape varieties permitted (>20) is still high. Figure 4 indicates the most important varieties and their representativeness in *port* production, with Table 1 noting their organoleptic contribution. Despite *ports* are normally considered to be red wines, white grape varieties are widely grown, constituting about 34% of vineyard hectarage.

Grapes Used in Sherry Production

For sherry production, only the three white grape varieties, Palomino, Pedro Ximénez, and Moscatel are permitted. These are also the grape varieties best adapted to the region's climate and soil. The Palomino Fino clone is the main grape variety used in sherry wine production. In contrast, Moscatel represents only 2% of the planting area, being mainly used to flavor wines, whereas Pedro Ximénez is used to sweeten wines and can be acquired from outside the demarcated area.

L. Grape Chemical Composition

Defining the desired grape maturity is a difficult task, as several physical and biochemical changes occur simultaneously

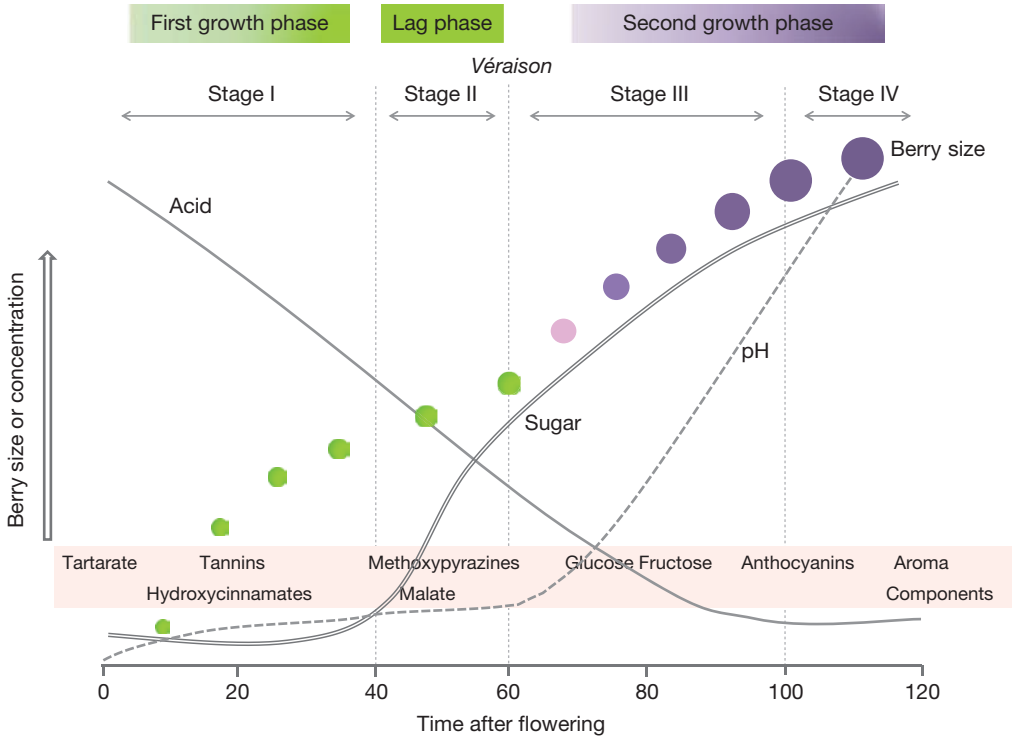

Figure 5 Schematic representation of grape berries composition change during development and ripening.

during grape ripening, affecting weight, sugar content, acidity, pigment development, and metabolic activity, among others. Grape berries exhibit two distinct growth phases (Figure 5), involving four stages.

Stage I begins after fruit set and can last about 40 days. It is characterized by pericarp growth (flesh and skin), increase in seed size, high tartaric and malic acid contents in the mesocarp (flesh), and limited sugar accumulation. The berries are green and hard. In most grape varieties, the first growth phase is followed by a lag phase (stage II), in which cell expansion slows, whereas seed maturation commences. The end of the first growth phase corresponds to the final grape herbaceous phase. Its duration depends on the variety, environment conditions, and agricultural practices. The onset of grape ripening (*véraison*) precedes stage III and interrupts the period of growth absence. It is characterized by an increase in sugar content and pH and decrease in acidity (Figure 5). Moreover, during *Véraison*, chlorophyll degradation and phenolic accumulation commence a color change, for example, yellow gold (flavonols) and pink/red (anthocyanins). Finally, stage IV, also known as engustment, is characterized by full maturity, aroma, and flavor components accumulation. In addition, the berries reach their maximum size and sugar accumulation slowly. The duration of each stage depends on the grape variety, environment, and agricultural practices.

Grape quality depends mainly on its primary and secondary metabolites. Secondary metabolites may not be crucial to plant survival, but they affect grape chemical diversity. They comprise a large number of phytochemical groups, such as alkaloids, terpenoids, tannins, sterols, saponins, and phenolics. Several of them have proved to be of great value in the pharmaceutical, agrochemical, food, and fragrance industries. Their levels can be regarded as a response of biological systems to genetic and environmental conditions. These metabolites occur in both free and glycosylated forms. The latter are aroma precursors, susceptible to transformation into volatile components during various stages of wine production and aging. The free forms, present mainly in grape skins, contribute directly to odor. These include terpenoids (e.g., mono-, di-, and sesquiterpenoids), C_{13} norisoprenoids, methoxypyrazines, thiols, and aromatic alcohols. The monoterpenoids have been associated positively with grape and wine complexity and quality due to their low odor threshold ($\mu g\, l^{-1}$) and pleasant odor descriptors (tea, violet, exotic flowers, and fruit). Similarly, β-ionone (violet-like) and β-damascenone (honey and flower notes) are examples of important C_{13} norisoprenoids. Nonvolatile, glycosylated odorless components are susceptible to transformation into volatile compounds during wine production and aging. Their contribution to wine quality depends on multiple factors, including their content (cultivar- and maturity-dependent) and release from glycosidic bonding by acid and/or enzymatic hydrolysis. Acid hydrolysis occurs slowly during wine storage, although heating can accelerate the process. Enzymatic hydrolysis occurs primarily via glycosidases that present a greater potential to release the aglycone than acid hydrolysis. This reaction starts with the cleavage of the terminal sugars by α-L-arabinosidase, α-D-apiosidase, and α-L-rhamnosidase, followed by the action of α-D-glucosidase (Figure 6). A recent study identified almost 100 odor-active components using enzymatic hydrolysis. However, the issue of which odorants play an active role in wine aroma development has not been systematically addressed.

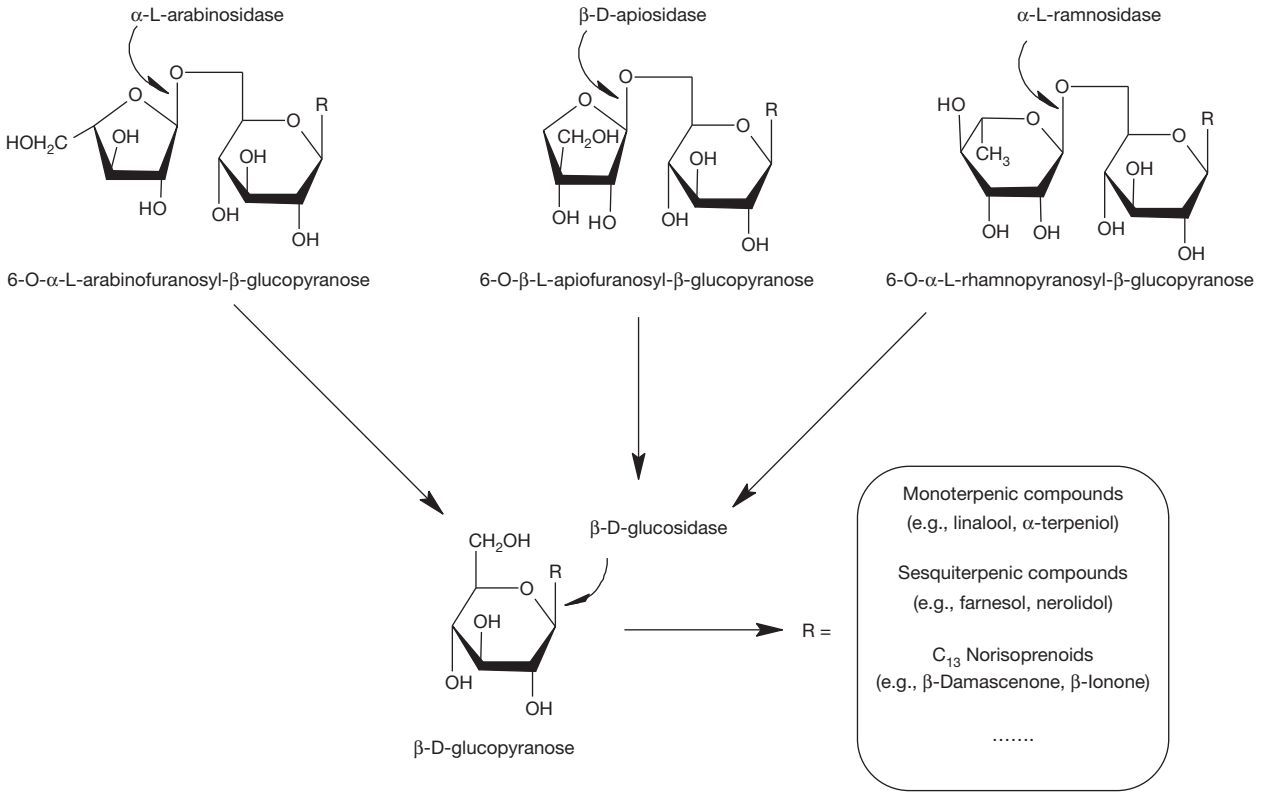

Figure 6 General glycoconjugate structures and hydrolytically released chemical groups occurring in *V. vinifera* L. grapes.

Winemaking Process

Madeira Wines

The grapes are collected and selected, crushed, and fermented using regular procedures. Depending on the style, fermentation is interrupted at different stages by the addition of neutral grape spirits (fortification to 18–19%). Figure 7 shows a schematic illustration of *Madeira* winemaking and aging.

The fortification procedure determines the sweetness level of the four main *madeira* styles (see Figure 8). Traditionally, Sercial is used to produce dry Madeira, Verdelho for medium dry wines, Bual for medium sweet wines, and Malvasia for sweet *Madeira* wines. A heating process, termed *estufagem*, is used to slowly heat the wine (at about 5 °C per day). This is achieved by immersing rods, containing hot water, into the wine. Once having reached 45–50 °C, the temperature is maintained within this range for a minimum of 3 months. During heating, wine organoleptic characteristics change due to the occurrence of several chemical reactions, mainly Maillard reactions and oxidation. After this step, the wines are transferred to oak casks and matured for a minimum of 3 years. The highest-quality *madeiras*, however, are not submitted to *estufagem*. Instead, they are aged in oak casks placed on supports (*canteiros*) in the top floors of cellars. Here, they are exposed to natural temperature and humidity fluctuations (up to 35 °C and 75% humidity during the summer) for up to 20 years or more.

Despite the process chosen, wine quality and production is regulated and controlled by IVBAM (Madeira Wine, Embroidery and Handicraft Institute). Based on their criteria, *madeira* can be characterized on four main parameters: grape variety, aging process, color variation, and wine structure (see Figure 8). It should be also noted that, although not considered in the chart, the heating process used during maturation markedly influences wine quality. The colors shown in the Figure 8 illustrate the color variation during aging. Top-quality *madeiras* typically state the variety used, the *canteiro* aging process, and the duration of maturation (20 years minimum for *Frasqueira*, for instance). Indication of age or harvest year is reserved for *madeiras* exclusively produced with noble cultivars and aged for a minimum of 7 years (for Sercial) and 5 years for the other varieties. Other *madeiras* fall within a broad range of qualities, depending on the duration of aging and blending procedures, *canteiro* being the simplest. In this case, the wine ages for a minimum of 2 years in wood, is then bottled, and is released to the market not before 3 years after harvest. At the other extreme are *solera madeiras*. Starting with good quality wines, 10% is bottled yearly and replaced by an equal amount of another wine of equivalent quality. This procedure can be repeated up to ten times, after which all the *solera* is bottled.

In *madeiras*, heating induces a thermoconversion of some constituents, leading to the production of multiple new aromatic compounds. These include furanic derivatives and volatile phenols. Additionally, wine oxidation is favored by the diffusion of oxygen through the pores of the cooperage (used in the top-quality wines) or controlled exogenously when stainless steel maturation tanks are used. These oxidation reactions are responsible for changes in the wine profile that

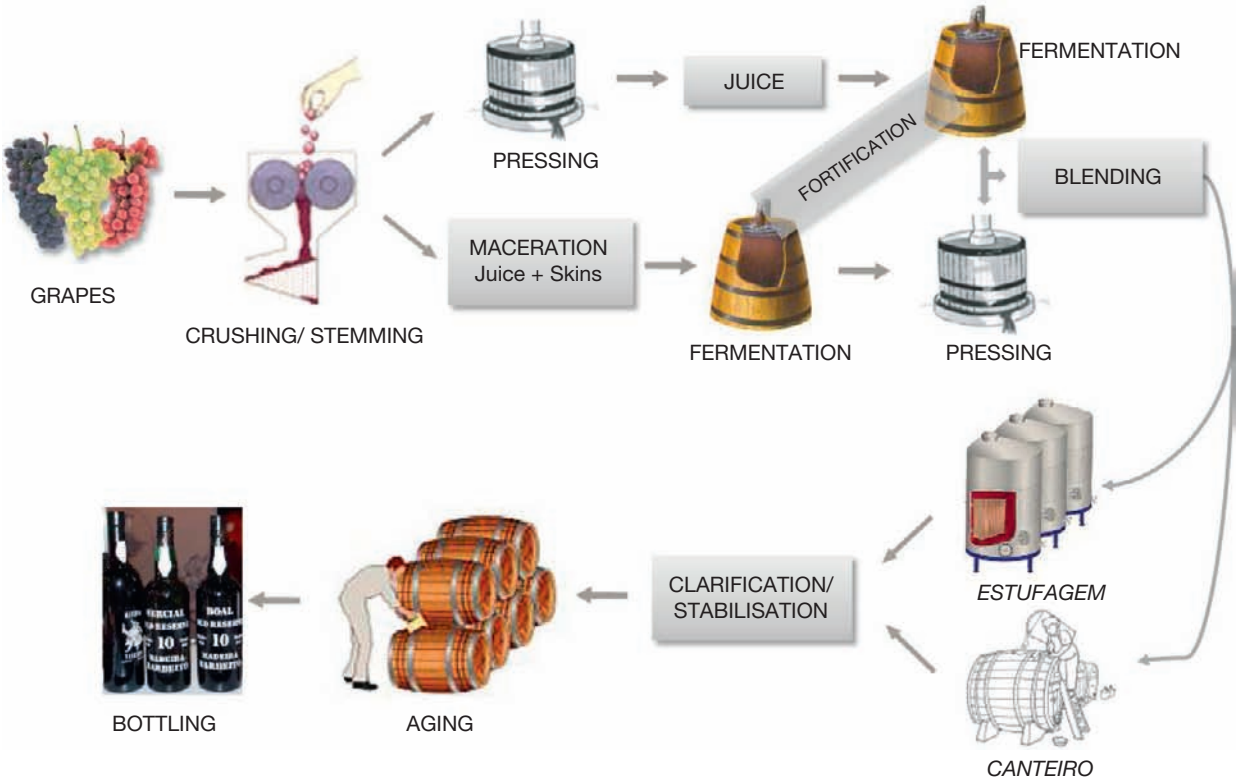

Figure 7 Schematic of winemaking and aging processes to obtain Madeira wine.

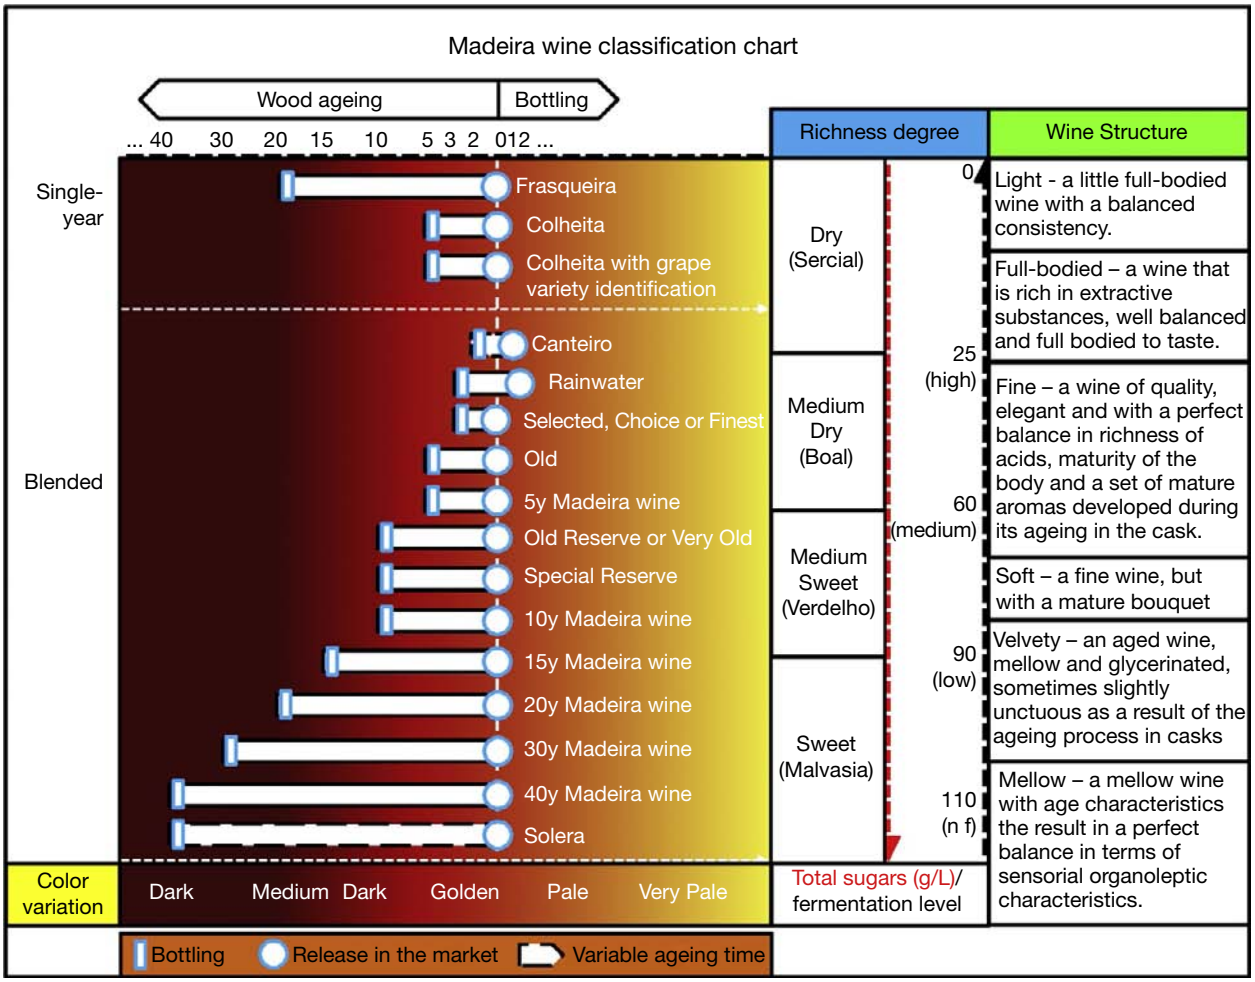

Figure 8 Madeira wine classification chart. The data used in this figure was obtained in the review from Perestrelo et al. (2011).

generate a separate organoleptic profile – usually described as oxidized in dry wines, rancio in sweet fortified red wines, and maderized in sweet fortified white wines. Nevertheless, the most elaborated *canteiro*-aged *madeiras* have a rich bouquet, containing more complex aromas and intense flavors than *madeiras* aged using the *estufagem* process. In fact, for these older *madeiras*, the bouquet is more dependent of the aging process than the grape variety.

Port Wine Production

Port winemaking still employs ancient and traditional procedures, differing only in mechanical improvements. These have been required to cope with the high labor costs associated with grape harvest and crushing (Figure 9). Wine production involves interrupting must fermentation by adding grape spirits (locally designated by *benefício*). This is followed by the preparation of different lots of wines, which are then matured in bottle or wood cooperage.

The grapes selected for vinification should have an alcohol potential between 12° and 14° Baumé. For red *ports*, the stalks are removed (destemmed) and grapes crushed, followed by extensive maceration to increase extraction from the grape skin (particularly the anthocyanins and tannins that confer the deep red color to the wine). This is performed in stainless steel tanks (similar to those used for table wines) to facilitate the control of several parameters, such as fermentation temperature and mixing during maceration.

Fermentation occurs most often spontaneously, using natural yeasts present on the grapes (and winery equipment) at a temperature between 25 and 30 °C. Fermentation continues until the desired residual sugar content is reached, usually within 2–3 days. At this point, fermentation is stopped by discarding the pomace and adding grape spirits (77.0 ± 0.5% ethanol). In the case of white *ports*, both maceration and fermentation with grape skins are virtually absent. An increasingly smaller portion of *Port* wine production involves manual labor, being confined to stalk removal and grape crushing. This is done by treading the fruit in granite tanks (*lagares*). This manual process is much more expensive and, therefore, reserved for selected grapes with the potential to produce a *port* of superior quality.

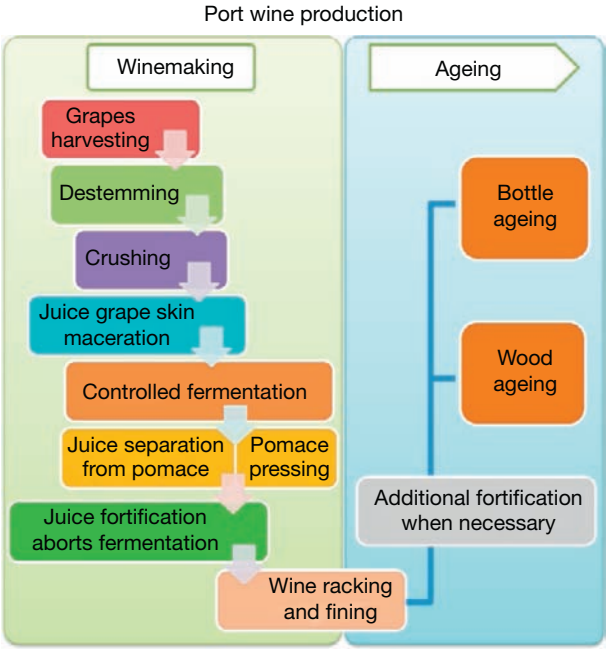

Figure 9 Schematic of winemaking and aging process used to produce port wine. The data used in this figure was obtained in the review from Moreira and de Pinho (2011).

Types of port *wines*

After production, the young wines may remain in the Douro or be transferred to cellars for maturation. Transport was once done in small boats (*rabelos*) along the Douro river but this tradition currently functions only as a trademark for Oporto and *port* wines. As soon as the wines arrive at the cellars in Gaia, they are racked and fined, the alcohol content raised if necessary and the quality assessed by an IVDP (Port and Douro Wines Institute) tasting panel. At this point, the wines follow different maturation processes, depending on their quality and the style preferred. As shown in Figure 10, red *port* maturation may follow two stylistic directions – ruby or tawny. Ruby wines are usually bottled young (after wood maturation for up to 3 years) and aged in bottle for several years, depending on their quality. Correspondingly, oxidation is limited and reductive aging occurs. This constitutes the simplest *port* style, retaining its deep red color and producing a full-bodied wine, rich in tannins and fruity aromas. In contrast, tawny wines are usually matured in small oak cooperage, with no in-bottle aging. Thus, the degree of oxidation is higher, although controlled. As oxidative maturation is prolonged, there is a concomitant loss in color, progressing from tawny, to medium tawny, to finally light tawny. Coincidently, the bouquet resembles dried fruits and develops wood flavors. White *port* wines are far less common. Several variations in the type and duration of maturation, as well as sweetness level, are of recent development. The simplest white *ports* are aged in stainless steel or neutral oak for 3 years, blended, bottled, and released. These *ports* are crisp, with an intense bouquet that combines aromas of melons and peach, with hints of citrus fruit, chamomile, and lemon. In contrast, white *ports* aged in oak for many years acquire a golden color, resembling an old tawny *port*, and show a complex aroma and nutty character.

Grape quality at harvest is the major factor determining the style chosen. As such, a small portion of the best wines is submitted to longer aging to produce the finest *ports*, whether in the ruby or tawny categories. As shown in Figure 10, ruby *ports* include single vintage-based wines: vintage and late-bottled vintage styles. *Colheita* ports are another single-vintage port but can mature in either a ruby or a tawny style. Single-quinta vintage ports are at the pinnacle of the port quality scale, having an additional requisite of being obtained from a single wine estate. All other wines are typically used for blending the great majority of ports, both ruby and tawny. Blending may involve wines from different *quintas*, as well as vintages, except for ports with a stated date of origin. For example, tawny ports are a blend of different lots of wines, matured in casks or vats for different periods, producing a cascade of quality: tawny, tawny reserve, and tawny with an indication of age (10, 20, 30, and 40 years old). Similarly, blended ruby ports may be designated as ruby, ruby reserve, and *crusted* (a blend of

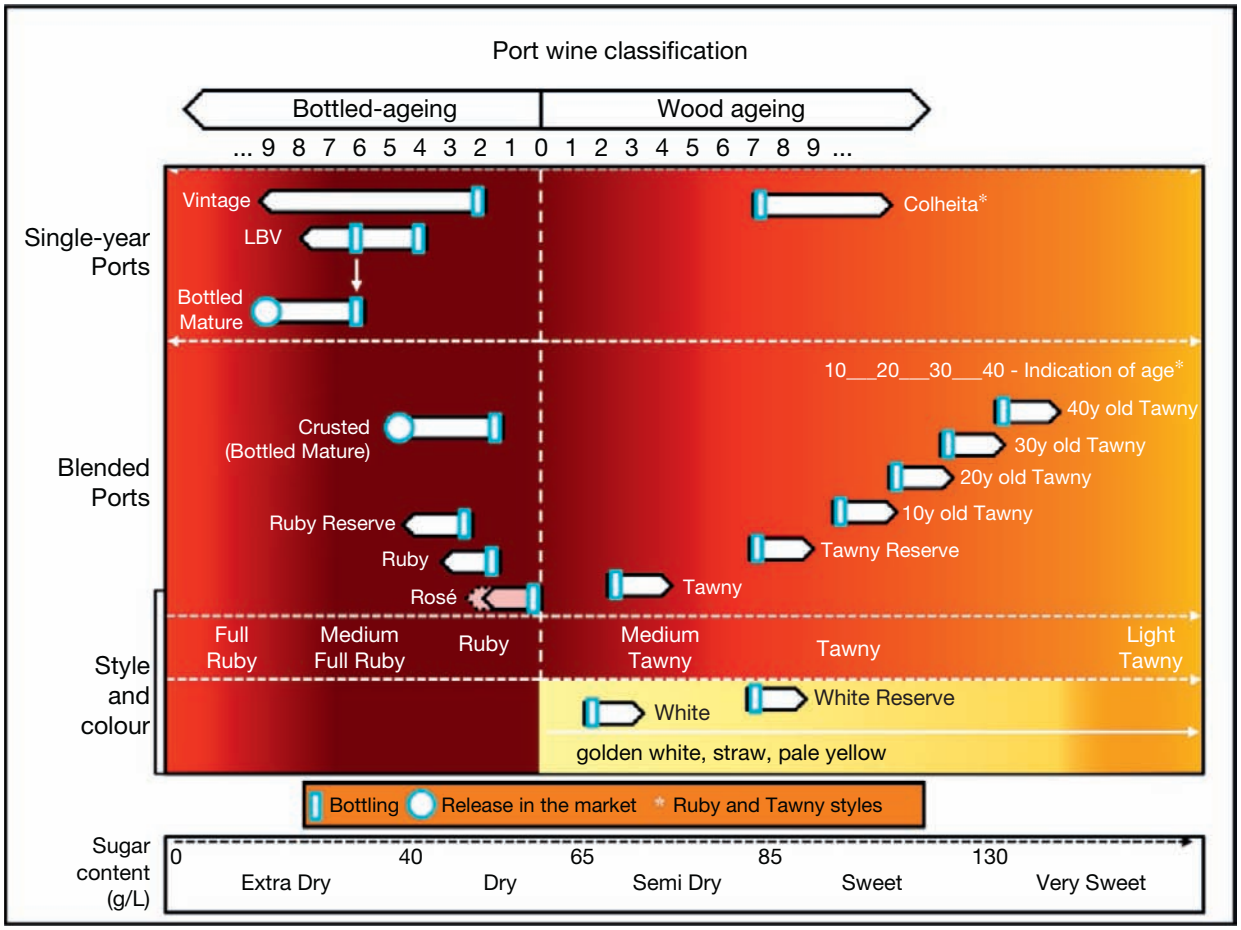

Figure 10 Port wine classification chart. There are several forms of port wine that can be differentiated by its style (ruby, tawny, white, or rosé), aging time and process (in wood, in bottle, or both), grape variety and wine composition (single-year or blended ports), and sweetness (sugar content in g l^{-1}). The colors used in the figure illustrate the variation that occurs in the different port wines during their production and aging and are just an approximation of the real color that the respective wines present. The data used in this figure was obtained in the review from Moreira and de Pinho (2011).

several vintages). In organoleptic terms, all these wines are distinct and become richer and more complex as maturation is prolonged. Generically, ruby-style ports are deep in color and present a full body with exuberant aromas of red fruits and wild berries, balanced with strong tannins. In contrast, tawny ports may possess a wide range of colors (from golden red to tawny) and have a rich bouquet dominated by aromas of dried fruits, roasting, wood, and spices.

Sherry Wines

Vinification starts with grapes harvesting and crushing (stalks included), followed by a rapid juice draining and pressing to limit fermentation in contact with the stems and grape skins. Figure 11 represents schematically the process of sherry wine-making and maturation.

Sherry production limits total phenol content to <200 mg l^{-1} in the free-run juice. Pressed fractions, containing a phenolic content up to 500 mg l^{-1}, can still be used, but heavily pressed juices, containing more than 850 mg l^{-1} total phenols, are not permitted. Wine derived from the first fraction undergoes biological aging (fino style), while that from the first press fraction is usually destined for oxidative aging (oloroso-type style). These fractions cannot exceed 70% of the total wine production each year. Harvesting must, therefore, be done quickly and carefully to avoid grape damage, leading to the release of polyphenol oxidases and juice browning. Similarly, grape crushing and juice separation are performed shortly after harvesting (up to 4 h). An additional requirement demands that juice solids constitute $<1\%$ the juice volume, before fermentation starts. For this, the juice is usually cooled to 12–15 °C, promoting solids precipitation (8–18 h rest period), followed by centrifugation. Fermentation usually involves yeasts naturally present on the grapes. Traditionally, it occurred in oak casks (500–600 l) but nowadays is performed in large, open, temperature-controlled (25 °C), cylindrical tanks (500–1000 hl). Fermentation is usually complete by the end of autumn. Cool temperatures at this time favor yeast and solids settling, which are eliminated by racking. The resultant pale dry wine, containing 11–12.5% alcohol, presents a delicate and slightly fruity flavor and low acidity. The finest wines undergo biological aging, yielding a fino *sherry*. In contrast, wines of more structure (known as *gordura*) are used for oloroso production, which involves oxidative aging. The stylistic direction of maturation is assisted by fortifying fino-style wines to 15.5% alcohol and oloroso *sherries* to

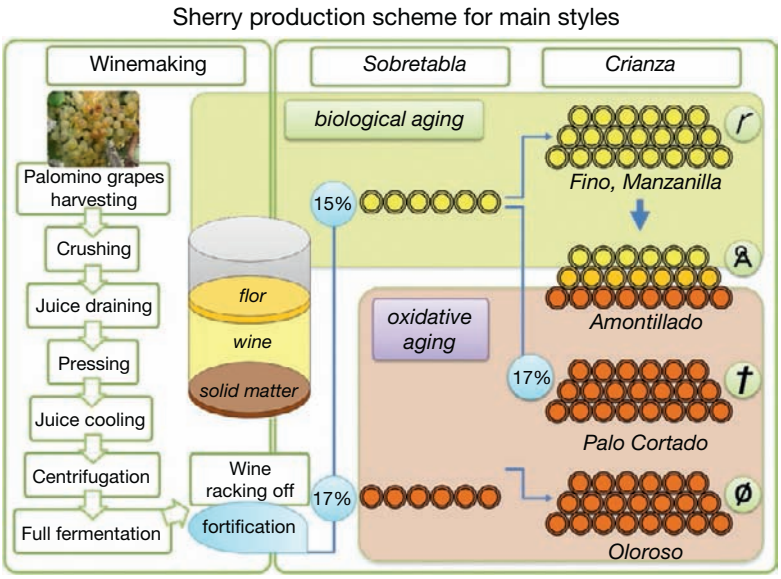

Figure 11 Schematic of winemaking and aging process used to produce sherry. The data used in this figure was obtained in the review from Pozo-Bayón and Moreno-Arribas (2011).

18–20%. These fortified wines, known as *encabezado*, are subsequently transferred to smaller oak barrels where they mature. In fino *sherries*, yeasts still present switch from fermentative to oxidative (respiratory) metabolism, using ethanol as a carbon source. This is associated with the formation of a surface yeast biofilm (velum) called *flor*. It produces a barrier limiting oxygen exchange and wine oxidation. Important metabolic consequences include the production of acetaldehyde and a reduction in glycerol and acetic acid contents. At this stage (*sobretablas*), the winemaker makes a final selection relative to stylistic direction (fino or oloroso). This is possible because additional fortification prevents yeast growth, essential to fino production. Following this decision, the wines are clarified by sedimentation, fortified (if necessary), and placed in oak butts, undergoing further maturation and blending (known as the *solera* and *criadera* system). Fino *sherries* produced in Sanlúcar de Barrameda are called *Manzanilla*, being the driest and most pungent *sherries*.

Oloroso-style aging begins under a *flor* velum, like a fino, but due to their higher polyphenol content and consequent organoleptic differences, wines are subjected to fractional blending involving only oxidative maturation. This starts with fortification to 18–20%, preventing any subsequent *flor* activity, leaving the wine in direct contact with air. Oxidation activates important changes in chemical composition, namely, polyphenol oxidation and a gradual darkening in color. This change is encouraged by putting the wine outside to heat under the high summer temperatures of southern Spain. When brown, the dry wine is known as an oloroso. A proportion may be sweetened with *arrope* and termed a *cream sherry*. The selection between fino or oloroso styles is also affected by climatic conditions during the growing season. In hot years, with drying easterly winds, the vintage is early, and more oloroso is produced, while in cooler, more humid years, the vintage is late, and more fino is produced.

Amontillado is an intermediate, highly appreciated sherry style. It starts out with biological aging (like a fino) but subsequently shifts to a slow oxidative aging (following fortification to 18–20%). Maturation usually lasts 8 years, producing an aromatic wine containing the complexities of both a fino and an oloroso. *Palo cortado* is a special oloroso sherry. The wine is fortified to 15% alcohol and undergoes maturation under *flor* until the *sobretabla* stage. If the winemaker detects special organoleptic characteristics, may select the wine for *palo cortado* production. This involves oxidative maturation and alcohol volume up to 17%. This creates an amontillado-like sherry with an oloroso character, but without losing the elegance of an amontillado. *Palo cortado* is one of the most exclusive *sherries*. Finally, Moscatel and Pedro Ximénez *sherries* are made from late-harvested or dried grapes (dried under the sun or artificially). Fermentation is stopped early to preserve the wine's sweetness and the wine left to oxidize like an oloroso. Figure 12 presents an overview of the different sherry styles and parameters that allow their distinction. As noted earlier, some styles are differentiated by their residual sweetness (based on the duration or absence of fermentation). The degree of oxidation (biological vs. oxidative aging) affects the wine color (from pale to dark).

The solera *and* criadera system*: a never-ending aging–blending system*

The *solera* and *criadera* system is one most distinguishing features of Spanish sherry production. Casks are stacked in rows (*criaderas*) so that all the wine in a single row is of the same type and age. The oldest wines are located at the bottom (the *solera*), followed by progressively younger wine rows. Each cask is filled to about 80% full, if *flor* yeast development is desired. Periodically, up to three to four times per year, about 40% of the *solera* wine is withdrawn for bottling and released to the market. This amount is replaced by wine from the first *criadera* (second row in the system), which in turn is replaced by wine from the second *criadera* (third row of the system). This continues until the uppermost *criadera* is reached and the volume of wine replaced with *sobretabla* wine. The number of *criaderas*

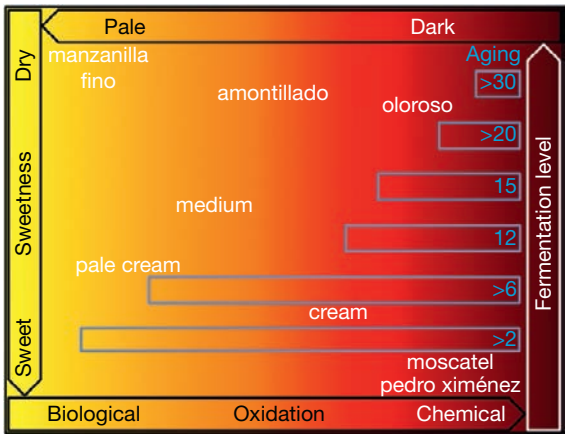

Figure 12 Sherry wine classification chart.

is positively correlated with the quality of the final blend, being typically between 4 and 6. This dynamic system facilitates a reliable, progressive, and fractional blending of the wines. Therefore, most *sherries* on the market are a blend of many vintages, maintaining specific proprietary characteristics. Although most *sherries* are *solera*-aged, there are vintage versions. These are produced via a static aging system known as *añadas*. They are a recent development established to differentiate special vintages, designated as *sherries* of certified age. Accordingly, *sherries* matured for over 20 and 30 years use the initials VOS and VORS, respectively.

Part II. Madeira, Port, and Sherry Fortified Wines: The *Sui Generis* and Notable Peculiarities, Major Differences and Chemical Patterns

Main Style Comparison: Differences and Similarities

Madeiras, *ports*, and *sherries* share several similarities, as well as significant differences (Table 1).

They are exclusively produced in delimitated or demarcated regions, using specific grape varieties (mainly five for *madeiras*, more than a dozen for *ports*, and three for *sherries*) and according to certain vinification specifications. They are fortified wines, meaning that grape spirits have been added during production, although their addition occurs in different stages in vinification and in different concentrations. *Madeiras* and *ports* usually possess an alcohol concentration between 19% and 22%, being lower for *sherries*, about 15% to fino-style versions, and 18% for the *olorosos*. Moreover, in *madeiras* and *ports*, fortification is used to stop fermentation at different stages, allowing a full range of wine sweetness, from dry to sweet. In contrast, in *sherries*, fortification occurs only after fermentation is complete. Therefore, all *sherries* are initially dry, except for the sweet Moscatel and Pedro Ximénez wines (which are not fermented at all). Regarding aging, most *sherries* undergo a unique biological aging process that occurs under a yeast layer (*flor*). This avoids the oxidative aging that occurs in some *sherry* styles. For *ports*, aging may be oxidative (in casks) or reductive (in bottle), while *madeiras* undergo a heating process, in which they are submitted to high temperatures for 3 months before oxidative aging. These particularities during fermentation and aging produce wines with distinctive characters that permit a clear differentiation among them. *Ports* and *madeiras*, for example, present richer, sweeter, and heavier textures than *sherries*, since fortification occurs halfway through the fermentation process. Regardless of these differences, longer oxidative aging produces wines that are more exclusive, possessing higher quality, and consequently are more expensive.

Finally, it is worth noting the differences in the blending procedures used in these wines. *Sherry* winemakers developed a sophisticated system (*solera* and *criaderas*) that allows an accurate and reliable blending from year to year. Thus, *sherry* vintages are infrequent. In contrast, vintage designation is common in superior years for *ports* and *madeiras*, although blended versions are the most common. Interestingly, there is a *madeira* style, *solera*, which is obtained using blending procedures resembling those of *solera* system *sherries*.

Chemical Profile of Fortified Wines

Wine aroma is one of the most important intrinsic factors that influences perceived wine quality and consumer acceptance. Aroma is the cumulative effect of a diverse group of volatile compounds typically detected at very low concentrations (between 10^{-4} and 10^{-12} g l^{-1}). These compounds include mainly alcohols, esters, aldehydes, ketones, fatty acids, terpenes, phenols, and sulfur compounds. Wide differences in their proportions and characteristics result from interactions among five factors: vineyard geographic location, soil, climate, grape variety, and winemaking practices. Several hundred volatile compounds have been identified in fortified wines. However, only a few are present at concentrations above their odor threshold (OT) and thus likely to be responsible for

Table 1 Comparison between fortified wines

	Madeira wine	*Port wine*	*Sherry wine*
Protected designation of origin (PDO)/demarcated region (DR)	Madeira wine/DR of Madeira, Madeira island, Portugal	Port wine/DR of Douro and Porto, Portugal	'Jerez-Xeres-Sherry' and 'Manzanilla of Sanlúcar de Barrameda'/Jerez de la Frontera and Montilla-Moriles, Spain
Alcohol content	19–22% vol	19–22% vol	15% (fino styles), 18% (oloroso styles)
Grape varieties	Bual, Malvasia, Sercial, Verdelho (white grapes), and Tinta Negra (red grape)	High number of varieties allowed, with minimum regulated proportions of ten specific red and white varieties	Palomino Fino, Pedro Ximénez, and Moscatel
Vinification and aging processes	Variable fermentation levels and fortification followed by *estufagem* or *canteiro* oxidation; final wood aging	Variable fermentation levels and fortification followed by wood (oxidative) and bottle (reductive) aging	Mostly full fermentation and fortification followed by biological (*flor*) or oxidative (wood) aging
Styles	Single-year (*Frasqueira* and *Colheita*) and several blends of aged wines	Single-year rubies (vintage, LBV, and *Colheita*) and tawny (*Colheita*) and several blends of aged rubies and tawnies (reserve and indication of age); rosé and white ports	Sophisticated blending system (*solera* and *criaderas*) used in several styles (fino, manzanilla, amontillado, oloroso, palo cortado, etc.). Vintages are not very frequent
Texture	Several textures from light, full-bodied, fine to soft, velvety, or mellow	Rich, heavy, and complex textures, with different degrees of sweetness	Mostly full dry wines, except for the sweet Moscatel and Pedro Ximénez sherries

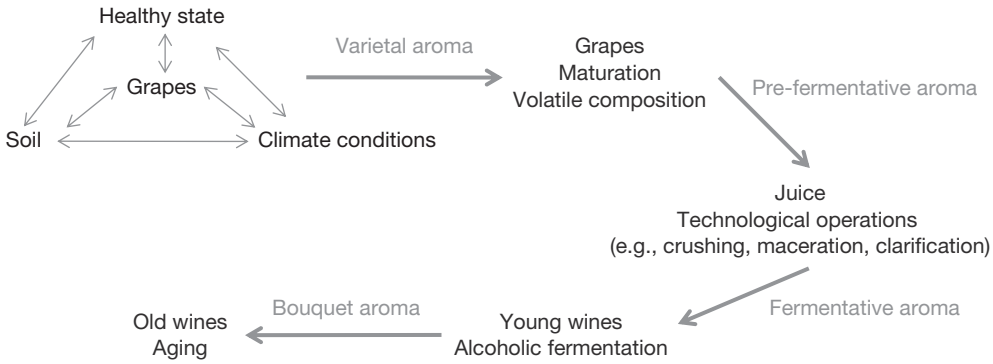

Figure 1 Technological sequence of winemaking process and its relation with different aroma types.

aromatic distinctiveness. These volatile compounds originate from grapes (varietal origin), technological procedures (e.g., crushing and pressing), fermentation, and reactions during maturation (e.g., wood extractives) (Figure 1).

Volatile Profile of Young Fortified Wines

Volatile profile plays an important role in wine quality. By generating odor and occasionally taste sensations, volatiles influence consumer acceptance or rejection. Theoretically, any compound at above its odor threshold (OT) may generate a characteristic aroma (impact odorant). However, impact odors often consist of combinations of distinct odorants. Many of these are present at only trace amounts ($\mu g\,l^{-1}$ or $ng\,l^{-1}$) and at concentrations below their individual OTs. Nonetheless, they may contribute to the overall aroma through interactions with other wine constituents, therefore impacting the wine's aroma.

The aroma profile of *madeiras* has been studied by several techniques. In all analyzed samples, the predominant volatiles identified have been ethyl octanoate, ethyl decanoate, and diethyl succinate. Traces of monoterpenoids (e.g., linalool, nerol oxide, and α-terpineol), C_{13} norisoprenoids (e.g., β-damascenone, β-ionone), and sesquiterpenoids (e.g., γ-eudesmol, α-cadinol, and ι-muurolol) were detected in *madeiras*, which are important from a sensorial point of view. Terpenoids can be employed to differentiate the must and *madeiras* based on the *V. vinifera* L. varieties used. Linalool, α-terpineol, citronellol, and farnesol are the predominant varietal terpenes in the grape varieties used. However, terpenes appear not to contribute significantly to the wine's aroma.

Malvasia musts show the highest terpenoid concentrations, whereas Verdelho the lowest. Malvasia wines are characterized by the highest monoterpenoid concentrations, whereas Bual wines are distinguished by C_{13} norisoprenoids, higher alcohols, and carbonyl compounds; Sercial wines by their acetate, acid, ethyl ester, and volatile phenolic contents; and Verdelho wines by the highest contents of ethyl esters and furans.

The aroma profile of young *ports* differs remarkably from that of oak- and bottle-aged *ports*. Young wines are characterized by floral, bergamot-like, violet, and jasmine descriptors, due to the presence of some terpenoids and norisoprenoids. Figure 2 demonstrates a comparison of volatile pattern of young *ports* and *madeiras*.

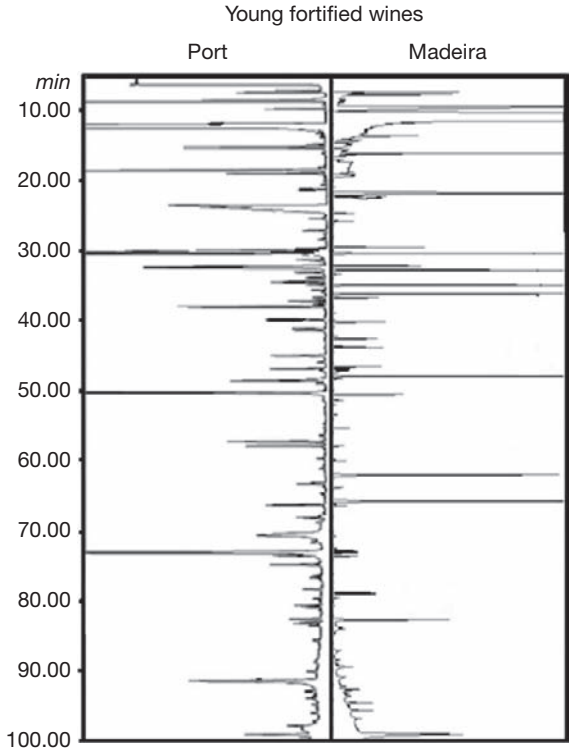

Figure 2 Typical GC–qMS chromatograms of a dichloromethane extract from young ports and madeiras.

The presence of nerol, linalool, citronellol, α-terpineol, geraniol, 1,2-dihydro-1,1,6-trimethylnaphthalene, (*E*)-β-damascenone, (*Z*)-β-damascenone, α-ionone, geranyl acetone, and some esters, like hexyl acetate, ethyl acetate, isovalerate, and ethyl 3-hydroxyhexanoate could explain the citrus and floral odors of young fortified wines. All these varietal and fermentative components, except ethyl acetate, possess low odor thresholds (Table 2).

More than 80 volatiles have been identified in Tinta Negra (used in producing *madeiras*). These include higher alcohols, ethyl esters, volatile acids, and lactones. 3-Methylbutan-1-ol, 2-phenylethanol, isoamyl acetate, diethyl succinate, 2-phenylethyl acetate, phenylacetaldehyde, γ-nonalactone,

Isoamyl octanoate	125	Fatty, fruity, green, sweet, waxy
Ethyl cinnamate	165	Balsamic, cinnamic, floral, fruity, spice, sweet
Ethyl dodecanoate	1500	Soap, sweet
Ethyl hexadecanoate	>2000	Cream, fruity, milk, rancid, sweet, waxy

ethyl hexanoate, ethyl octanoate, hexanoic acid, and octanoic acid seem to be the most sensory important odorants.

The volatile profile of fino *sherries* appears to be characterized by the presence of ethyl acetate, 2-methyl-1-butanol, isoamyl alcohol, 2,3-butanediol, ethyl lactate, 3-hydroxy-2-butanone, acetic acid, 2-phenylethanol, γ-butyrolactone, hexanoic acid, and octanoic acid.

Evolution of Volatile Compounds During Fortified Wine Aging

Aging promotes several modifications in fortified wine composition. These may involve baking, oxidative conditions, and, to a lesser extent, phenomena common to all wine, which are physical, chemical, and microbiological processes. The compounds released from the wood include aromatic aldehydes (e.g., vanillin) and γ-lactones (e.g., *cis*- and *trans*-oak lactones). These can have a great influence on the wine aroma, whereas 2-furfural and 5-methyl-2-furfural, also derived from oak, have little influence (Table 3).

Oxidative conditions can increase the aldehyde content, mainly acetaldehyde and acetals. At wine pH values, acetalization between acetaldehyde and glycerol is highly favored (Figure 3).

The heterocyclic acetals noted in Figure 3 have been shown to form during the aging of both Madeira and Port wines. The content of *cis*-dioxane and *cis*-dioxolane is directly correlated with wine age (Figure 4). The *cis*-dioxane isomer occurs at higher concentrations than its *trans*-isomer.

The predominant changes in *madeiras* during aging involve significant decreases in the concentration of fatty acid ethyl esters, acetates, and terpenoids that are responsible for fresh fruity odors. In contrast, the concentration of ethyl esters of diprotic acids, fatty acids, lactones, volatile phenols, and furanic compounds increases markedly during aging. Figure 5 shows the comparative profile of the volatile compounds of aged *ports* and *madeira*s.

Of more than 120 volatile compounds found in aged *madeiras*, only sotolon (3-hydroxy-4,5-dimethyl-2(5H)-furanone), 2-furfural, 5-methyl-2-furfural, 5-(hydroxymethyl)-2-furfural (HMF), 5-(ethoxymethyl)-2-furfural, *cis*-dioxane, and *cis*-dioxolane were directly correlated with age. The establishment of potential aging markers is important in fraud detection and to ensure wine authenticity. Techniques such as a combination of two dimensional gas chromatography–time-of-flight mass spectrometry (GC × GC–ToFMS) with solid-phase microextraction are aiding in the establishment of potential marker for different grape varieties, wine types, and ages. Considering the chemical groups furans, lactones, volatile phenols, and acetals, 103 volatiles have been tentatively identified. Diethoxymethane, 1,1-diethoxyethane, 1,1-diethoxy-2-methyl-propane, 1-(1-ethoxyethoxy)-pentane, *trans*-dioxane, 2-propyl-1,3-dioxolane, 5-methylfurfural, and *cis*-oak lactone are potential aging markers (Figure 6), independent of variety and wine type.

The impact of oxygen (O_2), temperature, pH, and free sulfur dioxide (SO_2) on the content of dimethyl sulfide (DMS), 2-mercaptoethanol, dimethyl sulfone, methional, and methionol in *ports* has been evaluated. Based on the results obtained, temperature and oxygen are the two main extrinsic factors that contribute to white wine deterioration, since methional level is greatly favored by elevated O_2 concentrations and higher temperatures. However, other studies have shown that methionol decreases significantly in the presence of O_2. Nonetheless, this decrease is not related with a conversion to methional. 2-Mercapethanol decreased in the presence of O_2, whereas the respective disulfide was formed. In summation, oxidative reactions, those occurring during the aging of *ports* in barrel, increase the aldehyde, methyl ketone, acetal, and lactone levels. Other studies have evaluated the influence of O_2, pH, free SO_2, temperature, and time on norisoprenoid content. Bottle-aged *ports* develop floral and violet notes that could be associated to the presence of some norisoprenoids, such as β-ionone, β-damascenone, vitispirane, 2,2,6-trimethylcyclohexanone (TCH), and 1,1,6-trimethyl-1,2-dihydronaphthalene (TDN). However, in traditional barrel aging, vitispirane, TDN, and TCH increased, whereas the levels of β-ionone and β-damascenone decreased. Aged *ports* had more than 15, 5, and 3 times higher level of TDN, vitispirane, and TCH than young versions.

The influence of barrels on the volatile composition of aged wines was studied relative to either French or American oak and at the end of their use cycle (5–6 years). Aging in American oak donates higher concentrations of *cis*-oak lactone (above its odor threshold) but lower concentrations of vanillin, syringaldehyde, and acetovanillone than French oak. For fino *sherries*, sotolon, 1,1-diethoxyethane, and *cis*-whisky lactone were the volatiles most associated with aging and odor impact among the 63 volatile compounds identified. Moreover, fino, amontillado, and oloroso *sherries* can be distinguished chemically relative to their biological or oxidative aging processes.

Impact Odorant in Fortified Wines

Volatile profile plays an important role in wine quality. They can promote several sensations during consumption: odors (due to molecules that can bind olfactory receptors) and tastes (due to molecules that simulate taste bud receptors), which can lead to either consumer acceptance or rejection. In general, a presence of a single molecule, at a concentration above its OT, is enough to provide a characteristic product aroma (impact odorant). Nevertheless, impact odorants often consist of a combination of several hundred of different odorants (molecules). Many of these are present in only trace amounts (usually at $\mu g\, l^{-1}$ or $ng\, l^{-1}$ level). However, even when present at concentrations below their OT, they may contribute to the overall aroma as a result of interactions with other molecules, thereby having an impact on wine aroma perception.

Information related to younger (3–5 years old) and older (10–40 years old) *madeira* aromas is shown in Table 4. It was obtained using a trained panel and is also supported by previous studies. As observed in Table 4, younger *madeiras* are characterized by their freshness and fruitiness descriptors (e.g., citrus, floral, and fruity), whereas old *madeiras* by caramel, dried fruits, spice, toast, and wood notes.

Figure 7 shows the aroma map network of *madeiras*, where each color represents an aroma note, normalized by the mean of OT of their respective chemical group. The line width corresponds to the number of shared aroma compounds. It indicates that grape variety seems to have a great impact on the sensorial properties of young *madeiras*, along with other parameters (e.g.,

Table 3 Volatiles related to fortified wines aged in oaks, their odor threshold (OT), and odor descriptors

Chemical groups	*OT ($\mu g\, l^{-1}$)*	*Odor descriptors*
Sulfur compounds		
2-(Methylthio)ethanol	250	French bean, meat, sulfurous
Methional	0.2	Baked potato, grass, soup
Methionol	1000	Boiled potato, cooked cabbage, rubber, soup
Furans		
2-Furfural	14 100	Almond, caramel, sweet, wood
2-Furanmethanol	15	Honey, medicinal, sweet, toast
2-Acetylfuran	10 000	Balsamic-cinnamic, cereal, sweet, toast, tobacco
5-Methyl-2-furfural	20 000	Acidic, almond, caramel, coffee, spice, toast
2-Pentylfuran	6	Buttery, green bean, mushroom
Ethyl 2-furoate	16 000	Balsamic, scorched tone, vanilla
Furaneol	5	Baked, caramel, cotton candy, toast
Maltol	35 000	Caramel, cotton candy, jammy fruity, sweet, toast
5-Ethoxymethyl-2-furfural	–	Curry, spice
5-Hydroxymethylfurfural	100 000	Almond, cardboard, nutty
Lactones		
γ-Butyrolactone	35 000	Caramel, coconut, cream, peach
Pantolactone	50	Caramel, licorices, sweet, toast
γ-Hexalactone	260	Apricot, peach
γ-Heptalactone	400	Caramel, cheese
γ-Octalactone	7	Coconut, cream, fatty, herbaceous, nutty
trans-oak-lactone	790	Coconut, nutty, toast, wood
cis-oak-lactone	67	Coconut, nutty, toast, wood
γ-Nonalactone	30	Butter, coconut, sweet
γ-Decalactone	10	Fruit, sweet
γ-Dodecalactone	7	Coconut, fruity, musk
δ-Dodecalactone	160	Coconut, fruity, musk, sweet
Sotolon		
Volatile phenols		
Phenol	5900	Bland, medicinal, phenolic, sweet
o-Cresol	31	Leather, spice
p-Cresol	55	Animal, phenolic, smoke
o-Guaiacol	10	Burnt, chemical, clove, phenolic, smoke
p-Ethylphenol	440	Animal, musty, shoe polish, urine
p-Methylguaiacol	65	Candy, eugenol, leather, smoke, spice, sweet, vanilla
p-Ethylguaiacol	33	Clove, leather, phenolic, smoke
p-Vinylguaiacol	40	Almond shell
Eugenol	5	Balsamic, camphoraceous, herbaceous, honey, spice
p-Propylguaiacol	10	Animal, leather
Methyl eugenol	820	Clove, spice
Vanillin	60	Sweet, vanilla
Ethyl vanillate	990	Honey, vanilla
Acetals		
Diethoxymethane	–	Acrid
1,1-Diethoxyethane	719	Green, licorices, nutty, pungent, wood
1,1-Diethoxy-2-methyl-propane	–	Fruity
cis-Dioxane	–	Old port, sweet
1,1-Diethoxybutane	–	Mild
cis-Dioxolane	–	Old port, sweet
trans-Dioxolane	–	Old port, sweet
1,1-Diethoxy-3-methylbutane	–	Fatty
trans-Dioxane	–	Old port, sweet
1,1-Diethoxyhexane	–	Apple, cognac, fruity, hyacinth, pear
1-(1-Ethoxyethoxy)-hexane	–	Earth, floral, fungal, green
1,1-Diethoxyoctane	–	Fatty, fruity, green, oil, spice, wood
1,1-Diethoxynonane	–	Aldehydic, wood
1,1-Diethoxydecane	–	Aldehydic, coconut, green, orange with cognac, waxy

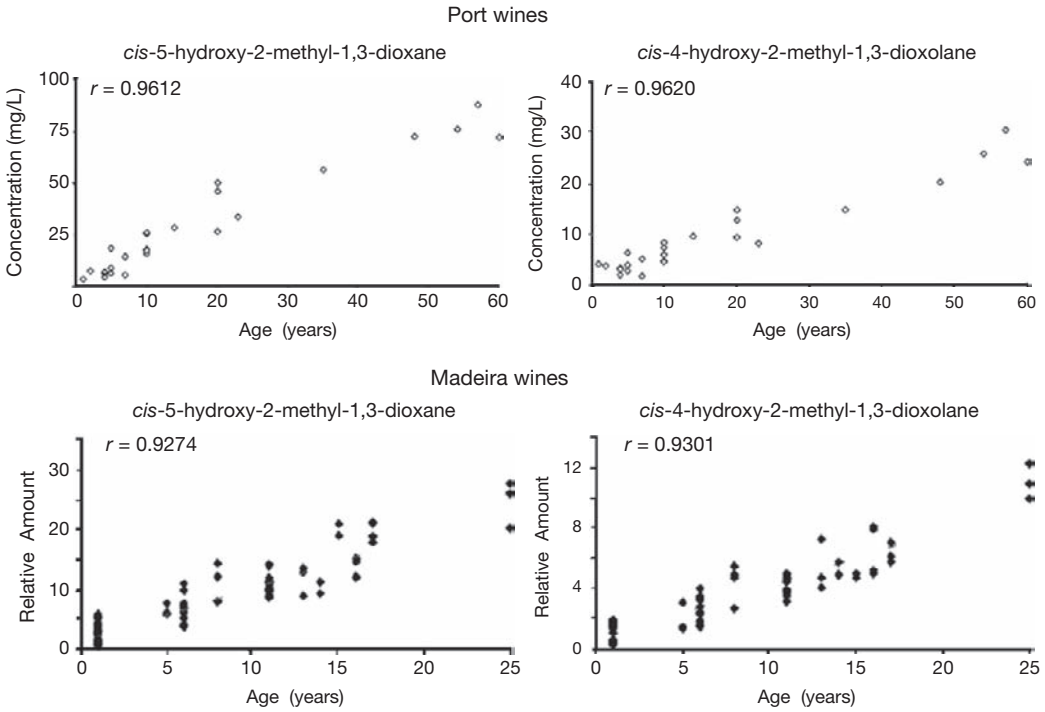

Figure 4 Evolution of *cis*-dioxane and *cis*-dioxolane with age for Port and Madeira wines.

vinification procedures). For example, Malvasia and Bual grapes, used to produce sweet and medium sweet *madeiras*, are characterized by almond and cocoa odors, whereas dry and medium dry versions produced from Sercial and Verdelho grapes are characterized by mushroom and honey notes.

Several studies have focused on potential impact odorants that could contribute to the overall aroma of *madeiras*. Gas chromatography–olfactometry (GC–O) and gas chromatography–mass spectrometry (GC–MS) have been used to establish the aroma profile of four *madeiras*. The GC–O profile of *madeiras* lacks important varietal odorants, such as linalool, 3-mercaptohexyl acetate, and methoxypyrazines, but is rich in sotolon, phenylacetaldehyde, and wood extractable aromas. It also contains a large number of unidentified, intense odorants not present in young *madeiras*. Moreover, furanic compounds, such as 2-furfural, 5-methyl-2-furfural, HMF, and 5-(ethoxymethyl)-2-furfural, are quantitatively predominant, but were not detected by GC–O. This suggests that these

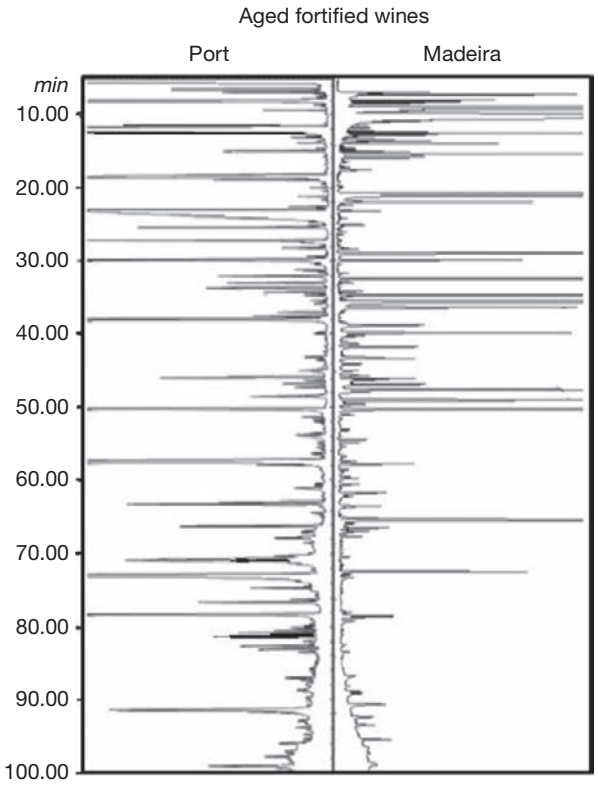

Figure 5 Typical GC–qMS chromatograms of a dichloromethane extract from aged port and madeira.

furanic compounds, although very abundant, are not relevant to a *madeira* aroma. The main reason for this is the high OT that these compounds present (Table 3). In addition, the lowest scores (OT) are related to spicy and lacquer descriptors, whereas the highest OT scores are related to candy, toasty, maderized, and dried fruits notes. However, these contributions depend on the grape variety, winemaking process, and aging. The impact of aging on *madeira* flavor was also studied by GC–O. For this purpose, an expert panel was used to analyze seven descriptors, including dried fruit, nutty, musty, baked, oak, mushroom, and brown sugar. On the basis of the aroma extract dilution analysis, several Maillard by-products such as sotolon, 2-furfural, 5-methyl-2-furfural, 5-(ethoxymethyl)-2-furfural, methional, and phenylacetaldehyde were identified. This may explain the baked, brown sugar, and nutty odor notes, characteristic of aged *madeiras*.

Sotolon is produced from an aldolization between α-ketobutyric acid (from the deamination of L-threonine) and acetaldehyde. Due to its low odor threshold (10 $\mu g\,l^{-1}$), sotolon is recognized as a key constituent in the typical aroma of barrel-aged *ports* and *sherries*. This donates a degree of similarity to old *madeiras*. Generally, the sotolon concentration in *sherries* is above 200 $\mu g\,l^{-1}$ but depends of the duration of aging. Thus, there is good correlation between wine age and sotolon content. The presence of sotolon is also dependent on O_2 regimes during aging, having a major impact on 'age perception' in barrel-aged *ports*. Other lactones extracted from oak constitute important odorants in barrel-aged fortified wines. Example includes α-butyrolactone, pantolactone, and *cis*- and *trans*-whisky lactone. Besides the duration of aging, lactone concentration is closely linked to yeast strain. Other compounds derived from precursors extracted by ethanol from the casks (Figure 8) contribute with clove-like spicy notes to fortified wines aroma, notably 4-ethylphenol, 4-ethylguaiacol, and eugenol. The concentration of these compounds increases with aging time.

From a sensorial point of view, using the calculated odor activity values (OAVs) and OT, sensorial differences were observed between the three types of Sherry wines. Fino *sherries* are marked by floral and fruity (e.g., farnesol, β-citronellol, and β-ionone), cheesy and rancid (e.g., butanoic acid), and pungent (e.g., acetaldehyde) notes. Oloroso *sherries* exhibit smoky and ethereal notes associated with 4-ethylguaiacol and ethyl acetate, respectively. Amontillado *sherries* exhibit flavor notes from both aging processes, resulting in the more complex aroma of the three styles analyzed. Acetaldehyde, ethyl acetate, ethyl lactate, β-citronellol, and β-ionone showed intermediate concentrations between fino and oloroso *sherries*, revealing the participation of both aging types. Recently, GC–O has been used to evaluate the evolution of the odor-active compounds in amontillado *sherries* during aging. Twenty-five odor-active compounds changed in during the first few years of oxidative aging. Ethyl octanoate, ethyl butanoate, eugenol, ethyl isobutanoate, and sotolon are the powerful odorants. Most analyzed odorants exhibited increases in concentration during aging, leading to the more intense flavor of the wines.

Phenolic Profile

Phenolic compounds are unstable, with their composition beginning to change as soon as crushing or pressing is complete and continues throughout winemaking and aging. These reactions may involve self-interaction and binding with aroma compounds. The latter can influence aroma release and thereby perception. The different winemaking procedures used in producing fortified wines result in remarkable differences in phenolic composition. Moreover, phenolic concentration increases due to extraction from wood cooperage. Wood type, storage time, and temperature can all influence phenolic structure and composition.

Gallic acid is the predominant phenolic in *madeiras*, followed by *p*-coumaric, caffeic acids, *trans*-resveratrol, and epicatechin. The antioxidant potential and color of the wines increase during *estufagem*, whereas phenolic content decreases, with the exception of caffeic, ferulic, *p*-coumaric, gallic, and syringic acids. Some of these time-related changes in phenolic content have been investigated as a means of verifying the stated ages of *madeiras* and *ports* wines. Particularly valuable in this regard are changes in the structure of anthocyanins. For example, acylation on the sugar moiety appears to decrease steadily with time. The rate of structural changes is also a function of maturation in oak, stainless steel, or glass interaction as well as oxygen exposure.

Changes in the phenolic content of *sherries* also reflect the production style (fino, amontillado, or oloroso) – greater oxidative aging enhancing the phenolic content. In fino *sherries*, phenolic aldehydes were low to almost absent, whereas benzoic acid contents increased. In oloroso *sherries*, benzoic and cinnamic acid contents remained constant, whereas phenolic

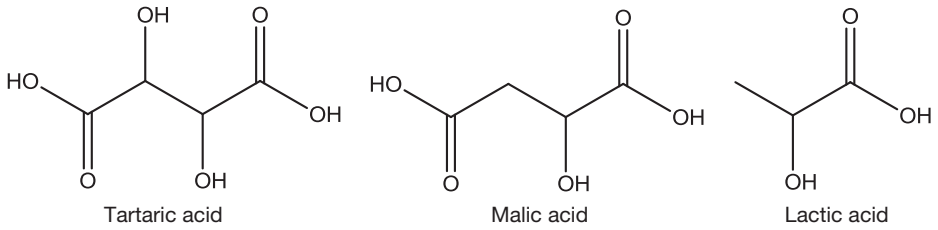

Figure 9 Chemical structure of predominant organic acids in Madeira wines.

acids, such as gallic, syringic, and caffeic acids, changed significantly. Not surprisingly, amontillado *sherries* were characterized by a phenolic composition between fino and oloroso styles. Some of these differences appear to be useful in chemically distinguishing *sherry* styles.

Organic Acids

The organic acid profile provides information relative to fermentation, wine stability, sensory attributes, microbial state, and geographic authenticity. Tartaric, malic, and citric acids (Figure 9) are grape in origin and the most common organic acids in wines, whereas succinic, lactic, and acetic acids result from alcoholic and malolactic fermentations.

In *madeiras*, with the exception of acetic acid, volatile acids usually occur below their odor threshold. In contrast, acetic acid occurs at low concentrations in *sherries*. This results from it being metabolized by *flor* yeast. Glucuronic acid levels can be used as a measure of the amount of rot in harvested grape. Only concentrations below 1 g l^{-1} are considered acceptable for *sherry* production.

Nitrogen-Containing Compounds

Proteins, peptides, and amino acids constitute the must's nitrogen pool. These are important as yeast nutrients, deficiencies often leading to sluggish or stuck fermentations. Occasionally, some amino acids can produce undesirable compounds, such as ethyl carbamate, biogenic amines, ochratoxin A, and carbolines. Factors influencing their occurrence include the grape variety, fertilization, season, ripeness, and enological practices.

The most abundant amino acids in *madeiras* are phenylalanine, arginine, and γ-aminobutyric acid, whereas biogenic amines occur at below their detection limit. This is not surprising as most biogenic amines are a by-product of malolactic fermentation, a process that does not occur during *madeira* production.

Sherry biological aging reduces the amino acid content and other nitrogenous constituents, such as ammonium and urea in the wine. Thus, proline remains the main nitrogen source for *flor* yeast growth during fino maturation. The consumption of several other amino acids is also accelerated during maturation.

Mineral Composition

Assessing mineral content is important as those such as potassium, calcium, iron, and copper can produce precipitates and cloudiness. Maximum contents are also set by the international community due to potential toxic effects. Mineral content can also affect a wine's geographic authentication or negatively influence its organoleptic properties. Content depends on features such as soil, viticulture practices, aging, environmental contamination, and adulteration. The mineral content of *madeiras* is in agreement with most values reported in the literature, except for sodium. Mineral content may also assist in validating a wine's geographic origin.

Only Fe and Mn contents appear to likely influence the browning of fino *sherries*. *Sherries* tend to have significantly higher levels of Ca and Mg ($p < 0.005$) than white and red table wines but lower Cu contents. Ca and Mg contents appear to be the best markers for wine region classification.

Recent Developments

Fortified wines, in particular *madeiras*, *ports*, and *sherries*, are primarily produced using ancient vinification procedures that have been empirically improved over time. Thus, they are not prone to innovation. Correspondingly, modifications to *madeira* production are uncommon. However, a new rosé style of *port* has been introduced, as well as dry versions of white *ports* with a lower alcohol content created. Rosé *port* derives its color from using a short maceration of red grapes and avoiding oxidation during it maturation. These wines are designed to be drunk young, being characterized by red fruits notes (cherry, raspberry, and strawberry). They are soft and pleasant on the palate and should be drunk chilled, with ice, alone, or in a cocktail. Light dry white *port* was developed to fulfill the demand for less alcoholic *ports*. This new variant of white *port* is characterized by a floral and complex aroma and an alcohol content about 16.5%. Finally, in the early 2000s, *sherry* age dating has been permitted to promote the sale of more expensive *sherries*. This initiative started with the *Vinum Optimum Signatum* and *Vinum Optimum Rare Signatum* designations for *sherries* of exceptional quality and aged for 20 or 30 years, respectively. Only amontillado, oloroso, palo cortado, and Pedro Ximénez *sherries* are suitable styles to receive either of these designations. Following the success of these rare sherries, another two age-dated series have been created, 12- and 15-year-old *sherries*. In this instance, only individual *soleras* of a certain age and quality are suitable for this classification. Again, they are not applicable to fino or manzanilla styles. Finally, there is a very rare style, *añada*, reserved for vintage-dated *sherries*. Considering the complexity of *sherries* production, much research has been conducted to improve some technological aspects, namely, those involving the biological aging. *Flor* is a very fragile structure, highly susceptible to

environment and climate conditions. Nonetheless, it has to be maintained on the top of the wine for at least 4 years. It has been proposed that microoxygenation in stainless-steel containers, followed by aging in oak casks under cellar conditions, could shorten the biological aging period without compromising wine quality. Another improvement related to the production of sweet *sherries* that has been already adopted is the use of driers to blow hot air over harvested grapes, thus facilitating rapid water loss. Rapid partial dehydration is crucial in concentrating the grape's sugar content and overcoming problems associated with the unfavorable climate conditions.

Wines: Types of Table Wines

RS Jackson, Brock University, St. Catharines, ON, Canada

© 2016 Elsevier Ltd. All rights reserved.

Classification is a common human trait. Without it, precise communication would be impossible. Unfortunately, the natural desire to group wines into logical categories is fraught with difficulties. Table wines are an eclectic mix of grape-based beverages. Their production reflects local soil and climatic conditions, indigenous grape varieties, technological developments, and cultural and stylistic preferences. To complicate matters further and to distinguish their wines from their neighbors, winemakers are turning to age-old, neglected techniques to provide that *je ne sais quoi*. Consequently, there is little rational or evolutionary affiliation among these diverse products, other than their typical consumption with food. In the absence of a fully useful basis for organizing wines, they have generally been grouped according to simplistic features that tend to be relatively stable and easily detected (e.g., color, effervescence, and alcohol content) or denoted (e.g., provenance or variety). Regrettably, most of these are of limited sensory value.

Despite its limitations, classification based on these features gives consumers the felling that they indicate their sensory attributes. For example, red wines typically are more flavorful, jammy, drier, and astringent than white wines, which generally have milder flavors, are more floral/fruity, and more acidic. White wines may also come in semisweet and sweet styles, something red wines seldom do. Other stylistic variations, not discussed here, include those with an obvious effervescence (see Sparkling Wines) and the various forms of fortified wines (see Fortified Wines). In contrast to table wines, sparkling wines are typically associated with celebration (but can also pair well with food). Fortified wines are typically taken alone, before eating as an aperitif (if dry), or after the meal (if sweet). The mention of a particular grape cultivar or region can suggest, to those possessing sufficient experience, the likely presence of a particular set of flavor and taste attributes. Provenance seldom does this, despite the common belief that it does. This view is one of the rationales for the common organization of wines by country and region. The division of wines into table, sparkling, and fortified categories is also often used by governments – the latter two being taxed more highly.

The problem with any of these empirical groupings is that whatever sensory predictive value they possess depends heavily on experience, a property most consumers lack. Although people can readily distinguish color categories (if in bottled in clear glass) and may recognize some geographic and stylistic names, they seldom have a clear concept of their range of sensory attributes, which can be enormous. Despite the value of a clear, useful, classification of table wines, the diversity of table wines is beyond any fully rational, readily understandable, coherent categorization. Ideally, organization should be based on those features that generate the diversity found in table wines (Figure 1). Although it would be more intellectually satisfying, it still fails to provide the neophyte with data sufficient to knowledgeably direct their purchases.

The most critical element influencing the sensory features of a wine is the winemaker. Although little is noted on wine back-labels or winery publicity, their significance is often considered pivotal to profitability. This significance is partially reflected in the increasing popularity of 'flying winemakers' – those who have developed a reputation for superior winemaking acumen. Winemaker input is so marked that, starting with red grapes, an almost infinite spectrum of wines can be produced – from almost colorless to yellow, pink, light red, and dark red purple, with equivalent variations in flavor intensity and aging potential. Fewer options are available employing white grapes, except where sweet table wines are concerned. In addition, the winemaker may direct production toward sparkling versions of any of the former styles or choose to produce sherry-, port-, or madeira-like wines. Wines may also be distilled to produce brandy. Possibly because the influence of the winemaker can be so marked, and unpredictable, it is typically neglected or submerged under regional or stylistic categories. This is possible because tradition, if not legal constraints, may severely limit winemaker freedom in the style(s) produced.

In Europe, most regions tend to specialize in one or very few wine styles, made from one or a few, typically local, grape varieties. This feature permitted the association of particular flavor traits with regionally produced wines. However, grape cultivars generally generate wine with similar flavor attributes elsewhere. For example, 'Cabernet Sauvignon' and 'Chardonnay' can produce wines equivalent to those produced in their respective homelands, Bordeaux and Burgundy. Sensory attributes are often more dependent of yearly climatic variations, and winemaker decisions, than soil characteristics. Thus, the predictive value of varietal origin depends more on the skill of the winemaker, and the maturity and health of the grapes, than geographic origin. Although winemaker skill is difficult to quantify, annual variations in grape and wine quality are often semiquantified in the now-ubiquitous vintage ranking found in the popular press.

Varietal Origin

Ideally, wine should be classified by the cultivar or cultivars used in its production. Varietal origin sets outer limits on the wine's sensory attributes. Unfortunately, most grape cultivars do not, or possibly more correctly are not known to, possess a characteristic or readily distinguishable varietal aroma. Thus, varietal origin is of significance only for those cultivars that possess, or develop, unique aromatic fragrances in their wines. In addition, its effective application can be severely compromised by the various synonyms under which cultivars may go. This applies not only among countries but also between regions. For example, *Syrah* in France is *Shiraz* in Australia; *Cannonau* in Sardinia is *Garnacha* in Spain and *Grenache*, *Alicante*, or *Carignane* in France; *Zinfandel* in California is

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00753-4

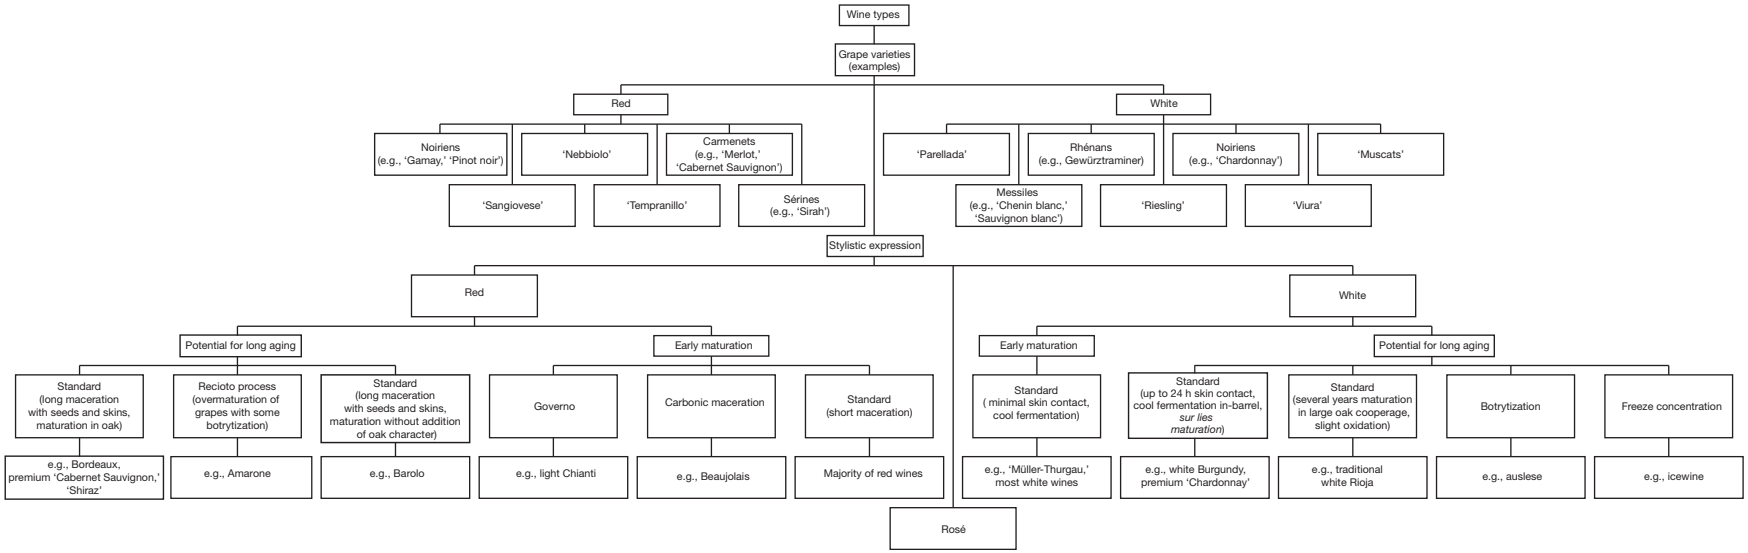

Figure 1 Categorization of table wines based on general sensory attributes, with some common examples.

Primitivo in southern Italy and *Crljenak kastelanski* in Croatia; whereas *Tempranillo* in much of Spain is called *Ull de Llebre* in Catalonia. The issue can be even more confusing when the same varietal name is applied to different cultivars. For example, the *Torrontés* in Argentina is equivalent to none of the cultivars so named in Spain. Finally, many European wines do not designate on the bottle label the cultivar or cultivars used. Furthermore, the blend of varieties used in regions such as Bordeaux and Châteauneuf-du-Pape can vary from year to year, depending on vintage conditions. Historically, varietal designation was not considered necessary because single regions, grew only one or a select few cultivars, produced in a relatively consistent style, and were often the only wines locally available. Labeling has not caught up to the realities of modern commerce. Thus, even with varietal or regional designation, the consumer must have considerable prior experience with these to be of benefit.

Most European wines carry geographic appellations that have become familiar over time. Nonetheless, consistency of style is more an illusion than reality. As noted in the preceding text, traditionally produced regional wines may be derived from a variable number of cultivars. In addition, the proportional mix can change from producer to producer, as well as vary from year to year, depending on vintage conditions and the views of the winemaker. Finally, with the spread and adoption of winemaking techniques around the globe, regional distinctiveness has blurred even further.

Several of the better-known cultivars, with the potential for donating a distinctive varietal character, are briefly noted in the succeeding text.

Red Cultivars

'Cabernet Sauvignon' is the best-known member of the Carmenet family of grape cultivars. Its renown comes from its involvement in most Bordeaux wines (France) and their equivalents elsewhere. Other members of the family include 'Merlot,' 'Malbec,' and 'Cabernet Franc.' Their inclusion in most Bordeaux blends moderates the tannin content donated by 'Cabernet Sauvignon' and adds complexity to the wine's fragrance. The tendency of 'Merlot' to mature more quickly has made it a useful addition and a popular substitute for 'Cabernet Sauvignon' on its own. It appears to be the result of 'Cabernet Franc' × 'Magdeleine Noire des Charentes' parentage. 'Cabernet Sauvignon' itself appears to be the result of a crossing between 'Cabernet Franc' and 'Sauvignon blanc.' Under optimal conditions, 'Cabernet Sauvignon' yields a fragrant wine possessing a blackcurrant aroma. Under less favorable conditions, it donates a marked bell pepper aroma.

'Gamay Noir à jus blanc' is the primary, white-juiced, Gamay cultivar. It is likely a crossing between 'Pinot noir' and 'Gouais blanc.' Its reputation has risen in association with the popularity of Beaujolais wines. Crushed and fermented by standard procedures, it produces a light-red wine with few distinctive aromatic characteristics. However, when the grapes undergo a crude form of carbonic maceration, it yields a distinctively fruity wine that can be drunk a few weeks after its production. Most of its unique fragrance comes from the initial grape-berry fermentation phase of carbonic maceration.

'Nebbiolo' is generally considered to produce the most highly regarded red wine in northwestern Italy. With traditional vinification, it produces a wine high in acidity and tannin content, requiring years to mellow. The color has a tendency to oxidize somewhat early. Common aroma descriptors include tar, violets, and truffles. Its parentage remains unknown but is suspected to have arisen indigenously in Italy's Piedmont region.

'Pinot noir' is the most famous Noirien grape variety. It is particularly environmentally sensitive, producing its unique fragrance (beets, peppermint, or cherries) only occasionally. The cultivar exists as a varied collection of distinctive clones. Usually, the more prostrate, lower-yielding clones produce more flavorful, varietally distinctive wines. The upright, higher-yielding clones are more suited to the production of rosé and sparkling wines. The origin of 'Pinot noir' is still a mystery. Due to its feral vegetative traits, and unusual anthocyanin content, it is presumed to be of ancient origin. It may be a fortuitous selection from local wild *V. vinifera* vines that once grew in the Burgundy.

'Sangiovese' is an ancient cultivar consisting of many distinctive clones, grown extensively throughout central Italy. It is most well known for the light- to full-bodied wines of Chianti, but it also produces many fine red wines elsewhere in Italy. Under optimal conditions, it yields a wine possessing an aroma said to be reminiscent of cherries, violets, and licorice. 'Sangiovese' is also grown under an extensive range of local synonyms, such as 'Brunello' and 'Prugnolo,' used in producing Brunello di Montalcino and Vino Nobile di Montepulciano wines, respectively.

'Shiraz' ('Syrah' in France) has become famous for yielding deep-red flavorful wine, with long aging potential in Australia. This has helped 'Syrah' regain the prominence it once held in the Rhône Valley and has promoted its cultivation in many parts of the world. Its wines have a distinctive peppery flavor, combined with aspects suggestive of violets, raspberries, and currants.

'Tempranillo' is arguably the finest Spanish red cultivar. It appears to be the progeny of two indigenous cultivars 'Albillo Mayor' and 'Benedicto.' Under favorable conditions, it yields a deliciously fragrant wine that ages well. It is the most important red cultivar in Rioja, used either alone or blended with other indigenous cultivars. Outside Spain, it is primarily grown in Argentina. In California, it usually goes under the name 'Valdepeñas.' 'Tempranillo' is considered to generate an aroma distinguished by a complex berry jam fragrance, with nuances of citrus and incense.

'Zinfandel' is extensively grown in California. Its European counterpart in southern Italy is 'Primitivo' and 'Crljenak Kaštelanski' in Croatia. The latter is thought to be its original provenance. Under any name, it is used to produce a wide range of wines, from ports to light blush wines, depending on the country. In rosé versions, it shows a raspberry fragrance, whereas full-bodied, red versions possess rich berry flavors.

White Cultivars

'Chardonnay' is the most famous white member of the Noirien cultivar family. It appears to be the progeny of a cross between 'Pinot noir' and 'Gouais blanc.' Not only does it produce wines with an appealing fruity fragrance, but also it tends to do well

worldwide, not just Burgundy. In addition to producing superb table wines, it is typically found alone, or in a blend, to produce champagne. Under optimal conditions, the wine develops aspects reminiscent of various fruits, notably apple, peach, and melon.

'Müller-Thurgau' is possibly the most well-known modern *V. vinifera* cultivar, being derived from a 'Riesling' and 'Madeleine Royale' crossing. It constitutes about 30% of German hectarage. Its mild acidity, subtle fruity fragrance, and early maturity are ideal for producing light wines in cool climates.

'Muscat blanc' is one of many members of an interrelated, ancient family of cultivars. Their aroma is so distinctive that it is described in terms of itself – Muscaty. Because of the intense flavor, slight bitterness, and tendency to oxidize, Muscat grapes have been used most commonly in producing dessert wines. The reduced bitterness and lower oxidation susceptibility of the modern Muscat cultivar, 'Symphony,' permit the production of dryer wines with better aging potential. 'Moscato bianco' is the primary variety used in the flourishing sparkling wine industry in Asti, Italy.

'Parellada' is a variety distinctive to the Catalonian region of Spain. It produces an aroma that is apple- to citrus-like, occasionally showing hints of licorice or cinnamon.

'Pinot gris' and 'Pinot blanc' are gray and colorless skin mutants, respectively, of the red 'Pinot noir.' They are both cultivated throughout the cooler climatic regions of Europe for the production of dry wines. 'Pinot gris' typically yields subtly fragrant wines with aspects of passion fruit, whereas 'Pinot blanc' is somewhat fruity, supposedly with suggestions of hard cheese.

'Riesling' is without doubt Germany's most highly respected grape variety. It appears to be an ancient cultivar possessing 'Traminer' in its lineage. It produces fresh, aromatic, well-aged wines, which can vary from dry to sweet, depending on grape ripeness and winemaker preferences. Its complex floral aroma, commonly reminiscent of roses and pine, has made it acclaimed throughout central Europe and much of the world. Outside Germany, its largest plantings are in California and Australia.

'Sauvignon blanc' is the main white Carmenet variety in Bordeaux and the principal white cultivar in the upper Loire Valley. It has become popular in California and New Zealand in the recent years. Often, its aroma shows elements of green peppers, as well as a herbaceous aspect, especially in cooler climates. Better clones possess a subtly floral character.

'Traminer' is a distinctively aromatic cultivar grown throughout the cooler regions of Europe and much of the world. Like 'Pinot noir,' it seems to be of ancient origin, being a selection from indigenous, wild grapevines. It consists of a wide variety of clones, the grapes varying from white to rosé colored. 'Traminer' is fermented to produce both dry and sweet styles, depending on regional preferences. Intensely fragrant ('Gewürztraminer') clones are generally distinguished by a lychee fruit aroma.

'Viura' is the main white variety cultivated in Rioja. In cooler areas, it produces a fresh wine possessing a subtle floral aroma with aspects of citron. After extended aging in large wood cooperage, it develops a golden color and rich butterscotch to banana fragrances. The latter characterizes the traditional white wines of Rioja.

Stylistic Origin

Although varietal attributes set the outer limits of a wine's sensory characteristics, its expression is often significantly influenced by enological procedures as well as regional, microclimatic, and annual variations in growing conditions. Thus, the way varietal attributes develop depends on both vine health and grape health and berry maturity, how the grapes are transformed into wine, and how the wine is subsequently matured and aged. Thus, after varietal origin, vintage and production conditions are the most important factors establishing the features that characterize wine. Production-derived attributes are organized in the succeeding text, based on whether these distinctive features developed arise before, during, or after grape fermentation.

Prefermentation Conditions

Carbonic maceration is probably one of the oldest production techniques known. If whole grapes are piled together in sufficient quantity, their respiration soon consumes all the available oxygen, and the fruit shifts to fermentative metabolism. This phase produces little alcohol (~2%) but generates a unique set of aromatic compounds. These grape-derived flavors give the wine a distinct raspberry–kirsch fragrance. They also tend to mask any grape varietal aromas. After berry fermentation ceases (the cells die), the fruit is crushed and yeasts consume the remaining grape sugars. The process produces a wine that is ready to drink a few weeks after production. In contrast, most wines are drinkable, at the earliest, a year or more after fermentation. Because the grape-fermentation odors fade rapidly, the wines often do not age well. This is particularly so with Beaujolais nouveau, where consumption is recommended within 6 months to 1 year post bottling.

Another technique that can fundamentally modify a wine's sensory attributes is grape overmaturation. It generally involves leaving the grapes on the vine for several weeks past normal maturity (late harvest). It often produces more a flavorful but more alcoholic wine. If fermentation does not go to completion, the wine has a sweet finish. Its most classic white versions, the grapes often undergo a 'noble' rot, caused by *Botrytis cinerea*. The infection not only concentrates the juice but also donates a unique apricot, honey-like fragrance to the wine. Examples are the Auslesen of Germany, the Tokaji wines of Hungary, and the Sauternes of France. Alternatively, juice concentration can be achieved by partial dehydration, involving leaving the harvested grapes under the sun on mats or stored on trays under cool, dry conditions. The latter process is commonly referred to as *appassimento*. Another form of juice concentration involves leaving the grapes on the vine until they freeze in late fall or early winter (>-7 to $-8\,^{\circ}C$). The grapes are then harvested and pressed while still frozen (most of the water remaining as ice in the press). The concentrated juice is very high in sugar content. Fermentation typically terminates before little more than half the sugars have been fermented, leaving the ice wine very sweet.

Although more commonly used in the production of white wines, overmaturation is occasionally used in the production of red wines. For example, in the production of Chianti, a portion of the harvest may be set aside to slowly dry and overmature,

while the majority of the crop is processed into wine. A month or so later, the overmatured portion is crushed, begins fermentation, and is added to the previously fermented wine. The effect of the second fermentation is to produce a wine that is fruitier and matures earlier than otherwise. The process is termed the *governo* process. It currently is less popular than in the past, possibly because it does not promote aging potential – the 'gold standard' of quality for many connoisseurs.

Appassimento is also used in Veneto to produce Recioto della Valpolicella Amarone. In this instance, specially selected mature grape clusters are laid thinly on trays stacked in well-ventilated, but unheated, storage sheds. After several months of partially drying, the grapes are crushed and fermented under cool conditions. During the drying process, a portion of the grapes may undergo a slow transformation under the action of *Botrytis cinerea*. This results in a marked increase in the concentration of glycerol and sugars, as well as the partial oxidation of grape phenolics. These appear to donate the distinctive tulip/daffodil pungency that characterizes the best amarones.

Prefermentative Skin Contact

For white wine production, the juice is separated from the seeds and skins immediately upon, to several hours after crushing, and prior to the commencement of fermentation. This limits the extraction of bitter/astringent phenolics from the seeds and skins but equally skin-derived aromatics. The result is a pale-colored to yellowish wine, unless red grapes are used. In the latter case, the wine will often possess a slightly pink to rosé color. For red wines, the juice is left in contact with the seeds and skins throughout much of the fermentation period. The duration of the maceration period with the seeds and skins significantly influences the flavor attributes derived from these parts of the grape. In contrast, skin contact has little effect on flavorants and other constituents found in the juice (e.g., sugars, acids, and non-flavonoid phenolics).

Fermentation Conditions

With red grapes, early (<24 h) separation of the fermenting juice from the seeds and skins yields a rosé. In contrast, for standard red wines, the fermenting juice is left in contact with the seeds and skins (pomace) for about 4–5 days. The duration and method of agitating the mixture during fermentation affect both color depth and stability, as well as tannin uptake. Red (anthocyanin) pigments tend to be extracted first, whereas tannins are dissolved more slowly. Traditionally, red wines designed for long aging have been left on the seeds and skins for more than 2–3 weeks. Although it generated more flavorful wines, it demanded prolonged aging before the high tannin content 'softened.' Modern techniques can now optimize both flavor and pigment uptake, without the extraction of excessive amounts of bitter, astringent tannins. Most varietal flavors are dissolved from the skins within 3–5 days. For grapes low or unstable in pigmentation, the crushed grapes may be given cold maceration prior to fermentation. Other techniques include thermovinification, the addition of the press material (seeds and skins) from additional grapes, or the addition of juice from white grapes possessing phenolics that enhance color stability.

Another condition that fundamentally affects wine characteristics is fermentation temperature. White wines are typically fermented at cooler temperatures than red wines. Cool temperatures (about 15 °C) enhance the production and retention of yeast-synthesized esters, giving the wine a fruity fragrance. This is particularly important for white wines produced from cultivars with little varietal aroma. Wines from aromatically distinctive varieties may be fermented at somewhat higher temperatures, to accentuate their varietal aroma. Red wines are typically fermented at about 22–25 °C. This facilitates yeast growth in the presence of grape phenolics and favors pigment and flavorant extraction.

Other fermentation conditions influence the stylistic expression of a wine, but their use is so variable as to negate their value in characterizing wine types. Examples are the use of different yeast strains, the employment of malolactic fermentation, and the use of in-barrel versus tank fermentation.

Maturation Conditions

Wines designed for early consumption are usually maturated in stainless steel or other inert cooperage. This avoids the expense and uptake of flavorants from the cooperage that could compromise the simpler or mild varietal characters of the wine. In contrast, wines benefitting from extended aging, or possessing a distinct varietal aroma, often merit from being matured for several months to years in oak cooperage prior to bottling. It adds an additional complexity often appreciated in such wines. For white wines, the oak exposure rarely lasts more than 6–12 months. This may or may not be combined with *sur lies* maturation (3–6 months' contact with the dead and dying yeast cells at the end of fermentation). The latter is often considered to enhance the wine's flavor. For red wines, maturation often occurs in new or used oak barrels (~250 l) or some combination thereof. Maturation in large (1000–10 000 l) oak tanks is now uncommon. These supplied less oak character while providing slower, but enhanced, oxidation. Where some oxidation is desired, without the uptake of oak flavors, several microoxidation procedures are available. It is thought, like oak maturation, to encourage earlier wine development (and drinkability).

Although these features can markedly influence the wine's sensory attributes, labels rarely, if ever, mention technical details. The only effect of wine production, typically denoted on the label, is terms relating to coloration (white, rosé, and red).

Geographic Expression

Although it is often implied that the sensory attributes of a wine are clearly impacted by its geographic origin, this is rarely the case. Even professionals often have difficulty identifying the varietal origin of wines, let alone more subtle aspects such as regional origin. Identification is, not surprisingly, more likely when the origin and selection are limited. When wines from a single region, derived from the same cultivar and produced similarly, are tasted together, it may be possible to differentiate regional expressions. However, if the wines come from different countries, it is unlikely that their individual geographic origins will be identified consistently. The critical word here is consistently. Yearly variations in weather

conditions, grape maturity, production decisions, and aging can generate greater fluctuations in sensory attributes than climatic differences among regions.

The prominence given geographic origin in most wine classifications comes from the familiarity that can be developed with their names. Nonetheless, even this can be a stumbling block to the neophyte. Typically, regional names bear no logical interrelationship. For example, Pommard and Pauillac do not obviously suggest that the first is from Burgundy and the second from Bordeaux, whereas Chianti and Valpolicella are noted without any indication of their Tuscan and Veneto provenances. Learning these appellations is often considered a rite of passage to connoisseurship. Because provenance is one of the simplest attributes of a wine, along with the wine's color, both features are predominantly employed in organizing wines. It also facilitates consumer purchases, typically based on geography, color, and price. That their associated sensory features may not be recognizable without the bottle seems unsuspected and immaterial.

Appellation Control Laws

The frequent grouping of wine by geographic origin and the economic value of clear distinction have combined to promote the establishment of AC laws. Although their dictates often vary from country to country, and even from region to region, they act as a certification of geographic origin. As such, they tend to prohibit blending from different regions. They may also regulate permitted varietal composition, conditions of grape culture, and fermentation and wine-processing procedures. Although important to protecting the use of regional names, they also denote cultural views on the origins of wine quality.

In most established European regions, it is often assumed that historically accepted practices and geographic features define and preserve wine quality. However, they tend to petrify production methods, limiting improvement. This is so significant that some producers selectively defy the requirements of the local AC laws. This leaves them free to experiment, often leading to superior wines. Furthermore, weather conditions can be so variable as to nullify any attempt or implication that the law guarantees wine quality. This is particularly so in the absence of effective yearly assessments of wine quality.

In Europe, AC laws fall into two philosophically distinct categories. One group ascribes greater importance to geographic features (e.g., France, Italy, and Spain), whereas the other accentuates the significance of grape maturity (e.g., Germany and Austria).

For example, in the French version, regions are classed according to historic percepts relative to their quality – premium (AOC – appellation d'origine contrôlée), superior (VDQS–vins délimités de qualité supérieure), good (vins de pays), and basic (vins de table). AOC regions are typically subdivided, with progressively smaller zones viewed as producing more distinctive (better) wines than those from larger regions. This subdivision may be taken down to single vineyards. In most cases, though, it goes down only to single parishes or townships. As the area becomes smaller, production regulations often become more precise and restrictive.

In addition to the classification of regions, individual vineyards (or wineries) may be hierarchically categorized. The most well-known example is the 1855 grouping of some Bordeaux vineyards. This arrangement is called the *cru classé* system. As in AC designations, the *cru classé* is based on historic potential to produce fine wine. Thus, yearly sensory assessments are deemed unnecessary.

In Italy, most wine regions are organized hierarchically into DOCG (Denominazione di origine Controllata e Garantita), DOC (*Denominazione di origine Controllata*), IGP (*Indicazione Geografica Tipica*), and Vino da Tavola categories. One of the unique features of the Italian system is its potential pyramidal interconnections. Wine production exceeding the quantities/vineyard surface area stipulated in the regulations is progressively demoted too lower and lower categories. The use of the highest (DOCG) designation requires annual, governmental, and sensory evaluation tests.

In the Germanic AC expression, the greatest emphasis is placed on grape maturity. Thus, it is prominently displayed, along with geographic origin, on the label. Examples are the *Prädikat*, *Spätlese*, *Auslese*, *Beerenauslese*, and *Trockenbeerenauslese* categories. In addition, annual achievement of a minimum score on a governmental sensory evaluation test is required before permission is granted to use any of the QbA (*Qualitätswein bestimmter Anbaugebietes*) or QmP (*Qualitätswein mit Prädikat*) designations. Geographic indications note only the source of the grapes used in producing the wine. Historical reputation has no influence on how the quality or geographic designations are denoted in the German system.

Most New World countries are developing AC regulations. In most instances, they relate primarily to geographic and varietal origin. This results from the diversity of wine styles produced within the designated regions. This achieves the primary purpose of geographic differentiation in the marketplace. Cultivar designation, typically denoted on the label, is there primarily as a guide to the general aromatic characteristics that might be expected. They usually do not require that only the cultivar(s) noted were used. Depending on the region, the minimum proportion of the named cultivars can vary. This flexibility permits the winemaker to blend to some particular flavor profile while still retaining the predominate attributes of the variety or varieties stated on the label.

Introduction

Wine consumed moderately (considered to be about 100–200 ml day^{-1}) is estimated to marginally extend life expectancy. This effect can be visualized graphically as a J-shaped curve (Figure 1). It illustrates that both abstainers and those consuming alcohol in excess have greater risk of earlier mortality than those consuming wine moderately. Although encouraging, the benefits of reduced morbidity (from a multitude of age-related chronic ailments) are even more heartening, but, regrettably, more difficult to quantify and, thereby, illustrate graphically. In addition, for those who appreciate wine, its sensory attributes and association with food and companionship are as important as, or more important than, its health benefits. Nonetheless, despite the benefits of moderate wine consumption in reducing overall health costs for wine consumers, most governments prefer to consider wine as a taxable luxury and consequently a desirable revenue source.

The positive contribution of moderate wine consumption to both physical and psychological health appears to be independent of factors such as educational level, wealth, food choice, and other environmental and cultural factors. However, correlation does not causation make. Establishing direct links demands a complete understanding of the chain of events from consumption, uptake via the alimentary tract, transport and survival in the blood, incorporation by tissue cells, and the molecular means by which wine-derived products have their beneficial effects. Studying the latter often involves tissue cultures in the laboratory, where the effects of individual chemicals can be more easily assessed. Many potentially beneficial effects, such as protection from the undesirable consequences of oxygen radicals, can often be detected within minutes. Such investigations provide plausible explanations for the observed long-term benefits of moderate wine consumption observed in population studies. Nonetheless, several steps in the sequence from consumption to cellular action still require elucidation. These include demonstrating that the chemicals found in wine, and demonstrated to have beneficial effects at the cellular level in laboratory studies, are absorbed via the intestinal tract and transported to and subsequently incorporated by cells in sufficient quantities to have the effects observed under laboratory conditions. Not uncommonly, physiologically active wine constituents are degraded in the intestinal tract, subsequently modified by plasma, liver, and cytoplasmic enzymes, and rapidly metabolized or eliminated in urine or feces (see Figure 2). All these factors potentially reduce or obviate *in vivo* effects. For example, the antioxidant activities of phenolics are often diminished as the active moiety (OH groups) reacts with other compounds in the body. Examples are reactions with sugars (glycosylation), sulfate (sulfation), methyl (methylation), or acyl (acylation) groups. These conjugation reactions, and other liver-induced changes, facilitate their rapid elimination in the bile and urine. Although glycosylation reduces the antioxidant potential of phenolics, it increases their solubility and, thereby, potential availability for cellular uptake. The presence in the plasma or lymph does not necessarily mean cellular uptake. The latter is often a function of appropriate transport systems in the cell membrane. This is particularly pronounced with access to the brain. The brain is protected from direct exposure to many compounds transported in blood plasma by a special layer of cells lining brain capillaries, termed the blood–brain barrier. It selectively regulates the passage of molecules into the cerebral fluids that surround brain tissue. Nonetheless, small amounts of anthocyanins and several flavonol monomers appear to gain rapid access to brain tissue. This feature may be associated with headache induction in some people, by activating prostaglandin production and its associated dilation of cerebral blood vessels in the meninges, increasing intracranial pressure. Finally, there are subtle, and not-so-subtle, differences in human physiology between individuals and ethnic groups. In addition, differences in intestinal flora influence the structural characteristics and concentrations of wine phenolics that become available for potential uptake in the blood. Thus, as with many medications, individual responses to wine constituents may differ markedly, making any blanket pronouncements on health benefits fraught with potential and unknown risk.

Establishing the dynamics of *in vivo* effects in humans is difficult, not only because of wine's chemical complexity and their various pleiotropic effects but also because of ethical issues surrounding clinical investigations, alcohol consumption, and epidemiological uncertainties. The latter include accuracy in the self-reporting of the quantity, type, consistency, and duration of consumption, as well as the difficulty of differentiating between the effects of wine, dietary factors, and lifestyle, such as exercise over the extended time frame required for such studies. In addition, most ingredients absorbed from the intestinal tract are quickly metabolized or eliminated. Consequently, any effects induced by wine constituents are likely to be of short duration, requiring prolonged and repeated intake to have long-term benefits. Thus, population studies need to be continued for decades. Nonetheless, there is currently sufficient consistency between population and laboratory findings to warrant the tentative conclusion that moderate wine consumption has several lifelong health benefits.

That wine has consistently been shown to have health benefits, in contrast to other alcohol-containing beverages, probably relates to the fortuitous combination of wine's moderate ethanol and relatively high phenolic contents. Both have independent and synergistic health benefits in moderate amounts. In addition, wine is frequently consumed with food. This both prolongs and delays ethanol uptake via the intestinal tract, thereby diminishing its maximal concentration while extending its duration in the plasma and, thereby, maintaining alcohol's beneficial cellular effects. Also, the likelihood of any toxic influences, such as oxygen-radical production, acetaldehyde accumulation, and inebriation associated with a

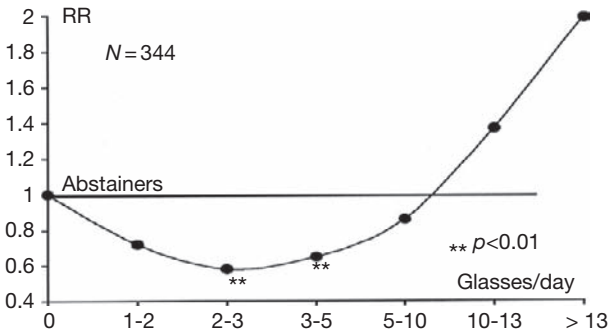

Figure 1 Relative risk (RR) of death from all causes in relation to the intake of wine compared to abstainers, adjusted for age, smoking, body mass index (BAI), and education. Other causes were the sum of the causes of death with the exception of cancer, cardiovascular causes, cirrhosis, and violent death. Reproduced with permission from Renaud, S., Lanzmann-Petithory, D., Gueguen, R., and Conard, P. (2004) Alcohol and mortality from all causes. *Biological Research* 37, 183–187.

rapid and excessive rise in blood-alcohol level, is reduced, if not totally obviated.

During fermentation, yeast action produces ethanol as its main by-product. Although ethanol assists other wine constituents in inactivating pathogenic bacteria and viruses, its most significant benefit derives from enhanced high-density lipoprotein (HDL) concentrations, resulting in reduced low-density lipoprotein (LDL) levels in the blood and vessel walls. Ethanol also reduces platelet aggregation, as well as accelerates clot dissolution. In addition, low levels of blood alcohol have a mild diuretic action, aid calcium retention in the bone, diminish the likelihood of age-related macular degeneration, appear to limit the stomach irritation associated with certain medications, act as a mild muscle relaxant and social activator (by suppressing certain areas in the brain), and may counteract insomnia. In the latter instance, elevated blood-alcohol levels are counterproductive as they provoke early arousal. Other yeast-synthesized alcohols are found in wine, but in very small amounts. Their significance relates only to their involvement in generating important aromatic wine flavorants.

Although wine's ethanol content has health benefits, additional benefits arise from the grape phenolics extracted during fermentation. They are produced as by-products of a complex secondary metabolic pathway in the fruit, commencing with the amino acid phenylalanine. The major branch of the pathway leads to the synthesis of flavonoids, notably flavones (e.g., quercetin), flavan-3-ols (e.g., catechins and their tannin polymers), and pigments (anthocyanins). Although the latter constitute the principal colorants in red wines, they contribute little to the health benefits of wine. Another metabolic branch of the pathway gives rise to stilbenes (e.g., resveratrol). Various flavonoid phenolics have antimicrobial and antioxidant actions, appear to retard platelet aggregation, delay neurodegeneration, possess phytoestrogenic effects, slow the onset of osteoporosis (by increasing Ca^{2+} uptake), and detoxify nitrites in food. Stilbene phenolics also possess antioxidant and anti-inflammatory properties, diminish platelet aggregation, and may reduce arthritic pain.

Although some phenolic-derived benefits are correlated with the presence of large polymers (tannins) in wine, their poor solubility restricts their direct absorption and transport to tissues in the body. Thus, *in vivo* activity of polymeric phenolics is indirect and depends first on their degradation by intestinal and colonic microbial enzymes to their constituent monomers. The uptake of these degradation products into and transport via the blood depends on their respective water and lipid solubilities and any selective transport proteins associated with the colon lining. Nonetheless, some monomeric anthocyanins and nonflavonoids appear to be directly and rapidly absorbed via the stomach. Exposure to stomach acids appears to have little, if any, effect on phenolic structure.

Beneficial Effects

Antimicrobial Activities

Possibly the first health benefit to be associated with wine consumption was its salubrious influence in reducing the incidence of gastrointestinal infections. In Roman times, wine was often added to drinking water before consumption. Although the microbial origin of many diseases was unknown until the middle of the 1800s, the effect of wine in making most water for drinking potable was empirically discovered millennia ago. Not only is wine's alcohol content mildly antimicrobial, but also this effect is enhanced by other wine constituents, notably its phenolic content, its acidity, and several fatty acids. The most beneficial wine phenolics are thankfully those found in the highest amounts – flavonoids and stilbenes. A secondary health benefit arose from wine's solvent properties. The combination of the fat- and water-soluble properties of wine's aqueous ethanol mixture helped solubilize the antimicrobial and other potential medicinal properties of many ancient herbal concoctions.

The antimicrobial effects of wine have been studied relative to their effects occurring before consumption (as in a marinade), during consumption (oral microbiology), shortly after consumption (in the stomach and small intestine), or later on the colon microbial flora and in the blood. Wine's antimicrobial influences have also been investigated relative to selected effects on specific types of bacteria and viruses. Another approach has been to consider how the antimicrobial effects are expressed – by direct inactivation or indirectly by preventing adhesion to cell surfaces and/or the formation of a biofilm, chelating essential nutrients, or by synergy with stomach acids or stimulating gastric acid secretion. Finally, the various effects of individual constituents, or their joint actions, have been investigated.

Due to ethical and economic reasons, most antimicrobial investigations have been time/inactivation studies conducted using solid or liquid bacterial cultures. Only a few investigations approximating *in vivo* conditions have been conducted, usually involving a simple food equivalent at pH levels similar to those found in the stomach. In either situation, wine often reduces the viable population of common food-/water-borne pathogens within several minutes to hours. Used as a marinade, wine's efficacy can be enhanced by combination with certain herbs and spices, notably oregano and thyme.

Although the antimicrobial efficacy of wine (and beer) was once of significance in Europe, improvements in food

(2013) Overview of metabolism and bioavailability enhancement of polyphenols. *Journal of Agricultural and Food Chemistry* 61, 12183–12199.

handling and water treatment have largely obviated its value. However, wine's antimicrobial action could still be efficacious in many parts of the world, but wine is seldom available, affordable, or permitted where its benefits would be of greatest value.

Because wine remains in the mouth for only a short period, any antimicrobial effect is probably limited to suppressing the adhesion and biofilm-forming potential of bacteria involved in tooth decay, notably *Streptococcus mutans*. However, in the stomach, wine enhances the effects of gastric juices (pH ~1–2) in inactivating many pathogenic bacteria (e.g., *Campylobacter jejuni*, *Helicobacter pylori*, *Listeria monocytogenes*, *Salmonella* spp., *Staphylococcus aureus*, and *Vibrio cholerae*). Regrettably, wine appears to be relatively ineffective against toxigenic strains of *E. coli*. While microbial inactivation occurs slowly, the time frame falls within the range that food tends to remain in the stomach. Most studies also indicate that the collective effect of all of a wine's constituents is more effective

than any of its individual constituents. For example, ethanol is one of wine's least effective antibiotic constituents (being most antiseptic at about 72–78% v/v). In addition, wine acids, pH value, phenolics, and fatty acids have been variously shown to have limited individual antibiotic effects, being dependent on the pathogenic agent and location within the gastrointestinal tract. The sulfur dioxide content of wine is too low to have any influence alone. Because wine composition is highly variable, changes during aging, as well as passage through the intestinal tract and presence in the plasma and cytoplasm, it is impossible to provide specific recommendations for particular wine types against individual enteric pathogens.

Far fewer studies have investigated wine's antimicrobial action within the small or large intestine. Nonetheless, wine appears to be capable of inactivating the toxin produced by *Vibrio cholerae*. Other studies have shown wine's potential to reduce the adhesion of enteric pathogens to the colon wall and inactivate *Bacillus cereus*. Wine phenolics are also known to variously aid or limit, depending on the compound, the attachment of beneficial probiotic lactobacilli to the intestinal wall. Studies of wine's activity against parasitic protozoa or as a vermifuge seem not to have been conducted. Even studies on wine's effectiveness against viruses are rare. Nonetheless, epidemiological data suggest a protective influence against viruses inducing the common cold and hepatitis A. Laboratory studies have also demonstrated wines' ability to inactivate several enteric viruses.

Even less is known about wine's effectiveness against internal disease organisms. Resveratrol, other phenolics, and ethanol are known to have anti-inflammatory and other immunologic effects. This could be beneficial in some situations, but detrimental in others. The same applies to wine's antioxidant effects. In most situations, wine's antioxidant action is beneficial, limiting the damage caused by free-oxygen radicals. Nonetheless, oxygen radicals are generated by lymphocytes as part of their arsenal in destroying pathogens. Thus, wine's medicinal properties seem similar to those of more traditional medications – potentially a double-edged sword, depending on the concentration and duration of their physiologically active presence.

Antioxidant Action

The principal antioxidant actions associated with wine consumption relate to its flavonoid and stilbene contents. These influences were first thought to be the principal beneficial effects of moderate wine consumption. Wine phenolics reduce the oxidative stresses associated with certain respiratory and other oxidative reactions. These are unavoidable consequences of normal cellular metabolism. In addition, free-oxygen radicals are produced as a consequence of inflammatory responses, following the return of oxygen to tissues occluded by blood clots (ischemia-associated reperfusion) or during the destruction of pathogens engulfed by phagocytic lymphocytes. Free oxygen radicals generated directly include the superoxide anion [$O_2^{\bullet -}$], the hydroxyl radical [$OH^{\bullet}$], hydrogen peroxide [H_2O_2], and hydrochlorous acid [HOCl] and, indirectly, lipid peroxide radicals [$LOO^{\bullet}$]. Although tissue cells produce several enzymes, notably superoxide dismutase, glutathione peroxidase, and catalase, that rapidly inactivate most oxygen radicals and have access to antioxidants such as glutathione, vitamin C (ascorbic acid), vitamin E (α-tocopherol), and carotenoids, these activities do not permanently protect cells against oxidative damage. Thus, over a normal life span, oxygen radicals slowly disrupt essential macromolecules and organelles, causing impairment in their structure and function. These changes can lead to the development of a range of age-related, chronic degenerative diseases. Wine (and other dietary) phenolics can reduce and/or retard this development by a variety of influences, such as inhibiting enzymes involved in oxygen-radical production, by chelating metals (e.g., iron and copper ions) essential in oxygen-radical production, by directly quenching oxygen radicals (forming more stable, less disruptive phenoxyl radicals), by enhancing the production of endogenous antioxidants such as glutathione, or by functioning as signaling molecules (stimulating the activation of endogenous oxygen stress-related pathways and antioxidant enzymes, such as catalase and superoxide dismutase). As signaling molecules, the trace amounts of phenolics typically found in blood, and their short half-lives, could still have marked beneficial effects. Synergism between the diverse phenolics found in wine, combined with daily consumption (maintaining low but effective levels of phenolics in the blood), could contribute to the observed long-term benefits of moderate wine consumption.

On a shorter term basis, wine phenolics help limit not only LDL peroxidation, an early stage in atherosclerosis, but also undesirable actions of lipoxygenases throughout the body. Particularly active in this regard are the tannin monomers (flavan-3-ols–catechins and epicatechins) and flavonols (such as quercetin). Resveratrol also has similar effects but often occurs at lower concentrations than do many flavonoid phenolics. The respective concentrations of the various types of phenolics in wine vary considerably, depending on the grape cultivar, grape maturity at harvest, the duration of skin contact before or during fermentation, the type of fining, duration of aging, and other factors. It is the popular impression that red wines are more beneficial than white wines, due to their higher flavonoid content. Nonetheless, it is a belief based largely on supposition, not comparative experimental data.

The alcohol content in wine is not itself an antioxidant. Nonetheless, ethanol can induce the production and enhance the concentration of hydroxytyrosol in blood. This influence is apparently more marked than achieved by consuming olive oil (hydroxytyrosol is one of the most important antioxidants in olive oil).

Cardiovascular Issues

The strongest association between alcohol consumption and health is found in data relating deaths due to heart disease (**Figure 3**). Similar correlations have been found with other cardiovascular issues, notably hypertension, peripheral vascular disease, and ischemic stroke. These diverse problems primarily arise from structural/functional changes in the vascular system (atherosclerosis) and an increased risk of thrombosis (blood clot formation). Atherosclerosis appears to develop as a response to chronic inflammation in artery walls. This, in turn, results from the slow oxidation of LDL deposits in vessel walls, inciting the formation of cytotoxins. These provoke immune and smooth muscle cells to accumulate around oxidized LDLs.

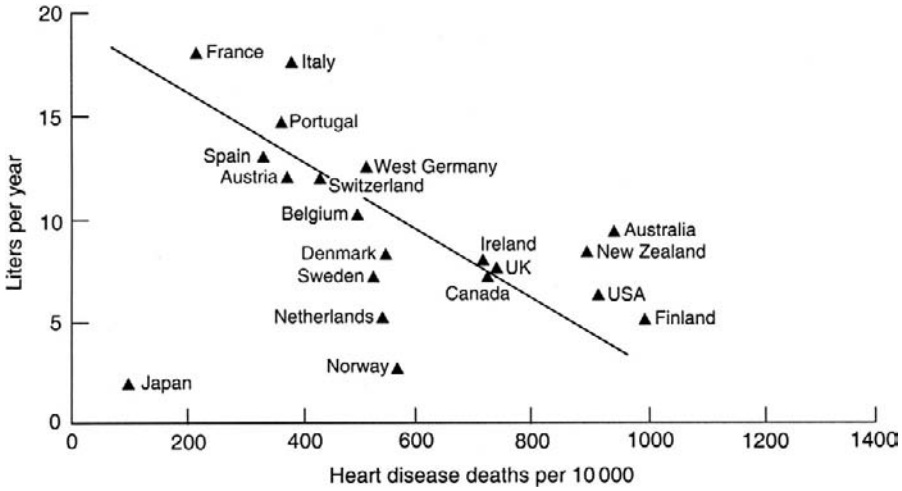

Figure 3 Relationship of per capita alcohol consumption with 1972 heart disease death rates in men aged 55–64 in 20 countries. Reproduced with permission from LaPorte, R. E., Cresanta, J. L. and Kuller, L. H. (1980) The relationship of alcohol consumption to arteriosclerotic heart disease. *Preventive Medicine* **9**, 22–40.

This, in turn, causes the formation and enlargement of swellings, termed plaques. If these bulge out into the vessel lumen, plaques induce progressive vessel occlusion (blockage). Reduced blood flow can aggravate hypertension and peripheral vascular disease. However, whether plaques bulge inward into vessel lumen or outward into surround tissue, if they rupture, thrombosis rapidly occurs, blocking the vessel. Depending on the nature of the size and location of the rupture, it may provoke a heart attack, stroke, or some less serious vascular problem.

Ethanol appears to reduce the incidence of cardiovascular disease by enhancing the production of a particular subclass of HDLs (HDL_3). They favor the removal of cholesterol (deposited within LDLS in vessel walls), thereby limiting cytotoxin production induced by cholesterol oxidation. Alcohol also increases the production of prostacyclin (which directly interferes with clot formation) and a plasminogen activator (a clot-dissolving factor). Moderate alcohol consumption (with meals) also has beneficial effects on blood glucose and insulin levels. The result is the maintenance of lower plasma triglyceride and LDL levels. These are both correlated with reduced cardiovascular risk. Procyanidins (small polymers of flavan-3-ols) also appear to counter cardiovascular problems by suppressing the production of endothelin-1 (a vasodilator) (Figure 4). Endothelin-1 is one of the activators of an early stage in plaque development and the localized movement and accumulation of immune cells in the artery wall. Wine phenolics can also bond with LDLs, limiting oxidation of their lipid constituents. Resveratrol has similar effects. It also favors the production of nitric oxide by endothelial cells (those lining the inner surface of blood vessels), as does chlorogenic acid (a nonflavonoid found in wine). Nitric oxide both induces vasodilation, resulting in reduced blood pressure, and limits platelet adhesion (stickiness) to vessel walls (part of clot formation). Low blood-alcohol contents also reduce the likelihood of thrombosis in a similar fashion.

Phenolics can also reduce some of the severe consequences of infarction size (the area with blocked blood flow), cardiomyocyte apoptosis (heart muscle cell death), and reperfusion following myocardial ischemia (the return of oxygen-laden blood to starved heart tissues) and improve postischemic ventricular performance (the two large chambers that pump blood away from the heart).

Neurodegeneration-Related Diseases

There is much concern about the rapidly rising incidence of Alzheimer's and other neurodegenerative diseases. This partially relates to increasing life span, providing more time for the effects of chronic nerve degeneration to express themselves. Correspondingly, there has been enhanced research into their causes and control options. Because oxidation of cellular structures and associated low-grade inflammation appear to be involved in so many chronic diseases, studies have focussed on the effects of dietary antioxidants and mild inflammation suppressors. In this regard, long-term moderate wine consumption has been correlated with delayed onset and occurrence of Alzheimer's and other forms of dementia. This is consistent with the established effects of phenolics and, to a lesser extent, small amounts of ethanol at a molecular level. For example, ethanol intake is correlated with enhanced omega-3 fatty acid content of the plasma. Omega-3 fatty acid is in turn correlated with improved neurological function as well as red blood cell concentration (better cerebral oxygen supply).

Wine phenolics have also been shown to have specific beneficial effects on what is currently thought to induce Alzheimer's disease. For example, tannins tend to inhibit the formation of and destabilize β-amyloid fibrils, whereas resveratrol promotes the degradation of β-amyloid peptides. Although the known effects are insufficient to induce one to begin to consume wine, its potential in retarding neurodegeneration may be a serendipitous side effect of enjoying wine.

Other Assorted Health Benefits

Among the lagniappes associated with moderate wine consumption is the reduced incidence and severity of osteoporosis

(the slow loss of calcium from bone). How wine has this effect is uncertain, but it may be connected with alcohol's enhancing the uptake and retention of calcium. However, since wine appears to have a greater protective influence than other alcoholic beverages, other wine constituents presumably must be involved.

Alcohol's well-known activity as a mild diuretic may be the origin of wine's correlation with reduced severity of some symptoms of arthritis and decreased incidence of kidney stone development – arthritis being partially connected with retention of fluid in joints and kidney stones with the accumulation of calcium oxalate, presumably due to insufficiently frequent urination. Alcohol's positive influence in retarding glucose uptake and reduced blood-insulin levels may partially explain wine's salubrious effect in diminishing the risk of developing type 2 diabetes. For example, ethanol increases the circulating levels of adiponectin and adipokine, thereby enhancing cell insulin sensitivity. Nonetheless, part of wine's effect may be related to the hypoglycemic effects of selected anthocyanins and the combined hypoglycemic and hypolipidemic effects of resveratrol.

Another J-shaped connection associated with moderate wine consumption is the reduced likelihood of age-related macular degeneration (separation of the retina from the back of the eye). Macular degeneration is correlated with a localized manifestation of atherosclerosis reducing oxygen and nutrient supply to the macula of the eye. A similar interrelationship has been found with cataract development. In contrast, periodic high alcohol intake, and its pro-oxidant influences, probably explains why the benefits associated with wine consumption are related only with long-term, moderate usage.

Ambivalent Effects

Digestion

For most consumers, wine is consumed with food, often being considered its foil. Correspondingly, one might expect wine's association with dining to be universally positive. Although largely so, it may not always be so. Part of the benefit derived with wine's consumption with food relates to its fragrance. It can activate the release of gastrin and gastric juices in the stomach, preparing it for digestion. The succinic acid content of wine also favors gastric juice release in the stomach. Wine also delays gastric emptying, favoring food digestion and its partial microbial sterilization. Delayed gastric emptying appears to be due to phenolics activating STC-1 cells in the stomach lining. These cells release a peptide hormone, cholecystokinin, that reduces gut peristalsis.

The moderate levels of ethanol in wine, as well as wine's acidity and some aromatic constituents, also activate the release of bile from the gall bladder into the small intestine. This facilitates fat emulsification, easing their breakdown, essential for their uptake and metabolism by the body. In contrast, high ethanol contents, typical of fortified spirits, can have the reverse effect, as well as potentially activate unpleasant stomach spasms.

Despite beneficial effects, high tannin levels in wine can interfere with the activity of some digestive enzymes, notably α-amylase, lipase, and trypsin. Tannins can also bind with and structurally modify some food proteins, complicating their digestion. Some protein–tannin polymers are readily reversible in the small intestine, whereas others are relatively stable until they reach the colon. Saliva proteins and some ionic carbohydrates in food tend to limit such polymer formation. In contrast to the tendency of tannins to retard protein digestion in the small intestine, several monomeric tannin components activate pepsin-induced protein digestion. Thus, as with many aspects of wine's association with health, the issue is complicated and will undoubtedly take decades to unravel.

Although wine influences food digestion, food conversely slows gastric emptying and, thereby, the rate at which alcohol enters the blood. About 80% of alcohol consumed is absorbed via the small intestine. Thus, retarding gastric emptying supplies additional time for liver metabolism to keep blood-alcohol content within safe limits. Rates of alcohol metabolism vary from person to person, and between men and women, but generally fall within the range of 90–130 mg $kg^{-1} h^{-1}$.

Cancer

The association between wine consumption and cancer is even more ambivalent than that with digestion, reducing the likelihood of some cancers but increasing the risk of others. This may not be as surprising as one might initially think. Cancer is a complex of syndromes of diverse etiology, linked semantically because they express relatively uncontrolled cell growth and a potential to become metastatic.

The strongest direct link between wine consumption and human cancers is that of the throat and gastrointestinal tract. The association is strongest with more than 'moderate' wine consumption. The other relatively clear link between wine consumption and cancer involves breast cancer. The link seems more marked with possession of the alcohol dehydrogenase gene variant (ADH1C*1). The gene facilitates fast ethanol metabolism, generating a rapid peak in acetaldehyde in the blood (the first by-product of ethanol metabolism in the liver). Acetaldehyde is a known carcinogen, reacting and binding with many proteins and DNA, as well inducing an immune reaction against these adducts. Ethanol by itself appears to not have these effects. Nonetheless, ethanol can enhance the transforming effect of some carcinogens. In contrast, at low concentrations, ethanol can reduce the carcinogenicity of others. Thus, as with so much in science, the issues are far more complex than we might prefer.

Another chemical with carcinogenic potential, once found in wine that had been heated, is ethyl carbamate. However, with its origin well understood, and limits set on its occurrence in wine, its involvement in any possible wine-associated cancer is unlikely.

Some phenolics in wine, normally viewed as beneficial, have been demonstrated to be mildly carcinogenic in standard laboratories mutagenicity tests (mutagenicity is often associated with carcinogenicity). However, as an indicator of the complexities of correlating laboratory results with *in vivo* situations, many of the phenolics associated with mutagenicity are only carcinogenic at concentrations significantly above those found in blood or tissue. Furthermore, quercetin, which has shown anticarcinogenic effects in whole-animal studies (where free-oxygen levels are low), can be carcinogenic at the much higher oxygen concentrations found in laboratory tissue cultures. In addition, most phenolics in the blood are quickly metabolized to glycosides. Glycosidic phenolics tend to lose any carcinogenic tendencies they might have shown as aglycones (not associated with sugar).

On the positive side, wine phenolics can detoxify the traces of nitrites commonly found in some foods. Thus, by reducing the concentration of free nitrites, marinating can reduce the production of carcinogenic heterocyclic amines and diazo phenols potentially generated during smoking and broiling/barbecuing food. Of even greater significance may be the laboratory-demonstrated anticancer effects of several wine phenolics. These include encouraging DNA repair (reversing mutations), direct carcinogen detoxification, enhanced apoptosis (programmed cell death, e.g., cancer cells), disruption of proliferative cell growth, and enhanced immunostimulation (favoring cancer cell recognition and destruction). A specific example is the effect of resveratrol in the redistribution of a cell membrane factor called Fas. It is the attachment site for an immune factor called tumor necrosis factor (TNF). TNF favors the destruction (apoptosis) of cells to which it is attached. Resveratrol is also an inhibitor of angiogenesis – the development of blood vessels essential for the nourishment of cancerous tumor growths. Furthermore, resveratrol has an inhibitory action on cyclooxygenase-2 and P450 1A1. Both appear to play a role in converting several environmental toxicants into carcinogens.

Negative Effects

For those who love wine, it would be pleasing if there were no negative side effects to even moderate wine consumption. Regrettably, for some people, or at times in their lives, even moderate wine consumption is contraindicated or needs to be strictly limited. This especially applies to individuals allergic and intolerant to certain wine additives. The most well-known potential allergen is sulfite, a by-product of the addition of sulfur dioxide to wine. The overzealous use of sulfites in salad bars provoked legislation requiring the indication 'may contain sulfites' on any food or beverage containing more than 10 ppm sulfites. The highest concentration of sulfites in wine occurs shortly after bottling, due to the addition of sulfur dioxide as a protection against wine oxidation and microbial spoilage. This value slowly decreases to undetectable as the wine ages. Sulfur is more commonly added to white wine than red wine because oxidation results in an obvious browning of white wines. Many in the wine industry consider browning to be sales-deterrent. Less obvious, but more significant, are oxidative changes in wine flavor. The antimicrobial action of sulfur dioxide also limits the likelihood of postbottling fermentation that could result in slight bubbling on bottle opening. In addition, it protects against far rarer wine 'diseases' that can provoke visual and flavor faults. While the wine industry is seriously searching for a substitute to sulfur dioxide, none has yet been found with its range of benefits, efficacy, and overall safety record. Nonetheless, the use of sulfur dioxide by the wine industry is considerably less than in the past. Despite

this, and even without the addition of sulfur dioxide, sulfites can accumulate in wine. Sulfite is a metabolic by-product of yeast degradation of sulfur-containing amino acids.

Sulfites in wine are quickly absorbed by blood via the stomach lining. For those sensitive to its presence, it induces contraction of smooth muscle around the bronchus, restricting breathing. The rapidity of the reaction suggests one or more of the following: reduced conversion of sulfites to sulfates by sulfite oxidase in the blood, a malfunction of glutathione *S*-transferase (reducing sulfite to glutathione *S*-sulfonate), and inadequate amounts of glutathione in the lung and bronchial lining. One of the conundrums associated with sulfite hypersensitivity is its episodic occurrence and more frequent connection with red wine. The concentration of sulfur dioxide is consistently lower in red wine, partially due to sulfite's binding with a multitude of wine constituents, but even more because the addition of sulfur dioxide to red wine is less necessary. Red wines, being less sensitive to oxidative browning and microbial spoilage, do not need the protection considered necessary for white wines. Thus, there appear to be additional, unknown factors involved in sulfite sensitivity than just sulfite levels.

The histamine content of wine was once thought to provoke or enhance the severity of allergic reactions. Nonetheless, the histamine content of wines is generally low, and the contents found in wine appear insufficient to provoke histamine-associated allergic reactions. Despite this, the administration of antihistamines has been found to reduce the rhinitis occasionally associated with drinking red wines. Whether this is due to a placebo effect or the administration of antihistamines is unknown.

Some people, more frequently of Asian ethnicity, have an allergy-like reaction to alcohol-containing beverages. It results in rapid facial and neck flushing (cutaneous erythema) and potentially other unnerving symptoms such as elevated heart rate, nausea, abdominal discomfort, and bronchoconstriction. This reaction has been correlated with a malfunctional variant of the gene (*ALDH2*2*) coding for mitochondrial acetaldehyde dehydrogenase (ALDH). The reaction is particularly marked in individuals homozygous for two copies of the malfunctional gene. ALDH is the principal enzyme involved in metabolizing acetaldehyde, the first breakdown product of ethanol metabolism, to acetic acid. Malfunction of one gene, and notably both genes, results in a rapid increase in blood acetaldehyde concentration in association with alcohol intake. It is acetaldehyde that is thought to provoke the diverse set of symptoms noted earlier. Some of the symptoms may also be provoked by the release of cellularly generated histamines by acetaldehyde. These reactions can be partially curtailed by the administration of antihistamines and acetylsalicylic acid (aspirin), prior to the consumption of wine or other alcohol-containing beverages.

Various idiopathic allergic or immunologic sequelae, such as nausea, vomiting, headache, and general malaise, have been reported in the medical literature in relation to wine consumption. In most instances, their cause(s) is unknown. However, in a few instances, they have been linked to the presence of trace amounts of pathogenesis-related proteins (often found in grapes). Other potential sources of allergic-type reactions include egg white or fish proteins (trace amounts may remain after their use in wine fining). Headache sequelae have also occasionally been associated with wine phenolics. In some instances, this can be prevented by taking a prostaglandin-synthesis inhibitor (e.g., acetylsalicylic acid, acetaminophen, or ibuprofen) shortly before wine consumption. This has been hypothesized to be associated with limiting prostaglandin production in the brain, in response to phenols traversing the blood–brain barrier. Prostaglandins can induce blood vessel dilation and thereby pain receptors in the meninges that cover the brain. Sensitivity to this type of wine-induced headache may be related to reduced activity of a plasma-bound enzyme, phenol sulfotransferase. It detoxifies phenols in the blood.

Some people associate one of the most severe headache sequelae, a migraine, with wine consumption, usually red wine. Because histamine and tyramine are often implicated in migraine inception, it has been natural to suspect wine's histamine content as the culprit. Nonetheless, wine histamine contents are usually lower than considered adequate to provoke a migraine attack. In addition, double-blind investigations appear to exonerate wine histamine content as a causal agent, at least by itself. The influence of ethanol in suppressing the action of diamine oxidase, an enzyme that inactivates histamine in the intestinal tract, may contribute to increasing histamine uptake by the blood. Another contributing factor may be the phenolic content of red wines. They are known to prolong the action of hormones and nerve transmitters such as histamine, dopamine, and serotonin. The latter is known to enhance blood vessel dilation. Clearly, more needs to be known before a more definitive answer can be given.

Whether fetal alcohol syndrome (FAS) or its milder version, fetal alcohol spectrum disorder, is implicated with moderate wine consumption is highly controversial. Due to the apparent complex etiology of these syndromes, and the first association of FAS in children born to women of poor diet, who also consumed illicit drugs, were alcoholics, and/or were heavy smokers, any association with moderate wine consumption has been difficult to prove or disprove. Thus, as a precaution, women who wish to become, or are, pregnant are typically counseled to avoid consuming any alcohol-containing beverage during these stages of their life.

Although most people would not associate the simple act of tasting wine with any unpleasant side effects, one of the potential occupational hazards of professional wine tasters is a unique form of dental erosion. It is most frequently expressed as cupping, a depression in the enamel, exposing the underling dentine on molar cusps. In extreme cases, it can lead to severe root abrasion at the gumline. These effects are thought to arise from extended dental contact with wine acids, dissolving calcium essential enamel's hardness. The softened enamel becomes prone to the abrasive action of mastication and tooth cleaning. To avoid this, it is now recommended that food consumption or toothbrushing be delayed for at least one hour after an extended tasting session. This period permits the reincorporation of the lost mineral content, reestablishing the surface enamel's original hardness.

Finally, but not least, there are a set of medical conditions for which wine (or any other alcohol-containing beverage) is contraindicated. Certainly, this applies to anyone with a past history of alcoholism and is a judicious precaution for those with a family history of alcohol abuse. Other situations where abstinence is required involve treatments for ulcers

and cancers of the oral and intestinal tract, liver and kidney diseases, and urogenital infections. Consumption of alcoholic beverages is also ill-advised several days prior to surgery as it reduces clotting time. Alcohol-containing beverages may also increase the severity or incidence of acid reflux, epileptic convulsions, and some consequences of cardiovascular disease, notably hypertension and atrial fibrillation. Even consuming some types of mushrooms with wine or other alcohol-containing beverages can lead to a set of very unsettling symptoms. These can include flushing, sweating, vertigo, nausea, chest pain, palpitations, and tachycardia (rapid heart rate). The mushrooms to avoid are inky cap (*Coprinus atramentarius*) and the lurid bolete (*Boletus luridus*). Similar reactions have occasionally been linked with taking certain antibiotics (e.g., cephalosporins, griseofulvin, chloramphenicol, sulfonylurea, and metronidazole).

Thankfully, the vast majority of wine consumers have none of these aforementioned problems and can enjoy wine without any ill effects (in moderation). In addition, it is pleasing to consider that what gives one sensory pleasure also is in no small measure reducing the risk of several chronic diseases usually associated with aging. Thus, Mark Twain's comment that

> The only way to keep your health is to eat what you don't want, drink what you don't like, and do what you'd rather not.

is not always the case.

Introduction

The key to the production of good wine begins in the vineyard. This article on wine production is based on the premise that grapes suitable for the intended wine style are available. The style may be commercial or lower price category where harvest yield is more significant than specific flavor development. On the other hand, grapes destined for wines at the top price bracket (<5% of total sales) have well-defined harvest criteria. The harvest yield, unless regulated, tends to reflect the intended wine category. This may range from 30 kg per vine for commercial wines to 0.5 kg per vine for premium wines.

An overview of the production of white wine and red wine following grape receival at the winery is presented. The object is not to provide a recipe, but rather to describe decisions that confront a winemaker during the vintage period. The production steps assume that sulfur dioxide will be used, as its use is still the mainstay in protection of wine from spoilage. Options for minimal sulfur dioxide use and natural wine production are mentioned.

White Wine Production

Figure 1 sets out the general processes for white wine production. There are a large number of options available, many of which relate to the final wine style that can range from delicate and aromatic, to robust and full-bodied, to dry and acidic, to high residual sugar.

Minimizing oxidation and the onset of fermentation from yeasts on the grape skins following harvesting is a challenge faced by all winemakers. Lowering the temperature and the addition of sulfur dioxide are approaches to preserving grape characters.

Grape Processing

The wine world is polarized as to whether grape handling prior to fermentation should be oxidative or reductive. Reductive handling assists in preserving grape aromas and flavors through to the finished wine. The downside of this approach is the retention of phenolic compounds that may be unattractive in more delicate wine styles. Oxidative handling makes no attempt to minimize oxygen access to grape juice. The deliberate addition of oxygen (hyperoxidation) will lead to the loss of phenolic compounds and increase the stability against oxidation in the finished wine. This in turn can lead to the requirement of lower SO_2 levels. Generally, juice oxidation will result in lower varietal aromas.

Destemming and crushing

It is now fairly common practice to remove the stems to minimize uptake of coarse phenolic compounds. The degree of crushing tends to be gentle, reducing the damage to grape skins and seeds with less chance of releasing oxidative enzymes. Modern destemmer/crusher units have considerable flexibility allowing the winemaker to target the operation to the desired wine style.

The must (crushed grapes and juice) should fall from the crusher to a hopper from where it can be pumped direct to the press or draining vessel. In warmer climates, the must may be passed through a heat exchanger to lower the temperature to 10–12 °C.

Draining and pressing

The juice from crushed white grapes flows relatively freely. Larger operations may use a vertical or horizontal drainer. While efficient in terms of juice yield, many drainers lead to high phenolic concentration that requires subsequent removal.

The alternative is to pump the must direct to the press, allowing the free-run juice to be collected first and then increasing the pressure and collecting the pressings until the phenolic content reaches an unacceptable taste level. The free run and pressings may be combined or kept separate.

Press types vary from the traditional basket press to the modern tank press in which the must is totally enclosed in the press tank. The modern presses give higher yields of good quality juice and minimize the juice/air contact, thereby reducing oxidation.

Some robust styles leave the juice from crushing in contact with the skins to extract some flavor and phenolic compounds. Timing of this contact is critical and care must be taken to ensure that fermentation does not commence.

Whole bunch pressing

Grape bunches are added direct to the press and under pressure burst to release juice. There is minimal contact with stalks, skins, and seeds, so the juice obtained by this method is lower in phenolic compounds and grape solids.

Clarification

The extent of juice clarification remains the subject of debate. Relatively clear juice will give a fruitier wine, while fermentation on grape solids can give rise to baggy or wet cardboard aromas. However, highly clarified juice may reduce the amount of nutrients available to the yeast leading to slow or even stuck ferments, whereas the inclusion of some solids may increase flavor complexity.

Clarification has been traditionally achieved by settling and the clear juice then removed from the lees. Poor settling can lead to considerable losses. Larger operations may have access to centrifugation, flotation, rotary drum or earth filtration, and membrane static or cross flow filtration. Pectin from the grape pulp can cause difficulty in clarification, so it is common practice to add pectolytic enzymes as an aid.

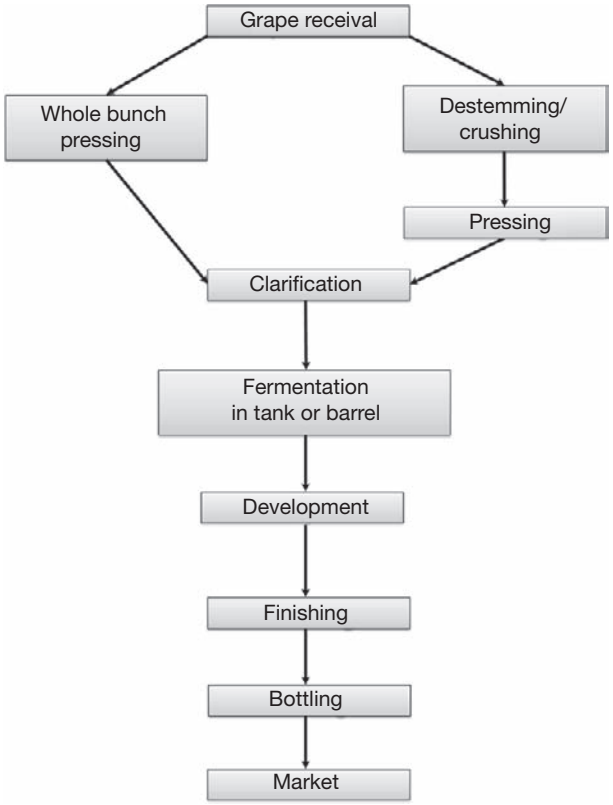

Figure 1 Major steps in white wine production.

Additions to juice

Some countries allow the addition of sugar (chaptalization). The amount of sucrose that can be added is usually regulated.

Acid adjustment may also be required. In warmer climates, tartaric acid may be added to increase the acidity. Ion exchange for pH adjustment is now not permitted in many countries. In colder climates, a high concentration of wine acids, especially malic acid, may require deacidification by the addition of calcium carbonate. Deacidification may be performed on the juice or after fermentation.

Fermentation Strategies

The two main options for fermentation vessels are stainless steel (inox) or oak vessels, although some concrete tanks are still in use. The choice is based on many factors including tradition, cost, efficiency of fermentation control, hygiene, final wine style, and scale of operation.

Temperature control

Temperature control is a critical issue in white wine fermentation as a high temperature can encourage oxidation and microbiological spoilage and the loss of desirable volatile and flavor compounds. Some yeasts will not function above 38 °C. On the other hand, if the fermentation temperature is too cold, the yeast may suffer stress causing the ferment to slow down, or even stop, with the consequent production of acetic acid. Many winemakers would argue for temperature control that allows about 1% alcohol increase per day.

Stainless steel tanks can be surface-cooled with cold water or circulating brine at −5 °C. Insulation can be used on tanks that are outside. Temperature control of barrel ferments is more difficult to achieve and an air-conditioned room is probably the best option. Refrigeration costs may total 50% or more of winery electricity consumption.

Fermentation vessels

Stainless steel tanks are available in various sizes to suit small or large operations. Generally, stainless steel tanks can be used for both fermentation and storage. Cleaning the tanks is a relatively easy task.

Oak barrels used for white wine fermentation tend to be barriques (225–228 l), puncheons (318 l), and hogsheads (238 l). If the purpose is to extract oak aromas and phenolic compounds, new oak barrels are required.

Oxygen

Early in the fermentation, there is sufficient carbon dioxide released to generate a protective cover over the wine. However, toward the end of fermentation, the carbon dioxide cover is less effective and exclusion of oxygen is essential. The use of an air trap is one effective means of stopping oxygen gaining access to the wine.

Yeast selection

There are a range of options available including the following:

- Natural yeasts from the surface of the grape (this is sometimes referred to as 'uninoculated' or 'wild' fermentations)
- A starter culture where a portion of an actively fermenting yeast culture with high cell numbers is added to the juice
- Inoculation with a selected (active) dried yeast after rehydration
- A combination of selected and natural yeasts

There is considerable argument as to the best option, much of which relates to tradition, wine style, and market positioning. The use of selected yeast cultures does allow for a more predictable fermentation.

Fermentation and wine composition

The critical role of the yeast is the conversion of glucose and fructose to ethanol. If insufficient ethanol is produced, the wine may be insipid, whereas a high concentration can lead to a hot taste sensation.

Glycerol is an important fermentation output. It is thought to contribute to mouthfeel, although the sensory aspects remain the subject of debate. There have been attempts to modify wine yeasts to increase glycerol production at the expense of ethanol production. These modified strains are not used for commercial wine production.

Several commercially available yeasts release fermentation esters that add to the aroma of the wine for some months after the fermentation. Other yeasts add little fermentation character and are labeled 'neutral.'

Many aroma compounds originating from the grape exist as nonvolatile glycoconjugates of volatile norisoprenoids, monoterpenes, and other volatile compounds. Commercial enzyme preparations are now available that contain

β-glucosidase activity, as well as α-arabinosidase, α-rhamnosidase, and pectolytic activities, that lead to enhanced wine aroma. As enzyme activity may be inhibited by glucose, they are commonly added toward the end of the fermentation.

Yeast health

Yeasts require nutrients, especially nitrogen, to maintain a healthy fermentation. If the yeast becomes stressed, off-odors can be produced. Winemakers may measure the amount of yeast available nitrogen or the yeast available amino nitrogen prior to commencing a fermentation and may supplement with diammonium phosphate (DAP) or other propriety nitrogen supplements. The release of hydrogen sulfide from yeast catabolism of sulfur-containing amino acids is an argument used to justify nitrogen supplementation.

Development Postfermentation

At the end of the fermentation, the wine is highly susceptible to oxidative spoilage. Sulfur dioxide is commonly added at this point as it has both antioxidant activity and antimicrobial activity. The amount of sulfur dioxide added is dependent on wine style, although 20–30 mg l^{-1} free sulfur dioxide is a common working rule. During this period up to bottling, the wine may be stored in stainless steel tanks or oak barrels or casks.

Malolactic fermentation

Malolactic fermentation (MLF) is an option that some winemakers choose, especially for the more robust wine styles. MLF is the conversion of malic acid to lactic acid leading to a reduction in acidity and the production of aroma and flavor compounds. The wine may be seeded with the required bacteria or use a natural source of the bacteria (uninoculated). MLF may be performed by inoculation during yeast fermentation. It is essential that the wine is checked regularly for the growth of unwanted yeast and bacteria especially oxidative film yeasts that lead to acetaldehyde production. Sulfur dioxide must be absent when the wine is going through MLF, increasing the potential for spoilage.

Time on lees

While it is common practice to rack the wine from its lees soon after the end of the fermentation, there are certain wine styles, notably Chardonnay and Muscadet, where the wine is left on lees for a considerable period. This *sur lie* practice is generally accompanied with stirring (*bâtonnage*) that distributes the yeast lees throughout the barrel and should be performed in full barrels without air ingress.

Finishing

Protein stabilization

The white wine at this stage will have residual protein that may be denatured, if the wine is not stored properly, resulting in brown haze formation. Treatment with bentonite clay is one way to achieve protein stability. When the bentonite with adsorbed protein has settled, the wine is racked off to a clean vessel. This also aids clarification but is slow and can lead to considerable wine losses. The impact on aroma and flavor is the subject of debate and the search for alternatives is continuing.

Tartrate stabilization

A white, generally crystalline, deposit of potassium hydrogen tartrate (KHT) may form in the bottle when the white wine is stored at cool temperatures. KHT stabilization can be achieved by holding the wine in tank at around −4 °C for several days and inducing crystallization by the addition of seed crystals. This process adds to refrigeration costs.

Fining

The wine may be fined to reduce the content of phenolic compounds and to soften the palate. The fining agents may be inorganic compounds (e.g., silica gel) or proteins. The proteins include gelatin, isinglass, egg white (albumin), and casein or skimmed milk, and each reacts with a specific class of phenolic compounds. The use of these fining agents, while successful, does require allergen labeling in many countries.

Final adjustments

Before bottling, the SO_2 concentration should be checked and adjusted if required. Ascorbic acid may also be added as an additional antioxidant. If acid adjustments are made, a further check on tartrate stability should be performed.

Wines of different varieties and years may be blended, although this is regulated in many countries. All checks should be performed on the blend, even if the individual components are stable before passing to bottling.

Red Wine Production

The major steps are summarized in Figure 2. Strategies are designed to extract the color and phenolic compounds from grape skins. Red wine styles range from light-bodied (soft and fruity), to medium-bodied, to full-bodied. Phenolic levels and astringent taste increase through these styles. Rosé wines have minimal color extraction and production tends to be closer to that for white wine.

Grape Processing

Destemming is normally employed as unripe stalks can contain undesirable phenolic compounds. One obvious exception to this approach is in Burgundy where stalks are routinely included.

Roller-type crushers are now routinely used. The rollers may be set to allow some whole berries to pass through or to achieve complete crushing. Older style 'beater' crushers can cause not only skin tearing and seed rupture that may lead to higher extraction of color and phenolic compounds but also the release of undesirable taste components.

Color and Phenolic Compound Extraction

The skins contain the colored anthocyanin compounds. The skins and seeds also contain various phenolic compounds, some of which are beneficial, while others are not.

Color extraction can be considered a combination of breakdown of grape skin cell membranes and diffusion of anthocyanin pigments from skin cells into the must. Cell breakdown

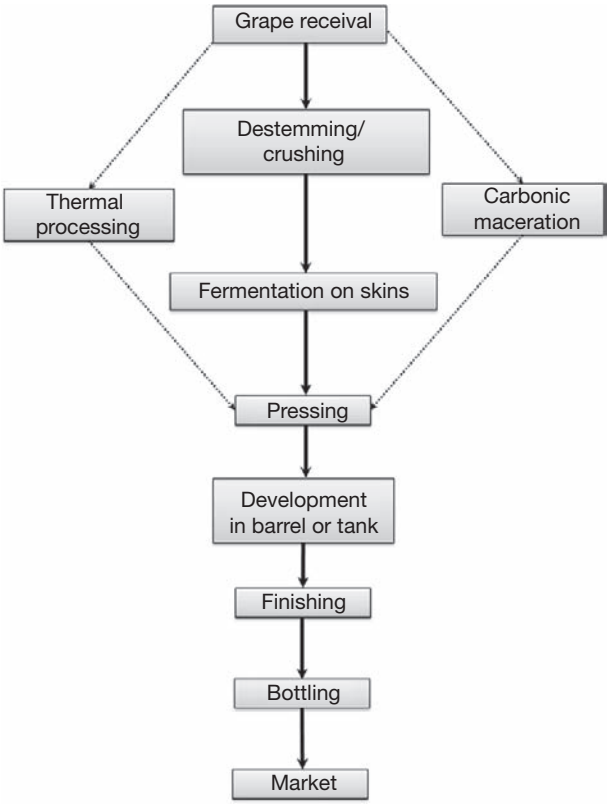

Figure 2 Major steps in red wine production.

can be achieved by exposure to an extracting solution (water and alcohol), higher temperature, and asphyxiation, while diffusion of pigments is best achieved by effective mixing.

There are several ways in which these requirements for color extraction can be met:

- Destemming/crushing followed by fermentation on skins
- Thermal processing of grapes or must
- Asphyxiation of intact berries as in carbonic maceration

Carbonic Maceration

This technique is most closely aligned with Beaujolais, although it is used elsewhere for the production of light-bodied wines. Intact bunches of berries are placed in a closed container and held under carbon dioxide. The berries asphyxiate and an anaerobic fermentation produces about 2% ethanol. This process may continue for about 2 weeks at temperatures up to 32 °C before the liquid is pressed off the skins and seeds and then allowed to ferment to dryness. MLF may follow the alcoholic fermentation.

There are many variations, both regional and personal, in carbonic maceration. The wines show a distinct strawberry or cherry aroma. Generally, the wines do not age well.

Thermal Processing

Extraction of anthocyanins, tannins, and polysaccharides using heat before alcoholic fermentation is useful for the production of lighter, fruitier wines. Two approaches have been adopted:

- Flash heating (flash détente) where ripe and destemmed grapes are rapidly heated to 95 °C and then placed under vacuum causing a breakdown of skin cells
- Thermovinification where berries or crushed grapes are heated to 70–75 °C for around 30 min, followed by pressing and cooling

Clarification by rotary drum vacuum filtration before inoculation is a lengthy and expensive procedure that generates large amounts of waste. Fermentation is normally performed at cooler temperatures. Thermal processing is potentially advantageous for grapes that are low in anthocyanin or are affected by *Botrytis* rot, as the heat removes any enzyme activity that can reduce color.

Fermentation on Skins

Preferment maceration

Before inoculation of the must, a preferment maceration or cold soak may be employed. The concept is to allow aqueous extraction of monomeric anthocyanins that may result in enhanced red color of the finished wine. The must should be kept less than 10 °C to limit the onset of fermentation. Added SO_2 can improve color extraction and minimize the growth of unwanted yeasts.

Yeast inoculation

Yeast selection has as many variables as in white wine production. The need for additional nutrients in a red wine fermentation is usually not an issue as the skins are a source of nitrogen. The measurement of available nitrogen may be performed before inoculation. Elevated temperatures can be an issue leading to hydrogen sulfide production and DAP may be added as a precaution.

Fermentation cap management

Once the fermentation commences, CO_2 evolution coupled with skin buoyancy causes the skins to rise to the surface forming a cap. Good mixing of the cap with the alcoholic fermenting medium is required for effective extraction of skin and seed phenolic compounds. The fermentation rate is faster in the cap, leading to an elevated temperature, and if not regularly mixed, it may dry out with significant production of acetic acid.

Fermenters can be broadly classified as either static or dynamic. Static fermenters can be constructed from stainless steel, oak, or concrete. Manual cap plunging can be achieved with a hand plunger, by foot or by a 'robotic foot.' Heading down boards that keep the cap below the surface can be placed in the ferment once CO_2 evolution has slowed. For larger vessels, the ferment can be pumped over the surface to irrigate the cap. Alternatively, in the *délestage* or rack-and-return approach, the fermenting liquid can be pumped to a separate tank and then pumped back on top of the skins/seeds.

A dynamic rotofermenter is essentially a large drum that mixes by rotation. Construction is expensive, but automation is possible. Fermentation occurs under a CO_2 atmosphere and aeration, if required, is difficult. The wine style obtained from a rotofermenter tends to be less astringent than from a static fermenter. In an autofermenter, pneumatic pistons are placed

in the lid of a tank to plunge the cap automatically. The timing of the piston plunging can be under computer control or activated by pressure from the evolving carbon dioxide.

Fermentation temperature

Temperatures lower than 20 °C retain fruit flavors and are more appropriate for early drinking styles. Temperatures up to 30 °C or even 32 °C result in more robust wines with greater mouthfeel complexity but less obvious fruit character and less yeast-derived fermentation characters.

Aeration during the ferment

The addition of air to the ferment can reduce the formation of H_2S and initiate the formation of polymeric phenolic compounds, which in turn leads to increased color stability.

Pressing the Wine from the Skins and Seeds

The fermentation is commonly allowed to continue until essentially all fermentable sugar is consumed (dryness) or it may be pressed off before completion and allowed to continue to dryness in a separate vessel. This approach may be used when the phenolic compounds being extracted late in the fermentation detract from overall wine quality.

Postferment maceration

Leaving the wine in tank in contact with skins and seeds post the end of the fermentation is a practice that perhaps developed in Bordeaux. The tank must be completely full and sealed during this maceration period. The technique seems to be effective with Cabernet varieties but is usually negative with Pinot Noir. During the maceration, phenolic compound extraction is mainly from the seeds, so it is essential to taste regularly and the maceration stopped if the wine is no longer harmonious.

Pressing options

Most modern-day wineries have elevated fermentation tanks so that the press can be moved into position underneath. When the tank door is opened, the wine, skins, and seeds will flow into the press, aided by a sloping floor in the tank. The traditional basket press may be used in small wineries, although most now use some type of membrane or bag press. The skins and seeds may be collected for further processing or for distillation.

There are significant compositional differences between the free-run wine and the pressed wine with higher color, astringency, and pH in the pressed wine. A membrane press will give about 700 l of wine per ton of grapes processed, while extensive pressing may give an additional 100 or so liters. Tasting determines the appropriate blend of free-run wine and pressed wine. Some of the hard-pressed wine may be blended with other wines that may require additional body.

Development

It is generally advantageous to rack the wine off yeast lees as soon as possible after the end of the fermentation as the lees can adsorb anthocyanins and thereby reduce color. The wine is pumped to a storage vessel for aging before bottling. The storage vessels may be either oak barrels, oak cubes, or stainless steel tanks. More recently, smaller wineries have shown interest in high-density polyethylene tanks.

Sulfur dioxide addition

The addition of SO_2 as soon as practical after racking helps ensure microbiological stability. Caution must be exercised in terms of the amount of SO_2 added as it can bind to anthocyanins, thereby bleaching wine color.

Malolactic fermentation

MLF is a routine operation in red wine production. As the concentration of SO_2 is lower in red wine compared with white wine, the conversion of malic acid to lactic acid removes a major substrate for potential microbiological spoilage.

MLF may be performed prior to or during the alcoholic fermentation, but it is more commonly carried out after the wine is racked off yeast lees. Post-alcoholic fermentation MLF results in an obvious aroma change with a reduction of fruit character and the appearance of diacetyl buttery aroma.

Oenotannin addition

If winemakers regard the wine tannin level as too low, the option to add tannin is a possibility permitted in most countries. There are a range of commercially available products marketed as oenotannins. These include grape tannin, gallotannins, and ellagitannins, the latter two sourced from oak and other plants. The advantages of this approach remain the subject of debate.

Oak treatment

Aroma and palate structural changes result from time in oak. The development of oak aromas requires new barrels, and this introduces a considerable production cost. French and American oak barrels are the most common. More recently, there has been considerable interest in oak sourced, for example, from Hungary or Russia. Oak forest, wood seasoning, and toasting level are some of the factors that impact on the type and amount of compounds that can be extracted from oak.

A cheaper alternative is to use pieces of oak that can be placed in stainless steel or plastic tanks. These include staves, cubes, chips, and powder, the latter three being contained in infusion bags. Wine price point tends to determine the selection of oak material.

Oxygen during development

Contact with oxygen during red wine development can be beneficial for color stabilization. Changes in tannin structure may also occur during this development phase, leading to a softening in palate sensory response. There is a slow permeation of air through the pores between the staves in barrels. Some plastic tanks are now marketed with the claim of defined oxygen permeation rates.

When stored in barrel or plastic tanks, quality control issues include temperature and humidity control, regular topping up, and regular sulfur dioxide checks. If the vessels are not completely full, a film *flor* yeast may grow on the surface and lead to enhanced acetaldehyde concentrations. The so-called 'Brett' character from the growth of *Dekkera* yeasts will result in

off-odors including 4-ethylphenol (band-aid and horse saddle) and 4-ethylguaiacol (smoked bacon).

Micro-oxygenation (MOX) is a means of introducing controlled amounts of oxygen into a wine stored in a stainless steel tank at a rate such that all oxygen is consumed by chemical reactions with wine components. MOX would appear to be effective in smaller tanks, but limited dispersion in large tanks questions its general application.

Clarification

Wine stored in barrel for 12 or more months is often free of particulate and colloidal material and can be directly bottled. In some cases, a settling agent may be added. Egg white is a common choice as it aids settling and softens the palate structure, although its use requires allergen labeling.

Bottling: The Final Step in White and Red Wine Production

There are two major considerations in the bottling process: the stability of the wine and using packaging materials that make the product attractive to consumers in a crowded marketplace.

Microbiological Stability

Sterile filtration is common practice for white, rosé, and lighter red wines but is more difficult to achieve for many red wines that may be bottled without filtration. All equipment used in filling and sealing the bottle should be sterilized before use. Hot water and steam are the best options.

Stability Against Oxidation

SO_2 levels should be adjusted to the desired level before bottling. It is advantageous to check the SO_2 levels for up to 4 weeks after bottling as a significant drop may indicate high potential for oxidative spoilage. Ascorbic acid may also be used in white wines as an antioxidant.

Every attempt should be made to exclude oxygen when filling and sealing the bottle. There is a variety of approaches used to minimize oxygen ingress, including purging with nitrogen or argon or using dry ice to expel air. Stability checks postbottling are always advisable as part of routine quality control.

Bottle Selection

There is a range of bottle colors and shapes. Winemaking issues include the ability to protect wine from light exposure and bottle weight. Clear or lighter-colored glass is preferable from a recycling perspective but offers less protection against light-induced spoilage. Newer lower weight bottles reduce transport costs, thereby lowering the carbon footprint.

Closures

While cork has been the traditional material used for closing the wine in bottle, there are several options available including agglomerated cork, synthetic extruded closure, and screw cap. Market acceptance of alternative closures is a major factor in decision making, as is effectiveness in sealing, potential shelf life, ease of closure removal, and evidence of tampering. The wines stored for protracted periods under screw cap may lead to sulfidic off-odor production. This is the subject of ongoing research.

Once the bottle is filled and sealed, it is washed and labeled. Some wine styles demand bottle aging, whereas others are released almost immediately. It is then time for the marketer to take over.

Summary

Sulfur dioxide has been described as the 'molecular guardian of wine' since it plays a dual role as an antimicrobial agent and as an antioxidant. The allergic reaction suffered by some consumers toward SO_2 has led to a search for alternatives. Ascorbic acid is now widely used as an antioxidant in white wine, although still in combination with SO_2. Glutathione is under investigation as another possible antioxidant. An effective alternative to SO_2's antimicrobial activity has not been found, despite extensive research.

Organic and biodynamic wines relate more to vineyard practices as the grapes, once harvested, tend to be processed by the steps described here. Natural wine is an extension of the organic/biodynamic vineyard practice as it applies to the production of wine with no or only minimal treatments and inputs. In essence, the hand-harvested grapes are fermented without external inoculation and the wine is preferably decanted and bottled without SO_2. The approach presents a major challenge for a successful outcome.

Wines: Wine Tasting

RS Jackson, Brock University, St. Catharines, ON, Canada

© 2016 Elsevier Ltd. All rights reserved.

In the popular mind, wine tasting conjures up images of vintners sampling wine out of barrels in cobwebbed cellars: aficionados clustered around old bottles, intensely swirling and sipping their wine; partygoers jostling one another to get to cheese, crackers, and wine; or some variant thereof. All are real, but the most serious wine tasting occurs in laboratories set up with individual cubicles, each equipped with dentist-style cuspidors, low-intensity lighting, and other features, designed to minimize distractions and maximize concentration, as well as computers for recording and analyzing data. This, the sober side of wine tasting, is typically termed sensory analysis and a far cry from most peoples' perception of wine tasting. Nonetheless, it is the most valuable aspect of tasting, relative to producing fine wines. It permits researchers, grape growers, and winemakers to assess the effects of adjustments to viticultural and/or enological procedures.

Critical sensory analysis is now a fundamental aspect of all university-based training and an integral part of research relating to wine production. In contrast, most consumer-based tasting is designed to enhance the appreciation of the finished product. This is as it should be. Nonetheless, both approaches require a method to detect the finest qualities a wine may possess. Otherwise, wine appreciation can degenerate into snobbism (derived from possession) rather than objective evaluation. Understanding the origin of wines, vintage details, producer renowned, and price can enliven discussion, but focusing attention on important aspect of the wine's relative quality is far more valuable. It is clearly detectable quality that gives (or should) distinguish premium wines from the pack. However, detailed tasting demands more time and concentration than most consumers know or may even be willing to bestow. Consequently, much fine wine is consumed without its full range of attributes ever being detected. For most wine, this may be a good thing – close scrutiny reveals both a wine's best and least desirable attributes.

Detailed assessment is most worthwhile with excellent wines. Regrettably, there are no external indicators that can accurately predict a wine's quality. It only begins to be detectable after being poured. Price, prestige, provenance, producer, and vintage are all inconsistent and, too frequently, poor predictors of wine quality. Interestingly, it is this particular feature (uncertainty) that provides connoisseurs with much of the intrigue that makes wine appealing. Unfortunately, variability also permits many a mediocre, but expensive, wine to masquerade under a premium label. Too often, features such as a poor vintage, bottle-to-bottle variation, or lack of personal acuity are used to explain away nondescript quality in pricey wines. Vinous quality should be obvious, not so subtle as to require an overactive imagination. Tasting should be conducted as a search for the truth – not to justify preconceived ideas or views. Personal perception should not be subjugated to the views of others, regardless of their 'authority,' nor become an act of genuflection to label prestige.

No one tasting approach is appropriate for all contingencies. What is appropriate depends on the situation and intent. For example, what is suitable at the dinner table would be unacceptable for critical appraisal. Detailed analysis of a wine at a meal is inconsistent with, and disruptive to, the principal function of dining with family or friends. However, when the purpose is to compare or analyze wines, every possible sensory attribute should be assessed. For aficionados, these are essential in fairly assessing wine quality, as well as attempting to divine its varietal, stylistic, regional, and aging potential attributes. The latter are often a critical element in connoisseur appreciation. Detailed assessment is also essential to winery and research analyses.

Often, those with little wine experience wonder if all the fuss is necessary or whether they have the sensory acuity to distinguish superior from ordinary wine. Assuming a willingness to focus attention, and the presence of a normal sense of taste and smell, the answer is definitively 'yes.' What cannot be predicted is whether the individual will consider the differences detected worthy of the effort. As in other aspects of life, what one gets out of an activity is usually directly proportional to what one puts in. Experience, habituation, inclination, maturity, and social pressure can all play roles in the evolution of a love for what may initially be disappreciated.

Figure 1 outlines a programmed set of steps designed to focus sequentially on every sensory aspect a wine may possess. It contains aspects that may not be necessary or appropriate under certain circumstances, but the schema provides a palate from which desired attributes can be adequately assessed.

Detailed Tasting Technique

Except when dining, most wine tastings are comparative – that is, several wines are sampled together. This has the advantage of highlighting differences that facilitate the identification of significant features. These include aspects such a varietal composition, wine style, provenance, and age. For this reason, and because all sensory analysis tests are done in a comparative fashion, much of what is described in the succeeding text relates to this situation. Nonetheless, regardless of the situation, the steps involved are identical, except where tasting is only cursory.

Because glass shape subtlety alters the dynamics and concentration of released aromatics, all wines need to be poured into identical vessels. Current practice prefers clear, tulip-shaped, stemmed glasses, with a capacity of about 215 ml. Of those available, the International Standards Organization (ISO) wine tasting glass (Plate 1) is ideal, being specifically designed and assessed for the purpose. The incurved sides facilitate swirling, promoting the release of volatiles, as well as their retention within the bowl. Thin lead crystal versions add at touch of class, but are unnecessary. Less expensive, noncrystal versions, or slight variations in design, are more

readily available and more dishwasher-friendly. An example is the Libbey Citation 8470. The only exception involves sparkling wines. In this instance, elongated, flute-shaped glasses are typical. They assist in recording details of the effervescent and mousse attributes of the wine.

Due to the influence of heat and volume on volatilization, all samples should be presented at the same temperature and in equivalent amounts. Volumes of about 30–50 ml are usually adequate. This permits both vigorous swirling and angling of the glass to assess the wine's countenance.

Each sample should be poured into identical, clear, tulip-shaped, wine glasses. They should each filled (1/4 to 1/3 full) with the same volume of wine.

I. Appearance

1- View each sample at a 30° to 45° angle against a bright, white background.
2- Record separately the wine's:
clarity (absence of haze)
color hue (shade or tint) and depth (intensity or amount of pigment)
viscosity (resistance to flow)
effervescence (notably sparkling wines)

II. Odor "in-glass"

1- Sniff each sample at the mouth of the glass before swirling.
2- Study and record the nature and intensity of the fragrance (see Fig 1.3 and 1.4)
3- Swirl the glass to promote the release of aromatic constituents from the wine.
4- Smell the wine, initially at the mouth and then deeper in the bowl.
5- Study and record the nature and intensity of fragrance.
6- Proceed to other samples.
7- Progress to tasting the wines (III)

III. "In-mouth" sensations

(a) Taste and mouth-feel

1- Take a small (6 to 10 ml) sample into the mouth.
2- Move the wine in the mouth to coat all surfaces of tongue, cheeks and palate.
3- For the various taste sensations (sweet, acid, bitter) note where they are perceived, when first detected, how long they last, and how they change in perception and intensity.
4- Concentrate on the tactile (mouth-feel) sensations of astringency, prickling, body, temperature, and "heat".
5- Record these perceptions and how they combine with one another.

(b) Odor

1- Note the fragrance of the wine at the warmer temperatures of the mouth.
2- Aspirate the wine by drawing air through the wine to enhance the release of its aromatic constituents.
3- Concentrate on the nature, development and duration of the fragrance. Note and record any differences between the "in-mouth" and "in-glass" aspects of the fragrance.

(c) Aftersmell

1- Draw air into the lungs that has been aspirated through the wine for 15 to 30 s.
2- Swallow the wine (or spit into a cuspidor).
3- Breath out the warmed vapors through the nose.
4- Any odor detected in this manner is termed aftersmell; it is usually found only in the finest or most aromatic wines.

[a] Although fragrance is technically divided into the aroma (derived from the grapes) and bouquet (derived from fermentation, processing and aging), descriptive terms are more informative.

Figure 1—cont'd

IV. Finish

1- Concentrate on the olfactory and gustatory sensations that linger in the mouth.
2- Compare these sensations with those previously detected.
3- Note their character and duration.

V. Repetition of assessment

1- Reevaluate of aromatic and sapid sensations of the wines, beginning at II.3– ideally several times over a period of 30 min.
2- Study the duration and development (change in intensity and quality) of each sample.

Finally, make an overall assessment of the pleasurableness, complexity, subtlety, elegance, power, balance, and memorableness of the wine. With experience, you can being to make evaluations of its *potential*– the likelihood of the wine improving in its character with additional aging.

Figure 1 Parts 1 and 2. Wine tasting sequence. Reproduced from Jackson, R. S. (2009). Wine tasting: a professional handbook (2nd ed.). London: Academic Press. Copyright Elsevier, with permission.

The palate should be cleansed between samples, to avoid residual effects influencing the perception of those subsequently assessed. Current data suggest that a 1% pectin solution is an effective cleanser. Unsalted crackers are a more common, but less ideal palate cleanser but far superior to water. Water is ineffective at removing residual tannic constituents and dilutes the saliva. Cheese should be avoided. It tends to suppress or mask several wine sensations. This effect, characteristic of food in general, is of value only if it is specifically desired. For example, the saltiness of cheese, or the proteins in food, mollifies both bitter and astringent attributes, respectively.

Appearance

The principal features of significance are color and clarity. Of these, color not only is the most obvious but also donates the wine's first esthetic pleasure. Young red wines are characterized by a rich, vivacious countenance, older versions progressively take on subtler brickish shades. White wine, if sweet, often possesses a golden opulence – it being a harbinger of the sapid pleasures to follow. Dry whites, depending on the cultivar, maturity, and duration of skin contact, vary from pale straw to yellow. With age, white wines darken in color, whereas reds lose color depth. Aberrant colors for age, cultivar, or style often foretell the presence of inappropriate fragrances or off-odors. Despite this, such clues should be taken with caution, to avoid unfairly prejudicing subsequent perceptions. Where color bias must be avoided (e.g., when sampling wines of different vintages or cultivars), sampling is often conducted under dim red lights (to disrupt color perception) or tasted in black glasses.

For color assessment, the glass is typically tilted at about a 30–45° angle and viewed against a bright, white background. This permits viewing the hue through varying wine depths. This is of particular value when sampling red wines. They typically show a clear rim and a purplish cast when young. The first sign of aging (or undesirable premature oxidation) appears as a brickish coloration at the rim.

Clarity assessment is also facilitated by tilting. With modern clarification and fining techniques, most wines remain perfectly clear. Nonetheless, some old red wines may develop sediment (precipitated tannins and tartrate salts). These may be resuspended during transport from storage or pouring, generating a haze and bitterish/clayey taste. This can be avoided by due caution during the transfer of old wine from a cellar and judicious decanting just prior to sampling.

Only wines possessing very high sugar, glycerol, and/or alcohol contents may show slight modifications in perceptible viscosity. Thus, this attribute is rarely of sensory or diagnostic value. The only significant exception involves a bacterial spoilage termed ropey.

Tears (legs) are another visual attribute of trivial sensory significance. They form following swirling, as a thin layer of wine adheres to the sides of the glass. The relatively greater volatilization of alcohol results in a progressive increase of the surface tension in the wine film. This, in turn, leads to the

formation of droplets ('tears'). As the droplets enlarge, gravity initiates their decent – *ipso facto*, the formation of 'legs.'

Occasionally, bubbles may develop along the bottom and sides of the glass. This typically results when the wine is bottled before the excess carbon dioxide, dissolved in a newly fermented wine, has had time to escape. Continuous bubble formation is a characteristic only of sparkling wines. In the latter instance, the size, number, and duration of effervescence, and the formation of a ring of bubbles next to the glass (*cordon de mousse*), are considered important and essential quality attributes.

Although a wine's visual features can act as harbingers of other sensory attributes to follow, it is usually more useful for consumers to concentrate on the pleasure so derived.

Aroma and Bouquet

Traditionally, two aromatic attributes have been distinguished – aroma and bouquet. Aroma is differentiated as being derived from the grape, whereas bouquet originates from fermentation or aging processes. While seemingly distinct, the compounds generating each may be identical. Correspondingly, the current trend is to avoid this distinction, choosing a more general term – fragrance.

Assessing a wine's fragrance involves two distinct aspects. The first assesses the fragrance orthonasally (in the glass) and later retronasally (in the mouth). Although essentially assessing the same compounds, their qualitative perceptions can differ markedly. Aromatics appear to be detected (and remembered) as temporal impulse patterns. These arise as aromatic pass over the olfactory patches in the nose. Because the receptors, responding to different aromatics, appear to be arranged in a more or less linear pattern along the olfactory patches, detection is sequential, similar to isolation via gas chromatography. Because the direction of flow is reversed when detection occurs via the back of the throat (retronasally), a different time-sequence pattern is generated. It may be the equivalent of playing a series of notes in reverse order. Depending on the number of different olfactory receptors involved, and their position, the time-sequence pattern can be markedly different. A classic example is the sensory difference between the smell and in-mouth response to Limburger cheese or durian fruit. In addition, the concentration of aromatic compounds entering the nose via the back of the throat is usually less than that received via the nostrils (affecting threshold-sensitive reactions). Selective absorption and enzymatic modification in the mouth can also modify the aromatic composition detected retronasally. The volatile dynamics of the wine's aromatics may be also affected by the temperature difference between wine in the glass and in the mouth.

To facilitate the escape of aromatics, the wine is swirled in the glass. This increases the surface area over which volatilization can occur, favoring concentration in the headspace above the wine. This is far more effective than the now-popular wine 'aerators.' Repeated swirling also creates turbulence that refreshes the concentration of aromatics at the surface of the wine (where volatilization occurs). For vigorous swirling, glasses should be no more than ⅓ full. The inward curve of tulip-shaped wine glasses also facilitates vigorous swirling and the retention of aromatic compounds in the bowl.

It is traditional to initiate fragrance analysis at the rim followed by in the bowl. This permits sensation of the aromatics at different concentrations, with only the most volatile/low-threshold members being initially detected at the rim. This may result in the generation of distinct sensations. Where the fragrance is mild, some professionals place a watch glass over the mouth of the glass. This permits even more vigorous swirling while trapping the aromatics within the bowl. Small petri dish covers or coffee cup tops can be used similarly where of an appropriate size.

Studies have shown that no particular technique need be learned for adequately assessing wine fragrance. Whiffs of about a second duration, separated by 20–30 s, appear fully adequate. This interval relates to the time required for olfactory receptors to regain their intrinsic sensitivity. Nonetheless, different sniffing procedures do seem to affect the qualitative perception of odors. For example, extended inhalation periods can facilitate the analysis of complexly aromatic wines, such as ports. As particular olfactory receptors adapt and no longer respond, the odorant pattern transmitted by those still being detected may generate different qualitative perceptions. This can activate a kaleidoscope of olfactory memories.

Professional tasters are usually trained in odor recognition, using samples specifically designed for the purpose. Reference samples are typically available during tastings. Precise and consistent term use is critical where panels of assessors are used to define and measure the differences among wines. Fragrance and off-odor charts may also be supplied, but these are more commonly used in wine appreciation courses or by wine tasting clubs. Although common, it is more valuable for consumers to concentrate on memorizing the holistic perceptions that distinguish particular wines than to focus on individual aromatic resemblances. This is akin to the greater value of recognizing faces than separately doting on individual facial features. In addition, overattention on designating aromatic descriptors can detract from the actual appreciation of the wine. Focusing on odor descriptors is best left to teaching people to take due notice of the most distinctive and variable attributes of a wine – its fragrance. This is a prerequisite to memorizing the more useful, distinctive odor patterns of different grape varieties, wine styles, aging attributes, and potential regional characteristics.

Both positive and negative impressions should be recorded. Figure 2 provides an example of a table designed to focus attention on a range of potential attributes. Simpler and more appropriate for consumers is graphic representation, such as illustrated in Figure 3. It has the advantage of being quick, succinct, and effective. In addition, it clearly represents the fleeting changes in flavor intensity and character that distinguish fine wines.

One of the principal values of recording impressions is the concentration it demands, leading potentially to enhanced appreciation. It facilitates detecting features that otherwise might be missed. It also encourages the development of a wine lexicon. Except where derived during training, the terms most people use strongly reflect individual familial, cultural, and geographic upbringing. That such a language may not be as precise, consistent, or even appropriate, as required for scientific investigation, is not a serious drawback for the consumer. Its primary purpose is for recording personal impressions and

Sample Number: ___	Wine Category: ___	Exceptional	Very Good	Above Average	Average	Below Average	Poor	Faulty	Comments

Flavor (taste, mouth-feel, retronasal odor)	Intensity								
	Duration								
	Quality								
Finish (after-taste and lingering flavor)	Duration								
	Quality								
Conclusion									

* *Intensity:* the perceived relative strength of sensation- too weak or too strong are equally undesirable.
** *Duration:* the interval over which the wine develops or maintains its sensory impact; long duration is usually a positive feature if not too intense.
*** *Quality:* the degree to which the feature reflects appropriate and desirable varietal, regional or stylistic features of the wine, plus the pleasure these features give the taster.

Figure 2 Wine tasting sheet for quality assessment. Reproduced from Jackson, R. S. (2009). Wine tasting: a professional handbook (2nd ed.). London: Academic Press. Copyright Elsevier, with permission.

focusing attention on the wine's attributes. However, using any olfactory vocabulary, both consistently and accurately, is difficult. Most people have great difficulty even correctly naming familiar odors in the absence of visual clues. Only pronounced odors, such as the smell of fried bacon, toast, or lilacs, are sufficiently intense as to develop an odor memory independent of visual or other clues. The problem of naming most recognizable odors has been aptly dubbed the 'tip-of-the-nose' phenomenon. This probably reflects the dominance of visual information in human sensory perception.

Recognizing the varietal, stylistic, age, or providence attributes of wines typically demands considerable concentration, as well as extensive experience. It often requires repeated sampling, employing both inductive and deductive memory searches. Features, both present and absent, are often required. Nonetheless, as the primary source of a wine's unique character, the study of fragrance warrants the intense scrutiny it demands.

Oral Assessment

After an initial assessing of the wine's orthonasal fragrance several times, attention begins to turn to in-mouth sensations. Small amounts of wine are sampled and rolled around in the mouth to contact all its surfaces. As far as feasible, the volume of each sample should be kept identical. This favors equivalent comparison of the samples.

Technically, taste is limited to sweetness, sourness, saltiness, savoriness (umami), and bitterness. Of these, only sweetness, sourness, and bitterness have relevance to wine tasting. The other major in-mouth sensation is astringency. It is considered a touch rather than a taste, due to its being detected by free-nerve endings of the trigeminal nerve rather by specific receptors localized largely within taste buds on the tongue.

Because many consumers fail to concentrate on the wine's fragrance, taste and touch sensations tend to be more significant to them than wine aficionados and judges. When specifically assessed, the distinctive temporal dynamics and relative location of each sensation help distinguish their relative intensities.

The in-mouth sensation most rapidly detected is sweetness. If present, sensitivity is most noticeable at the tip of the tongue. Occasionally, the illusion of sweetness is detected in dry, but fragrant, white wines. This results from previously learned associations between certain odorants and sweetness. This induces the brain to 'perceive' sweetness, even though the

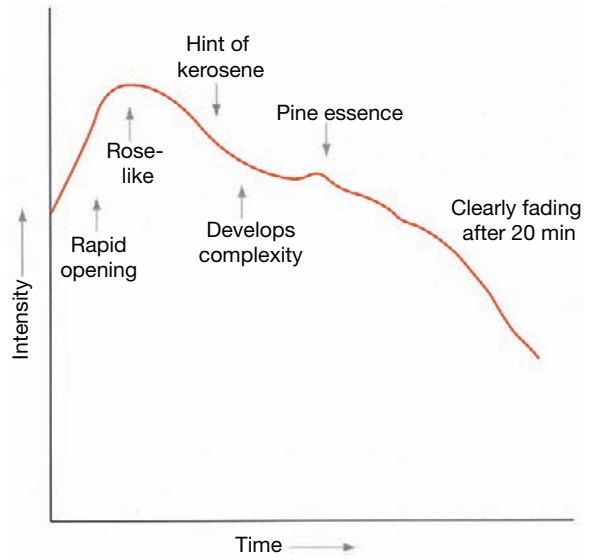

Figure 3 Graphic representation of the development of a wine's fragrance and its relative intensity. Specific observations can be written on the graph to represent when it was detected. Reproduced from Jackson, R. S. (2009). Wine tasting: a professional handbook (2nd ed.). London: Academic Press. Copyright Elsevier, with permission.

wine is dry (the illusion of sweetness disappears by pinching the nose).

In the absence of detectable sweetness, the first taste perception detected is sourness. This is frequently most obvious along the sides of the tongue and cheeks. When marked, it causes a puckery sensation as well as irritation in the mouth.

Detection of bitterness tends to require several seconds to develop. Except for some alkaloids found in vermouths, most wine bitterness is detected primarily at the back of the tongue. Alkaloids are often perceived at the tip of the tongue. Depending on an individual's personal sensitivity, it can take more than 15 s before the intensity of bitterness reaches its peak.

The last, prominent, in-mouth sensation, notably in red wines, is the tactile perception of astringency. Like bitterness, it is induced primarily by wine tannins. Due to their extreme variability in structure and size, they can activate a wide variety of mouthfeel sensations. These can range from dry, dust-in-the-mouth, puckery to velvety sensations. The response to astringency, similar to bitterness, is relatively slow to express itself, often taking 15 s or more to reach its maximum. The fading of the sensation is equal to, or slower than, its development. Unlike bitterness, it is detected throughout the mouth.

Other potentially detected in-mouth sensations include the burning sensation of alcohol (notably concentrations above 14%), the prickling aspect of carbon dioxide (sparkling wines), and temperature. Like all mouthfeel sensations (involving trigeminal nerves), they are sensed throughout the mouth.

Depending on the intention of the tasting, it may be worth noting differences between the first and subsequent sips. Tannins and acids react with salivary and membrane-bound proteins in the mouth, initially diminishing their respective bitter/astringent and sour/astringent sensations. Thus, the initial sample often appears smoother and more balanced than subsequent samplings. The first sample approximates the perception generated when wine is taken with food – proteins reacting with tannins and acids, reducing their initial intensity. If assessing how a wine might balance with food, sampling should progress slowly. This provides time for activated saliva production to compensate for its dilution during tasting. Cleansing the palate between samples reduces tannin and acid residual effects that can distort perception.

Professional tasters and aficionados often aspirate the wine to enhance retronasal odor detection. This involves closing the mouth while leaving the lips slightly ajar or pursing the lips and slowly drawing air through the wine. This has an effect similar to swirling wine in the glass, enhancing odorant release. The volatilized compounds migrate up into the nasal passages, especially during swallowing and breathing out. Slow, deliberate exhalation apparently improves retronasal detection, possibly only due to conscious focusing on the process. The olfactory sensations so induced, combined with gustatory sensations, generate the multimodal sensation termed flavor. Flavor detection, following swallowing or expectoration, is termed the wine's finish. Its duration is considered a quality factor. The importance of retronasal olfaction to flavor detection is immediately apparent by clamping the nose.

Fruity–floral essences, associated with refreshing acidity, epitomize most better white wines, whereas complex berry/jammy fragrances, combined with flavorful, velvety tannins, exemplify the best red wines. Fortified wines, possessing more intense flavors, have very long finishes. These attributes may be supplemented with, or enhanced by, oak-derived flavors. The nature of their contribution depends on the duration of contact, the type of oak used (European vs. American), and the degree of toasting during barrel construction. Additional flavor notes may be derived from malolactic fermentation and *sur lies* maturation. With aging, the initial varietal/fermentation flavors tend to fade, hopefully being replaced by aged fragrances. These tend to be relatively similar, regardless of the wine, at least for red wines.

Although significant in some critical tastings, noting a wine's individual taste/mouthfeel attributes is less important than concentrating on how they integrate to produce holistic perceptions, such as flavor, complexity, balance, and body. The duration and development in flavor over the course of the tasting are highly desired features.

When wines are assessed critically, expectoration is the norm. This helps minimize any increase in blood alcohol content and the associated decline in taster acuity and discriminatory skill. In social situations, expectoration is usually anathema and can be a waste of limited amounts of good wine.

Integration, Interpretation, and Quality Assessment

To experience the full range of a wine's sensory attributes, it is important to sample the wine over a 15–30 min period. Otherwise, features such as duration and development will not be adequately assessed. Duration relates to how long the wine retains a distinctive fragrance, whereas development refers to its qualitative changes. Development is often compared to the opening of a flower or the transformations of sunset. These features not only retain taster interest but also generate one of the rationales justifying the higher cost of premium wines. For these reasons, wine should not be opened or decanted in

advance – it can obviate the full detection of a wine's development.

During any tasting, attention slowly shifts from observing individual attributes to focusing on their integration and interpretation. This may involve assessing aspects such as conformity with, and distinctiveness within regional norms, varietal origin, stylistic characteristics, and an appraisal of the wine's overall (esthetic) quality. Quality, as independent from its historic, geographic, stylistic, or varietal attributes, is typically described in terms used in artistic appreciation. Complexity refers to the presence of many, distinctive, aromatic elements, rather than one or a few easily recognizable odors. Balance (harmony) denotes the perceived equilibrium of all olfactory and oral sensations, where individual attributes do not dominate. This is particularly desirable when the wine is to be sampled by itself. It is less significant when consumed with food, where balance involves how the wine complements and embellishes the appreciation of the food, and vice versa. Occasionally, an aspect of imbalance can be intriguing, donating the element of apparent 'nervousness.' Fine wines should ideally show extended duration, a fascinating development, and a lingering and appealing finish. These aspects both enthrall and sustain interest. Implied, but seldom enunciated, are properties such as power, elegance, and finesse. Without these attributes, attractiveness is shallow. Occasionally, these perceptions are so remarkable that the experience becomes unforgettable – a feature termed memorableness. Although highly desirable, it tends to require an element of surprise. This provides an additional incentive for tasting wines blind, that is, knowing nothing about its origin. This aspect is further enhanced when the wines are served in black glasses.

Other Tasting Situations

The previous section has dealt primarily with serious tasting – typically referred to as sensory analysis. The technique outlined focuses attention on all the sensory delights (and deficits) a wine may possess. Nonetheless, under most situations, its application is either unnecessary (wines of mediocre character), inappropriate (during a meal), or too prolonged (large stand-up tastings). Under such circumstances, the procedure needs to be truncated. Suggestions for such situations are briefly noted in the succeeding text.

Most wine and cheese parties are intended to promote social interaction, not assess either the wine or the cheese. Nonetheless, cheese mollifies the wine's less pleasant attributes and helps to keep the hands of participants occupied. The wines selected are all too frequently as innocuous or inexpensive as possible, to avoid interfering with the true function of the gathering. In addition, few attendees are really interested in the wine or cheese. Under such circumstance, there is little value in attempting a critical analysis, unless it is to confirm, if necessary, the nondescript nature of both the wine and the cheese. Many wine societies are also venues for developing social and business contacts rather than for learning about wine. The meal, usually an integral part of such gatherings, confounds the act of critical analysis but does favor an assessment of food and wine combinations. Although less than ideal for assessing the wine's full range of attributes, such tasting may indirectly act to encourage people to become more critical and thoughtful consumers.

Commercial tastings are usually designed to showcase participant wines and/or raise funds. In both situations, some of the wines may be of a quality worthy of assessment. Regrettably, the setting is usually not designed for critical appraisal – social interactions deflect attention from the wines, the time allotted for each wine tends to be too short, and the cheese/bread/food accompaniments, typically supplied, are inappropriate, albeit appreciated by most participants. Conditions are improved if the number of wines is limited, the tastings sequential and organized, and the participants seated. Despite these limitations, a reasonable evaluation of a select number of wines is possible, if sufficient concentration is applied to counter the all-too-abundant surrounding distractions of such venues. In contrast, large, stand-up tastings are reduced to quick swirls, sniffs, sips, and spits (or swallowing) – there being little opportunity to assess flavor duration or development. Although doing injustice to most quality wines, it favors the positive perception of wines that are ready for immediate consumption. This is not such a problem. These are usually the only wines presented. Because of the large number of wines available, those sampled should be judiciously chosen and limited to those that appear to warrant attention. Beyond a quick evaluation of the wine's immediate impression, attention may also be directed to evaluating the wines' expression of some geographic, stylistic, or varietal expression. Frequently, though, the wines are evaluated only on a personal preference, price/quality basis.

Most wine tastings, though, occur in association with food. This is a long-established European custom, probably reflecting wine's beneficial antimicrobial properties and its ready availability. Only sweeter or fortified wines tend to be balanced for consumption alone. In addition, there is no inherent compatibility between wine and food. The predominant flavors of wine (floral/fruity fragrances and acidic, bitter, astringent, and alcoholic attributes) find little in common with meaty or vegetal flavors. Nonetheless, wines do possess some of the features common to food condiments – adding elements of interest. Wines are also par excellent palate cleansers, refreshening the mouth, allowing one to enjoy anew the attributes of food. Conversely, food cleanses the palate of wine flavors, permitting the wine to be sampled afresh. Wines and food also tend to diminish each other's less pleasant attributes – wine's acidity, bitterness, and astringency are reduced and a food's fatty attributes diminished. The result is a mutual and synergistic enhancement in the appreciation of both. Thus, when attempting to critically assess a wine at the dinner table, it is better to sample the wine(s) in advance of the food's arrival. This avoids any skewing or reduction in the sensory characteristics of the wines. This is especially important for better wines, permitting their attributes to be fully detected. It also provides an opportunity to make comparisons, take notes, and share perceptions with fellow aficionados. Comparisons are more informative (less chance for knowledge-based bias) if the identity of the wines, or at least their order, is withheld during the sampling period. In contrast, if the tasting occurs synchronously with the meal, most young table wines will appear better by the combination and therefore beneficial. It is primarily with older, red table wines, which have developed subtle flavors,

that combination with food is usually a significant mistake. Unless the food is very mild-flavored, it will overpower the wine's ethereal characteristics, obviating a full appreciation of the qualities that may have taken decades to develop.

Introduction

The World Health Organization (WHO) is a specialized agency of the United Nations (UN), which is concerned with international public health. It is the directing and coordinating authority for health within the UN system. It is responsible for providing leadership on global health matters, shaping the health research agenda, setting norms and standards, articulating evidence-based policy options, providing technical support to countries, and monitoring and assessing health trends. It was established on 7 April 1948, headquartered in Geneva, Switzerland. The WHO is a member of the UN Development Group; its predecessor, the Health Organization, was an agency of the League of Nations. The constitution of the WHO had been signed by 61 countries on 22 July 1946, with the first meeting of the assembly (World Health Assembly (WHA)) finishing on 24 July 1948. It incorporated the International Office of Public Hygiene and the League of Nations Health Organization. Since its creation, it has played a leading role in the eradication of smallpox. Its current priorities include communicable diseases, in particular HIV/AIDS, Ebola, malaria, and tuberculosis. Among the remaining foci are mitigation of the effects of noncommunicable diseases; sexual and reproductive health, development, and aging; nutrition, food security, and healthy eating; occupational health; substance abuse; and driving the development of reporting, publications, and networking. The WHO is responsible for the World Health Report, a leading international publication on health, the World Health Survey, and the World Health Day (7th of April every year).

The WHO works directly with and through other agencies of the UN system, nongovernmental organizations, and collaborating centers across the world in numerous disciplines. Due to resource constraints in 1990s, the WHO places emphasis on meeting the most pressing health needs. In seeking to prevent and overcome malnutrition, the WHO promotes the tailoring of approaches to fit situation. While the rapidly increasing threat of noncommunicable diseases accounts for at least 40% of all deaths in developing countries and 75% in industrialized countries, many millions still cannot meet basic needs for energy and protein, are deficient in essential micronutrients, or are severely malnourished. Thus, coordinated action is called for on both fronts. The WHO has played a unique normative, scientific, and advisory role for the last half century. It strives to support all its member states in developing food and nutrition policies that will make healthy choices the easy choices for their populations.

Historical Background

The middle of eighteenth century saw the first international exhibition in London, at which products of technical skill and craftsmanship of many countries were displayed. This was possibly due to the increased speed and facility of transportation. But the same factor was also responsible for rapid and extensive spread of cholera that arrived in Europe and became a prominent reason for the origin of International Sanitary Conference, which opened in Paris on 23 July 1851. Eight years later, the second conference was held in Paris; it lasted for 5 months, during which a new draft was signed. This, in turn, was followed by a conference in Constantinople (1866), which ended in an agreement on a number of technical questions. On 1 July 1869, the fourth conference was held in Vienna, which resulted in a plan for a permanent International Commission on Epidemics followed by conferences in 1885 (Rome), 1892 (Venice), 1893 (Dresden), 1894 (Paris), and 1897 (Venice) with a focus on cholera or plague and removal of bars on trade. In 1903, the 11th conference was held at Paris with a more scientific approach toward epidemics. A proposal for translating scientific knowledge into practical public health measures by establishing the International Public Health Office was favorably received and acted upon on 9 December 1907, with the creation of the International Office of Public Hygiene (OIHP) in Paris. It was the first international office with the intent to disseminate to member state information on general public health, epidemics, and the ways to prevent and remedies for the same. Before the outbreak of the First World War, OIHP was working with an aim of controlling epidemics, opening and managing hospitals, and establishing food hygiene and biological standardization. Its activities were suspended in 1914, due to the outbreak of war, with the exception of the publication of its *Bulletin*. While OIHP was being formed, the Americans came up with International Sanitary Bureau in 1902, which was renamed as Pan American Sanitary Bureau in 1923. Besides these, there were various other regional councils of health in the eighteenth and nineteenth century in Egypt, in the Ottoman Empire, in the Moroccan region, etc.

Following the First World War, in 1920, a need for a larger, better organized, radical, dynamic, and better coordinated international health organization was felt. The world observed a breakdown of the sanitary conditions that caused the outbreak of cholera and typhus, both of which were endangering millions of lives in Poland, Russia, and other parts. The task of reestablishment of sanitary decency was a Herculean one, demanding an organization with a larger-scale, vaster outreach, more solid budget, and greater efficiency and effect. On the request of the Council of the League of Nations, International Health Conference met in London from 13 to 17 April 1920. After a lot of trials and tribulations, the league came up with its own health committee to work in coordination with OIHP. The two worked parallel for many years until after the Second World War, when the globe started making attempts to establish public health as fundamental to attainment of peace and prosperity. The UN Conference on International

Organization in San Francisco was held in 1945, at which an international health organization was established. The constitution of the WHO was approved in 1946 at the International Health Conference in New York. Along with 18 states, the Interim Commission (1946-48) took over the work of OIHP, the Health Organization of the League of Nations, and the Health Division of the UN Relief and Rehabilitation Administration. In 1948, the WHO Constitution obtained enough support to bring it into force and was established on 7 April 1948.

WHO: Structure and Management

The WHO consists of one headquarters (in Geneva) and six regional offices working together for three main bodies: the Health Assembly (HA), the Executive Board, and the Secretariat. Nearly 8000 employees from more than 150 countries work for the organization. The staff includes not only medical doctors, public health specialists, researchers, and epidemiologists but also administrative, financial, and information systems specialists, as well as experts in the fields of health statistics, economics, and emergency relief.

WHO: Headquarters

The WHO headquarters is in Geneva, operated by 1800 staff members. It contains different departments consisting of teams designed to work for specific projects/programmes. Each department has a director responsible for its functioning and reporting it to the higher authorities. The organization is headed by the director general, who is appointed by the HA on the nomination of the executive board.

WHO: Regional Offices

The WHO has six regional offices, namely, the African region, region of the Americas, the Southeast Asia region, the European region, the Eastern Mediterranean region, and the western Pacific region. It should be noted that the region of the Americas is embodied in the Pan American Health Organization (PAHO), which had been established 46 year before the founding of the WHO. All the regional offices are individual functional units with committees constituting the delegates from health ministries of that region's member states. The committee has a regional director that is selected every 5 years. It holds a meeting annually where the agenda for the coming year is decided upon and progress reports regarding earlier agendas are assessed. To ensure maximum coordination and transparency between the regional office and its member states, each state has a WHO representative. The WHO receives such huge amount of statistics, concerning old and new diseases, outbreaks, health indicators, preventive measures and their efficiency, nutrition, etc., from the regional offices.

WHO: Structure and Governance

The supreme governance of the WHO resides in the WHA, which is responsible for ratifying decisions. It generally meets every year in the month of May in Geneva and is attended by delegations from all 194 member states. Its main function is to determine the policies of the organization. The HA appoints the director general and also supervises the financial policies and reviews and approves the budget of organization. It similarly considers reports of the executive board, which instructs it in regard to matters upon which further action, study, investigation, or report may be required.

WHO: Executive Board

Executive board is composed of 34 individuals designated by a member state that the WHO elects. The elected board members are technically qualified in the field of health and are elected for a term of 3 years. Board meets at least twice a year, in January and May. The first meeting agrees upon the agenda for the forthcoming HA and second meeting immediately after the HA, for more administrative approvals. The main functions are to give effect to the decisions and policies of the HA, to advise it, and generally to facilitate its work. The board elects for itself a chairman, four vice-chairmen, and one rapporteur from among its members each year at its first session after the HA. The election follows a principle of rotation among geographic regions. The chairman of the board is not eligible for reelection for the next 2 years. During his course of work, the chairman is responsible for the declaration of the opening and closing of each meeting of the board, directing discussions, putting forth questions, according the right to speak, and ensuring the application of rules.

WHO: Committees of the Board

The board has the power to establish committees as and when necessary for the study of, and reporting on, any item on its agenda. Standing committees are composed of members of the board or their alternates. All committees other than standing committees are open-ended, composed of all interested member states to serve a specific purpose and also under exceptional circumstances. The position of chairman and that of other officers rotate regularly between regions and, wherever applicable, between developed and developing countries and countries in transition within the regions. The board reviews from time to time the need to maintain any committee established under its authority. The director general usually reports the board on the technical, administrative, and financial implications of all the agenda items submitted to the board. Communication of any reports of sessions of the board, containing resolutions, recommendations, summary, and other formal decisions to all member states and associate members of the organization, is the responsibility of the director general. Decisions by the board on important questions shall be made by a two-thirds majority of the members present and voting.

WHO: Ad Hoc Open-Ended Intergovernmental Working Group

The WHA in May 2001 proposed that the executive board should conduct a review of its and other subsidiary bodies' working methods, so that efficiency, transparency, and improved participation by member states can be ensured. Thus, it was decided to establish an ad hoc open-ended intergovernmental working group to make recommendations to the executive board on its working methods. Such a group was

established in the 109th session of executive board and had its first meeting held on 16 January 2002. The objectives decided for the working group were the following:

(1) To ensure that they are effective, efficient, and transparent and that participation of member states in the proceedings of the board, including working groups and drafting committees, is improved. The working group will conduct a review of the working methods of the executive board and those of its subsidiary bodies and include the rules of procedure in light of the functions of the board and interaction between the board and other organs of the WHO.
(2) To make recommendations for improvement and to include relevant cost implications.
(3) To report on its work at every session of the board.
(4) To prepare draft provisions and other measures for implementing its recommendations and to submit them to the board for consideration.

WHO: The Secretariat

The Secretariat is composed of the director general, six regional directors, and technical and administrative staff based in headquarters and regional offices and in specific countries. All countries that are members of the UN may become members of the WHO by accepting its constitution. Other countries may be admitted as members when their application has been approved by a simple majority vote of the WHA. Territories that are not responsible for the conduct of their international relations may be admitted as associate members upon application made on their behalf by the member or other authorities responsible for their international relations.

The Tasks Entrusted to the WHO

The WHO is defined by its constitution as the directing and coordinating authority on international health work. It was constructed with the aim of reducing incidences of disease and death throughout the world. Since the beginning, its functions have been manifold, which include the following:

- International protection against communicable diseases and comparability of the causes of death and disease
- Emergency measures to assist governments, trusts, territories, etc.
- Standardization of biological and pharmaceutical products and diagnostic procedures
- Improved standards of medical teaching
- Public health administrative technique and hospital services
- Scientific research with international coordination
- Statistics pertaining to health
- Central information for counseling on health issues
- Collaboration with governmental health administration
- Cooperation between the WHO and other organizations

The top priorities enlisted in WHO's agenda during its first assembly in June 1948 were malaria, women's and children's health, tuberculosis, venereal diseases, nutrition, and environmental sanitation. The WHO has come a long way since then in terms of both manpower and the vastness of issues it encompasses under its umbrella. The WHO covers health problems that were not even known in 1948, including relatively new communicable diseases such as HIV/AIDS, Ebola, malaria, and tuberculosis. It also is responsible for the mitigation of the effects of noncommunicable diseases; sexual and reproductive health, development, and aging; nutrition, food security, and healthy eating; occupational health; substance abuse; and driving the development of reporting, publications, and networking. The major functions of the WHO are enlisted in the succeeding text:

- To provide leadership on matters critical to health and engage in collaboration in joint ventures
- To shape the research agenda and stimulate the generation, translation, and dissemination of valuable knowledge
- To set norms and standards and to promote and monitor their implementation
- To articulate ethical and evidence-based policy options
- To provide technical support, catalyze change, and build sustainable institutional capacity
- To monitor the health situation and assess health trends

The general programme contains the earlier mentioned elements as the core functions, which provides framework of work, budget, resources, and results.

The WHO is striving ceaselessly to accomplish the tasks it is accountable for through a varied range of outputs available for monitoring and maintaining the global health situations mentioned in the succeeding text:

- An access to WHO projects, initiatives, activities, information products, and contacts related to various health topics
- Exhaustive data files on various communicable and noncommunicable diseases, injuries, health systems, and various millennium development goals (MDGs)
- Maintaining a media center that updates itself on recent disease outbreaks, prevention methods, statistics, factsheets, situation assessments, crises, and emergencies all round the world
- Publishing annual World Health Reports, World Health Statistics, and various journals concerning sanitary, disease, and nutrition topics
- Country-wise data on health profile, mortality and burden of disease, nutrition and child malnutrition data, and strategy briefs on collaboration of the country with the WHO
- Recommendations that can impact upon health policies or clinical interventions

WHO's Work

The work like its structure is also decentralized to six regional offices in Cairo, Copenhagen, Brazzaville, New Delhi, Manila, and Washington. Each regional office has a regional director who is responsible to the director general and the regional committee for carrying out the various programmes of the organization. To these regional offices, the governments bring their requests for assistance, in the form of surveys, and support for eradication programmes, seeking advices on national health planning, trainings, or fellowships for training. The requests are analyzed and approved based on their priority and value and then included in headquarters' programme and budget. Since

its inception, the WHO has worked for the prevention and curing of various diseases and health conditions, such as chickenpox, yellow fever, typhoid, and river blindness, and achieved success in partial control or total eradication of many such global health issues. The efforts taken by the WHO have given significant results; few landmark achievements of WHO campaigns are given in the succeeding text:

Landmark achievements of the WHO or with WHO support

1948: The WHO took over the responsibility for the International Classification of Disease (ICD), which dates back to the 1850s and was first known as the International List of Causes of Death. The ICD is used to classify diseases and other health conditions and has become the international standard used for clinical and epidemiological purposes.

1952–64: Dr. Jonas Salk (the United States) develops the first successful polio vaccine. One of the first diseases to claim WHO's attention was yaws, a crippling and disfiguring disease that afflicted some 50 million people in 1950. The global yaws control programme, fully operational between 1952 and 1964, used long-acting penicillin to treat yaws with one single injection.

1967: South African surgeon, Christiaan Barnard, conducts the first heart transplant.

1970: Apart from disease control, the WHO has also worked in the area of family planning for which it launched its Expanded Programme of Research, Development and Research Training in Human Reproduction, which was to focus on fertility regulation and birth-control methods.

1974: Beginning in this year, the WHO worked for 30 years to eliminate onchocerciasis (also known as 'river blindness') from West Africa. More than 600 000 cases of blindness have been prevented and 18 million children spared from the disease. Thousands of farmers have been able to reclaim 25 million hectares of fertile river land that had been abandoned because of the risk of infection. The WHA adopts a resolution to create the Expanded Programme on Immunization (EPI) to bring basic vaccines to all the world's children and immediately launches its EPI, aiming the vaccination of children worldwide against diphtheria, pertussis, tetanus, measles, poliomyelitis, and tuberculosis. This goal has now been transferred to Global Alliance for vaccines and immunization.

1977: The first essential medicine list appeared in 1977, 2 years after the WHA introduced the concepts of 'essential drugs' and 'national drug policy.' 156 countries today have a national list of essential medicines.

1978: The International Conference on Primary Health Care, in Alma-Ata, Kazakhstan, sets the historic goal of 'Health for All' – to which the WHO continues to aspire. The WHO adopted the Declaration of Alma-Ata, calling on all governments to make high-quality primary health care an essential feature of their national health systems.

1980: The most prominent and celebrated achievement of the WHO has been the eradication of smallpox as a result of an aggressive campaign. The last natural case of infection by smallpox occurred in 1977, and the declaration of world being smallpox-free by Global Commission for Certification of Smallpox Eradication came in 1980.

1983: Institut Pasteur (France) identifies the human immunodeficiency virus (HIV), the etiologic pathogen for the acquired immunodeficiency syndrome (AIDS).

1988: Global Polio Eradication Initiative is established. Since its launch in 1988, the Global Polio Eradication Initiative has reduced the number of cases of polio by more than 99% – from more than 350 000 per year to 1956 in 2006. Spearheaded by the national governments, WHO, Rotary International, US Centers for Disease Control and Prevention, and UNICEF, it has immunized more than two billion children thanks to the mobilization of more than 20 million volunteers and health workers. As a result, five million children are today walking, who would otherwise have been paralyzed, and more than 1.5 million childhood deaths have been averted. Next is the control of polio disease, confining it to Africa and South Asia only. The campaign started in 1988 and the declaration of America being polio-free came in 1994, Western pacific region in 2000, Europe in 2002, and India in 2013.

1990: The WHO launched various programmes against lifestyle diseases such as cancer, cardiovascular disease, and diabetes and promoted healthy and tobacco-free living.

2003: Severe acute respiratory syndrome (SARS) first recognized and the initial outbreak was controlled.

2004: The Global Strategy on Diet, Physical Activity and Health was adopted.

2005–07: The WHA revises the International Health Regulations (IHR). The IHR came into force. This legally binding instrument is the primary means of protecting the world from new and reemerging diseases, microbial shocks, and other threats to public health and global health security. Countries are obligated, by 2016, to establish a series of functions to ensure that they can detect, verify, assess, and respond to public health threats. The core capacities needed to fulfill these functions include national legislation, policy, and financing; coordination and communication through a national focal point; surveillance; response; preparedness; risk communication; human resources; and laboratories. For many countries, implementing all of the IHR's provisions is a challenge. In 2007, the WHO organized work on pandemic influenza vaccine development through c9: initial trials in collaboration with many experts.

2009: A pandemic involving the H1N1 influenza virus was declared in April 2009. A number of vaccines were approved for use 3 months after the pandemic declaration. This response was only possible because of the extensive preparations undertaken in during the last decade.

MDGs of the WHO

The UN MDGs include eight goals that were signed in the UN Millennium Declaration on September 2000 by all 191 UN member states, as goals to be achieved by 2015. The MDGs are interdependent and influence health, and health influences all the MDGs. Each MDG has targets set for 2015 and indicators to monitor progress from 1990 levels. The eight MDGs are summarized as follows, along with comments on the progress toward each:

Note: The registry of the goals is missing.

MDG1: To Eradicate Extreme Poverty and Hunger

The indicator for undernutrition is the proportion of underweight children under the age of 5 in region as undernutrition

includes fetal growth restriction, stunting, wasting, and deficiencies of vitamin A and zinc, along with suboptimal breastfeeding. Undernutrition in children is responsible for about 45% of all deaths under 5 years of age. In developing countries, between 1990 and 2012, a remarkable decline was observed in underweight children from 25% to 15%, which was close to the rate required to meet the MDG target, though being uneven across regions.

MDG2: To Achieve Universal Primary Education

The goal was to ensure that all children, boys and girls alike, can complete a full course of primary schooling. The efforts have encouraged an enrolment of 43 million children worldwide between 1999 and 2009, and the rate of enrolment in sub-Saharan African has increased from 58% to 76%. Some of the challenges before the WHO are that there are still 61 million children left to be enrolled in schooling, and the youth illiteracy rate exceeds more than 120 million people worldwide.

MDG3: To Promote Gender Equality and Empower Women

The MDG 3 indicators track key elements of women's social, economic, and political participation and guide the building of gender-equitable societies. Empowerment of women, including ensuring access to health information and control of resources such as money, is important for achieving gender equality and health equity. However, the ratio of female-to-male earned income is well below parity in all countries for which data are available. Up to one in three women worldwide will experience violence at some point in her life, which can lead to unwanted pregnancy and abortion, among other things. In partnership with member states and others, it will further empower the women, support the prevention of and response to gender-based violence, promote women's participation and leadership, define ways in which men can be engaged to promote gender equality and to contribute more to their own health and that of their families and communities, build the capacity of the WHO and its member states to identify gender equality-related gaps, and provide support for gender-responsive policies and programmes.

MDG4: To Reduce Child Mortality

Across the globe, the progress in this goal was significant with the reduction being 47% (6.6 million) deaths of children under 5 years as compared to 12.6 million in 1990 and the global reduction being 3.9% during 2005–12. But still, the world is unlikely to achieve the MDG target of a two-third reduction in 1990 mortality levels by the year 2015. It has been achieved through increase in levels of immunization coverage, with 66% member states reaching 90% coverage.

MDG5: To Improve Maternal Health

Maternal deaths were significantly reduced to 289 000 in 2013 from an estimated 523 000 in 1990, but this reduction was not able to achieve the target set by MDG, which was only less than half of a three-quarter reduction in the mortality ratio between 1990 and 2015. In three of the six WHO regions, births attended by skilled personnel, which is crucial for reducing perinatal, neonatal, and maternal deaths, were above 90%. In African region, the coverage for improving maternal health needs to be increased as its remains $<50\%$.

MDG6: To Combat HIV/AIDS, Malaria, and Other Diseases

In case of newly HIV-infected people in 2012, as compared to 2001, an estimated reduction of 33% was reported. Scaling-up malaria interventions during the 2000–12 period helped to save about 3.3 million lives worldwide, and mortality rates of population at risk and due to malaria have fallen to about 42% and 29%, respectively. It was observed among neglected tropical diseases (NTDs) that in about 119 countries in which leprosy was endemic and was a great concern for public health, it was totally eradicated. In case of dracunculiasis (a crippling parasitic disease), an incidence of only 148 was reported in 2013. In 2011, worldwide, about 728 million people were treated for at least one NTD through chemotherapy. But still, neglected diseases, which are caused by a variety of pathogens including viruses, bacteria, protozoa, and helminths, affect more than one billion people.

MDG7: To Ensure Environmental Sustainability

As compared to 76% in 1990, the target for access to safe-drinking water has been met by 90% of the world's population using an improved source of drinking water. But the rate of progress regarding basic sanitation is slow, as depicted in the data stating nonaccessibility to improved sanitation facilities to about 2.5 billion people worldwide.

MDG8: To Establish a Global Partnership for Development

Prices of medicines are higher in private sector as compared to public sector, but worldwide, large groups of people are forced to purchase through the private sector due to scarcity of medicines. Per the data of a survey conducted in 2007–12, availability of generic medicines in the public sector was only 57%, in low- and middle-income countries. Some generic medicines have higher costs than comparable prices in the international reference. For some generic preparations, the lowest price in private sector averages from 5 up to 16 times higher than references (public sector) prices.

In developing countries, even treating common disease may be beyond the reach of the low-income households, while the patients suffering from chronic diseases always end up paying the greatest price for generic medicines. Treating global chronic disease remains a great challenge, and the burden to treat them is increasing, as in most of the countries treating chronic disease still remain out of reach.

WHO: Food Safety and Security

Freedom from hunger and malnutrition is among the fundamental rights of every human being. There can be no sound social and economic development without adequate food and nutrition. This is not the same as saying that people in rich

countries necessarily have a better chance of being properly nourished than do people in poor countries. To meet the continuously growing food demand, food production in case of either agricultural or animal/livestock products is intensified or industrialized throughout the world. Food safety has become a great concern and is presenting new opportunities and challenges for food technologists. Food safety is also affected by climatic changes including temperature that can render the food unsafe for human consumption by increasing the risks associated with food production, storage, and distribution. It is estimated that about two million casualties take place every year only from foodborne and waterborne diarrheal disease in which most of them are children.

In general, the WHO is working in multiple areas to ensure safe and ample food supply globally by adopting various measures such as aiding in detection and management of foodborne diseases by generating data on diseases, supporting implementation of infrastructure, promoting safe food handling, educating food handlers and consumers on hygiene, and controlling microbiological risks by providing guidelines on risk assessment, management, and communication of chemical hazards. The WHO also defines the critical exposure levels to chemical hazards to ensure the safety of the public, which forms the base for drafting and setting the national and international food safety standards; it serves two causes, that is, to protect the consumers and also help in implementing fair-trade practices. It also has set limits for usage of antimicrobials in foods to avoid overexposure of drugs in consumers. The WHO also strives continuously in collaboration with Food and Agriculture Organization (FAO) for advancement of food technology and safety, and then, the WHO provides scientific advice on the assessments of food and food products that have been produced by using technological advancements such as genetic modification and nanotechnology to its member states.

With the advancement of food technology and modern manufacturing techniques, chances of contaminations rendering the food unsafe have also increased; in order to cater the needs related to food safety, the WHO has established International Food Safety Authorities Network (INFOSAN), with whom it helps to manage food safety risks to its member states and ensures that the information pertaining to food safety is shred throughout them. During food safety emergencies, INFOSAN along with the WHO helps to identify and stop the supply of contaminated food from one country to another among its member states. Recently, in August 2014, decisions were taken for linking the activities of INFOSAN with other food safety programs in the region and must also be bridged with the IHR (2005). It states that food safety and nutrition are inextricably linked, particularly in places where food supplies are insecure. It is observed that with rise in food scarcity, the chances of manufactures to ignore hygiene, safety, and nutrition increase. Less availability of good food makes people shift to less nutritious diets and consume more unsafe food, and to overcome this problem, the WHO has the Department of Nutrition for Health and Development, which has set global targets 2025 for improving maternal, infant, and young child nutrition. The targets include the Healthy Growth Project, aiming at a 40% reduction in the number of children under age of 5 years who are stunted, and the Iron Deficiency Anemia Project, targeting a 50% reduction of anemia in women of reproductive age. Other goals across the agenda include care of the preterm/low-birth-weight infants: reducing low birth weight by 30%, increasing the rate of exclusive breastfeeding in the first 6 months up to at least 50%, and reducing and maintaining childhood wasting to $<5\%$.

WHO: Ebola Virus

Ebola virus disease is a severe, often fatal illness, with a death rate of up to 90%. Ebola affects humans and nonhuman primates (monkeys, gorillas, and chimpanzees). In humans, infection of Ebola generally occurs from direct contact through broken skin or mucous membranes with the blood or other bodily fluids or secretions (stool, urine, saliva, and semen) of infected people. Infection can also occur if breaks in the skin or mucous membranes of a healthy person come into contact with environments that have become contaminated with an Ebola patient's infectious body fluids such as soiled clothing, bed linen, or used needles. In the current outbreak in West Africa in March 2014, the majority of cases in humans have occurred as a result of human-to-human transmission. In August 2014, the WHO declared an epidemic as the world health emergency.

The UN Mission for Ebola Emergency Response (UNMER) has set the goals of '70–60.' This corresponds to the aim to isolate and treat 70% of cases suffering from Ebola and to safely bury 70% of the deceased, and all these activities will be completed in 60 days from the beginning of October 2014. The WHO is continuously supporting this cause by working in various Ebola-affected countries like Sierra Leone, Liberia, and Guinea by training burial teams in protecting themselves while caring patients; in contact tracing, social mobilization, and case management; and in conducting safe and dignified burials. As of 24 November 2014, the WHO had received US $162 million, with a further $35 million pledged.

The WHO aspires to give in-clinic training to 40 national and international personnel per week over two training sessions, after already training 100 participants in the hot zone (phase 3) in Guinea. In Sierra Leone also, the WHO along with the UK government has trained 4115 health-care workers, hygienists, and trainers in basic personal protective equipment, infection prevention and control, and site layout and plans to other treatment centers in other areas. It is also running community-based programmes in enabling them to recognize symptoms of Ebola early and move their family members to care so they do not infect other family members or their society. In August 2014, the WHO released a roadmap on Ebola to scale up response to the outbreak and stop transmission in affected countries within 6–9 months, prevent international spread, and assist governments and partners in the revision and resourcing of country-specific operational plans for Ebola response and the coordinating international support for their full implementation.

The WHO is also been providing regular epidemiological support on Ebola, such as data situation reports and an assessment of the response measured against the core indicators, wherever available. Updates about the Ebola are generally provided to the countries, which have been reported with widespread and intense transmission of Ebola. The nations

are classified as those with or that have had an initial case or cases or with localized transmission and those countries that neighbor or have strong trade ties with areas of active transmission.

The WHO has also developed a consolidated Ebola virus disease preparedness checklist to ensure countries are ready to respond in cases of outbreak. They are provided with checklist, simulation exercises, and methods to test their level of readiness. The WHO, the UN, and other partners are accelerating the deployment of international preparedness strengthening teams to help countries build upon their existing work and planning. At the end of each mission, technical experts remain in country to support and maximize capacity-building efforts to prepare for public health emergencies, including EVD.

Yeasts

R Tofalo and G Suzzi, University of Teramo, Mosciano Sant'Angelo (TE), Italy

© 2016 Elsevier Ltd. All rights reserved.

General Consideration and Taxonomy

The association of yeasts with human society was probably initiated many thousands of years ago. Evidence for the production of fermented beverages by yeasts, mostly *Saccharomyces cerevisiae*, dates back as far as 7000 BC, which is documented by several archaeological sites in China, Iran, and Egypt. Ancient humans unwittingly utilized yeasts to produce either alcohol-containing beverages or carbon dioxide for leavening. These practices and their associated yeasts spread throughout the world, inducing a particular selection, that is, 'domestication,' in particular for some foods such as bread, beer, and wine. However, the deliberate addition and commercial use of yeasts started only at the end of the nineteenth century after isolation and identification by Pasteur. Today, many species of yeasts contribute to the production of a myriad of commodities other than bread, beer, and beverages. Food-grade yeasts are now used as sources of high-nutritional-value proteins, enzymes, and vitamins, and processing aids are derived from them. With respect to foods and health foods, yeasts are utilized as nutritional supplement, food additives, conditioners, and flavoring agents and as starter cultures for producing specific foods or for their probiotic activity. Antifungal activity is exhibited by some yeasts that can be considered as biocontrol agents of food spoilage. Unfortunately, there are some drawbacks to yeast activity too, because some can cause spoilage of many commodities and may lead to pathogenic infections in immunocompromised persons or lead to allergic reactions. Table 1 reports the main roles of yeasts in food production and in the health of consumers.

The name yeast derives from the German word 'gift,' which describes the foam formed during beer fermentation. Yeast can be also described using the French word 'levure,' which indicates the role of yeasts inducing bread dough to rise. Yeasts are eukaryotic microorganisms whose vegetative growth results predominantly from budding or fission and that do not form their sexual states within or upon a fruiting body. Yeasts have two valid names: the first referring to the sexual state (teleomorph) and the second one to the asexual state (anamorph). The rules of yeast taxonomy are established in the 'International Code of Nomenclature for algae, fungi, and plants,' which was adopted at the 18 as apex International Botanical Congress in Melbourne, Australia. The 5 as apex edition of 'The Yeasts: A Taxonomic Study' in 2011 describes 1500 yeast species; but this number is increasing. The difference between the number of described species and that of new species is due to the fact that some ecological niches are far from being completely investigated and to the presence of cryptic species, which still have not been carefully characterized. Yeast taxonomy is based on biochemistry and molecular biology and is rapidly evolving. Criteria for differentiating genera have focussed on spore and cell morphology, type of conidiogenesis, life cycles, biochemical features, type of coenzyme Q, and G+C content. However, DNA hybridization or reassociation contributes to the establishment of relationships among yeast species. Two species are considered conspecific if they share more than 70% of DNA sequence homology, but this method does not allow assessing phylogenetic relationships between yeasts. Recently, the application of rapid, easy, and reliable molecular techniques allowed describing new phylogenetic relationships. As a result, the number of separate species groups was reduced and the diversity within them was increased. The most diffused molecular methods used in the identification of yeast species are based on the variability of the ribosomal genes 5.8S, 18S, and 26S because they show a low intraspecific polymorphism and a high interspecific variability. The first marker used for separation of the hemiascomycetes from the filamentous ascomycetes was the 18S rRNA gene. Subsequently, the D1/D2 variable region of the 26S rRNA (600 bp) has been adopted to differentiate basidiomycetes, hemiascomycetes, and filamentous euascomycetes. The availability of whole-genome sequences of yeasts revolutionized the taxonomy leading to the description of new markers for yeast phylogeny. Traditionally, the main genera can be divided into two groups: ascomycetes and basidiomycetes. However, budding and fission ascomycetes can now also be differentiated from each other and from euascomycetes by molecular methods, with the only exception of genus *Eramascus* (which does not form budding cells). A similar approach is applied to separate basidiomycetes from mushrooms and from taxa forming fruiting bodies.

The Yeast Cell and Its Organelles

Yeast cells possess ultrastructural features typical of other eukaryotic cells, with the presence of membrane-bound organelles (Figure 1). Often, the words 'yeast' and '*S. cerevisiae*' are used as synonyms. Saccharomyces means 'sugar fungus' in Greek. Yeast cells exhibit a great diversity with respect to cell

Table 1 Main activities of yeasts in food production and in the human health

Activity	*Yeast species*	*Effect*
Food and beverage fermentation	*Candida milleri*, *Debaryomyces hansenii*, *Galactomyces candidus*, *Hanseniaspora uvarum*, *Kluyveromyces marxianus*, *K. lactis*, *Schizosaccharomyces pombe*, *S. cerevisiae*, *Kazachstania exigua*, *Torulaspora delbrueckii*, *Zygosaccharomyces rouxii*, *Yarrowia lipolytica*	Fermentation, flavor and color development, rheology
Food additive production	*Lindnera jadinii*, *K. marxianus*, *S. cerevisiae*, *Y. lipolytica*, *Rhodotorula glutinis*, *Sporidiobolus salmonicolor*	Release of B vitamins, proteins, peptides, amino acids, minerals, antioxidants, aromas, colorants, glutamic acids, nucleotides, vanillin, citronellol, linalool, geraniol, decalactones, β-glucans
Probiotic	*Saccharomyces cerevisiae* var. *boulardii*	Effect on enteric bacterial pathogen, maintenance of epithelial barrier Integrity, anti-inflammatory effects, effects on immune response, trophic effects on intestinal mucosa, clinical effects on diarrheal diseases
Food spoilage	*Brettanomyces bruxellensis*, *Pichia kudriavzevii*, *C. parapsilosis*, *D. hansenii*, *H. uvarum*, *Pichia membranaefaciens*, *Rhodotorula mucilaginosa*, *Rhodosporidium toruloides*, *S. cerevisiae*, *S. pombe*, *Kazachstania exigua*, *Zygosaccharomyces bailii*, *Z. bisporus*, *and Z. rouxii*	Blown cans of soft drinks, cloudy refermented wine, pink or red slime dripping from refrigerated meat, white yeast colonies on food, tainted fruit juices, off-odors, and off-tastes
Allergenic	Different yeast species	Food intolerance, migraines, respiratory problems, chronic fatigue syndrome, dysfunctional gut syndrome, irritable bowel syndrome
Pathogenic	*Candida* spp., *Filobasidiella neoformans*, *P. kudriavzevii*, *W. anomalus*, *K. marxianus*, *S. cerevisiae*, and *Rhodotorula* spp.	Mucocutaneous, cutaneous, respiratory, central nervous, systemic, and organ infections

Nomenclature is in agreement with the yeasts: a taxonomic study (5 as apex edition).

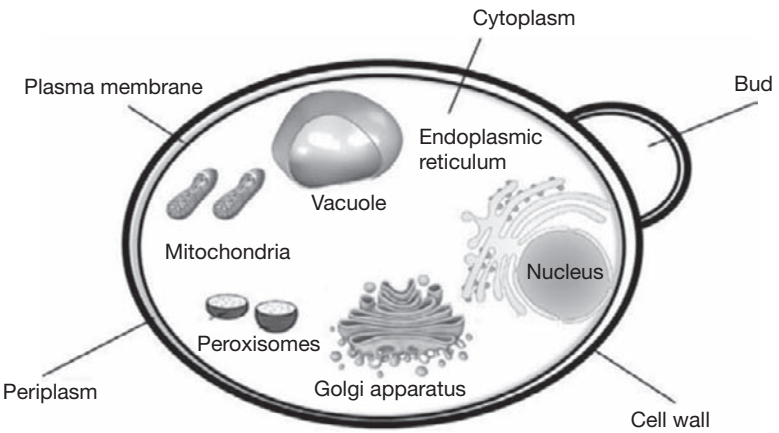

Figure 1 Yeast cell and its main organelles.

size, shape, and color. Cell size may be 2–3 μm in length up to 20–50 μm with a diameter of 1–10 μm. The yeast cell wall is a rigid structure about 100–200 nm thick and constituting about 25% of the total dry mass of the cell. The macromolecules that compose the wall are highly glycosylated glycoproteins (mannoproteins), two types of β-glucans, and chitin. The overall composition can vary considerably in relation with the growth conditions. The surface plasma membrane of yeast is a lipid bilayer, which harbors proteins serving as a cytoskeleton and enzymes for cell wall synthesis, signal transduction, and transport. The lipid components comprise mainly phospholipids and sterols (principally ergosterol and zymosterol). The periplasmic space is a region external to the plasma membrane (35–45 Å) that contains proteins unable to permeate the cell wall, such as invertase and phosphatase.

The yeast cytoplasm is an aqueous, slightly acidic colloidal fluid that contains proteins, glycogen, other soluble macromolecules and larger macromolecular entities such as ribosomes, proteasomes, and lipid particles. Many essential functions for cellular integrity are localized in the cytoplasm. The cytoskeleton of yeast cells comprises microtubules and microfilaments. In the center of the cell or slightly excentrically, the nuclear structure is located, which is surrounded by a double membrane that separates the nucleoplasm from the cytoplasm. The outer nuclear membrane is contiguous with the membrane of the endoplasmic reticulum.

The nucleolus within the nucleus is the specialized subnuclear compartment for ribosome synthesis. The nuclear chromosomes are in the nucleoplasm and packed into a chromatin structure; the genome sizes of yeasts are relatively constant and generally range from 10 to 15 Mb, whereas the number and sizes of the single chromosomes vary among species. Yeast cell contains different organelles surrounded by individual membranes, mostly the endoplasmic reticulum, the Golgi apparatus, and transport vesicles that are necessary for the manufacturing and trafficking of proteins, vacuoles, mitochondria, and microbodies. Structurally, the endoplasmic reticulum is a complex network of membranes, part of which is connected to the nucleus. The endoplasmic reticulum membrane forms a continuous sheet enclosing a single internal space called the endoplasmic reticulum lumen, separating it from the cytosol. It is involved in the selective transfer of secretory proteins between the endoplasmic reticulum and the Golgi apparatus. It also plays a key role in lipid and protein biosynthesis; in fact, it is the site of production of the transmembrane proteins and lipids for most of the cell's organelles (e.g., the endoplasmic reticulum itself, the Golgi apparatus, lysosomes, and endosomes). The Golgi apparatus is composed of stapled stacks of membranes called *cisternae*. Transport vesicles, received from the endoplasmic reticulum, are further processed and sorted for transport, for instance, releasing secretory proteins in the growth medium. Vacuoles are organelles involved in intracellular protein trafficking, receiving proteins from differing routes. In the vacuoles, there are degradative processes catalyzed by different hydrolases, such as phosphatases, phospholipases, lipases, nucleases, endopeptidases, aminopeptidases, and carboxypeptidases. Vacuoles also are involved in other physiological functions, such as the storage of amino acids, polyphosphates, and some metal cations (K^+, Mg^{2+}, and Ca^{2+}). Yeast mitochondria resemble the organelles found in higher eukaryotes, surrounded by an outer membrane and an inner membrane, the two of which embody an intermediate space that contains the mitochondrial matrix. If sufficient oxygen and carbon sources are supplied, few and large mitochondria carry out respiration and synthesis of ATP, whereas under anaerobic conditions, they reduce their size and activity. Other functions are the synthesis and desaturation of fatty acids, biosynthesis of ergosterol, adaptation to stress, mobilization of glycogen, and synthesis of enzymes. Microbodies (peroxisomes and glyoxysomes) consist of a proteinaceous matrix, surrounded by a single membrane that is involved in the primary metabolism of various carbon and organic nitrogen sources, such as ethanol, methanol, primary amines, *n*-alkanes, and fatty acids (oleic acid).

Metabolism

Yeasts are heterotrophic organisms in which the energy and carbon metabolism are interconnected and anabolism is coupled to catabolism. Yeasts preferentially metabolize sugars that are converted principally to ethanol and carbon dioxide, but they can utilize different carbon sources, such as amino and organic acids, polyols, alcohols, fatty acids, and other compounds, depending on the species. According to the process utilized to generate energy (respiration and/or fermentation), they can be classified as:

- nonfermentative yeasts with only a respiratory metabolism;
- obligate-fermentative yeasts, only capable of metabolizing glucose through alcoholic fermentation;
- facultative-fermentative yeasts, possessing either a fully respiratory or a fermentative metabolism or even both in a mixed metabolism depending on the growth conditions, the type and concentration of the carbon source, and/or oxygen availability.

The main nitrogen substrates used by yeasts during growth in food are inorganic ammonium compounds and free amino acids. Decarboxylation of amino acids leads to the production of amines, whereas metabolism of arginine and citrulline gives urea, precursor of the potential carcinogen ethyl carbamate. Whereas yeasts produce organic acids, with succinic and acetic acids being the main acids produced during sugar fermentation, some yeast species can use acetic and lactic acids and weak monocarboxylic acids under starvation conditions. Consumption of organic acids by yeasts may thus create conditions favorable for certain spoilage microorganisms. In cheese, lactate catabolism by some species such as *Debaryomyces hansenii*, *Kluyveromyces lactis*, and *Kluyveromyces marxianus* induces an increase of pH at the cheese surface, having a key role during ripening.

Sulfates are utilized to produce volatile sulfur compounds such as hydrogen sulfide, sulfur dioxide, and at lesser amounts mercaptans, thioesters, and other organic sulfites. Yeasts also show proteolytic and lipolytic activities depending on the species and strain.

Yeasts in Fermented Food and Beverages

Yeasts are undoubtedly one of the most important groups of microorganisms that are exploited for the elaboration of fermented foods. Fermentation is one of the oldest and most economical methods of producing and preserving food, providing also a natural way to reduce the volume of the material to be transported, to destroy undesirable components, to enhance the nutritive value and appearance of the food, to reduce the energy required for cooking, and to make a safer product. In these processes, mixed cultures of yeasts, bacteria, and fungi are active, participating either in parallel or in a sequential manner with a changing dominant microbiota during the course of the fermentation. Some yeast species are included in starter cultures for the production of specific types of fermented foods like cheese, bread, sourdoughs, fermented meats, and fermented vegetable products. Common fermenting yeasts, often selected as starter cultures, belong to the *Saccharomyces* genus, which results in alcoholic fermentation.

Yeasts in Dairy Products

Yeasts play an important role in flavor and texture development during the production of fermented milks, such as kefir and koumiss, and the ripening of cheese. They are used as secondary starter cultures to enhance the aroma or improve

the growth of lactic acid bacteria or brevibacteria. The most important and dominant species, besides *S. cerevisiae*, are *D. hansenii*, *Yarrowia lipolytica*, *K. marxianus*, and *Galactomyces candidus*.

Yeasts in Fermented Meat Products

Studies on the presence and role of yeasts in fermented meat product are limited. The high salt concentration and the low water activity that are typical of fermented sausages favor the growth of *Debaryomyces* species, mostly *D. hansenii*, *Y. lipolytica*, and various *Candida* species, contributing to the development of color (by removing the oxygen) and flavor (by degrading peroxides and via lipolytic and proteolytic activities). Hydrolytic and oxidative changes carried out by yeasts during ripening produce the distinctive flavors of these products.

Fermentation of Cereal Products

Cereals, as a global staple food, are often fermented to improve shelf life and nutritional properties in comparison with the raw material. Fermented cereal products are produced from different cereal substrates and a number of them consist of a combination with legumes, thus improving the overall protein quality of the fermented product. Fermentation improves the nutritional value, sensory properties, and functional qualities. Besides the global importance of (sourdough) bread, a wide variety of different products come from Africa and Asia, as is the case for koko, banku, panjabi waries, papadams, jalebis, idli, dosa, dhokla, kishk, tarhana, ogi, kenkey, pozol, injera, and kisra. The microbiota responsible for the fermentation is in many cases indigenous and includes lactic acid bacteria, yeasts, and fungi. *Saccharomyces cerevisiae* strains are often found in the fermentation of various cereal products. Other yeast species frequently detected are *Kazachstania exigua*, *Candida milleri*, *Torulaspora delbrueckii*, and *Pichia* spp. The yeast species diversity in fermented cereal products, as well as their numbers, is affected by the degree of tolerance to the organic acids produced by the lactic acid bacteria.

Fermented Beverages

As regards the fermented beverages produced by musts obtained from fruits (grape, cider, mixed tropical fruits, etc.), the natural fermentation is started by some non-*Saccharomyces* yeasts, such as species of *Hanseniaspora uvarum*, *Candida stellata*, *Wickerhamomyces anomalus*, *Metschnikowia pulcherrima*, and other yeasts. After 1 or 2 days, species of *Saccharomyces*, in particular *S. cerevisiae*, develop and dominate fermentation by forming high amounts of ethanol. During fermentation, many compounds are produced or metabolized by yeasts contributing to the aroma of beverages. However, during must fermentation, yeasts can produce off-flavors too, as is the case for *Brettanomyces*/*Dekkera* species that are reported to be involved in wine spoilage. Nowadays, selected starter cultures of *S. cerevisiae* are generally used to carry out must fermentation. In beer fermentation, two types of *Saccharomyces* yeasts are involved, that is, ale yeasts (top-fermenting yeasts, *S. cerevisiae*) and lager yeasts (bottom-fermenting yeasts, *S. pastorianus* (synonym *S. carlsbergensis*)). More than a thousand single different starter cultures of brewing yeasts have been described, varying in their technological properties, such as aroma production, rate and degree of attenuation, flocculation, oxygen requirement, and reproduction.

Cash Crops

Cocoa beans and coffee beans must undergo processes that involve the action of yeasts of various species of *Saccharomyces*, *Hanseniaspora*, *Kluyveromyces*, *Saccharomycopsis*, *Candida*, and *Pichia*. Cocoa beans have to be fermented to drain the pulp, stabilize the beans, and generate precursors for chocolate flavor, whereas coffee beans are mostly fermented to remove the pulp and the mucilaginous materials from the seeds.

Yeast for Health

Yeast as Probiotics and Nutraceuticals

The World Health Organization officially defined probiotics as "live microorganisms which, when administered in adequate amounts, confer a health benefit on the host." Most probiotic microorganisms are bacteria, usually including selected strains of certain genera of *Lactobacillus* spp. or *Bifidobacterium* spp. In recent years, the interest in using yeasts as probiotics increased, not only for human health but also to improve growth and health of animals and birds, in particular in aquaculture or with respect to industry cattle, pigs, and poultry.

Yeasts are able to face the stresses of the gastrointestinal tract, such as enzymes, bile salts, organic acids, and considerable variations of pH and temperature. The first species described as an effective biotherapeutic agent has been *S. cerevisiae* var. *boulardii*, isolated from lychee fruit in Indochina in the 1920s. This yeast is commonly used as a probiotic in different countries, as both a preventive agent and a therapeutic agent for diarrhea and other gastrointestinal disorders caused by the administration of antimicrobial agents. *S. boulardii* has many properties, such as survival transit capacity through the gastrointestinal tract, among other reasons because its temperature optimum is 37 °C, both *in vitro* and *in vivo*. Moreover, the species exerts inhibitory effects toward various enteric pathogens as its cell wall shows binding capacity to enterohemorrhagic *Escherichia coli* and *Salmonella enterica* serovar Typhimurium. Additionally, the yeast inhibits adherence of *Clostridium difficile*. Other probiotic beneficial effects on human health associated to the administration of *S. boulardii* include:

- maintenance of epithelial barrier integrity and permeability,
- restoration of the tight-junction structure,
- reduction of inflammation during bacterial infection by interference with host cell signaling pathways,
- stimulation of the host cell immunity in response to pathogenic infections,
- prevention of reaction to food antigens in particular when mucosal permeability is increased.

Other species, such as *D. hansenii*, *T. delbrueckii*, *K. lactis*, *K. marxianus*, and *Kazachstania lodderae*, have also shown tolerance to passage through the gastrointestinal tract and

inhibition of enteropathogens. Recently, many researchers have focussed on the antioxidant ability and cholesterol assimilation of yeasts. Some reports indicated that *S. cerevisiae*, *K. lactis*, and *Pichia kudriavzevii* can remove cholesterol *in vitro*.

Yeasts can also produce nutraceuticals useful for the development of functional foods and for the protection from cardiovascular disease. The most important compounds seem to be the β-glucans, which act as bioactive polysaccharides, and bioactive peptides that inhibit angiotensin I-converting enzyme activity, reducing peripheral blood pressure and exerting antihypertensive effects *in vivo*. Only some yeast species, that is, *K. marxianus* and *S. cerevisiae*, have been shown to produce these compounds in fermented milks such as koumiss and kefir. Recent studies also indicate that some foodborne yeasts (especially *D. hansenii* and *S. cerevisiae*) are able to reduce the potential genotoxic risk due to mutagenic and genotoxic compounds. A recent study indicated that *S. cerevisiae* and *D. hansenii* show inhibitory activity against two model genotoxins, 4-nitroquinoline-1-oxide and *N*-methyl-*N*′-nitro-*N*-nitrosoguanidine. The antigenotoxic activity is probably due to the formation of a complex between genotoxins and thermolabile soluble cellular oligosaccharides (i.e., mannans and glucans). Nevertheless, a similar complex may also occur between the genotoxins and other compounds derived from yeast metabolism such as polyamines, mainly spermidine and spermine or the glutathione system.

These healthy effects appear to be promising features for the use of well-characterized yeasts as natural protective agents. In addition, yeast cells are also good sources of vitamins (thiamine, pantothenic acid, riboflavin, biotin, folic acid, B_6, and B_{12}), ergosterol, and coenzyme Q.

Antioxidants

In the past, yeasts and yeast extracts were used as a source of antioxidant compounds to be added to prevent oxidation of food products. Now, natural antioxidants, presumed to be safer for human, can also be used in nutraceutical applications as supplements. Natural antioxidants act by donating hydrogen protons to substrates, rendering them nonreactive to reactive oxygen species. This involves enzymes such as catalases, superoxide dismutases, glutathione (L-γ-glutamyl-L-cysteinylglycine), and NADP-dependent dehydrogenases. Several compounds involved in antioxidant actions are produced by yeasts and can be used to retard oxidative degeneration of fatty substances in food and to improve health and well-being in nutraceutical supplements. They consist of torularhodin, coenzyme Q, glutathione, hydroxymethyl and hydroxyethyl furanone (2H), tocotrienol, α-tocopherols, and other forms of tocopherols, riboflavin (vitamin B_2), and derived flavins. Several oxygenated carotenoids, selenium-enriched yeast cells, the wine component resveratrol, octacosanol, cell wall β-glucans, proteins produced in yeasts under oxidative stress, sulfur-containing amino acids, and cytochrome C are present at the end of fermentation in the products and/or in the yeast biomass.

Single-Cell Proteins

The use of yeasts for single-cell protein (SCP) production is convenient, resulting in nutritional supplements for animal feeds and human foods. In fact, yeast SCP is considered as a potential source of proteins, carbohydrates, fats, vitamins, minerals, and essential amino acids. SCP for human consumption should be free from nucleic acid as purine bases are metabolized to uric acid, a problem for some humans that do not possess the enzyme uricase. SCP production has been obtained by yeasts cultivated in mixtures of sugars and minerals, such as molasses, starch, cassava, whey products, brewing by-products, potato and cellulosic wastes, or other waste streams from agricultural and industrial processes. The yeasts are washed, thermolyzed and dried, and usually spray-dried into a powder. The production of value-added SCP from inexpensive substrates could beneficially contribute to the food supply. Whereas for human applications, *S. cerevisiae* (baker's and brewer's yeast) is the currently the organism of choice, animal feeds rely on *Lindnera jadinii*.

β-Glucans

β-Glucans have several beneficial properties and have found a variety of uses in human and in veterinary medicine, immunopotentiation, pharmaceutical, cosmetic and chemical industries, and food and feed production. Yeast is a good source of β-glucans that are present in the cell walls as branch-on-branch molecules containing linear (1,3)-β-glucosyl chains joined through (1,6)-linkages. Spray-dried yeast β-glucans are useful for food production, as food thickeners, replacers, dietary fibers, emulsifiers, and films. Furthermore, yeast glucans have important properties as water-holding, fat-binding, and oil-binding characteristics, as well as gelling properties. For these reasons, they can also be used in the production of sausages and meat products, mayonnaise, and other food products, such as dressings, frozen desserts, sauces, yogurts, and other fermented milks and soft doughs. They are safe for oral application and have a GRAS (generally recognized as safe) status.

Allergenic or Pathogenic Yeasts

Viable populations of a diversity of yeast species present in fermented foods (dairy products, fermented and cured meats, fruits and fruit salads, table olives, and beer and wine) are unknowingly and inadvertently ingested. Unlike bacteria, viruses, and some filamentous fungi, yeasts are rarely associated with outbreaks of foodborne gastroenteritis or other foodborne infections or intoxications. However, an increase of yeast infections is reported, and some yeasts are now considered as opportunistic pathogens, such as *Candida albicans* and *Filobasidiella neoformans*, which can cause mucocutaneous, cutaneous, respiratory, central nervous, systemic, and organ infections. Moreover, other species that are frequently found in foods, such as *P. kudriavzevii*, *W. anomalus*, *K. marxianus*, *S. cerevisiae*, and various *Rhodotorula* species, can be potential pathogens. Even *S. cerevisiae*, intensively used in industrial processes, has been described as a pathogen in 1958. It displays low virulence against humans, but invasive *S. cerevisiae* infections have been increasingly common in recent decades, having been identified in blood cultures,

including those from immunocompetent subjects. Therefore, vigilance on yeasts and foodborne diseases is required because there is a literature that connects yeast presence in foods to the onset of a broad range of allergic and hypersensitive reaction in humans. Indeed, yeasts may cause or contribute to food intolerances, migraines, respiratory problems, chronic fatigue syndrome, dysfunctional gut syndrome, and irritable bowel syndrome. Generally, these adverse reactions could be associated to the yeast cells themselves, yeast extracts, or associated metabolites such as sulfur dioxide, proteins, and biogenic amines. The latter, especially histamine, tyramine, phenylethylamine, putrescine, and cadaverine, are associated to headaches, hypotension, migraines, and digestive disturbances in humans. Although the quantity produced is not enough to create health concerns, yeasts can thus contribute to the accumulation of biogenic amines in fermented foods and beverages.

Yeasts Technological Features

Aromas

During fermentation, yeasts produce many aromas. For alcoholic beverages, this involves over 400 different chemical compounds, of which fusel alcohols, fatty acids, and their ester represent the main groups. In addition, carbonyl compounds, acetals, phenols, hydrocarbons, nitrogen compounds, sulfur compounds, lactones, sugars, and a variety of other unclassified compounds are present. Besides, yeasts also contribute to the aroma of bread, cheese and other dairy products, fermented meat, cocoa, vanilla, and fermented soy-derived foods.

Colors

The yeasts have been used as sources of a number of carotenoids for use as food colorants such as astaxanthin, β-carotene and γ-carotene, lycopene, lutein, torulene, torularhodin, and zeaxanthin. For instance, *Phaffia rhodozyma* and *Xanthophyllomyces dendrorhous* have been used in industrial-scale production of the carotenoid astaxanthin. This compound can be used for aquafeed as a colorant or as an immunostimulant in food or in poultry, fish, or mammalian feed. Other colorants produced by yeast fermentation are riboflavin and caramel colors produced from the processing of yeast extracts.

Flavors

Flavors produced by yeasts, such as yeast extract, autolysates, and dried preparations, are commonly used in the food industry as a source of savory accents (roasted, nutty, meaty, and other flavors). These flavors can originate from yeast metabolic products including alcohols, amino acids and derivatives, carbohydrates and glycosides, fatty acids and their esters, organic acids, lactones, and aldehydes. Among the yeast-derived products, yeast extract is often produced from spent brewer's yeast and provided as powders or pastes. Yeast extracts are flavor ingredients of which the quality is affected by the specific cell composition. Hydrolyzed edible proteins and peptides from yeasts, which are a good source of the essential amino acid L-lysine, are limited in sulfur-containing amino acids, such as cystine and methionine, which have to be added. Some extracts are also enriched in glutamic acid and nucleotides that function as strong flavor enhancers. Yeast-derived lecithin, inositol, glycerol, and glycolipids, recovered from the cell membrane lipid extracts or from fermentation broth, can be used as flavors in foodstuffs as emulsifiers and surfactants. Moreover, they show additional health benefits so they can also be used as food supplements.

Yeast Spoilage

Food and beverages spoilage by yeasts has been well documented in many recent reviews. Yeasts can cause defects in the final products, and problems with hygiene procedures appear upon failures in the decontamination procedure, leading to significant economic losses. Generally, yeast spoilage occurs in food products characterized by a retarded or inhibited bacterial growth, that is, without bacterial competition. Foods that are usually subjected to yeast spoilage are characterized by low pH, high sugar levels (e.g., more than 10%, w/v), high salt levels (more than 5% NaCl), and low levels of organic acids (e.g., sorbic, benzoic, and acetic). Fruits and derived products (juices, drinks, pulps, concentrates, and syrups), confectionery products, alcoholic beverages, carbonated beverages, vegetable salads with acid dressings, salt- and acid-based sauces, dairy products, and fermented or cured (salted) meat products represent the main candidates for yeast spoilage.

The main spoilage yeast species are *B. bruxellensis*, *P. kudriavzevii*, *Candida parapsilosis*, *D. hansenii*, *H. uvarum*, *Pichia membranaefaciens*, *Rhodotorula mucilaginosa*, *Rhodosporidium toruloides*, *S. cerevisiae*, *Schizosaccharomyces pombe*, *K. exigua*, *Zygosaccharomyces bailii*, *Z. bisporus*, and *Z. rouxii*. However, with the years, some other common food-contaminating yeasts have been described, such as *Y. lipolytica*, *Zygosaccharomyces lentus*, *Z. kombuchaensis*, *Candida wyomingensis*, *C. boidinii*, *Cryptococcus uzbekistanensis*, *Candida natalensis*, and *Pseudozyma antarctica*. The main alterations caused by yeasts in food include the alteration of physical and sensorial properties, discoloration, gas production, cloudiness, sedimentation or pellicle formation, and the formation of off-flavors. For instance, *D. bruxellensis* is responsible of serious economic losses in the wine industry because it produces volatile phenols (4-ethylguaiacol and 4-ethylphenol), which generate off-odors in wines. Exposure of beer to air will induce the growth of oxidative yeast genera such as *Pichia*, *Debaryomyces*, *Candida*, and *Hansenula*, which cause off-flavors and ferment residual dextrans in the beer.

Yeast as Biocontrol Agents

Several yeast species show a strong antagonistic activity against filamentous fungi. For this reason, they can be used for biocontrol of fungi that cause pre- and postharvest spoilage of fruits and vegetables, increasing food quality and hygienic safety. As such, they can the control the development of *Botrytis*, *Penicillium*, *Aspergillus*, and *Rhizopus* spp., reducing the need

for chemical fungicides and, consequently, their potential oncogenic risks. The yeast species showing biocontrol capacity are mostly *M. pulcherrima*, *Candida sake*, *Sporobolomyces roseus*, *W. anomalus*, *Aureobasidium pullulans*, and various *Cryptococcus*. For commercial use, the main species diffused are *C. oleophila* and *Pseudozyma flocculosa*, which are registered as Aspire and Sporodex, respectively. The combination between *C. oleophila* and two bacterial strains is widely used as biocontrol agent of postharvest diseases of citrus and apple fruits. Yeast antagonistic activity is mainly related to the production of killer toxins, inhibitory proteins and peptides, lytic glucanases, and chitinases, which act against fungal cell wall. Moreover, they inhibit fungal development through nutrient competition and the production of toxic metabolites, such as ethanol, acetaldehyde, ethyl acetate, and fatty acids. The use of yeasts as biocontrol agents has several advantages because they are easy to cultivate, are characterized by a fast growth, and can be found in several ecological niches.

Conclusion

In summary, yeasts play an essential role in many food and beverage fermentations, conferring the required stability, safety, and sensory properties to the final product. Moreover, several beneficial health effects are clearly evident such as probiotic (prevention and treatment of intestinal diseases and immunomodulatory action), antigenotoxic, and antioxidant activities. Recent advances in molecular biology (DNA recombination, mutagenesis, etc.) can be applied to obtain specialized yeasts with new properties to improve human life.

Yersinia enterocolitica: Detection and Treatment

D Rodríguez-Lázaro, University of Burgos, Burgos, Spain
M Hernández, Instituto Tecnológico Agrario de Castilla y León (ITACyL), Valladolid, Spain

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Yersinia genus comprises 11 species: *Y. aldovae*, *Y. bercovieri*, *Y. enterocolitica*, *Y. frederiksenii*, *Y. intermedia*, *Y. kristensenii*, *Y. mollaretii*, *Y. pestis*, *Y. pseudotuberculosis*, *Y. rohdei*, and *Y. ruckeri* (Table 1). Only three of them are pathogenic to humans: *Y. enterocolitica*, *Y. pestis*, and *Y. pseudotuberculosis*, causing from pneumonic plague to acute gastroenteritis. *Y. enterocolitica* comprises both pathogenic and nonpathogenic genotypes and is regarded as a relevant zoonotic foodborne pathogen, ranking just third among the notifiable bacterial zoonoses in the EU (6471 cases in 2013). *Y. enterocolitica* has been mainly isolated from pig meat and products thereof and in bovine meat and raw cow milk intended for direct human consumption as well as in other animal species, including wildlife animals, cattle, sheep, goats, dogs, cats, and solipeds. More details on *Yersinia enterocolitica* characteristics are provided elsewhere in this encyclopedia.

Detection of *Y. enterocolitica*

The main biochemical characteristics of *Y. enterocolitica* and related species are listed in Table 2.

Classical Microbiological Methods for Detection of *Y. enterocolitica* in Food

There is an international standard developed by the International Organization for Standardization (ISO) for the detection of pathogenic *Y. enterocolitica*: *ISO 10273:2003 Microbiology of food and animal feeding stuffs – Horizontal method for the detection of presumptive pathogenic Yersinia enterocolitica*. This standard protocol compromises three consecutive steps: enrichment in selective broths, isolation in specific agar plates, and final confirmation. The flowchart is described in Figure 1.

Twenty-five grams or milliliters of food samples is homogenized in 225 ml of peptone–sorbitol–bile salt (PSB) broth, and subsequently, a fraction of this mixture is also 1:10 homogenated in a second selective broth irgasan ticarcillin chlorate (ITC). The sample containing PSB is incubated at 25 °C during 48–72 h with agitation or up to 5 days without agitation, whereas the sample containing ITC is incubated 25 °C during 48 h. Afterward, ITC and PSB broths are streaked on the cefsulodin–irgasan–novobiocin (CIN) agar and on the *Salmonella–Shigella* agar with deoxycholate and calcium chloride (SSDC) agar, respectively, and the plates are incubated at 30 °C for 24–48 h. In parallel, 0.5 ml of the PSB enrichment is transferred into 4.5 ml 0.5% potassium hydroxide solution (KOH) and is mixed gently and is also streaked on the CIN agar, and the plates are also incubated at 30 °C for 24–48 h. The typical *Y. enterocolitica* colony morphology on CIN agar plates is small colonies (1–2 mm diameter) with a deep red center surrounded by a clear, colorless zone with entire edge (a bull's eye aspect). For SSDC agar, the typical *Y. enterocolitica colony* morphology is ≈1 mm diameter small gray colonies with a non-defined border. Those presumptive colonies should be confirmed, and for that, up to five colonies should be taken for further analysis for species confirmation by presumptive assays (urea–indole, Kligler, and oxidase tests) and confirmation biochemical tests (lysine, ornithine, sucrose, rhamnose, trehalose, xylose, citrate, and Tween esterase tests) (Table 3). Once the isolates are confirmed as *Y. enterocolitica*, the biotype must be determined (Table 4) as well as the pathogenic character by presumptive pathogenicity tests (esculin, pyrazinamidase, and Ca^{2+} dependency tests at 37 °C) (Table 3). In addition, it is also advisable to

perform serological tests using the somatic O-antigen for epidemiological purposes.

The US Food and Drug Administration (FDA) has a similar procedure for classic microbiological detection of *Y. enterocolitica*. Twenty-five grams or milliliters of food samples is also homogenized in 225 ml of PSB broth, but the miscut is incubated at 10 °C for 10 days. Afterward, 0.5 ml of the PSB enrichment is transferred into 4.5 ml 0.5% KOH and is mixed gently and streaked on both MacConkey and CIN agars and the plates are incubated at 30 °C for 24–48 h. The typical *Y. enterocolitica* colony morphology on MacConkey agar plates is small (1–2 mm diameter) flat, colorless, or pale pink colonies. Those presumptive colonies from both agar media (MacConkey and CIN) should be confirmed, and for that, up to five colonies should be taken for further confirmatory tests.

Alternative Methods for Detection of *Y. enterocolitica* in Food: Molecular-Based Methods

As described in details earlier, the detection of *Y. enterocolitica* in foods by classical methods becomes a laborious and time-consuming task; it requires at least 7 days for a presumptive result and additional tests and time are required for discrimination between pathogenic and nonpathogenic strains. In addition to this, the commercially available selective media are not completely specific for the *Y. enterocolitica* pathogenic strains hampering the correct selection of the pathogenic strains for confirmation due to the high amount of *Y. enterocolitica*-type colonies present in the agar and that the pathogenic and no pathogenic isolates are virtually indistinguishable.

To overcome those drawbacks, molecular-based methodologies have been developed to reduce the time for final results as well as to increase remarkably the detection sensitivity. Particularly, real-time polymerase chain reaction (PCR)-based methods can facilitate the rapid, sensitive, and specific detection of pathogenic *Y. enterocolitica*. In this sense, the international bodies for standardization ISO and CEN have an ad hoc expert group for molecular detection methods in food (TAG·), which recently has prepared a standard draft for the detection of pathogenic *Yersinia enterocolitica* and *Yersinia pseudotuberculosis*, the *ISO/CD TS 18867 Microbiology of food and animal feed – Polymerase chain reaction (PCR) for the detection of food-borne pathogens – Detection of pathogenic Yersinia enterocolitica and Yersinia pseudotuberculosis*.

This standard method compromises four consecutive steps: microbial enrichment, nucleic acid extraction, amplification, and detection and isolation. The first step, the microbial enrichment, increases the number of pathogenic *Y. enterocolitica* cells by growth in a nonselective or semi-selective liquid nutrient medium. Subsequently, bacterial cells are separated from the nutrient broth and lysed and the nucleic acid extracted for use in a probe-based real-time PCR. After a PCR-positive result, *Y. enterocolitica* can be optionally isolated by using culture methods. The flowchart is described in Figure 2. In more detail, at least 25 g or ml of the sample is properly homogenized with 225 ml of PSB broth and is incubated at 25 °C for 24 h, but this period can be increased up to

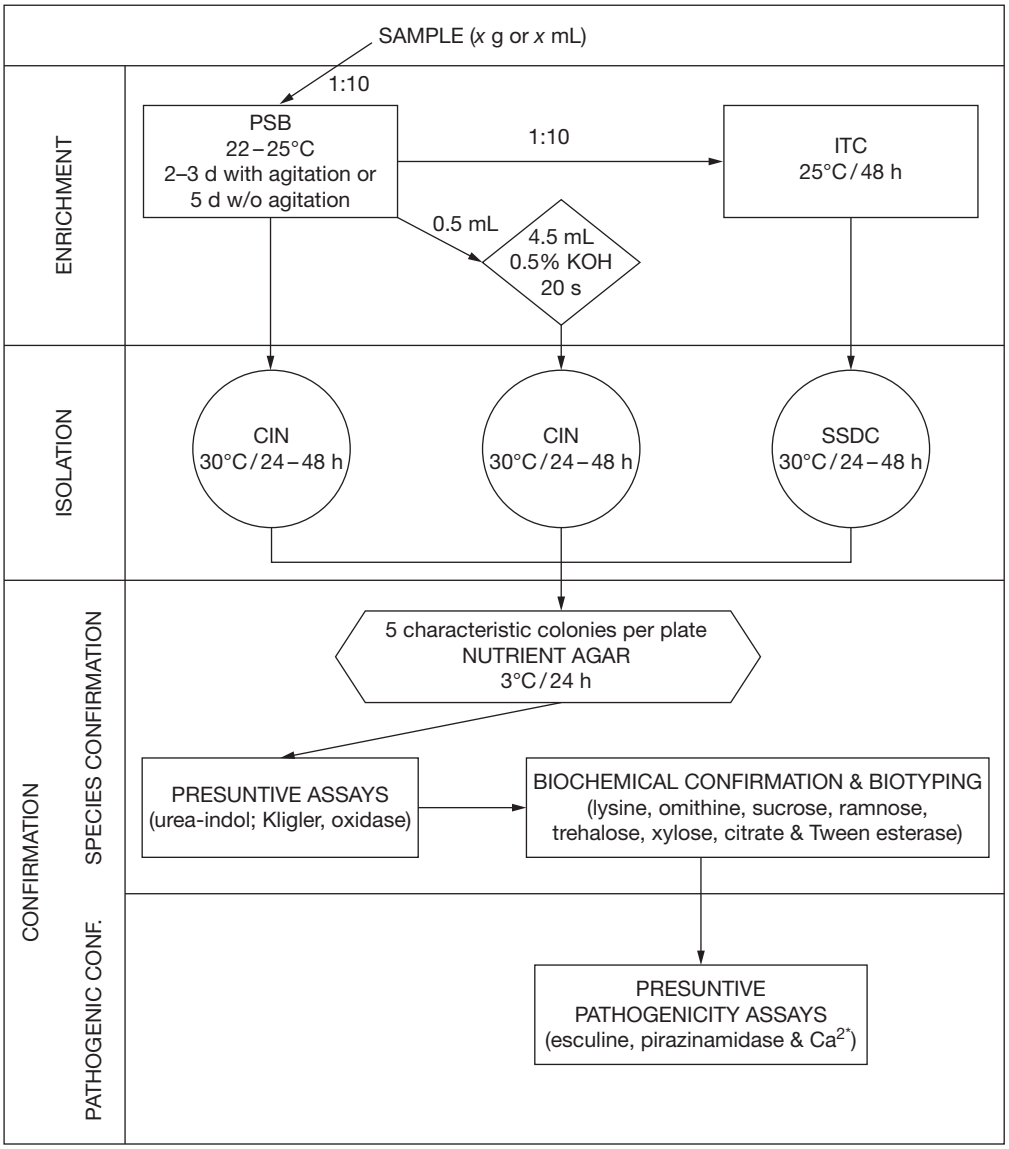

Figure 1

48 h as recommended in the classical standard method, ISO 10273, for certain food matrices. Then, 1 ml of the enriched culture is used for bacterial DNA using a suitable procedure appropriate for Gram-negative bacteria. Finally, a probe-based real-time PCR assay is used for the amplification of the extracted DNA targeting the *Y. enterocolitica* chromosomal virulence *ail* gene. Optionally and in parallel, the isolation of pathogenic *Y. enterocolitica* colonies can be performed. Five hundred milliliters of the PSB enrichment is transferred into 4.5 ml 0.5% KOH and is mixed gently, and 1, 10, and 100 µl of the mixture are inoculated on the surface of three CIN agar plates, which are incubated at 30 °C for 24 h. In parallel, the first 24 h enrichment is also extended for further 24 h and a second plating on CIN agar following KOH treatment is also made. The pathogenic *Y. enterocolitica* in CIN agar plates has a bull's eye appearance and has to be confirmed according to ISO 10273.

Treatment of *Y. enterocolitica*

The optimal treatment strategies for *Yersinia* infections are not evident; antibiotic treatment appears not to impact, in general, uncomplicated acute diarrhea and the value of antibiotic therapy has not been clearly established. Uncomplicated cases usually resolve on their own without antibiotic treatment, and the treatment is primarily supportive, with fluid and electrolyte replacement and good nutrition, avoiding antimotility medications, which could lead to invasion and bacteremia. However, antimicrobial treatment should be prescribed for patients with severe enterocolitis (Box 1), in which antibiotic chemotherapy can reduce the duration of illness, and in invasive infections with bacteremia and extraintestinal manifestations (Box 2).

The antibiotic arsenal available is wide, and *in vitro* susceptibility has been demonstrated to aminoglycosides,

trimethoprim-sulfamethoxazole, chloramphenicol, tetracyclines (doxycycline), piperacillin, fluoroquinolones (ciprofloxacin), and third-generation cephalosporins. *Y. enterocolitica*, and particularly the serotype most commonly associated with illness (O:3), is often resistant to penicillin, ampicillin, and first-generation cephalosporins. Resistance to cefotaxime, macrolides, and fluoroquinolones is also sporadically reported.

Clinically, the first drug options are aminoglycosides and trimethoprim–sulfamethoxazole, but also doxycycline, third-generation cephalosporins, and ciprofloxacin can be used (Box 3). However, the use of tetracyclines is not recommended in children <8 years, and fluoroquinolones such as ciprofloxacin are not approved in the United States for use in children <18 years.

Box 3

Type of Antibiotics Used in the Treatment of* Y. enterocolitica *Infections

Antibiotic	Description
Gentamicin	Aminoglycoside It acts by inhibiting bacterial protein synthesis Active against Gram-negative bacteria Not helpful for uncomplicated gastroenteritis
Trimethoprim and sulfamethoxazole or co-trimoxazole	They act by blocking the synthesis of dihydrofolic acid Active against Gram-negative and Gram-positive bacteria and protozoa Not helpful for uncomplicated gastroenteritis
Ciprofloxacin	Second-generation quinolone It acts by interfering with DNA gyrase Active against Gram-negative and Gram-positive bacteria
Ceftriaxone	Third-generation cephalosporin It acts by disrupting the synthesis of the peptidoglycan layer in the bacterial cell wall Active against Gram-negative
Cefotaxime	Third-generation cephalosporin It acts by disrupting the synthesis of the peptidoglycan layer in the bacterial cell wall Active against Gram-negative bacteria Not helpful for uncomplicated gastroenteritis
Doxycycline	Tetracycline It acts by inhibiting bacterial protein synthesis by binding with the 30S and 50S ribosomal subunits Active against Gram-positive and Gram-negative bacteria, as well as against *Mycoplasma*, *Chlamydia*, and *Rickettsia*
Chloramphenicol	It acts by inhibiting bacterial protein synthesis by binding to 50S bacterial-ribosomal subunit Active against Gram-negative and Gram-positive bacteria
Piperacillin and tazobactam sodium	An extended-spectrum beta-lactam antibiotic (ureidopenicillin class) (piperacillin) associated with a beta-lactamase inhibitor (tazobactam) It acts by inhibiting the biosynthesis of cell wall mucopeptide Active against Gram-negative bacteria

Yersinia enterocolitica: Properties and Occurrence

S Joutsen and M Fredriksson-Ahomaa, University of Helsinki, Helsinki, Finland

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Yersinia enterocolitica is one of the three human pathogenic species in the genus *Yersinia*. *Y. enterocolitica* and *Yersinia pseudotuberculosis* are enteropathogenic species that have an oral transmission route, while plague-causing *Yersinia pestis* is mainly transmitted by a flea vector. *Y. enterocolitica* is the most common species causing human enteric yersiniosis worldwide. Most of these cases are sporadic and outbreaks are uncommon. *Y. enterocolitica* can cause a variety of symptoms depending on the virulence of the strain and/or the age and the immune status of the infected person. Common symptoms are diarrhea and abdominal pain. Right-sided abdominal pain can be confused with appendicitis. Occasionally, typically among adults, joint pain (reactive arthritis) and skin rash (erythema nodosum) may occur. *Y. enterocolitica* can be transmitted to human via contaminated food, especially via contaminated pork. Pigs are so far the most important reservoir for human pathogenic strains. Because a vast amount of nonpathogenic *Y. enterocolitica*- and *Y. enterocolitica*-like strains are circulating in the environment, it is important to differentiate between pathogenic strains with clinical significance and harmless nonpathogenic strains. Furthermore, *Y. enterocolitica* strains are very heterogeneous in their biochemical and antigenic properties.

Properties

Taxonomy

Y. enterocolitica is one of the three human pathogenic species in the genus *Yersinia*. The two other human pathogenic species *Y. pseudotuberculosis* and *Y. pestis* share only about 50% DNA homology with *Y. enterocolitica*. At the moment, the genus *Yersinia* comprises 17 species including the fish pathogen *Y. ruckeri*. *Yersinia* is a member of the family *Enterobacteriaceae* belonging to *Gammaproteobacteria* class of phylum *Proteobacteria*. *Yersinia* bacteria are a group of gram-negative, oxidase-negative, catalase-positive, lactose-negative, and facultative anaerobic rods or coccobacilli of $0.5–0.8 \times 1–3$ μl in size. They possess neither a capsule nor spores. *Y. enterocolitica* strains are mostly urease-positive, and they ferment sucrose but not rhamnose and melibiose. The chromosome of *Y. enterocolitica* strains is about 4.6 Mb. The G + C content of 47.3% is lower than that of most members of *Enterobacteriaceae*. The 16S rRNA gene sequence similarities of *Yersinia* strains range from 96.9% to 99.8%. *Y. enterocolitica* has been subdivided into two subspecies based on the 16S rRNA sequences and DNA–DNA reassociation values. *Y. enterocolitica* subsp. *enterocolitica* comprises the *Y. enterocolitica*-type strain ATCC 9610^T and strains from high-pathogenic biotype 1B, while *Y. enterocolitica* subsp. *palearctica* comprises the strains from low-pathogenic biotypes 2–5 and nonpathogenic biotype 1A.

Biochemical Properties

Yersinia strains are more active biochemically between 25 and 30 °C than at 37 °C, and thus, temperatures between 25 and 30 °C are typically used for biochemical tests. Identification of *Y. enterocolitica* is still mainly based on biochemical reactions, typically by using commercial kits. However, it may be difficult to differentiate *Y. enterocolitica* from some nonpathogenic *Yersinia* spp. like *Y. massiliensis*, *Y. mollaretii*, and *Y. bercovieri* by biochemical tests. For proper identification and pathogenicity assessment, genotypic methods are often needed.

Y. enterocolitica species is a heterogeneous group of bacteria based on biochemical, antigenic, and virulence properties. Based on biochemical properties, *Y. enterocolitica* strains can be divided into six biotypes. At least five biochemical reactions have to be tested to identify the different biotypes (Table 1). Strains of biotype 1A are considered nonpathogenic, but strains belonging to the biotypes 1B and 2–5 are human and/or animal pathogens. Biotype 1B strains are highly virulent, whereas biotypes 2–5 have a lower pathogenicity. The pyrazinamidase activity test is used to differentiate between potentially pathogenic and nonpathogenic strains.

Antigenic Properties

Serotyping based mainly on the surface O antigenic variation of lipopolysaccharides (LPS) in the cell wall is widely used for *Y. enterocolitica*. Subdivision of *Yersinia* species to serotypes provides useful information concerning their potential pathogenicity and possible reservoir. *Y. enterocolitica* comprises over 30 serotypes. Serotypes O:3, O:5, O:8, and O:9 are associated with human diseases; however, they can also be found in nonpathogenic strains. In Europe, predominating human serotypes are O:3 and O:9. Pigs are worldwide the most important reservoir of the serotype O:3.

Biotype and Serotype Combinations

Only certain bioserotypes of *Y. enterocolitica* have been associated with human and animal diseases. The most common bioserotypes recognized in human yersiniosis are 4/O:3, 2/O:9, 2/O:5,27, 3/O:3, and 1B/O:8. Bioserotype 4/O:3 is the most common through the world followed by 2/O:9 and 2/O:5,27. Bioserotype 3/O:3 is most commonly reported in Japan and China. Highly pathogenic bioserotype 1B/O:8, which has originally been isolated mainly in the United States and Canada, has appeared also in Europe and Japan. An increasing number of human yersiniosis due to clonal 1B/O:8 strains have been reported in different regions in Poland. Strains belonging to bioserotypes 3/O:1,2,3 and 5/O:2,3 have been isolated from chinchillas and hares, respectively. Biotypes 3 and 5, serotype O:2,3 have also been reported in sheep and goats in Australia. Additionally, pathogenic

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00763-7

Y. enterocolitica of bioserotype 5/O:3 has been isolated from an alpine ibex in Switzerland.

Phage Types

Y. enterocolitica strains can be divided into phage types. Two schemes (Swedish and French) have been used for typing. French scheme recognizes 12 phage types (I–X, including IXa–c) and Swedish scheme seven phage types (A1, A2, B1, B2, C32, C61, and E1). The French scheme has been used more frequently. Bioserotype 4/O:3 strains, which belong to phage type VIII, predominate in Europe and Japan, whereas phage type IXb has been isolated in Canada. Phage typing is available only in few laboratories and thus very rarely used.

Antimicrobial Resistance

Several antimicrobial agents have been used to study the susceptibility of *Y. enterocolitica* strains. *Y. enterocolitica* strains are mostly resistant to penicillins and first-generation cephalosporins due to β-lactamase production. *Y. enterocolitica* strains are typically sensitive to aminoglycosides, third-generation cephalosporins, co-trimoxazole, tetracyclines, chloramphenicol, and fluoroquinolones. Sporadic resistance to amoxicillin/clavulanic acid, streptomycin, tetracycline, and sulfamethoxazole/trimethoprim occurs (Table 2). There are some differences between the resistance patterns among strains of different bioserotypes; biotype 2 strains are more frequently resistant to amoxicillin/clavulanic acid and bioserotype 4/O:3 strains to streptomycin (Table 2). So far, multiresistant *Y. enterocolitica* strains have rarely been reported. Nalidixic acid resistance in *Y. enterocolitica* strains has been linked to the point mutation in the *gyr*A gene.

Trehalose acidification	+	+	+	+	+	−

[a]Tryptophan in the test medium and a heavy bacterial suspension are needed for a clear positive reaction.

Virulence

Y. enterocolitica strains are transmitted via the oral route. After passage through the stomach, pathogenic strains colonize the intestinal tract, penetrate the intestinal mucosa, and infect the underlying tissue. Pathogenic *Y. enterocolitica* strains are invasive and have a capacity to resist nonspecific immune responses.

All pathogenic *Yersinia* strains carry an approximately 70-kb virulence plasmid abbreviated as pYV (plasmid for *Yersinia* virulence), which is essential for the virulence (Table 3). The pYV allows *Yersinia* to survive and replicate within lymphoid tissues of the host. It codes for the outer membrane protein YadA (Yersinia adhesion A), a set of secreted proteins called Yops (Yersinia outer membrane protein), and their secretion apparatus called Ysc (Yop secretion), which is a type III secretion system (T3SS). The genes on the pYV are controlled by temperature and calcium concentration and are optimally expressed at 37 °C and in low calcium ion conditions.

Host cell invasion is promoted mainly by the chromosomal-encoded Inv (invasion) and Ail (attachment invasion locus) proteins and the pYV-encoded YadA protein. Inv binds to β1-integrin receptors on the M cells and induces uptake of the bacteria into the epithelial cells during the initial stage of infection. Ail, which is typically found in pathogenic strains, is involved in the attachment and invasion of the host

	ybt	Yersiniabactin	Iron acquisition
	ure	Urease	Survival in acidic environments

cell. It enables bacterial dissemination to mesenteric lymph nodes by protecting bacteria against host immune system. YadA is a multifunctional virulence factor that promotes binding to collagen, fibronectin, and laminin. It is upregulated at 37 °C when the bacteria are replicating in the Peyer's patches. YadA-promoted adhesion to collagen is crucial to the inflammation of joints in reactive arthritis.

Furthermore, extracellularly located *Y. enterocolitica* strains deliver Yops into the cytosol of the target cell with the Ysc. These Yops destroy the phagocytic and signaling capacities of host macrophages and finally introduce apoptosis and in this way enable *Yersinia* to survive in the host environment.

Serum resistance is critical for the survival of invading bacteria like *Y. enterocolitica* and the establishment of disease. Pathogenic *Y. enterocolitica* strains have the ability to withstand the activity of complement-dependent killing. Two outer membrane proteins of *Y. enterocolitica*, pYV-encoded YadA and chromosomally encoded Ail, are the main factors involved in the serum resistance. They protect the bacteria from complement-mediated lysis and phagocytosis. YadA is the most important serum resistance factor needed for long-term survival. Ail provides a short-term survival and it delays the bacterial killing. In addition, the outer membrane LPS may indirectly be involved in the serum resistance.

The highly pathogenic *Y. enterocolitica* 1B strains harbor the high-pathogenicity island (HPI) in the chromosome. The HPI is a cluster of genes intended for iron uptake and is involved in synthesis of the yersiniabactin, a siderophore responsible for the systemic dissemination of bacteria in the host. Biotype 1B strains are lethal to mice in contrast to strains of biotypes 2–5, which do not kill mice unless iron is made available to bacteria by pretreatment of mice with desferrioxamine.

A heat-stable enterotoxin called Yst is produced by *Y. enterocolitica*. There are three subtypes of Yst: YstA, YstB, and YstC. YstA is mainly produced by pathogenic strains and YstB by nonpathogenic ones (Table 3). The role of Yst in the pathogenesis of *Y. enterocolitica* infection is still unclear; however, the YstA, which is produced by pathogenic strains, may contribute to the pathogenesis of diarrhea.

Presence of Virulence Genes

Y. enterocolitica strains can carry different genes associated with the pathogenicity on the pYV and in the chromosome (Table 4). The occurrence of these genes has been extensively studied. Most of the *Y. enterocolitica* strains carry the urease-encoding gene complex (*ure*) in the chromosome. Urease helps *Yersinia* strains to survive the gastric barrier of the stomach before entering the small intestine. Some *Y. enterocolitica* strains, especially the pathogenic ones, carry the chromosomal *myf*A gene, which encodes the production of mucoid *Yersinia* fimbriae (MyfA) associated with the colonization of intestinal epithelium. The chromosomal *ail* gene is assumed to be detected only in pathogenic *Y. enterocolitica* strains; however, recently, this gene has also sporadically been found in nonpathogenic strains. The *yst*A gene is present mainly in

pathogenic strains, while *yst*B is frequently present in nonpathogenic *Yersinia* species.

Pathogenic strains belonging to biotypes 1B and 2–5 typically carry the virulence genes located on the pYV and the most important chromosomal genes: *ail*, *yst*A, and *myf*A. The highly pathogenic biotype 1B strains carry the *ybt* genes located in the HPI, and these genes are missing in the strains with lower pathogenicity. Biotype 1A strains of *Y. enterocolitica* are considered to be nonpathogenic because they always lack the genes on the pYV and in the HPI. Additionally, they typically also miss the most important chromosomal virulence genes: *ail*, *yst*A, and *myf*A (Tables 3 and 4). The *yst*B gene is usually detected in the biotype 1A strains.

Growth Factors

Y. enterocolitica strains are nutritionally very unfastidious. In food, pH and a_w values are the most important intrinsic factors for the growth of *Yersinia*. The optimum pH is around 7, but *Y. enterocolitica* is able to multiply over a pH range from 4 to 10 and can survive alkaline conditions better than many other gram-negative bacteria. Alkalotolerance of *Yersinia* has been used to separate *Yersinia* strains from background organisms by the treatment of enrichment broth with potassium hydroxide (0.25–0.5%) before streaking onto the agar plates. Survival of *Y. enterocolitica* during the passage through stomach suggests that *Y. enterocolitica* strains are also relatively acid-resistant. Salt (NaCl) tolerance of *Yersinia* is moderate and strongly dependent on storage temperature. *Yersinia* strains can tolerate NaCl at concentrations of up to 5%, while 7% of NaCl has shown to be bacteriostatic. Thus, salt alone will typically not prevent the growth of *Yersinia* and other preservative hurdles like nitrate/nitrite are needed.

The most important extrinsic factors include temperature and gas atmosphere. *Y. enterocolitica* strains are psychrotrophic and have an ability to grow at temperatures between 0 and 44 °C. The optimum growth temperature is around 30 °C. Even though *Yersinia* strains can grow at refrigeration temperatures (0–6 °C), they grow much more slowly below 5 °C. *Yersinia* strains can survive in frozen foods for extended periods even after repeated freezing and thawing. They are susceptible to heat and can be destroyed by pasteurization at 72 °C for 15–20 s. As a facultative anaerobic bacterium, *Y. enterocolitica* can grow in aerobic and anaerobic conditions. *Yersinia* strains can also grow well in modified atmosphere with higher levels of CO_2. Pathogenic *Y. enterocolitica* 4/O:3 strains have shown to grow well on meat when packaged in modified atmosphere with high carbon dioxide (30%) and oxygen (70%) levels and stored at 6 °C even in the presence of high number of lactic acid bacteria.

Occurrence

In Humans

Pathogenic *Y. enterocolitica* strains have been isolated from humans on all continents but the reported incidences differ greatly. Over 7000 cases of yersiniosis were reported in the European Union (EU) in 2011. *Y. enterocolitica* was the most common species reported; it was identified from 98% of the confirmed cases. The number of cases increased by 3.5% compared to 2010. The highest country-specific notification rates were reported in Lithuania and Finland, 11.4 and 10.3 cases per 100 000 inhabitants, respectively. The EU case fatality rate was low (0.02%) in 2011. The incidence of yersiniosis was highest among children under 5 years. However, comparison of the data between different countries is not possible because of the inconsistency of surveillance systems.

Y. enterocolitica bioserotype 4/O:3 is the most common type associated with human disease followed by bioserotype 2/O:9 in Europe. Strains belonging to biotype 1A are usually regarded as nonpathogenic, but discussion has been raised of a potential pathogenicity of some strains of the biotype 1A. However, biotype 1A strains, which were recently isolated from feces of humans with and without diarrhea in Switzerland, were characterized, and no clear difference between *Y. enterocolitica* 1A strains isolated from healthy and symptomatic humans could be demonstrated.

In Animals

Numerous studies have been conducted to isolate *Y. enterocolitica* strains from a variety of animals including farm animals, domestic pets, experimental animals, wild animals, and captive animals. Most of the strains isolated from animal sources, except pigs, are missing the important virulence genes needed for infection. Furthermore, they usually differ both biochemically and serologically from strains isolated from humans with yersiniosis.

Human pathogenic strains have frequently been isolated from pigs. The occurrence of pathogenic *Y. enterocolitica* is dependent on the age of the pigs and sample source: the pathogen can at first be isolated from feces and tonsils before antibodies can be detected by serology. The highest occurrence of pathogenic strains has been obtained in the tonsils of finishing pigs probably due to the high number of this pathogen present in the tonsils. The isolation rates of pathogenic *Y. enterocolitica* strains in pig tonsils at slaughter have shown to be very high in Europe (Table 5). The most frequently isolated bioserotype is 4/O:3, which has a worldwide distribution in the pig population. Serological investigations have shown that 60–90% of the herds are infected and nearly all finishing pigs in infected herds are seropositive. Pathogenic *Y. enterocolitica* strains have typically not been isolated from young breeding pigs but from pigs that have been moved to the fattening pens. More intensive farming and production systems have probably contributed to the high occurrence of this pathogen in fattening units. The occurrence has been shown to be highest in fattening units where pigs have been purchased from various pig producers. Recently, it has been shown in Belgium that there can be a large variation in the within-batch occurrence (between 0% and 83%) among pig farms.

Pathogenic *Y. enterocolitica* strains of different bioserotypes have occasionally also been isolated from cats and especially from dogs. Wild animals, especially wild rats near the pig houses, have shown to excrete pathogenic *Y. enterocolitica* sporadically in the feces. Recently, pathogenic *Y. enterocolitica* 5/O:3 was isolated from an alpine ibex in Switzerland; however, all strains isolated from wild deer were nonpathogenic *Yersinia* spp. indicating that the occurrence of pathogenic

Table 5 Recent isolation rates of pathogenic *Yersinia enterocolitica* in pig tonsils

Country	*Occurrence (%)*	*Bioserotypes*

Effect of sampling and short isolation methodologies on the recovery of human pathogenic *Yersinia enterocolitica* from pig tonsils. *Foodborne Pathogens and Disease* **9**, 600–606.

Y. enterocolitica is low in wild ruminants. The occurrence in wild boar is clearly higher being around 10%.

In Food

Food, especially raw or undercooked pork, has often been suggested to be the main infection source of human *Y. enterocolitica* infections even though pathogenic strains have seldom been isolated from food samples. Using Polymerase Chain Reaction (PCR), pathogenic *Y. enterocolitica* has been detected more frequently not only especially in pig offal samples (the tongue, lungs, heart, liver, and kidney) but also in samples from the surface of freshly slaughtered pig and poultry carcasses and in pork samples (Table 6). In the United States, the occurrence of pathogenic *Y. enterocolitica* 4/O:3 has shown to be high in chitterlings, a traditional holiday dish made of pig intestines in the south.

In the Environment

Nonpathogenic *Yersinia* strains are common findings in the environment, while pathogenic *Y. enterocolitica* strains are rare. However, strains of biotype 4/O:3 have occasionally been isolated from the environment of slaughterhouses and butchers. Using PCR, pathogenic *Y. enterocolitica* strains have been detected in a variety of environmental sources in pig slaughterhouses (Table 7). In case–control studies, untreated drinking water has also been reported to be a risk factor for sporadic *Y. enterocolitica* infections, and thus, drinking water has relatively widely been investigated. However, only rarely have pathogenic strains been found in water samples. Pathogenic *Y. enterocolitica* strains have occasionally been isolated from sewage water.

Conclusion

Y. enterocolitica is one of the three human pathogenic *Yersinia* species. It is the most frequent cause of yersiniosis, which is one of the most frequently reported bacterial enteric diseases, especially among young children, in Europe. Strains belonging to *Y. enterocolitica* species are very heterogeneous in their biochemical, antigenic, and virulence properties. Pathogenic strains carry the pYV virulence plasmid and several important chromosomal genes associated with the virulence. The most common and widely distributed human pathogenic *Y. enterocolitica* belongs to the bioserotype 4/O:3. This type is frequently isolated from the tonsils of finishing pigs at slaughter. *Y. enterocolitica* strains missing the virulence plasmid and the important chromosomal virulence genes are ubiquitous and frequently isolated from nonhuman sources. Thus, it is important to confirm the pathogenicity of the isolated strains to assess their significance for human and animal health.

Yogurt: Dietary Importance

P Behare, VK Lule, and P Patil, National Dairy Research Institute (NDRI), Karnal, India

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Yogurt is a semisolid fermented milk product obtained by the action of specific lactic acid bacteria (*Streptococcus thermophilus* and *Lactobacillus delbrueckii* subsp. *bulgaricus*) when added to heat-treated milk. In some countries, the term yogurt is restricted to products made exclusively by the two cultures, while other countries also allow adjunct probiotic cultures to be labeled as yogurt. According to the National Yogurt Association's criteria for 'live and active culture yogurt,' the finished product must contain live bacteria in amounts of $\geq 10^8$ organisms per gram at the time of manufacture, and the cultures must remain active at the end of the stated shelf life.

Regulatory authorities and scientific institutions in most countries acknowledge the importance of yogurt as part of a balanced and healthy diet. Yogurt is often included in the lists of healthy foods due to its high nutritive value. It is an excellent source of proteins, vitamins, and minerals. Yogurt can be prepared specifically to meet particular nutritional requirements of people whose normal processes of metabolism are altered or those who want a particular effect by controlled intake of foods or certain nutrients. Dietary strategies include lowering of calorie content by reducing fat and lactose content and fortification of minerals, vitamins, bioactive substances, or beneficial organisms.

Nutritional Value

Yogurt contributes to diet quality by providing substantial amounts of macronutrients and essential micronutrients. The composition of yogurt is similar to that of the milk from which it is produced; however, the changes in milk constituents that occur during lactic acid fermentation influence the nutritional value of the finished product. The final nutritional composition of yogurt is also affected by the strains of bacteria used, sources and types of milk solids added to milk before fermentation, and the temperature and duration of the fermentation. Moreover, a wide variety of yogurt is available globally, varying in fat and additive content and differing in nutritional status (Table 1).

Milk and milk products are the exclusive source of the lactose in human diets. Before absorption, lactose is hydrolyzed by intestinal β-galactosidase (lactase) into glucose and galactose. These monosaccharides are absorbed and used for energy in the body. However, those with impaired lactose metabolism (lactose-intolerant) cannot utilize lactose. Yogurt bacteria produce functional lactase, the enzyme that hydrolyses 20–30% milk lactose to its more readily absorbed monosaccharides, which may contribute to better tolerance of lactose in yogurt by those who are lactose-intolerant.

Protein in yogurt is more digestible than native milk proteins as bacterial proteolytic enzymes predigest milk proteins. Among the yogurt cultures, *L. delbrueckii* subsp. *bulgaricus* is more proteolytic in nature, which increases the amounts of peptides and free amino acids after milk fermentation. The amino acids liberated also stimulate growth of *S. thermophilus* in a symbiotic association. Heat treatment and acid production during fermentation result in finer coagulation of casein, which may contribute to improved protein digestibility. Both the caseins and whey proteins in yogurt are rich sources of essential amino acids, and the intestinal availability of nitrogen has been reported to be as high as 93%.

Fat undergoes minor changes due to lipase activity, which liberates free fatty acids after fermentation of milk. Yogurt has been shown to have a higher concentrations of conjugated linoleic acid (CLA), a long-chain biohydrogenated derivative of linoleic acid. In addition, yogurt is an excellent source of highly bioavailable calcium and phosphorus. The acidic pH ionizes calcium and magnesium, which facilitates intestinal uptake. One of the major functions of calcium in conjunction with vitamin D is in bone formation and mineralization.

Dairy products in general are an excellent source of B vitamins (riboflavin, niacin, vitamin B6, and vitamin B12). However, during fermentation, some are lost because vitamins are sensitive to changes in environmental factors. Similarly, lactic acid bacterial (LAB) species require B vitamins for growth, but some cultures are capable of synthesizing it. Significant losses can be corrected with the careful use of supplementary LAB cultures that are capable of synthesizing B vitamins. Folate is one of the best examples of a B vitamin that some LAB species synthesize in situ. Depending on the bacterial strains used, folate content of yogurt can vary widely, ranging from 4 to 19 μg/100 g. Inclusion of folate-producing cultures will increase the folate content of the final product.

Dietary Yogurt

Modern consumers are increasingly interested in their personal health and expect the foods they consume to be healthy or support optimal health, reducing the risk or preventing noncommunicable diseases. A number of functional ingredients are being incorporated in yogurt and yogurt-related products to improve market value.

Low-Calorie Yogurt

Over the past decade, attempts to develop low-calorie yogurts to meet consumer needs have been made with some success. Fat and lactose are two major components responsible for increased caloric value of yogurt. For the production of low-calorie yogurt, strategies include either removal of these components from the yogurt base or replacement with low-calorie alternatives. In the case of reduced/

low-lactose yogurts, three approaches have been used: (a) ultrafiltration of skimmed milk to decrease lactose, (b) addition of lactase and/or prolonged culture to further reduce the lactose content, and (c) artificial sweeteners. The yogurt produced is low in calorie, artificially sweetened with low/very low levels of lactose.

Low-fat and fat-free yogurts have gained popularity because of increasing demand for more healthy options across product categories. In the case of reduced fat yogurt, ingredient selection is important, such as skimmed milk and nonfat dry milk (NFDM). The consequences of adding NFDM, however, can be undesirable since about half of NFDM is lactose, which increases the caloric value of the resulting product. A powdery flavor can also be detected in yogurts fortified with too much of NFDM. Attempts have been made to produce nonfat low-calorie yogurt by adding sugar esters as a fat substitute, aspartame as a sweetener, and a cream-like substance as a flavor enhancer, which provides a better mouthfeel and texture compared with yogurt without fat substitutes. Nonfat yogurt is normally softer and low in total solid (10–12%), and consequently, whey separation is common. To reduce syneresis, thickening agents such as gelatin, starch, cellulose derivatives, alginates, and carrageenan, approved by FDA, can be added. Gelatin and carrageenan promote clustering of casein micelles, while other additives thicken the liquid content, thereby reducing syneresis. Yogurt texture may also be improved by the utilization of ropy strains of yogurt bacteria, that is, *S. thermophilus* and *L. bulgaricus*.

Yogurt with Bioactive Compounds

Almost all milk components may contribute to potential health benefits including proteins, peptides, lipids, carbohydrates, minerals, and vitamins. Some are native to products, while others are produced as a result of bacterial activity or added subsequently to improve functional characteristics (Table 2).

The presence of lactic acid bacteria is thought to be essential for yogurt to exert immune-stimulatory effects, but components of nonbacterial origin, such as whey protein, short peptides, and CLA, are also believed to contribute to beneficial effects as well. Besides the main proteins and naturally occurring bioactive peptides and minor proteins in milk, the activities of bacterial proteases during the fermentation change the physicochemical state(s) of milk proteins leading to the release of free amino acids and bioactive peptides. The most important metabolites in fermented milk may be peptides, which are not present prior to fermentation. Table 3 summarizes the bioactive components found in yogurt and related fermented milk products.

Lactic acid bacteria possess cell envelope-located proteinases, which cause degradation of caseins into oligopeptides. Because

Table 2 Examples of bioactive components in yogurt

Category	*Examples*
Bioactive peptides	α-S1-casecidin, isracidin, casein phosphopeptide, morphiceptin, α-lactorphin
Major milk proteins	α-S1-casein, α-S2-casein, β-casein, κ-casein, α-lactalbumin, β-lactoglobulin, proteose–peptone, glycomacropeptide
Minor proteins and naturally occurring bioactive peptides	Adrenocorticotropic hormone, calcitonin, plasmin enzymes (plasmin, catalase, glutathione peroxidase, and lactoperoxidase), growth factors, immunoglobulins, insulin, lactoferrin, lactoperoxidase, luteinizing hormone-releasing hormone, lysozyme, prolactin, relaxin, somatostatin
Bioactive lipid	Conjugated linoleic acid (CLA)
Vitamins	Vitamin D, vitamin B12, thiamine, riboflavin, niacin, folate
Minerals	Calcium, phosphorus, magnesium, zinc

Table 3 Bioactive peptides derived from milk fermentation and/or processing according to their physiological classification

Protein precursor	*Peptide name*	*Physiological classification*
α-S1-casein	α-S1-casecidin	Antimicrobial
	Isracidin	Antimicrobial
	α-S1-casokinin-5	ACE inhibitor
	Casein phosphopeptide	Calcium binding and transport
	α-S1-casein exorphins	Opioid agonist
	Casoxin D	Opioid agonist
	α-S1-casein exorphins	Opioid agonist
α-S2-casein	Casocidin-1	Antimicrobial
	Casein phosphopeptide	Mineral binding
β-Casein	β-Casokinin-7	ACE inhibitor
	β-Casokinin-10	Immunomodulatory and ACE inhibitor
	Antihypertensive	Peptide antihypertensive
	Immunopeptide	Immunostimulatory
	β-Casomorphin-4, -5, -6, -7, and -11	Opioid agonists
	Morphiceptin	Opioid agonist
	Casein phosphopeptide	Mineral binding
κ-Casein	κ-Casecidin	Antimicrobial
	Casoplatelin	Antithrombotic
	Thrombin inhibitory peptide	Antithrombotic
	Casoxin A	Opioid antagonist
	Casoxin B	Opioid antagonist
	Casoxin C	Opioid antagonist
	Casein phosphopeptide	Mineral binding
α-Lactalbumin	α-Lactorphin	ACE inhibitor and opioid agonist
β-Lactoglobulin	β-Lactorphin	ACE inhibitor and opioid agonist
Lactoferrin	Lactoferricin A	Opioid agonist
	Lactoferricin B	Immunomodulatory and antimicrobial
Lactotransferrin	Thrombin inhibitory peptide	Antithrombotic
Bovine serum albumin	Serorphin	Opioid agonist

microbial proteases hydrolyze milk proteins more randomly than intestinal proteases, fermentation results in significantly more free amino acids and bioactive peptides in yogurt. A large body of scientific research has established that the action of bacterial proteases on milk proteins during yogurt fermentation, or digestion by gut bacteria, results in the release of bioactive peptides, exhibiting different bioactivities, which may be beneficial to health.

Biochemical changes in milk fat also occur during fermentation for yogurt production. Through the activity of bacterial lipase, large amounts of free fatty acids are released. Biohydrogenation during fermentation results in higher CLA concentrations in yogurt than milk. Since low-fat and nonfat varieties of yogurt are preferred, hydrolysis of milk lipids contributes little to the composition of most yogurt products. However, research indicates that the CLA composition can be manipulated/increased while CLA-enriched yogurts have been shown to affect positively energy metabolism and adipose tissue gene expression in healthy subjects.

The beneficial role of dietary fiber in human nutrition has led to growing demand for incorporation of novel fibers in functional foods. Among the various insoluble fibers from soy-, rice-, oat-, corn- and sugar beet-fortified sweetened plain

Table 4 Health Benefits of yogurt and fermented milks

Beneficial effect	*Possible mechanisms*
Improved digestibility	Partial breakdown of proteins, fats, and carbohydrates
Improved nutritional value	Higher levels of B vitamins and certain free amino acids, viz., methionine, lysine, and tryptophan
Improved lactose utilization	Reduced lactose in product and further availability of lactase
Antagonistic action toward enteric pathogens	Disorders such as diarrhea, mucous colitis, ulcerated colitis; prevention of adhesion of pathogens
Anticarcinogenic effect	Reduction of carcinogen-promoting enzymes; inhibitory action toward cancers of the gastrointestinal tract by degradation of precarcinogens; stimulation of the immune system
Hypocholesterolemic action	Production of inhibitors of cholesterol synthesis; use of cholesterol by assimilation and precipitation with deconjugated bile salts
Immune modulation	Enhancement of macrophage formation; stimulation of production of suppressor cells and γ-interferon

yogurt, oat-fortified yogurt resulted in higher apparent viscosity and accelerated acidification rates. Similarly, β-glucan used in low-fat yogurt increased consistency and firmness and decreased syneresis.

Prebiotics are nondigestible complex carbohydrates that selectively stimulate growth and activity of bacteria in the colon and also beneficially affect the host. Examples of prebiotic ingredients being tested for yogurt production are β-glucans, inulin, pectin, gums, and resistant starch.

Yogurt with Health-Promoting Organisms

Most of the health benefits associated with yogurt and fermented milk products are listed in Table 4. A large amount of literature has been accumulated regarding health benefits including improved lactose tolerance, antimicrobial activity, resistance to gastrointestinal infections, anticancer, reduction in serum cholesterol, and immune system stimulation.

Probiotic microorganisms can exert beneficial properties through two mechanisms: (1) direct through live bacteria (probiotics) and (2) indirect via metabolites. Yogurt is seen increasingly as a safe and enjoyable means to deliver probiotics to the gut, where individuals can benefit from both the nutrients and probiotic content. Probiotic species, *L. acidophilus*, *L. rhamnosus* GG, *L. casei*, *Bifidobacterium bifidum*, *B. longum*, etc., are used in yogurt manufacture, and products are reported to enhance resistance to intestinal pathogens, mainly via antimicrobial mechanisms, including competitive colonization and organic acid production (e.g., lactic and acetic acids), bacteriocins, and other primary metabolites.

Conclusion

The market for dietetic foods is increasing tremendously, especially for those containing functional ingredients such as bioactive peptides, CLA, dietary fibers, and probiotic organisms. Consumers are also increasingly health-conscious and demand natural, healthy foods and products with functional aspects. Yogurt is inherently nutritious and provides opportunities for including functionally important compounds and microorganisms.

Introduction

An ancestral version of yogurt probably appeared 9000 or 8000 years BC in Mesopotamia and Egypt and subsequently spread in the northeast of Africa, in the Middle East, in Central Asia, and later in Balkan countries, offering a large variety of 'fermented milks.' Originally, yogurt resulted from a spontaneous, accidental lactic acid fermentation leading to the acidification and coagulation of milk, thus resulting in an efficient way to preserve this raw material otherwise vulnerable to spoilage. Along the following centuries, the knowledge for making homemade yogurts and fermented milks spread all over the world. The first attempts to produce yogurt industrially were performed in Barcelona in 1919 by Isaac Carasso. Since the 1950s, the production of yogurt has grown significantly thanks to the intervention of several powerful agrofood groups setting up international activities. If 'set-type' and 'stirred' yogurts are the basic products, a large number of new recipes and processes have been created to diversify the products and address market demands. These alternations include the modification of the texture, resulting in drinking, frozen, and concentrated yogurts; modification of aroma and taste by addition of fruit, jam, and aroma compounds; modification of nutritional properties by changing the fat and sugar contents; and development of health-related elements with the use of probiotic strains or the inclusion of vitamins or phytostanols. The coverage of these issues has been contributing to a significant expansion of the overall consumption of yogurt and fermented milks worldwide.

As a result, the industrial production of yogurt and fermented milks in the world reached about 32–35 million tons in 2012, for an expected global market in 2015 of about $67 billion. In Europe (27 countries), the annual production was around 9.3 million tons, with Germany, France, and Spain being the three main producers covering 20%, 18%, and 9% of the European production, respectively. For the last 5 years in Europe, the total production increased by 10%, whereas for the last 30 years in France, the increase was of 38%. Besides Europe, the main producers of yogurt are China, Russia, Iran, and the United States, with 4.0, 2.5, 2.2, and 2.0 million tons per year, respectively. Production in South America and Central America and in Africa remains low with 1.5 and 0.4 million tons per year, respectively.

Definition and Main Types of Yogurts

Definition of Yogurt and Probiotic Fermented Milks

In essence, yogurts are fermented dairy products obtained from lactic acid fermentation by two species of lactic acid bacteria, that is, *Streptococcus thermophilus* and *Lactobacillus delbrueckii* subsp. *bulgaricus*. This fermentation leads to acidification and milk coagulation, without addition of rennet (as in cheese), and allows an increase of the shelf life as a result of the low pH. The sensory properties of yogurts rely on three main characters: (1) the composition of milk as raw material, which differs according to the milk source (e.g., cow, goat, or sheep; conventional or organic) and the fat content that can be adjusted to obtain full-fat, low-fat, or nonfat products; (2) the addition of ingredients that allow modifying the sensory properties (flavor, color, and texture) of the products, such as sweetening agents (sugar or other sweeteners for low-calorie products), flavoring agents (fruit aromas or vanilla) or fruits (small pieces enriched with sugar or jam), stabilizers (pectin, starch, or gelatin), or emulsifiers; and (3) the technology employed for the manufacture, which may vary depending on the operations during milk pretreatment (fat and nonfat solid standardization, homogenization, or heat treatment) or yogurt post-treatment (stirring, concentration, mixing, cooling, drying, or freezing).

Even if yogurt is the most consumed within the wider family of fermented milks, many probiotic fermented milks are traded around the world. They involve probiotic bacteria, which are defined according to the FAO/WHO in 2011 as 'live microorganisms that, when administered in adequate amounts, confer a health benefit on the host.' As European regulation has stated that these health benefits have to be demonstrated before using the probiotics in foods and supplements, the health claims are not anymore maintained. In other countries, and depending on the country regulation, the following health benefits are recognized: reduction of lactose intolerance, prevention of microbial infections, stimulation of the immune system, and regulation of immune responses.

Main Types of Yogurts and Fermented Milks

Yogurt diversification is reflected by various textures (set-type or firm, stirred, drinking, frozen, concentrated, or powder yogurts), numerous flavors (natural, sweetened, flavored, or with added pieces of fruits or honey), and diverse shelf life and nutritional (fat content and residual lactose content) properties. Figure 1 proposes a synthetic scheme of the several characters that lead to yogurt diversity.

Classification of fermented milks is also based on their potential health properties. They are mainly related to the decrease in lactose content in the product, as a result of lactic acid production. Some strains of *S. thermophilus* and *L. delbrueckii* subsp. *bulgaricus* are able to survive in the gastrointestinal tract, thus being able to play a role in the gut health. Finally, the development of US versions of Greek yogurt is associated to high protein but low carbohydrate contents, thus contributing to the weight management of consumers.

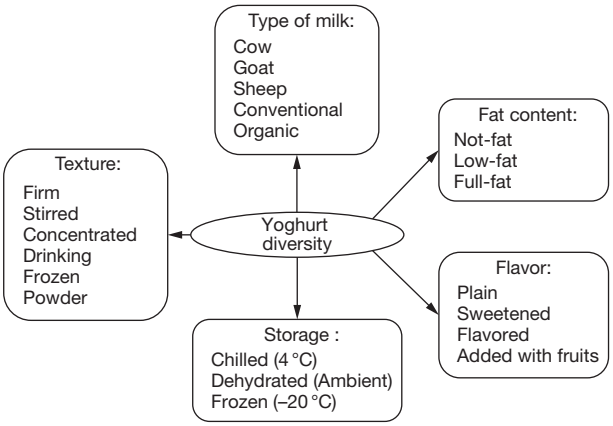

Figure 1 Classification scheme for yogurts and fermented milks.

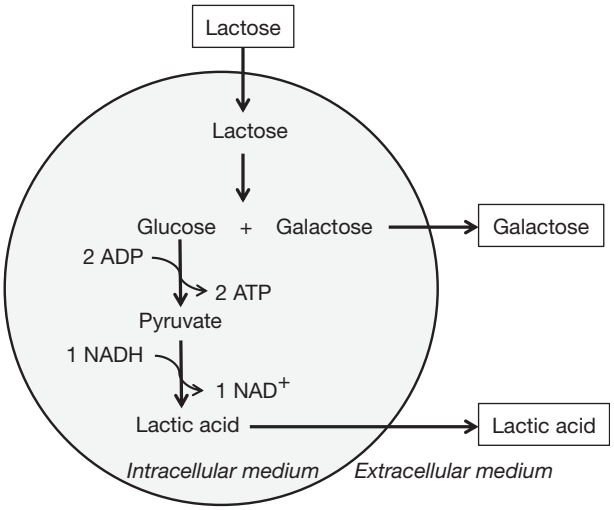

Figure 2 Simplified scheme of metabolic reactions involved in homofermentative metabolism in yogurt bacteria.

Microbiological and Biochemical Mechanisms Involved in Yogurt Manufacture

Microbiological Characteristics of Yogurts

The two thermophilic lactic acid bacteria, *S. thermophilus* and *L. delbrueckii* subsp. *bulgaricus*, which trigger yogurt fermentation, are considered as 'Generally Recognized as Safe' in the United States and possess the 'Qualified Presumption of Safety' status in Europe, as a consequence of a long history of safe use in food and an absence of pathogenicity. They are Gram-positive, anaerobic, aerotolerant, and catalase-negative, do not form spores, and have less than 55% G+C content in their DNA. They are able to grow between 42 and 50 °C, but not at 10 °C. *S. thermophilus* forms linear chains of rods, whereas *L. delbrueckii* subsp. *bulgaricus* grows as ovoid cells. They convert lactose into galactose that is not metabolized and glucose that is fermented predominantly to lactic acid, thus corresponding to homofermentative metabolism.

In milk, these two species demonstrate a positive interaction called protocooperation, which is mutually favorable. This phenomenon induces a more rapid growth and acidification, higher production of aroma compounds and exopolysaccharides, and more pronounced proteolysis. An upregulation of biosynthesis pathways for nucleotides and sulfur-containing amino acids is also observed. Growth of *S. thermophilus* is promoted by free amino acids and small peptides that arise from milk proteins by the action of the cell wall protease PrtB of *L. delbrueckii* subsp. *bulgaricus*. In return, *L. delbrueckii* subsp. *bulgaricus* is stimulated by formic acid, folic acid, and CO_2 that are synthesized by *S. thermophilus* in milk. As a consequence of this interaction, growth of *S. thermophilus* starts first by using the nitrogen compounds and stops early as this species is very sensitive to lactic acid inhibition. Growth of *L. delbrueckii* subsp. *bulgaricus* begins later but is prolonged even at low pH, due to the better resistance of this species to acidity.

Probiotic bacteria involved in fermented milk production other than yogurt include different lactobacilli and bifidobacteria. The main bacterial species found in commercial products are *Lactobacillus acidophilus*, *L. casei*, *L. paracasei*, *L. rhamnosus*, *Bifidobacterium animalis* subsp. *lactis*, and *B. breve*. These bacteria demonstrate numerous interactions with the classical yogurt cultures, which depend on specific strain associations.

Biochemical and Physicochemical Changes During Lactic Acid Fermentation

Growth of lactic acid bacteria in milk induces many changes that are desirable in yogurt. These changes include the synthesis of different metabolites (lactic acid, exopolysaccharides, and aroma compounds) and the modification of the texture and the nutritional value of the product.

Lactic acid production

As a result of glycolysis, one mole of lactose is theoretically transformed into one mole of galactose and two moles of lactic acid, together with the production of intracellular energy in the form of two moles of ATP. *S. thermophilus*, *L. delbrueckii* subsp. *bulgaricus*, and *L. acidophilus* operate these reactions according to a homofermentative metabolic pathway that is summarized in Figure 2.

Lactose is first internalized into the cell with the help of a lactose permease energized by a proton gradient. Intracellular lactose is then hydrolyzed into glucose and galactose by the enzyme α-galactosidase. Glucose is catabolized to pyruvate via the glycolytic pathway (Embden–Meyerhof–Parnas), whereas galactose is excreted out of the cell. Pyruvate is then reduced into lactic acid through a lactate dehydrogenase, together with the reoxidation of NADH formed earlier. Two different isomers are synthesized: L(+) lactic acid by *S. thermophilus* and D(−) lactic acid by *L. delbrueckii* subsp. *bulgaricus*. Finally, the intracellular lactate is excreted out of the cell via a symport with protons, thus inducing acidification of extracellular medium and progressive inhibition of bacterial growth.

Other lactobacilli and bifidobacteria may use heterofermentative pathways to produce their intracellular energy together with lactic acid. *L. rhamnosus*, *L. casei*, and *L. paracasei* produce one mole of each lactic acid, ethanol, CO_2, and ATP from one mole of glucose. Bifidobacteria synthesize three moles of acetic acid and two moles of (L+) lactic acid and ATP, without generation of CO_2 from two moles of glucose. These different pathways induce different acidification

rates and, consequently, different sensory properties of the final product.

Proteolysis

During milk fermentation, the proteolytic system of lactic acid bacteria degrades caseins into peptides and free amino acids that are essential to bacterial growth and participate in the generation of flavor. *L. delbrueckii* subsp. *bulgaricus* possess the cell surface proteinase PrtB that is highly active and promotes fast growth and rapid acidification of milk. In contrast, even if a few strains of *S. thermophilus* possess the cell wall proteinase PrtS, most strains are protease-negative. Growth of *S. thermophilus* is nevertheless effective in mixed cultures, since available nitrogen compounds are supplied from the proteinase of *L. delbrueckii* subsp. *bulgaricus*.

Flavor compound production

Yogurt taste is mainly characterized by an acid character due to the presence of lactic acid in the product. Yogurt aroma is characterized by about hundred volatile compounds that consist of carbonyl compounds (mainly acids and esters), alcohols, and heterocyclic and sulfur-containing compounds. Among them, acetaldehyde is the major flavor compound of yogurt, where it confers a pleasant fresh and fruity aroma. It is produced by the lactic acid bacteria at a final concentration comprised between 5 and 40 mg kg^{-1}. Most of the acetaldehyde is directly synthesized from pyruvate with the aid of pyruvate decarboxylase or indirectly from acetyl coenzyme A, through the action of pyruvate dehydrogenase and aldehyde dehydrogenase. *L. delbrueckii* subsp. *bulgaricus* is also able to convert threonine into acetaldehyde and glycine, through the action of serine hydroxyl-methyl transferase. In addition, *S. thermophilus* produces α-acetolactate that is partially metabolized into diacetyl or acetoin through the action of α-acetolactate decarboxylase that allows regulating leucine and valine biosynthesis.

Coagulation

Acidification of milk leads to coagulation as a result of destabilization of the casein micelles. The mechanism relies on two concomitant phenomena. During acidification, the net negative charge on casein micelles decreases, thus reducing electrostatic repulsion between charged groups. In the same time, the colloidal calcium–phosphate complex is solubilized, which results in the depletion of calcium in the micelles. Then, electrostatic and casein–casein attractions increase due to enhanced hydrophobic interactions. When the isoelectric point of caseins (pH 4.6) is achieved, coagulation occurs as a result of the formation of a three-dimensional network consisting of clusters and chains of caseins, which leads to the formation of the yogurt gel.

Exopolysaccharide production

Some strains of lactic acid bacteria contribute to the physical properties of stirred fermented milks through biosynthesis of extracellular polysaccharides (EPS), which are either homo- or heteropolysaccharides. These polymers are composed of several hundreds to thousands of repeating units of monosaccharides such as D-glucopyranose, D-fructofuranose, D-glucose, D-galactose, L-rhamnose, *N*-acetyl-D-galactosamine, and *N*-acetyl-D-glucosamine, with molecular masses ranging between 4×10^4 and 6×10^6 Da. *S. thermophilus* and *L. delbrueckii* subsp. *bulgaricus* produce EPS during growth, to final concentrations comprised between 30 and 600 mg l^{-1} in milk.

Biosynthesis of exopolysaccharides is governed by well-characterized gene clusters. It involves the production of precursors that are formed in the cytoplasm, related to the sequential addition of activated carbohydrates (UDP-glucose, UDP-galactose, and dTDP-rhamnose) by specific glycosyltransferases. These repeating units are coupled to lipid carriers and translocated across the membrane before polymerization.

Changes in nutritional value

Nutritional characteristics of yogurts differ from those of milk by the three main following aspects: (1) as a consequence of lactic acid production, the lactose content is lower in yogurt (30 g l^{-1}) than in milk (50 g l^{-1}), which is important for lactose-intolerant people, by limiting the formation of organic acids, hydrogen, methane, and carbon dioxide in the human gut; (2) the levels of calcium and potassium are higher in yogurt than in milk (200 and 255 mg 100 g^{-1}, respectively), as a consequence of nonfat solid adjustment; and (3) the concentration of folic acid is higher in yogurt than in milk. The latter essential vitamin is biosynthesized by *S. thermophilus* in the range of 20–150 μg l^{-1}, during which it is consumed by *L. delbrueckii* subsp. *bulgaricus*, thus leading to an average net level in yogurt of 80 μg l^{-1}, which exceeds the one in milk (40 μg l^{-1}).

Yogurt Manufacture

General Diagrams of Yogurt Manufacture

The industrial manufacture of yogurts is organized along three main steps: (1) the preparation of the mix and all corresponding physical treatments such as homogenization, heat treatment, cooling, and deaeration; (2) the fermentation process starting after inoculation of the mix; and (3) the yogurt harvesting, post-treatment, and packaging. Depending on the steps performed, at least four types of yogurt can be considered, whose manufacture is presented in Figure 3. One has to notice that each step of the manufacture affects the final quality of the yogurts and that, except for set-type yogurts, the product flavoring and the cup filling are performed after fermentation.

Preparation of the Mix

Milk standardization

In order to obtain the mix to be fermented, milk preparation involves mainly fat and protein content standardization and optional addition of sweeteners and stabilizers. Fat standardization consists of fat removal by centrifugation (at about 55 °C), followed by cream reincorporation to reach the targeted fat content, ranging from nonfat (0.01%), to low- or light-fat (1–2%), to whole-fat yogurts (>3.2%). Protein standardization aims at increasing the protein content of the mix (from 3% to 5–15%) in order to improve the yogurt firmness (texture) and reduce its syneresis. It is mostly done by addition of milk powder, which is the easier and traditional way. The use of milk proteins or milk replacers as caseinates or whey

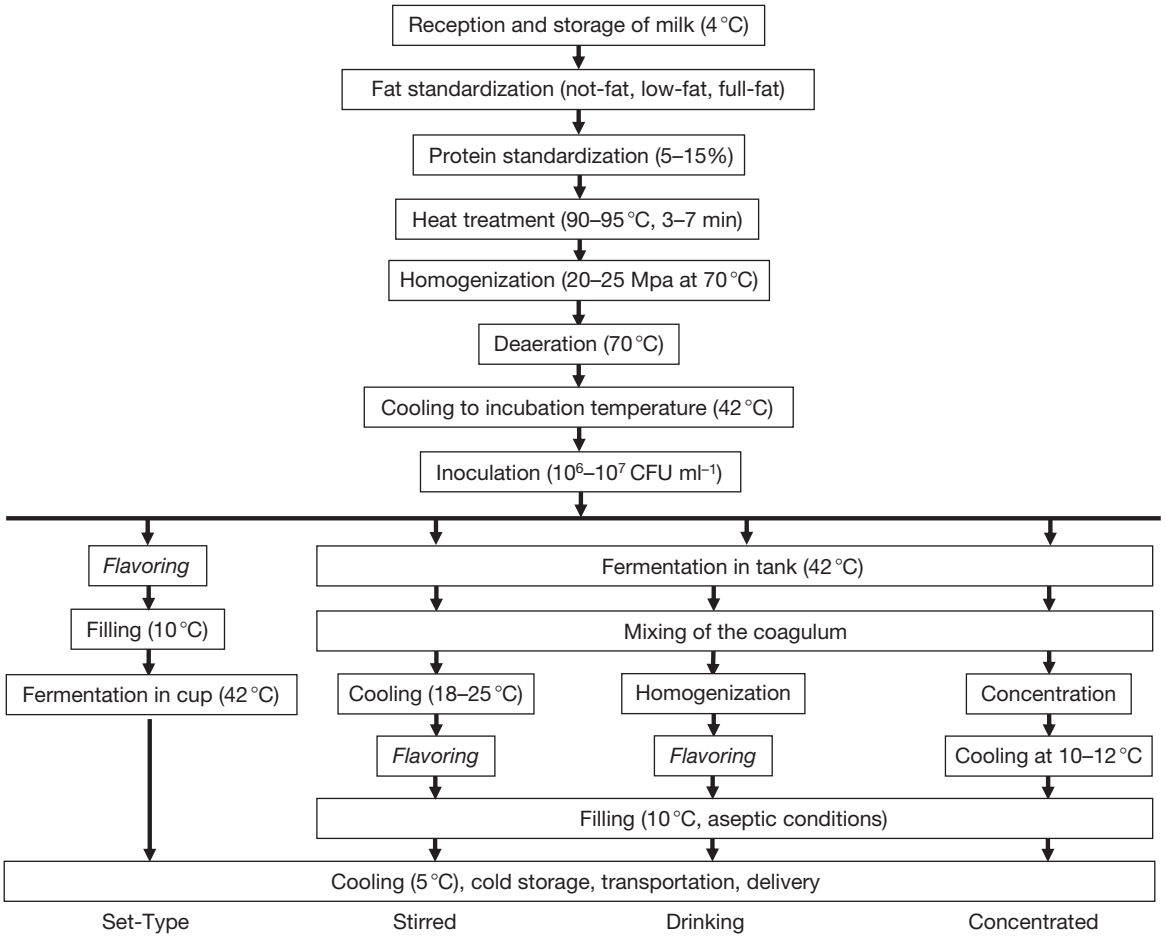

Figure 3 Schematic diagram of the production processes of set-type, stirred, drinking, and concentrated yogurts.

powders is also common. A complete mixing of the dry ingredients without air incorporation is recommended. Concentration of milk by membrane processes (ultrafiltration and reverse osmosis) is an alternative method to increase the protein content of the mix.

For some yogurt recipes, sugars or other sweetening agents are added to the mix, generally after the physical treatments described in the succeeding text. In some countries, the use of thickeners and stabilizers (gelatin, pectin, xanthan gum, carrageenan, starch, etc.) at concentrations varying from 5% to 10% is allowed by FAO/WHO to improve the yogurt texture.

Physical treatments of the mix

Heat treatment is an essential step of the mix preparation. It allows removing spoilage microorganisms, inactivating lactoperoxidases and producing stimulatory compounds in milk. In parallel, heat treatment contributes to improved yogurt texture by allowing whey protein denaturation and interaction with casein, resulting in a decrease of gel syneresis and an increase of gel firmness. During industrial yogurt manufacture, the mixes are generally heated at 90 or 95 °C for 3–7 min before cooling down to fermentation temperature. Plate heat exchangers, with a tubular holding zone, are generally used and are designed in order to cool the mix accurately at the fermentation temperature (between 37 and 43 °C).

Two other physical treatments of the mix, deaeration and homogenization, are closely associated with the heat treatment, and the design of the heat exchangers takes into account the temperature favoring their effect. Homogenization is compulsory for yogurt quality, as it increases the gel texture and reduces syneresis. It provokes a reduction of the size of the fat globules (near 2 μm) and a better link between fat and hydrophilic proteins. Homogenization of the mix is done at high pressure (20 or 25 MPa) and at a temperature close to 70 °C. Associated with the heat treatment of the mix, it takes place just after the holding section of the heat exchanger. Double-stage high-pressure homogenizers are recommended for high-fat yogurts. Vacuum deaeration of the mix is performed at large industrial scale to reduce its oxygen content and consequently shorten the fermentation time, as to improve the yogurt texture and to remove off-flavors. This step is generally performed at 70 °C, before homogenization.

The Fermentation Process

Inoculation of the mix

At industrial scale, yogurts are prepared through inoculation of the mix with concentrated starter cultures of the two yogurt bacteria (*S. thermophilus* and *L. delbrueckii* subsp. *bulgaricus*). The commercial starter cultures are composed of specific

blends of selected and well-defined strains, at a concentration higher than 10^{10} colony-forming units (CFU) g^{-1}, and are preserved as frozen or freeze-dried formulations. The inoculated mix contains generally 10^6–10^7 CFU ml^{-1} of bacteria. After mixing, it is transferred to the fermentation tanks (for stirred, drinking, or concentrated yogurt manufacture) or directly to the packaging machine for fermentation in cups (for set-type yogurt manufacture).

Fermentation step

During the lactic acid fermentation of milk, numerous parameters vary as a function of time, as shown in Figure 4. The growth of *S. thermophilus* occurs first, followed by that of *L. delbrueckii* subsp. *bulgaricus*, reaching final concentrations close to 10^9 CFU g^{-1} (Figure 4(a)). The consumption of lactose and nitrogenous compounds permits the growth of both strains and leads to the accumulation of many relevant metabolites. Lactic acid, galactose, acetaldehyde, and exopolysaccharides are the most important ones, contributing to flavor and texture of the yogurt (Figure 4(b)). The synthesis of extracellular lactic acid provokes an acidification of the mix characterized by a decrease of the pH (Figure 4(a)), the coagulation of proteins, and the subsequent gel formation. Acetaldehyde confers to yogurt its particular aroma, and exopolysaccharides contribute to its texture.

The acidification process is controlled by the final pH of the yogurt and the acidification rate, which are key factors to master quality. The fermentation is stopped (by a fast cooling of the product) when the final pH of the yogurt is reached. The targeted final pH varies from 4.8 to 4.5, as a function of the type of yogurt. A significant postacidification during the yogurt's cooling, harvesting, and storage has to be considered in defining this target. Generally, online measurement of pH of the mix is avoided, because the glass pH probes may break inside the mix and need to be submitted to cumbersome protocols of cleaning and calibration. Consequently, only manual sampling is done during the acidification process to allow offline pH measurements, and the decision to stop the fermentation by cooling requires a good expertise of the process. The acidification rate acts directly on the fermentation time, so that its knowledge and control are very important to properly schedule industrial production. It is influenced by various factors, such as starter composition and activity, mix composition and physical treatments, and fermentation temperature. However, accurate temperature control is quite impossible during yogurt fermentation because of the coagulation phenomenon that occurs at about pH 5.2. As a consequence, the fermentation time can vary in important ranges. For probiotic yogurt, fermentation time can reach 6–8 h, whereas for stirred yogurt, a 3–4 h

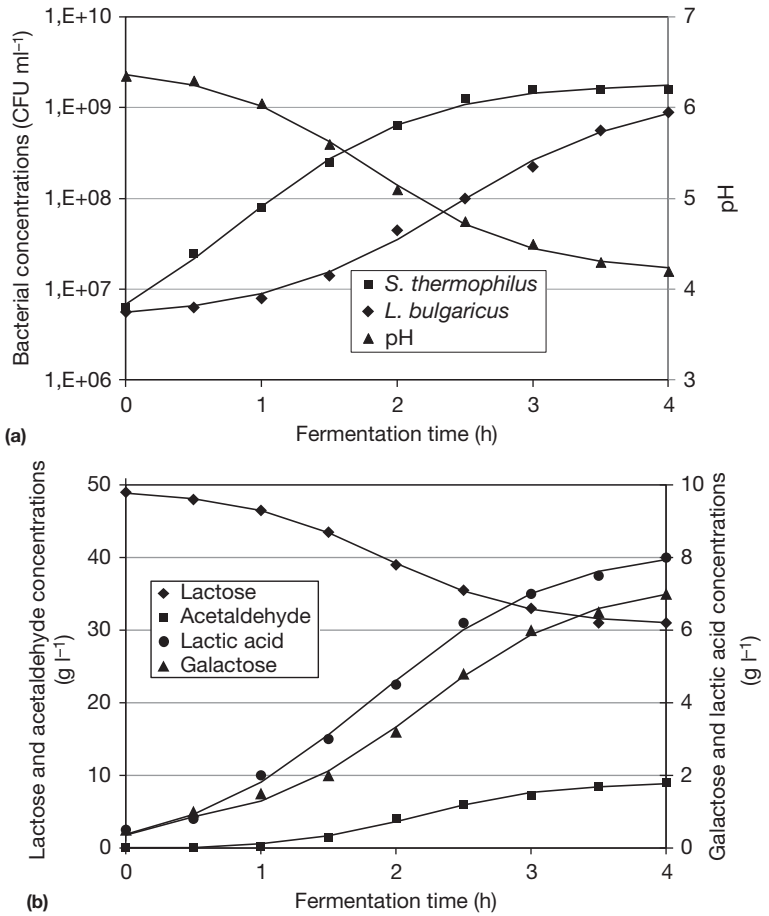

Figure 4 Growth of *S. thermophilus* and *L. delbrueckii* subsp. bulgaricus and milk acidification (a) and evolution of lactose, galactose, lactic acid, and acetaldehyde concentrations (b) as a function of fermentation time.

process is the common target. However, industrial manufacturers have difficulties to master perfectly all the parameters of the process, and longer fermentation times (5 or 8 h) are frequently attained.

The fermentation of set-type yogurts is generally performed in cabinets, incubation rooms, or large tunnels in which the pallets move forward gradually with forced ventilation of warm air. The fermentation of stirred yogurts is performed in large tanks (15–20 m^3 for the largest ones) equipped with mixing devices for mix homogenization, starter mixing, and gel breaking after fermentation.

Yogurt Harvesting and Packaging

Cooling and harvesting of yogurt

The first step in yogurt harvesting corresponds to a fast cooling of the product in order to stop its acidification. It takes place when the required final pH of yogurt is obtained. Set yogurts are cooled within 1 or 2 h to 4 or 5 °C using cold air in ventilated cabinets, cooling rooms, or tunnels, as a function of the size of the manufacturing unit. For stirred yogurt, the cooling is performed in an external heat exchanger reaching an intermediate temperature (between 18 and 25 °C) in less than 1 h (20–60 min for industrial tanks). At this temperature, some additives as aroma compounds, sweeteners, and fruits (jam, pulp, and pieces) can be added to stirred yogurts. In modern large plants, these additions are generally performed online at the level of the packaging machine, using metering pumps and mixers.

The final texture of yogurts, especially stirred ones, is a critical factor for consumer acceptance. As the texture is influenced by many factors (mix composition, strains used, and processing conditions), it is a real challenge to obtain the targeted texture. The mechanical constraints exerted on stirred yogurt by all the harvesting devices (pumps, heat exchangers, pipes, mixers, filling machine, etc.) tend to reduce its texture but can give them some smoothness.

Packaging of yogurt

Yogurt packaging ensures its hygiene and protection during distribution. If plastic and glass cups are always used for set-type yogurts, large up-to-date packaging units use the 'form–fill–seal' technology. The same packaging machine realizes the three main following operations: (1) the thermoformation of the containers at 150–200 °C, using multilayer thermoplastic materials, (2) the filling of the preformed containers under a closed environment and sterile air overpressure, and (3) the thermosealing of the filled containers with an aluminum lid labeled to deliver product information. These high-tech packaging machines allow reaching high security and high capacity (up to 70 000 cups per hour) standards. Consequently, they correspond to the most expensive investment in an industrial manufacturing unit of yogurt.

Overpackaging is then carried out, in the form of multipacks of 2, 4, 8, or 16 cups, with the help of an automatic tray packer. After packaging and overpackaging, the yogurts are stored at low temperature (4 or 5 °C), which is maintained during transportation and commercialization. This low temperature maintenance permits limiting the postacidification in the products and preserving their safety.

Industrial Design of Yogurt Manufacturing Units

All equipments used for milk storage, mix preparation, fermentation and yogurt cooling, and harvesting and packaging are especially designed to allow for the cleaning in place (CIP) procedures commonly used in dairy industry. These procedures assume the existence of a CIP kitchen in the factory to automatically provide the cleaning mixtures at the right temperature and for the right duration.

Yogurt fermentation is a batch process, but some operations such as mix preparation and treatment and yogurt cooling and packaging are designed and managed as continuous or semicontinuous processes. In industrial manufacturing units, automation and process control systems are more and more popular. They encompass (1) sensors that essentially measure physical parameters such as temperature, pressure, level, and weight; (2) programmable logic controllers controlling valves, pumps, and motors that permit the regulation of the main process parameters; and (3) computer supervision that allows traceability. Nevertheless, as an accurate control of the yogurt acidification rate remains limited, optimization of yogurt manufacture is not possible.

Finally, even if the acidity of yogurt contributes to its safety, industrial manufacturers observe good manufacturing practices to control the microbial risk. They act mainly on food contact surfaces that have to be cleaned and sanitized before use and impose clothing and hair covering for the staff.

Control of Yogurt Quality

Yogurt quality requires controls of the raw materials, during the course of the manufacturing process and on the final products.

Quality Controls of Raw Materials

Microbiological controls are carried out on raw materials, in particular fresh milk, powder milk, fruits, sweeteners, and starters. Somatic cell counts are also verified on fresh milk. In addition, many physicochemical properties are checked: (1) temperature, titratable acidity, and fat and protein contents of the fresh milk; (2) the absence of antibiotics, solubility, moisture, and fat content of the milk powder; and (3) pH, viscosity, and Brix of the added fruits. Acidification activity of starter cultures is also assessed, mostly by using the Cinac system that allows determining various quantitative kinetic descriptors such as the absolute value of the maximum acidification rate (Vm, in min^{-1}) and the time (tm, in min) necessary to reach Vm. The lower the value of tm and the higher the value of Vm, the higher the acidification activity will be. Figure 5 shows typical acidification curves and corresponding first derivatives (kinetics) of two yogurt starter cultures growing in milk and displaying low (Vm = −1.33 pH unit h^{-1}; tm = 2.55 h) or high acidification activity (Vm = −1.44 pH unit h^{-1}; tm = 2.05 h).

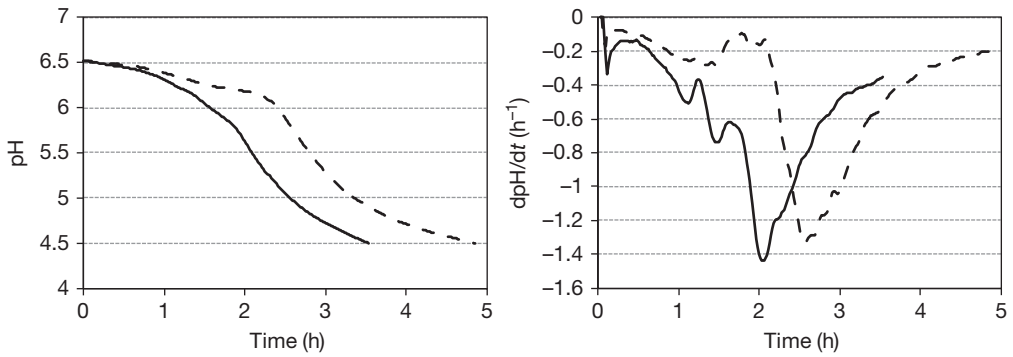

Figure 5 Acidification activity of two yogurt starter cultures, displaying high acidification activity (—) and low acidification activity (—) determined using the Cinac system.

Controls During the Process

During yogurt manufacture, controls are accomplished to ensure repeatability of the productions and maximal levels of quality and food safety of the products. They refer mainly to the control of temperature (in fermentation tanks, heat exchangers, incubation rooms, and cooling systems), pH (by sampling either in the fermentation tanks or directly in cups), and duration of the different steps of manufacture.

In addition to these controls, the use of food safety management systems such as ISO 22000 or International Food Standards is requested to control foodborne safety hazards and guarantee the products' safety. By implementing Hazard Analysis and Critical Control Point systems according to the Codex, three steps are identified as critical control points for microbiological hazards during yogurt manufacture: pasteurization of milk, refrigerated packaging, and cold storage. In addition, packaging is also related to physical hazards.

Quality Controls of the Final Product

Various controls are performed on the final products at the end of their manufacture and during their shelf life. The frequency of sampling is defined by each dairy factory, as stated by its own good hygiene practices.

Counts of *S. thermophilus* and *L. delbrueckii* subsp. *bulgaricus* are controlled to verify that the targeted value of 10^7 CFU g^{-1} at shelf life is achieved. The presence of spoilage and pathogenic microorganisms, including *Listeria monocytogenes*, *Salmonella* spp., coliforms, yeasts, or molds, is also checked.

Physicochemical analyses consist of the verification of the fat and total solid contents, the titratable acidity or the pH of the products, and the assessment of some texture parameters including firmness, consistency, or viscosity, depending on the type of yogurt (set-type, stirred, or drinking yogurt). Sensory evaluations are completed with experienced panelists. The following main sensory attributes are generally employed: appearance (syneresis and color), texture (palatability, firmness, and consistency), aroma and odor, and taste and aftertaste (freshness, acidity, and persistency).

Conclusion

Yogurt is an ancient traditional fermented food that has known, since half a century, a tremendous industrialization of its manufacturing conditions. In more recent years, an intense innovative diversification of recipes and products occurred, which partly explain the increase of their consumption. Although artisan production schemes persist, including homemade yogurt manufacture, the industrial manufacture of yogurt is now well established. Breakthrough innovations are limited and the improvements in process productivity relate mainly to the design and the management of the manufacturing units. Nevertheless, the interesting nutritional properties of yogurts and more generally of fermented milks, their diversity, and the opening and increasing of new markets offer important perspectives for their development at world scale.

Yogurt: Yogurt Based Products

P Behare, H Kumar, and S Mandal, National Dairy Research Institute, Karnal, India

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Yoghurt or yogurt is a dairy product made by lactic fermentation of milk, usually using a defined mixed starter culture. The term 'yoghurt' relates to the Turkish word '*Jughurt*' and in particular to *yogurmark* 'to knead' and *yogum* 'dense' or 'thick.' It is believed that Ancient Turkish nomads were the inventor of yoghurt, which they called '*yoghurut*,' after which Turkish immigrants brought it to North-America in the eighteenth century. Isaac Carasso was the person who started industrial production of yoghurt in 1919 under the brand name 'Danone' in Barcelona. The traditional method of yoghurt manufacture employs 'back-slopping,' according to which a part of a previous day's product is added to fresh milk as a starter inoculum. With the advancements in starter culture technology during the last five decades and due to the microbiological problems sometimes associated with the use of back-slopping, which may lead to failed fermentations, yoghurt manufacturers have shown their interest in applying pure forms of starter cultures.

Historical evidence suggests traditional occurrence of yoghurt and yoghurt-based fermented milk products all over the world, although different terminologies are used in different countries. The method of manufacture for these products is nevertheless quite similar to yoghurt production. The only difference is in the use of specific cultures, incorporation of additives, curd treatment, and method of packaging. Generally, commercial yoghurt is produced from cow milk but milk from other animal species like buffalo, goat, camel, yak, sheep, and mare can also be used, in particular in traditional and ethnic products. Recently, plant 'milks' such as soy, coconut, almond, and sesame milk are used to alter the functionality of yoghurt. In order to improve functional and therapeutic importance, yoghurt containing selected probiotic microorganisms has also been developed.

Types of Yoghurt

Yoghurt produced around the world can be categorized on the basis of chemical composition, method of production and texture formation, the use of additives and special cultures, and based on the post-incubation treatments employed (Figure 1). With respect to the chemical composition, the fat content is crucial. As such, yoghurt is classified as skimmed, partially skimmed, and high-fat or full-fat yoghurt. The fat content is adjusted before the heat treatment is given to the milk. On the basis of texture, two main types of 'set' and 'stirred' yoghurt are produced. In addition, a cocktail of set or stirred type product can be made when combining different varieties of yoghurt (flavored/fruit, fortified, low-fat, plain, sweetened, and probiotic yoghurt) (Figure 2). Further, to enhance the shelf life of yoghurt, certain post-incubation processes are employed and the product obtained is termed as heated, frozen, or dried yoghurt. The different global types and varieties of yoghurts are explained below.

Based on Chemical Composition

The Codex Alimentarius has mentioned three types of yoghurt on the basis of the milk fat content. The milk solids other than fat ($\geq$8.25%), the titratable acidity ($\geq$0.9%), and the pH ($\leq$4.5) remain almost similar for full-fat, partially skimmed, and skimmed yoghurt.

Full-fat yoghurt

Full-fat yoghurt is prepared from high-fat milk. As per the standards, milk fat content in full-fat yoghurt should not be less than 3.0%. *Rahmjoghurt* is a type of full-fat creamy yoghurt in Germany consisting of about 10% fat.

Partially skimmed yoghurt

Partially skimmed yoghurt is prepared from milk containing medium fat levels, generally ranging between 0.5 and 3.0%. The fat content in the final product should not be less than 0.5% and not more than 3.0%.

Skimmed yoghurt

Skimmed yoghurt is also called low-fat or reduced-fat yoghurt. The fat content is very low, namely below 0.5%. This form of yoghurt is particularly popular in contemporary food markets and there is growing demand for such products. However, poor flavor, body and texture and more syneresis are the major problems encountered during the production of skimmed yoghurt. These problems can be partially overcome via an increase in the total solid content of milk by addition of skim milk powder, whey protein concentrate, sodium and calcium caseinates or other milk protein-based gradients into the milk before fermentation.

Based on Method of Manufacture/Texture Formation

Set yoghurt

Set yoghurt has gel-like characteristics with particular texture and rheological properties. During its production, the fermentation of milk occurs in cups or containers and the final product remains as such until its distribution and consumption.

Plain yoghurt is a simple type of set yoghurt without use of additives. By virtue of their metabolic activities, yoghurt bacteria convert lactose into lactic acid and produce flavor compounds like acetaldehyde and acetoin during milk fermentation. As a result, the final product exhibits a mild to acidic taste with balanced amounts of natural yoghurt flavor. Plain

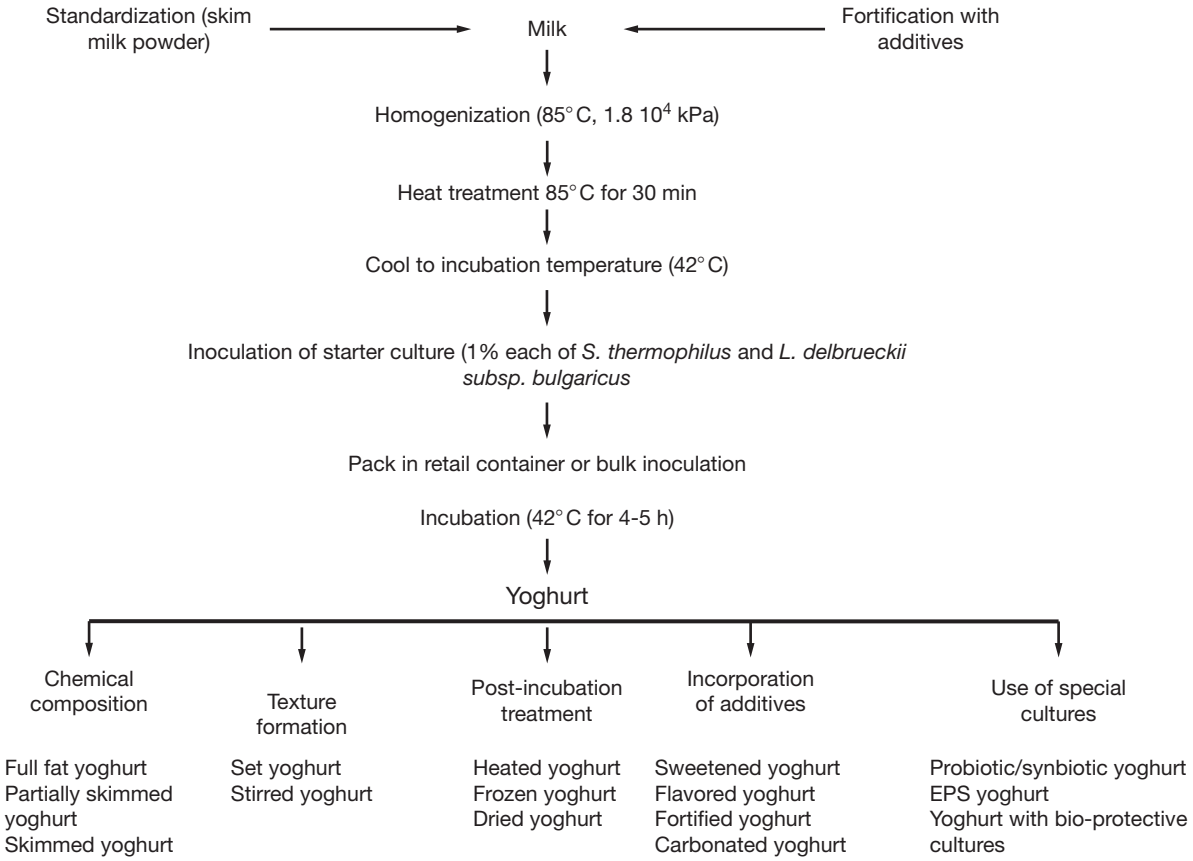

Figure 1 Flow diagrm for manufacture of major types and varieties of yoghurt.

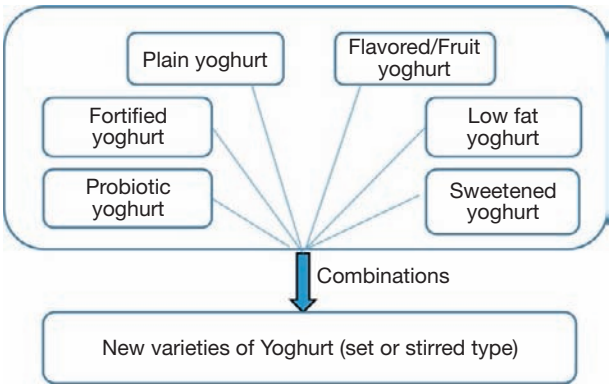

Figure 2 Cocktail of set and stirred yoghurt varieties.

yoghurt is usually consumed with salad or blended with salt or sugar.

Stirred yoghurt

Stirred yoghurt has a semi-solid consistency and is usually prepared by shearing of set yoghurt. The final product does not have gel like texture. Mechanical damage causes whey separation, which is overcome by supplementation of the skim milk powder and addition of stabilizers. Another category of stirred yoghurt is drinking or fluid yoghurt, which has a low viscosity.

Based on Post-Incubation Treatment

Heated yoghurt

Natural yoghurt stored at 4 °C gives a shelf life of one to 3 weeks, depending on the initial quality (based on pH, titratable acidity, and microbial contaminants present). This is due to the increase in acidity by the starter bacteria that continue to grow even at low temperature (post-acidification), resulting in a product that is too sour. Spoilage can also occur due to the growth of fungal contaminants. To increase the shelf life, the yoghurt may be heated at 60–70 °C for 1–5 min. Heated yoghurt is called 'pasteurized'/'UHT'/'heated'/'long life' yoghurt, depending on the time/temperature combination used. Such heating extends the shelf life of yoghurt up to 8 weeks. However, heat treatment also increases whey separation, decreases flavor, and destroys the live (starter) bacteria. As such, it creates legal complications related to regulations based on the FAO/WHO definition, implying that the presence of viable starter organisms in abundance is essential. Use of certain hydrocolloids, such as pectins, alginates, and carboxymethyl cellulose, when added to yoghurt before heat treatment, reduces whey separation and – up to some extent – damage by heat treatment.

Frozen yoghurt

Frozen yoghurt has an ice cream-like texture with a yoghurt flavor. It is generally prepared by mixing plain yoghurt to an ice

Table 1 Varieties of frozen yoghurt

Soft frozen yoghurt	*Hard frozen yoghurt*	*Frozen yoghurt mousse*
Made with a 80% yoghurt base blended with 20% fruit syrup	Made by blending of a 35% fruit syrup and stabilizers/emulsifier into a 65% yoghurt base	Made by mixing of yoghurt with a hot mousse base mixture that consists of skim milk, sugar, and stabilizers/emulsifiers

cream mix, followed by freezing. Different varieties, such as soft, hard, and mousse-frozen yoghurts exist (Table 1). The temperature used during freezing varies from −6 to −25 °C. There are no official standards for frozen yoghurt but some countries have specified that the final product should have more than 3.25% milk fat, 8.25% non-fat milk solids, and 0.15–0.30% of titratable acidity.

Ice cream mixes for frozen yoghurt contain hydrocolloids, emulsifiers, sweeteners, non-fat solids, and fat replacers. From a consumer's health point of view, low-calorie frozen yoghurt has been made by addition of isomalt and soluble dietary fibers. Addition of polydextrose, inulin, and isomalt increase the nutritive value, enhance viscosity, lower the caloric density, and reduce the melting of frozen yoghurt. Addition of a probiotic culture also enhances the perceived health properties as the supplementation of, for instance, *L. acidophilus* and *B. longum* to frozen yoghurt may bestow certain health benefits, such as an improved control of intestinal infections, lactose utilization, and anticancer activity. However, these claims are not always based on solid scientific data. Also, there may be problems associated with the survival of starter and probiotic bacteria due to the frozen food matrix. Addition of sweeteners at high concentration also causes a negative impact on bacterial performance. Other problems encountered with probiotic product varieties are related to the acidic conditions in the final product and the presence of oxygen, that often inhibit *Bifidobacteria*, albeit in a strain-dependent manner. Microentrapment or microencapsulation of probiotic bacteria can partially solve this problem.

Dried yoghurt

Dried yoghurt or powder yoghurt production is practiced in many countries. The main objective for the production of dried yoghurt is to extend shelf life and to facilitate easy handling and transport. Dried yoghurt can be produced by sun drying, air drying, spray drying, freeze drying, or microwave drying. Spray-dried instant yoghurt powder and skim-milk yoghurt powder are prepared commercially. Drying of yoghurt causes low water contents and creates unfavorable conditions for the growth of spoilage-causing microorganisms, especially yeasts and molds. *Kurut* in Turkey is an example of dried yoghurt. However, the nutritive value of yoghurt is degraded during the concentration process and the drying causes a loss of volatile flavor compounds. Powder yoghurt can be used as an ingredient for the manufacture of confectioneries, bakery foods, soup bases, dips, and sauces.

Based on Incorporation of Additives

Sweetened yoghurt

Sweetened yoghurt is prepared by addition of sugar syrup, honey, and cane juice to obtain a sweet taste. *Misti dahi*, *Shrikhand*, and *Kossam* are popular types of sweetened yoghurt in India and Cameroon (see below). Caramelization of sugar may impart a light brown color to the final product as in the case of *Misti dahi*. Yet, high sugar contents in such products also increase the caloric content and may inhibit the growth of starter organisms. Generally, high-sugar tolerating strains are used to produce sweetened fermented milk products. Attempts have been made to reduce calories in these products by replacing sugar with artificial sweeteners like aspartame and acesulfame-K.

Flavored/fruit yoghurt

Flavored yoghurt is very popular among consumers. This form is generally prepared by addition of fruit pieces or cubes, pulp, juice or concentrated juice, paste or flavored syrup, or spices or spice-extracts to milk prior to fermentation. More than 40 types of fruit or their cocktails have been used for the production of fruit yoghurt, often including strawberry, mango, kiwi, peach, apricot, banana, and blue berry fruits.

Fortified yoghurt

A food fortification strategy is used to target specific micronutrient deficiencies among the population. According to the FAO/WHO, fortification refers to 'the practice of deliberately increasing the content of an essential micronutrient, i.e. vitamins and minerals (including trace elements) in a food irrespective of whether the nutrients were originally present in the food before processing or not, so as to improve the nutritional quality of the food supply and to provide a public health benefit with minimal risk to health.' Yoghurt is consumed worldwide and considering the popularity, it has been fortified with micronutrients via the addition of whey powder or specific compounds such as iron, magnesium, or certain vitamins (Table 2).

Carbonated yoghurt/yoghurt soda

Carbonated yoghurt is prepared on the basis of carbon dioxide gas, generally recognized as safe by the U.S. Food and Drug Administration (FDA), after the fermentation of milk has been performed. Carbon dioxide is incorporated in the cooled yoghurt (0.08–0.09 kg cm^{-2}) by the way of a hose. It is made to improve the refreshing ability of yoghurt. Carbonated yoghurt also has a longer shelf life, as carbon dioxide creates an anaerobic environment, inhibiting aerobic microorganisms. Carbon dioxide also forms carbonic acid in an aqueous medium and thus decreases the pH of product, which inhibits the growth of spoilage microorganisms. *Doogh* is an example of a carbonated yoghurt-based beverage. Similarly, carbonated plain yoghurt, flavored yoghurt, and fruit yoghurt can be prepared.

Table 2 Varieties of fortified yoghurt (non-exhaustive list)

Yoghurt type	*Concentration of added compounds*	*Properties*
Mango-based soy yoghurt	14.5% soy milk 7.2% mango pulp	Soy bean provides micronutrients, whereas mango pulp provides easily digestible carbohydrates and improves flavor
Yoghurt with added grapes marc flour	2% marc flour of grapes	Grapes marc provides proteins fibers, phenolic compound, and fructo-oligosaccharides
Yoghurt with added wheat bran and carrots	Carrot 1% Wheat bran 1%	Carrots provide vitamins (ß-carotene), minerals and dietary fiber, whereas wheat bran provides dietary fibers
Inulin-fortified yoghurt	2.5% long-chain inulin	Inulin acts as dietary fiber and prebiotic
Yoghurt with added grape seed extract	5–10 mg gallic acid in 100 g of yogurt	Grape seed extract provides polyphenols and enhances the antioxidative and antiradical activity of yoghurt
(Strawberry) yoghurt fortified with marine fish oil	2% fish oil	Fish oil is source of long-chain $n-3$ fatty acids
β-Glucan fortified set yoghurt	0.3% β-glucan	β-Glucan improves Probiotic viability and stability
Iron-fortified yoghurt	20 mg of iron per kg of milk	Provides iron (a limiting micronutrient in conventional dairy products)
(Lemon-flavored) folic acid-fortified yoghurt	400 μg folic acid in 224 ml of yogurt	Folic acid reduces the risk of colorectal and breast cancers
Yoghurt fortified with vitamins A, D and/or C	10 000 IU of vitamin A and 300 ng of vitamins C and D in a 227 g container of yoghurt	Provides vitamins A and C and vitamin D improves glycemic control in patients
Leutin-fortified (strawberry) yoghurt	Up to 3 mg in 170 g of yogurt	Lutein is a carotenoid that may help to prevent age-related macular degeneration (AMD)

Based on the Incorporation of Special Cultures

Probiotic and synbiotic yoghurt

According to the FAO/WHO standards, yoghurt is 'the coagulated milk product obtained by lactic acid fermentation through the action of *Streptococcus thermophilus* and *Lactobacillus delbrueckii* subsp. *bulgaricus*.' In addition, adjunct cultures and probiotic cultures belonging to the genera of *Lactobacillus*, *Bifidobacterium*, *Enterococcus*, *Propionibacterium*, and *Pediococcus*, as well as yeast and molds are sometimes used in yoghurt-like products. Yoghurt is an often used and suitable carrier for the administration of probiotic bacteria, often in a drinkable form. Probiotics are sometimes used in combination with prebiotics, which is known as a synbiotic approach. Prebiotics are non-digestible food ingredients that selectively stimulate the growth and metabolism of beneficial microorganisms, such as probiotics. Commonly used prebiotics include inuline, fructooligosaccharides, and galactooligosaccharides.

Exopolysaccharide-containing yoghurt

Starter cultures producing exopolysaccharides (EPS) have interesting commercial application. To reduce the amount of added milk solids, improve yoghurt viscosity, enhance texture and mouth feel, and to avoid syneresis during fermentation or upon storage of the fermented milk products, EPS-producing functional starters have received much attention. In the recent past, EPS-producing strains of *S. thermophilus* and *L. delbrueckii* subsp. *bulgaricus* have been used, especially in low-fat/non-fat yoghurts to improve the rheological and sensory properties. Because milk fat contributes to the body, texture, and flavor development of the dairy products, fat reduction may lead to suboptimal product quality. Fermented milk manufacturers have used texture-promoting or ropy starter cultures for many years, particularly when the addition of stabilizers is prohibited or undesired.

Yoghurt with bio-protective cultures

The shelf life of yoghurt is short, i.e., 1 day under ambient condition (25–30 °C) and around 5 days at 7 °C, often due to the growth of yeasts and molds (e.g., *Saccharomyces*, *Candida*, *Debaryomyces*, *Kluyeromyces*, *Rhodotorula*, *Penicillium*, and *Aspergillus* species). Growth of these fungi deteriorates the physicochemical and sensorial characteristics of yoghurt, rendering the product unacceptable for human consumption. Certain *Lactobacillus* species have shown potent antimicrobial activity. For instance, selected *Lactobacillus casei* strains may produce antifungal compounds such as lactic acid, cyclo-(Leu-Pro), 2,6-diphenyl-piperidine, and 5,10-diethoxy-2,3,7,8-tetrahydro-1H,6H-dipyrrolo[1,2-a;1′,2′-] pyrazine that can enhance the shelf life of yoghurt up to 14 days at 30 °C. During their growth in milk, protective cultures secrete arrays of antifungal metabolites, composed of organic acids, phenyllactate, antimicrobial peptides, and cyclic dipeptides, that act on the spores, conidia, and cells of fungi and prevent germination. Potent antifungal lactic cultures can thus be used as starter or adjunct or antimicrobial preparations to enhance the shelf life of yoghurt. Commercial antimicrobial preparations of *Propionibacterium shermanii* or specific lactococci, consisting of propionic acid, acetic acid, diacetyl, and other inhibitory metabolites that control the growth of yeasts, molds, and gram-negative psychrophiles can enhance the shelf life of commercial yoghurt up to 82 days at 5 °C. Similarly, a protective culture of *Propionibacterium jensenii* has been used alone and in combination with a *Lactobacillus* culture to enhance shelf life without change in sensory properties.

Yoghurt-Based Products

Dahi

Dahi is a popular fermented milk of India and its neighboring countries. Its therapeutic effects are mentioned in the

Ayurveda, the oldest system of medicine in India. Its body and texture are similar to set yoghurt. Homemade versions are prepared by a traditional method, where a part of old *Dahi* is used as a natural starter culture to prepare a fresh batch. *Dahi* generally contains mixed starter communities, consisting of species of *Lactobacillus*, *Streptococcus*, *Lactococcus*, *Leuconostoc*, *Enterococcus*, etc. *Dahi* is also made as an intermediate product in the manufacture of *Desi* butter and ghee or *Shrikhand*. Many commercial players have started manufacturing the product on an industrial scale in India. Value-added *Dahi* with enhanced nutritive and therapeutic properties is now prepared by fortification of fruit pulp, spices, honey, and cereals.

Misti Dahi

Misti Dahi, *Lal Dahi*, or *Payodhi*, a sweetened variety of dahi similar to sweetened yoghurt, is a popular fermented milk product in the Indian subcontinent, especially in eastern India. Metabolic activity of mixed starter cultures of *S. thermophilus* and *L. delbrueckii* subsp. *bulgaricus* converts buffalo and/or cow milk into firm set curd. Traditionally, *Misti Dahi* is prepared from boiling buffalo milk with 6–25% of cane sugar and partially concentrating it by simmering over a low fire during which the milk develops a distinctive light cream to light brown caramel color and flavor. This is then followed by lactic fermentation by using a previous lot of *Misti Dahi* as natural, back-slopping starter culture. It contains a high level of total solids, which give a firm body and develop the brown color and typical caramelized flavor after intense heating. The product is prepared by the Halwais on a small scale. It is a delicacy of choice during religious festivities and is considered an auspicious item to serve before starting a journey or any important work. The product is commonly sold in earthen pots of varying sizes, and served chilled.

Kossam

Kossam is a sweet set fermented milk product of Cameroon prepared by inoculation of yoghurt starter or old *Kossam* in fresh milk. Sugar is added to warm heated milk to minimize the caramelization of sugar.

Shrikhand

Shrikand is a sweetened, semi-solid fermented milk product, popular in the western part of India. It is made from chakka intermediate product and resembles strained yoghurt. Final products have high total solid contents (50–60%). Flavored *Shrikhand* with high nutritive value is prepared by adding cardamom, keser, fruit pulp (apple, mango, banana, papaya, etc.), and flavor (rose). The starter cultures used in the manufacture of *Shrikhand* are similar to the ones that are used in *Dahi* manufacture.

Lassi and *Rob/Roub*

Lassi is a refreshing fermented milk beverage prepared by churning of *Dahi* or yoghurt. It is popular in the northern region of India and mostly consumed during the summer season. Addition of sugar, salt, spices, and fruit pulp enhances its flavor and nutritive value.

Rob/Roub is similar to *Lassi* and popular in Sudan. During its production, churning of yoghurt is done in a goat skin container called Si'in or in a container called Bukhsa. The final product has a low pH of 4.0–4.5 and a pleasant and sour flavor.

Gariss

Gariss is a full-cream, sour, fermented camel milk product popular in Sudan. Milk fermentation occurs in a tanned goat skin bag continuously for months. Mixed cultures of *Streptococcus thermophilus*, *Lactobacillus* spp. and yeasts (*Kluyveromyces marxianus* and *Issatchenkia orientalis*) are involved in the fermentation. At intervals, a portion of the product is withdrawn from the bag and fresh milk is added to make volume.

Zabadi

Zabadi is a fermented milk popular in Egypt. A portion of old *Zabadi*, containing *S. thermophilus* and *L. delbrueckii* subsp. *bulgaricus*, is inoculated into buffalo milk which has been previously concentrated by boiling. The culture-containing milk is then incubated and further concentration of milk solids is achieved by heating the curd and separating whey. The final product shows cooked flavor and a firm texture.

Amasi

Amasi is a fermented milk product of Zimbabwe made by fermentation of bovine raw milk by the natural starter present in milk, container, and air. Fermentation is carried out for 3 days. However, use of raw milk and natural starter culture may hamper the microbiological quality of *Amasi*.

Ergo and *Urubu*

Ergo is a yoghurt-like traditional product of Ethiopia. Spontaneous fermentation of raw milk for 2–4 days results in a final product with a typical sour flavor, thick semisolid consistency and a prolonged shelf life of 15–20 days. *Kibe* (butter) and *Arerra* (buttermilk) are formed after churning of *Ergo*.

The Burundian fermented milk *Urubu* is similar to *Ergo* and is prepared by spontaneous fermentation of milk for 2–3 days. *Amavuta* (butter) and *Amateregwa* (buttermilk) are formed after churning of *Urubu*.

Laban/Leben/Lben

Laban is a set-type, yoghurt-like fermented milk product popular in Lebanon. *Leben* and *Lben* are similar products made in Morocco and Arab countries. Traditional methods of preparation use artisanal, natural starter cultures, whereas for industrial production commercial yoghurt cultures are used. More firm texture is developed using exopolysaccharide-producing strains. *Laban* prepared with undefined natural starters is said to have a more typical flavor.

Gioddu

Gioddu is a Sardinian yoghurt prepared from milk of sheep, cow, or goat. Lactic acid bacteria and yeasts are involved in the fermentation of the milk resulting in an acid-alcoholic product.

Kule naoto

Kule naoto is famous among the Maasai communities in Kenya and Tanzania. It is a yoghurt-like fermented milk product prepared from the raw milk of Zebu cattle. Spontaneous fermentation of the milk is done according to a traditional method with a prolonged incubation period of 5 days. *Lactobacillus*, *Enterococcus*, *Lactococcus*, and *Leuconostoc* species are the predominating microbiota and *L. plantarum* is the dominating bacterium among the lactobacillus species.

Nunu/Nono

Nunu is a Nigerian fermented milk product obtained via an unknown lactic starter fermentation of cow milk for 1–2 days. Fermentation of milk occurs in calabashes or rubber buckets. Final products have a sharp, sour, and bitter flavor.

Nyarmie

Nyarmie is a naturally fermented yoghurt-like milk product of Ghana. Both unpasteurized and pasteurized milk can be used for its production. The final product has a pleasant flavor and displays a prolonged shelf life both at ambient and low temperature. Dominant lactic acid bacteria present are *Leuconostoc mesenteroides* subsp. *mesenteroides*, *S. thermophilus*, *L. delbrueckii* subsp. *bulgaricus*, *L. helveticus*, *L. delbrueckii* subsp. *lactis*, and *Lactococcus lactis*, while predominant yeast include *Saccharomyces cerevisiae*.

Raib/Rayeb

Raib and *Rayeb* are Algerian and Moroccan fermented milk products prepared by spontaneous and uncontrolled fermentation of raw cow or goat milk. Natural lactic starter bacteria are involved in the lactic fermentation. From *Rayeb*, different milk products like *lben*, *zebda beldia* (butter), *Jben*, *Klila* (cheese), and *Smen* (rancid butter) are prepared.

Xueo

Xueo is a yoghurt-like product prepared in Tibet by backslopping of old *Xueo* in boiled and subsequently cooled yak milk. After incubation, a viscous yoghurt-like final product is formed with a shelf-life of 10 days at room temperature. In *Xueo*, *Enterococcus durans* is a dominating bacterium along with *L. fermentum* and *L. paracasei*.

Doogh

Doogh is an Iranian beverage, traditionally prepared by churning of water-diluted yoghurt or fermented milk. Some aqueous extracts of local herbs, spices such as thyme, cucumber, and garlic essence are blended in it to enhance the flavor and functional properties. It differs from *Ayran* in Turkey and *Lassi* in India by dilution ratio, fat content, and rheological and sensory characteristics. For commercial production of *Doogh*, skim milk yoghurt is used. Fortification, carbonation, and addition of gum to overcome phase separation problems are among the new advancements in *Doogh* production.

Ayran

Ayran is considered as a national drink in Turkey and is a cold yoghurt beverage, mixed with salt to enhance flavor. Traditionally, it is made by diluting yoghurt with water at a level of 30–50% and table salt at a maximum level of 1%. In the industrial manufacture of *Ayran*, the milk with adjusted milk solids is fermented by exopolysaccharide-producing strains and the highly viscous curd obtained is diluted with salt and water. The product is then cooled to stop fermentation and further acidity development.

Tarag

Tarag is a Mongolian yoghurt-based product, prepared by lactic fermentation of cow, yak, goat, and/or camel milk. The predominating microbiota of *Tarag* includes *L. delbrueckii* subsp. *bulgaricus*, *L. helveticus*, and *S. thermophilus*.

Kurut

Kurut is a yoghurt-based product, known but prepared differently in two countries, namely Tibet and Turkey. In Tibet, *Kurut* is an acidic and alcoholic fermented milk product made by prolonged natural fermentation (10–15 °C for 6–7 days) of yak milk. *L. delbrueckii* subsp. *bulgaricus* and *S. thermophilus* are the major dominating bacteria. In Turkey, however, *Kurut* is a dried fermented milk product made from cow milk strained yoghurt. Concentrated yoghurt is cut or rolled into small pieces and then air and sun dried for 10–15 days. The drying process enhances its shelf life up to several months.

Suusac

Suusac is a Kenyan yoghurt-based product prepared from camel milk. Unheated or unpasteurized fresh camel milk is spontaneously fermented by an acquired mixed microbiota in smoked Gourd (hollow, dried-out shell of the fruit of the two genera of the calabash tree) or a clay pot at ambient temperature (25–29 °C) for 1–2 days. *Leuconostoc mesenteroides* subsp. *mesenteroides*, *Candida krusei* and *L. plantarum* are predominant microorganisms found in *Suusac*.

Advances in Yoghurt

Plant 'Milk' Yoghurt

Yoghurt can be made from plant 'milks,' such as soy, coconut, almond, sesame, and peanut milk. Plant milks contain reduced content of cholesterol, lactose, and saturated fatty acids and their consumption potentially provides health benefits to humans, in particular with respect to lactose-intolerant

persons. Among the various types, soy milk yoghurt is the most popular variant. Lactic fermentation of soy milk improves typical soy flavor and enhances the nutritional content. In addition, soy is a rich source of antioxidative compounds, isoflavones, and daidzein. Soy yoghurt enriched in glyceollins (a novel class of soybean phytoalexins with potential cancer-preventive and antiestrogenic effects) and probiotic soy yoghurt are manufactured to further enhance nutritive effects. Like soy yoghurt, yoghurt prepared from coconut milk is rich in taste and contains high levels of calcium and other minerals and nutrients of interest.

Yoghurt Bites

Yoghurt bites are ready-to-eat, small-sized frozen yoghurt pieces usually eaten by hand. Yoghurt bites are available in plain, flavored, and fruit-based form. Plain yoghurt bites are small pieces of plain yoghurt, contain total solid contents not less than 22% and are covered with a fat-based coating. Fruit-based yoghurt bites are frozen products that have fruit pieces coated with plain or flavored yoghurt (*e.g.*, strawberry and blueberry-based yoghurt bites).

Conclusion

Yoghurt and related products are very popular in different parts of the world not only because of their nutritional value but also because of their potential health benefits. The recent trend is to manufacture yoghurt with probiotic microorganisms and natural, value-added, often microbial-derived components that provide additional nutritional and functional properties to the end users. Moreover, various milks from animal and plant sources have been applied to manufacture novel yoghurt and have given appreciable results.

Zinc: Physiology and Health Effects

Physiology

The body content of Zn is second only to iron among the trace elements with approximately 2 g in the adult female and 2.5 g in the adult male. Zn is remarkable for the range of its major biological roles in virtually every cell in the body. At a basic level, this can be attributed to Zn's exceptional ability to form ligands with the side chains of proteins and other organic molecules – ligands that are strong, but flexible and readily exchangeable. Now, prominent among the biological roles of Zn is the Zn finger motif present in the multiple side chains or fingers of an ever-growing number of relatively small, metabolically active proteins. Structurally, the Zn finger motif is a recurring pattern of amino acids with cysteine and histidine at the base, to which Zn binds in a tetrahedral fashion. The number of genes coding for Zn finger domains exceeds 3% and has been reported to be as many as 10% of all identified human genes. Zn fingers vary in their precise conformation. Steroid hormone receptors, for example, have several such domains that are involved in the structure and one each for binding to DNA and RNA polymerases. Many transcription factors contain the Zn finger motif, thus giving the metal a broad role in gene expression. These roles include self-regulation of its own metabolism and induction of metallothionein with which its metabolism is closely associated. Zn binds directly and reversibly to the Zn finger domains of the metal-response element-binding transcription factor-1 (MTF-1), which functions as a cellular Zn sensor. As a result of this binding, MTF-1 assumes a DNA-binding conformation and translocates to the nucleus, where it binds to metal-response elements of the metallothionein gene, thereby initiating transcription. MTF-1 regulates many genes. Polymorphisms suggest that genetic variation in response to MTF-1-regulated genes could be related to dietary Zn intake. Stress hormones are also powerful inducers of metallothionein, suggesting a key role for Zn in the inflammatory response.

Originally identified for their role in initiating transcription by linking with specific sites on the DNA double helix, these proteins have multiple roles in addition to their involvement in gene transcription. These include translation, mRNA trafficking, cytoskeleton stabilization, epithelial development, cell adhesion, protein folding, protein modeling, and Zn sensing.

Zn has multiple roles in addition to those involving Zn finger proteins, including the structure and function of proteins and roles in DNA and RNA metabolism. The number of Zn metalloenzymes with known three-dimensional structures exceeds 200, most notably at the catalytic site. Zn metalloenzymes have been identified in each of the six major enzyme classifications. Zn is also an important regulator of apoptosis, especially via its role in the caspase family of enzymes.

Zn has a major role as a signaling mediator, acting as an intracellular signaling molecule and as a communicator between cells, converting extracellular stimuli to intracellular signals and controlling intracellular events. Zn is involved at all levels of signal transduction. For example, Zn can modulate cellular signal recognition, second messenger metabolism, and protein kinase and phosphatase activities. Early Zn signaling occurs when an extracellular stimulus, including cytokines and growth factors, directly induces elevated 'free' Zn levels within minutes by releasing Zn from a Zn store, as in metallothionein, which then serves as an intracellular signaling molecule or a second messenger. Free Zn itself affects a variety of signaling molecules and also activates ion channels. In the central nervous system, free Zn stored in synaptic vesicles acts as neurotransmitters, being released by exostosis, and then activates postsynaptic cells through transmitter-gated ion channels.

Another major biological role of Zn is that of late Zn signaling, taking several hours to respond, which depends on transcriptional changes to Zn transporters (see succeeding text), MT, and other Zn-related molecules. The Zn transporter, in turn, can alter the Zn intracellular status, thus acting as a second messenger capable of transducing the extracellular stimulus into an intracellular signaling event. Among many examples, there is evidence that Zn has a partially identified role as a novel second messenger that augments insulin activity – which could be pertinent to insulin resistance. Zn has other roles in diabetes, evidence including variants in the Zn transporter, which may have a role in the occurrence of type 2 diabetes.

Though Zn has been termed a relatively safe essential micronutrient, elaborate measures to maintain Zn homeostasis within individual cells and within the mammalian body as a whole, including the human body, developed in early stages of evolution and are very apparent today. These measures are recognized in both protecting against the accumulation of excessive Zn and averting Zn depletion when the availability of Zn for individual cells or/and for the body as a whole is suboptimal. The major role in maintaining Zn homeostasis is attributable to the Zn transporter families of proteins.

Zn delivery to tissues and cells and its intracellular distribution are tightly regulated by a family of proteins that control

uptake, efflux, and compartmentalization of Zn. In mammals, this is accomplished by numerous Zn transporters encoded by at least 27 genes from three families. These are the SLC30 (cation diffusion facilitator/ZnT), the SLC39 (ZIP solute transporters), and the Zn-sensitizing MTs (diffusion facilitator proteins). The metallothioneins (MTs) have a regulatory role in Zn uptake, storage, distribution, and release. The ZIP family facilitates the influx of Zn into the cytosol from the outside of the cells and from the lumen of intracellular vesicles, and the ZnT transporters enable the efflux of Zn out of the cytosol into the lumen of intracellular organelles and to the outside of the cells. ZIP and ZnT transporters work in an opposite but coordinated manner to maintain cellular Zn homeostasis (though elucidation of the mechanism of their coordinated roles remains unclear). The distribution of these transporters is tissue-specific. Each of these Zn transporters has its own subcellular localization and its own physiological roles. A description of these, except for those having a role in Zn homeostasis in the GI tract and in inborn errors of metabolism, is beyond the scope of this article. However, from a clinical perspective, it should be mentioned that many ZnT and ZIP transporters are also regulated by cytokines or hormones. ZIP14, for example, is upregulated by Il-6 in mouse hepatocytes. This may have a role in hypozincemia that accompanies the acute phase response to inflammation and infection.

Whole Body Zinc Homeostasis

The gastrointestinal tract has the major role in maintaining whole body Zn homeostasis. Results of Zn isotope studies are consistent with ingested Zn^{++} entering a common pool in the acid milieu of the stomach but quickly liganding to proteins and their products (peptides and amino acids, notably histidine) and possibly a range of small organic molecules on entering the alkaline medium of the duodenum. Inositol hexaphosphate or phytic acid has received much attention as a major dietary constituent, especially in grains, that influences Zn bioavailability by forming strong ligands with Zn as the chyme passages through the pylorus to the alkaline medium of the upper small intestine. The potentially major impact of these Zn-phytate ligands on Zn absorption in adult humans is widely accepted and is evident in the results of modeling total daily absorption of Zn as a function of dietary zinc and phytate.

ZnT1, ZIP4, and ZIP5 are involved in Zn transport into, across, and out of the enterocyte. ZIP4 is not only localized at the apical surface of the enterocytes, primarily in the duodenum and jejunum, but also recognized in the stomach, cecum, and colon. Abundance of ZIP4 localized to the plasma membrane increases with zinc depletion and decreases with excess Zn availability to this protein. ZIP4-mediated transport and, therefore, Zn uptake into the enterocyte is a saturable process. ZIP4 expression appears to be regulated by transcriptional and posttranscriptional mechanisms in response to Zn availability to ZIP4 at the apical surface of the enterocyte. Adaptation to changes in quantities of available Zn occurs within hours, with Zn repletion resulting in rapid endocytosis into the enterocyte to counterbalance the decrease in the availability of Zn at the apical surface. This may well substantially alter the dissociation constant (thereby, e.g., competing more effectively with phytate for Zn binding). ZnT1 responds to excess Zn in the cytosol of enterocytes (and all other cells) by extrusion of excess Zn (either across the basolateral membrane or into the gut lumen) and Zn vesicular deposition. ZIP5 is localized to the basolateral surface under Zn-replete conditions; it may oppose ZIP4 and be involved in enterocyte sensing of increases in body Zn, thereby increasing serosal to mucosal transport of Zn. ZnT2 and ZnT4–7 are localized to vesicles and the Golgi apparatus and appear to be involved in various phases of membrane trafficking within the enterocytes.

Zn stable isotope techniques are increasingly effective in providing measurements demonstrative of the regulation of Zn homeostasis in the GI tract, including excretion of endogenous Zn that has been secreted primarily via the pancreas. Zn absorption is understood to occur primarily in the duodenum and jejunum though further studies are needed, especially with respect to the reabsorption of endogenous Zn including that secreted in Zn metalloenzymes required for protein digestion.

Zn absorbed into the portal circulation is transported loosely bound in the portal blood to the liver, which has a key role in Zn metabolism, and then into the systemic circulation loosely bound to albumin with a small percentage tightly bound to alpha-2 macroglobulin. The liver is the principal contributor to the exchangeable Zn pool (EZP). Apart from the liver, Zn in all other soft tissue/organs is thought to contribute to this pool, which accounts for approximately 10% of total body Zn and which is regarded as of special metabolic importance. About 60% of total body Zn is in the muscle and 30% in the bone. Excretion of endogenous Zn is primarily via the gut, where it has an important role in regulation of body Zn. The kidneys and integument have secondary excretory roles in normal circumstances.

Significant stores of body Zn have not been identified, though the quantity in intracellular vesicles varies with Zn status, suggesting a substantial readily available store in times of Zn sufficiency for these cells. The liver also contains a modest store 'in times of plenty.' Bone accounts for approximately 30% of body Zn; the availability of this Zn in times of body Zn depletion remains controversial, but the balance of current evidence suggests that at least some of this Zn can be regarded as a store and readily exchanges with plasma Zn, though not so readily as the much smaller liver 'store.' Because of the high percentage of total body Zn in bone, even 20% readily available represents a substantial store.

Health Effects

Though the complex interplay of the impressive number of Zn transporters that have evolved serves to minimize the risks of mammalian Zn depletion or excess, this system lacks perfection. Detectable excess, due primarily to accidental acute or chronic ingestion of large overdoses, is rare but potentially lethal. In contrast, Zn deficiency is common in certain populations and environmental circumstances, though both the incidence and range of adverse effects of acquired Zn deficiency remain to be defined. The difficulty in assessing incidence can be attributed to the meager number and reliability of biomarkers of Zn deficiency, despite extensive efforts to find suitable biomarkers. Furthermore, the symptoms and signs of Zn

deficiency are primarily nonspecific, perhaps reflecting the wide range of the biological roles of Zn in all cells. This has resulted in a number of clinical or public health features of Zn deficiency for which there is some tantalizing evidence but which lack sufficient confirmation. A further confounder is that, judged on plasma/serum Zn data or on the absence of the classical features of Zn deficiency as demonstrated in untreated *acrodermatitis enteropathica* (see succeeding text), even apparently mild Zn deficiency can be associated with or be a primary contributor to a fatal outcome. Is it then correct to consider this a mild Zn deficiency state?

Zn deficiency likely affects every cell in the body. Initially, this may be limited to exporting stored Zn in vesicles. Some cells with rapid turnover are, however, especially vulnerable to Zn deficiency. Notable among these are cells lining the gastrointestinal tract and the central nervous system and cells comprising the immune system. Epiphyseal growth, especially rapid growth in young childhood, is also vulnerable to Zn deficiency. It is the effects on these systems (and possibly others, including the reproductive system in adolescence) that are especially important to the clinical and public health effects of Zn deficiency. The skin and mucosal surfaces are the first tissues to be overtly affected in experimental Zn deficiency. The greatest concern globally for the largest population known to be afflicted by Zn deficiency is for the vast number of poor young children who are dependent virtually entirely on a vegetable-based diet after the early months of breast-feeding. Those who are fortunate enough to also receive a regular supply of animal milk are likely to be at least a partial exception. At the time that our genome developed, including genes vital for Zn homeostasis, our Paleolithic ancestors were hunter-gatherers. Even before they could chew solid meat, a major source of bioavailable Zn, their mothers would premasticate and feed their young from their mouths. Furthermore, they did not cultivate grains, which now provide the bulk of complementary foods and which include substances that impair the bioavailability of Zn. Most notable among these substances is inositol hexaphosphate (phytate) though recent data have suggested that phytate may not play such a prominent role in inhibiting Zn absorption in children as has been observed in adults. The WHO has concluded that Zn deficiency is associated with as many as 300 000 diarrheal-related deaths per year in this population, which typically is bedeviled by an environment characterized by poor sanitation, poor hygiene, dirty water, lack of maternal education, and inadequate nutrition. With a recent notable overall decrease in under-five mortality, this figure requires reevaluation. Meanwhile, heroic, costly, and minimally successful (overall) efforts continue to be directed to the distribution of Zn as an adjunct treatment to oral rehydration fluids (also frequently unavailable). Adequate studies of what it will take to prevent rather than treat the Zn deficiency causally associated with severe diarrhea await attention. Underlying the role of Zn deficiency itself (and its basic poverty-driven causes) are damaged gut mucosa, villous atrophy, and intestinal inflammation. Disruption of the immune system has an intimate relationship to these defects. Zinc deficiency has adverse effects on all aspects of the innate and adaptive immune systems. T-cell functions are especially sensitive to Zn deficiency as is the balance between different T-cell subsets. Other examples of specific defects include the number and function of neutrophils, monocytes, and NK and B cells. Other recognized effects of Zn deficiency that are not readily apparent from specific signs and symptoms include evidence of inflammation, oxidant stress, and DNA damage.

Not all communities, populations, or even entire developing countries have young children who are at high risk of Zn deficiency. The WHO has identified three indicators of populations of young children at high risk of Zn deficiency: prevalence of inadequate dietary Zn, a stunting rate $> 20\%$, and low serum/plasma Zn levels. The challenge of identification is apparent from critical evaluation of each of these indicators; for example, not all stunting can be attributed to Zn deficiency. Though a serum Zn of 70 $\mu g\ dl^{-1}$ is often quoted as a lower limit of normal, this limit depends on age, physiological state, and the conditions, including time of day, under which the sample is collected. Moreover, moderate hypozincemia may be attributable to inflammation. Nevertheless, with due caution in interpretation, some information on Zn status may be gleaned from modest–moderate hypozincemia, and more severe hypozincemia can be used to confirm clinically evident Zn deficiency.

While dietary data are potentially the most useful indicator of the three (a prevalence of $>25\%$ inadequate Zn intake using the cut-point method), there are many pitfalls, especially the uncertainty of the bioavailability of the Zn. Host factors may also be the major factor impairing absorption. This provides one of the persuasive reasons for applying Zn stable isotope techniques combined with Zn analyses of duplicate diets, based on typical daily diets of the population, to a limited number of representative subjects, with data analysis including saturation response modeling. The goal is to determine the quantity of Zn absorbed each day. An example of the latter as well as of impaired bioavailability is illustrated in **Figure 1**, using data from a study of young children in Belgaum, India.

Note the low Zn absorption at low levels of dietary Zn compared with data used for control purposes (presumably despite maximal possible upregulation of ZIP4 in a potentially damaged gut) resulting in a higher level of dietary Zn required to meet normal physiological requirements. Note also that the slope of the curve at Zn intakes higher than that required to meet high physiological requirements is subsequently maintained at a higher level than controls (presumably still at maximal rates of upregulation). This relationship between daily Zn absorption and daily dietary Zn is compatible with the hypothesis, at this stage tentative, that physiological requirements are abnormally (pathologically) high. At a minimum, these data underscore the importance of more extensive studies. Meanwhile, such data potentially provide an improved assessment of dietary Zn requirements for this population.

Though most studies in recent years have focused on young children, the first reports of human Zn deficiency were in relation to the syndrome of adolescent nutritional dwarfism characterized especially by severe stunting and hypogonadism. It is unclear whether this syndrome is still evident in Egypt and Iran, and there has been a notable lack of more recent studies of potential Zn deficiency during the adolescent growth spurt.

Zn deficiency has received primary attention internationally because of current concern about the global extent and adverse effects of inadequate intake and absorption of this prominent micronutrient. However, attention is also merited

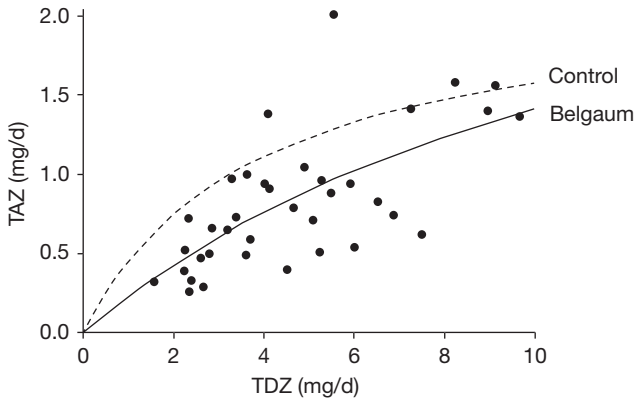

Figure 1 Saturation response model of daily Zn absorption vs daily Zn intake in children ($n = 40$) aged 18–36 months in rural Indian village compared to control subjects (normal fully breast-fed infants aged 4 months). The horizontal line shows the normal physiological requirement for 1–3-year-olds. The vertical lines show the intake needed to meet the physiological requirements.

for acquired Zn deficiency in more affluent countries, especially in recognized subgroups of the population. These include especially premature and low-birth-weight infants; prolonged breast-feeding without adequate Zn from complementary foods; intravenous feeding without adequate Zn in the infusate; disease states, especially of the gastrointestinal tract and probably the pulmonary system; elderly subjects; subjects with more generalized malnutrition; and those on diets low in bioavailable Zn. With respect to more generalized suboptimal nutrition, Zn deficiency has been documented to affect weight gain as well as retard linear growth.

Recent renewed attention has been directed to Zn requirements of premature, especially very low-birth-weight, infants. This has included a randomized controlled study with generous quantities of Zn resulting in favorable clinical outcomes. Current concern is addressed especially to the lack of availability of Zn to add to intravenous nutrition infusates. This concern is not limited to premature infants and is reminiscent of the *acrodermatitis* pattern of skin lesions recognized in the 1970s to result from omission of Zn from the formulas for intravenous feeding.

Breast milk has favorable concentrations of Zn in early lactation. However, there is a notable physiological decline in Zn as lactation progresses to levels that are too low to meet estimated Zn requirements of the infant with breast-feeding alone between 4 and 6 months' lactation. This, not infrequently, becomes a practical health issue during late infancy and the second year with resulting poor growth, poor appetite, and irritability. The feeding difficulties can be especially stressful to mothers and to family dynamics.

The relationships between Zn deficiency and disease of the gastrointestinal tract are likely two-way and complex, having adverse effects on Zn homeostasis and on the progress of gut-related disease of which diarrhea is but one manifestation.

Acquired Zn deficiency or/and favorable effects of Zn therapy have been linked to many other diseases but are beyond the scope of this article.

Inherited diseases of Zn metabolism/homeostasis, though rare, are important for two reasons. First, the clinical manifestations can be treated effectively and, if necessary, for a lifetime with adequate Zn supplements. Second, they have yielded important insight into normal Zn homeostasis. The prototype is *acrodermatitis enteropathica* (AE), which is an autosomal inherited disorder attributable to one of several polymorphisms of the SLC39A4 gene encoding for the ZIP4 zinc transporter. This transporter, when localized to the apical surface of enterocytes primarily in the duodenum and jejunum, has a role in the active, saturable absorption of Zn from the gut lumen. Experimentally, this active saturable pathway has the major role in Zn absorption when available Zn levels in the lumen are not excessive but adequate to meet physiological requirements if the ZIP4 transporter is functioning normally. AE, therefore, provides indisputable evidence of the importance of ZIP4 to the maintenance of normal Zn status and avoidance of severe Zn depletion.

Classically, this disease presents clinically with a severe erythematous rash, primarily in the perineal region and around the body orifices. Other classical signs, that is, alopecia and diarrhea, are inconsistent, though most untreated cases have GI manifestations. Psychological disorders are typical, including loss of hedonic tone. Anorexia also occurs frequently. Growth failure is also apparent in untreated cases. Since 1970, when the empirical value of Zn was first noted, treatment with Zn, sometimes at very high levels, has resulted in correction of the phenotypic abnormalities. However, before Zn therapy was introduced, these infants classically had a progressive downhill clinical course with frequent infections, severe growth failure, and a fatal outcome before the end of infancy. Some AE patients survived into adult life without Zn therapy, contributing factors including the empirical use of dihydro-dioxiquin or less lethal polymorphisms Typically, these subjects had more chronic psoriasiform rashes distributed anywhere on the skin, stunting, depression, and, if pregnant, a high risk of congenital malformations in the offspring. A transient early infancy syndrome with a similar phenotype in the occasional breast-fed infant is attributable to a defect in ZnT2 required for the secretion of Zn into human milk.

Summary

The molecular biology of Zn has been reviewed with special regard to the Zn transporter families, which have a dominant role in Zn absorption and Zn homeostasis in and between all cells, which includes a major contribution of Zn to cell signaling. Clinical effects of Zn deficiency, with emphasis on effects of

global public health relevance, are reviewed. AE is allotted special attention because of the insights it has provided into the clinical effects of severe Zn deficiency and the indisputable evidence it provides of the outstanding role of ZIP4 at the apical surface of the enterocyte in regulating Zn absorption. Both the value and potential (combined with saturation response modeling) of appropriately designed Zn stable isotope studies are emphasized as investigative tools of comparable importance to randomized controlled studies of Zn supplementation. At a basic and human research level, much remains to be learned about Zn, a relative newcomer to that small group of microminerals of major importance for human health.

Zinc Properties

Zinc is the thirtieth element of the periodic table (atomic number 30). Its symbol is Zn, and it is included in group 12 (or IIB), thus corresponding to the transition metals. The element was probably named by the alchemist Paracelsus after the German word *zinke*. Later, Andreas Sigismund Marrggraf, a German chemist, isolated this element for the first time in 1746 by heating calamine and carbon. It has a hexagonal crystal structure, a bluish color, a melting point of 419.6 °C, a boiling point of 907 °C, an atomic weight of 65.39, and a relative density of 7.133 g cm^{-3}. The melting point is the lowest of the transition metals aside from mercury and cadmium.

It has an electronic structure of [Ar] $3d^{10}$ $4s^2$ with two electrons in the first electron shell, eight electrons in the second electron shell, 18 electrons in the third electron shell, and two electrons in the fourth electron shell. Therefore, it is very easy that these two later electrons are lost forming the Zn^{2+} cation, its most common state.

Zinc is a hard, brittle metal and the 24th most abundant element in the earth's crust (0.0075%) with a medium valor of 64 ppm. Seawater contains 30 ppb of zinc. The element has a low affinity for oxides and prefers to bond with sulfides. It is widely distributed in minerals such as sphalerite [(Zn,Fe)S], calamine or hemimorphite ($Zn_4Si_2O_7(OH)_2 \cdot H_2O$), smithsonite [$ZnCO_3$], hydroxincite [$Zn_5(CO_3)_2(OH)_6$], or wurtzite [another zinc sulfide]. This element exists in nature in five isotopes: ^{64}Zn (48.89%), ^{66}Zn (27.81%), ^{67}Zn (4.11%), ^{68}Zn (18.56%), and ^{70}Zn (0.62%). The radioactivity of ^{64}Zn and ^{70}Zn with a half-life of 4.2×10^{18} and 1.3×10^{16} years, respectively, can be ignored.

This element is normally found in association with other metals such as copper and lead in minerals. Long before the discovery of zinc as a metal, zinc ore was already being used to produce the copper–zinc alloys (commonly called brasses in metallurgy). Objects made of brass are known from Babylonia and Assyria from 3000 BC and from Palestine dating from 1400 to 1000 BC. Currently, brasses are used to manufacture wires, weapons, coins, boilers, and several musical instruments such as the saxophone. Until the end of the eighteenth century, zinc was generally imported from India and was considered to be very costly. Other zinc applications include anticorrosive agents with metals, use as an anode with other metals in batteries, automotive industry, luminescent paint, fungicide, protecting wood against fire, and rubber from ultraviolet radiation.

Zinc is a mineral element that is spread throughout the organism with more than 95% located in intracellular space. The highest proportion of body zinc is found in the skeletal muscle (50–60%) and bones (30%) though there are other organs with high levels of zinc such as the liver and kidneys (50–60 μg g^{-1}). The exchange of zinc in these tissues is slow, making it not accessible in deficiency status. Although in short-term zinc deficiencies, small amounts of zinc can be available coming from the hepatic reservoir, generally it is recognized that an organism does not have any specific reservoir of zinc, and therefore, it depends on a regular intake.

It plays an essential role in the genetic expression and regulation of cellular growth and differentiation because it participates as cofactor in more than 120 enzymes (alkaline phosphatase, superoxido dismutase, alcohol dehydrogenase, and peptidases, among others) involved in carbohydrates, proteins, and nucleic acid metabolism. Therefore, it is necessary for DNA, RNA, and protein synthesis, and it plays an important role in the immunologic system and in the masculine reproductive function as it is involved in the mechanism of action of testosterone. In addition, zinc is required for the maintenance of healthy bones, being essential for normal collagen synthesis.

There are several sources of zinc in the diet. Red meats, liver, and mollusks (particularly oysters) are important sources of bioavailable zinc. Presence of zinc in red meat (cow and sheep meat) contributes to meat color; indeed, zinc content in these kinds of products is almost twice as high as in chicken meat. However, in several world regions, most zinc incorporated in human diet comes from cereal and legumes. Among vegetables with high content in zinc could be highlighted beans, lentils, and nuts. Most of zinc content in cereals is in the external part; therefore, zinc content depends on the refinement level of the cereal. Aside from milk, fruits and vegetables are low in zinc. Therefore, zinc bioavailability can be low in vegetarian diets, in particular in those based on integral cereal and vegetables, due to the high content in phytic acid, which is a powerful inhibitor of zinc absorption.

As shown, there are several factors that determine zinc absorption (promoting or impairing its bioavailability). They are classified in physiological or dietary factors. Among dietary factors it has been widely reported that the presence of phytic acid (myoinositol hexaphosphate) may compromise zinc bioavailability from meals because it has strong tendency to form chelates with multivalent metal ions. Similarly, it has been described in the literature several zinc–iron and zinc–calcium interactions. Several studies have found a significant negative interaction between zinc retention and iron content in food. However, this interaction seems to depend on the iron chemical form (heme iron or inorganic iron) and the presence of other dietary components. In contrast, the presence of animal proteins (meat factor) seems to enhance zinc bioavailability. This effect is due to the formed products during the digestion of proteins that bind zinc and facilitate its absorption. Nevertheless, this influence will depend on the digestion level of proteins and its composition of sulfur-containing amino acids such as cysteine because zinc usually binds to proteins via these residues. Finally, several studies have shown that hydrolysis of caseins may have a similar effect. Many of these peptides (called casein phosphopeptides)

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00768-6

contain highly polar acidic sequences of three phosphoserines followed by two glutamic acid residues, it being partly resistant to the enzymatic hydrolysis in the digestive system. The negative charges of phosphate groups belonging to casein phosphopeptides can form soluble complexes with divalent cations such as zinc producing a gradual release of this element in the intestinal lumen and improving their absorption due to no saturation of determined transport mechanisms.

Zinc Analysis

Sample Treatment

Most of the analytical methods used for zinc determination in food and biological samples require the availability of a sample solution. Only few techniques (such as infrared spectroscopy or x-ray fluorescence) are able to carry out a direct analysis of solid samples. Even these techniques may require in many cases a pretreatment of the sample for its correct use. For this reason, the sample treatment could be defined as the step that involves subjecting the sample to a number of physical and chemical processes to prepare it for analysis. However, it should be noted that the risk of sample contamination and analyte loss at this stage are often high.

In relation to zinc analysis in food samples, this process often involves the destruction of organic matter and other matrix constituents that may interfere with the studied analyte. A common practice is incineration of the sample in a muffle furnace using a time–temperature controlled program (dry mineralization). Therefore the oxidation of organic matter is achieved. Process efficiency and risk of analyte loss primarily depends on the food matrix and the time–temperature program applied. The ash residue is usually dissolved with acids (HCl, HNO_3, etc.) after a blanching step.

The main disadvantages of dry mineralization are that it is a very slow procedure, requires several hours to complete, and is influenced by numerous factors such as time, temperature, and acid mixture. For these reasons, an appropriate alternative method is wet mineralization, which is based on the oxidizing action of strong acids either alone or in acid mixtures that sometimes include hydrogen peroxide. These reagents are very useful for zinc and trace elements determination in a great variety of samples thanks to the availability to release low volatile cations and keep them in solution.

Another drawback of the preceding mineralization methods is that in the case of highly volatile elements such as selenium, mercury, or arsenic, there is a significant risk of analyte partial losses. For zinc determination, this problem is not initially present unless sample preparation is oriented to determine these volatile elements simultaneously. In such cases, performance of wet mineralization in microwave ovens using pressure vessels is recommended as an alternative. These systems have the advantage of using a smaller volume of reagent than traditional ones. The most significant disadvantage is the risk of explosion due to pressure increase caused by the destruction of organic matter. The pressure vessels are placed on a turntable to avoid problems arising from lack of homogeneity in the distribution of radiation within the microwave oven.

Usually, liquid samples treatment is much easier than solid samples. They may require filtration, centrifugation (in the case of suspended particulate matter), and mineralization. Finally, in some cases zinc can be presented in the sample at low concentrations that are below the detection limit of the analytical technique used. To overcome this problem, several zinc preconcentration methods have been studied which are discussed in the following section.

Preconcentration Methods

Determination of zinc in foods and biological samples cannot be easily achieved in many cases because of two main difficulties: the very low concentration of zinc (may be below the detection limit of several analytical techniques) and the interfering effects of the matrix to be analyzed. In these cases, preconcentration and/or separation methods prior to zinc analysis are therefore needed to improve sensitivity and selectivity. Several procedures, such as solid phase extraction, liquid–liquid extraction (LLE), cloud point extraction, and coprecipitation, have been proposed and applied for the enrichment and separation of zinc from a sample matrix. Table 1 summarizes some published papers on zinc preconcentration techniques in foods.

Solid phase extraction (SPE) is a sensitive, inexpensive, and fast sample preparation process that involves partitioning between a liquid phase (sample or solvent with analytes) and a solid phase (sorbent). The analytes, which are dissolved or suspended in a liquid mixture, are separated from the solution by sorption on the solid sorbent according to their physical and chemical properties. The general procedure is to load a solution onto the solid phase, remove undesired components, and later capture the desired analytes with another solvent into a collection tube. The selection of an appropriate SPE extraction sorbent depends on the mechanism of interaction between the sorbent and analyte of interest. Furthermore, control of process parameters such as pH, sample flow rate, and sample volume is highly important. Various solid phase extractants have been used to zinc preconcentration such as alumina, adsorption resin (Amberlite XAD – 16), columns packed with ethyl vinyl acetate, microcrystalline triphenylmethane, multiwalled carbon nanotubes, and modified silica gel, among others. Carbon nanotubes are an allotrope of carbon. They are relatively new materials that have attracted great attention in recent years in analytical chemistry due to a high surface area and strong adsorption ability. A carbon nanotube is a one atom thick sheet of graphite rolled up into a seamless cylinder with diameter of the order of a nanometer.

Liquid–liquid extraction (LLE) is the oldest and the most widely used method in preconcentration procedures for the determination of trace elements due to its simplicity. In this technique, the metal is distributed between two immiscible liquid phases (usually an aqueous and an organic phase). Preconcentration of metals is achieved by the addition of a chelating agent to an aqueous sample and extraction of formed metal complexes into an organic phase. In the case of zinc, ammonium pyrrolidin thiocarbamate and diethylammonium-diethyldithiocarbamate have been used with successful results. In parallel, trichlorotrifluoroethane (Freon TF) or xylene are

the best choices for extraction phase due to their low solubility of these solvents in water. For the analytical measurement of the extracted zinc ion, a back extraction step to an aqueous medium, usually acid, is recommended. Although LLE has shown excellent results for multielement analysis with a high extraction efficiency, some drawbacks such as the use of large volumes of toxic organic solvents, high sensitivity to operational conditions, and time-consuming process have made LLE a technique not easily automated.

Cloud point extraction (CPE) is related to LLE but has emerged as an alternative for several reasons: (i) its excellent concentration factors, (ii) the smaller required sample size, (iii) the use of a small volume of organic solvent that is generally toxic, (iv) the use of nontoxic surfactants, (v) the reduction of laboratory residues, and (vi) it is recognized as a safer, simpler, and cost-effective procedure. CPE is based on the following phenomenon: in much diluted solutions of nonionic surfactant, the monomers are dispersed in the solvent. But above the critical micellar concentration of the surfactant, these monomers associate spontaneously, forming aggregates of colloidal dimensions termed micelles, due to the diminished solubility of the surfactant in water. The surfactant solution becomes turbid because it attains the cloud point. This clouding phenomenon can be induced by changing the temperature, surfactant concentration, or the choice of a compatible pH buffer, resulting in the separation of a single isotropic micellar phase into two phases, a surfactant-rich phase of small volume and an aqueous phase. Choosing an appropriate chelating agent, able to form with the metal ion a hydrophobic complex that is entrapped by micellar structures, extraction and subsequent preconcentration of zinc in the surfactant rich phase can be achieved. Among the nonionic surfactants commonly used, Triton X – 114 (octylphenoxypolyethoxyethanol) is the most feasible for preconcentration cloud point. Regarding chelating agents, 1-(2-pyridilazo)-2-naphthol, 8-hydroxyquinoline (8-HQ), 4-(2-pyridylazo)-resorcinol (PAR), and 1-(2-thiazolylazo)-2-naphthol have been used in determination of zinc.

Finally, coprecipitation is another technique for zinc preconcentration and separation of food matrices prior to analytical determination. It offers some advantages such as simplicity and the fact that various analyte ions can be preconcentrated and separated simultaneously from the matrix. In the coprecipitation procedure, a precipitate is formed by combination of a carrier element and a suitable inorganic or organic coprecipitant. Further, this precipitate is separated by centrifuging, filtering, or washing. For zinc coprecipitation technique, it has been applied with successful results, several combinations of a carrier element such as cobalt (III), lanthanum (III), molybdenum (IV), or nickel (II) with a suitable organic ligand like diethyldithiocarbamate (DDTC), 8-hydroxyquinoline (8-HQ), 2-nitroso-1-naphthol-4-sulfonic acid (NNSA) or an inorganic ligand like gallium hydroxide.

Atomic Absorption Spectroscopy

The analytical techniques commonly used for the determination of zinc in food samples are the inductively coupled plasma optical emission spectrometry (ICP-OES), inductively coupled

plasma mass spectrometry (ICP-MS), electrothermal atomic absorption spectrometry (ETAAS), and flame atomic absorption spectrometry (FAAS). Nevertheless, among these techniques, ETAAS and FAAS are extensively employed because of their high sensitivities, wide availability in analytical and clinical laboratories, and low cost. Both techniques fall within atomic absorption spectroscopy (AAS) in which electromagnetic radiation at a specific wavelength is passed through a cell containing gaseous free atoms. Atoms can be produced in two different ways using AAS: flame atomization (FAAS) and electrothermal atomization through a graphite furnace and a L'vov platform (ETAAS). Thus, the determination of zinc using an atomic absorption spectrophotometer requires a light source (wavelength $\lambda = 213.9$ nm) and an atomization source. For the light source, arc discharge lamps may be used for zinc, although hollow cathodes are preferred. Lineal calibration is required to obtain analyte concentrations in the sample. Standard working conditions for analyzing zinc by atomic absorption spectroscopy are listed in Table 2.

The flame atomizer consists of a nebulizer (which is designed to convert the sample solution into an aerosol) and a burner. The sample is aspirated through a capillary into a chamber through which oxidant and fuel are flowing. Air–acetylene and nitrous oxide–acetylene are the most commonly used oxidant–fuel mixtures. When conventional FAAS proves impractical because of zinc values are below or near the detection limit of the instrument, it is recommended to use ETAAS. In ETAAS the atomization is produced by the passage of electrical current through a cylindrical graphite tube (called graphite furnace). This process comprises several steps: preheating, drying, pyrolysis, atomization, and cleaning, which are achieved by a temperature–time interval program (ramps heating). During the drying stage, liquid from the sample is evaporated and driven off. In the pyrolysis stage some of the concomitants in the sample are removed. Finally, the temperature is rapidly increased to quickly vaporize and atomize the sample. During this process, the system is flushed with protective gas (usually argon) to exclude air from the sample compartment and to minimize oxidation of the atomizer material at high temperatures.

To reduce matrix effects when ETAAS is used, samples can be simply diluted with water, or various matrix modifiers are added. To avoid the risk of contamination due to excessive sample handling and/or addition of reagents during the dilution procedure, a flow injection system (FI-ETAAS) has been used to determine zinc in biological samples such as human saliva.

Detection limit ($\mu g\ ml^{-1}$)	0.168
Quantification limit ($\mu g\ ml^{-1}$)	0.560

Inductively Coupled Plasma-Optical Emission Spectrometry (ICP-OES)

Plasma may be defined as a luminous volume of partially ionized gas. It is generated from radiofrequency magnetic fields induced by a copper coil wound around the top of a glass torch. ICP-OES is a multielemental technique that is able to determine concentrations of multiple elements in a sample with a single aspiration obtaining a high degree of variability and minimum interferences. The sample solution is introduced into the core of an inductively coupled argon plasma that generates a temperature on the order of 10 000 °C where it rapidly undergoes dissolvation, vaporization to molecular level, and dissociation into atoms (some of the atoms are ionized). These atoms are excited in the plasma, and they revert to their ground state emitting light with a characteristic wavelength, which is measured using an optical spectrometer. Therefore, argon plasma is needed to produce atomization and excitation. The nearly complete atomization of the sample minimizes chemical interferences.

Samples can be prepared by dry, wet, or microwave digestion method, and a wide range of concentrations can be used without the need to dilute or concentrate the sample. For zinc determined by ICP-OES, a solution detection limit of 5 $\mu g\ l^{-1}$ and a sample detection limit of 2.5 $\mu g\ g^{-1}$ can be achieved. Also, many of the other mineral elements can be quantified, thus reducing time of analysis. These advantages, together with the high speed and excellent instrument stability, make ICP-OES highly attractive.

ICP-OES has been used for zinc determination in a great variety of food samples such as wines, infant foods, fruits, vegetables, fish, and shellfish, among others. There is also an AOAC Official Method (2011.14) for the determination of zinc in infant and follow-up formula by means of ICP-OES. The analytical lines used for zinc are 213.856 (most used), 206.200, and 202.548 nm, respectively. Other parameters that must be controlled are RF power (W): nebulizer flow ($l\ min^{-1}$), auxiliary gas flow, plasma flow ($l\ min^{-1}$), and sample flow ($l\ min^{-1}$).

Inductively Coupled Plasma-Mass Spectrometry (ICP-MS)

ICP can also be used coupled with a mass spectrometer leading to inductively coupled plasma-mass spectrometer (ICP-MS). The inductively coupled argon plasma is once again used as an excitation source for the elements of interest. However, in contrast to ICP-OES, the plasma in ICP-MS is used to generate ions that are then introduced to the mass analyzer through a sampler cone followed by a skimmer cone. Mass spectrometers are instruments that separate ions according to their mass to charge ratio (m/z) and then accurately quantify the resulting ions once they pass through a detector.

ICP-MS is also a multielement technique, characterized by low background and offers extremely high sensitivity to a wide range of elements with a lower limit of detection than ICP-OES. For zinc determination by ICP-MS a solution detection limit of 0.1 $\mu g\ l^{-1}$ and a sample detection limit of 0.05 $\mu g\ g^{-1}$

can be achieved. Regarding interferences, spectroscopic interferences are probably the largest ones in ICP-MS and are caused by atomic or molecular ions that have the same m/z as the analytes of interest. Current ICP-MS instrumental software makes a correction for all known atomic 'isobaric interferences,' or those caused by overlapping isotopes of different elements; however, they do not provide corrections for most polyatomic interferences. Such interferences are caused by polyatomic ions that are formed from precursors having numerous sources, such as the sample matrix; reagents used for preparation, plasma gases, and entrained atmospheric gases. Table 3 shows the main polyatomic interferences for zinc determination.

According to Table 3, zinc has five stable isotopes. Different zinc isotopes, including ^{64}Zn, ^{66}Zn, and ^{68}Zn, have usually been attempted for zinc determination in biological samples. The determination of zinc in this type of sample makes difficult by the different degrees of S-containing interferences on the zinc isotopes. It has been demonstrated that apparent zinc concentrations at masses 64, 66, and 67 increase linearly with the concentration of sulfuric acid. Only mass 68 shows no interference due to S-containing polyatomic ions. Therefore, the use of ^{68}Zn is generally recommended for body fluids analysis eliminating the interferences from sulfur with ^{64}Zn and ^{66}Zn.

This technique is also recommended for zinc bioavailability studies. The bioaccessibility of zinc in seafood has been assessed using ICP-MS following a continuous sample leaching procedure with artificial saliva or gastric juice. The methodology was validated using certified reference materials and mass balance calculations by carrying out total digestion of the remaining sample residues. On the other hand, bioimaging studies to quantify zinc and other trace elements within tissue sections have been achieved using laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS). This technique has been also applied over brain, hypothalamic rodent, or wheat grains cross sections with a spatial resolution ranging about 10–100 μm.

Finally, these multielement techniques (ICP-OES and ICP-MS) have also been used to guarantee the authenticity of some protected designation of origin food commodities. Both techniques provide quick and accurate results when employed as a basis for authentication of products with a certain quality standard, thus refusing possible imitations (see Table 4).

Table 3 Polyatomic interferences for the determination of zinc in ICP-MS

Isotope	*Abundance*	*Interference*
^{64}Zn	48.89	$^{32}S^{16}O_2^+$, $^{48}Ti^{16}O^+$, $^{31}P^{16}O_2^1H^+$, $^{48}Ca^{16}O^+$, $^{32}S^+$, $^{31}P^{16}O^{17}O^+$, $^{34}S^{16}O_2^+$, $^{36}Ar^{14}N_2^+$
^{66}Zn	27.81	$^{50}Ti^{16}O^+$, $^{34}S^{16}O_2^+$, $^{33}S^{16}O_2^1H^+$, $^{32}S^{16}O^{18}O^+$, $^{32}S^{17}O_2^+$, $^{33}S^{16}O^{17}O+$, $^{32}S^{34}S+$, $^{33}S2^+$
^{67}Zn	4.11	$^{35}Cl^{16}O_2^+$, $^{33}S^{34}S^+$, $^{34}S^{16}O_2^1H^+$, $^{32}S^{16}O^{18}O^1H^+$, $^{33}S^{34}S^+$, $^{34}S^{16}O^{17}O^+$, $^{33}S^{16}O^{18}O^+$, $^{32}S^{17}O^{18}O^+$, $^{33}S^{17}O_2^+$, $^{35}Cl^{16}O_2$
^{68}Zn	18.57	$^{36}S^{16}O_2^+$, $^{34}S^{16}O^{18}O^+$, $^{40}Ar_{14}N_2^+$, $^{35}Cl^{16}O^{17}O^+$, $^{34}S_2^+$, $^{36}Ar^{32}S^+$, $^{34}S^{17}O_2^+$, $^{33}S^{17}O^{18}O^+$, $^{32}S^{18}O_2^+$, $^{32}S^{36}S^+$
^{70}Zn	0.62	$^{35}Cl^{35}Cl^+$, $^{40}Ar^{14}N^{16}O^+$, $^{35}Cl^{17}O^{18}O^+$, $^{37}Cl^{16}O^{17}O^+$, $^{34}S^{18}O_2^+$, $^{36}S^{16}O^{18}O^+$, $^{36}S^{17}O_2^+$, $^{34}S^{36}S^+$, $^{36}Ar^{34}S^+$, $^{38}Ar^{32}S^+$

x-Ray Fluorescence Analysis

x-Ray fluorescence (XRF) is based on bombarding a small area of the sample with x-ray photons, which are sufficiently energetic to cause ionization of inner electrons of the atoms. Because of this unstable atomic configuration, this vacancy of an inner electron is filled by an electron from an outer orbital which emitted the difference of energy between the two orbitals as a "secondary" (or fluorescent) x-ray photon. The main difference with other spectrometry techniques (i.e., AAS or ICP-OES) is that in the latter the absorbed or emitted radiation covers the ultraviolet-visible region of the spectrum.

XRF permits a direct and fast analysis of solid samples without any chemical sample preprocessing, and it is also a multielement technique. The main advantage is an easier, cheaper analysis and a green alternative to other methods because of the reduced need for the use of reagents. The main drawback is a low sensitivity and high matrix effects being necessary to use chemometrics methods to extract the information contained in these spectra.

Although this technique is not commonly used in zinc analysis, it has been applied to determine zinc and other trace elements of various biological samples such as human diets, rice, human placenta, and blood. The bibliography describes different XRF analysis techniques for measuring zinc, which are summarized in Table 5.

Ion-Selective Electrodes

The potentiometric determination of zinc with ion-selective electrodes is recognized as an accurate, easy-to-implement, and low-cost technique. Moreover, it is applied to online analyses. The potentiometric property of the ion-selective electrode is determined by the ionophore, the key element of membrane composition. Different types of electrodes to determine zinc ions have been described. Those based on ion-exchanger or chelates give poor selectivity and undergo strong interference effects. Zinc solid electrodes based on zinc sulfide, telluride, or selenide (for example, an electrode with a membrane made of a zinc sulfide–silver sulfide mixture applied on a silver wire). Finally, another option is to use a liquid electrode containing zinc dithiozonate as an ionophore. However, because of the insufficiently high sensitivity and selectivity of these potentiometric methods at zinc levels found in food and biological samples, atomic absorption spectroscopy has remained the most used technique.

Currently, zinc-selective electrodes based on crown ethers have been developed. They are cyclic chemical compounds with a ring containing several ether groups. Several factors influence the use of these compounds as an electro active material for zinc-selective electrodes such as structure and cavity size of the cyclicether, stability and selectivity of zinc ion complex, and solubility and ability of the crown ether to extract the zinc ion into the membrane phase. It has been demonstrated that the substitution of some oxygen atoms of crown ethers by nitrogen atoms increases the stability of metal complexes formed with soft transition and heavy metal ions. Based on these considerations, several zinc-selective electrodes have been developed using crown ethers such as *N*,*N*′-bis (acetylacetone)ethylenediamine), dibenzo- 24-crown-8 or 1,4,7,10-tetraoxacyclododecane. They are usually incorporated in a PVC matrix combined with an anion excluder (sodium tetraphenylborate) and a plasticizer.

Together with the aforementioned electrodes, other macrocycle compounds are being employed as the carriers in zinc-selective extraction and membrane transport. Calixarenes are cyclic oligomers of phenol-formaldehyde condensates. The phenolic group of the macrocyclic molecule can also be converted into derivatives containing a wide range of functional groups with ionophoric properties. Another promising material is graphene. The possibility of using noncovalently functionalized graphene layers for potentiometric determination of zinc (taking advantage of adsorption through noncovalent interactions, due to π–π interactions with an aromatic moiety of ligands) has been recently studied with promising results.

Table 5 x-Ray techniques for zinc analysis in food and biological samples

Total reflection x-ray fluorescence and energy-dispersive x-ray fluorescence analysis of runoff water and vegetation from abandoned mining of Pb–Zn ores	Marqués, A. F., Queralt, I., Carvalho, M. L. and Bordalo, M. (2003). *Spectrochimica Acta Part B* **58**, 2191–2198
Determination of copper, iron and zinc in spirituous beverages by total reflection x-ray fluorescence spectrometry	Capote, T., Marcó, L. M., Alvarado, J. and Greaves, E. D. (1999). *Spectrochimica Acta Part B* **54**, 1463–1468

Other Techniques

There are other techniques less used for zinc analysis. For instance, fluorometry has been applied using fluorescent adducts of zinc-chelating peptides. The main disadvantage of this technique is the interference problems caused by other transition metal cations, mainly with cadmium, which have similar chemical properties than zinc thus producing insufficient selectivity.

On the other hand, UV–visible spectroscopy has been applied with an intensely colorimetric sensor based on hetarylazo derivative. It shows a high selectivity based on a color change from red to faint orange on sensing of zinc ions. The presence of cations such as cadmium does not interfere in the sensing process, although mercury does at high concentrations.

Neutron activation analysis (NAA) has been applied for determination of trace amounts of zinc. The technical basis is that samples are first irradiated with a flood of neutrons generated by a nuclear reactor, creating radioactive isotopes of present elements. The concentration of zinc can be determined through their long-lived radionuclide ^{65}Zn ($t_{1/2} = 244$ days). It is recommended to make an extraction step with dithiocarbamates prior to NAA because the major interfering elements (sodium, chloride, and bromide) do not form complexes with the extracting reagents and are avoided.

Finally, near infrared (NIR) radiation is the electromagnetic spectrum radiation encompassing the interval 780–2500 nm

being situated between the middle infrared and visible radiations. NIR spectroscopy has been used for determining zinc concentration, due to association between minerals and organic functional groups in the sample matrix and the effect on O—H bonding. The main drawback of this technique is the complexity of NIR spectra, with overtones and combination bands generated by different functional groups such as C—H, N—H, and O—H being necessary to use chemometric techniques to extract the information contained therein.

Zoonoses

AT Rantsios, EBTE (Biologic Technological Applications), Consultants, Marousi, Greece

Introduction

According to the Joint WHO/FAO Expert Committee on Zoonoses, Second Report, in the year 1959, zoonoses (the expression zoonotic diseases is also used) are "those diseases and infections which are naturally transmitted between vertebrate animals and man." The transmission may take place directly or indirectly by means of vectors. The severity of zoonotic diseases in humans varies from mild symptoms to life-threatening conditions.

Zoonotic diseases are usually transmitted at the human–animal interface through exposure to animals (e.g., rabies), animal products (e.g., brucellosis and salmonellosis), or their contaminated environment (e.g., echinococcosis/hydatidosis). Transmission may occur by a diseased animal or by a clinically normal animal that, nevertheless, is able to transmit pathogens to humans (e.g., campylobacter and verotoxin producing *Escherichia coli* (VTEC)). A distinction is made between foodborne and nonfoodborne diseases. A concise list of zoonoses appears in Table 1.

Emerging and Neglected Zoonotic Diseases

Emerging infectious diseases (EIDs) are diseases appearing in a geographic area or population for the first time. The term reemerging diseases is also used for ancient diseases that are 'forgotten' and thought to be controlled or extinct from a particular area or population and manifest a new appearance. The emergence of EIDs is thought to be driven by socioeconomic, environmental, and ecological factors. They are, mostly, related to free-living wild animals.

The term neglected tropical diseases is used for a certain list of 17 diseases recognized as such by the WHO, including a number of zoonotic diseases appearing in Table 2. Neglected tropical zoonotic diseases are ancient endemic zoonoses in Europe and North America. They are largely controlled and tended to be overlooked, while the attention is shifted to newly emerged zoonoses. They can be, potentially, turned into a pandemic.

Significance of Zoonoses

Although, at the time of the aforementioned WHO report, the number of zoonoses was at the level of 100, they are doubled by then and still counting. Zoonoses may be bacterial, viral, parasitic, or due to unconventional agents (e.g., prions). It is estimated that out of the about 1500 human nosogenic factors, due to biological agents, 60% have multiple hosts and move between species. In addition, 75% of the EIDs, in the last ~30–35 years, are zoonotic; again, 75% of which originate from wild animals.

Further to the significance of zoonoses for human health, one must not underestimate the impact they are having in preventing the efficiency in animal food production and enhancing problems in living animals and animal products international trade.

As an indication of the significance of zoonotic diseases for human health, you can see, in Table 3, the most important zoonoses in terms of human health impact, livestock impact, amenability to agricultural interventions, severity of diseases, and emergence.

Environmental Aspects

Zoonoses present a major threat to human and animal health. These diseases, as already indicated, are multifactorial manifestations and therefore a reflection of the complexities of ecosystems in which animals and humans coexist. They are influenced by multiple interrelated global factors, including ecological evolution, human demographics, and behavior.

Emerging and reemerging diseases represent failures in understanding the socioecological systems we live in and respond to new conditions. What we learn from these failures will largely determine how successful we are in developing sustainable and healthy human communities.

As can be seen in Figure 1, humans, livestock, and wildlife can expose each other and spread, among them, potential pathogenic agents. Any one of these players, therefore, can spill over pathogens to the others. More specifically, changes in human behavior, expressed as population increase and urbanization, and the demand for improved living conditions, requiring in turn proportional increase in food production and related economic activity, in particular agricultural development, are a decisive contributing factor.

For example, water management, associated with still water collections, one way or another, increases mosquito breeding opportunities, which in turn may result in enhancing disease occurrence, like Rift Valley fever. Such conditions are observed after the construction of dams and irrigation networks. Similarly, intensive animal farming promotes disease transmission through untreated or poorly treated waste material spread in the environment or through ventilation system diffusion of contaminated material carrying pathogens.

Due to the problems related to high animal population density, maintained in intensive livestock production (e.g., pigs and poultry), which facilitated disease transmission, efforts were made to combat them with the use of antibiotics, either therapeutically or preventatively. However, these schemes resulted in widespread antibiotic-resistant pathogens, including those of zoonotic significance. These conditions, more specifically, can contaminate animal food products and potentially provide for the production of unsafe foods. It is important in this respect to mention that, according to EU food

Table 1 Concise list of zoonoses[a]

Disease	*Causative organism*
Bacterial diseases	
Anthrax	*Bacillus anthracis* (e–fb)
Bordetellosis	*Bordetella bronchiseptica* (e)
Brucellosis	*Brucella abortus* (e), *Brucella melitensis* (fb–e), *Brucella suis* (e), *Brucella canis* (e)
Campylobacter enteritis	*Campylobacter jejuni* (fb–e), *Campylobacter coli*, *C. fetus*, *C. laridis*
Capnocytophaga infection	*Capnocytophaga canimorsus* (e), *C. cynodegmi* (e)
Cat scratch disease	*Bartonella henselae* (e), *B. quintana* (e)
Clostridial diseases (see also 'Tetanus' in the succeeding text)	*Clostridium perfringens*, type A (e)
Erysipeloid	*Erysipelothrix rhusiopathiae* (e)
Escherichia coli infections (only some infections are considered zoonotic)	Certain strains of *E. coli*, including O157:H7 and others (fb–e)
Glanders	*Burkholderia mallei* (e)
Leptospirosis	*Leptospira interrogans* (e–fb)
Listeriosis	*Listeria monocytogenes* (fb)
Lyme disease (borreliosis)	*Borrelia* species (vb)
Melioidosis (pseudoglanders)	*Pseudomonas pseudomallei* (e)
Mycobacteriosis	Mycobacterium avium–intracellulare complex (fb)
Pasteurellosis	*Pasteurella multocida* and other species (e)
Plague	*Yersinia pestis* (vb–e)
Psittacosis and ornithosis	*Chlamydophila psittaci* (e)
Rat bite fever	*Streptobacillus moniliformis*, *Spirillum minus* (e–fb)
Relapsing fever (borreliosis)	*Borrelia recurrentis* (vb)
Salmonellosis	*Salmonella enterica* (fb–e)
Southern tick-associated rash illness	*Borrelia lonestari* (vb)
Streptococcal infections	*Streptococcus pyogenes*, other streptococci (fb–e)
Tetanus	*Clostridium tetani* (e)
Tuberculosis (see also 'Mycobacteriosis')	*Mycobacterium bovis* (e–fb), *Mycobacterium tuberculosis* (e)
Tularemia	*Francisella tularensis* (e–vb–fb)
Vibriosis	*Vibrio parahaemolyticus* (fb–e), *V. vulnificus*, and other vibrios *Vibrio cholerae* (fb–e)
Yersiniosis	*Yersinia pseudotuberculosis* (fb–e), *Yersinia enterocolitica* (fb–e)
Rickettsial diseases	
Boutonneuse fever, tick bite fever	*Rickettsia conorii*-related *Rickettsia* (vb)
Ehrlichiosis	*Ehrlichia chaffeensis* (vb), *Anaplasma phagocytophilum* (vb), *Ehrlichia sennetsu* (vb), *Ehrlichia ewingii* (vb)
Eperythrozoonosis	*Mycoplasma* (*Eperythrozoon*) species (e–vb)
Murine typhus	*Rickettsia typhi* and related species (vb)
Q fever (query fever)	*Coxiella burnetii* (e–vb–fb)
Queensland tick typhus	*Rickettsia australis* (vb)
Rickettsial pox	*Rickettsia akari* (vb)
Rocky mountain spotted fever	*Rickettsia rickettsii* (vb)
Spotted fever group	*Rickettsia parkeri* (vb)
Scrub typhus	*Orientia tsutsugamushi* and related species (vb)
Typhus	*Rickettsia prowazekii* (vb)
Fungal diseases	
Actinomycosis	*Actinomyces israelii* (e), rarely other *Actinomyces* species (e)
Aspergillosis (allergic bronchopulmonary aspergillosis)	*Aspergillus* species (e)
Blastomycosis	*Blastomyces dermatitidis* (e)
Candidiasis (moniliasis)	*Candida* species (e)
Coccidioidomycosis	*Coccidioides immitis* (e)
Cryptococcosis	*Cryptococcus neoformans* (e)
Dermatophilosis	*Dermatophilus congolensis* (e)
Histoplasmosis	*Histoplasma capsulatum* (e)
Nocardiosis	*Nocardia* species (e)
Pneumocystis pneumonia	*Pneumocystis carinii* (human strain) (e)
Rhinosporidiosis	*Rhinosporidium seeberi* (e)
Ringworm (dermatophytosis)	*Microsporum* (e), *Trichophyton* (e), and *Epidermophyton* species (e)
Sporotrichosis	*Sporothrix schenckii* (e)
Parasitic diseases – protozoans	
Babesiosis	*Babesia microti* (vb), *B. bovis* (vb), *Babesia divergens* (vb)

Disease	*Causative organism*
Balantidiasis	*Balantidium coli* (fb)
Chagas' disease (American trypanosomiasis)	*Trypanosoma cruzi* (e)
Cryptosporidiosis	*Cryptosporidium parvum* (e–fb)
Giardiasis	*Giardia lamblia* (fb–e)
Leishmaniasis (kala-azar (visceral))	*Leishmania donovani* and other species (vb)
Malaria of nonhuman primates	Many species of plasmodium (vb)
Microsporidiosis	*Microsporidia* (e–fb), *Enterocytozoon bieneusi* (e–fb), *Encephalitozoon cuniculi* (e–fb), *Encephalitozoon intestinalis* (e–fb), *Encephalitozoon hellem* (e–fb)
Sarcocystis (sarcosporidiosis)	*Sarcocystis suihominis* (fb), *S. hominis* (fb)
Toxoplasmosis	*Toxoplasma gondii* (fb)
Trypanosomiasis (African sleeping sickness)	*Trypanosoma brucei* (vb), *T. brucei* rhodesiense (vb), *T. brucei* gambiense (vb)
Parasitic diseases – trematodes (*flukes*)	
Clonorchiasis	*Clonorchis sinensis* (Chinese liver fluke) (fb)
Dicrocoeliasis	*Dicrocoelium dendriticum* (fb), *D. hospes* (lancet fluke) (fb)
Echinostomiasis	*Echinostoma ilocanum* (fb) and other *Echinostoma* species (fb)
Fascioliasis	*Fasciola hepatica* (fb), *F. gigantica* (fb)
Fasciolopsiasis	*Fasciolopsis buski* (fb)
Gastrodiscoidiasis	*Gastrodiscoides hominis* (vb?–fb?)
Heterophyiasis	*Heterophyes* (fb) and other heterophids (fb)
Metagonimiasis	*Metagonimus yokogawai* (fb)
Opisthorchiasis	*Opisthorchis felineus* (cat liver fluke) (fb), *Amphimerus pseudofelineus*, *Opisthorchis viverrini* (small liver fluke) (fb)
Paragonimiasis (lung fluke disease)	*Paragonimus westermani* (fb), *P. africanus* (fb), *P. mexicanus* (fb), and other species (fb)
Schistosomiasis (bilharziasis)	*Schistosoma japonicum* (vb), *Schistosoma intercalatum* (vb), *Schistosoma mansoni* (vb), *Schistosoma matthei* (vb), *Schistosoma mekongi* (vb)
Swimmer's itch	*Schistosome cercariae* (vb)
Parasitic diseases – cestodes (*tapeworms*)	
Asian taeniasis	*Taenia asiatica* (fb)
Bertielliasis	*Bertiella studeri* (vb?–fb?), *B. mucronata* (vb?–fb?)
Coenurosis	*Taenia multiceps* (fb?), *Taenia serialis* (fb?), *Taenia brauni* (fb?)
Diphyllobothriasis (fish tapeworm infection)	*Diphyllobothrium latum* (fb), *D. pacificum* (fb)
Dipylidiasis (dog tapeworm infection)	*Dipylidium caninum* (fb?)
Echinococcosis	*Echinococcus granulosus* (fb?)
Echinococcosis	*Echinococcus multilocularis* (fb?) *Echinococcus vogeli* (fb?)
Hymenolepiasis (dwarf tapeworm infection)	*Hymenolepis nana* (fb?–vb?)
Inermicapsifer infection	*Inermicapsifer madagascariensis* (fb?)
Mouse or rat tapeworm	*Hymenolepis nana* (vb?), *H. diminuta* (vb?)
Raillietina infection	*Raillietina* species (fb?)
Sparganosis	*Spirometra* species (fb–e?)
Taeniasis (beef tapeworm disease)	*Taenia saginata* (fb)
Taeniasis (pork tapeworm disease), cysticercosis, and neurocysticercosis	*Taenia solium* (fb)
Parasitic diseases – nematodes (*roundworms*)	
Angiostrongyliasis	*Parastrongylus costaricensis* (fb), *Angiostrongylus cantonensis* (fb)
Anisakiasis	Larvae of *Anisakis* (fb) and *Pseudoterranova* species (fb)
Capillariasis (intestinal)	*Capillaria philippinensis* (fb)
Capillariasis (liver)	*Capillaria hepatica* (fb?)
Capillariasis (lung)	*Capillaria aerophila* (fb)
Dioctophymosis (giant kidney worm infection)	*Dioctophyme renale* (fb)
Dracunculiasis (guinea worm infection)	*Dracunculus insignis* (fb)
Dirofilariasis (heartworm infection)	*Dirofilaria immitis* (vb)
Gnathostomiasis	*Gnathostoma spinigerum* (fb)
Gongylonemiasis	*Gongylonema pulchrum* (fb?–vb?)
Larva migrans, skin (see also 'Gnathostomiasis')	*Ancylostoma braziliense* (e), *A. caninum* (e), *Uncinaria stenocephala* (e), *Strongyloides stercoralis* (e)
Larva migrans, visceral (see also 'Angiostrongyliasis' and 'Anisakiasis')	*Toxocara canis* (fb), *T. cati*, *Baylisascaris procyonis* (fb)
Malayan filariasis	*Brugia malayi* (vb)
Strongyloidiasis	*Strongyloides stercoralis* (e), *S. fuelleborni* (e)
Thelaziasis	*Thelazia* species (vb)

(*Continued*)

Table 1 (Continued)

Disease	*Causative organism*
Trichinosis (trichinellosis)	*Trichinella spiralis* and subspecies (fb), *T. nativa* (fb), *T. britovi* (fb), *T. nelsoni* (fb), *T. pseudospiralis* (fb)
Tropical eosinophilia	*Brugia pahangi* (vb)
Parasitic diseases – others	
Hirudiniasis	*Limnatis nilotica* (e) and other leeches (e)
Macracanthorhynchosis	*Macracanthorhynchus hirudinaceus* (fb?) and other species (thorny-headed worms) (fb)
Diseases spread by insects, ticks, or mites	
Acariasis (mange)	Mites of *Sarcoptes* (e), *Cheyletiella* (e), *Dermanyssus* (e), and *Ornithonyssus* species (e)
Myiasis	*Cochliomyia hominivorax* (screwworm), *Chrysomya bezziana* (Old World screwworm), *Cuterebra* species (rodent or rabbit bot fly), *Hypoderma lineatum*, *Gasterophilus* species (equine bot fly), *Oestrus ovis*, *Rhinoestrus purpurensis*, *Hypoderma bovis* (warbles), *Wohlfahrtia* species, *Dermatobia hominis* (human bot fly), *Cordylobia anthropophaga* (tumbu fly)
Nanophyetiasis	*Troglotrema salmincola* (fb)
Pentastomid infections	*Linguatula serrata* (fb), *Armillifer* species (tongue worms) (fb)
Tick paralysis	Envenomation of ticks (vb), *Dermacentor andersoni* (vb), *D. variabilis* (vb), and sometimes *Ixodes*, *Haemaphysalis* (vb), *Rhinocephalus* (vb), and *Argas* species (vb)
Tunga infections	*Tunga penetrans* (sand fleas and jiggers) (e)
Viral diseases	
Argentinean, Bolivian, Brazilian, or Venezuelan hemorrhagic fever	Various arenaviruses (e)
Central European tick-borne encephalitis	Central European encephalitis virus (vb–fb)
Colorado tick fever	Colorado tick fever virus (vb)
Contagious ecthyma (orf)	Orf virus (parapox) (e)
Cowpox	Cowpox virus (e)
Crimean–Congo hemorrhagic fever	Nairovirus (vb)
Eastern equine encephalomyelitis	Eastern equine encephalomyelitis virus (vb)
Ebola hemorrhagic fever, Marburg hemorrhagic fever	Ebola and Marburg viruses (e)
Encephalomyocarditis	Encephalomyocarditis virus (e)
Far Eastern tick-borne encephalitis (Russian spring–summer encephalitis)	Far Eastern (Russian spring–summer encephalitis) virus (vb)
Foot-and-mouth disease	Foot-and-mouth disease virus (e)
Hantavirus pulmonary syndrome	Sin Nombre virus, black creek canal virus (e)
Hemorrhagic fever with renal syndrome	Hantaan virus (e), Dobrava virus (e), Puumala virus (e), Seoul virus (e)
Hendra virus infection	Hendra virus (e)
Hepatitis E	Hepatitis E virus (vb–e)
Herpes B virus disease	Cercopithecine herpesvirus 1 (herpesvirus simiae, B virus) (vb–e)
Influenza type A (swine flu, avian flu, bird flu, and Hong Kong flu)	Influenza virus (myxovirus) (e)
Japanese B encephalitis	Japanese encephalitis virus (vb)
Kyasanur forest disease	Kyasanur forest virus (vb)
La Crosse encephalitis	Bunyavirus species (vb)
Lassa fever	Lassa virus (e)
Louping ill	Louping ill virus (vb)
Lymphocytic choriomeningitis	Lymphocytic choriomeningitis virus (e)
Menangle virus infection	Menangle virus (e)
Milker's nodules (pseudocowpox)	Pseudocowpox virus (e)
Monkeypox	Monkeypox virus (e)
Murray Valley encephalitis	Murray Valley encephalitis virus (vb)
Newcastle disease	Newcastle disease virus (e)
New World hemorrhagic fever	Arenavirus (e)
Nipah virus infection	Nipah virus (e)
Omsk hemorrhagic fever	Omsk hemorrhagic fever virus (vb–e)
Rabies and rabies-related infections	Lyssaviruses (rabies virus, Duvenhage virus, Mokola virus, and Ibadan shrew virus) (e)
Rift Valley fever	Phlebovirus (vb–e)
Ross River fever	Ross River virus (vb)
St. Louis encephalitis	St. Louis encephalitis virus (vb)
Severe acute respiratory syndrome (SARS)	Coronavirus (e)
Sindbis virus disease	Sindbis virus (vb)
Tahyna fever	Bunyavirus species (vb)
Venezuelan equine encephalomyelitis	Venezuelan equine encephalitis virus (vb)

Table 1 (Continued)

Disease	*Causative organism*
Vesicular stomatitis	Vesicular stomatitis virus (e–vb)
Wesselsbron fever	Wesselsbron virus (vb)
West Nile virus infection	West Nile virus (vb–fb?)
Western equine encephalomyelitis	Western equine encephalomyelitis virus (vb)
Yellow fever	Yellow fever virus (vb)
Prion diseases	
Variant Creutzfeldt–Jakob disease	Prion protein (likely from bovine spongiform encephalopathy, also known as mad cow disease) (fb)

vb, vector-borne; e, exposure to infectious material (work-related, contacts, wounds, bites, scratches, 'licks,' and airborne); fb, foodborne; nd, neglected disease; em, emerging–reemerging disease; wb, waterborne.

[a]Many proved zoonoses, including some relatively rare viral infections carried by insects and infections caused by parasitic worms, have been omitted, as well as those diseases caused by fish and reptile toxins.

legislation (EU Regulations 178/2002 and 852/2004), primary food production premises are considered as food business operations. Consequently, they are obliged to certain responsibilities, related to putting together and effectively implementing and functioning a food safety management system (FSMS), tailor-made for each particular activity.

In Table 4 appears a list of zoonoses emergence linked to agricultural intensification and environmental changes.

Evidently, ecosystems are complicated, and the impact they are having on fauna and thereof on conditions potentially harboring zoonotic agents does not provide for a general interdisciplinary multipurpose approach, with patterns applicable in all cases. On the contrary, principal factors, among others, biological, ecological, economic, and social characteristics, and climatic conditions must be assessed, ad hoc, locally within each ecosystem.

The implementation, therefore, of the concept of One Medicine and One Health, which, as an integrated approach, is very important for facing zoonotic diseases per se because not, only it contributes to animal and human health but also it significantly supports, apart from aspects of economic development, food safety and security.

Foodborne Zoonotic Diseases

Foodborne zoonotic pathogens are transmitted through consumption of contaminated food and drinking water. Infectious agents present in foodstuffs include bacteria (e.g., *Salmonella* and *Campylobacter*), viruses (e.g., norovirus and hepatitis A virus), parasites (e.g., *Trichinella*), and prions (infectious agents of bovine spongiform encephalopathy).

Challenges to food safety continue to increase in unpredictable ways, largely due to changes in food production, processing, distribution, and the environment, which may contaminate food; to emerging germs and toxins of food safety significance; and to new conditions, created by new food technology applications, with an impact on food safety (e.g., minimally processed foods and maintenance of cold chain).

In Table 5, a list of the most important biological hazards responsible for foodborne illnesses appears, along with the relevant most important foods involved in each case.

Nonfoodborne Zoonotic Diseases

Nonfoodborne zoonotic diseases are transmitted through the following:

- *Direct contact or close proximity* with infected animals or through *the environment*. Examples are the following:
  - *Avian influenza*, a viral disease occurring mainly in poultry and other birds but transmissible to other animals or humans.
  - *Q fever*, caused by the *Coxiella burnetii*, affecting animals and humans. Human infection mainly results from the inhalation of contaminated dust from the placenta and birth fluids or feces from infected animals.
  - *Salmonella* infections, which can originate from contact with infected reptiles and amphibians such as pet snakes, iguanas, and frogs or their environment.
  - VTEC, which can be acquired through contact with infected farm animals.

Table 3 The most important zoonoses in terms of human health impact, livestock impact, amenability to agricultural interventions, severity of disease, and emergence

Disease	*Wild life interference*	*Human deaths (annual)*	*Affected humans (annual)*	*Death >1000 people*	*Affected >1 million people*	*Annual impacts high*	*Farm intervention*	*Others (score = 1)*	*Total score*
Gastrointestinal (zoonotic)	Important	1 500 000	2 333 000 000	2	1	1	1	0	5
Leptospirosis	Very important	123 000	1 700 000	2	1	1	1	0	5
Cysticercosis	Some importance			50 000	50 000 000	2	1	1	1
0	5								
Tuberculosis (zoonotic)	Some importance			100 000	554 500	2	0	1	1
0	4								
Rabies	Important	70 000	70 000	1	0	0	1	Severe	4
Leishmaniasis	Important	47 000	2 000 000	2	1	0	1	0	4
Brucellosis	Some importance			25 000	500 000	2	0	1	1
0	4

Emerge	3								
Dengue fever	Minor	20 000	50 000 000	2	1	0	0	0	3
Ebola	Very important	500	800	2	0	0	0	Severe	3
Hanta disease	Very important	1750	175 000	2	0	0	0	Emerge	3
Avian influenza	Important	77	145	0	0	1	1	Emerge	3
Bovine spongiform encephalopathy	Some importance			182	188	0	0	1	1
Severe	3								
Psittacosis	Important	2250	22 000	2	0	0	1	0	3
Japanese encephalitis	Possibly, bats	11 000	40 000	2	0	0	1	0	3
Buffalopox	Not important	Negligible	Common	0	1	1	1	0	3
Rift Valley fever	Important	45	150	0	0	1	1	Emerge	3

Data from the WHO and authoritative literature: when there are several authoritative estimates, the midpoint is given.

Note: High human mortality gets a double weight as the most important criterion for many stakeholders. Total score = (human death × 2) + (humans affected) + (high livestock impacts) + (farm intervention possible) + (other concerns: severe or emerging disease). The maximum possible score is therefore 6 and the minimum 0.

[a]Importance of zoonotic transmission not fully known. Not a problem in poor countries.

Adapted from, ILRI, 'Mapping of poverty and likely zoonotic hotspots.'

- *Vectors* that can transmit diseases such as malaria, West Nile virus, Lyme disease, tick-borne encephalitis, leishmaniosis, and Crimean–Congo hemorrhagic fever.

Prevention and Control

For zoonoses prevention, the focus is on surveillance, rapid detection, and quick response. Zoonotic infections in animals may produce a distinctive recognizable disease, such as rabies, or they may manifest themselves as a mild illness or the animal may be entirely asymptomatic. However, in this last case, if the pathogen is transmitted to humans, it may result in illness if they lack the specific immunity required.

Anyone, who has contact with animals, can get a zoonotic disease, but some people may be more at risk than others. Risk

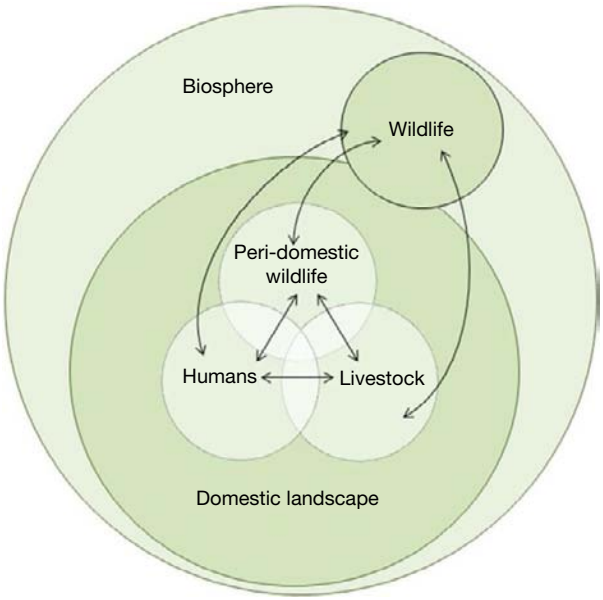

Figure 1 Pathogen flow at the wildlife–livestock–human interface. Arrows indicate direct, indirect, or vector-borne candidate pathogen flow. In each host species, there are a vast array of constantly evolving microorganisms, some of which are pathogenic in the host. These are a source of new organisms for other host species, some of which may be pathogenic in the new host or may evolve in the new host to become pathogenic. If the pathogen is also transmissible in the new host species, then a new transmission cycle may be established. The rate and direction of candidate pathogen flow will depend on the nature and intensity of interaction between wildlife, livestock, and human compartments and the characteristics of the compartments (**Table 2**). Adapted from *Proceedings of the National Academy of Science*, May 21, 2013, Vol. *110*, No 21, p. 8400.

factors for susceptibility to zoonoses, among others, are certain population groups, including professional and occupational groups working in close contact with animals (like livestock attendants, slaughterhouse workers, and veterinarians); homeless and poor people; and in general, people with a weakened immune system, children aged less than five, the elderly, and pregnant women.

The factors promoting zoonotic disease outbreaks in humans, apart from frequent contact with animals, include intensive livestock production, poor animal and personal hygiene, and overlap with wildlife habitat. A common way for vector-borne diseases to spread is through the bite of a mosquito or tick. People can get diseases in most places, where they might have contact with infected animals and insects, including animal displays, farms, petting zoos, county or state fairs, pet stores, child care facilities or schools, nature parks, and wooded and bushy areas.

In order to reduce the risks of transmission of zoonoses from pet animals to humans and also to production animals, the concept of responsible pet ownership (RPO) is advocated. It is recognized that education and awareness promotion of pet owners, for RPO, to prevent zoonoses related to companion animals, is of a paramount importance for eliminating these diseases.

The WHO and EFSA promote activities, of the general public's concern, for preventing zoonoses. They include the following:

- Promotion of awareness to understand the potential risk for human infection from zoonotic diseases, after contact with animals.
- Specific risk communication, as it may be required, through appropriate public actions.

Table 4 Zoonoses emergence linked to agricultural intensification and environmental change

Type of wildlife–livestock–human interface	*Level of biodiversity*	*Characteristics of livestock population*	*Connectedness between populations*	*Examples of zoonotic disease with altered dynamics*
'Pristine' ecosystem with human incursion to harvest wildlife and other resources	High	No livestock	Very low, small populations and limited contact	Ebola, HIV, SARS, and Nipah virus in Bangladesh and India
Ecotones and fragmentation of natural ecosystems: farming edges, human incursion to harvest natural resources	High but decreasing	Few livestock, multiple species, mostly extensive systems	Increasing contact between people, livestock, and wild animals	Kyasanur forest disease, bat rabies, and *E. coli* interspecies transmission in Uganda and Nipah virus in Malaysia
Evolving landscape: rapid intensification of agriculture and livestock, alongside extensive and backyard farming	Low, but increasing peridomestic wildlife	Many livestock, both intensive and genetically homogenous, as well as extensive and genetically diverse	High contacts between intensive and extensive livestock, people, and peridomestic wildlife. Less with endangered wildlife	Avian influenza and Japanese encephalitis virus in Asia
Managed landscape: islands of intensive farming, highly regulated. Farm land converted to recreational and conservancy	Low, but increased number of certain peridomestic wildlife species	Many livestock, mainly intensive, genetically homogeneous, biosecure	Fewer contacts between livestock, and people; increasing contacts with wildlife	Bat-associated viruses in Australia, West Nile virus in the United States, and Lyme disease in the United States

Conceptual framework of types of wildlife–livestock–human interface and their characteristics.
Adapted from *Proceedings of the National Academy of Science*, May 21, 2013, Vol. *110*, No. 21, p. 8402.

Table 5 Biological hazards responsible for most important foodborne illnesses and related foods

Campylobacter (poultry)
E. coli O157:H7 (ground beef, leafy greens, and raw milk)
Listeria (deli meats, unpasteurized soft cheeses, and produce)
Salmonella (eggs, poultry, meat, and produce)
Vibrio (raw oysters)
Norovirus in many foods (e.g., sandwiches and salads)
Toxoplasma (meats)

- Improvement in the level of personal hygiene by
  - acquiring the habit to wash hands thoroughly and frequently, after contact with animals.
  - closely supervising children to ensure they wash their hands properly and avoid hand-to-mouth activities (thumb sucking, eating, and use of pacifiers) after animal contact.
- The use of registered insect repellents and products that contain repellents for use on clothing. Accordingly, treat clothing and gear, such as boots, pants, socks, and tents.
- Inspection for and removal of ticks from the human body, with specific care for children.
- Limitation in the number of places around residential areas for mosquitoes to breed by eliminating places holding water.

For health professionals, recommendations may include the following:

- Responsible services to systematically search for potential sources of human infection from animal sources and the environment
- Joint efforts and coordination among public health authorities and related professionals, both public and private
- Risk communication and information sharing among responsible health services and close coordination to manage risks related to the movement and trade of livestock
- Concerted actions for
  - good practices in the efficient implementation of biosecurity measures in farms and at border or territory crossings;
  - continuously reminding and training people, who work with livestock and in slaughterhouses, for the significant importance of personal hygiene practices;
  - the implementation of the One Health concept

Zoonotic diseases are strongly influenced by social and economic practices. Many of them are thus not only diseases related to climate and environment but also diseases of poverty. In epidemiological terms, conditions of poverty increase the probability of enhanced contact and hence increase the likelihood of epidemics. Combating diseases like tuberculosis and malaria has much more to do with housing, nutrition, and water management than with any advances in biomedical science.

Animal migrations facilitate the global spread of pathogens and increase cross-species transmission. Understanding, predicting, and controlling diseases at the human–animal interface are a huge challenge, for health professionals, in today's world, where international trade and travel globalized diseases. However, even when risks are identified, adequate underlying infrastructure and resources are required to take the measures needed, if outbreaks and emergencies are to be prevented or controlled.

Special consideration needs to be given to vector-borne diseases. Vectors may move to long distances and therefore may introduce disease, in new geographic areas, by means of human traveling, international trade, animal movement (more specifically livestock and migratory birds), the wind, and changes in agricultural practices.

One Health

Health is a state of complete physical, mental, and social well-being and not merely the absence of disease or infirmity. It is the outcome of a complex of several interdependent medical, economic, sociocultural, environmental, and ecological factors. People's health and well-being and equally animal health and welfare are strongly interlinked. Both also influence and are impacted by the health of the environment. Health is a precondition for well-being and respectively welfare. Well-being and welfare reinforce health. The advancement of the health and well-being of people and animals depends on effective and sustained cooperation between varied professions and disciplines, in both the public and private sectors (World Veterinary Association (WVA) position).

Therefore, multisectoral horizontal links at all levels between human and animal health professionals, public and private, are needed to face zoonotic diseases. Reducing relevant risks is impossible to be achieved alone by a particular sector, regardless of its importance. Therefore, there is an increasing convergence to a One Health approach, which incorporates, in an integrated manner, cross-sectoral, multidisciplinary cooperation. One cannot distinguish human, animal, and environmental health. The health of each one of them is the precondition for the health of the others (see again **Figure 1**).

Building sustainable national mechanisms for more effective cross-sectoral cooperation has greatly facilitated risk assessment and management of specific diseases, such as H5N1 influenza and Rift Valley fever. At the international level, strong cooperation among the WHO, OIE, and FAO is improving the efficiency of surveillance, including data collection, risk assessment, and risk management options, allowing for consistent, science-based risk communication on global health threats at the human–animal–ecosystem interface. A strategic agreement outlines the sharing of responsibilities and enhanced coordination of complementary roles and activities between the FAO, OIE, and WHO at national, regional, and global levels. Internally, cooperation takes place across departments, clusters, and regions of the aforementioned organizations. Externally, further cooperation materializes with links and contacts to additional international partners, such as international agencies and networks, NGOs, and academia, and to national agencies, such as institutions and administrative governmental units.

According to statements made by EU officials in support of it, One Health is linked to livelihood and equity and fits with EU objectives to promote global security, social justice, international cooperation, and multilateralism and fight poverty. Further, there should be no resignation vis-à-vis the existence of different health standards across nations.

For the EU, the One Health movement has in many senses grown out of the response to influenza-related crises. The definition of One Health chosen by the European Commission in its external relations and actions reads as follows: the One Health approach consists of (i) improving health and well-being through the prevention of risks and the mitigation of the effects of crises that originate at the interface between humans, animals and their various environments; (ii) for that purpose: (a) promoting a multi (cross) sectoral and collaborative approach; and (b) promoting a 'whole of society' approach to health hazards, as a systemic change of perspective in the management of risk.

In May 2010, a meeting was organized by the Centers for Disease Control and Prevention (CDC), Atlanta, Georgia, the United States, titled 'Operationalizing "One Health": A Policy Perspective.' 'Critical enabling initiatives' such as 'training,' 'one health global network,' 'information clearing house,' 'needs assessment,' 'capacity building,' 'proof of concept,' and 'business plan' were identified as fundamental to moving forward One Health.

Further, it seems reasonable to think that an improved coordination that includes intersectoral cooperation in surveillance, communications, outbreak response, and sample sharing community-based interventions for the prevention and control of zoonotic diseases is needed. There is further and more specific need for systematic cooperation between strong and autonomous public health services and strong and autonomous veterinary services, in the respect of their specific expertise.

However, a culture of cross-sectoral cooperation does not yet exist all along the chain. Fostering such a culture, stretching from the field level to that of international organizations, is the big challenge for successfully controlling zoonotic diseases in general and more particularly either emerging or neglected ones.

There is a deficit in current university medical training, due to the fact that the whole training concept is geared to treat, rather than prevent, diseases and preserve and promote health. A cultural change putting emphasis on the prevention and appreciation of the importance of the connection, in terms of health and well-being, between humans, animals, and ecosystems, is required. Combating zoonotic diseases is not how to clean up the disease mess after the fact, but on how to prevent the mess from occurring in the first place. It would almost appear that the ideological lenses through which diseases in general are being studied preclude acting on the evidence. This, if nothing else, should raise a warning flag that those who study disease are not necessarily well equipped to promote health.

Fujian Academy of Agricultural Sciences, Fuzhou, China

X Zhu
Nanjing Agricultural University, Nanjing, China

E Zoidis
Agricultural University of Athens, Athens, Greece

INDEX

This index is in letter-by-letter order, whereby hyphens and spaces within index headings are ignored in the alphabetization, and it is arranged in set-out style, with a maximum of four levels of heading. Location references refer to the volume number, in bold, followed by the page number. Page numbers suffixed by *b*, *f* and *t* refers to boxes, figures and tables terms respectively. *vs.* indicates a comparison. **Bold locators** refers to main articles.
