shrimp, crabs, oyster, and finfish. Levels of concerns were calculated for 13 PAHs and their alkylated homologues selected among the most studied PAHs in petroleum mixture, namely, Na (including C1, C2, C3, and C4 homologues), F (including C1, C2, and C3), A and Pa (including C1, C2, C3, and C4), P, Fl, Ch, BkF, BbF, BaA, BaP, DBahA, and IP. A daily consumption of $13\ g\ day^{-1}$ for shrimp and crab, $12\ g\ day^{-1}$ for oyster, and $49\ g\ day^{-1}$ for finfish was considered for a reference person of 80 kg (http://www.fda.gov/food/ucm217601.htm).

Since 2001, the Canadian legislation has settled a limit of $3\ \mu g\ kg^{-1}$ for the sum of heavy PAHs (BaP, DBahA, BaA, BbF, BkF, IP, Ch, and BghiP) calculated on the basis of the toxic equivalence to BaP only in pomace oil. The toxic equivalence factor approach considers the risk of any single PAH compared to that of BaP. This approach assumes the additivity of the risks, but some studies showed that PAH mixtures can present not only additive but also synergistic and/or antagonistic effects. On the other hand, the toxicity of most environmentally relevant PAHs has not yet been quantified; therefore, the risk may be underestimated.

The Chinese government set a maximum level for the only BaP content in different classes of product, namely, $5\ \mu g\ kg^{-1}$ for cereal and cereal products, meat and meat products, and fish and fishery products both smoked and roasted and $10\ \mu g\ kg^{-1}$ for fats and oils (GB2762-2012).

In Australia and New Zealand, no regulatory limits have been set for PAHs, but the general approach is to minimize the exposure following the ALARA (as low as reasonably achievable) principle and applying good operational practices.

Source and Occurrence in Food

PAHs are formed from both natural and anthropogenic sources. The former includes natural combustion, such as forest fires and volcanoes, and long-term degradation followed by synthesis (fossil fuels contain extremely complex mixtures of these compounds, with a prevalence of highly alkylated ones). The anthropogenic sources are mainly related to incomplete combustion of organic material (forming mainly parent PAHs). The formation mechanism occurs primarily by partial cracking of organic compounds to smaller unstable fragments at high temperatures (pyrolysis), mostly radicals, which recombine to give relatively stable PAHs (pyrosynthesis). The main rate of formation occurs linearly between 500 and 750 °C, whereas above 3000 °C, they are not formed. The ratio between alkylated PAHs and parent PAHs can be an indication of a source of contamination.

Foods can be contaminated by PAHs through two main routes, namely, environmental pollution and lack of good manufacturing practices during food production. The two sources are discussed separately in the following sections.

Environmental Sources

Natural sources of PAH emissions in the environment are forest fires, volcanoes, hydrothermal process, oil seepage, and carbonization. Nevertheless, they are present in the environment mainly due to anthropogenic sources, such as exhaust from motor vehicles; domestic combustion of wood, oil, gas, and charcoal; industrial biomass combustion; open burning of agricultural debris; tobacco smoke, laying tar, coke oven, and roofing tar emission; asphalt roads; and coal, coal tar, and hazardous waste sites.

Once released to the atmosphere, PAHs may be transported quite far from the emission source and can be removed from the atmosphere by wet and dry deposition onto soil, water, and vegetation. In the air, PAHs are subjected to reactions with oxidant gases, such as NO_2, O_3, and SO_3, and are photooxidized. Many PAHs, such as BaP, are rapidly destroyed by UV light.

After deposition, PAHs may undergo different fates: In surface water, they can be volatilized, photolyzed, biodegraded, and bound to suspended particles or sediments or accumulate in aquatic organisms; in soil, they can be volatilized or undergo biotic or abiotic degradation, mainly photolysis and oxidation. PAHs in soil can also enter groundwater and be transported within an aquifer.

The relative solubility in water and organic solvents (characterized by the log K_{ow} value) affects transport and distribution of PAHs between different environmental compartments and their uptake and accumulation by living organisms. The chemical reactivity influences their adsorption to organic matter or their degradation. The PAH mixture profile, which may be found in foods and feeds contaminated by environmental sources, can be very different from the original source, due to the different properties within the large group of PAHs.

Due to the lipophilic characteristics of PAHs, high-water-content plant tissues have a limited amount of these contaminants, but the waxy surfaces of vegetables and fruits can concentrate PAHs through surface adsorption. The superficial contamination of vegetables in urban areas can be up to 100 times higher than in rural areas. Some authors found that the amount of BaP in fruits from rural areas ranged between 0.19 and $0.34\ \mu g\ kg^{-1}$, while in urban areas, it ranged between 30 and $60\ \mu g\ kg^{-1}$. Up to 50% of these kinds of contamination can be removed by careful washing of the surface of vegetables and fruits.

Technological Processing

Heat-processing procedures during food preparation, in particular grilling, roasting, and smoking, involving direct contact with combustion gases, are among the major sources of PAH

contamination in food. The level of contamination in smoked products is related to the time and temperature of processing, humidity, types of control and smoke used, and the design and types of kilns. Modern kilns have strict electronic control of the entire process. Different types of wood or woodchips used to generate smoke produce different amounts of PAHs, with the highest concentration found when spruce, hazel tree, plum tree, and aspen are used, whereas they are lowest when apple tree, alder, and maple are burned. Over the last decades, commercial smoked food production has generally replaced the traditional smoking process with the use of liquid smoke flavoring. The latter derives from smoke subjected to fractionation and purification; thus, the content of PAHs on the final product is greatly reduced and strictly controlled.

It has been demonstrated that in canned smoked fish, over 70% of the entire amount of BaP migrates from the fish to the oil fraction.

Roasting may also lead to direct or indirect contamination, but to a small extent, considering that the temperature reached is relatively low for PAHs formation (up to 260 °C). It has been proven that strong coffee bean roasting conditions lead to significant levels of P, Ch, and BaA but low BaP (approximately 0.2 μg kg^{-1}). However, the transfer from the coffee bean to the coffee brew was reported low (in general lower than 140 ng l^{-1}) and obviously related to the water solubility of the specific PAH.

Differently from industrial process, considerable variability was found in the PAH level in domestic grilled products, depending on the heat source, the type and geometry of the grill, the composition of the food grilled, and the cooking time. However, since PAHs arose mainly from the pyrolysis of fat dropped into the flame, as long as the food is protected from direct contact with flames, contamination can be controlled.

Another important source of contamination of PAHs is related to the mineral oil contamination, which is composed of two main groups of compounds, mineral oil saturated hydrocarbons (MOSH) and (mainly alkylated), mineral oil aromatic hydrocarbons (MOAH). Mineral oils, previously purified of the aromatic fraction (food-grade quality), are widely employed in the food industries as releasing agents, antidust agents, etc. However, accidental or intentional contamination with nonfood-grade mineral oil may occur. The main sources of the latter are jute bags, recycled cardboard, plastics, lubricating oils, printing inks, and environmental contamination.

Occurrence and Dietary Intake

Several reports have been published concerning surveys of PAH contamination in foodstuffs. The most recent one is the report published by EFSA in 2008 on the data collected from the European member states on request of the EC (Rec. 2005/108/EC). Figure 2 outlines a summary graphic on the BaP content (average and the maximum amount found) in different Codex food categories, extrapolated from the most relevant data in the report (considering only the food categories in which more than ten samples were analyzed).

Among the main categories, the most contaminated ones, on average, were coffee and tea, food supplements, herbs and spices, fresh and treated mollusks, and fats and oils. There is no specification of the type of lipids included in the two distinct categories reported, namely, fats and oils and vegetable oil. However, in a previous report published in 2004 by the EC, olive pomace oil, grape seed oil, and seed oils resulted much more contaminated compared to virgin olive oil, due mainly to the drying process carried out before oil extraction and the raw material handling. The refining process reduces the amount of PAHs; specifically deodorization removes light PAHs, while bleaching in the presence of activated charcoal reduces heavy PAHs.

A high level of contamination can be found in smoked meat and fish, which is related to the method of smoking. The liquid smoked products are practically noncontaminated, while the traditionally smoked products can present over 5 μg kg^{-1} of BaP.

Seawater may be highly contaminated with PAHs due to oil spills, industrial and urban effluents, and leaking from creosote wharfs and pilings. However, bluefish species, such as tuna, mackerel, and salmon, generally present lower contamination than mollusks. Indeed, fish, in contrast with bivalves, oxidize and metabolize PAHs to water-soluble compounds, which are gradually excreted. Since bivalves filter large volumes of water, their levels of BaP can be significantly high (several hundreds of ng g^{-1}).

There are not many studies on the dietary intake of PAHs, and it is difficult to generalize since it is strictly related to the availability of food consumption surveys and their criteria and the PAH occurrence data in the national diet. In 2005, the EFSA claimed the necessity of a common database on food consumption to improve the consistency and reliability of exposure assessment carried out by the various EFSA Panels. As a result, in 2007, the development of the Concise European Food Consumption Database started, which was published in 2008.

Upon processing of such data, cereals and seafoods were the main contributors to the dietary intake, mainly due to high consumption, rather than a high contamination level of these products. In particular, cocoa butter and pomace oil were excluded from the food categories examined, since they were not consumed as such; therefore, the fats and oils category, which was among the main sources in a previous survey by the JECFA, was surpassed by seafood.

Notwithstanding the general low consumption, some foodstuffs present very high levels of contamination and may affect the overall exposure in particular cases. Some food supplements (such as fish oil, ginseng, bee products, and plant extract), whose consumption is very variable depending on their intended use, were found highly contaminated (up to 270 μg kg^{-1}). Equally, some spices were found with very high level of PAHs (up to 75 μg kg^{-1}, with an average of 4.75 μg kg^{-1}).

Considering all the European Countries, an average daily intake can be estimated in the 185–255 ng day^{-1} range for BaP and in the 936–1449 ng day^{-1} and in the 1415–2136 ng day^{-1} range for PAH4 and PAH8, respectively.

Toxicity and Risk Assessment

PAHs, once absorbed in the organism, become toxic during the attempt to eliminate them through feces or urine. In fact, some intermediates of the metabolic pathway are very reactive,

forming adducts with DNA, while the final product can be used as an exposure biomarker.

Absorption

There are three main routes of absorption of PAHs in humans: inhalation, skin contact, and ingestion. The rate of absorption by the lungs depends on the structure of the PAH, the size, and the chemical nature of the particles where PAHs are adsorbed. The absorption through skin contact is characteristic of occupational exposure, like coal cooking, petroleum refining, and road paving, and it involves both diffusional and metabolic processes. The main route that will be discussed hereafter is ingestion of PAHs occurring through food and water. Some authors have suggested two phases involved in the absorption process: uptake by the mucosa, followed by diffusion through the intestinal wall. The composition of the diet affects PAH absorption. In fact, it has been shown that lipophilic foods increase absorption of ^{14}C-BaP, while cellulose, lignin, bread, rice flakes, and potato flakes suppress it in Wistar rats.

Due to the lack of functional groups, these compounds can easily pass through lipoprotein membranes and reach all internal organs. Several authors have shown that detectable levels of PAHs can be identified in almost all internal organs. Organs rich in adipose tissue can store hydrocarbons and gradually release them, while the gastrointestinal tract contains high

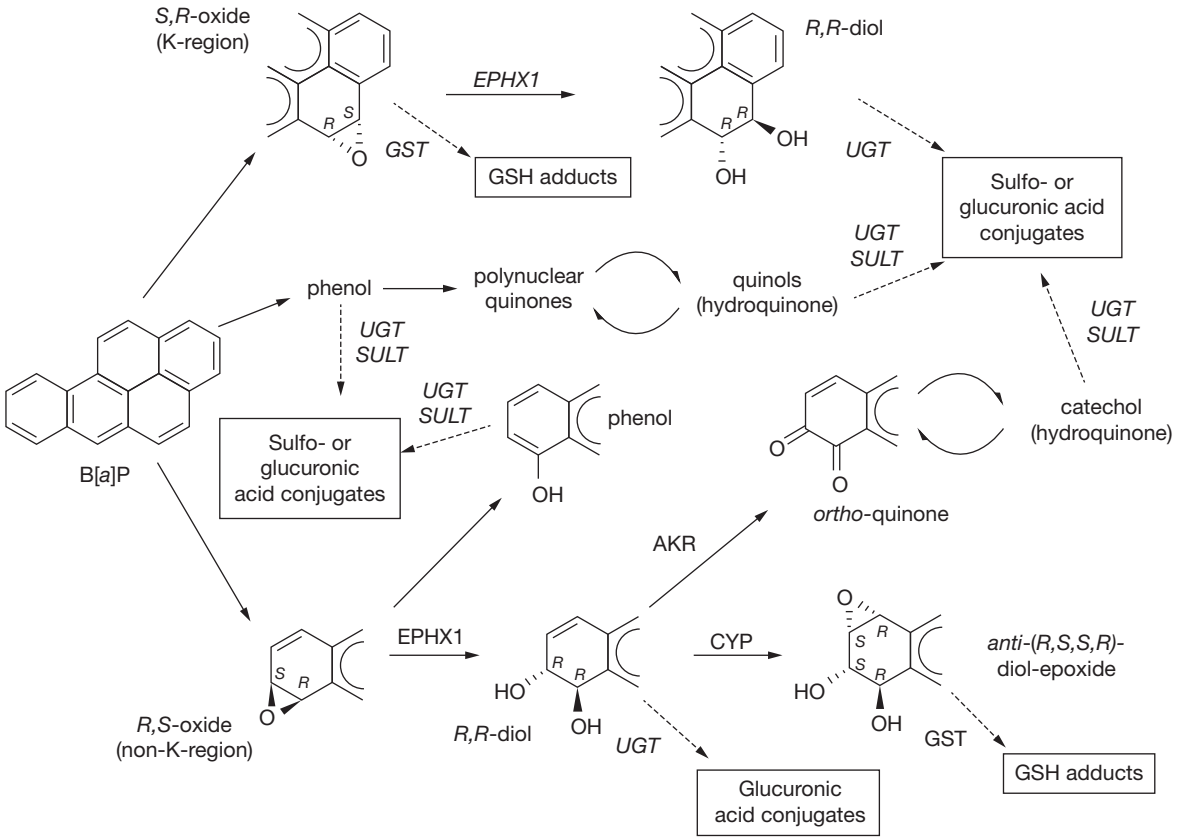

Figure 3 Scheme of benzo[a]pyrene metabolism. Reproduced from Luch A., Baird W.M. (2010). Carcinogenic polycyclic aromatic hydrocarbons. In McQueen C. A. (ed.) Comprehensive Toxicology (2nd ed.), pp. 85–123. Elsevier.

levels of PAHs and their metabolites, independently of the route of absorption.

Metabolism and Excretion

The metabolism of PAHs, using BaP as an example, is schematized in Figure 3.

The general scheme of the PAH metabolism involves oxidation to a range of primary (epoxides, phenols, and dihydrodiols) and secondary (diol epoxides, tetrahydrotetrols, and phenol epoxides) metabolites, followed by conjugation with glutathione, glucuronic acid, or sulfate. A large number of inducible enzymes are involved in these stages (microsomal cytochrome P450-dependent monooxygenase, glutathione transferases, dehydrogenases, hydrolases, peroxidases, and oxidoreductases). The most important metabolite of BaP is benzo[a]pyrene-7,8-diol-9,10-epoxide, which presents the highest tumor-inducing activity, because it forms adducts with proteins or DNA. The main site for bonding is the amino group of guanine or adenine (Figure 4). If the adduct PAH–DNA is not repaired, it can start a carcinogenic process.

The major metabolites of BaP excreted through different routes are 3-hydroxy- and 9-hydroxy-BaP, part of them conjugated to sulfate or glucuronic acid.

Most of the metabolites are excreted through feces, while a smaller proportion by urine. Excretion of metabolites through milk may occur as well, but to a lower extent. The proportion among the excretion routes varies with the PAH congener.

Although the use of several biomarkers in urine, such as 1-hydroxypyrene, hydroxynaphthalene, and hydroxyphenanthrene, is widely accepted to estimate the PAH exposure in workplace and in smokers, there are still few studies on dietary exposure evaluation. Several methods have been developed to assess human exposure through urinary biomarkers, such as 1-hydroxypyrene, a metabolite of pyrene. However, the relative amount of P and BaP may vary considerably between different sources of contamination, and proofs of correlation are still weak. Quantification of adducts of PAHs with DNA in peripheral lymphocytes, and other tissues and with proteins, such as albumin, has also been used as an indicator of the dose of the reactive metabolite.

Toxicity Evaluation and Risk Assessment

Most of the toxicity studies on PAHs have been carried out on dermal, subcutaneous, and inhalation exposure, while only limited studies have dealt with oral administration.

Table 4 reports the evaluation of toxicity (genotoxicity and carcinogenicity) according to the International Programmme on Chemical Safety (IPCS) of the WHO, the International Agency for Research on Cancer (IARC), and the SCF.

Fourteen of the 33 PAHs considered by the study of the SCF published in 2002 showed clear evidence of both genotoxicity

Metabolic activation of polycyclic and heterocyclic aromatic hydrocarbons and DNA damage: a review. *Toxicology and Applied Pharmacology* 206(1), 73–93.

and carcinogenicity, according to both SCF and IPCS. The PAHs are BaA, BbF, BjF, BkF, BaP, Ch, CPP, DBahA, DBaeP, DBahP, DBaiP, DBalP, IP, and 5-MeCh. BghiP is considered genotoxic, but not carcinogenic due to the limited data. According to IPCS, the carcinogenicity of Ac, Ap, benzo[g,h,i] fluoranthene, benzo[a]fluorene, benzo[b]fluorene, benzo[e] pyrene, coronene, Na, Pa, and P was considered questionable. Among these, Na was considered to be noncarcinogenic due to its negative genotoxicity. Finally, A, benzo[g,h,i]fluoranthene, F, 1-methylphenanthrene, perylene, and triphenylene were evaluated as noncarcinogenic.

According to the experiments carried out using the same route of exposure, the most potent carcinogenic PAHs seem to be DBahA, DBahP, DBalP, BaP, BbF, and 5-MeCh. BjF and BkF are of moderate potency, while BaA and Ch are relatively weak.

Tumor formation is related to the route of administration but not restricted to the site of application, that is, oral administration can induce tumor of the gastrointestinal tract, dermal application can induce mainly skin tumors, and inhalation can induce mainly lung tumors; however, liver and mammary gland tumors may be developed as well.

The risk assessment process consists of several steps including hazard identification, hazard characterization, exposure assessment, and risk characterization.

For most toxic process, there is a critical level of interaction, below which the homeostatic mechanisms would be able to avoid any structural or functional changes. Nevertheless, when genotoxic substances interacting with DNA, directly or after metabolic transformations, are considered, the absence of a threshold in their mechanism of action is generally assumed. This means that there is no dose without a potential effect. The general approach to minimize the exposure to these xenobiotics is expressed in the ALARA (as low as reasonably achievable) principle. However, this principle is not helpful to the risk management, which should establish a reasonable level of risk.

To evaluate the cancer risk of any xenobiotic, epidemiological data are the more informative and reliable way. However, when the latter are not available, animal assays are used to determine the risk. These experiments are carried out by exposing animals to high levels of toxic compounds in order to compensate for the low number of experimental groups and to detect significant tumor incidence in a reasonable time frame. Therefore, the extrapolation of low levels of exposition to which a human population may be exposed is necessary and very delicate. A wide range of models can be used to extrapolate these data, but unfortunately, each leads to a very different conclusion. In 2005, the SCF suggested the possibility to use the margin of exposure (MoE) approach. It is similar to the

margin of safety (MoS), where the no observed adverse effect level is compared to human exposition to the xenobiotic. However, the MoS approach is not appropriate for carcinogenic and genotoxic substances, where there is not a level without effect, while the MoE is. The MoE is the ratio between a defined point on the dose – response curve for the adverse effects and the human intake. To establish the appropriate point on the dose – response curve the SCF considered the benchmark dose (BMD), which is calculated on the best-fitting curve to the experimental data. In particular, it has been recommended to use the BMDL10 (BMD lower confidence limit 10%), which is the lower limit of the interval of confidence at 95% of the BMD, because this is the lowest effect measurable as statistically significant. Furthermore, considering that at low doses the carcinogenic process seems to be nonlinear, and the assays are carried out on animals, other two factors of 100-fold have been added to include the inter- and intraspecies variability and the uncertainty of the carcinogenic process. Therefore, an MoE of 10 000 or higher would generally be of low concern for the public health.

Comparable approaches have been used by Health Canada for Priority Substances under the Canadian Environmental Protection Act, the National Health and Medical Research Council in Australia and New Zealand for the Toxicity Assessment for Carcinogenic Soil Contaminants, and the JECFA.

Analytic Determination

Sample Preparation

Analytic methods have to be carefully optimized and be very sensitive and selective, minimizing handling to avoid spurious contributions from solvents and glassware and manipulation. Plastic materials have to be avoided since PAHs can be adsorbed (especially in polyethylene); thus, inert materials, such as aluminum, glass, and stainless steel, previously rinsed with high purity acetone or hexane, should be used. Extracts have to be protected from light by using amber or foil-wrapped vials to avoid photooxidation of analytes, and drastic evaporation should be avoided to minimize loss of more volatile compounds. The use of a keeper, such as toluene, may reduce such a loss.

For PAH determination in complex samples, the first step is to extract the lipid fraction to which PAHs are associated. Traditionally, Soxhlet extraction or saponification using alcoholic KOH, followed by a purification step performed by gel

permeation or, recently, by solid phase extraction (SPE), was employed.

Over the last decades, more efficient and/or rapid techniques, which minimize sample manipulation and solvent consumption, have been largely employed for PAHs analysis.

Many papers report the use of ultrasound-assisted extraction, a cheap and easy technique, which, if properly optimized, can be a satisfactory alternative to Soxhlet and saponification extraction, depending on the nature of the contamination and the complexity of the matrix. Generally, the sample has to be lyophilized to optimize the extraction yield.

More innovative techniques have been used exploiting the effect of pressure and temperature to improve the extraction efficiency and rapidity, such as pressurized liquid extraction (PLE), microwave-assisted extraction (MAE), and supercritical fluid extraction (SFE) using CO_2. To obtain a satisfactory extraction yield over an extended range of PAHs by SFE, the addition of a modifier (e.g., methanol) was reported, leading to a necessity of a further purification step. More effective results were obtained by mixing a sorbent (e.g., C18 beads) with the ground sample directly on the extraction thimble (Figure 5).

Applying classical PLE extraction (with the extraction vessel packed with the ground sample and inert material), a further cleanup step is required to purify the analytes from the coextracted lipids. Many works proposed the use of a sorbent directly mixed in the vessel to perform a single extraction/purification step. In general, activated silica (over Florisil®, sulfuric acid-impregnated silica, and neutral, basic, and acidic alumina) gave better results.

A different approach to reduce coextracted lipid matter can be applied in the MAE technique. A simultaneous saponification and extraction method can be performed in the same extraction vessel. The approach succeeded for simple samples, such as vegetables and propolis, but still a mild purification was needed when complex samples, such as fish and meat, were analyzed.

SPE is the most applied approach for purification, not only for lipid extracts but also for fatty and nonfatty liquid foods, such as edible oil, milk, water, and beverages (wine, beer, and spirits). Many different sorbent phases have been employed to exploit different retention mechanisms according to the nature of the sample. Among the traditional stationary phases, silica, C_{18}, C_8, Florisil®, styrene–divinylbenzene, or mixture of these phases has been the most employed, giving satisfactory purification and recovery results. Recently, the applications of novel sorbent phases for PAHs analysis have been published, such as molecular imprinted polymers, sulfonated graphene sheets, and carbon nanotubes.

Solid-phase microextraction (SPME) has been largely employed thanks to its peculiar characteristics. In fact, it is easy to use, rapid, and practically solvent-free. It can be used both in the head-space (HS) and in direct immersion (DI) mode by carefully selecting the fiber coating. HS-SPME is obviously more selective for more volatile PAHs (2–4 rings compounds) rather than a heavy one. However, even in the DI mode, the selectivity does not improve much when a polydimethylsiloxane (PDMS) fiber is employed for analyzing PAHs in water (Figure 6). Sensitivity can be much improved using a stir bar sorptive extraction approach, which exploits the same principle as SPME, employing a larger amount of coating on a magnetic stir bar, but the discrimination between light and heavy PAHs persists.

Interesting results were obtained using a noncommon fiber coating, namely, Carbopack Z/PDMS, which has a high affinity for heavy PAHs, while very low, almost none, for light PAHs. The primary mechanism, when dipped in a nonpolar solvent, is the π–π interaction between the carbon surface and the planar aromatic compounds. Such a fiber was used directly immersed in a diluted oil solution, obtaining very good limits of detection and repeatability. Sensitivity can be further improved by performing a rapid liquid–liquid extraction of the edible oil to reduce the bulk of triglycerides, thus improving the signal-to-noise ratio in the gas chromatographic (GC) analysis.

Chromatographic Techniques

Both liquid chromatographic (LC) and GC techniques can be used to analyze PAHs after sample purification. The LC systems are usually equipped with fluorimetric detectors (FLD), which give very high selectivity and sensitivity, although in recent years, the use of the mass spectrometer (MS) has been increased, obtaining sensitivity comparable to FLD. Despite the significant lower sensitivity, UV detector is still used in several works.

LC equipped with dedicated C_{18} columns were widely employed to easily resolve the 16 EPA PAHs, but since the focus has moved to the 16 EU PAHs, a proper separation of all the isomers has become more cumbersome. Some critical pairs, such as P and BcF, BjF and BeP, and DBahP and BghiP, are not resolved even using a different step elution gradient; thus, more FLD detectors in series are employed by setting different wavelengths for the eluted PAHs in each FLD, thus exploiting the selectivity of the detector. Furthermore, the use of a UV detector is required to detect CPP, which does not give rise to fluorescence. GC-MS is a valid alternative to circumvent the absence or the low intensity of the fluorescence signal, as is the case of CPP and alkylated PAHs. Sensitivity of the pg order can be reached using the single ion monitoring (SIM) mode in

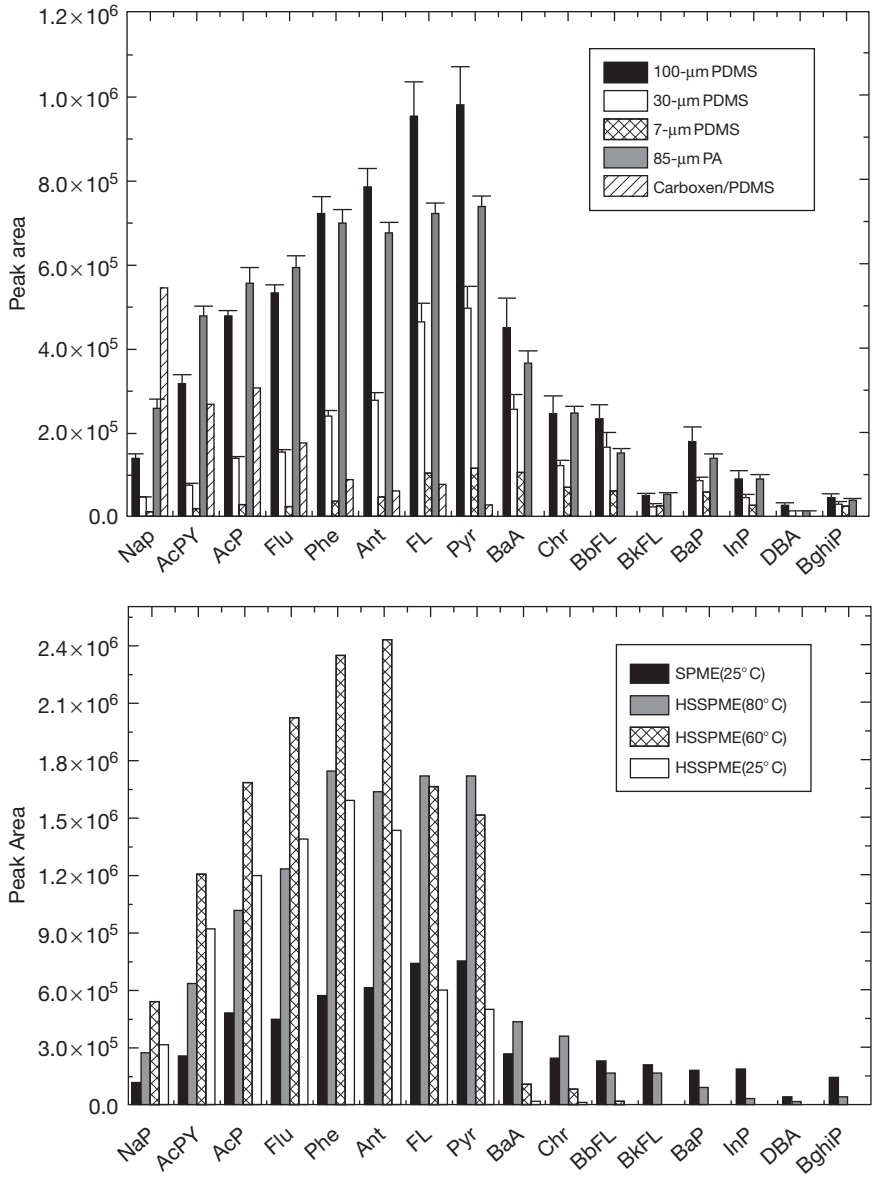

Figure 6 Profile of PAH uptake obtained using different fiber coating in SPME in (a) head-space mode and (b) comparison between direct immersion and head-space at different temperature. Reprinted with permission from Doong R., Chang S., Sun Y. (2000). *Journal of Chromatography A* 879, 177–188.

the MS detector. The US EPA did not consider the GC reliable enough due to several coelution problems, thus suggesting the use of LC, but it has been largely proved that a careful selection of the stationary phase and column dimensions gives an optimal resolution of critical pairs. Good results can be obtained using a 50% phenyl column. The selection of the injection mode (splitless, PTV, or on-column), along with the proper injection liner (multibaffle, packed, etc.), is fundamental in avoiding discrimination, especially of the lighter PAHs.

Hyphenated Chromatographic Techniques

An interesting approach to reduce sample manipulation and thus the risk of cross contamination is the application of hyphenated techniques. The most exploited technique is the coupling of an LC step (equipped with one or two LC columns) for purification purposes, followed by GC analysis for the final determination. This technique has been mainly applied to analyze alkylated PAHs.

The analysis of parent PAHs can be performed using a silica column in the LC purification, retaining triglycerides, which are then removed by backflushing the column, while PAHs are eluted and analyzed in GC-MS, obtaining a limit of detection of about 0.5 $\mu g\ kg^{-1}$ in SIM mode. Coupling two LC columns of different selectivity prior to GC analysis made it possible to analyze alkylated PAHs in edible oil. A first silica column removed triglycerides, while a second amino one allowed to fractionate PAHs according to the ring number.

Several applications coupled two LC systems or similar chromatographic systems, such as the donor-acceptor complex chromatography (DACC). The working principle of DACC is based on the π–π interaction between PAHs and the sorbent, which was exploited to retain PAHs while removing the matrix interferences, and then PAHs were backflushed directly onto the LC analytic column to be analyzed. A silica column was also applied as preparative chromatography prior to a C_{18} column for PAH separation.

Although comprehensive multidimensional GC ($GC \times GC$) cannot disregard a preparation step, the increased separation power, obtained by coupling two columns with different selectivity, can enable the isolation of matrix interferences; thus, in several cases, a less intensive cleanup step can be performed. $GC \times GC$ has been often applied to characterize alkylated PAH contamination, rather than to analyze parent PAHs, even if some few papers have been published on this.

Conclusion and Future Perspective

PAHs are a class of compounds that have been under investigation for a long time. However, further investigation is still needed, in particular considering the high toxicity of such compounds, along with the possible occurrence in rather complex mixtures. In particular, the EFSA is still requiring data on oral carcinogenicity of mixtures relevant for dietary exposure and occurrence data for less considered and often less abundant compounds, such as BcF. Therefore, to satisfy such requirements, improved analytic methods, in terms of both selectivity and sensitivity, are required to study the occurrence of PAHs in different food matrices and of metabolites in biological fluids. Miniaturized and hyphenated techniques will lead the development of further methods in the next future following the general trend of reducing solvent and time consumption and reducing sample manipulation avoiding artifacts formation.

An interesting future challenge will be to extend the study to the reliable identification and quantification of not only parent PAHs but also the alkylated ones, for which a detailed toxicological evaluation is still lacking.

Sources and Production

A Brief History

Although the remains of domestic species of pigs were not discovered until Neolithic times, fossilized pig skeletons have shown their emergence as early as 2.6–5.3 Ma (Pliocene period) in Europe and Asia. The domesticated pigs of Europe and North America are descendants of two species of wild pigs: *Sus scrofa* and *Sus scrofa vittatus*, the wild boar of Europe found north of the Alps and wild pig found only in the Malay Peninsula, respectively. Pigs are a nonnative species to the Americas and were transported across by early explorers and settlers of the new world. Other wild pigs, such as *S. scrofa cristatus*, are found in India and Ceylon, and there is also a number of subspecies of wild swine currently recognized, for example, Sus scrofa scrofa (Europe), S. scrofa meridionalis (Mediterranean), S. scrofa barbarous (North Africa), and S. scrofa attila (East Asia). Consumption of pigs (wild, large and small) is evidenced in the archaeological investigations surrounding prehistoric civilization eating places, but evidence of their domestication is not apparent until man's transition from hunter to settled farmer around 6900–6400 BC. The reason for this may be due their intractable nature and that they do not herd easily like ruminants. Another factor could have been the parasites they carry, such as pork trichinella, which could also explain the underlying reason for religious movements preventing their consumption. However, a number of factors may have endeared them to primitive farmers, such as their rooting habits (reducing woodland undergrowth and allowing grass to grow), used to hunt for underground mushrooms (truffles), or their passing over seeded ground to embed the seeds before plowing equipment was discovered.

Pork Quality

The eating and technological quality of pork will ultimately determine the success of the commodity in global markets. Pork quality can be considered as a series of interacting chemical, biochemical, physical, and biological components that determine the suitability of pig meat for further processing and storage. The technological quality would be affected by attributes such as breed, genotype, preslaughter handling, stunning, and slaughter method, while quality attributes (fat content, oxidative stability, and uniformity) would be affected by genotype and feeding strategy. Other key characteristics, such as water holding capacity (WHC) and color, would be affected by most or all of these factors.

Primary Production

Breeding and Breeds

Breeding is the act of selecting specific animal types for reproduction in order to promote certain desirable traits considered to be advantageous. Producers have had to adapt to the demands of consumers as early as the eighteenth century. For example, pigs that were able to store large quantities of fat were then prized due to differing consumption patterns of the era, that is, its high calorific content was ingested for energy due to the considerably more common labor-intensive working day (preindustrial revolution). Other reasons for their popularity were the widespread use of animal fats in cooking, soap making, and candle making, as grease in burning lamps, and as lubrication in simple machinery such as pulleys and gears. This demand was replaced in the 1900s when people began to utilize more plant-based oils (e.g., vegetable oil). Other more desirable traits in pigs were sought, and they were soon recognized for their efficiency in converting feed into protein. Therefore, contemporary demand dictates an intensive selection against fatness, where lean muscle and characteristics that promote flavor development are favored. Table 1 shows a mixture of traditional and commercial breeds, and while the list is not exhaustive, it tries to cater for the most commercially relevant and some historically significant pig breeds still in use and previously used by producers. While some of these breeds are now of little numerical importance, supporters carry on with dedication the maintenance of these heritage breeds. As economic factors and consumer preferences fluctuate, so to the fortunes of particular breeds rise and fall. Furthermore, it is prudent to maintain small distinct populations of the rarer breeds in case they are required to provide some particular characteristic(s), which may be lacking in the current commercial population.

The structure of most national herds is pyramidal in nature. A small number of prominent breeders occupy the apex of the pyramid who supply stock to a large number of other breeders further down the hierarchy. These breeders multiply the breeding stock, which finds its way to the commercial herds forming the majority of the herds at the base of the pyramid. Most EU countries have tried to manipulate this structure by ensuring that the breeds that occupy the apex make the greatest possible progress in pig improvement, for example, body responsible for this in the United Kingdom is the Agriculture and Horticulture Development Board (previously the Meat and Livestock Commission (MLC)). Pedigree breeds are ones where the ancestry of the stock has been recorded accurately. It is usually administered by a central agency, such as a breeding society. These groups, for example, the Tamworth Breeders' Club, are responsible for all aspects pertaining to administration/record keeping, such as birth records and herd book numbers to adult breeding stock, specifying correct breed (color/conformation), and also for promoting the breed both nationally and internationally. In the mid-1960s, there was a movement towards developing pig quality by geneticists who worked on a successful development strategy in poultry. It was felt that this success could be replicated in the pig industry, and this pioneering

Table 1 Pig breeds considered commercially or of historical importance

Breed	*Origin*	*Characteristics*	*Type*
Berkshire	The United Kingdom	Black, six white points (legs, nose, and tail), erect ears, upturned noses, long carcasses	Traditional
British Saddleback	The United Kingdom	Black head and neck, white belt extending over the shoulders to the forelegs, body returns to black, white feet and tip of the tail, good grazing and mothering, very hardy breed	Traditional
Chester White	The United States	Solid white, droopy ears, most durable of white breeds, good mothering, large litter size and percentage ham	Commercial
Duroc	The United States	Red, large-framed, medium length and muscular, with partially drooping ears, one of the least aggressive of all the swine breeds, superior growth rate, and feed efficiently	Commercial
Gloucestershire Old Spot	The United Kingdom	Predominantly white with black spots, long head length with a slightly dished nose, ears well set apart and dropping forward to the nose, known for docility, profligacy, and intelligence	Traditional
Hampshire	The United States	Black with white belt around the shoulders, erect ears, muscular, rapid growers, and exhibiting good carcass quality, good mothering, and good-tempered	Commercial
Iberian	Portugal/ Spain	Red or dark in color, if black ranging from dark to gray, with little or no hair and a lean body, high capacity to accumulate intramuscular and epidermal fat – prized for their flavor due to IMF and its traditional feeding based on acorns	Traditional
Lacombe	Canada	White, medium-sized, docile temperament, large drooping ears, long bodied, comparatively short legs, meaty in conformation, noted for rapid gain (especially sows)	Traditional
Landrace	Denmark	White, grow well producing long acceptable carcasses, large droopy ears, and surpasses most breeds for litter size and mothering ability	Commercial
Large Black	The United Kingdom	Black, hardy, docile, known for large litters	Traditional
Large White (Yorkshire)	The United Kingdom	Big, solid white, erect ears, dished face, rugged and hardy, large litters, good length and mothering, excellent for cross breeding. Originally developed for outdoors but is one of the most favored by commercial pig breeders today, lending uniformity to pigs produced for meat on a large scale	Commercial
Mangalica	Hungary	Characterized by its hairy 'fleece'/long coat, direct descendant of the wild boar, originally bred as a lard pig that would explain its decline in popularity	Traditional
Middle White	The United Kingdom	White, pricked ears, short snout, sharply upturned snub nose, docile, outdoor grazer, known as a pork producer (rather than bacon or lard type pigs)	Traditional
Piétrain	Belgium	Spotted, black and white in color, with droopy ears and long, wide body. Widely recognized as the world's leanest, heaviest muscle breeds	Commercial
Poland China	The United States	Typically black, occasionally with 6 white patches, known for their large size. America's oldest breed	Traditional
Taihu/Meishan	China	Large, black, heavily wrinkled face, large head with broad forehead, large folded ears, high reproduction rate (litters size up to 20), and highly disease-resistant making it a breed of considerable interest to research	Traditional
Tamworth	The United Kingdom	Pale ginger to dark mahogany red, elongated head shape, long narrow body, erect, pointed ears, face has rectilinear lines as well as the snout, considered medium-sized porcine, small litter sizes compared to other commercial breeds	Traditional
Welsh	The United Kingdom	Large, white, hardy outdoor, long, pear-shaped body, wide head with lopped ears and straight nose, regarded for quality bacon it produces – despite this, it is not extensively found outside of the United Kingdom	Traditional

work inspired both meat processing companies and traditional breeders to compete with pedigree breeders for a larger stake in the breeding business.

Pale, Soft, Exudative (PSE)

Pale, soft, exudative (PSE) meat is a condition that has classically been associated with pork (although it is known to occur in other species), which has been studied for over 50 years. The development of PSE in pork is described in the succeeding text: all muscle tissue undergoes a reduction in pH as a result of ATP hydrolysis during the conversion of muscle to meat. The typical pH profile in pork would be between 6.5 and 6.7 with a temperature of 37 °C at 45 min postmortem. However, in aberrant carcasses, the pH may drop to 6.0 in the same time period. It is this latter condition of rapidly decreasing pH in combination with high carcass temperature that results in denaturation of some of the contractile proteins, with consequent loss of water holding capacity (WHC). It has significant implications on fresh and processed pork, that is, the former is more likely to be rejected by consumers due to its physical appearance, and its compromised technological performance also makes it a less attractive raw material for the processing industry in the latter. The main causes for the condition are known to be antemortem stressors for the animal, for example, handling, welfare, heat, physical exercise, transportation, and mixing of unfamiliar animals. There is also evidence that genetic factors within a specific breed may further its

predisposition to the condition. These are discussed in more detail in later sections of the text.

Dark, Firm, Dry (DFD)

Dry, firm, dark (DFD) meat is a meat quality defect that is associated with beef, but it is known to also occur in pork. It is characterized by high pH_{24} values resulting from low muscle glycogen and creatine phosphate levels present at the time of slaughter (restricting lactate formation). The result is meat that has a considerably higher WHC than normal as the pH (6.0) is further away from the isoelectric point of myosin (5.0). This advantage is largely offset by its susceptibility to increased microbial growth and its color that are more likely to be rejected by consumers. The dark color is a result of the high postmortem pH that keeps the muscle protein highly charged, thereby maximizing the separation of the muscle myofibrils and reducing the light scattering. Furthermore, mitochondrial respiration at higher pH also reduces the fraction of oxymyoglobin in the tissue. DFD can be caused by a number of factors such as hunger (starvation), exercise (exhaustion), and long-term stress in the live animal. Its incidence rates tend to be seasonal, with higher rates reported when animals are subjected to long periods of cold and damp weather.

Genotype

Genetics play an important role in determining pork quality, which can comprise differences between breeds and differences between animals of the same breed. Genetic effects can be categorized as follows:

1. Polygenic: large numbers of genes having relatively small effects (this characterizes most of the effects associated with meat quality traits).
2. Monogenic: these 'major genes' are genes that are necessary and sufficient by themselves to cause a condition, for example, halothane, RN^-, and androstenone (boar taint) genes.

The Halothane Gene

Otherwise known as the porcine stress syndrome gene, the halothane gene causes malignant hypothermia, which can be triggered by stress or exposure to the anesthetic gas halothane. It has been studied for half a century due to its close association with PSE. In the 1960s, some breeds were noted for containing a large proportion of PSE-prone animals (Piétrain and Poland China), which gave rise to the study of and resultant discovery of the halothane gene. Subsequently, the presence of the halothane gene has been eliminated from many selection lines.

The RN^- Gene

The RN^- gene was identified in the Hampshire breed and is closely related to a reduction in technological yield. The term 'RN' originates from the French 'Rendement Napole,' which translates as Napole yield (Napole being a method for estimating technological yield in cooked ham). The condition is characterized by high-muscle-glycogen stores and an extended pH decline postmortem. While there is limited effect in the early postmortem period, the low pH_{24} results in low WHC and high reflectance (lightness) in the meat. The term 'acid meat' was coined to describe the phenomenon. When compared to the halothane gene that dramatically hinders WHC, the RN^- gene only results in small increases in drip loss ($\approx$1%). However, technological yield is decreased by 5–6% compared to noncarriers and halothane gene carriers (2–3%). A similar strategy to the approach applied to the halothane gene that is selectively eliminating the RN^- gene from selection lines has been discussed.

Boar Taint/Odor

Boar taint is an objectionable odor or taste that can be evident during the cooking or eating of pork or pork products derived from noncastrated male pigs (boars) once they reach puberty. The flavor is produced by a testosterone derivative and by skatole, produced by the intestinal microbial breakdown of the amino acid tryptophan. The testosterone derivative, 5-alpha-androstenone, starts to accumulate in the fat of male pigs when they are sexually mature or exceeding 90 kg. Skatole on the other hand can be detected in pork from males and females. Most boars (80%) do not have taint and are slaughtered before puberty so it is not an issue. However, research suggests that 75% of consumers are sensitive to boar taint, with women and certain ethnic groups showing a higher degree of sensitivity than men. The high sensitivity shows that it is necessary for producers to control it despite its low prevalence in the pig population. Although castration was the preferred method of control in the past, research is under way to find alternatives (e.g., selection) to reducing boar taint without resorting to castration.

Polygenic Effects

Excluding those mentioned earlier, the heritability of most attributes relating to pork quality is low to moderate. The notable exception is intramuscular fat (IMF). Increased IMF content is usually associated with improved eating quality. While the heritability of IMF percentage and fat tissue is high (0.5 and 0.69, respectively), the genetic correlation between them is low (0.11). This suggests that selection for high IMF in lean carcasses should be possible.

Production Systems

The profitability of a pork production system depends on three main factors:

1. High sow productivity (a number of piglets reared per sow per annum)
2. Conversion of feed to pig meat
3. Lean carcass production (currently most favored by consumers)

Many of the improvements are simple to address and pertain to animal welfare issues, such as correct management of feed, housing, and health. As the margin between processors has narrowed, genetic-based improvements of performance traits have been the favored method of increasing the profitability of

the production system. The generally available tools that breeders have to bring about this genetic improvement are selection of superior individuals as parents within a breed and choice of breeds or composite lines to be used in crossbreeding systems. Performance traits that determine system efficiency can be grouped into two broad categories:

1. Reproductive traits, for example, age of puberty, fertility, and litter size, are expressed only in breeding animals.
2. Production traits, for example, growth rate, feed efficiency, and carcass composition, are expressed in market animals and animals destined for the breeding herd.

Most pork quality traits are only expressed in market animals. Genetic improvement of reproductive and production traits through the selection of superior parents is possible and dependent on a number of factors, such as the heritability of the trait, the amount of variation between potential replacements, and the superiority of chosen replacements.

Another very important option to breeders is crossbreeding. This offers the potential to exploit the differences between breed lines and enhance the inherited traits by mixing the genetic contribution of the parents (heterosis). A terminal static cross in which all the offspring are market animals takes the greatest advantage of the differences in the strength of the breeds. Lines with increased genetic merit for the reproductive traits provide the females for the crossbreeding system, while lines with superior genetic merit for the production traits provide the males. For example, the first cross gilt of a large white boar and a Landrace sow is one of the most popular crossbred lines and generally gives excellent prolificacy, good feed efficiency, and progeny with a highly lean carcass when mated back to one of the two parent breeds.

Production Phases

Pigs breed at all times of the year so pork production can be considered a continuous cycle. Producers also fall into a number of categories depending on their farming operation. Some operations keep and mate sows, farrow litters, and raise piglets to market weight, that is, farrow-to-finish operations. However, some specialized operators choose to concentrate on specific stages of the production sequence. For example, weaner producers maintain breeding herds but sell their pigs' offspring at 10 weeks. The recipient of these piglets is often a finishing/feeder operator who feed the pigs until they reach market weight. Pork production can be broadly characterized into four main phases and their satisfactory completion will result in animals ready for market:

1) Breeding: Historically, sows have been bred by placing a number of them in a pen with one or more boars. The boars are often rotated between sow pens in order to ensure all sows are fertilized while they are in heat. Sows that are kept in enclosures enter estrous (the period when a sow can be bred – also termed standing heat) 3–5 days after their young are weaned. In general, sows will display signs outwardly that she is willing to accept the boar that is holding her ears erect and standing still if a producer applies downward pressure her back. If the sow is not bred during this time, she is considered unproductive (as the animal is required to be fed and housed). However, she will return to estrous approximately 3 weeks later. These two periods are termed 'first' and 'second' -heat breeding, respectively. Modern operations only have sows bred on first heat with unproductive sows sent to market and replaced with gilts (young female) removed from the grow–finish phase. Thereafter, the sow will gestate her litter for approximately 115 days until the pigs farrow.
2) Farrowing: Before giving birth, sows are generally moved to a farrowing room where she will birth 8–12 piglets, collectively referred to as a litter. Most confinement operations place the sow in a temperature-controlled environment and usually a farrowing pen/crate that restricts her movement to protect the baby pigs (from crushing when she lies down). Average reproductive rates for sows are approximately three to five litters over their lifetimes. However, they may be culled due to health problems, age, failure to conceive, or low litter ratio. Pigs are born with eight sharp teeth that are clipped to prevent injury to the sow's udders and other piglets and curly tails that are shortened to prevent biting. Piglets weigh between 1.1 and 1.3 kg when they are born and are weaned from the sow at two to three weeks.
3) Nursery pigs: After weaning, pigs can be placed in a nursery (although joint nursery/grow–finish operations are now common) – a temperature-controlled environment (to keep the animals warm and dry throughout the year) with a plastic or plastic-covered steel slotted floor, which provides the young pigs a more comfortable environment than a concrete floor space. About 0.25 m^2 is afforded for each pig, and they have easy access to feed and water. Slotted floors can sometimes be raised to prevent chilling to the animals, while temperatures range from 29 °C (after weaning) to 21 °C as the pigs start to grow. After six to ten weeks, pigs are moved from the nursery to the grow–finish building.
4) Grow–finish: Pigs are fed until they reach their market weight c.150 kg and their space requirements increase to approximately 0.75 $m^{2.}$ On average, duration to market is five to six months, which is dependent on intrinsic factors such as breed and susceptibility to disease. Some gilts are removed at this point to replenish the sow herd (breeding phase), and the older sows are culled. Pigs that are in the grow–finish phase produce a considerable amount of heat. Therefore, adequate building ventilation is required to keep the animals from overheating. This can be managed naturally (wind-driven) or mechanically (wall fan) depending on the climate the producer lives in.

Feeding

Pigs, like humans, are monogastric animals and many of the components of their diets are easily transferred from the feed they ingest to the muscle and fat tissues. This has a subsequent effect on pork eating quality, and a number of feeding strategies have been researched to exploit this trait. In some cases, it is used to counteract a resultant technological problem that stems from the processing of the animal into meat or is inherent in the breed (e.g., dietary intervention to offset the effects of

stress on meat quality) or to enhance or change the underlying composition of the muscle tissue (supplementation with ingredients known to have a beneficial effect for health in consumers):

1. Technological: In order to offset deleterious effects of conditions such as DFD meat, feeding strategies involving the manipulation of the muscle glycogen levels have been investigated. For example, feeding a carbohydrate-rich feed (sucrose or other digestible carbohydrates) has been shown in a number of studies to have resulted in increased muscle glycogen and subsequently decreased pH_{24}. It should be noted that other researchers also concluded that care is needed when applying this approach (sugar feeding), particularly with breeds known to be carriers of the halothane gene, as it may increase the incidence of PSE meat. Creatine monohydrate has also been investigated as an alternative to sugar-based feeds to increase muscle energy stores (and offset early glycogen metabolism and resultant slow pH decline).
2. Physiological: Stress responses can have a direct influence on the quality of meat. When an animal is subjected to stress, it releases brain neurotransmitters that in turn release stress hormones into the blood. These hormones can stimulate muscle metabolism that can have detrimental effects on meat quality. This is particularly relevant in pork as certain breeds can be very susceptible to stress factors. Research into magnesium supplementation prior to slaughter has shown it has beneficial effects for WHC and pork quality. Magnesium appears to reduce neuromuscular stimulation by interfering with calcium. Tryptophan supplementation has also shown positive effects on the number of reduced aggressive acts prior to slaughter and PSE incidence in pork. This may be due to serotonin (popularly thought to be associated with feelings of well-being and happiness), which is biochemically derived from tryptophan. While these stress-reducing feeding strategies do show promise as potential tools for improving pork quality, very little is still known and it requires further research.
3. Health: This will be detailed in the 'Health Effects' section.

Secondary Production

Preslaughter Handling

Preslaughter handling involves the handling, mixing, transit, and storage of animals. All handling practices have the potential to induce psychological and physiological stress, and it represents both an animal welfare and a subsequent quality issue. Preslaughter-induced stress can be broadly categorized into the following:

1. Long-term stress factors: on-farm handling, mixing of unfamiliar animals, loading, and transport. These factors mainly lead to the development of DFD meat.
2. Short-term stress factors: lairage conditions and driving towards the stunner. These factors mainly lead to the development of PSE meat.

Reduction or effective management of these factors has been shown to have a positive effect on meat quality. For example, optimum lairage time has been reported to be between two and three hours, to allow time for the animals to calm down but not afford them too much time to begin to fight.

Slaughter

Healthy animals that have reached their finishing weight are sent for slaughter. In the EU, there are a number of regulations governing the hygiene of preparing foodstuffs, which included the slaughter of pigs, such as 852/853/854-2004. Pigs are generally fasted (16–24 h) prior to slaughter in order to reduce complications (contamination) and to ensure completeness of bleeding and easy evisceration (removal of internal body parts and organs). The animal's sex, breed, ID number, and live weight are recorded. Dressing percentage is calculated from the carcass weight (typically taken warm/hot as chilling will decrease the weight by up to 2% through moisture evaporation) divided by the live weight multiplied by 100. Typically, pigs have a dressing percentage of 70%, of which only 57% of the original live weight goes on to become retail cuts. Animals must be stunned that is rendered unconscious, prior to slaughter. Therefore, the animals must be immobilized in some fashion. In small operations, a small confinement pen and a squeeze gate are all that are required, while larger operations may require a series of chutes, restrainers, and conveyers. Three primary methods of stunning are available:

1. Electrical stunning: the application of electrical tongs to deliver between 70 and 90 V (0.3 A) for 2 to 10 s is sufficient to render a pig unconscious.
2. Mechanical stunning: the application of a compressed air/cartridge propelled compression bolt (fitted with mushroom-shaped or penetrating heads) to the forehead of the animal.
3. Chemical stunning: fast becoming the standard practice throughout the industry, it involves the exposure of the animals to carbon dioxide (CO_2)-rich environment that starves the animal's blood of oxygen, rendering them unconscious. Danish research has shown that common injuries sustained by animals during electrical stimulation, such as shoulder and backbone fracturing, are greatly reduced, and it also appears to minimize the incidence of pale, soft, exudative (PSE) meat. Most setups involve animals entering a conveyer cage, which is lowered into CO_2 confined chamber (CO_2 is heavier than air).

The stunned animal is shackled and suspended at the Achilles tendon and exsanguinated (bled) by severing the carotid artery and jugular vein using a 'sticking' knife. A precise cut is required to avoid cutting into the muscle tissue and exposing it to blood flow (contamination) and also to ensure a quick, humane death. Pig carcasses must undergo scalding, which is the process of hair removal by drenching the carcass in a hot water device. The most effective and uniform results are achieved when the carcass is fully submerged and continuously rotated. Water temperature of approximately 61 °C is reported to give adequate results; however, care should be taken to avoid overscalding, which can result in contaminated scalding water (with blood) and damage to the animal tissues. Additional hair removal can be carried out manually using clippers/

blades and a blow torch if necessary. In order to adequately chill and facilitate ease of cutting and cut fabrication, carcasses are split in half using a circular saw. The internal and external surfaces should be washed top to bottom with water or a mild sanitizing solution (low salt, e.g., 0.1 M KCl, or weak organic acid, e.g., 2% lactic acid) to remove any residual blood, bone fragments, and in particular bacteria. At this point, the carcasses are inspected for the final time, checking for abscesses/growths and contaminants, weighed, and stamped for identification of wholesale cuts. They can be boned directly at this point (hot boning) or transferred to commercial chilling facilities (0–1 °C; air speed 2.2-6.7 ms^{-1}) for 24 h.

Postslaughter Handling and Interventions

The manner in which animal carcasses are handled postslaughter can also have a significant influence on the meat quality. As muscle pH and temperature are intrinsically linked, the thermal conditions that they are subjected to postslaughter have a direct effect on their physicochemical and eating quality performance thereafter. Hence, pH and temperature conditions should always be considered in full cognizance of each other to avoid inducing unwanted conditions, such as PSE and DFD meat. Postslaughter interventions like electrical stimulation and accelerated (hot) boning can be applied in order to improve the technological or financial performance of meat. However, chilling regimes should be specifically designed to accommodate any of the following postmortem interventions as they may have a fundamental effect on the underlying biochemistry, that is, pH.

Electrical stimulation

Electrical stimulation is when an electrical current is applied through a carcass. It effectively hastens the process of rigor mortis by accelerating postmortem metabolism, changing the initial pH and the rate of pH decline. In this regard, it is an invaluable tool for offsetting deleterious conditions such as cold and heat shortening and subsequently improve tenderness. Significant improvements in other meat quality characteristics, such as improved WHC and color, have also been reported. High- or low-voltage applications are available and effective, although the latter are often favored due to operator and plant staff safety. Electrical parameters such as waveform and pulse frequency, duration, delay prestimulation, subsequent chilling regime, and species can be considered for optimizing final meat quality. In pork, electrical stimulation has been shown to encourage a greater incidence and extent of PSE and is therefore considered much more successful for beef and lamb applications. Electrical stimulation should be considered as part of a total process (from slaughter to sale) as it has particular advantages for ultrafast cooling and hot boning applications.

Hot boning

Hot boning involves the removal of muscles or cuts up to about 90 min postmortem, before the onset of rigor mortis. The main meat quality advantage of hot boning is the reduction of weight loss during chilling and drip loss during storage, due to increased WHC of the muscle proteins at the higher pH. Furthermore, significant financial savings could be made as space requirements could be reduced as much as 50% (individual muscles rather than whole carcasses), while refrigeration costs could be up to 80% lower (faster chilling times and more uniform cooling) than conventional boning practices. Much of the early hot boning research was carried out using pork. Unlike other meats, hot boning of pork frequently goes beyond the fresh meat application (initial carcass fabrication) to include further processing, such as injected whole muscle and comminuted products. Combinations of hot boning and electrical stimulation are often used with beef and lamb. However (as mentioned earlier), due to the inherent susceptibility of PSE condition in pork muscles, this can be exacerbated by combining the two techniques in pork processing. Alternative techniques to electrical stimulation that have been investigated in beef and lamb, such as high-temperature conditioning (less dramatic pH decline than electrical stimulation), may be useful to alleviate the potential undesirable effect of PSE in pork.

Altered hanging (aitch-bone/pelvic suspension)

The principle of suspending carcasses from the aitch-bone (pelvic), rather than the more conventional Achilles tendon, for improving tenderness in beef and lamb has been known for many years. By suspending the carcasses in this manner, some of the commercially more important muscles are stretched, thereby preventing them from shortening when *rigor mortis* sets in. It has also been suggested as a method for improving pork tenderness. By stretching the muscles, the resulting increase in sarcomere lengths is associated with increased tenderness. Pelvic suspension also appeared advantageous over electrical stimulation, as it not only prevented toughening but also consistently reduced drip. However, research has shown considerable variation between muscles in the relative length change induced by pelvic suspension. Sarcomere length changes were much larger in topside (m. *semimembranosus*) and silverside (m. *biceps femoris*) than in the loin (m. *longissimus dorsi*) without producing proportional tenderness improvement. M. *rectus femoris*, a major muscle in the leg, actually shortens after pelvic suspension. The practice of pelvic suspension has been commercially adopted by both the beef industry and the pork industry to improve tenderness.

Carcass Grading

The aim of carcass grading is to ensure fair payment to producers, obtain transparency, and compare/standardize across different markets. The set conditions are specific to market requirements for the commodity. In pork, lean content is the most highly sought attribute, and the basis for its assessment is uniformity in the following criteria: (a) the definition of grading standards, (b) systems of assessment, and (c) estimation formulas. Up until the mid-1980s, carcass grading was carried out subjectively by visual determination. However, a more objective approach has been carried out since then by the use of instrumental measurement. Despite this, the systems of pig carcass grading are far more developed than beef and lamb. A number of technologies are used to determine lean content of carcasses, and these vary greatly from country to country. Some examples include the Fat-o-Meater, the Hennessy probe, ultrasound system, x-ray absorptiometry, AutoFOM (automatic Fat-o-Meater), and a simple ruler to measure fat thickness. The

adoption of the technologies will depend on initial cost, training required (operators), and the overall resultant benefits of its adoption. For example, some technologies such as x-ray absorptiometry would be impractical in a large-scale fast-moving production facility. Regardless of the technology adopted, fat thickness plays an important role in the determination of lean carcass percentage as it is the most variable tissue in the carcass, and as such, it is included in every calculation. In Europe, lean meat content is determined using the EUROP classification, which is based on muscle and fat thickness. In this system, lean meat occupies the following percentages: E = >55%, U = 50–55%, R = 45–50%, O = 40–45%, and P = < 40%.

Patterns of Consumption

Despite its consumption being prohibited by Judaism, Islam, and certain Christian denominations, pork is an important commodity in most parts of the world. It ranks first among all meat sources and accounts for approximately 40% of global meat consumption. Its high palatability, nutritional value, and versatility for processing and cooking for many different cultures contribute to its nearly worldwide appeal. The main markets for pork are in East Asia and the Pacific region. In particular, it is held in high esteem in Chinese cuisine (mostly for aesthetic reasons). China is both the largest producer of pork and also its largest consumer (Tables 2–3). Domestic consumption in China exceeded 56 million tons in 2014 and it accounts for more than half of global pork consumption. The large growth in Chinese consumption has been attributed to increasing disposable income and urbanization over the past decade. China is one of the largest net importers of pork and their imports are forecast to exceed a record 1 million tons in 2015.

The combined nations of the European Union (EU) collectively account for about a fifth of the world production of pork. Of these, Denmark, Belgium/Luxembourg, Holland, Spain, and Austria have the highest per capita production of pork in the EU. Denmark exports up to 80% of its pork (although its per capita consumption is high) to major markets in the United Kingdom (a net importer of pork) and Asia (particularly Japan). The United States accounts for about 10% of global pork production. However, it consumes substantially less and is mostly exported. It should be noted that up until the mid-1990s, the United States was a net importer of pork.

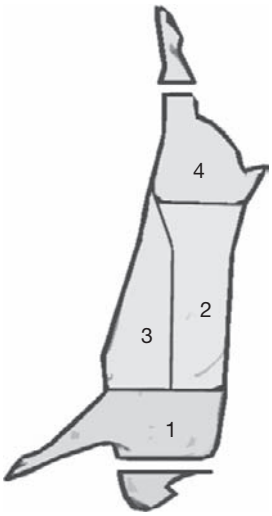

Figure 1 Carcass position of popular pork cuts.

Common Fresh Cuts of Pork

The methods of cutting pigs for wholesale markets may differ slightly from region to region, but in general, four large sections are recognized (Figure 1):

1. Shoulder: It accounts for approximately 25% of the carcass weight and is typically subdivided into two sections, that is, upper ('Boston butt/blade Boston') and lower ('picnic'). The cuts are considered flavorful but connective tissue is significant due to the considerable work carried out by the animal in the shoulders. Therefore, roasting, braising, and marinating are popular cooking techniques with these cuts.
2. Loin: It contains the rib, loin, and sirloin sections and accounts for 22% of the carcass weight. Typically, these are the most highly prized cuts as they are characterized by being very lean and tender (e.g., tenderloin). The loin can be whole or cut, that is, pork chops, while the ribs are noted to have higher meat content than their spare rib counterparts from the side.
3. Side ('belly'): It accounts for 23% of the carcass weight and contains both the spare rib and the belly. The meat is streaked with fat and is often cured and/or smoked to produce bacon, for example, pancetta. Spare ribs are usually trimmed of excess belly fat and slow baked or barbecued.
4. Leg ('ham'): It contains large muscles with low connective tissue content that account for 30% of the carcass weight. Hams can be purchased either bone-in or boneless, and in some cases, the skins can be left on. Typically, hams are consumed cured or smoked but fresh hams are also available.

Some of the other popular meat types include minced/ground pork, which is a mixture of trimmed meat and fat predominantly from the shoulder and leg. The lard of the pigs is also still heavily used for artisan baking, particularly in pastry. Furthermore, specialty meats such as pork liver, tongue, heart, feet/knuckles, neck bones, jowls, and tails are often utilized in fine dining restaurants, where they are considered delicacies.

Cured Meats

Pork is used as the primary constituent of many traditional cured meat products. Curing involves the addition of salt, sugar, nitrate/nitrite, and other curing adjuncts for the purposes of preservation, flavor, and color development. Historically, curing literally is translated as 'saving of meat,' and the first written evidence was documented by the ancient Greeks who described the preservation of meat by packing in salt. Saltpeter (sodium/potassium nitrate), a commonly occurring impurity in salt, was reduced by the natural microorganisms present to nitrite allowing for the formation of its characteristic color. However, the emergence of cured meats in Europe occurred in the sixteenth century when the nitrite compound became readily available (primarily used for medicinal applications). This is thought to be the origin of the now established food curing processes of drying, smoking, and salting. The basic principle is the application of salt in order to reduce the available water and make the environment less ideal for microbial growth and subsequent spoilage. Salt can be applied to the meat as a dry rub or submerged in a salted liquid (brine). The meat cell fluids are less concentrated than the salt water. Water flows out of meat and salt passes into the meat (osmosis). The salt action helps dissolve some of the muscle proteins. The cell's fluids become more concentrated, which draws water back inside. The advantages include preservative effects, reduction in rancidity, and imparting of characteristic flavor and color. Cured meats can be divided into four many categories:

1. Dry cured: Very much rooted in the traditional curing methodology. Ingredients are applied dry in the form of a rub to the outside of the meat over a number of time intervals. The rate of curing is dependent on the diffusion of salt from the exterior to the interior of the meat. The products are often time-intensive, with some products taking years to be ready, which is often reflected in the price they command at retail and their status as premium specialty meats. Common examples in pork include prosciutto and serrano hams.
2. Wet cured: Has largely superseded dry curing and now represents the standard industry practice for most cured products due to its flexibility and time-saving. Brines are injected directly into the meat using a multineedle injector and often tumbled for a short time to ensure good distribution of the cure ingredients. Common examples in pork are bacon (belly or shoulder regions of the pig) and hams (pork leg).
3. Smoked meats: Having a strong characteristic flavor, smoking also has a preservative effect on meats. Nonresinous woods are deemed suitable for the smoke generation, although hard woods such as oak, beech, and hickory have been traditionally favored. Modern smokers are usually carried out in special units that are separate from the cooking chamber so they can be controlled independently of oven temperature and humidity. Another time-consuming process, modern advances include the use of smoke concentrates/essences that can be sprayed onto the product instead of producing the natural smoke. Common examples in pork are smoked bacon and hams.
4. Fermented meats: In curing, selective microbiological effects are commonly termed as 'active' or 'live' brines. The addition of starter cultures is a common practice in the meat

fermentation industry to increase uniformity of the batches. The most commonly used bacterial species are lactic acid bacteria, which are designed to give a unique flavor profile through acidification and related changes in the meat. Common examples in pork are Wiltshire bacon that uses a 'live' brine in the immersion stage of the Wiltshire process.

Sausages

Sausages represent one of the oldest forms of processed food that predate Roman times. The primary economic purpose of these products is to present relatively large proportions of fat in palatable ways. Comminution of the fat is therefore a common feature. Sausages are defined in the United Kingdom as cylindrical products with hemispherical ends. The word is derived from the Latin word salus, meaning salted, and sausages consisted of meat, blood, and other ingredients, which were filled into animal gut and consequently preserved. The products' composition has remained relatively similar throughout the millennia, and the basic principle behind sausage production is outlined in the succeeding text (although some additional/reduction of steps may be required for specialty sausages). Meat is primarily responsible for binding the product together. It is modified by its treatment with salt and water and mechanical action to bind water, hold fatty tissue, and free fat in the sausage matrix. Water (usually added as ice for moderating temperature during processing) and fat are added. Sausages are emulsion-like products (not true oil in water emulsions like mayonnaise). The meat is chopped (comminuted) to varying degrees to help extract the proteins. Salt is added to help further extract salt-soluble proteins (like actin and myosin) and for flavor. The extracted proteins coat the fat and water forming a structure similar to that of an emulsion. At this point, other ingredients and additives can be added to help improve technological performance or cost effectiveness. A wide range of cereals (flours, starches, bread, and bread crumbs) have been traditionally used in sausages. More common today is the use of rusk, a product derived from biscuit dough that can be ground to various sizes, which is employed for texture and water-binding properties (up to three times its own weight under the right conditions). Other additives, such as polyphosphates, can be added to improve water binding and lessen cooking losses, while others can be added to enhance flavor (monosodium glutamate and spices) and extend shelf life (sulfur dioxide). Protein substitutes (blood plasma, skimmed milk powder, casein, and whey) can also be added subject to regulation. The resultant batter is filled in to sausage casings and tied in sausage links. Modern sausage casings (skin) are usually made from one of the following:

1. Natural casings: cleaned intestines
2. Artificial casings: (a) regenerated collagen (derived from animal hide or other collagenous materials) or (b) cellulose (plant wall material), which is usually peeled off after cooking (skinless sausage type).

Heating (if applied) stabilizes the system by denaturing the proteins and gelatinizing heat-labile proteins (collagen).

There are broadly three categories (although among all the sausages made in various countries there are many variations in detail and much overlapping among the types):

1. Fresh: Typically uncured and sold uncooked. As a result, they have a short shelf life and examples come with varying degrees of comminution (although they are most commonly coarsely comminuted). Common examples include British and Irish types of fresh sausage that contain varying levels of meat content.
2. Emulsion: These are usually made from finely comminuted meat/fat and are more highly flavored than fresh sausages (spices). Emulsion sausages usually undergo some additional processing, such as cooking, curing, and smoking/drying. Therefore, they have an intermediate shelf life. Popular examples include frankfurter, Vienna sausage (wiener), bratwurst, and saucisson.
3. Fermented/dried: Lactic acid is produced by fermentation of microorganisms introduced in the form of a starter culture. These organisms were also historically important in the curing process – by reducing unrefined nitrate salts (saltpeter) to nitrite. Finally, the products usually undergo a drying step in the latter stages of manufacture. This gives the products a long shelf life (up to 1–2 years), but the process is complex and difficult to manage (often reflected in the price and high-quality status of such products). Common examples include salami, coppa, cervelat, and rosette.

Availability, Absorption, and Metabolism

Meat that has been prepared using similar principles but originating from the different species has comparable amounts of nutrients. For example, pork from modern, muscular pig breeds has comparable cholesterol to its bovine, ovine, and poultry counterparts. However, this was not always the case as previously discussed. Significant changes in pork over relatively few generations are evidenced in research published by the National Pork Producers Council in 1999, which found that fresh pork is 31% lower in fat, 14% lower in calories, and 10% lower in cholesterol than pork produced in 1983. Many of these reductions can be attributed to improved production practices such as better genetic selection, nutrition, welfare, parenting, and changes in consumer demands. Table 4 shows the general composition of pork, fresh, composite of retail cuts (leg, loin, and shoulder), separable lean only, and cooked.

Protein and Amino Acid Metabolism

Pork, like all meats, is a good source of dietary protein. When ingested, protein macromolecules are broken down into amino acids and simpler derivative compounds by a digestion process termed protein catabolism. Dietary proteins are first acted upon hydrochloric acid and nonspecific endo- and exoproteases such as pepsin, trypsin, chymotrypsin, and elastase to form smaller peptide chains and amino acids by various enzymes such as carboxypeptidase, aminopeptidase, and dipeptidase in the gastrointestinal tract. This breakdown into smaller peptides (tri- and dipeptides) is to facilitate their absorption into the intestines. Different enzymes are selective for specific substrates, for example, trypsin cleaves peptide chains predominantly at the carboxyl side of the amino acids arginine and lysine (except when either is followed by proline). In order to prevent

unwanted or premature digestion, the enzymes are secreted in an inactive form, which is activated only in very specific circumstances. For example, pepsinogen (inactive precursor of pepsin) is secreted by the stomach and only becomes active in the high-acid environment of the stomach. The amino acid compounds have to constantly be degraded as there is no store for excess quantities in the body due protein turnover. They are degraded by the removal of the α-amino group (transamination) and subsequently converting the resultant carbon skeleton into one or more metabolic intermediates. If the carbon skeletons give rise to the net gain in glucose, they are termed glucogenic and ketogenic if they give rise to ketone bodies. The acceptor for the transamination reaction is typically α-keto acid, which results in the formation of glutamate and α-keto acid. The coenzyme of all transaminases is pyridoxal phosphate, which is derived from vitamin B_6 and is converted to a transient intermediate during transamination. The glutamate produced from transamination is oxidatively deaminated by glutamate dehydrogenase to produce ammonia. This enzyme can utilize either NAD+ or NADP+ and the coenzyme is used in the biosynthesis (NADP+) or degradation (NAD+) of glutamate. It is subject to allosteric regulation, that is, GTP and ATP are allosteric inhibitors, while GDP and ADP are allosteric activators. Therefore, when the energy of the cell is low, that is, more ADP and GDP than the triphosphate form, glutamate dehydrogenase is activated and the oxidation of amino acids increases. The resultant carbon skeletons are utilized as a carbon fuel feeding into the citric acid cycle and ultimately to energy production through oxidative phosphorylation. The amino acids can also be broken down and synthesized into other amino acids and macromolecules, such as fat (which will not be discussed here).

Fat and Fatty Acid Metabolism

For fat to be absorbed, it must first be broken down (emulsified) into a more digestible form. Emulsification takes place

in the duodenum, when bile is secreted (from the liver) into the small intestine on ingestion of food. The bile acts as a surfactant, aggregating around lipids and preventing the lipids from reaggregating together to form larger fat particles. The increased surface area of the micelles makes it easier for pancreatic lipases (enzymes specific for breaking down fat) to act upon the fatty core of the triglycerides, resulting in the formation of two fatty acids and a monoglyceride, which is absorbed by the villi. A process known as β-oxidation breaks down fatty acids in the mitochondria. The rate of degradation is dependent on the availability of free fatty acids in the blood, which arise from the breakdown of triglycerides. The fatty acids are converted into their acyl coenzyme A (CoA) derivatives before entering the mitochondria. The fatty acid breakdown involves a repeating sequence of four reactions:

1. Oxidation of the acyl CoA by FAD to form trans-Δ^2-enoyl CoA
2. Hydration to form 3-hydroxyacyl CoA
3. Oxidation of NAD^+ to form 3-ketoacyl CoA
4. Thiolysis by a second CoA molecule to form acetyl CoA and acyl CoA shortened by two carbons

The pathway produces $FADH_2$ and NADH directly, which are then oxidized by the respiratory electron transport chain to yield energy in the form of ATP. The energy yield from the degradation processes, for example, for palmitate (C16:0), is 129 ATP molecules (taking into account the two ATP equivalents required to activate the C16:0 to its acyl CoA derivative). Pork has a higher degree of unsaturated fatty acids than lamb or beef. Unsaturated fatty acids require additional enzymatic breakdown (isomerase (unsaturated fatty acids) and 2,4-dienoyl CoA reductase (polyunsaturated fatty acids)) before they can be completely broken down by β-oxidation. Excess acetyl CoA produced from β-oxidation is converted to other compounds collectively known as ketone bodies that provide an alternative energy source for the brain under starvation conditions or in diabetes.

Vitamin Metabolism

Pork is an excellent source of B vitamins that along with vitamin C are classified as water-soluble vitamins. These water-soluble vitamins are partially enzyme-digested and typically absorbed in the duodenum and the jejunum, respectively (parts of the small intestine). They then pass through the intestinal wall into the blood stream. Many of the B vitamins are water-soluble but are bound to proteins that must be removed before absorption. This is carried out by digestion with proteinases and stomach acids as outlined earlier. When separated from their protein complex, B vitamins are absorbed in the ileum. However, due to their water-soluble nature, they are much more easily excreted; thus, a regular source in the diet and/or supplement is recommended, particularly in the vulnerable groups like the elderly. Vitamins A, D, E, and K are categorized as fat-soluble vitamins. Like protein-bound water-soluble vitamins, they must be separated from the fats before they can be absorbed (as described earlier). Unlike their water-soluble counterparts, fat-soluble vitamins can be readily stored (in the liver or fatty tissues around the body), and therefore, there is less of a requirement for them to be ingested regularly as part of the diet.

Health Effects

Meat is a very good source of essential amino acids and, to a lesser extent, certain minerals from a nutritional standpoint. While it is also a good source of essential fatty acids and vitamins, the body often relies on other dietary sources for their absorption. Despite this, its long-term consumption from a health standpoint is still widely debated due to its apparent association with the development of many chronic diseases, for example, carcinoma, cardiovascular disease, and hypertension. However, implicating meat consumption as the direct cause of such conditions is not borne out by the available medical literature, which has found contradictory results in many of the studies.

In general, pork is more unsaturated (softer) than beef and lamb. Its fatty acid composition varies directly in response to diet, that is, it can become gradually more unsaturated when pigs are supplemented a diet high in polyunsaturated fatty acids (PUFA), for example, fish meal or plant oils. Pork is high in protein content and contains a better balance of amino acids than most plant proteins, while its amino acids are more efficiently utilized by the human digestive system. It is an excellent source of water-soluble vitamins but less so of fat-soluble vitamins. Pork is high in thiamine, providing nearly 75% of an adult human's guideline daily allowance (GDA) in a 100 g serving. As with all animal proteins, it is an excellent source of vitamin B_{12}, riboflavin, and niacin compared to plant-based alternatives. As a source of minerals, pork is an excellent source of potassium, phosphorus, iron, zinc, manganese, and magnesium. However, it is a relatively poor source of calcium and sodium. Despite this, bioavailability of minerals from pork is considered high.

Improving Healthy Characteristics of Pork through Dietary Intervention

In pigs, the fats ingested in the diet are absorbed in the intestine and incorporated into tissue lipids unaltered. Certain polyunsaturated fatty acids (PUFA), linoleic and α-linolenic acids, cannot be synthesized *in situ*, and therefore, the tissue concentration can vary greatly with changes in dietary habits. On the other hand, saturated and monounsaturated fatty acids (SFA and MUFA, respectively) are adequately produced, leading to a less direct effect of diet. Modification of the native animal fat composition through feeding has been known for many years. More recently, emphasis has focused upon changing these characteristics for human health, that is, optimizing the ratio of saturated and unsaturated fatty acid profile. However, excessive supplementation can lead to the onset of undesirable quality traits:

1. Texture modification (softer meat), which is perceived as inferior by consumers. A standard value of 16 g of linoleic acid per kg feed has been agreed to avoid this quality defect.

2. Increased oxidation due to increased unsaturation. This can reduce the shelf life, particularly in products that have gone for further processing.

In recent years, much research has focused on specific or essential fatty acids in feed supplementation work. The potential of conjugated linoleic acid (CLA – a group of isomers (>20) of linoleic acid (C18:2) mostly derived from the meat and dairy products of ruminants) as a food supplement in pork has been investigated in a considerable amount of studies. This is due to its positive health effects in animals, which may have potential for human health through ingestion. In pigs, CLA supplementation has shown to improve performance, reduce fat deposition, and increase lean meat composition. In pork meat, CLA has been shown to increase the saturated–unsaturated ratio, pH_{24}, and WHC and improve belly firmness. However, it has been also shown to decrease the perceived eating quality of the pork (flavor, tenderness, juiciness, and overall acceptability).

Vitamin E as a supplement in feed has also gained much attention. Traditionally, it was considered important for animal nutrition and was added in order to maintain normal animal reproduction. More recently, however, it has been noted more for its potential radical chain-breaking antioxidant properties. In this regard, it is seen as important in protecting the integrity of tissues and it has a fundamental role in life processes. It also has functionality independent of its antioxidant/radical scavenging properties, that is, protein kinase C inhibitor, promotes the growth of certain cells, and is involved in the transcription of some genes. Furthermore, it protects against lipid oxidation in fresh and processed pork when supplemented to pigs at a level of 200 mg kg^{-1} feed. Lipid oxidation and microbial spoilage are the primary cause of pork quality deterioration. The rate and extent of the lipid oxidation are dependent on the vitamin E concentration and the native fatty acid composition of the meat. Discoloration in meat is the result of both oxidation and enzymatic metmyoglobin reduction systems. While vitamin E supplementation in beef was shown to be effective in promoting color stability in beef, the results in pork have been inconsistent. WHC in pork is generally considered to be improved with vitamin E supplementation. The suggested mechanism is that the vitamin E preserves the muscle cell membranes by preventing oxidation of the membrane phospholipids during storage.

Reformulation of Pork Products and Functional Foods

There are a number of approaches that can be taken to improve the health profile of pork, such as changes during the animal production phases, that is, genetic strategies (selection, breeding, and modification) and nutrition and feeding considerations as previously discussed. However, pork is often the major component of many processed meats, such as sausages, and cured and fermented products. Altering the components of one of these products during one of their preparation stages offers the most flexible opportunity to reformulate. It should be noted that this is in no way limited to pork and is being investigated across all meat types. The most investigated strategies are reductions of the added-fat content; modification of the fatty acid profile; reductions of cholesterol, calories, sodium chloride, and nitrites; and fortification with vitamins and minerals. In some of these cases, ingredients that are termed 'clean label' (ingredients considered naturally occurring or additive free) are used as substitutes for some of the removed additives in order to maintain technological quality of the products, for example, walnut, seaweed, carrot, and herb extracts. The use of pork and its products to act as a carrier of functional ingredients (an ingredient that offers an additional benefit other than that of basic nutrition) such as pro- and prebiotics, bioactive peptides, plant sterols, dietary fibers, and antioxidants has been investigated. Finally, the conditions in which these products are processed, stored, and consumed are also important. Maximizing the retention of bioactive compounds (vitamins, minerals, and added-functional ingredients) and retaining their bioavailability while simultaneously minimizing the formation of compounds known or suspected to be unhealthy (polycyclic aromatic hydrocarbons, heterocyclic amines, biogenic amines, nitrosamines, and lipid oxidation products) could be achieved through the use of smarter storage conditions (active packaging) and novel nonthermal and thermal processing technologies.

Negative Health Effects

While pork is inherently a safe food to ingest as part of a balanced diet, it does have safety issues specific to its species. There are three critical safety issues regarding pork:

Trichinosis

Trichinosis is a condition caused by a genus of parasitic roundworms (phylum: Nematoda) called *Trichinella spiralis*. These parasites encyst in the muscle of host. If present in pork, humans can be infected by consuming the pork. Human digestive juices dissolve the cyst, releasing the parasite into the body. The larvae penetrate the body where they mature into adult worms and mate. It is at this point that some initial symptoms (diarrhea and abdominal cramping) may be experienced. After approximately 1 week of ingestion, the adult female worms produce larvae that penetrate the intestinal wall, enter the bloodstream, and eventually burrow into muscle/tissue. The tissue invasion may cause the onset of other symptoms, such as fever, muscle pain/tenderness, facial swelling, weakness, headaches, photosensitivity, and conjunctivitis. Only in rare severe cases do symptoms lead to more serious complications (myocarditis, encephalitis, meningitis, bronchopneumonia, nephritis, sinusitis, and pneumonia). Treatment is usually in the form of corticosteroids and inflammation reduction strategies. The problem persists worldwide because pigs and other hosts (rodents/other mammals) are frequently infected, making it difficult to eradicate. The incidence and infection rate can vary from region to region. Asian countries can report 100s or 1000s of cases per year. However, the number of cases in the West has decreased markedly over the past decades, for example, the United States records only a few cases annually. The decreased incidence of trichinellosis in the United States is attributed to changes in pork industry management standards and government regulations. Proper culinary preparation of pork ensures protection from *Trichinella* infection. Cooking pork to internal temperature of 77 °C or freezing for 20 days at −15 °C destroys

the parasite. Irradiation treatments have also proved successful in eradicating the parasite in the United States.

Foodborne Pathogens

Like all foodstuffs, pork is susceptible to contamination from serious pathogens, for example, food poisoning incidences in pork and pork products have been previously attributed by pathogenic strains of *Salmonella*, *E. coli*, and *Campylobacter*. This is due to the fact they are ubiquitous in the environment, and as a result, contamination can occur at any point in the processing and retail cycle (farm to fork). Accepted regulatory standards of hygiene are in place at local, regional, national, and international level to ensure the curtailment of microbial contamination. As with *Trichinella*, adequate handling and proper cooking are key to their destruction prior to consumption.

Antibiotic Residues and Antibiotic-Resistant Bacteria

Subtherapeutic antibiotics are used in some territories throughout the world to treat, combat, and/or control disease and help promote growth in pigs. For example, the United States has maintained such a practice for over 50 years. The Food and Drug Administration (FDA) regulates the sale of 'antibiotic-free' pork, meaning that preslaughter withdrawal times for each approved antibiotic must be adhered to, in order to guarantee that maximum recovery limits are not exceeded in tested market animals. Unlike in the United States, the administration of subtherapeutic antibiotics to pigs in the EU is prohibited. The ban, which came in to force from 1999, was in response to the perceived risk of an increasing number of antibiotic-resistant strains of microorganisms. Opponents of such a ban being applied in the United States assert that eliminating the use of antibiotics would lead to more diseased animals, an increased bacterial load in meat, and an increase in the overall production price of pork.

Introduction

Potassium is the most abundant intracellular cation in the human body and plays an important role in a variety of cell functions. This article summarizes the main aspects of potassium physiology and nutrition, including absorption, transport, distribution, storage, and excretion, as well as homeostatic mechanisms of K balance.

Role in the Body

Potassium is essential for the muscular, cardiovascular, nervous, endocrine, respiratory, digestive, and renal systems. Cell metabolism depends on the maintenance of a high intracellular K^+ concentration. Many of the body functions of potassium are due to its ionic character: it generates gradients of concentration, potential, and pressure. Potassium is the predominant osmotically active species inside the cell. Together with other ions such as sodium and chloride, which are characteristic of the extracellular fluid (ECF), potassium determines osmolarity and plays a major role in the distribution of fluids inside and outside the cell and hence in the maintenance of cellular volume. In addition, potassium participates in the regulation of the acid–base balance and is involved in cellular growth and division, energy transduction, glycogenesis, protein synthesis, hormone secretion, etc. Consequently, its deficiency causes growth retardation, with a pronounced decrease in circulating levels of growth hormone and somatomedin C and inhibition of protein synthesis.

Cell excitability and muscle contraction depend on potassium. The transmembrane electrical potential is determined by the ratio of the intracellular to extracellular potassium and sodium concentrations, in particular that of potassium. Differences in K^+ and Na^+ concentrations across cell membranes are maintained by the specific permeability to each of these ions and by K^+/Na^+-ATPase activity (K^+/Na^+ pump). Thus, K^+ is critical for the excitability of nerve and muscle cells.

During vigorous exercise, potassium is released from muscle cells, leading to an increase in extracellular potassium concentrations, which facilitates ongoing muscle contraction and induces vasodilatation, increasing local blood flow. However, liberation of potassium also leads to muscular fatigue. Training reduces the exercise-induced rise in plasma K^+ concentration and also increases the total activity of Na/K pumps in muscle. The potassium internal balance helps to delay the onset of fatigue during exercise and to restore homeostasis during recovery.

Potassium can be defined as a cardioprotector nutrient. It acts directly on the heart, regulating its mechanical and electrical properties. Epidemiological data suggest that potassium intake and blood pressure are inversely correlated. The greatest hypotensive effect of potassium occurs in hypertensive patients and in subjects with a high sodium intake. The mechanisms involved include enhancing natriuresis, baroreflex sensitivity, direct vasodilatation, catecholaminergic functions, improvement of glucose tolerance, and effects on the central nervous and the renin–angiotensin–aldosterone systems.

Potassium also protects against stroke, which is the third leading cause of death worldwide (after coronary artery disease and cancer). This electrolyte may decrease ischemic as well as hemorrhagic stroke risk through its effect on blood pressure on the one hand and by inhibiting the formation of free radicals at the endothelial cell level, thus affecting vasomotion, on the other hand. Moreover, potassium inhibits the proliferation of smooth muscle cells, platelet aggregation, and arterial thrombosis. Potassium may also prevent the death of cerebellar neurons.

Interrelationships exist between potassium and other nutrients. Potassium and sodium are strongly metabolically interrelated, principally due to K^+/Na^+-ATPase. This enzyme also provides the driving force for the transport of other solutes, such as amino acids, phosphate, vitamins, and glucose. Potassium depletion, which is more intense if there is a simultaneous excess of sodium, enhances urinary loss of calcium. This interaction may have adverse effects on the bone and blood pressure.

Requirements and Daily Intakes

To date, no recommended potassium intake has been unanimously established. The UK report on dietary reference values established a reference nutrient intake of 3500 mg day^{-1} for adults. Lower amounts were recommended for infants (mg day^{-1}): 800 and 850 for 0–3 months and 4–6 months, respectively; 700 for 7–12 months; 800 for 1–3 years; 1100 for 4–6 years; 2000 for 7–10 years; and 3100 for 11–14 years. No specific levels were recommended during pregnancy and lactation or for the elderly. The Nutrition Working Group of the European International Life Sciences Institute suggested a higher recommended daily intake (3900 mg). This recommendation was aimed at promoting a potassium intake similar to that of sodium, in molar terms, that is, an intake of 100 mmol day^{-1} of each cation (2300 mg and 3900 mg for Na and K, respectively). However, more recently, a Na:K ratio below 1 (1600 mg and 3500 mg for Na and K, respectively) has been recommended to prevent hypertension, stroke, and cardiovascular disease.

During exercise, potassium needs may be increased owing to higher losses in sweat, especially in hot climates and in

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00554-7

unaccustomed individuals. These needs should be satisfied by eating food rich in potassium and exceptionally by potassium supplements.

Published values of nutrient consumption demonstrate that in some populations, sodium intake is higher than recommended, while potassium intake should increase. In the United Kingdom, the 1991 report of the National Food Survey Committee showed that the average sodium intake was 170% of the reference intake, while that of potassium was 80% of the reference value. In Spain, data from the same year revealed that the estimated potassium intake was satisfactory but that of sodium was 140% above the reference value.

Potassium is ubiquitous in all kinds of food, but the best sources are vegetables and fruits because they combine a high potassium content with low sodium concentration (Table 1). Potassium is an essential element of all forms of life, whereas sodium and chlorine are essential for animals but not for many plants. Meat and fish contain important amounts of potassium because they are highly cellular tissues, but they also contain large amounts of sodium chloride, due to the ECF present in animal food. Raw foods are preferable to processed ones because during food preparation, salt is usually added to enhance flavor and retard bacterial growth (e.g., bread, bacon, tomato ketchup, and cookies). Potassium salts, however, are not palatable and are not added to food during processing.

Table 1 Potassium and sodium content of various foods (mg per 100 g of edible portion)

	Potassium	*Sodium*
Vegetables		
Potatoes	320	11
Cabbage	275–310	7–12
Carrots	235	60–90
Spinach	500–633	65–140
Legumes		
Red kidney beans	1370	18
Soya beans	1730	5
Lentils	940	12
Fruits		
Banana	400	1
Melon	100–310	5–32
Avocado pear	400–600	2–4
Orange	195	2–3
Apple	120	2–3
Dried fruits		
Raisins	1020	60
Figs	970	62
Almonds	780	14
Walnuts	450	7
Cereals		
White bread	100	460–540
Brown bread	175–240	540–636
Rice	110	6
Meat and fish		
Beef, veal, lamb	230–360	52–110
Chicken	320	81
Bacon	350	1860
Herring	320	120
Halibut	410	60
Tuna	400	47
Mussels	320	290
Milk		
Whole cows' milk	140	55
Various		
Chocolate	300	11
Tomato ketchup	590	1120

Legumes represent a good source of potassium because they provide at least 1 g potassium per 100 g portion and very little sodium. Dried fruits, for example, apricots, figs, and prunes, should also be mentioned, since they often exceed 0.5 and even 1 g potassium per 100 g portion. Nuts such as pistachios and almonds contain a considerable quantity of potassium, but the addition of salt during roasting upsets the ideal sodium-to-potassium ratio normally present in these foods. Bananas are known to be one of the fruits richest in potassium, together with coconuts, melons, avocados, and kiwi fruit. Milk is the largest dietary source of potassium for infants.

All these data should be considered, taking into account the amount of each food item consumed. For example, a ration of legumes is ~80 g, while those of meat and milk can easily reach 200 g. Although cereals are low in potassium, they account for almost 75% of potassium ingestion in Western diets. There is a wide range of potassium intake by Western populations (1560–5850 mg). It is higher in vegetarians and people who consume more food from plant than animal sources. The Mediterranean diet provides a mean daily intake of potassium equivalent to the recommended value (3500 mg).

Although thermal treatments have no effect on dietary potassium, during processes such as boiling, soaking, and canning, it can be reduced as a result of leaching, particularly if food is to be cut into pieces and the liquid is not consumed.

In order to protect against hypertension and stroke, except in clinical hypokalemia, potassium from good dietary sources should be encouraged rather than potassium from supplements, because such supplements may have severe adverse effects. Fruits and vegetables also contain magnesium and fiber, which seem to have protective effects.

Absorption

Normal subjects absorb about 90% of ingested potassium in the intestinal tract. The net absorption is the difference between fluxes from lumen to blood and from blood to lumen. In the human small intestine, K^+ permeability is high and potassium absorption is carried out across the epithelium of duodenum, jejunum, and ileum by passive mechanisms in response to electrochemical gradients and solvent drag. In the proximal small bowel, K^+ is concentrated through the absorption of water, providing a driving force for the movement of this cation across the intestinal mucosa, preferably through the tight junctions between enterocytes. Duodenum and jejunum absorb this ion even more rapidly than water. Indeed, shortly after a meal, the K^+ concentration $[K^+]$ in jejunum rapidly reaches plasma levels. In the ileum, the transepithelial electrical potential difference strongly influences its movement. There is no evidence of active potassium absorption in the small intestine, but the existence of an apical membrane H^+/K^+-ATPase could suggest active K^+ transport.

In the colon, K^+ may be secreted or absorbed in response to variations in potassium status: net secretion occurs when the luminal concentration is $<20–25$ mmol l^{-1}, while net K^+ absorption takes place when levels are above 25 mmol l^{-1}. There are two mechanisms for K^+ secretion; the major mechanism involves potential-dependent, passive flux, mostly via the tight union or by facilitated transcellular diffusion. The second is an active serosa-to-mucosa secretory mechanism in the proximal and distal colon, which is the result of uptake across the basolateral membrane mediated by Na^+/K^+-ATPase and $Na^+/K^+/Cl^-$ cotransport and movement across the apical membrane through potassium channels. Active K^+ absorption also occurs in the distal colon, in which the K^+ uptake appears to be an exchange for H^+ across the apical membrane. This process is energized by adenosine triphosphatases (ATPases) located in that membrane. Passive potassium absorption may also take place in the proximal colon.

Bioavailability

The availability of dietary potassium is high because potassium salts are entirely soluble and few dietary factors modify its digestive utilization. Olive oil favors potassium uptake, while some fibers and certain ion exchange resins may decrease K^+ absorption.

Physiological status also affects the nutritive utilization of potassium. Infants absorb a greater proportion of salts than adults. This may be due to the increased permeability of the immature small intestinal epithelium of newborns, and especially to a higher activity of the K^+-absorptive pumps in the colonic apical membrane, while K^+-secreting channels are less relevant. During the second half of pregnancy, fecal potassium decreases. Urinary K^+ output increases in parallel with Na^+ retention; nevertheless, enough potassium is retained to cover gestational needs. Glomerular filtration rates fall with age, accompanied by limitations of K^+ secretion and Na^+ conservation. Many drugs used in the elderly alter potassium homeostasis.

Transport

Potassium, being an electrolyte, is transported mainly under ionic form in the body fluids. Intracellular potassium concentration is 110–160 mmol l^{-1} of cells, while plasma concentration averages 4–5 mmol l^{-1}, of which only 10–20% is bound to proteins.

Figure 1 schematically illustrates the intracellular and paracellular mechanisms of potassium transport. Different potassium transport mechanisms can operate simultaneously. They are usually interrelated and are also linked to other ion transport systems. Each name, except the last one, corresponds to an entire family of transporters.

Na^+/K^+-ATPase activity is responsible for the maintenance of the extra- and intracellular Na^+ and K^+ concentrations against electrochemical gradients. This ATPase is found in the plasma membrane of virtually all animal cells and represents an enormous metabolic energy cost, which increases the entropy of the system. It is a carrier protein that pumps $2K^+$ in and $3Na^+$ out of the cell during each cycle of conformational changes driven by adenosine triphosphate (ATP) hydrolysis. This process is electrogenic, meaning that one net positive charge is removed from the cell every pump cycle. Many

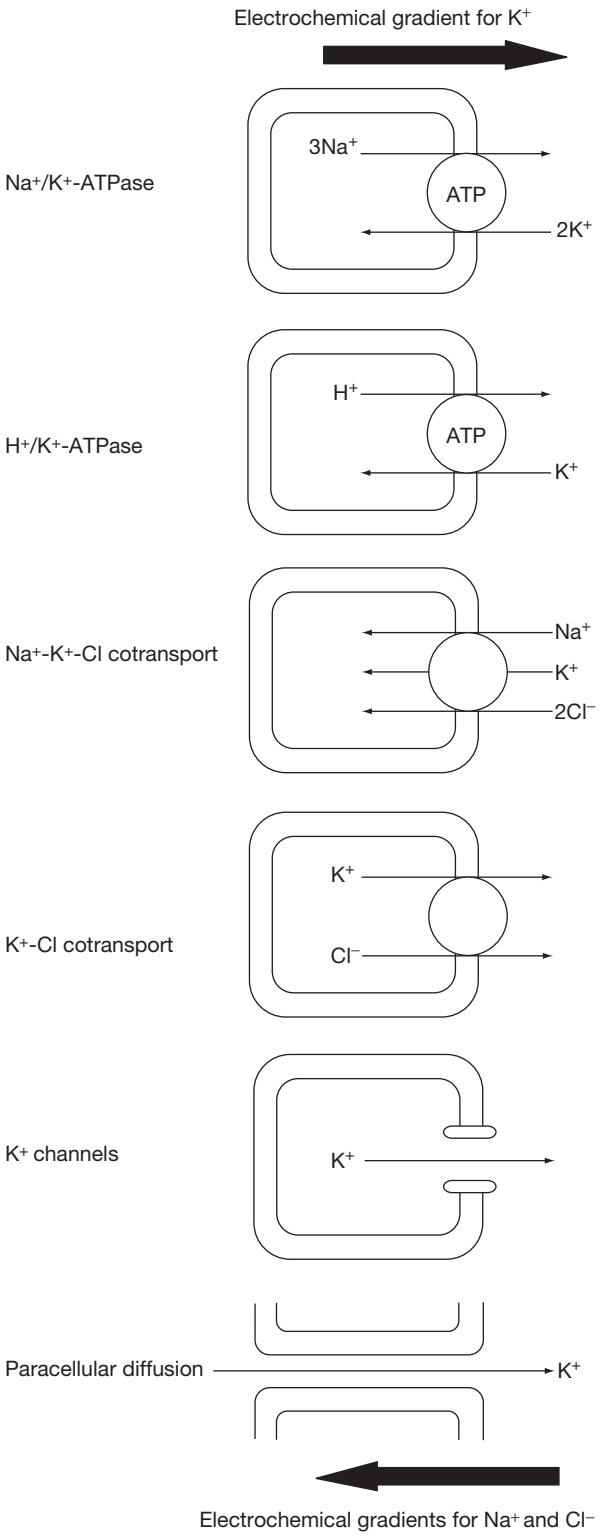

Figure 1 Potassium transport via intracellular and paracellular pathways. ATP, adenosine triphosphate.

hormones and various neurotransmitters can modulate K^+/Na^+-ATPase activity.

Another active K^+ transport is controlled by the H^+/K^+-ATPase, which ejects H^+ in exchange for K^+. This pump has an important role in some gastrointestinal cells and in the renal tubules.

Other potassium transport systems are driven by the force of ion gradients. The free energy gained during the movement of an inorganic ion down an electrochemical gradient (sum of the concentration gradient and the electrical potential difference) is used as the driving force to pump other solutes against their electrochemical gradient. Thus, the carrier protein acts as a coupled transporter and electroneutrality is maintained. Cotransport depends on ATP only indirectly. Various $Na^+/K^+/Cl^-$ cotransporters, which carry $1Na^+$, $1K^+$, and $2Cl^-$ inside the cell, have been identified in salivary glands, gastrointestinal tract, and renal tubules. The K^+/Cl^- cotransporter, related to the former ones, plays an important role in erythrocytic volume. The first cotransport mediates K^+ influx, while the second mediates efflux.

Passive transport of K^+ occurs via intracellular and paracellular pathways. The intracellular mechanism involves K^+ channels, which are pores in the plasma membrane made by a specific protein. Channels have 'gates' that open and close in response to specific stimuli: voltage, stretch, ATP, Ca^{2+}, hormones, neurotransmitters, etc. Various stimuli sometimes act together on a channel. K^+ channels exhibit great diversity and participate in many cell functions.

Distribution and Storage

Body potassium concentration is 45–55 mmol kg^{-1} of body weight; thus, a 70 kg adult man contains ~135 g potassium. Women have 35–40 mmol kg^{-1} of body weight, and in the elderly and children, body potassium concentration is also lower than that for young men. These differences are due to the lower muscle mass in these groups. Almost 98% of the potassium in the body is inside the cells, making it the major intracellular cation. More than 95% of total potassium is exchangeable.

Total potassium is an index of lean body mass because potassium is only present in the fat-free compartments of the body. It can be measured with K^{40}, a natural isotope present as a small fraction of the total potassium, which emits γ-rays and can be detected by a sensitive whole-body counter, although other isotopes and other techniques that are not based on total potassium are also available.

Studies of body composition in healthy humans have demonstrated that the total body potassium/total body nitrogen ratio is constant. However, in chronic protein-energy malnutrition, this ratio can decrease owing to the reduction of muscle proteins and loss of intracellular potassium. The cellular exchange of sodium and potassium is altered, leading to potassium loss and increased intracellular sodium and water. In contrast, exercise and training increase total lean body mass, thereby causing a rise in potassium body content. Increase in muscular mass is only possible if proteins, as well as potassium, phosphorus, and magnesium, which are the main intracellular elements, are present in the diet in adequate amounts.

In the ECF, an increase of potassium equivalent to 1% of total body potassium may double the concentration of potassium in plasma, resulting in muscle hypopolarization. However, if such an increase is stored in the cells, only minor intracellular changes would result, with little change to the potassium concentration difference across the cell membranes. To accomplish this buffer function, the major reservoir of potassium is the muscle, followed by the liver and erythrocytes, although each cell possesses the capacity for accumulating potassium.

Excretion

About 90% of daily potassium intake is excreted in the urine and 10% in the stool, although this last percentage can be somewhat higher in cases of diarrhea. When dietary potassium is severely restricted, its fecal loss decreases to ~3.5 mmol day^{-1}. This presumably represents obligatory potassium losses related to K^+ digestive secretions (salivary, gastric, biliary, and pancreatic), cell desquamation, and mucus secretion. Potassium concentration in sweat is about 10 mmol l^{-1}, so loss through perspiration is small, provided that the climate and exercise conditions are not extreme.

Renal Potassium Handling

The kidney plays the main role in potassium excretion. Renal potassium excretion shows a circadian rhythm, characterized by peak output during the subject's activity.

K^+ is freely filtered by the glomerulus. Usually, urinary potassium excretion is 5–15% of the amount filtered, which indicates the existence of tubular potassium reabsorption. The renal tubules are capable of reabsorbing and secreting potassium in response to various stimuli.

Proximal tubule

The proximal tubule is responsible for the reabsorption of ~60% of previously filtered potassium. Solvent drag and diffusion have been proposed as the major driving forces of this process, and K^+ is reabsorbed largely via the paracellular pathway. However, some observations suggest participation of a transcellular route of potassium reabsorption by an active mechanism. The fractional rates of K^+ reabsorption are similar to those of sodium and water along the proximal tubule, and changes in fluid and potassium transport are closely coupled.

In this region, the basolateral K^+ channels have higher conductance than the apical ones, and this is essential to maintain a negative intracellular potential and hence promote reabsorption of positively charged carriers (Na^+–glucose cotransport).

Loop of Henle

The concentration of K^+ increases as the filtrate passes through the loop of Henle, where permeability for potassium is very high. At the end of the descending limb, the amount of K^+ present usually exceeds that of the glomerular filtrate. There is a net passive secretory entry of potassium into the proximal

straight tubule and the descending thin limb of Henle, which arises from reabsorption in the collecting tubule and partly in the ascending limb. These pathways of K^+ transport constitute potassium recycling in the renal medulla.

In the thick ascending limb, potassium is mainly reabsorbed. The mechanism of active transport includes apical uptake by $Na^+/K^+/Cl^-$ cotransport and passive paracellular exit across the basolateral membrane by diffusion. Driven by transepithelial potential difference, reabsorption also occurs through the paracellular pathway.

The role of this limb in potassium secretion has also been recognized. The K^+ secretion through apical K^+ channels is important for net Na^+ and Cl^- reabsorption through $Na^+/K^+/Cl^-$ cotransport, since luminal Na^+ and Cl^- concentrations are higher than luminal K^+ levels.

Distal tubule and collecting duct

These tubules are the major determinants of urinary K^+, since they are able to either reabsorb or secrete potassium at rates that depend on K^+ intake and other factors.

Potassium secretion occurs in 'principal cells' by active uptake across the basolateral membrane by Na^+/K^+-ATPase and passive diffusion into the lumen across the apical membrane by K^+ channels or using a K^+/Cl^- cotransport (Figure 2). K^+ transport follows this route toward the lumen thanks to a favorable electrochemical gradient and the greater K^+ permeability of the apical membrane in comparison with the basolateral one. High Na^+ concentration in the lumen favors K^+ secretion, as the entrance of Na^+ into the cell generates a potential difference that tends to make the interior positive, so K^+ diffuses in the opposite direction. Simultaneously, the enhanced delivery of Na^+ into principal cells facilitates the action of Na^+/K^+-ATPase, and the accelerated potassium uptake favors its secretion toward the lumen.

Potassium reabsorption mechanisms have been detected in the intercalated cells of the distal tubule and collecting duct. It appears that there is a component of potassium reabsorption even during net secretion. Several isoforms of H^+/K^+-ATPases are able to reabsorb K^+ in exchange for H^+. The $Na^+/K^+/Cl^-$ cotransport may also introduce K^+ into the cell, while the basolateral K^+ channels enable potassium to pass from the cell into the interstitial space. Proton secretion by H^+/K^+-ATPase, together with that by H^+-ATPase, contributes to urine acidification. These enzymes participate in the acid–base balance and potassium status.

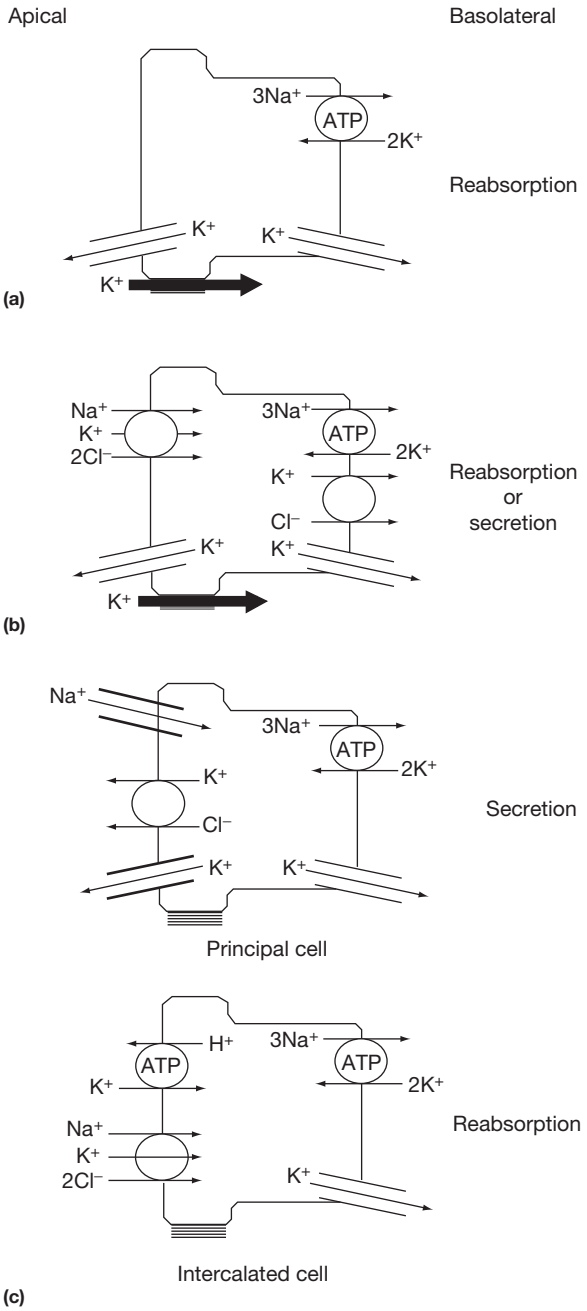

Figure 2 Principal mechanisms of potassium transport in the major tubular segments of the nephron: (a) the proximal tubule; (b) thick ascending limb; (c) distal tubule and collecting duct. ATP, adenosine triphosphate.

Potassium Balance and Homeostasis

Intra- and extracellular potassium concentrations must be maintained within narrow limits, despite wide fluctuations in dietary intake. This is achieved, on the one hand, by 'internal balance' (distribution of K^+ between the intracellular fluid and ECF carried out mainly by Na^+/K^+-ATPase) and, on the other hand, by 'external balance' (maintenance of the amount of K^+ in the body through equilibrium between K^+ intake and excretion, which is achieved principally not only in the kidney but also in the intestine). After a meal, the absorbed K^+ rapidly enters the ECF. The subsequent rise in plasma $[K^+]$ is attenuated by a rapid cellular K^+ uptake (which occurs within minutes). To maintain external K^+ balance, all of the K^+ absorbed in excess must be excreted slowly by the kidneys.

Potassium Homeostasis

To maintain the equilibrium previously described, several factors that act at different levels contribute to potassium homeostasis (Figure 3).

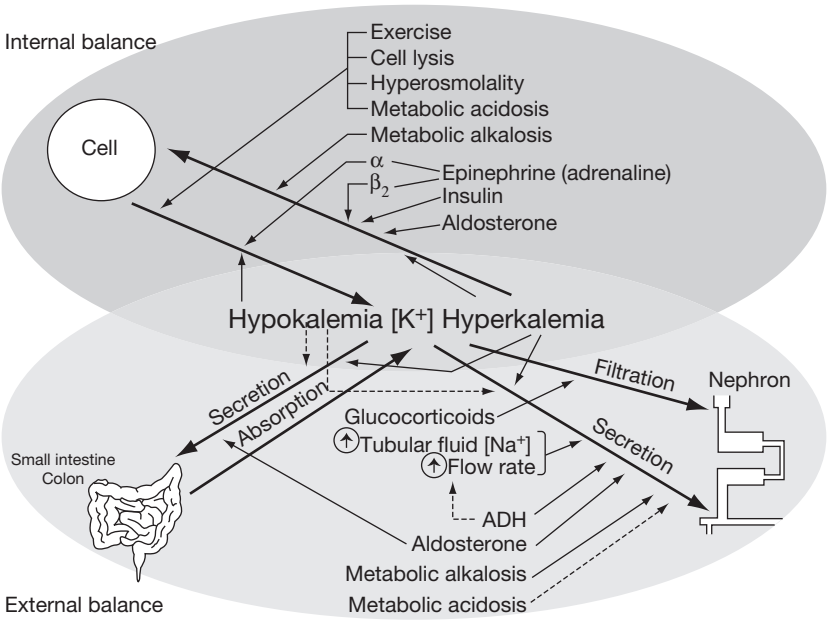

Figure 3 Potassium homeostasis. ADH, antidiuretic hormone. Continuous arrow, increase; dashed arrow, decrease.

Internal balance

A rise in plasma [K^+], especially with hyperkalemia, and the hormones insulin, epinephrine or adrenaline (by activating β_2-receptors), and aldosterone promote K^+ uptake by the muscle, liver, bones, and red blood cells. In contrast, a decrease in plasma [K^+], such as with hypokalemia, and stimulation of α-adrenergic receptors induce K^+ transport from cells to the ECF. Moreover, hyperkalemia stimulates insulin, aldosterone, and epinephrine secretions, while hypokalemia has the opposite effect. These are the major physiological factors involved in internal K^+ balance homeostasis.

Furthermore, other factors that are not normal homeostatic mechanisms influence K^+ movements across the plasma membrane: metabolic acidosis promotes exit of K^+ from cells, whereas metabolic alkalosis favors its uptake. Increased osmolality of the ECF enhances K^+ release by cells. Cell lysis (severe trauma, burns, etc.) induces K^+ release and may produce hyperkalemia. During intense exercise, K^+ is also released from skeletal muscle cells.

External balance

There are two hypotheses concerning the homeostatic mechanisms, which regulate external K^+ balance:

1. The first involves a peripheral mechanism without central nervous system (CNS) intervention. In this case, [K^+] would stimulate urinary K^+ excretion and aldosterone secretion directly.
2. The second attributes K^+ regulation to a reflex mechanism initiated by K^+ receptors in the portal vein and liver stimulated by high [K^+]. Afferent fibers would transmit signals to CNS – 'K control center' – and efferent limbs, mediated by several hormones and other factors, would modulate urinary K^+ excretion in response.

In any case, plasma [K^+] and aldosterone are the major physiological regulators of K^+ excretion. High [K^+] increases aldosterone secretion and both act synergistically, stimulating K^+ elimination by the intestine (particularly increasing colonic secretion) and, above all, by the kidney (promoting secretion in the distal tubule and collecting duct). Renal secretion is due to stimulation of the Na^+/K^+-ATPase pump, increased permeability of the apical membrane to K^+, and greater K^+ uptake across the basolateral membrane. Hypokalemia decreases K^+ secretion by antagonist action. Under repletion conditions, potassium transported by Na^+/K^+-ATPase and H^+/K^+-ATPase recycles back into the lumen through K channels; however, when potassium levels are low, little potassium is wasted through luminal channels and passage of K through basolateral channels predominates.

Aldosterone secretion is favored by angiotensin II. On the other hand, aldosterone stimulates Na^+ and water reabsorption and consequently decreases tubular flow at first. However, flux is restored in time, permitting aldosterone to increase K^+ renal excretion.

Antidiuretic hormone (ADH) increases K^+ secretion in the apical membrane of the principal cells in exchange for Na^+ absorption. However, because ADH also decreases tubular flow, changes in ADH levels do not substantially alter urinary K. K^+ secretion rises along the distal tubule in a flow-dependent manner and it is influenced by dietary potassium intake. This means that diuretics may enhance urinary K^+ excretion. However, K^+ excretion and distal flow rate are not completely coupled, and the K^+ balance is maintained through compensatory mechanisms when necessary.

Physiological [Na^+] does not alter K^+ secretion but high [Na^+] in tubular fluid increases K^+ secretion, whereas a fall in concentration has the opposite effect. Acid–base balance is another factor that modulates K^+ secretion: alkalosis increases secretion, whereas acidosis decreases it. Glucocorticoids are

kaliuretic, but their effects appear to be a consequence of an increase in the glomerular filtration rate.

K^+ itself exerts a feedback regulation over most of its own control factors. Together, all these mechanisms allow the human body to maintain normal plasma [K^+]. However, the equilibrium can sometimes be altered, causing either hyperkalemia (extracellular [K^+] over 5.5 mmol l^{-1}) or hypokalemia (extracellular [K^+] below 3.5 mmol l^{-1}).

Hyperkalemia may be the consequence of a K^+ shift from cells to ECF or the effect of excessive K^+ retention. The first signs are flaccid paralysis, natriuresis, and other minor effects. The most important consequences are ventricular fibrillation and cardiac arrest. Hyperkalemia may be either of the following:

- Without potassium excess: caused by K^+ shift from cells (acute acidosis, hyperosmolality, insulin deficiency, β-adrenergic blockers, vigorous exercise, etc.)
- With potassium excess: impaired renal excretion (renal failure, aldosterone deficiency, and primary tubule dysfunction) (inappropriately high oral or parenteral K^+ administration)

Hypokalemia may be the result of either intracellular shift or K^+ depletion or both. Among its clinical sequelae is hyperpolarization of membrane, which affects nerves and muscle activity and produces renal, cardiac, and metabolic alterations. The hypokalemia may be caused by the following:

- Intracellular shift: alkalosis, insulin excess, familial periodic paralysis, catecholamine increase, intoxications, etc.
- Extrarenal causes: insufficient K^+ intake, diarrhea, vomiting, skin loss, etc.
- Excessive renal losses: renal tubular acidosis, hyperaldosteronism, syndrome of chloride depletion, and diuretic condition

Properties and Determination

Potassium is a light, soft metal and a strong reducing agent, discovered by Davy in 1807 in caustic potassium (KOH). It is widely distributed in minerals such as sylvin (KCl), carnallite ($KMgCl_3$ or $MgCl_2{\cdot}KCl$), langbeinite [$K_2Mg_2(SO_4)_3$], or polyhalite [$K_2Ca_2Mg_2(SO_4)_4{\cdot}2H_2O$]. Potassium is an abundant metal and is the seventh most abundant element in the earth's crust. Seawater contains 380 p.p.m. of potassium, making the mineral the sixth most abundant in solution.

Potassium is used extensively, mainly in the form of potassium salts, in various fields such as medicine (iodide as a disinfectant), photographic processing (carbonate), explosives (chlorate and nitrate as powder), defreezing agents, poisons (potassium cyanide), metallurgy, basic chemistry (hydroxide in, e.g., strong bases, oil sweetening, CO_2 absorbent, chromate and dichromates as oxidants, and carbonate in the glass industry), fertilizers (nitrate, carbonate, chloride, bromide, and sulfate), detergents and soaps (hydroxide and carbonate), and coolants in nuclear reactors (NaK alloy), etc.

Potassium (atomic number = 19) forms part of the group of alkali metals classified between sodium (atomic number = 11) and rubidium (atomic number = 37). It has an atomic weight of 39.098, an oxidation state 1, and an electronic orbital structure of [Ar] $4s^1$. This electronic configuration (one electron in the 4s orbital) enables potassium to ionize easily to the cation K^+ owing to the loss of its most external electron. It does not appear as a native metal in nature. Potassium exists in nature in three isotopes: ^{39}K (93.26%), ^{40}K (0.0117%), and ^{41}K (6.73%). ^{40}K is radioactive and responsible for most of the naturally occurring internal radioactivity in the body. This property enables researchers to monitor total body potassium values as a function of age and disease.

The behavior of potassium in its metallic form is similar to that of sodium, with which it is closely related. Both are alkali metals essential for life owing to their involvement in cellular physiological development and the regulation of body fluids, together with chlorine, thus explaining why it is common for both alkali metals to appear in the form of their corresponding chloride salts. Given this relationship with cellular liquids, potassium, sodium, and chlorine are also known as electrolytes (ions with greater proportions in the composition of organic fluids).

The K^+ ion is the main intracellular cation, with an approximate [K^+] of 5.6 g l^{-1} in cellular fluids, ~30 times more concentrated than in plasma or interstitial liquid (0.15–0.20 g l^{-1}). Its high intracellular concentration is regulated by the cell membrane through the sodium-potassium pump. The intracellular K^+ regulates the catalytic action of numerous enzymes, through the attachment of the cation to active locations with negative charges of the enzymatic proteins, modifying the conformation of the molecule and its activity, as well as participating in cellular division processes.

The small percentage of extracellular potassium (2% of body potassium) is of great physiological importance since it is a critical determinant of neuromuscular excitability (nervous impulse and contraction of bone muscles). At a cellular membrane level, the transport and permeability of energy-dependent potassium, with simultaneous excretion of sodium linked to the Na/K enzyme ATPase, is essential for generating the potentials of membranes required for the proper functioning of nervous and muscular cells. It also helps to maintain the acid–base equilibrium and blood pressure.

Homeostasis of potassium is still the subject of research, although it is known that 90% of dietetic potassium is absorbed in the small intestine and that body potassium (1.6–2 g kg^{-1} of body weight) is regulated by renal glomerular filtration and tubular secretion, with potassium being lost on a daily basis through urine, gastrointestinal secretions (ileum and colon), and, to a lesser degree, sweat. Provided that renal function is normal, it is practically impossible to reach an excessive level of potassium with normal dietary intake, since the kidney is capable of excreting more potassium than it can filter.

The effect of potassium on blood pressure has been discussed in recent reports on metaanalysis; these have confirmed that increases in doses of potassium from 60 to 80 mmol day^{-1} (2.3–3.1 g day^{-1}) may prompt a decrease of 4 mmHg in systolic blood pressure and possibly reduce the number of deaths related to high blood pressure by 25%.

The use of potassium chloride salts as substitutes for sodium chloride, in individuals with whom the intake of sodium is restricted because of problems relating to hypertension, is a questionable alternative, since cardiac arrhythmias have been reported in association with the excessive intake of salt substitutes containing potassium chloride. Although hyperkalemia is highly unlike in normal diets, it can be produced with healthy individuals for intakes exceeding 17.5 g day^{-1}. In the case of individuals with renal dysfunctions this disorder may appear with intakes of potassium exceeding 5.9 g day^{-1}. Cardiovascular or neuromuscular complications arising from situations of hypo- and hyperkalemias are resolved favorably by correcting the plasmatic potassium levels.

The mean potassium intake in Western populations ranges between 1.6 and 5.9 g day^{-1}, and the required dietary intakes of this are met without any problem, thanks to the ubiquitous presence of potassium in both vegetable- and animal-based foods. The Scientific Committee for Food of the European Community recognizes that the minimum recommended intake of potassium is 1600 mg day^{-1}, and the reference intake for the population is 3100 g day^{-1}.

Analysis of Potassium

Potassium can be analyzed using a number of different methods, although many of these are not commonly used for

routine analysis of potassium in food and biological samples. In the case of potassium, there has been a shift from the old gravimetric methods, based on the precipitation of potassium using chloroplatinate or tetraphenylboron, to the spectroscopic methods, mainly atomic emission and atomic absorbance spectroscopy, and which, according to the scientific community, are the most commonly used.

However, there are other techniques for analyzing potassium that are not as 'popular' as those mentioned above, and are equally applicable to other mineral elements. These include selective electrodes, nuclear magnetic resonance (NMR) spectroscopy, x-ray analysis, helium glow photometry, inductively coupled plasma atomic fluorescence, ion-scattering spectrometry and other methods. Another procedure can be used – namely, radioactive dilution of potassium isotopes – when determining both potassium content and its distribution in extra- and intracellular compartments.

Emission and absorbance spectrometry have been the most widely used techniques for analyzing trace elements in biological and food samples. Their widespread use is justified by their analytical specificity, good detection limits, excellent accuracy, and relatively low cost. Both techniques are based on energy modifications of the electronic orbital structure of the atoms of mineral elements in response to certain stimuli (flame, plasma, and incidence of a beam of light of specific wavelength for absorption).

The determination of potassium by spectroscopy requires a stage of preparation of samples for analysis that entails the drying, grinding, and destruction of the organic matter of the sample. There are two alternatives for destroying the organic matter of biological and food samples, both with different variants: wet oxidation and dry ashing. Both techniques yield reasonably comparable results and it is often the analyst who decides which technique to employ.

Atomic Absorption Spectroscopy

In atomic absorption spectroscopy (AAS), electromagnetic radiation at a specific wavelength is passed through a cell containing gaseous free atoms. Atoms are produced in two different ways using AAS: flame atomization (FAAS) and electrothermal atomization (ETAAS) (graphite furnace and a L'vov platform). Thus, the determination of potassium using an atomic absorption spectrophotometer requires a light source (wavelength for $K = 766.5$ nm) and an atomization source. For the light source, arc discharge lamps may be used for *K*, although hollow cathodes are preferred. Lineal calibration is required to obtain analyte concentrations in the sample. Standard working conditions for analyzing potassium by AAS are listed in Table 1.

Atomic Emission Spectroscopy

The determination of potassium in biological and food samples, as in the case of sodium, may be performed using flame photometers and atomic absorption spectrophotometers (with the option of working in emission conditions). In recent years, some manufacturers have named atomic emission spectroscopy (AES) instruments as 'optical emission spectrometers' (OES) because they measure the emitted light when excited atoms return to the ground state. Since this latter term is more widely used, we will use OES rather than AES onwards in the article, but the terms are practically interchangeable. There are two ways to produce the excitation of the atoms in food analysis: flame emission spectroscopy or the use of electrically generated plasmas (highly ionized gases) resulting in inductively coupled plasma–optical emission spectroscopy (ICP–OES). Flame emission can be used for the thermal excitation of elements with relatively low excitation energies such as potassium. A specific wavelength of 766.5 nm is used in order to determine potassium, and the equipment reading resolution is adjusted to the response given to the pattern of greatest concentration used. An effort must be made to avoid possible interference problems due to the matrix characteristics of the sample in flame emission photometry; this can be achieved by separating the element from the object of study, eliminating the ions responsible for the interferences, or using a compensatory technique. For this purpose, recommended practice for correcting interferences includes the addition of lithium (as an internal standard) either to the samples or to the standards. It is important to obtain a suitable calibration curve, either linear by diluting the samples, or by logarithmic adjustment between emission values and potassium concentration.

When comparing flame emission spectroscopy and AAS, the detection limits for potassium ($\mu g\,ml^{-1}$) are 0.0005 and 0.005, respectively. Using an atomic absorption spectrophotometer, the accuracy and precision of potassium analysis by flame emission can be obtained (Table 2).

Table 3 shows a series of official methods for determining potassium, based on flame emission and absorption spectrophotometry.

Table 1 Standard conditions for potassium analysis by AAS

Spectrometers setting	*Potassium*
Wavelength/slit (nm)	766.5/0.2
Nebulizer	Spoiler
Oxidant	Air
Fuel	C_2H_2
Flame condition	oxidizing
Optimum concentration range in solution ($\mu g\,ml^{-1}$)	1–10
Detection limit ($\mu g\,ml^{-1}$)	0.005
Sensitivity 1% absorption ($\mu g\,ml^{-1}$)	0.05
Interferences	Ionization

Inductively Coupled Plasma–Optical Emission Spectrometry

The above analytical techniques are shown to be sensitive enough to detect potassium and other trace elements, however, as mono-elemental techniques; they become slow and tedious when a large number of elements are analyzed. ICP–OES is a multi-elemental technique that is able to determine concentrations of multiple elements in a sample with a single aspiration obtaining a high degree of variability and minimum interferences. As already mentioned, argon plasma is needed to produce atomization. The nearly complete atomization of the sample minimizes chemical interferences. Samples can be prepared by either wet oxidation or dry ashing, and a wide range of concentrations can be used without the need to dilute or

Table 2 Accuracy and precision of the potassium analysis by flame emission

Accuracy	*Certified (g kg^{-1})*	*Found (g kg^{-1})*	*IC (95%)*[a]	*Rec (RSD)*[b]

Table 3 Official methods recognized for potassium determination

Official methods	
Sodium and potassium in seafood	Flame photometric method, AOAC Official Method 969.23
Potassium in fruits and fruit products	Rapid flame photometric method, AOAC Official Method 965.30
Potassium and sodium in wines	Flame spectrophotometric method, AOAC Official Method 963.13
Potassium in distilled liquors	Flame photometric method, AOAC Official Method 963.08
Potassium in beer	Atomic absorption spectrophotometric method, AOAC Official Method 987.02
Potassium in water	Atomic absorption spectrophotometric method, AOAC Official Method 973.53
Potassium in infant formula, enteral products and pet foods	Atomic absorption spectrophotometric method, AOAC Official Method 985.35

concentrate the sample. For example, it is possible to measure samples varying in concentration from 1 μg l^{-1} to 1 g l^{-1} without having to recalibrate the instrument. Also, many of the other mineral elements can be quantified, thus reducing the time of analysis. These advantages, together with the high speed and excellent instrument stability, make ICP–OES highly attractive.

For potassium determined by ICP–OES in plant tissues a solution detection limit of 0.06 (μg ml^{-1}) and a sample detection limit of 2.0 (μg g^{-1}, based on a 2-g sample diluted to 50 ml) are recommended. There is also an AOAC Official Method (984.27) for the determination of potassium in infant formula by means of ICP–OES, which recommends the following ICP emission spectrometer operating parameters for potassium: wavelength (nm) = 766.5, no background correction, and low standard = 0 and high standard = 200 (μg ml^{-1}). The AOAC also recommends an Official Method (985.01) for the analysis of potassium in plants and pet foods by inductively coupled plasma spectroscopy.

ICP can also be used coupled with a mass spectrometer leading to inductively coupled plasma–mass spectrometer (ICP–MS). MSs are instruments that separate ions according to their mass to charge ratio (m/z) and then accurately count these ions as they strike a detector. ICP–MS is also a multielement technique with very low detection limits and being highly appropriate for the determination of elements present in low levels. Thus, although ICP–OES is a widely used method for the analysis of potassium, ICP–MS can also be used when other elements found in foods in trace amounts are determined simultaneously.

Near Infrared Spectroscopy

The near infrared (NIR) radiation is the electromagnetic spectrum radiation encompassing the interval 780–2500 nm being situated between the middle infrared (MIR) and visible radiations. In spite of the early discovery of NIR radiation in 1800, NIR spectroscopy has not gained interest for chemical analysis up until recently. The main reason has been the high complexity of NIR spectra, which is the result of overtones and combination bands generated by different functional groups such as C–H, N–H, and O–H. Classical statistical methods, such as univariate analysis, are not considered valid to obtain this information. Instead, this disadvantage can currently be overcome using suitable chemometrics techniques, such as multivariate analysis (partial least squares (PLSs) or modified-partial least squares (MPLSs)).

As already mentioned, NIR spectrum of an organic material gives a global signature of composition based on the assessment of the organic chemical structures containing C–H, N–H, and O–H bonds. However, the determination of inorganic compounds such as potassium is more challenging compared to organic compounds owing to the lack of a direct relation between the element involved and the spectra obtained. In this case, NIR spectroscopy could be used for determining mineral concentration, due to association between minerals and organic functional groups in the food matrix and the effect on O–H bonding. The determination of potassium and other mineral elements by NIR is, therefore, generally dependent on the presence of those elements in mixtures of organic or hydrated compounds and salts (cations and anions).

NIR spectroscopy is being widely adopted for potassium analysis of many food products, such as wine, cheeses, and human diets, among others. The main advantage of this analytical technique lies on its speed, accuracy, and low cost (it does not require samples processing). Besides, it is non-destructive and more environmentally respectful when compared with other analytical techniques. Three different measurement setups can be performed to obtain a NIR spectra: reflectance, transmittance, and interactance modes. In reflectance mode, the light source and detector are mounted under a specific angle (e.g., 45°) to avoid specular reflection. In transmittance mode, the light source is positioned opposite to the detector. Finally, in interactance mode, the light source and detector are positioned parallel to each other in such a way that, due to specular reflection, light cannot directly enter through the detector. For potassium analysis, reflectance mode has been widely reported in literature as having an acceptable prediction of the potassium content in foods.

Potassium-selective electrodes

Potassium-selective electrodes have been developing from the first ion-selective glass electrodes, with little ion selectivity, to potassium-sensitive electrodes based on valinomycin, a highly-specific neutral carrier compound for analyzing potassium, to potassium-sensitive electrodes with ion-exchange compounds dissolved in organic solvents that are not specific due to significant interferences induced by the presence of sodium and other cations in organic solutions. Ion-exchange electrodes have faster response times than those with membranes of valinomycin, although the latter show fewer interferences from other ions. However, neither type of electrode is effective in organic solvents. Furthermore, electrodes measure ion activity and therefore, do not detect ions linked to other molecules or potassium that is not in solution.

Ion-selective electrodes are also incorporated into gasometric equipment for measuring electrolytes (Na, K, Cl, and ionized Ca), oxygenation, ventilation, basic – acidic state, and electrolytic metabolism of patients with respiratory problems. In this context, it is useful to quantify the exchange of gases and electrolytes through cellular membranes. For this purpose, the so-called *anion gap* is calculated, which interrelates with sodium (*anion gap Na*), potassium (*anion gap K*), bicarbonate, and chlorine. This parameter provides information on electrolytic alterations and the presence of toxins in blood, and also helps to control quality in laboratories by interrelating standards.

Some developments in the field of potassium-selective electrodes have focused on the appearance of novel potassium-selective valinomycins in the development of ion-selective sensors based on new technologies and on the combination of these ion-selective electrodes with other analytical methodologies, as shown in Table 4.

Carbon materials, such as graphene sheets, have been used as the intermediate layer between an ionophore-doped solvent polymeric membrane and a glassy carbon electrode. The results showed that the graphene layer is capable of both ionic and electronic charge transfer, providing a good Nernstian response to potassium, with a detection limit of 10^{-5} M. Similarly, carbon nanotubes, with a high surface area, have been used as ion-selective electrodes for other elements, such as calcium. Finally, a potentiometric microelectrode method for intracellular K^+ determination based on ZnO nano-wires has recently been reported. These new materials offer promising results to developed ion-selective electrodes with excellent potential stability, low cost, ability to miniaturize, and mass fabrication.

Nuclear Magnetic Resonance

NMR is used to studying the relationship between metabolism and function in living systems as simple as cells in a culture and as complex as human subjects (e.g., the effect of temperature on the sodium/potassium pump in red blood cells). As a non-invasive, non-destructive spectroscopic technique, NMR offers

a powerful approach to the study of ion balance in intact biological systems. The aims are to validate new NMR methods, to elucidate tissue-specific mechanisms, and to draw conclusions with respect to basic concepts and design in tissue metabolism and function.

The possibility of determining potassium by NMR is due, on the one hand, to the relatively high concentrations of the cation in cellular tissue and, on the other hand, to the natural abundance of ^{39}K nuclide (NMR receptivity is about 2000 times less than that of one hydrogen atom) and the short longitudinal relaxation time. The concentrations of intracellular and extracellular potassium in tissues may be quantified by applying impermeable cell-membrane chemical shift reagents.

However, this quantification by NMR measurement depends on the NMR invisibility of the potassium actually present, in accordance with other techniques. Several previous studies have shown that only ~20% of cardiac intra-cellular potassium is visible with current NMR techniques. This NMR sensitivity of potassium (about 60%) represents a serious obstacle to its proper quantification in biological tissues.

A study of factors affecting ^{39}K NMR detectability in rat thigh muscle showed that the signal may be substantially higher (up to 100% of total tissue potassium) than values previously reported of around 40%. These signals present two superimposed components – one broad and one narrow – and involve improvements in spectral parameters (signal-to-noise ratio and baseline roll), together with computer simulations of spectra, that enable a spectrum quality with a major effect on the amount of signal detected, largely due to the loss of detectability of the broad signal component.

Biological and biochemical cellular research in connection with the quantification of ions in intracellular and extracellular compartments, transport, and ionic metabolism at the level of different cells and biological tissues, as well as on the union capacity of cations Na^+ and K^+ to other cellular components, are based on the use of ^{39}K NMR spectroscopy, together with ^{23}Na and ^{31}P NMR studies.

Proper ion equilibrium between intra- and extracellular compartments is required for normal physiological function. Conversely, alterations in membrane ion transport occur in numerous pathological states. By introducing an anionic paramagnetic shift reagent into the medium, NMR signals of intra- and extracellular Na^+ and K^+ could be resolved, enabling ion transport processes to be studied by NMR. Unfortunately, rare NMR active nuclides that are isotopes of the 100% naturally-abundant $^{23}Na^+$ and $^{39}K^+$ are unavailable for tracer kinetic studies of Na^+ and K^+ transport. However, Cs is a biologically active analog of K^+ and the 100% naturally-abundant NMR active $^{133}Cs^{++}$ nuclide can be employed to examine K^+ transport. Other studies have shown the potential of ^{39}K NMR as a useful tool in the study of protein-cation interactions and the binding of K^+ to double-helical DNA.

x-Ray Fluorescence Analysis

x-Ray fluorescence (XRF) can be successfully used for the qualitative and quantitative elemental analysis of various agricultural products. It belongs to a family of atomic spectrometry techniques but has some distinctive analytical advantages compared with other techniques, such as AAS and ICP–OES. Its simplicity, high throughput and automation possibilities make it useful for screening large numbers of samples. Another major advantage is that it is able to determine almost all the elements in the periodic table – including potassium – simultaneously at very low concentrations. XRF is based on bombarding a small area of the sample with x-ray photons, which are sufficiently energetic to cause ionization of inner electrons of the atoms. Because of this unstable atomic configuration, this vacancy of an inner electron is filled by an electron from an outer orbital, which emitted the difference of energy between the two orbitals as a 'secondary' (or fluorescent) x-ray photon. The main difference with other spectrometry techniques (i.e., AAS or ICP–OES) is that, in the latter, the absorbed or emitted radiation covers the ultraviolet–visible region of the spectrum.

The methods for preparing the specimens of liquid media of the organism and XRF analysis are simple and fast, entail no disintegration of the sample, and allow measurements of elements at sigma $1 = 0.02$ at concentrations of 12 $\mu g\ ml^{-1}$ to be obtained. The bibliography describes different XRF analysis techniques for measuring potassium in food and biological samples, as indicated in Table 5.

Wavelength dispersive x-ray fluorescence (WDXRF) spectrometry has universal application in a wide range of environmental and geo-chemical samples, such as soils, plants, and water. WDXRF instrumentation uses an x-ray tube as the excitation source and is available with one or two scanning goniometers or, alternatively, with a number of multiple fixed goniometer channels for rapid simultaneous elemental detection. Currently, WDXRF has been used for determination of potassium in human placenta and food samples such as beans.

Energy dispersive x-ray fluorescence (EDXRF) incorporates a solid-state semiconductor detector, which offers different detection characteristics with parallel detection of the full x-ray spectrum. Another difference with WDXRF is that adequate excitation is provided by a lower–power x-ray tube arranged for direct or secondary target excitation. Potassium content in human blood, spinach, and human diets has been studied using EDXRF. Furthermore, ED spectrometers have no moving parts and have benefited extensively from the miniaturization that has taken place in integrated circuit technology.

Table 5 x-Ray techniques for potassium analysis in food and biological samples

Samples	*x-Ray analysis*
Human placenta Beans	Wavelength dispersive x-ray fluorescence (WDXRF)
Walls of the mosaic virus infected wheat leaf cells Perisperm tissues of seeds Human blood and human diets Vegetables (spinach)	Energy dispersive x-ray fluorescence (EDXRF)
Cancerous and normal tissues In vegetable foodstuffs and their respective cell fractions Cancerous breast tissue	Total reflection x-ray fluorescence (TXRF)
Human brains Human atherosclerotic artery wall	Proton induced x-ray emission (PIXE)
Breast tissue	Synchrotron x-ray fluorescence (SRXRF)

The use of total reflection x-ray fluorescence analysis (TXRF) in life sciences is considered a powerful analytical tool for simultaneous multielement determination. TXRF is basically an energy-dispersive technique, with the sample being excitated in total reflection geometry. This technique only requires a few nanograms of sample, with simple preparation, and involves a large dynamic measuring scale. Simultaneous detection of almost all chemical elements and lower limits of detection are achievable in optimized excitation conditions. The preferred sample types are aqueous and acidic solutions, particularly samples digested with HNO_3. Special preparation techniques are required for solids and other samples.

The application of the proton-induced x-ray-emission (PIXE) method has enabled us to determine not only the concentrations of elemental composition, including K, but also their localization in different artery-wall regions. Furthermore, the usefulness of the micro-PIXE method for studying biomedical materials has been also considered.

Finally, synchrotron x-ray fluorescence has also been used in studies on trace elements and potassium in breast tissue. Synchrotron radiation is emitted when charged particles are accelerated by means of a magnetic field perpendicular to their direction of motion. The brightness and intensity of synchrotron x-rays are many orders of magnitude more than x-rays produced in conventional x-ray tubes. A promising tool is the combination of high flux and low divergence provided by synchrotron source with microscopic analysis for elemental mapping of biological samples.

Radioactive Isotopes

The dilution of radioactive isotopes of potassium is applied to establish the concentration and distribution of the amounts of potassium in the different body compartments. For example, the differences in potassium concentrations between the extra- and intracellular spaces may be studied by such techniques.

For this purpose, it is important to take into account that animal and plant tissues present different potassium compartments in which the ions accumulate, and this conditions the radioactive isotope dilution process. In animal tissue, three cellular compartments (plasma + extracellular fluid, cells, and spaces where ions are closely fixed or form complexes) are described, whereas in plant tissue only two spaces (cytoplasm and vacuoles) must be considered since the extracellular space is small in size. This compartmental distribution conditions the process of radioactive isotope dilution.

In animal tissue, the method involves incorporating a known amount of the tracer isotope of potassium into the extracellular compartment and monitoring the changes in plasma isotope concentration until equilibrium is reached with all the compartments. This entails estimating the distribution of potassium (1) in extracellular fluid, using tracer polymers (inulin or polyethylene glycols) that cannot penetrate cell membranes, (2) in cellular volume, by subtracting extracellular volume from total distribution space (determined by using labeled water, tritiated, or deuterated), and (3) in the space where the ion is strongly fixed or forms complexes (this is calculated by subtracting the amount of extracellular potassium + cellular potassium from the amount of potassium isotope injected).

In plant tissue, the dilution of radioactive isotopes of potassium presents limitations due to the difficulty involved in terms of separating vacuolar volume and cytoplasmic volume. For this reason, more appropriate methods than radioactive dilution methods have been developed for determining cytoplasmic and vacuolar potassium concentrations, namely ion-selective microelectrodes or x-ray microprobe analysis.

A related technique with the use of radioactive isotopes is neutron activation analysis (NAA). It has become an important analytical tool in the food science and nutrition field, providing sensitive trace element analysis. The technical basis is that samples are first irradiated with the flood of neutrons generated by a nuclear reactor, creating radioactive isotopes of present elements. By monitoring the subsequent decay of these radioisotopes, it is possible to identify and accurately quantify the elements in the sample. It is also a non-destructive technique that only requires sample preparation with a high sensitivity and accuracy.

NAA has been selected for analyzing potassium of cereals and legumes samples with a limit of detection 14.4 $\mu g\, g^{-1}$. It has also been used for determining potassium content in other biological samples, such as human hair and kidney stones, among others. Finally, a promising prospect about this technique in quality control of the food industry is that NAA could be used in multielement analysis – including potassium – combined with chemometric methods to characterize the geographical origin of foodstuffs and reject possible imitations.

Introduction

The potato is the world's number one nongrain food commodity and is the world's fourth most important food crop after wheat, rice, and corn. Potato occupies third position in terms of consumption after rice and wheat. It is a staple food for the human diet and as such is an integral part of the global food security system. In order to emphasize the importance of potato in providing world food security and alleviating poverty, the United Nations General Assembly officially declared 2008 as the 'International Year of the Potato.' Potatoes originated in the Andes of South America near Lake Titicaca, located between Peru and Bolivia, and were brought to Europe by the Spanish in the sixteenth century. It was domesticated between 10 000 and 7000 years ago. The Incan people (thirteenth to sixteenth century AD) regarded the potato as crucial to their food security since the crop could easily be stored as dehydrated, freeze-dried, and fresh forms for consumption during times when other crops failed. The Spanish introduced potato to Spain after conquering Peru, and then, it spread to European countries by the end of the sixteenth century. Despite the initial aversion to potato consumption in many parts of the continent, by the 1700s, potato was gradually accepted as a high-yielding stable crop that was a high-calorie food source for feeding both livestock and humans. Ireland was particularly dependent on this crop by the mid-1800s. 'Late blight' caused by the fungi *Phytophthora infestans* first appeared in 1845, and it devastated potato crops in Ireland resulting in three consecutive crop failures between 1845 and 1848 disrupting its highly vulnerable agricultural-based economy. During this period, more than 1.5 million people died of starvation or were forced to emigrate from Ireland. Late blight disease virtually wiped out the European descendants of the original *S. tuberosum* ssp. andigena by the mid-nineteenth century, and they were replaced by *S. tuberosum* ssp. tuberosum. Potato also reached Asia, New Zealand, and Africa through various colonial activities. In this article, we are providing an overview of the nutritional composition and bioactives of potato and their health benefits.

Current Trends in Production (FAOSTAT)

Potato cultivation has expanded globally and is currently grown in more than 160 countries around the world. China is ranked as the top producer (became the top producer) with 85 860 000 million metric tons contributing 23.3% of world production. China is followed by India, the Russian Federation, and Ukraine. The United States occupies fifth position. Demand for potatoes and potato products continues to increase in developing countries. In the United States, the consumption of the fresh potato has declined, while processed potato consumption has increased over the last 10 years. Almost half of the potato produced globally is consumed in Asia and is increasing on a per capita basis. Over the past 20 years, potato-growing areas have declined in North America, Europe, and the former Soviet Union. In developing countries including those in Africa, Asia, and Latin America, production areas have doubled. In Asia, potato production is increasing at a fast pace due to increasing interest in processed potatoes and use as animal feed for the livestock industry. There has been an increase in potato production at an annual rate of 4.5% over the last 10 years. Currently, the potato is the most predominant vegetable in the United States in terms of production, sales, and consumption. In the United States, fresh potato consumption has decreased by 50%, while processed potato consumption has increased by approximately two-thirds. Potato became the first vegetable to be grown in space in October 1995, with a goal of feeding astronauts during long space journeys.

Solanaceae Family

The potato (*Solanum tuberosum* L.) is a member of the Solanaceae or 'nightshade' family, genus *Solanum*, and section Petota. Section Petota are divided into two subsections, Potatoe and Estolonifera. Potatoe are characterized by the presence of underground tubers and include the potato and its wild relatives. Estolonifera are non-tuber-bearing and nonstoloniferous species that resemble the true potatoes. Solanaceae also includes other economically important plant species such as the tomato (*Solanum lycopersicum* L.), pepper (*Capsicum annuum* L.), and eggplant (*Solanum melongena* L.). *Solanum tuberosum* is divided into two cultivar groups: Andigenum (Andean) and Chilotanum (Chilean). Andigenum is adapted to short-day conditions and is mainly grown in the Andes, while Chilotanum is the European potato adapted to the long-day conditions. It is believed to have developed from Andean cultivars introduced first into Chile and then into Europe.

Potato Plant and Tubers

Solanum tuberosum is an herbaceous perennial that can grow to about 60 cm in height. In modern-day farming, potato is cultivated as an annual species grown and harvested every year. Plants are characterized by long pinnate leaves, and they bear white, pink, blue, or purple flowers with yellow stamens in clusters. Potatoes are mostly pollinated by insects such as bumblebees, though self-fertilization also occurs. Fruit of *S. tuberosum* resembles green cherry tomatoes with or without seeds. Fruits are unsuitable for human consumption as they contain substantial amounts of the toxic alkaloid solanine. As the potato plant grows, it produces enlarged underground stems known as the tubers, which are the edible portion of the plant. Tuber is the only commercially important part of this

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00556-0

plant. Tubers store and reserve food that enables the plant to survive the cold and are also involved in vegetative plant propagation. The skin of the tuber consists of two layers, an outer epidermal layer of single cells and an inner layer called periderm, consisting of several layers of corky cells. Beneath the periderm is the cortex followed by the vascular ring. Internal to the vascular ring is the medulla that represents the primary storage area for the potato tuber. Each tuber has two to ten 'eyes' or buds arranged spirally around its surface. The eyes are capable of producing new shoots and plants under favorable conditions. Potato plants are usually vegetatively propagated by planting tubers rather than from true seeds. Plants grown from seeds show wide variations, while tuber-propagated plants are clones of the parent plant. Seed propagation is a time-consuming and labor-intensive process, and the resultant progenies have poor vigor and lower yields. For propagation, tubers are cut into pieces with at least one or two eyes (seed tubers) before planting. Each section sprouts and develops into a new plant. However, tubers can carry pests and diseases that affect the tuber quality and yield of the harvest. High costs of transportation and storage and low multiplication rate are some other constraints of using seed tubers. True potato seed (TPS) is an alternative to seed tubers for growing potato. Ease of handling and transportation and low incidence of diseases are some of the advantages of TPS over tubers. However, TPS are produced as a result of a sexual generation and are genetically different from the parents.

Cultivation

Potato is generally a 'cool-weather crop,' but they are cultivated in more than 160 countries under temperate, subtropical, and tropical conditions. The potato can thrive and adapt well even without the ideal soil and growing conditions. Temperature is the main limiting factor for its production. Tuber growth is inhibited below 10 °C and above 30 °C, while optimum mean daily temperature is in the range of 18–20 °C. Potato is a very adaptable plant; however, it is also prone to a number of pest and diseases. For that reason, farmers avoid growing potatoes in the same land from year to year. Growth of potato plant occurs in five stages. Cultivation of potato begins with planting of cut and healed seed tubers with a strong sprout. The initial phase of growth starts with sprouting of seed potatoes and the beginning of root growth. Next, the vegetative growth phase starts and proceeds with the development of vegetative aboveground parts of the plant. During this phase, leaves, branches, roots, and stolons are formed. Soil is mounted to the base of the plant (hilling) to promote tuber production and to keep the plants in an upright position. Stolons will grow into the soil and tubers develop as swellings on these stolons. Hills ensure that the tubers will remain underground and away from sunlight to avoid greening and production of toxic glycoalkaloids. Plants will enter into flowering phase and then initiate tuber growth. In the fourth stage, tubers undergo bulking or size increase. Maturity depends on the cultivar and environmental factors. At the end of the maturity period, the aboveground vegetation (or vines) dies and the tubers are left in the ground for 2 weeks for hardening. Tubers are harvested after hardening and used as fresh or stored for use in the future. Vine killing can also be induced by applying chemical vine killer 2 weeks prior to harvest. Vine killing allows tuber skin maturation, thus reducing bruising of tubers during transportation and storage.

Harvesting and Postharvest Handling

During harvesting and handling, bruising of tubers should be avoided. In the early stages of postharvest handling, potatoes can get nicked and become susceptible to pathogens and microorganisms causing severe losses. Before storage, any damaged, diseased, or frozen tubers should be culled. Potatoes bound for storage should also be cured by exposing to temperatures between 10 and 15.5 °C and 95% relative humidity for 10–14 days. Curing heals the potato skin, making it less susceptible to infections and injury. During the curing process, tubers form new cell layers that protect the internal living tissues from injuries and pathogens. Potatoes are then stored in refrigerated warehouses or in bulk bins.

Tuber Specific Gravity

Specific gravity is an important potato quality attribute used as a basis for nondestructive quality evaluation especially in processing. This attribute of a tuber is an indication of maturation that the industry uses as a reference to judge fry quality, baking characteristics, and storability. Specific gravity is the weight of the tuber compared with the weight of the same volume of water. There is a high correlation between the tuber specific gravity, the starch content, and also the percentage of dry matter or total solids. The potato processing industry values high tuber specific gravity. Specific gravity and solid content have also been shown to have an effect on fat uptake by French fries. The higher the specific gravity, the higher will be the rate of recovery and the better will be the quality of the processed product. It has been shown that potatoes with high specific gravity produce a high yield of French fries with a lower fat content than potatoes with lower specific gravity.

Potato Cultivars

Today, vast numbers of potato cultivars exist. Potatoes are genetically very diverse with many favorable genes introgressed from wild to the cultivated species. Potato varieties can be classified based on a number of criteria. They can be classified based on days of maturity as very early (65–70), early (70–90), mid-season (90–100), late (110–130), or very late (110–130). Varieties can also be classified based on tuber qualities. Cultivars used for frying can be separated into chipping (round) or French fry (elongated) types.

Uses of Potato

Potatoes are the world's most popular and versatile vegetable that is used in the cuisines of countries around the globe. Indigenous people developed processing methods to extend

the storability and portability of potato products. *Chuño* is a freeze-dried potato product that is without any bitter glycoalkaloids and can be stored for several years. During *chuño* preparation, tubers undergo several rounds of freezing and drying followed by washing and soaking in running water and finally sun-dried for 10–15 days. Another native potato product is *papa seca* (dehydrated potato). To prepare *papa seca*, tubers are boiled, peeled, cut into chunks, sun-dried, and ground into starchy powder and consumed with pork, tomatoes, and onions. Potatoes are used for a variety of purposes other than a vegetable for cooking at home. Less than 50% of potatoes cultivated worldwide are consumed fresh. The rest are processed into various food products and ingredients, used to feed livestock and for industrial purposes and used as seed tubers to grow next season's crop. Potatoes should be cooked because of the indigestibility of raw starch, and cooking can involve baking, boiling, steaming, roasting, deep-frying, or microwaving. They are used to make mashed potatoes, potato pancakes, dumplings, soups, and salad. Potato processing has grown into an expanding global industry. The majority of processed potato products are potato chips and French fries. Industrial production of crisps (chips) started in 1920 and French fries in the 1950s. Potatoes can also be made into frozen products including most of the French fries. To make frozen French fries, potatoes are peeled, cut, parboiled, air-dried, par-fried, frozen, and then packaged. Potato crisp, another processed potato product, is made from thin slices of deep-fried or baked potato. Dehydrated potato flakes and granules are used as ingredients in snacks and are made by drying, mashing, and cooking potatoes to a moisture level of 5–8%. Potato flour, also made from ground, whole-cooked potatoes, is used as a thickener in gravies and soups. Potato starch is also used to make fermented alcoholic beverages such as vodka. Besides the food use, potato starch is widely used by industries to make adhesive, animal feed, and fuel-grade alcohol.

Nutritional Profile of Potato

Carbohydrates

Potatoes are regarded as good dietary sources of carbohydrates. Nutritional composition of various potato products is presented in Table 1. Potatoes are touted as an energy-dense food due to their high carbohydrate content, which makes up to 75% of their dry weight contributing 90% of their total energy. Without the addition of extra fats during preparation, lipid content of potatoes is very low (0.1% of FW). Saturated fatty acid forms one-third of the total fat in white potatoes, and the remaining is primarily polyunsaturated fatty acids. Additionally, the fat content of potatoes is lower than that of pasta (0.9%) or rice (0.2%). However, they are a cheap source of energy due to their carbohydrate-rich composition. Potatoes are not typically considered as a good dietary protein source due to their low overall protein content. The low protein content of potatoes constitutes about 1–2% of tuber FW. Although low in content of sulfur amino acids, potatoes are good sources of lysine. Patatin is the principal storage protein and is an allergen to some people. Heating and cooking reduce its allergenicity.

Starch is the principle carbohydrate in potato, and it is composed of a mixture of amylose and amylopectin in a 3:1 ratio. Amylopectin, the predominant branched form, allows greater digestibility. Amylose, the linear form, is the 'resistant' starch and is resistant to digestive enzymes. Raw potato starch is indigestible and has a crystalline structure. Cooking gelatinizes the starch, increasing the solubility and digestibility of starch. Cooking followed by cooling will result in a change in starch structure called retrogradation, making the potato starch more resistant to digestive enzymes. These changes are related to the amount of glycosyl residues and to the relative ratio of amylose to amylopectin in potato. This explains the lower glycemic index of cooked and cold versus cooked and hot potatoes. Only a small portion of potato starch is resistant starch, which is resistant to digestion by enzymes in the stomach and small intestine. Resistant starch is fermented in the large intestine to produce short-chain fatty acids that act as a prebiotic by promoting the growth of colonic bacteria. Resistant starch occurs naturally in other foods such as legumes, underripe bananas, and some whole grains. Resistant starch is considered to have health benefits as it is considered a form of dietary fiber offering protection against colon cancer and improvement of glucose tolerance and insulin sensitivity. It also lowers plasma cholesterol and triglycerides and increases satiety. In potato, resistant starch amounts are dependent on methods of preparation. Boiled potatoes were reported to have a resistant starch content of 2.0% of total starch, while commercially processed potato products had a higher resistant starch content of 4.8–9.0% of total starch. Dietary fiber can be obtained from the cell walls in the peel of potatoes. Cooked potato with and without the skin can supply 2.1 and 1.8 g fiber per 100 g, respectively. Potato contains more fiber than white rice.

Vitamins and Minerals

Potatoes are crucial sources of vitamins including B_6, B_1, and C. The most abundant vitamin in potato is vitamin C, which ranges between 84 and 145 mg per 100 g dry weight. Potatoes supply about 13 mg of vitamin C per 100 g (14% RDA for adult men). In many parts of the world, potatoes serve as an important dietary source of vitamin C. Potatoes can be considered as a good source of vitamin B_6. The amount of ascorbic acid in potato differs widely among the various cultivars and in planting site and postharvest storage conditions and is also influenced by the cooking methods. About 25–50% of the daily recommendation of vitamin C can be obtained from 100 g of cooked potatoes. Additionally, they also provide minerals, such as potassium, phosphorus, calcium, and magnesium, and micronutrients, such as iron and zinc. Among the minerals, potassium is the most abundant, while the concentration of iron and zinc is low compared with that in cereals and legumes. Interestingly, the bioavailability of iron in potato is greater than that in cereals and legumes due to the presence of vitamin C and low levels of phytic acid. One serving per day of potato cultivars such as 'Russet Burbank,' 'Freedom,' and 'Yukon Gold' can significantly contribute to the intake of microminerals including magnesium, phosphorus, and potassium and trace minerals including copper, iron, selenium, and zinc.

Table 1 Nutritional profiles of potatoes cooked by various methods (value per 100 g; nutrient values and weights are for edible portion)

Nutrients	*Unit*	*Russet potato flesh and skin baked*	*Potato white flesh and skin baked*	*Potato red flesh and skin baked*	*Potato, boiled cooked with skin, flesh, without salt*	*Potato, boiled, cooked without skin, flesh, without salt*	*Potato, French fried, all types, salt added, frozen, as purchased*	*Potato, microwaved, with skin and flesh, without salt*	*Potato, roasted, salt added in processing, frozen, unprepared*

Potato Phytochemicals

In addition to the vitamins and minerals, potatoes also contain a number of health-promoting phytonutrients such as phenolics and carotenoids. Potatoes can supply 25% of the vegetable phenolics recommended in the American diet. Both the skin and flesh of potatoes contain phenolic constituents, the concentration being higher in skin. Phenolic compounds in potatoes were reported to be in the range of 530–1770 μg g^{-1}. The presence of lignin, coumarins, anthocyanins and flavones, tannins, monohydric phenols, and polyhydric phenols was identified in potato. Red and purple varieties of potato are particularly rich in phenolic compounds. Phenolic acids constitute the most abundant polyphenolic compound in potato. Chlorogenic acid is the predominant phenolic acid accounting for about 90% of the total potato phenolic compounds. Caffeic, protocatechuic, vanillic, sinapic, p-coumaric, salicylic, and ferulic acids also occur in potato, and they are concentrated in the skin. Generally, purple-fleshed cultivars tend to have the highest phenolic acid content compared with white-, yellow-, or red-fleshed types. Colored potatoes such as red- and purple-skinned potatoes contained approximately twice the concentration of phenolic acid than white-skinned tubers.

Flavonoids such as catechin, epicatechin, kaempferol, and naringenin have been detected in potatoes. Higher flavonoid contents were reported for purple- (~900 mg per 100 g FW) and red-fleshed (500 mg per 100 g FW) varieties. Studies have shown that flavanone and flavonoid extracts had high free radical scavenging actions. Potatoes also have aglycones, which are antioxidant compounds. The most abundant flavonols are rutin and kaemferol-3-rutinose. Quercetin, a potent antioxidant flavonol, was identified in the potato peel. Anthocyanins are present in negligible amounts in white potatoes. Generally, pigmented potatoes have higher anthocyanin contents than white- or cream-colored varieties. Anthocyanin content of 5.5–35 mg per 100 g FW has been reported. Red-fleshed potato varieties contain acylated glycoside derivatives of pelargonidin and peonidin as the predominant anthocyanins. Glycosylated delphinidin and malvidin also occur at low concentrations. Purple cultivars have acylated petunidin and malvidin glycosides and lesser amounts of glycosylated delphinidin.

Potato also contains carotenoids and their derivatives, xanthophylls. Lutein, zeaxanthin, violaxanthin and neoxanthin are the principal carotenoids in potatoes. But only trace amounts of β-carotene is present in potato. Zeaxanthin and lutein imparts orange or yellow color to the potato tubers. Yellow- or orange-fleshed potato varieties have more carotenoids than the white-fleshed varieties. The carotenoid contents of potato tubers are related to flesh color. White- or cream-colored potatoes typically have low concentrations of carotenoids, with lutein, violaxanthin, and beta-carotene being the predominant forms. Zeaxanthin is the predominant carotenoid in yellow-fleshed potatoes and the total carotenoid concentration is about 1840 μg per 100 g FW. Yellow-fleshed potato has about 1290 μg per 100 g zeaxanthin content. This is of particular importance as dietary sources of zeaxanthin are quite scarce. Cooking seems to have no negative effect on the lutein and zeaxanthin concentrations. The nutrient profiles of potatoes are greatly influenced by the genotype. Navarre and coworkers reported that a wide variation exists among potato genotypes in their phenolic content. Purple-fleshed wild varieties contain higher amount of phenolics (>5–6 mg g^{-1} DW) than white-fleshed varieties (<4 mg g^{-1} DW). In another study conducted in 26 pigmented potato cultivars, anthocyanin content of about 7 mg g^{-1} FW was detected in the skin and 2 mg g^{-1} FW in the flesh.

Glycoalkaloids

Glycoakaloids are steroidal nitrogen-containing metabolites found in potatoes and in many solanaceous plants. They are antinutritional substances highly concentrated in tissues with high metabolic activity including flowers, young leaves, unripe berries, and sprouts. Small immature tubers are also high in glycoalkaloids being metabolically active. Two major glycoalkaloids in potatoes are α-solanine and α-chaconine, which comprise about 95% of the total glycoalkaloids content in the plant. Solanine is a combination of a sugar molecule (solatriose) with an alkaloid (solanidine), and chaconine is chacotriose combined with solanidine. Mechanical injury or pest-induced injuries, fungal attack, poor growing environment, and poor storage conditions can influence the concentration of glycoalkaloid content in tubers. They are often produced in tubers on exposure to sunlight and characterized by greening of the skin of tubers. Glycoalkaloids at lower levels enhance the flavor of tubers, while at higher concentration, they confer bitterness. When present in large amounts glycoalkaloids are toxic and undesirable. Most potato tubers for human consumption have about 7.5 mg per 100 g FW of α-solanine and α-chaconine. The allowed level of glycoalkaloids in tubers is 20 mg per 100 g FW. At high concentrations, these concentrations may be lethal to humans causing gastrointestinal and neurological disorders. Their mechanism of toxicity includes inhibition of acetylcholine esterase activity and disruption of membranes. Glycoalkaloids impart protection to the plants against various pathogens. The levels of glycoalkaloids are dependent on a number of factors including genotype, climate, storage conditions, maturity, temperature, light, and tuber damage. Glycoalkaloids are not uniformly distributed in tubers. Concentration is relatively lower towards the pith and higher in the periderm and cortex.

Acrylamide

Formation of acrylamide was noticed in starchy foods that are baked, fried, or roasted at high temperature. Acrylamide is formed when asparagine, a free amino acid, reacts with reducing sugars at high temperature via a complex process involving Maillard and related reactions. Potato cultivars have considerable amounts of reducing sugars and free asparagine at varying levels. Presence of acrylamide was reported in French fries and potato chips. Concerns about the health issues associated with the intake of acrylamide have been expressed because acrylamide is known to be a neurotoxin and genotoxin, and it is also classified as a probable carcinogen in humans. A number of factors such as the amount of asparagine and reducing sugars, cooking process, temperature and time, the pH, and the surface to volume ratio of food materials influence acrylamide formation. Various effective measures have been suggested to reduce levels of acrylamide in foods. Reducing the pH by pretreatment with citric and other organic acids has been suggested as an effective strategy.

Effects of Cooking/Processing on Nutrient Composition

Digestibility of starch in potato is greatly improved by cooking and processing. Unpeeled potato shows better nutrient retention than peeled potato. Generally, boiling of cut and peeled potatoes result in loss of water-soluble vitamins and minerals including potassium and copper due to leaching. This loss was further increased with prolonged cooking time and very high temperature. Baking, frying, and roasting leads to lower nutrient losses than boiling. Peeling reduces the fiber content of potatoes. Frying or chipping of potatoes in oil and addition of extra fat raise the fat content and caloric intake of potatoes, making it unhealthy. Steaming and microwaving are the best methods for cooking potato to minimize the loss of nutrients. The method of cooking reduces the vitamin C content in potato. Microwaved or baked potatoes have approximately twice the amount of ascorbic acid compared with fried or boiled potatoes (Table 1). Studies have found that tubers boiled with skin on had higher vitamin C content than those baked or cooked in a microwave oven.

Health Benefits

Despite contributing significant amounts of vital vitamins and minerals to human diet, potato has been mistaken as a contributor to the high prevalence of obesity, diabetes, and cardiovascular diseases in the United States.

Antioxidant Activity

Consumption of antioxidant compounds through fruits and vegetables in our diet could potentially prove to be an effective strategy towards defending our bodies from illness such as cardiovascular diseases, cancer, and diabetes by limiting oxidative stress. Although potatoes contain a variety of antioxidant compounds exhibiting a multitude of anti oxidant mechanisms, the light-skinned potatoes are not known as a food item with high antioxidant activity. Total antioxidant potential of potato is highly correlated with total phenolic

contents contributing greatly to the total antioxidant activity. Its daily consumption can contribute to high total phenolic content to our diet. Carotenoids and ascorbic acid also serve as major antioxidants in potato. Antioxidant activity varies among potato cultivars. The antioxidant capacity of the potato cultivars is dependent on the color of the skin and flesh. Colored-fleshed potato varieties are particularly high in anthocyanins. Anthocyanins are mostly concentrated on the peel of potatoes, and anthocyanins are 3–4 times higher in potato peel than in tuber. Anthocyanins are known to have antioxidant, antimicrobial, and antiobesity potentials.

Cardiovascular Health and Diseases

Consumption of potato products with high lipids such as French fries and chips is often discouraged by nutritionists. For cardiovascular benefits, cooking of potatoes with less fat and sodium is also suggested. A human intervention study examined the effects of pigmented potato consumption on antioxidant status, oxidative stress, and inflammation in healthy adult males. Consumption of both yellow- and purple-fleshed potato decreased oxidative damage and inflammatory cytokine concentration compared with those participants who consumed white-fleshed potato. Additionally, purple-fleshed potato consumption also decreased C-reactive protein concentration. Some animal studies provided evidence that chlorogenic acid reduces plasma total cholesterol and LDL cholesterol levels, and potato peptides have the ability to alter serum lipids.

Lowering of Blood Pressure

Potatoes contain several nutrients that help lower blood pressure. Potatoes are good sources of potassium compared to other fruits and vegetables and are very low in sodium. Evidence from animal studies, observational studies, and clinical trials has associated intake of adequate amounts of potassium with reduced blood pressure. Human studies have shown that two small helpings of purple-fleshed potatoes a day decrease blood pressure without affecting weight gain while increasing plasma antioxidant capacity. In another human interventional study, intake of potatoes (versus refined starch) caused an increase in blood and urine antioxidant capacity, whereas refined starch caused a decrease in both. Additionally, a drop in blood pressure was noticed in a study carried out in overweight individuals with high pressure after potato consumption. More studies are needed to confirm these beneficial effects of potatoes. Proteins isolated from potatoes and potato products have shown angiotensin-converting enzyme inhibitory activity *in vitro*.

Anticancer

Evidence from some animal and *in vitro* studies points towards the anticancer properties of potatoes, but this is an area where more research is required. One study reported the antiproliferative properties of colored potato extracts and an anthocyanin fraction on prostate cancer cells. Similarly, potato extracts also suppressed the proliferation of colon and liver cancer cells. Research carried out with individual phenolic compounds has suggested that chlorogenic acid may be the primary compound responsible for the antiproliferative activity. Also, purple-fleshed potatoes were more effective in conferring antiproliferative activity on colon carcinoma cells than either white- or yellow-fleshed potatoes. This is likely related to the higher antioxidant potential of purple-fleshed potatoes. Research showed that chlorogenic acid could selectively inhibit matrix metalloprotease, an angiogenic enzyme responsible for tumor progression and metastasis. Chlorogenic acid also showed anticarcinogenic property in a number of studies using cell models.

Antidiabetic

The association between potato consumption and the risk of type 2 diabetes has been evaluated. Data from a Nurses' Health Study showed that substituting one serving of potato per day for 1 serving of whole grains per day increased the risk of type 2 diabetes in obese women by 30%, but this association risk was not found for nonobese women. Another study found that high intake of energy-dense foods including fried potatoes was associated with higher levels of biomarkers of inflammation and increased risk of type 2 diabetes. On the other hand, the Shanghai Women's Health Study found that the intake of potato tubers was associated with lowering the risk of type 2 diabetes. A few other studies also found no association between potato intake and type 2 diabetes. Chlorogenic acid has been studied for its health benefits, and it might be helpful in lowering the glycemic index of potatoes as it slows down the release of glucose into the bloodstream as suggested by some animal studies. It appears that chlorogenic acid increases insulin sensitivity rather than affecting the release of insulin.

Potatoes and Related Crops: Role in the Diet

S Turner, University of Wisconsin-Madison, Madison, WI, USA

Origins and Historical Context

South America (Center of Origin)

Potato (*Solanum tuberosum* L.) is a versatile staple crop with a unique and historically significant story of domestication. Originating in the Andean highlands almost 10 000 years ago, potato has since spread to all continents with a vast range of climate conditions, ranging from temperate to tropical regions. Even Charles Darwin commented on the wide adaptation of potato in *The Voyage of the Beagle* writing, "It is remarkable that the same plant should be found on the sterile mountains of Central Chile, where a drop of rain does not fall for more than six months, and within the damp forests of the southern islands."

Potato domestication began in South America, where potatoes were planted on high-altitude lands in raised beds to protect from frost damage. Initially, cultivated potatoes were adapted to long-day conditions, but converted to short-day conditions following hybridization with a wild species. This adaptation was crucial for the spread of potato production to other continents, particularly regions of North America, Europe, and Asia, where most production occurs today.

Europe and North America

It is postulated that potato was first introduced to Europe by Spanish explorers *c.*1565. As part of the notoriously toxic nightshade family, it was regarded with skepticism and thought to cause leprosy, gas, and other ailments. Despite these superstitions, potato was quickly adopted as a staple food crop in England when wheat became too expensive. Potato offered a satiating, cheap, and sustainable food supply during famine and had a key role as a food source for workers during the industrial revolution in the nineteenth century.

The utilization of potato as a staple food in Europe was not entirely a success story, as evidenced by the Irish potato famine from 1845 to 1852. Spanish explorers introduced the potato to Ireland in the late sixteenth century, where it was rapidly implemented as a staple food to feed the starving population. The cool, damp climate in Ireland was ideal for potato production, providing high yields and a reliable food supply for nearly a century, during which time the population of Ireland increased by almost five million, approximately 60%. Ireland relied almost exclusively on potato for sustenance, with consumption estimated at up to 12–14 pounds (~5.4–6.4 kg) per day for an adult male. Unfortunately, the climate was also ideal for the late blight pathogen, *Phytophthora infestans*, which swiftly descended across Ireland and devastated crop production. The resulting crop failure, coupled with other socioeconomic issues, resulted in the Great Irish Famine, during which an estimated one million lives were lost from starvation or disease. Much of the crop failure is attributed to a lack of genetic diversity, as farmers relied almost entirely on the cultivar Lumper, which had poor resistance to late blight.

Details about the introduction of potato to North America are sparse. Potato was planted in North America as early as the 1600s, but was not widely adopted until the eighteenth century, when Scotch-Irish immigrants introduced it to New England. As in Europe, initial acceptance of potato as a food source was slow but, by the time potato was included on the US Census in 1840, production had progressed to 728 100 tonnes.

Asia and Africa

Mariners from Europe are credited with the dissemination of potatoes throughout the remainder of the world. Introduction to China occurred in the seventeenth century, most likely via Dutch trading routes, where the higher yielding potato quickly usurped traditional crops such as barley and oat.

Although reported on the Canary Islands as early as 1567, European colonists and missionaries did not introduce potato to Africa on a large scale until the late nineteenth century. Again, as with other parts of the world, the uptake was slow but gradually increased as potato was adopted as a staple crop.

Production Trends

Current Production Statistics

Potato is the most important vegetable crop and the fourth most important food crop worldwide, outranked only by maize, rice, and wheat. Worldwide, more than 150 countries produce potatoes, with over half of global potato production in developing countries. According to the Food and Agriculture Organization of the United Nations (FAO), the highest production of potatoes is observed in Asia (49%), followed by Europe (30.7%), the Americas (11.6%), Africa (8.2%), and Oceania (0.5%).

Prior to the 1990s, most potato production and utilization occurred in Europe, North America, and countries formerly part of the Soviet Union. Since then, potato production and popularity has markedly increased in Asia, Africa, and Latin America. As of 2005, production in the developing world began to exceed that of the developed world, with China and India contributing almost a third of world production. This is not surprising as potatoes are an essential part of food security for millions of people in the developing world.

Management Practices

Potatoes are most commonly grown from seed potatoes, which consist of small tubers or sections of a larger tuber with buds, and undergo a period of dormancy to induce sprouting. As a highland tropical crop that thrives in cooler temperatures, potato cannot tolerate frost and is grown during the spring in temperate regions and as a winter crop in hot, tropical

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00555-9

climates. Potatoes have adapted to a wide range of growing conditions, but perform best when grown with irrigation in a sandy loam soil. During cultivation, potatoes are often treated with a variety of pesticides to control insects, most notably the infamous Colorado potato beetle, and pathogens. Additional chemical applications include fertilizers, which can also function to improve the mineral content of tubers. Following harvest, tubers are frequently treated with sprout inhibitors and can be stored for several months, with care to avoid disease development and physical damage, such as bruising. Optimal storage conditions consist of a dark, well-ventilated, and humid area around 4 °C. Colder temperatures should be avoided to prevent the conversion of starch to sugar.

As an underground tuber, potatoes are highly susceptible to many fungal, bacterial, and viral pathogens. Disease mitigation strategies include crop rotation, chemical control, and use of disease-free seed tubers. Because seed potatoes are derived from the previous crop year, virus load increases with each successive generation. Thus, it is important to obtain certified, virus-free seed tubers every few generations. Tubers afflicted with common ailments such as early blight, late blight, and soft rot most often result in crop loss, while tubers with silver scurf, scab, and *Rhizoctonia*, colloquially known as 'the dirt that won't wash off,' are still marketable provided the damage is minor. Zebra chip, a relatively new disease, causes losses due to plant death and darkening in fried products.

Breeding Resources

Maintenance of genetic diversity is paramount to continued improvement of existing potato cultivars and to prevent disasters such as the Irish potato famine. Breeding efforts for potato focus on disease resistance, quality traits, yield, and adaptation to diverse growing environments. Wild species and indigenous cultivars are valuable sources of genetic variation for breeding efforts. Central and South America, particularly Bolivia and Peru, are still home to the greatest range of potato diversity, boasting over 4000 varieties of native potatoes and more than 180 wild potato species adapted to various altitudes and climatic conditions. The International Potato Center (CIP), based in Lima (Peru), is part of the Consultative Group for International Agricultural Research (CGIAR) and houses the largest collection of potato germplasm *in vitro*, with 80% of known wild potato species and over 1500 accessions of native Andean root and tuber crops. This collection is available for distribution to breeding programs as a valuable resource to improve adaptation to changing climates and to aid farmers. Additionally, the NRSP-6 Potato Genebank in Sturgeon Bay (WI, the United States), a part of the USDA National Genetic Resources Program (NGRP), maintains over 5000 entries available for breeding efforts.

Patterns of Consumption

Potato is widely consumed as a dietary staple around the world. Less than half of potatoes grown are consumed fresh, while the remainder are used for processed products, animal feed, starch, and seed tubers. Based on data from FAO, Asia accounts for almost half of world utilization, with an average annual per capita consumption of 23.9 kg, while the highest annual per capita consumption is observed in Europe and North America, at 87.8 kg and 60 kg, respectively. Consumption in Europe and North America is relatively stable, while consumption in Asia and Africa is steadily increasing. As the wealth status of a country improves, consumers tend to prefer 'convenience' foods, such as fried and processed products. More detail on global utilization and per capita consumption by region can be found in Figure 1.

Culinary Applications

Potatoes have a wide range of culinary applications and are most often consumed baked, boiled, or fried. Potatoes are categorized based on harvest date, optimal cooking method, storage properties, and appearance. Common market classes and traditional culinary uses include russet (baking and French fries), white (boiling/mashed and chipping), red (boiling/mashed and roasting), and novelty classes (e.g., purple/blue) with various shape, pigment, and texture combinations (e.g., waxy or mealy) (Figure 2). Additional consumption is in the form of processed commodities, such as frozen potatoes, French fries, chips, and dehydrated products. According to the US National Potato Council, potato consumption in the United States is highest for frozen products (42.8%), followed by fresh (30.5%), chips (14.5%), dehydrated (11.4%), and

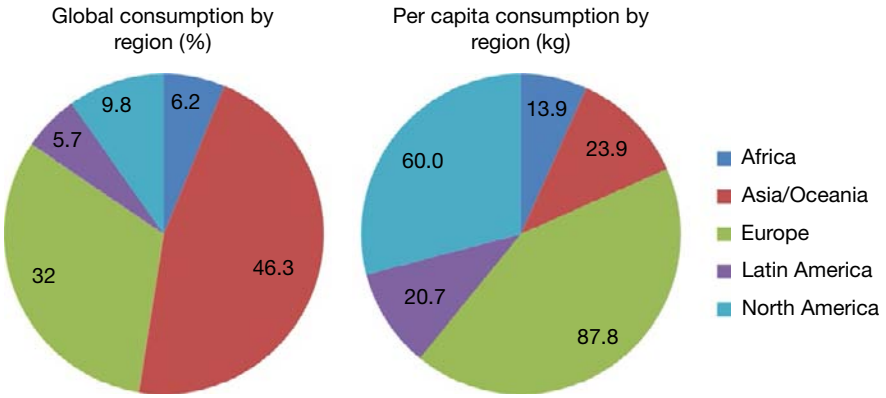

Figure 1 Global potato consumption (%) by region contrasted with per capita consumption (kg) by region. Data were adapted from FAOSTAT.

Figure 2 An image showing tuber diversity for skin color, flesh color, shape, and texture. Image courtesy of the Texas A&M Potato Breeding and Variety Development Program.

canned (0.01%) products. Patterns in the United Kingdom are similar according to the Agriculture and Horticulture Development Board (AHDB), but consumption of fresh potatoes is highest (52.3%), followed by frozen (27.1%), chips (17.4%), dehydrated (2.7%), and canned (0.5%) products. Consumption of processed or convenience products is highest in the developed world and expected to rise in countries with increasing wealth.

Nutritional Content

As part of a balanced diet, potatoes offer a nutrient-dense, satiating, and phytochemical-rich source of calories. Considerable variation exists for nutrient composition among cultivars, which can also be influenced by growing environment, storage conditions, and cooking method. Nutritional values for a standard, medium sized (138 g) potato are provided in Figure 3. Breeding efforts and management practices can be used to increase nutritional value and decrease undesirable qualities, such as glycoalkaloid content.

Carbohydrates, Proteins, and Lipids

Historically, potato obtained status as a staple crop by providing a high yielding source of carbohydrates. Additionally, potato supplies more protein per unit area than cereal crops. Carbohydrates, mainly starch, contribute around three-fourths of the dry matter content in tubers. Raw potatoes contain mostly resistant starch, which has low digestibility and essentially functions as dietary fiber. During cooking, starches solubilize and become highly digestible, rapidly increasing blood sugar following ingestion. For this reason, potato is described as having a moderate to high glycemic index (GI), depending on the preparation method. Other major carbohydrates include sucrose and the reducing sugars glucose and fructose. Cold temperatures during storage can increase the ratio of reducing sugars to starch and contribute to darkening after cooking, which is discussed in more detail later.

Figure 3 Nutritional values for raw potato (100 g) with skin (38 g). Data were sourced from the US Department of Agriculture (USDA) National Nutrient Database for Standard Reference.

Potatoes contain relatively little dietary protein, which constitutes around 1–2% of the dry matter in the tuber. While only present in small amounts, protein in the tuber has a high biological value (BV), meaning most of the nitrogen absorbed during digestion is retained by the body. Most of the protein content is stored as patatin, which is allergenic for some people, but usually innocuous after cooking. Potatoes also contain minimal levels of fat, most of which is present as unsaturated and saturated fatty acids, and no dietary cholesterol. The fat content of potatoes is often increased by preparation methods, such as frying with oils, and high-fat additives, such as butter.

Vitamins and Minerals

The primary vitamin in potatoes is vitamin C, or ascorbic acid, which functions as an antioxidant and can facilitate uptake of iron, an essential nutrient limited in many diets. Potatoes may have helped prevent scurvy in early European sailors and continue to supply an important source of vitamin C in many parts of the world, with one medium potato (138 g) providing 26% of the daily value (DV) based on the US Food and Drug Administration (FDA) standards. Although the content is less than other sources (e.g., citrus and peppers), potatoes constitute the primary source of vitamin C in many countries. Potatoes are also a good source of pyridoxine (vitamin B6) and contain many other B vitamins, including folate (B9), niacin (B3), riboflavin (B2), and thiamin (B1).

Important minerals in potato include potassium, phosphorus, calcium, magnesium, iron, and zinc. Comparatively by weight, potatoes contain more potassium than bananas, spinach, or broccoli, with a medium potato providing around 16% of the DV. Mineral content can be improved by mineral fertilization, exploiting existing variation for mineral accumulation, or genetic engineering.

Phytochemicals

Phytochemicals have been studied widely because of their role as bioactive dietary compounds in the prevention/risk reduction of chronic diseases, such as cancer and cardiovascular disease. The most common phytochemicals in potatoes include phenolics, carotenoids, and alkaloids. Both phenolics and, to a lesser degree, carotenoids contribute to tuber coloration, while alkaloids are monitored strictly to prevent toxicity.

Phenolic compounds, primarily phenolic acids and flavonoids, are the most abundant phytochemicals in potato. Most of the phenolic compounds are concentrated in the skin and decrease towards the center of the tuber. Phenolic acids, particularly chlorogenic acid, constitute the majority of the total phenolic content. Within the skin, primary phenolic acids include chlorogenic, protocatechuic, and caffeic acids, along with lower levels of vanillic, *p*-coumaric, ferulic, sinapic, and salicylic acids. Tuber flesh has a similar profile, containing predominantly chlorogenic acid and low levels of caffeic, protocatechuic, *p*-coumaric, ferulic, gallic, and sinapic acids. Flavonoids are present to a much lesser degree, with moderate amounts of eriodictyol and naringenin in tuber skin, along with trace amounts of catechin, epicatechin, and eriodictyol in tuber flesh.

Flavonoids, specifically anthocyanins, also contribute red, blue, and purple pigments to potato skin and flesh, which is particularly important for the specialty potato market. Anthocyanins are putative antioxidants, and red- and purple-flesh potatoes typically have higher antioxidant activity than their white-flesh counterparts. Common anthocyanins in potato include pelargonidin, peonidin, malvidin, delphinidin, peonidin, and petunidin.

Carotenoids are lipid-soluble compounds that determine the amount of yellow or orange pigmentation in tuber flesh. Potatoes contain primarily oxygenated carotenes (xanthophyll), specifically lutein, neoxanthin, zeaxanthin, antheraxanthin, and violaxanthin, along with trace amounts of β-carotene. Of these compounds, zeaxanthin and lutein are found at the highest concentrations in yellow- and orange-flesh tubers.

Effects of Postharvest Storage and Cooking Method

Potatoes are commonly stored and cooked prior to consumption, both of which impact phytochemical levels. Existing literature is contradictory on the effects of long-term cold storage to increase anthocyanin, phenolic acid, and carotenoid content, but there is a consensus that no degradation occurs during storage. Removal of the tuber skin not only reduces glycoalkaloid content but also reduces the amount of phytochemicals and fiber. Common preparation and cooking methods, such as baking, boiling, microwaving, and frying, influence phytochemical levels and antioxidant capacity to varying degrees. Boiling tends to result in the loss of water-soluble nutrients but may increase antioxidant capacity by increasing bioavailability of compounds. Although the application of heat degrades vitamin C, methods such as baking, frying, and microwaving typically preserve the majority of phytonutrients. Diverse results in cooking studies may be due to different cooking temperatures and duration as well as differences in the cultivars used or original content.

Relation to Human Health

As a staple in the human diet, potato has a large influence on health. While potato is a valuable addition to a balanced diet, many people are concerned about its associations with weight gain, acrylamide, and toxicity. However, potato also provides notable levels of phytochemicals, which are linked to numerous health benefits.

Glycemic Index (GI) and Weight Gain

Potatoes often receive negative press for association with weight gain and diabetes. Concerns related to weight gain and diabetes both stem from the relatively high starch content in potatoes, which is approximately 15% by weight. As a result, potatoes have an intermediate to moderately high rank on the glycemic index (GI) and consumption may cause rapid increases in blood sugar. Several studies have also identified an association with weight gain, most often when consumed as French fries and potato chips.

Although the starch content in potato is high, the digestibility is contingent on cooking method and genotype. Raw potatoes mostly consist of resistant starch, which is not easily digested, has a low glycemic load, and essentially serves as a source of dietary fiber. After cooking, this resistant starch is converted into rapidly digestible starch and, thus, results in a higher GI. Cooling potatoes after cooking can cause a reversion back to slowly digestible starch, which could be used to develop products with improved nutrition. Concerns about GI and weight gain can be addressed by selecting varieties with reduced starch content, limiting intake of fried products, reducing the use of high-fat toppings, such as sour cream, butter, or cheese, and consuming cooled or reheated potatoes.

Acrylamide

Currently, fried potato products are under scrutiny for high levels of acrylamide, which is a potential carcinogen. Acrylamide is produced during the frying process from the combination of asparagine and reducing sugars at high temperatures, known as the Maillard reaction. The amount of acrylamide in fried potato products is influenced largely by storage conditions and genetic background. During cold storage, the starch in potato is converted to glucose and fructose, increasing the potential for acrylamide production. Additionally, some market classes of potato (e.g., red potatoes) contain more reducing sugars and are better suited to baking or boiling. Although the evidence is inconclusive on the effects of dietary acrylamide in humans, efforts are being made to reduce acrylamide content in potato products through changes in breeding, molecular genetics, production practices, and postharvest storage.

Glycoalkaloid Toxicity

Concern about toxicity stems from the presence of glycoalkaloids, which are naturally occurring secondary metabolites produced by the nightshade family. Glycoalkaloids function as plant defense compounds to protect against a variety of pathogens and herbivores but can induce toxicity in humans. As a result, glycoalkaloid content is monitored strictly in commercial potatoes. Total glycoalkaloid content in potatoes is estimated as the combined amounts of the most common glycoalkaloids in potato (i.e., α-solanine and α-chaconine), which cannot exceed 200 mg kg^{-1} of fresh potato, the point at which potatoes develop a bitter taste and consumption causes adverse symptoms. Green or sprouting potatoes, which accumulate glycoalkaloids, can also cause toxicity and should not be eaten. The toxicity of glycoalkaloids results primarily from disruption of cell membranes and inhibition of acetylcholinesterase, which is a neurotransmitter. Mild exposure to glycoalkaloids results in gastrointestinal discomfort (nausea, vomiting, and diarrhea) and may aggravate irritable bowel syndrome, while significant exposure may cause a neurological response. However, it is possible that the different types of glycoalkaloids have variable toxicity in mammals. Potential benefits of glycoalkaloids include the capacity to lower cholesterol, anti-inflammatory activity, antibiosis against food-borne pathogens, and anticancer activity.

Potential Health Benefits

With high levels of consumption, and notable levels of beneficial phytochemicals, potatoes are an ideal delivery system for beneficial compounds. Small increases in nutrient and antioxidant content in potato can have a significant impact, especially in regions with micronutrient deficiencies. Genetic variation exists for phenolic, carotenoid, and mineral content, including essential minerals such as zinc and iron, which are common nutrient deficiencies. Increasing the antioxidant content in potatoes may also improve consumer perception of potatoes as a functional food.

Phenolic compounds are well known for their association with the prevention of chronic diseases, such as cancer and cardiovascular disease. Currently, there are no long-term studies confirming the effects of potato consumption on cancer in humans, but several studies have demonstrated the anticancer activity of potato extracts on human prostate, stomach, and breast cells *in vitro*. Although potentially toxic, there is evidence that glycoalkaloids also promote apoptosis and reduce proliferation in human liver, colon, stomach, and prostate cancer cell lines. Glycoalkaloids are a diverse group of compounds, and further characterization may allow the selection of potato cultivars containing less toxic, more beneficial glycoalkaloids.

Despite the association of potatoes with weight gain, potatoes can contribute to satiety, or a feeling of fullness and satisfaction, following a meal. Reducing the consumption of fried potato products and the addition of fattening toppings may improve the role of potato as part of a balanced, healthy diet.

Summary

From humble origins in the South American highlands, potato has become a dietary staple around the world. Initially regarded as a famine food, potato has developed into a nutritious and satiating source of calories with a wide range of culinary uses. Production and consumption remain relatively stable in the developed world but are steadily increasing in developing countries, where potatoes offer a practical solution for food security. Major dietary concerns include weight gain, high GI, glycoalkaloid toxicity, and acrylamide content, all of which can be mitigated by altering consumption habits, cooking methods, and plant breeding. Potatoes also contain notable levels of health-promoting phytochemicals and there are opportunities for breeding to improve the nutritional content.

Poultry: Processing

S Barbut, University of Guelph, Guelph, ON, Canada

© 2016 Elsevier Ltd. All rights reserved.

Introduction

The poultry processing industry has seen a lot of changes over the past half a century. New equipment has helped to reduce labor cost and increase efficiency and line speed. The steps involved in a typical primary processing plant are shown in Figure 1.

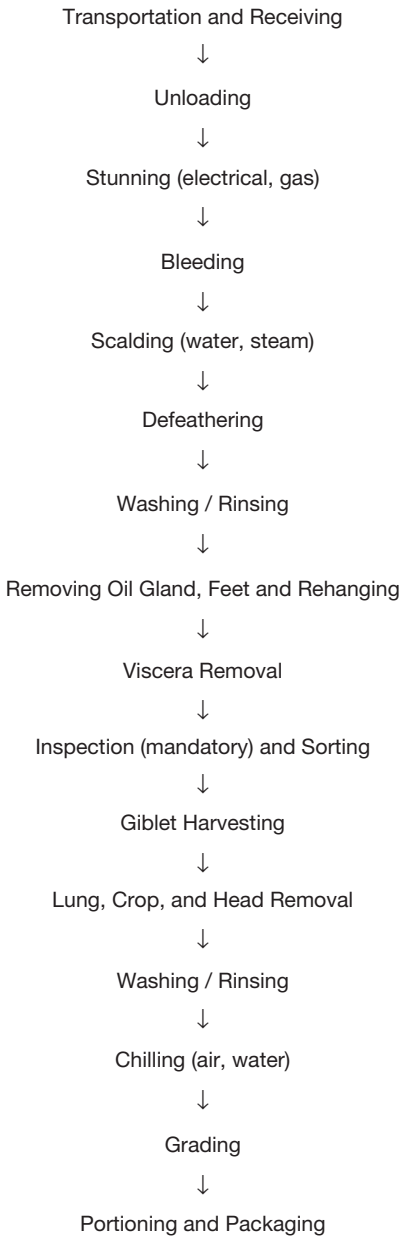

Figure 1 Typical sequence of operations in a poultry processing plant. Based on Barbut, S. (2010). Past and future of the poultry meat harvesting technologies. *World's Poultry Science Journal* **66**, 399.

Table 1 Increase in broiler processing line speed (bird per hour) from 1970 to 2015

Year	*Line speed*	*Equipment development*
1970	3000	Mostly manual operation
1975	4500	Semiautomatic evisceration
1980	8000	Fully automatic evisceration
1990	9000	Giblet harvesting
2000	10500	Cut-up machines together with in-line chilling
2010	12000	Automated unloading and gas stunning
2015	14000	More computer control

Mechanization and automation of different steps has helped improve output. In the 1970s, line speed was about 3000 birds per hour, and today, it can reach 14000 on a single line (i.e., can be split at certain areas such as at the point of inspection).

Some of the major developments in machinery and processes are outlined in Table 1. One of the first processes to be mechanized was the evisceration process where previously many people were needed to carefully perform the opening cut (e.g., in order to eliminate gut spills that would contaminate the carcass) and withdraw the viscera. A few generations of machines have gone through extensive developments, and today, this process is fully automated with a line speed four times higher than 50 years ago. Giblet harvesting systems were also developed at the same time with the challenge of handling soft tissues. Later, more attention was given to semiautomated/fully automated cutting and portioning equipment as the demand for deboned meat increased (both for the fast food industry and for home consumption of raw and convenience-type poultry products). Other areas of great importance are the unloading and stunning of animals. These areas have received more attention over the past few years as there has been a major focus on animal welfare and meat quality issues. To address these points, semiautomated and fully automated unloading systems have been developed to minimize stress to the birds, help increase efficiency, and reduce labor cost. In some of the new gas stunning systems, birds are either kept in the crates during stunning or automatically removed from the crates by gentle tilting.

The following sections will describe the different processing stages in more detail and focus on new developments.

Transportation and Receipt of Poultry at the Plant

Poultry is commonly transported from the growing farm to the processing plant by a truck where the birds are loaded into small crates (4–10 birds) or large modules (40–60 birds). Prior to loading, feed and water are removed from the growing barn, so collection is easier and more efficient. The birds are usually kept off feed for 4–8 h before they arrive to the plant. The time off feed and conditions on the truck should be carefully monitored to avoid dehydration, extreme temperature conditions,

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00557-2

and problems with air-flow fluctuation, which could stress and hurt the birds. On arrival, it is recommended to allow a rest period (1–3 h) for the birds in order to reduce transportation stress (i.e., rest period also depends on distance traveled, outside temperature, and feed withdrawal time). Optimally, this should be done in a temperature-controlled environment (20–25 °C) and under dim light (i.e., especially important if controlled atmosphere stunning is used; see discussion in the succeeding text) as high stress levels can ultimately and negatively affect meat quality. Prior to unloading, the weight of the birds is determined and used as the basis for calculating the payment to the farmer.

Unloading and Stunning

Unloading the birds from the crates and placing them on a moving shackle line are done manually by people standing by the truck or by the unloaded crates onto a conveyor belt (most common method) or semiautomatically by carefully tilting the modules. In some plants, a fully automated system is used to place the crates on a conveyer belt and move them through a special controlled atmosphere tunnel. In this situation, the birds inside the crates are stunned by CO_2, argon gas, or a mixture of both and later removed while they are unconscious (this can help reduce bruising of the more excited birds taken out of a crate).

Stunning is common in most plants, except when religious considerations are involved (e.g., kosher or halal regulations usually do not permit stunning). Stunning is usually carried out by utilizing electrical current or gas; less often is this process carried out using mechanical means. Stunning should produce a rapid onset of stress-free insensibility of sufficient duration, to allow the animal to remain unconscious, until it is dead. Currently, electrical stunning is the most common method used for poultry. The equipment is relatively inexpensive and simple to use (a fiberglass brine/water bath fitted under the overhead shackle line from which the suspended birds are moved forward), does not require much space, and is compatible with current line speeds. The birds pass through the stunner in a continuous procession (e.g., 140–180 birds/min in a modern processing plant). The voltage is applied between the submerged electrode and the ground. A renewed interest in gas stunning has emerged over the past few years, mainly to overcome problems (e.g., hemorrhages) encountered when high electrical currents are mandated. Carbon dioxide, argon, and nitrogen are used in different ratios to render the birds unconscious. Currently, carbon dioxide is the most commonly employed gas because at concentrations of 20–30%, this gas has been shown to have an anesthetic effect. Later, its concentration can be raised to achieve a longer stunning period. In this instance, unloading should be done fairly quickly after stunning so that sufficient time is not allowed for the birds to regain consciousness.

Bleeding

Bleeding is done by cutting the blood vessels in the neck. The so-called modified kosher is one of the most common methods, which results in cutting the jugular vein just below the jowls, so that the windpipe and esophagus remain intact (this can be important when automated equipment is later used to pull out the windpipe). The 'modified kosher' method is easy to perform (with both manual and automated equipment) and results in a good bleed-out. Automated high-speed equipment employs a railing system that positions the neck, of the suspended bird, in such a way that precise cutting can be performed. For kosher and halal slaughter, only manual cutting of the blood vessels is permitted.

The bleed-out phase takes anywhere between 2 and 5 min, depending on bird type and size. During the process, 35–50% of the total blood is lost; however, considerable variation can exist between individual birds and flocks. Other factors affecting blood loss include stunning method and time interval between stunning and bleeding. It is important to note that a poor bleed-out can increase the prevalence of carcass downgrading owing to conditions of muscle blood spots and, in particular, engorged or hemorrhagic wing veins.

Scalding

Scalding is done to loosen the feathers prior to plucking, and this process is performed by immersing the birds in warm water or through the use of a newly developed process that involves exposure to steam. In a small plant, manual scalding is done by placing the carcasses in a hot water tank. In large plants, this is done in a continuous manner where the birds are dipped in a single or multistage scalding bath while suspended from a moving shackle line (Figure 2). There are three commonly employed scalding schemes: The first is the so-called soft scalding/semiscalding, which is performed at water temperature of 50–53 °C for 1–3 min and used for young broilers and turkeys. The second is medium scalding/subscalding, which is performed at 54–58 °C for 1–2 min and is used for mature birds (where feathers are more tightly attached). The third is hard scalding where a temperature of 60–63 °C is used for 0.75–1.5 min and is used for waterfowl (ducks, geese, etc.). Selecting one process over another depends on the degree of difficulty in removing the feathers, chilling method to follow (e.g., water or air), and age of the bird. Higher scalding temperatures are better for loosening feathers from their follicles, but this is also more harsh on the skin (i.e., the outer layer of the skin, epidermis, becomes loose and is later removed by the automated plucking equipment; see next section of this article). The removal of the epidermis can also result in skin discoloration if the skin is allowed to dry during a subsequent air chilling operation. However, hard scalding is the only satisfactory way to release the feathers of waterfowl. Generally speaking, hard scalding does not cause as much discoloration in the thicker skin of waterfowl as it does in young broilers or turkeys. As indicated earlier, soft scalding/semiscalding is commonly used for young broilers and turkeys since it does not damage as much of the epidermis while still allowing for relatively easy feather removal. Adequate agitation of the scald water and uniform application temperature are essential to ensure good feather removal. To improve meat hygiene, careful equipment design is required as contamination (e.g., 1 g of fecal material can contain 10^8–10^9 bacteria) from one bird can affect the other birds in the flock. In the new steam scalders, there is less of a problem since the condensed water

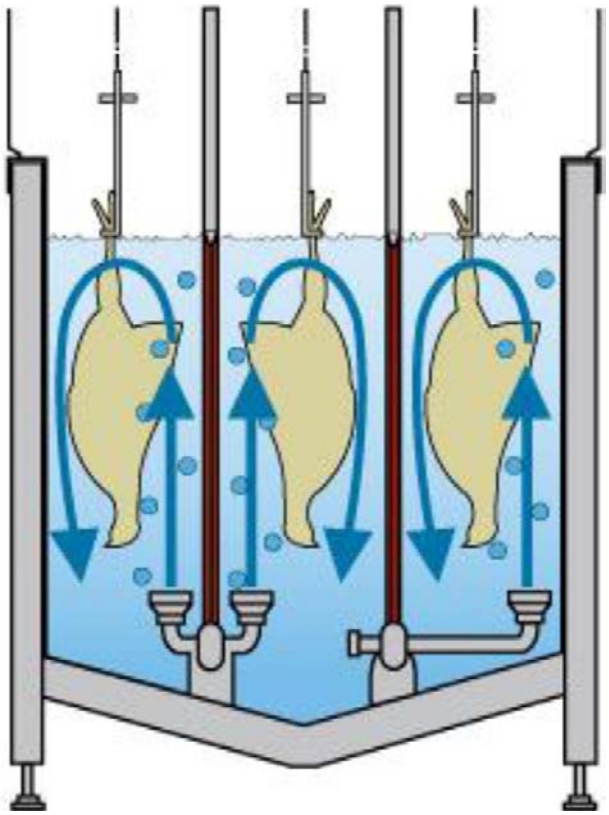

Figure 2 Scalding operation showing how birds move through the scalding tank while streams of air bubbles help to agitate the birds and assure good water penetration in between the feathers. Courtesy of Marel.

vapor drips off the bird. Controlling the temperature in the conventional water bath scalder is also a key feature in keeping bacteria load under control. Another way to reduce bacterial load on bird carcasses is through the use of a counterflow design (i.e., clean water introduced at the exit end of the tank, and water flows toward the entrance where the birds are introduced). Installing a multistage scalding tank system can further reduce contamination problems (i.e., two to four water tanks, where the birds are moved from the initial, more contaminated tank to successively cleaner tanks while water drips off the carcasses in between).

Defeathering

Feather removal is commonly performed by mechanical pickers equipped with rubber fingers that rub the feathers off the carcass. In a continuous operation, this is carried out while the birds are hanging upside down and moved in between two/three sets of rotating disks equipped with plucking fingers (Figure 3). The fingers are made of rubber and also contain a certain degree of lubricating agent that controls their hardness and elasticity. The hardness varies depending on the task required, machine speed, type of birds, etc. The fingers can also be mounted on drums that rotate toward the center. The space between the two sides is adjusted to accommodate bird size variations of different flocks.

Figure 3 Different types and arrangements of feather-picking fingers used by the industry. The disks are positioned along the line, at different heights, and the birds are passed in between the rotating fingers. See text for further explanation.

As indicated previously, scalding significantly reduces feather attachment, and it has been reported that scalding broilers at 50 °C (122 °F) reduced feather pulling force by about 30% compared to pulling similar feathers from a stunned bird. When scalding temperature is raised to 53 °C (128 °F), force is reduced by about 50%, and when 60 °C (140 °F) is used, about a 95% reduction can be seen. It is also known that the force required to pull the feathers in the femoral area is higher than in the pectoral area, with sternal feathers requiring the least force.

When pinfeathers are a problem, as with waterfowl, wax dipping is common after mechanical picking (this is performed by suspending the carcasses in hot wax, followed by cold water immersion and peeling off the wax); the wax can be reused after reheating and filtering. Singeing is used when only a small amount of pinfeathers exists and the process consists of burning small feathers with a clean gas-operated burner (no off-flavor or odors generated from the burning gas). The carcasses are then washed (Figure 1) to remove any soiling left after defeathering and singeing. Note that manual picking of the feathers is often carried out in small-scale operations.

Removing Oil Gland, Feet, and Rehanging

Once birds have been defeathered, feet are removed and birds are transferred to another line to minimize contamination in the following steps. Feet removal can be done manually or by automated equipment. In an automated process, the knee joint is positioned, by guiding bars along the shackle line, on an angle and severed when passing by a circular rotating blade. It is important that the cut be done between the bones and not through a bone, since the latter will appear dark/red in the chilled bird and almost black in the cooked product. Some of the new automated leg cutters first bend the leg and then perform a small incision, which allows further bending prior to cutting through the joint with a rotating circular blade. The oil gland is usually removed at this point by first positioning

the bird at a certain angle (by a set of metal bars/rails, along the shackle line) allowing a rotating blade to cut off the oil gland from the tail area. After removing the oil gland and feet, the carcasses are moved to another line. This can be done manually as the carcasses fall onto a sorting table or automatically by transferring the birds to another line where they are suspended from the knee joint. It should be pointed out that when birds are initially unloaded from the crates, they are placed on the line with their feet suspended from a shackle. As indicated earlier, this also assists in reducing contamination since the dirty shackles, used for the live birds, are replaced with clean ones.

An automated rehanging system consists of a large wheel with slots for grabbing the birds from underneath the knee joints and a device to push them into the evisceration line. Using automated rehanging equipment allows for labor savings and better hygiene (i.e., birds are not piled on a sorting table). In addition, fast rehanging can prevent variation in meat quality since rigor starts to set in at this stage, and if rehanging is done without delay, all birds are processed the same way.

Viscera Removal

During this stage, the body cavity is opened and the viscera (intestines, gizzard, gallbladder, and crop) are withdrawn. It can be done manually by using a knife and a pair of scissors, semiautomatically (with a circular rotating blade), or fully automatically by using a circular cutting blade and a scoop-like arm to withdraw the viscera. Fully automated processes can be done on high-speed lines (e.g., up to 14 000 birds per hour). In all procedures, special care should be taken not to damage the viscera and contaminate the carcass. In some countries, such a contamination results in condemnation of the whole bird or parts, whereas in other countries, washing and reprocessing of moderately contaminated carcasses are permitted.

During a manual operation, the abdominal skin is cut open along the midline (anterior part of the breast bone toward the cloaca), while the skin around the cloaca is trimmed in a circular pattern to minimize gut content spilling. Automating the process requires precise control of the same operation. Adjusting the equipment to accommodate size variations is of great importance, since unadjusted equipment can result in tearing of the intestines, causing gut spills and damaging the carcass itself. In semiautomated or fully automated evisceration processes, the first step is to cut around the cloaca, using a circular rotating blade. Some of the new devices are equipped with a vacuum device so potential fecal contamination is reduced, and the knife is rinsed after each insertion. The viscera are then withdrawn from the body cavity and remain attached to the carcass for inspection purposes. Alternatively, automated equipment can also be used for viscera separation right after its withdrawal and placement on a parallel line (i.e., can further improve the hygiene of the process). Once the viscera pack is exposed, the birds are inspected.

Meat Inspection

Inspection requirements can somewhat differ among countries and are usually carried out by a government official. This process is essential in ensuring that only wholesome birds, free of disease, will get to the marketplace. In some countries, it is required to inspect each individual bird by a qualified veterinarian, whereas in other countries, inspection is performed on a whole flock basis, and only certain carcasses are inspected by a designated veterinarian/inspector. Inspection is then performed when all the internal organs are visible to the inspector to reveal diseases/problems with the carcass itself and/or the internal organs. The inspection area should be provided with adequate bright light, a handwashing station, a rake for placing suspected birds, and a bin for condemned birds. The suspected birds receive a more thorough inspection, and all or some parts can be salvaged. Requirements about line speed or splitting the line so each inspector can check an adequate number of birds can usually be found in the regulations of each country. A mirror is often installed on the far side of the carcass, so the inspector can view both sides of the bird without touching it. Some processors and government agencies are currently evaluating computer vision systems (producing a digital image that can be compared with a reference) to assist inspection. It is important to note that many new lines already use a camera system to help with grading as well as assisting decisions about how to market each bird (e.g., cut-up and whole bird).

Giblet Harvesting

After inspection, the viscera are removed and the giblets (liver, heart, and gizzard) are salvaged and washed using a separate processing line. This is an optional step, where all or only some organs are harvested, depending on market demand and price. In the past, the process could only be done manually, but today, semiautomated or fully automated equipment is used. The gizzard (stomach used to grind the food, since birds have no teeth) is first cut open, the contents are removed, and the lining is peeled off. This can be done today by equipment that peels off the lining. The machine consists of two rollers that 'catch' the lining and pull it away. The equipment is showered all the time to keep it clean and cold. The hearts and livers can also be collected (manually or automatically), inspected, washed, and chilled. The chilled giblets are then packed in a paper bag (sometimes the neck is included) and inserted back into the eviscerated whole bird, collected and sold in bulk, or used for further processing in the plant.

Lung, Crop, and Head Removal

Removing the lungs, head, and crop is commonly done after inspection; however, in some operations, one or all are removed prior to inspection. The lungs can be removed manually by using a rake-like device that is inserted into the abdominal cavity. A semiautomated process employs a vacuum gun, which is inserted, by a plant employee, into each bird. A fully automated process employs the same type of gun, guided by a machine. Head removal can be performed by using a knife or a pair of shears. Automated systems usually consist of a puller that results in detaching the neck (of the forward moving carcass) at the weakest point between the atlas and the axis vertebrae. The

advantage of this device is that the esophagus and trachea (windpipe) can also be pulled out at the same time.

Bird Washing/Rinsing

Rinsing off all processing debris after removing the internal organs helps to keep the process clean. There are different devices that can be used at certain stages along the processing line. One of the most common control washing/rinsing stages is prior to chilling. The washing device usually consists of multiple spray nozzles positioned to cover the whole bird or critical carcass areas for washing off debris or blood residues. The carcass cavity area is also commonly rinsed by spray nozzles or by a retracting shaft equipped with high-pressure nozzles. The water can then be drained through the abdominal opening (created during evisceration) or by tilting the carcass. In the case where a retracting shaft is used, it can be pushed toward the neck opening (formed after pulling out the windpipe and the crop), and the carcass does not have to be tilted to drain the water. For rinsing the surface, some designs consist of spray heads positioned along the moving shackle line, washing first the upper part of the carcass and gradually the lower parts. Where permitted, antimicrobial agents such as chlorine and organic acids are also used. Chlorine is one of the most commonly used agents and is typically used at 20–50 ppm. The washing operation is critical in keeping the carcasses visibly clean and reducing the number of microorganisms on the carcass. The importance of obtaining low microbial counts (including pathogens) for food safety and shelf-life reasons are discussed in subsequent sections.

Chilling

Meat is a perishable item and therefore must be quickly chilled to minimize microbial growth. End-point temperatures and times to reach them are mandatory in many countries. The most common methods used include water immersion chilling, air chilling, and spray chilling. In a large-scale operation, immerse chilling is performed in long chillers with a counterflow of cold water (Figure 4), sometimes supplemented with ice, to help bring the carcass temperature to about 4–5 °C within 50–75 min. The carcasses are placed into a trough-like structure, which usually contains a large diameter auger that moves the birds forward; other designs employ large paddles. Most chillers today employ counterflow of products and water since it is more efficient (coldest water at the exit end) and more hygienic compared with parallel-flow chillers (i.e., product and water flow in the same direction). The microbial quality of birds coming out of a water chiller is often better than before chilling, since the water allows for washing off of bacteria.

Employing a prechiller and/or a postchiller is another improvement in obtaining a cleaner product. In the prechiller, water is used for the initial chilling and washing of the carcasses. The product is then lifted, drained, and passed into a long chiller where clean cold water is used to continue cooling the product. The amount of water overflow in the chilling tank is regulated in some countries (e.g., in Europe, 2.5 l for birds $\leq$2.5 kg). A short postchiller tank is now also becoming popular in North America (i.e., where the use of antimicrobial agents such as peracetic acid is allowed), to further help reduce microbial counts, including pathogens such as *Salmonella*. The short configuration allows for the use of high enough concentration of acid in an economical way. The product coming out of the chiller is allowed to drip for a few minutes so excess water is drained. The amount of water picked up, during the chilling process, is regulated in various countries, and is usually based on a percentage of the carcass weight (e.g., in the United States, 6% for birds up to 4.5 kg).

Using cold air chilling is more commonly used in Europe, but such operations are now starting to appear in North America and elsewhere. Since cold air, at medium flow rate, is used as the chilling medium, care must be taken not to overdry the product surface and increase weight loss. That can be achieved by wetting the product at some point(s) along the line (also helps to increase the environment's relative humidity). A normal chilling operation should usually result in a 0 to −1% carcass weight loss. A typical air chilling tunnel includes an overhead railing that goes back and forth along a chilling room, the overall length of the line can be a few km. Depending on the tunnel capacity, size of the birds, and volume of the product going through, chilling can be achieved within 75–150 min. The air-chilled birds do not, and should not, show much exudation (drip loss) in tray packs. Some processors claim that the microbial quality of the air-chilled product is better than that of a water-chilled product, but this is not always the case.

Spray chilling is a hybrid between water and air chilling. During the process, cold water is constantly sprayed over the carcasses while they are moved along the line. Moisture pickup is less than during water chilling but higher than during air chilling with only intermittent moisturizing of the carcasses.

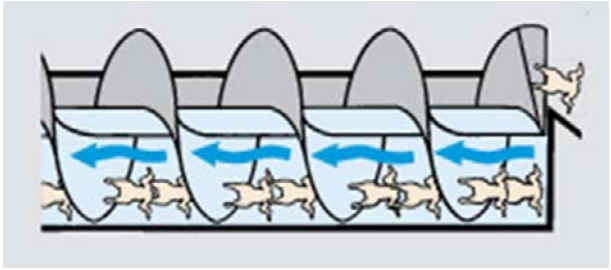

Figure 4 Water-chilling operation showing a spin chiller with a counterflow of clean cold water from the exit side, Courtesy of Stork.

Grading, Portioning, and Packaging

Poultry carcass grading is not mandatory in all countries, but is done in most large markets to facilitate sales. The grade is based on carcass conformation, relative muscling, the presence of tears/bruises/pinfeathers, and missing parts. Different countries usually have their own specifications, but generally speaking, a bird (chicken, turkey, or duck; see also meat compositional differences in Table 2) with adequate muscle deposition and no missing parts/esthetic defects will be classified as grade A. Minor defects will result in a grade B, and more

Table 2 Composition and nutritional value of different raw poultry meats

Source of meat							
Species	*Meat*	*Skin*	*Water (%)*	*Protein (%)*	*Fat (%)*	*Calcium (mg)*	*Calories (kcal)*
Chicken	White	+	68.6	20.3	11.1	0.86	186
		−	74.9	23.2	1.6	0.98	114
	Dark	+	65.4	16.7	18.3	0.76	237
		−	75.9	20.1	4.3	0.94	125

serious defects will result in a grade C. The last two categories are usually not sold as whole birds, but rather as parts (no grade labeling required) or used for further processed products. Grading can be done by a qualified person or with the assistance of a computerized machine vision system, as indicated previously. The appearance of the carcass and final grade can also be affected by processing conditions used (e.g., high electrical stunning can result in some bone dislocation and blood spots), as well as feeding, growing, and transporting parameters (e.g., bruising during loading of birds) described in more details in other sections.

Weighing of the ready-to-sell birds (whole bird or portions) is done manually or by automated weighing equipment connected to a computer network. A computerized system can also be employed to automatically print labels on individual/bulk packages. Automated portioning equipment is used in large plants where simple portioning is done (e.g., nine cuts commonly used for fast food chains), or more sophisticated cutting and deboning (e.g., breast meat fillets, drumstick meat) are performed by high-speed equipment guided by cameras/laser sensors that first produce accurate 3-D images of the portions to be cut. Selling portioned poultry to consumers interested in only buying certain parts (skinless breast fillets, drumstick meat) has allowed the industry to significantly increase sales and also move some items such as whole turkey (i.e., traditionally consumed during Thanksgiving and Christmas) to an all year-round product.

Prebiotics

PS Panesar and V Bali, Sant Longowal Institute of Engineering and Technology, Longowal, India

© 2016 Elsevier Ltd. All rights reserved.

Introduction

There has been a remarkable increase in people having gastrointestinal and digestive problems without showing the characteristic clinical symptoms (i.e., associated with changing life style and age). These are caused due to imbalances in the intestinal microflora, referred to as dysbiosis. To overcome this problem, probiotics and prebiotics play a major role in prevention of dysbiosis. Probiotics are beneficial bacteria that colonize in human intestines (mainly the colon) and provide health related benefits to the host. These probiotic microorganisms may not be able to survive the harsh, acidic conditions of the stomach; thus, making it difficult to colonize in the intestine. Most of these bacteria are strict anaerobes and obtain their energy by fermentation of food. Therefore, food and energy in the form of dietary supplementation work to restore the intestinal ecology of the probiotic microorganisms. The food and dietary supplements that stimulate the growth and multiplication of the microorganisms that are beneficial to our health (mainly lactobacilli and bifidobacteria) are termed as prebiotics. Thus, prebiotics are nondigestible food ingredients which enhance the growth and colonization of probiotic bacteria, and contribute to the improved health of the host. Prebiotics were recognized in the 1950s, but the term 'prebiotics,' was coined by Gibson and Roberfroid in 1995. The contribution of colonic microbiota to the health associated benefits to the host has been a breakthrough in the field of medical and nutrition research.

The main types of fermentative substrates of dietary origin are as follow:

- Nondigestible carbohydrates such as resistant starch, nondigestible oligosaccharides, non-starch polysaccharides.
- Undigested proteins that escape digestion in the small intestine and reach the colon.

Out of these, the dietary carbohydrates (10–60 g day^{-1} reaches the colon) serve as the major substrate for the bacterial growth. They include resistant starch (8–40 g day^{-1}, fermented by most of the colonic bacterial species including *Bacteriodes* sp., *Eubacterium* sp., *Bifidobacterium* sp., etc.), non-starch polysaccharides (8–18 g day^{-1}), unabsorbed sugars (2–10 g day^{-1}), and oligosaccharides (2–8 g day^{-1}). Out of these, prebiotics such as fructo-oligosaccharides (FOS), galacto-oligosaccharides (GOS), xylo-oligosaccharides, lactulose, etc. are selectively fermented by the probiotic microorganisms, thereby resulting in their growth and multiplication and hence are termed as prebiotics.

Sources of Prebiotics

The short chain prebiotic oligosaccharides occur widely in nature and can be obtained in small amounts by direct extraction from natural sources such as plants – including chicory, onion, garlic, asparagus, artichoke, bananas, tomatoes, and leeks. These are reported to be present in animal sources such as human milk and colostrum (in relatively smaller amounts). They can also be produced in comparatively larger amounts by using microorganisms and their enzymes at large scale. Enzymes, mainly hydrolases (E.C. 3.2.) and transfereases (E.C. 2.4.), of plant origin can also be used for enzymatic synthesis of prebiotic oligosaccharides. Prebiotic oligosaccharides can also be produced by controlled hydrolysis of natural polysaccharides. To make the production process economical, prebiotics can also be synthesized by using agro-industrial waste/byproducts like whey, wheat and rice straw, and sugarcane bagasse.

Characteristics of Prebiotics

Prebiotics are short, have low molecular weight, and are heat resistant bio-molecules with three to ten sugar moieties. They possess β-glycosidic bonds which enable them to resist hydrolysis by human salivary and pancreatic enzymes. They have low caloric value – 4.l2–8.4 kJ g^{-1}. Figure 1 represents the structure of some common prebiotics. The characteristics of ideal prebiotics are:

(i) They should not be absorbed or hydrolyzed by mammalian tissues or enzymes.
(ii) They should selectively enhance the growth and multiplication of beneficial/probiotic microorganisms.
(iii) They should beneficially alter the activity of the intestinal micro-flora.
(iv) They should have beneficial effects on the host defense system.
(v) They should be stable across a wide range of pH in the stomach and colon.
(vi) They should be advantageous to the host's defense system.

Types of Prebiotics

Common prebiotics in use include inulin, FOS, GOS, soya-oligosaccharides, xylo-oligosaccharides, pyrodextrins, isomalto-oligosaccharides, lactulose, pectic oligosaccharides, lactosucrose, sugar alcohols, gluco-oligosaccharides, levans, and resistant starch. These can be produced using various substrates such as lactose, sucrose, starch, and xylan by both chemical and enzymatic methods through transgalactosylation activity on respective carbohydrates (Figure 2). Enzymes from different microbial sources, such as bacteria, yeast, and fungus, are responsible for the production of prebiotics.

Prebiotics have been classified into two categories: established prebiotics and emerging/tentative prebiotics. Established prebiotics include inulin, GOS, FOS, and lactulose. Emerging/tentative

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00560-2

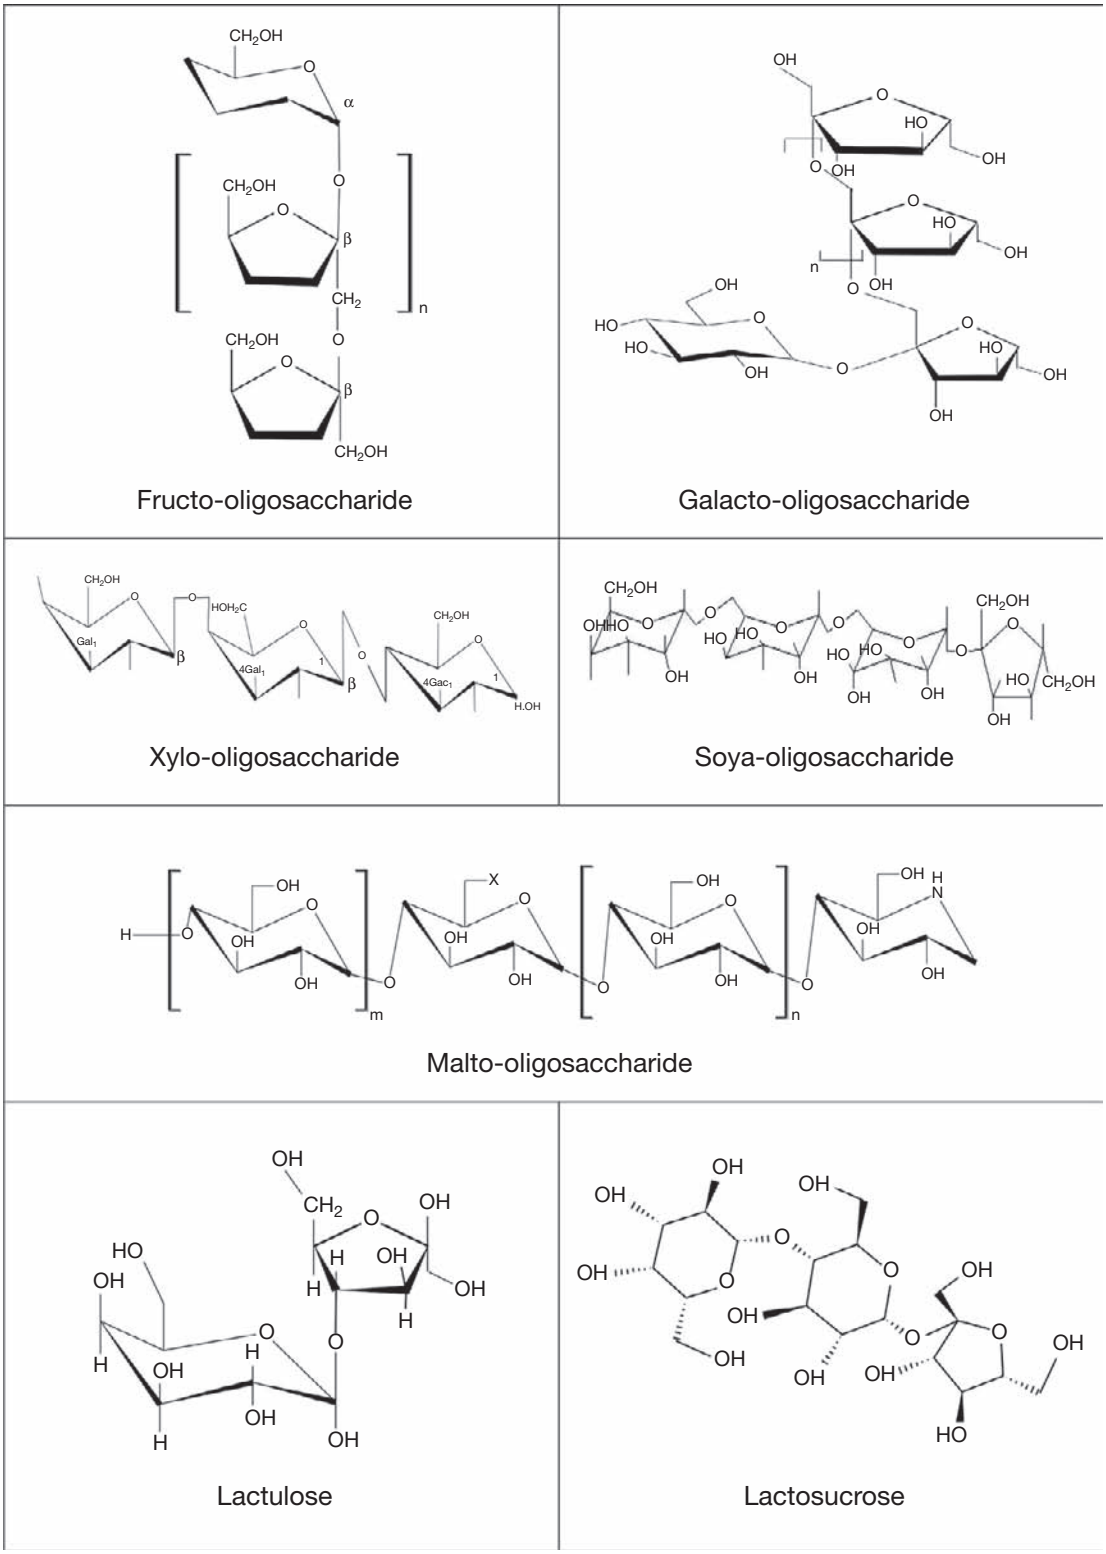

Figure 1 Some common prebiotics and their structure.

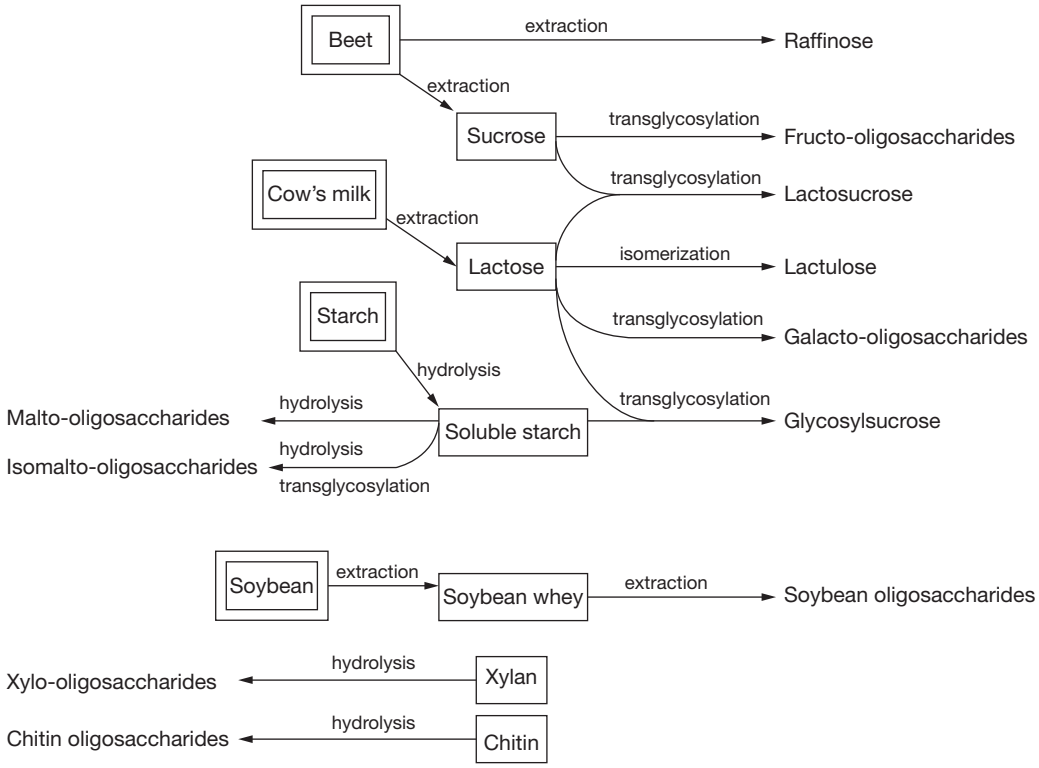

Figure 2 Production process of nondigestible oligosaccharides. Reproduced from Sako, T., Matsumoto, K. and Tanaka, R. (1999). Recent progress on research and applications of non-digestible galacto-oligosaccharides. *International Dairy Journal* **9**, 69–80, with permission.

prebiotics include isomalto-oligosaccharides, xylo-oligosaccharides, and soya-oligosaccharides. Prebiotics can also be distinguished on the basis of the substrate used for their production, such as:

(i) lactose derived prebiotics, including GOS, lactosucrose and lactulose;
(ii) sucrose derived prebiotics, including FOS, isomaltulose;
(iii) starch derived prebiotics, including isomaltose-oligosaccharide, isomaltotriose; and
(iv) xylan derived prebiotics including xylo-oligosaccharide.

Galacto-oligosaccharides

GOS made up of β-linked (mostly β-[1→4], but β-[1→2]-, β-[1→3]-, or β-[1→6] linkages are also observed) galactose units with mainly glucose residue at its reducing end. These are synthetically produced by the trans-galactosylation activity of β-galactosidase (E.C. no. 3.2.1.23), or β-glycosidase (E.C. no. 3.2.1.21), enzymes using lactose, glucose, or galactose as a substrate having lactose as a galactosyl donor. These enzymes can be obtained by using different microorganisms such as *Lactobacillus reuteri*, *Bifidobacterium longum*, *Lactobacillus acidophilus*, or *Kluyveromyces lactis*. Oligomate 55, Cup-oligo H-70, Vivinal-GOS, and TOS-syrup, are some of the commercial available GOS. They are mainly used as cosmetic additives, bulking agents, low-calorie sweeteners, and food ingredients in breads, jams, marmalades, desserts, etc.

Fructo-oligosaccharides

FOS, generally known as fructans, are of the inulin and levan type, including 1-kestose (GF2), nystose (GF3), and 1-β-fructofuranosyl nystose (GF4) composed of fructosyl (F) units linked by β-(2→1) glycosidic bonds. These are mainly produced by the transfructosylation activity of β-fructofuranosidase (E.C. no. 3.2.1.26) or fructosyltransferase (E.C. no. 2.4.1.9) enzymes using sucrose as a substrate. These can also be synthesized by the hydrolysis of inulin using endoinulase as enzymes. Enzymes from microbial sources, such as *Aspergillus japonicus*, *A. niger*, *Penicillium citrinum*, *Arthrobacter* sp., *Zymomonas mobilis*, *Lactobacillus reuteri*, and *Candida*, are used for the production of prebiotics. FOS occur naturally in wheat, onions, bananas, garlic, artichoke, dahlia tubers, etc. Commercially available FOS includes Actilight, NutraFlora, Raftilose, Inulin FOS, Fibrulose, etc. These have low calories, are safe for diabetics, are not cariogenic, have bifidus-stimulating factors, and aid immune-regulatory functions.

Xylo-oligosaccharides

These constitute oligosaccharides made up of xylose units (2–10) that are linked through β-(1→4) linkages. They also possess side groups such as α-D-glucopyranosyluronic acid and 4-*O*-methyl derivative. They are produced through the hydrolysis of xylan by xylanase enzymes, and mainly consist of xylobiose, xylotriose, and xylo-tetraose. Enzymes involved in their production are endoxylanase (E.C. no. 3.2.1.8), β-D-

xylosidases (E.C. no. 3.2.1.37), and debranching enzymes like esterases (E.C. no. 3.1.1.72). These enzymes are produced by microorganisms such as *Aspergillus* sp., *Trichoderma* sp., *Penicillium* sp., *Thermomyces lanuginosius*, *Bacillus halodurans*, and *Pichia stipiti*. Xylo-oligosaccharides are present in fruits, vegetables, bamboo, honey, and milk and can be synthesized on a large scale from xylan-rich substrates or agricultural waste/by-products such as cornstalks, bagasse, and corncobs. Xylo-oligosaccharide 95P, 70L, 35P, 20P, etc. are commercially available xylo-oligosaccharide products. These have an acceptable odor, as well as non-cariogenic and low-caloric properties.

Soya-oligosaccharides

Soya-oligosaccharides are composed of trisaccharide raffinose (consists of one unit of D-galactose, D-glucose, and D-fructose) and tetrasaccharide stachyose (consists of two molecules of D-galactose and one of D-glucose and D-fructose), which are linked by α-(1→6) linkages. These oligosaccharides have degrees of polymerization ranging from 3 to 4 (trisaccharide raffinose and tetrasaccharide stachyose). These can be extracted from soya beans, peas, and some other beans. They may have a role in the prevention of allergies and may be used in the treatment of galactosemia and lactose intolerance.

Lactulose

Lactulose is a ketose disaccharide, chemically known as 4-*O*-β-D-galactopyranosyl-D-fructose. The enzymes used for the biocatalytic production of lactulose are β-galactosidase (EC 3.2.1.23) and β-glycosidase (EC 3.2.1.21) – using lactose and fructose as a substrate. It can also be produced by the alkaline isomerization of lactose. Microorganisms used for the production of lactulose are *Kluyveromyces lactis*, *Sulfolobus solfataricus*, *Arthrobacter* sp., *Pyrococcus furiosus*, etc. Some of the commercial preparations of lactulose include Duphalac, Bifiteral, Chronulac, Cephulac, etc. It is mainly used as a laxative and may be used for prevention of hepatic encephalopathy.

Lactosucrose

Lactosucrose (lactosylfructoside) is a trisaccharide that consists of galactose, glucose, and fructose units, chemically known as *O*-β-D-Galactopyranosyl-(1→4)-*O*-α-D-glucopyranosyl-(1→2)-β-D-fructofuranoside. Being an artificial oligosugar, it is low in caloric content and stimulates the growth of bifidobacteria present in the colon. It can be synthesized by transfructosylation of lactose with sucrose using levansucrase (E.C. no. 2.4.1.10) and fructofuranosidase (E.C. no. 3.2.1.26) enzymes; or, by transgalactosylation of sucrose with lactose using β-D-galactosidase enzymes (E.C. no. 3.2.1.23). Microbial sources used for their production are *Zymomonas mobilis*, *Paenibacillus polymyxa*, *Bacillus subtilis*, *Bacillus circulans*, etc. The commercially available lactosucrose products are Nyuko-Oligo LS-40L, Nyuko-Oligo LS-55P, Pet-Oligo L55, Newka-Oligo LS-35L, etc. These may be used as pet foods, table sugar, drinks, or confectionery ingredients.

Isomalto-oligosaccharides

These are oligosaccharides having α-D-(1→6) linked glucose moieties (and rarely α-D-(1→4) glucosidic linkages) with degrees of polymerization ranging from 3 to 6. These occur naturally in honey and fermented food products such as sake and soybean sauce. These oligosaccharides can either be produced by using dextranase (E.C. no. 3.2.1.11) and dextransucrose (2.4.1.5) as enzymes with starch as a substrate; or, by transglucosidase (E.C. no. 2.4.1.24) enzymes using sucrose as a substrate. Transformation of maltose into isomalto-oligosaccharide can also be achieved using α-glucosidase enzymes (E.C. 3.2.1.20). *Penicillium lilacinum*, *Saccharomyces carlsbergensis*, *Saccharomyces cerevisiae*, etc. are the microbial sources for the enzymes. The commercially available isomalto-oligosaccharide products are IMO-900, IMO-800, etc. It has been reported that they may be used in the treatment of constipation and hyperlipidemia in elderly and hemodialysis patients.

Isomaltotriose

Isomaltotriose, chemically known as α-D-glucopyranosyl-(1→6)-α-D-glucopyranosyl-(1→6)-D-glucose, consists of three molecules of isomaltose. Isomaltotriose can be synthesized by the hydrolysis of dextran using dextranase enzymes (E.C. no. 3.2.1.11). *Flavobacterium* sp., *Streptomyces anulatus*, etc. are the microbial sources for the production of isomaltotriose using dextrans as a substrate. The commercially available isomaltotriose products are available under the brand name Isomaltotriose, manufactured by Santa Cruz Biotechnology Inc. (California), Advanced Technology & Industrial Co. Ltd (Hong Kong), etc.

Isomaltulose (Palatinose)

Isomaltulose, chemically known as 6-*O*-α-D-glucopyranosyl-D-fructose, is a structural isomer of sucrose constituting of glucose and fructose units linked by α-(1→6) glycosidic bonds. It is commonly produced by the enzymatic rearrangement of sucrose using α-glucosyltransferase (i.e., isomaltulose synthase [E.C. no. 5.4.99.11]). Isomaltulose can also be synthesized by palatinose synthetase followed by the interamolecular dehydration of palatinose. The microorganisms responsible for the conversion of sucrose into isomaltulose are *Erwinia* sp., *Klebsiella planticola*, *Serratia*, etc. Isomaltulose occurs naturally in products such as sugarcane and honey. The commercially available isomaltulose products of are available under the brand name Isomaltulose, manufactured by Shaanxi Sciphar Hi-Tech Industry Co. Ltd (China), Xian Yuensun Biological Technology Co. Ltd (China), and Palatinose manufactured by Shanghai Honghao Chemicals Co. Ltd (China) etc.

Resistant Starch

Resistant starch is a small fraction of the starch that escapes digestion in the small intestine and reaches the colon. This portion of starch that is resistant to digestion is then fermented in the large intestine, mainly the colon, by the endogenous microflora. Starch is basically glucose molecules linked by α-D-(1→4) or α-D-(1→6) glycosidic bonds, and is digested in the small intestine. It comprises mainly amylose (straight chains

that form 15–20% of starch possessing α-D-[1→4] linkages) and amylo-pectin (highly branched and a major component possessing both α-D-[1→4] and α-D-[1→6) linkages]. Amylopectin is a highly branched structure that provides more surface area available for digestion in the small intestine. Resistant starch possesses a higher amount of amylose, which limits the exposed surface area. Therefore, starch with a high amylose content is digested slowly, and some parts of it escapes digestion in the small intestine and reaches colon. On the basis of its structure and complexity, resistant starch is further classified into four classes. Type I includes physically inaccessible starch granules. Type II includes resistant starch granules. Type III includes retrograded starch. Type IV includes chemically modified starches. Resistant starch naturally occurs in under-ripe bananas, oats, lentils, white beans, etc. Commercially available resistant starch products include Hi-maize, CrystaLean, Novelose, Amylomaize VII, etc. These are reported to contribute in promoting apoptosis and reducing the risk of colon cancer.

The Prebiotic Effect

Movement of food is rapid through the stomach and small intestine (~4–6 h) compared to colonic transit time, which is around 48–70 h. This results in the formation of a stable microbial community in the large intestine. Prebiotics (along with other dietary fibers and undigested proteins) escape the upper part of the gastro-intestinal tract undigested, thus serving as a potential substrate for probiotic endogenous bacteria (bifidobacteria and lactobacilli) in the colon. Most of the microflora in the colon are strict anaerobes and derive their energy through fermentation. Prebiotics increase the population growth rate of bifidobacteria and lactobacilli from tenfold to a hundredfold. The presence of 'osidic' bonds makes prebiotics nondigestible by human salivary and intestinal enzymes; therefore, they reach the colon in the undigested form. The hydrolysis and fermentation of these prebiotic oligosaccharides in the intestine by colonic microflora results in their breakdown – mainly into short chain fatty acids. Prebiotics provide energy, metabolic substrate, and essential micronutrient selectively to the endogenous probiotic bacteria. These probiotic bacteria have health related effects on the host by reducing the risk of intestinal infections. The end product of these prebiotics include short chain fatty acids (such as acetate, butyrate, and propionate), lactate, pyruvate, ethanol, succinate, polyamines, bacitracin, and gasses such as H_2, CO_2, CH_4, H_2S. Short chain fatty acids are mainly responsible for causing the prebiotic effect. Short chain fatty acids lower luminal pH, which restricts the growth of disease-causing and putrefactive microorganisms like *Escherichia coli*, *Salmonella*, *Listeria*, and *Shigella*. Short chain fatty acids have also been reported to contribute in the regulation of absorption of sodium and water, maintenance of cholesterol, and increased absorption of calcium and other minerals by the host.

Health Benefits for Human

Changes in dietary habits influence the balance of colonic bacteria in the human gut. Probiotics and prebiotics, together known as synbiotics, have associated health benefits. Prebiotics have been studied for their role in reducing the risks of cancer, acute gastroenteritis, osteoporosis, cholesterol, and hyperlipidaemia; as well as for their bifidus-stimulating ability and immuno-modulatory effects.

Production of Short Chain Fatty Acids

The fermentative end products (short chain fatty acids) of prebiotic oligosaccharides produced by probiotic microorganisms are in the order of acetate > propionate > butyrate in the ratio of 3:1:1 (Figure 3). Probiotic microorganisms use fermentation as their energy source. Production of short chain fatty acids results in a decreased pH, which leads to the reduced levels of pathogenic bacteria, decreases bile acid solubility, and reduces ammonia absorption. Short chain fatty acids are water soluble and are readily absorbed into the blood stream by diffusion or through anion exchange. They also influence intestinal motility. Only 5–10% of short chain fatty acids are eliminated in the feces. Short chain fatty acids contribute to the growth and physiology of intestinal tissues and systemic metabolism. Table 1 represents the function of various short chain fatty acids.

Acute Gastroenteritis

Acute gastroenteritis is a disease state that occurs when food or water that is contaminated with pathogenic microorganisms (such as *Clostridium perfringens*, *Vibrio cholera*, *E. coli*,) or their toxins is consumed. Some of its symptoms are nausea, vomiting, diarrhea, and abdominal pain. Prebiotics help in overcoming this problem by stimulating the growth of bifidobacteria and lactobacilli, which act as a barrier against the invasion of food pathogenic microorganisms. The probiotic bacteria compete for nutrition and colonization sites, produce short chain fatty acids, lower the pH, and secrete antimicrobial agents against the pathogenic bacteria, thereby reducing their invasion in the gut.

Cancer Risk

Colorectal cancer has been reported mostly in people having a family history of colon cancer, high smoking rate, high body weight, greater consumption of alcohol and meat, lower physical workload, and lower intake of fruits and vegetables. Prebiotics have been reported to enhance detoxification, reduce toxic metabolite production, and provide protection against tumor development in the colon. Prebiotics, along with probiotics (bifidobacteria), have been studied to reduce a significant number of colonic aberrant crypt foci and inhibit the propagation phase of the carcinogen. The activity of colon cancer causing bacterial enzymes such as β-glucuronidase, β-glucosidase, and nitroreductase (which convert pre-carcinogens to proximal carcinogens) was observed to be reduced by prebiotics by way of reducing the pH of the colon. Prebiotics also reduce indole and isovaleric acids levels, which are markers of putrefaction.

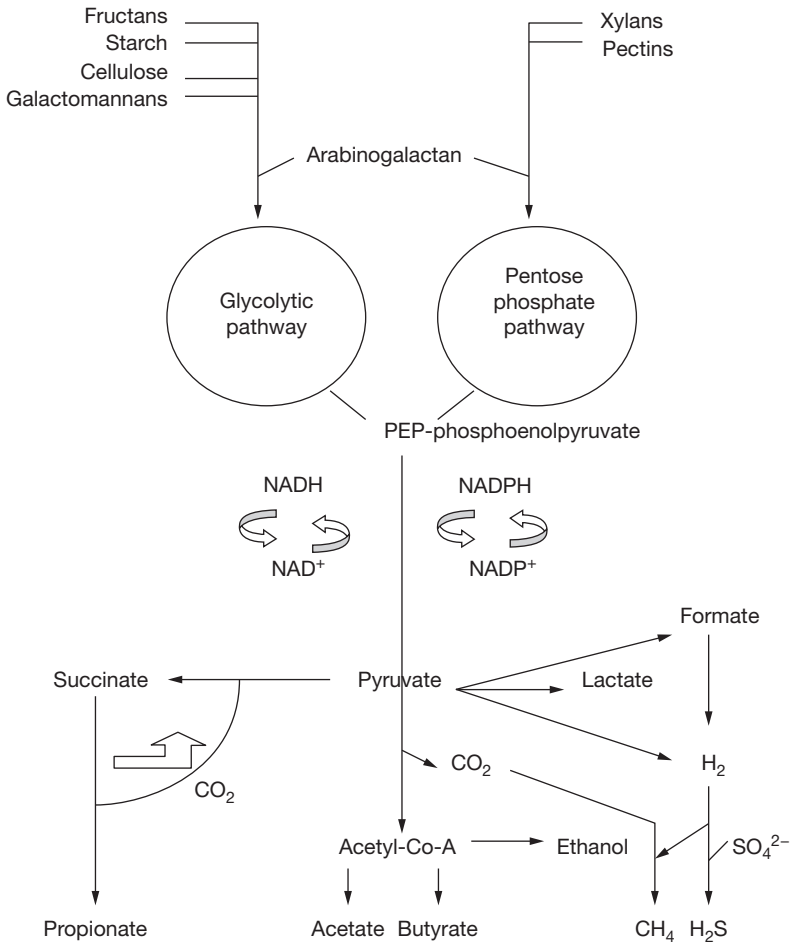

Figure 3 The basic pathway for production of short chain fatty acid metabolites by bacterial fermentation in the colonic lumen. Reproduced from Macfarlane, G. T. and Gibson, G. R. (1997). Carbohydrate fermentation, energy transduction and gas metabolism in the human large intestine. In: Mackie, R. I. and White, B. A. (eds.) *Ecology and physiology of gastrointestinal microbes: gastrointestinal fermentations and ecosystems*, pp. 269–318. New York: Chapman and Hall, with permission.

Table 1 Functions of short chain fatty acids

Short chain fatty acid	*Function*
Acetate	Energy source for body; metabolized by skeletal muscle, heart, kidney, and brain
Propionate	Reduces hepatic glucose output and cholesterol biosynthesis, regulates adipose tissue deposition; metabolized by liver
Butyrate	Energy source for colonocytes; modules colonocyte differentiation and proliferation, regulates gene expression and transcriptional protein

Mineral Absorption

Prebiotics stimulate the absorption of minerals, such as calcium, magnesium, zinc, and iron, which improves bone mineralization. Prebiotic oligosaccharides (3–6 sugar moieties) can bind minerals in the small intestine and release them in the large intestine, where they are absorbed in a much better way. Short chain fatty acids, which are formed in the intestine due to fermentation, can also assist the absorption of these minerals by modifying the electrolyte exchange, thus lowering the risk of osteoporosis. Their effect on bones is further dependent on the time, dose administered, and age of the host.

Reduction in Constipation

Elderly people, pregnant and nursing women, travelers, and people on weight loss diets commonly face the problem of constipation (or irritable bowel disease). Prebiotics play a significant role in overcoming the problem of constipation by increasing the fecal biomass which, in turn, increases the fecal microbial mass, thereby further reducing the transit time of stool. This results in the reduction of colonic water resorption which, in turn, results in a softer and heavier stool with increased frequency. Prebiotics, like oligofructose, inulin, xylo-oligosaccharide, and lactulose, have significant roles in reducing constipation.

Lipid Regulation

Prebiotics lower total cholesterol, LDL-cholesterol, and triglyceride levels, thus showing hypolipidaemic and

hypotriacylglycerolaemic effects. The increased production of short chain fatty acids through fermentation of prebiotics decreases, as well as inhibits, liver lipogenesis in hepatocytes. This may be due to modified gene regulation, which further leads to down regulation of all hepatic lipogenic enzymes. Prebiotics, like GOS, xylo-oligosaccharide, and isomalto-oligosaccharide, have been reported to have a significant role in reducing serum cholesterol and triglycerides.

Immune Modulation

Fermentative end products of prebiotics (i.e., short chain fatty acids) have been reported to contribute to boosting the immune response by selective stimulation of specific membranes of probiotic microflora. The G protein coupled receptors of immune cells contain receptors that interact with short chain fatty acids. These short chain fatty acids also play a significant role in cytokine production, up regulation of gut-associated lymphoid tissue expression of secretory IgA, anti-inflammatory profile, and increased chemotactic response of neutrophiles, thereby modulating the immune system of the host.

Effect on Dental Caries

The nondigestible oligosaccharide cannot be fermented by *Streptococcus mutans*, which is a causative agent of dental caries and plaque formation in humans and animals. Thus, prebiotics such as nystose have been reported to show low cariogenic properties and may serve as alternative sweeteners with reduced dental problems.

Global Status

Due to increasing awareness in consumers, and the wide applications of prebiotics in various fields (including health drinks, dairy products, beverages, bakery and pet food), demand for these products is increasing globally. According to Multi-Sponsor Surveys' 2012 Gallup Study of Probiotic & Prebiotic Consumers, 31% of the population is aware of prebiotics (http://www.nutraceuticalsworld.com/issues/2013-03/view_trendsense/getting-ahead-of-the-curve-prebiotics/#sthash.PoGUV4Zw.dpuf). The number of new prebiotic products has increased almost threefold from 2009 to 2013. The prebiotics market value (Nutraceuticals) in Europe and North America has been estimated at $355.69 million USD and $321.18 million USD, respectively, for the year 2018 – as per the reports of Micromarket Monitor (http://www.micromarketmonitor.com/). In Asia, the market of prebiotics was estimated to be $2.3 billion in 2012, and is likely to grow at CAGR of 11.4% and reach $4.5 billion by 2018 (http://www.nutraceuticalsworld.com/issues/2014-04/view_features/flourishing-flora-probiotics-prebiotics-market-update/#sthash.2zJ6hHlH.dpuf).

Conclusions

Prebiotics are potent agents that contribute to the nutritional, physiological, and digestive functions of the host. Prebiotics improve and maintain the balance of beneficial intestinal microflora in the gut of animals and humans. Because of their properties, prebiotics (along with probiotics) can be helpful in the treatment of various diseases such as acute gastroenteritis and osteoporosis. They can also reduce the risk of cancer, and help to lower cholesterol and hyperlipidaemia. Prebiotics also possess the characteristics of having bifidus-stimulating ability, immuno-modulatory effects, and low cariogenicity. These properties of prebiotics, along with their safety aspects, have created countless new opportunities in both the food industry, and in academia. With their low cost of production, the future is open for designing new prebiotic, functional food products, as well as studying their structure, function, relationship, and their mode of action. Also, the increasing awareness of consumers is making prebiotics a promising market in the coming times.

Pregnancy: Dietary Guidance for Pregnancy

M Blumfield, Monash University, Clayton, VIC, Australia.

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Nutrition is a major environmental factor that influences the health of both mother and infant during pregnancy. Foods and drink consumed during pregnancy play an important role in maternal health and fetal growth and development. A mother's food choice affects the supply of nutrients to the fetus and has a primary influence on fetal nourishment throughout each stage of gestation. The pattern of nutrient demand varies in relation to maternal and fetal metabolism during each stage of pregnancy and the growth of the fetus. Macronutrients provide energy and protein for fetal growth, while micronutrients are involved in the metabolism of macronutrients and the structural and cellular metabolism of the fetus. Changes in diet at different stages of gestation may lead to developmental adaptations that permanently alter fetal physiology and metabolism. This can influence the child's risk of metabolic, cardiovascular, and/or endocrine diseases in later life. Therefore, supporting women to adopt healthy eating patterns needs to be prioritized. Making smart food choices is a huge responsibility, but fortunately, it is fairly simple.

Nutrient Partitioning during Pregnancy

Historically, it was accepted that a fetus acts as a parasite that could successfully compete with its maternal host for nutrients in the event of reduced availability. However, in the last 30 years, evidence from animal and human models has contradicted this theory by demonstrating that the division of nutrients favors the maintenance of maternal body weight, rather than normal fetal growth. Biological competition may exist when nutrient restriction leads to the loss of maternal body stores, although proportionally, the mother will continue to receive a larger share of the nutrients. When a mother exhibits excess maternal body/nutrient stores, fetal growth may still be maintained when her nutrient supply is inadequate. This suggests maternal nutritional status at conception will influence how nutrients are partitioned between mother and offspring during pregnancy. If maternal diet at conception and during pregnancy is inadequate, fetal growth will only be sustained when dietary intake is able to support some maternal weight gain. Thus, when maternal nutrient stores are restricted, then fetal growth will be restricted. The quantity and quality of maternal diet are fundamental for the maintenance of optimal fetal growth because fetal parasitism does not sustain fetal growth at the expense of maternal tissue.

Dietary Recommendations during Pregnancy

Dietary recommendations for pregnancy differ by geographic region. In 1991, the United Kingdom became the first country to develop a set of estimated dietary requirements for pregnancy using the dietary reference values. More recently, the Institute of Medicine's Food and Nutrition Board adopted a similar approach on behalf of the US and Canadian governments, with similar guidelines also now available in other developed countries including Australia, New Zealand, Japan, and Europe.

Energy and Macronutrients

Table 1 summarizes the daily dietary recommendations for energy and macronutrient intakes during pregnancy and the food sources providing those nutrients. Dietary guidelines for macronutrient intakes contain population nutrient intake goals that are expressed as a percentage of total energy intake and referred to as either an adequate macronutrient distribution range (AMDR) or a dietary goal. AMDRs and dietary goals are associated with reduced risk of chronic disease while ensuring adequate intakes (AIs) of essential nutrients. If dietary intake exceeds the AMDR or the dietary goal, there may be an increased risk of chronic diseases and/or inadequate intake of essential nutrients.

The systematic review by Blumfield and colleagues showed that in developed countries (the United States, Canada, the United Kingdom, Europe, Australia, New Zealand, and Japan), energy and macronutrient recommendations do not match with reported intakes of pregnant women. Energy and fiber intakes were consistently lower than recommendations, total fat and saturated fat intakes were generally above recommendations, and carbohydrate and PUFA intakes were either lower or marginal compared to recommendations. Due to limited experimental data, many nutrient targets for pregnancy have been set on the basis of theoretical calculations to establish what is believed to optimize the health and well-being of pregnant women and their offspring. Therefore, until epidemiological studies demonstrate consistent associations between exposure and health or disease outcomes, the implications of such macronutrient intakes for mother and offspring will be unknown.

Interestingly, a recent Australian study has shown that a moderate intake of protein (18–20% of total energy intake) allows pregnant women to eat the best range of foods across all the healthy core food groups in the Australian Guide to Healthy Eating (Australia's national food selection guide) while optimizing vitamin and mineral intakes. The ratio of protein to carbohydrate intake in the maternal diet during pregnancy has also been related to the amount of muscle and fat tissue in the developing fetus. While more research is needed, macronutrient intakes during pregnancy may contribute to offspring risk of developing diabetes in later life.

Micronutrients

Table 2 summarizes the daily micronutrient intakes recommended during pregnancy and the food sources providing

[c]Energy values expressed as the additional estimated energy requirement. 1 cal = ~4.2 kJ.

those nutrients. Each dietary guideline contains nutrient intake values suitable for comparison with group population intakes, which are referred to as an estimated average requirement (EAR), an AI, or an acceptable range of intake (ARI). The EAR is the daily nutrient level estimated to meet the requirements of half of the healthy individuals in a particular life stage and is used to estimate the prevalence of inadequate intakes in groups. The proportion below the EAR provides an approximation of the prevalence of inadequacy. When an EAR could not be set, either an AI or an ARI, which is the average daily nutrient intake level or the range of intakes that are assumed to be adequate, respectively, is used instead. The distribution of nutritional requirements within the population is illustrated in Figure 1.

Specific micronutrients are required during different periods of pregnancy for optimal fetal development, which influences fetal metabolism, organ growth, development, and function. The systematic review by Blumfield and colleagues showed that in high-income countries (the United States, Canada, the United Kingdom, Europe, Australia, New Zealand, and Japan), pregnant women consistently report intakes of folate, iron, and vitamin D that are below national recommendations. Thus, these nutrients require particular attention prior to conception to build up maternal nutrient

stores and during pregnancy to ensure women consume sufficient amounts.

Alcohol

Alcohol consumption during pregnancy can lead to miscarriage, stillbirth, premature birth, and/or fetal alcohol syndrome. Currently, there is no safe level of alcohol consumption during pregnancy identified. The National Institute for Health and Clinical Excellence (NICE) advises that pregnant women and women trying to conceive a baby should avoid alcohol altogether, especially in the first 3 months of pregnancy.

Table 3 Caffeine intake during pregnancy

The amount of caffeine found in some foods and drinks is as follows:
- One mug of instant coffee: 100 mg
- One mug of filter coffee: 140 mg
- One mug of tea: 75 mg
- One can of cola: 40 mg
- One can of energy drink: up to 80 mg
- One 50 g bar of plain chocolate: up to 50 mg
- One 50 g bar of milk chocolate: up to 25 mg

So caution is needed. For example, in one day, a woman will reach the 200 mg limit of caffeine if she has one of the following:
- One bar of plain chocolate and one mug of filter coffee
- Two mugs of tea and one can of cola
- One mug of instant coffee and one can of energy drink

Caffeine

Caffeine is present in tea, coffee, chocolate, cola drinks, energy drinks, and many over-the-counter remedies for colds and flu. Research by the CARE Study Group in 2008 suggests that small amounts of caffeine (up to 100 mg/day) are safe during pregnancy, but high levels (greater than 200 mg/day) increase the risk of miscarriage, premature birth, and low-birth-weight babies. The Food Standards Agency (FSA) recommends that pregnant and breastfeeding women limit their caffeine intake to 200 mg/day (Table 3).

Dietary Supplements

Women trying to conceive are advised by the NICE guidelines to supplement their dietary intake with 400 μg of folic acid daily 1 month before pregnancy and throughout the first trimester to prevent neural tube defects (NTD), which include anencephaly, spina bifida, and myelomeningocele. If there is a

family history of NTD, or the woman has previously had a baby with an NTD or has diabetes, then 5 mg of folic acid daily is recommended. Vitamin D supplements (10 μg/day) are recommended to support optimal fetal bone development and prevention of rickets during childhood. Women with dark skin or who always cover their skin are at particular risk of vitamin D deficiency.

The World Health Organization and other international government authorities (the United States, Australia, and New Zealand) recommend pregnant and lactating women consume a daily iodine supplement of 150 μg. Evidence from the Avon Longitudinal Study of Parents and Children (ALSPAC) suggests that pregnant women in the United Kingdom are at risk of mild–moderate iodine deficiency, which increases the risk of poor neurodevelopmental outcomes in children. Iodine deficiency should be treated as an important public health issue and iodine supplementation recommended for pregnant women. However, for pregnant women with preexisting thyroid disease, it should be managed individually to ensure normal thyroid function.

There is currently not enough evidence to support the recommendation of other supplements routinely during pregnancy, including multivitamin supplements. Multivitamin supplements may be recommended when there is a fairly high chance of not meeting nutrient needs from food. This is more likely for pregnant adolescents; vegetarians; those on preexisting special diets; individuals with drug, tobacco, and alcohol addiction; or obese pregnant women on medically restricted diets to limit weight gain. Pregnant women are at particularly high risk of low iron levels and iron-deficiency anemia. Thus, iron status needs to be regularly monitored and supplements commenced in cases of deficiency. Importantly, supplements containing vitamin A should be avoided during pregnancy, as they are teratogenic in the immediate postconception period. If inadequate nutrient intake is suspected or nutrient deficiency present, referral to a dietician is recommended for assessment and advice.

Food Recommendations during Pregnancy

Since individuals consume whole foods not just individual nutrients, food recommendations are often provided in a food selection guide to accompany dietary recommendations. A food selection guide is an educational and promotional tool, which converts scientific knowledge of food composition and nutritional requirements for health into a practical guide for food selection.

In the United Kingdom, the eatwell plate can assist individuals to choose a healthy, balanced diet by encouraging daily consumption of a wide variety of foods from each of the four core food groups (Figure 2). The core food groups include (1) bread, rice, potatoes, and other starchy foods (33% dietary intake); (2) fruit and vegetables (33% dietary intake); (3) milk and dairy foods (15% dietary intake); and (4) meat, fish, eggs, beans, and other nondairy sources of protein (12% dietary intake). A noncore, fifth food group contains foods and drinks that are high in fat and/or sugar (8% dietary intake).

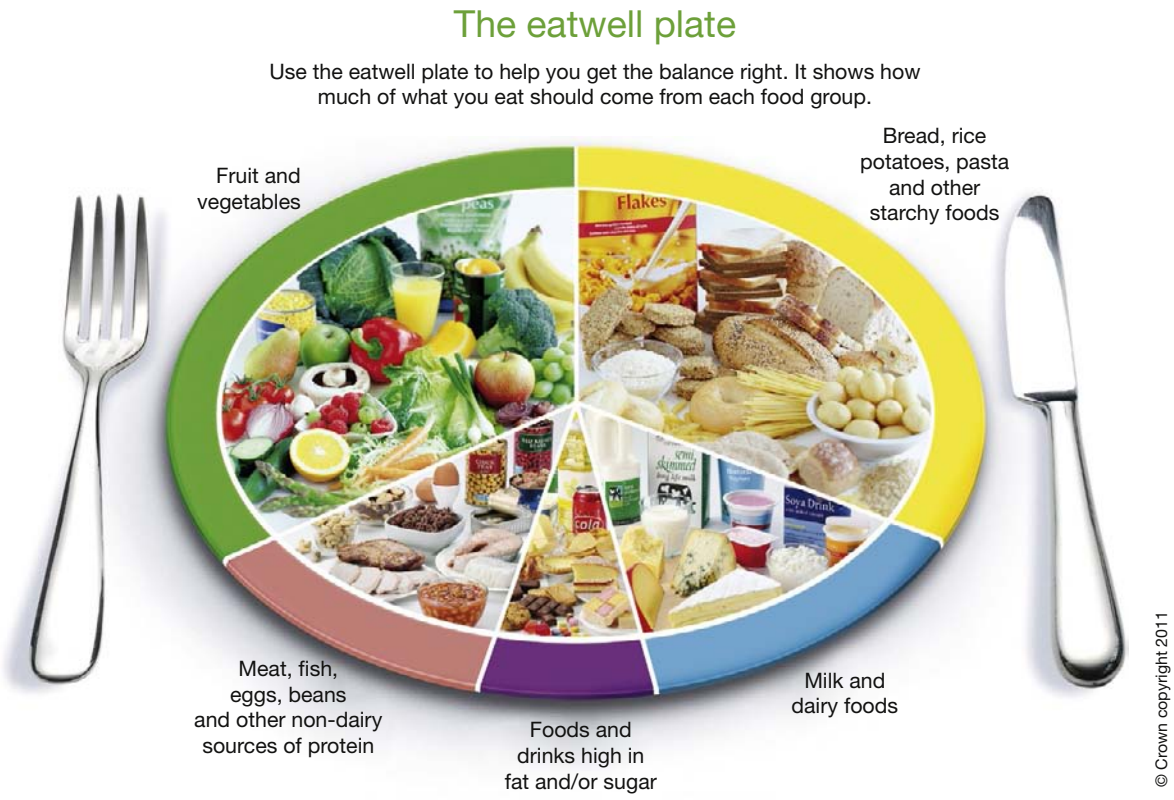

Figure 2 The eatwell plate.

Foods/drinks within this food group are not essential to a healthy diet and are only recommended in limited amounts due to being high in calories (energy) but low in nutrients. The eatwell plate is a visual tool that illustrates the proportion of total dietary intake that should come from each food group, including snacks. However, it does not include recommendations for number of daily servings or portion sizes, except for fruit, vegetables, and fish (see Figure 2).

In 2011, the US Department of Agriculture (USDA) and the US Department of Health and Human Services created MyPlate to provide food guidance to Americans, including individualized recommendations for pregnant women (see Figure 3). MyPlate is based on the 2010 Dietary Guidelines for Americans and illustrates five food groups that include grains, fruits, vegetables, protein, and dairy. The MyPlate resources are available in multiple languages that include English, Spanish, Chinese (simplified and traditional), Filipino, Hindi, Indonesian, Japanese, Korean, Malay, Pashto, Thai, Urdu, and Vietnamese. Promotion materials such as cookbooks are also available to translate recommendations to differing cultural eating patterns (www.choosemyplate.gov/).

During pregnancy, women are advised to follow a healthy diet that includes a large variety of foods from each food group. A similar illustrated food selection guide, adapted to the food habits and choices of other countries in the north and south of the planet, would benefit gestational nutrition worldwide. If individualized nutritional advice is required or women have specific issues that affect their eating habits or nutritional status, then consultation with a registered dietician is recommended.

Eating for Two during Pregnancy

Women do not need to 'eat for two' during pregnancy. While a woman's nutrient needs are higher during pregnancy, total energy requirements are only slightly higher (Table 1). Therefore, to meet the high nutrient demands of pregnancy, nutrient-dense foods need to be chosen from the five food groups (see Figure 2) to ensure excess calories are not consumed. Total energy requirements during pregnancy are dependent on many factors including physical activity. While energy is required for fetal growth and maternal fat deposition throughout pregnancy, women compensate for these additional demands by slowing down, becoming less active, and becoming more metabolically efficient. The best way to determine whether a pregnant woman is consuming an adequate energy intake is to monitor her weight gain and/or have her dietary intake assessed by a registered dietician.

Whole Foods versus Supplements

Nutritional requirements can be met through consumption of whole foods or whole foods plus supplementation. A recent review of nutrition research and practice has found that health benefits may be stronger when nutrients are consumed in a synergistic dietary pattern rather than in their purified form. The theoretical framework surrounding this concept has been termed 'food synergy.' Food synergy is based on the notion that the interrelations between constituents in foods are significant. This significance is dependent on the balance of constituents in food, the ability of the constituents to survive digestion, and their bioavailability at a cellular level. Different effects are likely to be evident between constituents in foods taken directly from their biological environment and those formulated through technological processing.

While supplementation may be beneficial in states of insufficiency, each nutrient has an asymmetrical U-shaped curve characterizing deficiency, safe range, and toxicity, which vary by individual and life stage. The risk of harm depends on the safe intake range of the nutrient, the susceptibility of the individual, and the absorption from alternative forms of dietary intake such as other supplements and whole foods. The UK dietary guidelines advocate that nutritional needs during pregnancy are to be met primarily through consumption of nutrient-rich foods within a varied diet. Supplements are not a food substitute, but may be useful when adverse health outcomes can be prevented or treated by a therapeutic nutrient dose when it is unable to be obtained through dietary intake alone. Therefore, to promote optimal maternal and fetal health during pregnancy, it is recommended that foods be considered first rather than supplements to address nutritional requirements. If nutrient needs are unable to be met through food intake alone, as is often the case with iron, supplements should be considered to ensure AIs are achieved.

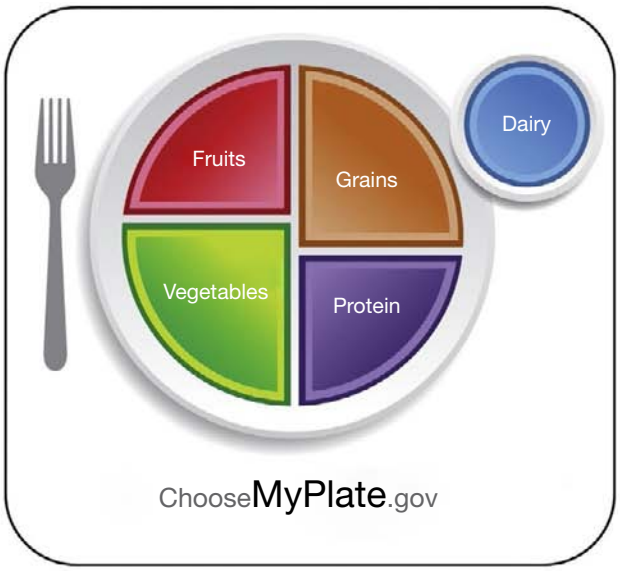
Food Safety during Pregnancy

There are some foodborne illnesses that cause adverse outcomes or harm the fetus during pregnancy. Pregnant women need to be especially careful to protect themselves and their unborn fetuses from listeriosis, salmonellosis, and toxoplasmosis. During pregnancy, women are more susceptible to these infections due to some suppression in their immune function. Additional awareness surrounding mercury is also required to ensure safe fish consumption. However, there is much confusion among the public and health professionals about which foods are safe to eat during pregnancy.

Listeriosis

Listeria monocytogenes is a microorganism found widely in the environment and can cause foodborne illness in pregnant women if ingested in a large dose. While the actual clinical burden of listeriosis is low, the consequences of infection are severe. Listeriosis during pregnancy can cause miscarriage, premature birth, neonatal infection, and/or fetal death following transmission of the organism across the placenta. *Listeria* is managed by hygienic preparation, storage, and handling of food. To reduce the risk of listeriosis during pregnancy, it is recommended that pregnant women wash their hands carefully and frequently and avoid specific 'high-risk' foods such as soft cheeses, cold meats, seafood, unpasteurized dairy products, and preprepared fruit and vegetables while consuming safer alternatives. Recommendations are summarized in Table 4.

However, the perceived risk of *Listeria* infection in pregnancy for many women appears to be much greater than the actual risk. This leads some women to severely restrict all



Food Group	1st Trimester	2nd and 3rd Trimester	What counts as 1 cup or 1 ounce?	Remenber to...
	Eat this amount from each group daily.*			
Fruits	2 cups	2 cups	1 cup fruit or juice ½ cup dried fruit	*Focus on fruits* — Eat a variety of fruits.
Vegetables	2 ½ cups	3 cups	1 cup raw or cooked vegetables or juice 2 cups raw leafy vegetables	*Vary your veggies* — Eat more dark-green and orange vegetables and cooked dry beans.
Grains	6 ounces	8 ounces	1 slice bread 1 ounce ready-to-eat cereal ½ cup cooked pasta, rice, or cereal	*Make half your grains whole* — Choose whole instead of refined grains.
Meat &	5 ½ ounces	6 ½ ounces	1 ounce lean meat, poultry, or fish ¼ cup cooked dry beans ½ ounce nuts or 1 egg 1 tablespoon peanut	*Go lean with protein* — Choose low-fat or lean meats and poultry.
Milk	3 cups	3 cups	1 cup milk 8 ounces yogurt 1½ ounces cheese 2 ounces processed cheese	*Get your calcium-rich foods* — Go low-fat or fat-free when you choose milk, yogurt, and cheese.

*These amounts are for an average pregnant women. You may need more or less than the average. Check with your doctor to make sure you are gaining weight as you should.

Figure 3 MyPlate food recommendations for pregnancy, published by the United States Department of Agriculture.

potential food sources of *L. monocytogenes*, which has implications for diet quality and nutrient intakes. The avoidance of foods potentially containing *L. monocytogenes* has been associated with lower nutrient intakes during pregnancy. This presents a challenging issue for public health authorities and pregnant women. Therefore, pregnant women must be encouraged to consume safer alternatives of high-risk foods to ensure nutritional adequacy is not compromised.

Table 4 Listeriosis during pregnancy. Examples of higher-risk foods and safer alternatives

Food type	*Higher-risk examples*	*Safer alternatives*
Cold meats	Unpackaged ready-to-eat from delicatessen counters, sandwich bars, etc. Packaged, sliced ready-to-eat	Home cooked meats. Store in fridge and use within a day of cooking
Chicken	Purchased (whole, portions, or diced) ready-to-eat	Home cooked chicken. Ensure chicken is cooked thoroughly, use immediately. Store any leftovers in the fridge and use within a day of cooking Hot takeaway chicken (whole or portions). Use immediately or store any leftovers in fridge and use within a day of purchase
Pate	Refrigerated pate or meat spreads	Avoid. No safe alternative
Salads (fruit and vegetables)	Preprepared or prepackaged salads from salad bars, smorgasbords, etc.	Homemade, freshly prepared salads. Wash all vegetables and fruits thoroughly. Store any leftover prepared salads in fridge, and use within a day of preparation
Chilled seafood	Raw (e.g., oysters, sashimi, or sushi), smoked ready-to-eat. Ready-to-eat peeled prawns (cooked) in prawn cocktails, sandwich fillings, prawn salads, etc.	All freshly cooked seafood. Use immediately. Store any leftovers in fridge and use within a day of cooking
Cheese	Soft, semisoft, and surface ripened cheeses – prepackaged and from delicatessen (e.g., brie, camembert, ricotta, feta, and blue)	Hard cheese (e.g., cheddar and tasty), processed cheese, cheese spreads, plain cream cheese, plain cottage cheese. Store in the fridge. Purchase cheeses packaged by the manufacturer
Ice cream	Soft serve	Packaged frozen ice cream. Maintain the ice cream frozen
Other dairy products	Unpasteurized dairy products (e.g., raw goats milk)	Pasteurized dairy products (e.g., yogurt, pasteurized milk, custard, and dairy dessert). Store in the fridge
Canned and similarly packaged foods	None	All. Store unused portion in the fridge in clean, sealed containers and use within a day

© Food Standards Australia New Zealand.

Table 5 Tips for safe food handling during pregnancy to prevent foodborne illness

- Always wash and dry hands thoroughly before and after handling food to prevent the spread of bacteria
- Keep cold food below 5 °C in the fridge and hot food above 60 °C (steaming) before serving. This will stop the growth of food poisoning bacteria
- Keep raw and cooked food separate. Do not use the same utensils, especially cutting boards and knives, for both
- Defrost frozen food in the fridge or microwave – never on the bench or in the sink
- Cook foods thoroughly. Poultry and meats should be well done with no pink visible and juices should be clear
- Avoid foods past their 'best before date' or 'use by' date

Salmonellosis

Salmonella is a common cause of food poisoning. Pregnant women are not at an increased risk of contracting salmonellosis, but severe cases can trigger intrauterine sepsis, miscarriage, or premature labor. To reduce the risk of salmonellosis, pregnant women should avoid foods containing raw egg, ensure animal products (meat, chicken, and eggs) are cooked thoroughly, and adopt good hygiene practices. Table 5 provides some tips for safe food handling to prevent foodborne illnesses.

Toxoplasmosis

Toxoplasma gondii is an organism that can be found in unpasteurized milk, undercooked meat, and unwashed fruit and vegetables and most commonly in cat and dog feces. Pregnant women have an increased susceptibility to *Toxoplasma gondii* infection due to alterations in cell-mediated immunity that occur during gestation. Toxoplasmosis during pregnancy is often asymptomatic and can lead to fetal brain damage and/or blindness. Therefore, pregnant women should wear gloves when gardening, wash hands after touching animals, not handle cat litter, and keep pets out of food preparation areas. Further tips to avoid toxoplasmosis include consumption of pasteurized dairy products, well-cooked meat, and freshly washed fruit and vegetables.

Mercury and Other Contaminants in Fish

Fish and seafood can be an important part of a healthy pregnancy diet. Fish is rich in protein and minerals, low in saturated fat, and a major source of healthy omega-3 fatty acids. During pregnancy, omega-3 fatty acids play an important role in the developing fetal central nervous system and are building blocks for the brain and retina. Research shows that maternal omega-3 fatty acid consumption during pregnancy (diet and/or supplements) is associated with improved neurodevelopmental outcomes in the child, while animal studies suggest deprivation of omega-3 fatty acids during pregnancy is associated with irreversible visual and behavioral deficits in offspring. Population surveys indicate that pregnant women do not consume adequate amounts of omega-3 fatty acids and eat minimal fish, in part due to fears surrounding adverse effects of mercury and other harmful toxins (e.g., polychlorinated biphenyls).

Table 6 Guidelines for how pregnant women can safely include fish in their diet

1 Serve equals 140 g
2 Serves per week of any fish and seafood not listed below
OR
4 Medium cans per week of tuna (140 g each) and 2 serves per week of oily fish
OR
1 Serve per week of orange roughy (deep-sea perch) or catfish and no other fish that week
AND
Pregnant women should not eat shark (flake) or billfish (swordfish, broadbill, and marlin)

Mercury occurs naturally in the environment and accumulates in fish as methylmercury. Fish absorb the methylmercury as they feed on other fish, with levels dependent on the amount of fish eaten and the levels of mercury in those fish. Processing techniques such as canning, freezing, and cooking do not reduce the mercury content in fish. Table 6 presents guidelines for how pregnant women can safely include fish in their diet to ensure they consume the necessary important nutrients to optimize fetal development.

Barriers to Nutritional Adequacy

Three reviews have evaluated the effectiveness of nutrition education interventions to promote healthy eating in pregnancy. The reviews report that pregnant women appear motivated to improve dietary intakes and make lifestyle changes in line with recommendations when provided with education. However, pregnant women commonly described barriers to making changes to achieve nutritional adequacy that included understanding the importance of good nutrient intakes, limited nutrition knowledge, anxiety with avoiding the risk of *Listeria* infection, quality of experiences with health professionals, and physical health. In focus group sessions conducted in Australia, pregnant women were aware that a healthy diet was important but were unsure what this meant in practical terms during this life stage. There was uncertainty surrounding food serving sizes. Many women believed the importance of maternal diet was secondary, as fetal nutritional needs would be met irrespective of maternal dietary intake. Pregnant women reported knowledge of the consequences of listeriosis but found it difficult to get consistent information, had difficulty making suitable food choices, and ultimately experienced a large amount of guilt and responsibility attached to making possible 'wrong' food choices. General practitioners were viewed as having an important role in distributing quality nutrition information. However, the quantity and quality of the nutrition information received were highly variable, and printed material often lacked the practical information required to select and achieve a healthy diet. Lastly, food cravings and conditions such as hyperemesis gravidarum, constipation, and heartburn also influenced dietary intake during pregnancy.

Common Nutrition-Related Concerns of Pregnancy

Nausea and vomiting, constipation, heartburn, and food sensitivities are common nutrition-related symptoms in pregnancy. Dietary strategies to minimize these maternal discomforts are listed in Table 7.

Nausea and Vomiting

Nausea and vomiting (often called morning sickness) is experienced by most pregnant women and can range in intensity from slight to severe. While symptoms are more common in the morning and early stages of pregnancy (4–16 weeks gestation), they can occur at any time of the day or night and at any stage of pregnancy. Possible causes include high levels of hormones (including estrogen), fluctuations in blood pressure (particularly lowered blood pressure), and altered carbohydrate metabolism. Severe vomiting during pregnancy or hyperemesis gravidarum can cause weight loss and dehydration, and women may require hospitalization, intravenous fluids, and parenteral nutrition. Health professionals are urged to reassure women that nausea and vomiting during pregnancy will have no adverse effect on their developing fetus. Strategies to minimize nausea and vomiting during pregnancy are listed in Table 7. Although some women may benefit most from simply consuming the foods they enjoy when they feel like eating. Comfort may also be found in more temperate environments.

Heartburn

Gastroesophageal reflux disease, or heartburn, occurs in 40–85% of pregnant women. Similar to nonpregnant women, reflux during pregnancy is due to a decrease in lower esophageal sphincter pressure (caused by estrogen and progesterone changes) and/or an increase in intra-abdominal pressure (caused by the growing fetus). This combination enables the stomach acid to back up into the lower esophagus and creates a burning sensation near the heart. Although heartburn is occasionally experienced in the first trimester, it is more common in the third trimester. Ways to help relieve heartburn are included in Table 7.

Constipation and Hemorrhoids

Constipation can develop or increase in severity during pregnancy, with prevalence reported as 11–38%. Constipation during pregnancy has been linked to rising hormone levels (both progesterone and estrogen) relaxing the muscles of the bowel, low fluid and fiber intakes, parity, and previous cesarean delivery. Women usually prone to constipation are more likely to become constipated during pregnancy and may further develop hemorrhoids (swollen veins of the rectum). Hemorrhoids can be painful and straining during bowel movements may cause bleeding. Pregnancy-induced constipation is usually mild and can be self-treated with a mix of high-fiber foods, including soluble (oats, lentils, dried peas and beans, and psyllium) and insoluble (whole wheat and whole grain breads and cereals, wheat bran, vegetables, and fruit) fibers or nonprescription methods (Table 7).

Table 7 Institute of Medicine weight gain recommendations for pregnancy[a]

Prepregnancy weight category	*Body mass index*[b]	*Total weight gain range (kg)*	*Rates of weight gain*[c] *in the 2nd and 3rd Trimester (mean range in kg/week)*
Underweight	<18.5	12.5–18.0	0.5 (0.5–0.6)
Normal weight	18.5–24.9	11.5–16.0	0.5 (0.2–0.5)
Overweight	25.0–29.9	7.0–11.5	0.3 (0.2–0.3)
Obese (includes all classes)	≥30.0	5.0–9.0	0.2 (0.2–0.3)

[a]Rasmussen, K. M., and Yaktine, A. L. (eds.). (2009). Weight gain during pregnancy: re-examining the guidelines. Washington DC: Institute of Medicine, National Academy of Sciences.
[b]Body mass index is calculated as weight in kilograms divided by height in meters squared or as weight in pounds multiplied by 703 divided by height in inches.
[c]Calculations assume a 0.5–2 kg (1.1–4.4 lbs) weight gain in the first trimester (based on Siega-Riz et al., 1994; Abrams et al., 1995; Carmichael et al., 1997).

Food Cravings and Aversions

Pregnant women often experience food cravings and aversions, with worldwide prevalence reported between 50% and 90%. The most common cravings include dairy and sweet foods such as fruit and fruit juices, sweet desserts, and chocolate, whereas the most common aversions are to alcohol, caffeinated drinks, meats, fish, poultry, and eggs. These behaviors are particularly prominent during the first and third trimesters of pregnancy.

Despite significant research in the field, the etiology of these behaviors remains inconclusive. It is likely that the cause for food cravings and aversions is multifactorial and involves a combination of biological, psychological, and environmental factors, as opposed to purely reflecting physiological needs. Therefore, common cravings of ice cream during pregnancy are unlikely to signify a calcium deficiency. Importantly, not all food cravings and aversions contribute to a nutritious diet. Some women develop cravings for nonfood items such as detergents, clay, or soil, which is known as pica. Pica is particularly common in African American women and is often associated with iron-deficiency anemia. However, whether iron deficiency leads to pica or pica leads to iron deficiency remains unclear. Additionally, women often report aversions for meats and eggs, which could lead to a reduced protein intake, a key macronutrient for fetal growth and development. Knowledge of a pregnant woman's total dietary intake is required before the nutritional effect of food cravings or aversions can be assessed. In general, most food cravings increase calcium and energy intakes, while food aversions decrease intakes of alcohol, caffeine, and animal protein. Generally, these behaviors do not have a deleterious effect on diet quality. However, repeated intakes of energy-dense foods may promote excessive weight gain during pregnancy and increase the risk of pregnancy complications.

Weight Gain during Pregnancy

Weight gain during pregnancy plays an important role in the growth and development of the fetus, placenta, amniotic fluid, maternal tissues (uterus and breasts), blood supply, extracellular fluid, and maternal fat stores. Sufficient maternal weight gain is essential to prevent low-birth-weight babies, a significant determinant of neonatal mortality, infant/childhood morbidity, and child's risk of chronic disease in later life. The World Health Organization states that maternal weight gain between 10 and 14 kg during pregnancy is associated with optimal birth weight outcome (between 3.1 and 3.6 kg) and will reduce the risk of fetal and maternal complications.

However, weight gain recommendations for women during pregnancy are largely dependent on prepregnancy weight. Underweight women are encouraged to gain more weight and overweight women may need to put on less weight. Importantly, excessive weight gain should be avoided. Excessive weight gain during pregnancy increases the risk of complications such as gestational diabetes, pregnancy hypertension, preeclampsia, and congenital defects. It also increases the risk of birth complications including induced labor, instrumental delivery, shoulder dystocia leading to obstructed labor, cesarean delivery, and postpartum hemorrhage. Weight loss during pregnancy is not recommended as the relationship between weight change during pregnancy and fetal outcomes is not fully elucidated and sufficient dietary consumption is required for optimal fetal growth and development. Therefore, women should ideally commence pregnancy at a healthy body weight (body mass index (BMI), 18.5–24.9 kg m^{-2}). The Institute of Medicine weight gain recommendations for pregnancy are presented in Table 8.

Ideally, women with a BMI over 30 would be encouraged to lose weight before pregnancy and need to be informed about the increased risks to themselves and their babies. If already pregnant, then encourage moderate weight gain only, with weight loss delayed until after pregnancy. Refer pregnant obese women (BMI ≥ 30) to a dietician for assessment and individualized dietary advice. It is important to monitor weight gain during pregnancy by weighing women regularly.

Fetal Origins of Noncommunicable Diseases

The rapid worldwide shift towards a population with a greater obesogenic phenotype suggests it may be driven by environmental factors as opposed to genetic contributions. Although current lifestyle factors play a vital role in the progression of

Table 8 Dietary strategies to minimize common maternal discomforts during pregnancy

To minimize nausea:	*To prevent/minimize constipation*:	*To prevent/minimize heartburn*:
Eat small, frequent meals (i.e., every 2 h). An empty stomach can cause nausea	Eat a variety of high-fiber foods (fruits, vegetables, whole grain cereals, legumes, nuts, and seeds)	Eat small, frequent nutritious meals (avoid large meals)
Avoid foods with offensive odors	Try a mix of brans including wheat bran, oat bran, and psyllium. Aim for 1–2 tablespoons/day	Drink between meals rather than with meals
Avoid large drinks. Have frequent small drinks, preferably between meals to avoid dehydration	Aim for a fiber intake between 25 and 28 g/day	Avoid high-fat foods, spicy foods, and caffeine
Limit fatty, spicy, and fried foods	Drink plenty of fluids (preferably water)	Eat slowly and chew food thoroughly
Have someone else prepare meals or prepare food at times of the day when you feel better	Aim for fluid intake between 1.5 and 2.0 l/day	Always sit down to eat.
Eat dry toast or plain crackers on waking and arise slowly	Exercise regularly	Avoid eating on the run
Eat a healthy snack before bed at night	Respond promptly to the urge to defecate	Wait 1–2 h after finishing a meal before lying down or exercising
Drink ginger root tea, but limit intake to no more than 3 g of raw ginger per day (approx. three teaspoons)	If laxatives are required, only use those prescribed by your doctor. Not all laxatives are safe during pregnancy. Only occasional/short-term use is advised to avoid dehydration, electrolyte imbalances, and dependency	Elevate the head with a couple of pillows while sleeping
	Oral iron supplements can sometimes cause constipation. If you suspect this may be causing constipation, consult your doctor	Avoid wearing tight clothing

adverse health outcomes, mounting evidence indicates that early life environmental factors such as maternal nutrition during pregnancy can program the health outcomes of an individual in later life. Presently, the maternal nutritional insults that have been found to program a range of adverse health outcomes in later life are overnutrition, hyperglycemia, and undernutrition of energy, protein, vitamins, or iron. Specific evidence indicates that the intrauterine environment can program a child's body composition and metabolic-endocrine axes. This has implications for the susceptibility and adaptability of the child to future environmental conditions. Therefore, maternal insults that influence the intrauterine environment have the potential to play an extremely important role in the prevention of noncommunicable diseases.

Maternal Undernutrition

Maternal undernutrition was first investigated in pregnant women exposed to the Dutch famine during World War II in 1944–45. Retrospective human data showed that famine during pregnancy had adverse effects on adult health, and outcomes were dependent on the gestational period in which the dietary restriction occurred. Exposure to undernutrition in the first trimester produced children with an increased susceptibility to coronary heart disease compared with those exposed in other trimesters. Undernutrition in the second trimester was associated with an increased incidence of renal disease, while exposure in the third trimester was associated with reduced birth weight and decreased glucose tolerance. These differential effects align with the chronological development of the fetus. Cardiovascular growth takes place during early gestation, kidney development during midgestation, and adipose and muscle tissue growth during late gestation.

David Barker and colleagues reported an association between lower birth weight and increased risk of cardiovascular disease, stroke, hypertension, glucose intolerance, and T2DM. It was concluded that the fetal environment played a critical role in susceptibility of cardiometabolic disease. Rodent studies have used overall calorie restriction to model maternal undernutrition during pregnancy. Results reported were dependent on the timing, length, and degree of dietary restriction. A 50% calorie restriction in the first and second trimester led to hyperphagia and delayed-onset obesity in male (not female) offspring independent of postnatal diet. A strict 30% of ad libitum diet throughout pregnancy resulted in offspring with adult-onset obesity, hyperinsulinemia, and hyperleptinemia associated with hyperphagia and hypoactivity, whereas a mild 30% calorie restriction throughout gestation reduced birth weight and increased catch-up growth and sensitivity to high-fat diet (HFD)-induced obesity.

Maternal Overnutrition

Maternal overnutrition is characterized as excess dietary intake and may lead to diet-induced obesity. Epidemiological evidence indicates a positive relationship between maternal obesity during pregnancy and the onset of obesity and metabolic syndrome in offspring. This relationship has been found to be independent of gestational diabetes. In human studies, offspring adiposity has been positively related to a woman's BMI during gestation, while weight gain and BMI between pregnancies can influence a child's susceptibility to obesity in both directions, compared to their siblings. This disproportionate risk in children from the same mother under different intrauterine conditions supports the effect of environmental stimuli on the physiological programming of offspring phenotype.

In animal studies, the most common model of maternal overnutrition has involved feeding animals an HFD or obesogenic diet (high fat and sugar). Rhesus macaques fed with an HFD during pregnancy produced offspring that developed nonalcoholic fatty liver disease that included triglyceride accumulation and a twofold increase in percent body fat. Interestingly, in subsequent pregnancies, when these mothers consumed a control diet, the adverse effects in offspring were prevented. In rats, an HFD during pregnancy produced offspring with increased adiposity, insulin resistance, and

hypertension. Consumption of a junk food diet (high energy, fat, sugar, and salt) during gestation led to offspring with hyperphagia, reduced skeletal muscle mass, a postnatal preference for junk food, and increased weight gain when weaned onto a junk food diet. In sheep, maternal diet-induced obesity led to fetuses with increased triglyceride levels and offspring with upregulated inflammatory signaling and lipogenic genes, increased fat deposition, and reduced skeletal muscle development. Metabolic syndrome constituents were intensified in offspring exposed to maternal overnutrition *in utero* and an obesogenic postnatal environment. However, interpretation of the evidence remains complicated by the different durations of exposure and dietary compositions reported in each model. An increase in one dietary component will result in the reduction of another. It is unknown whether the causal factor is the increased fat content or the reduced carbohydrate or protein contents or simply the excess energy content in maternal diet.

It remains inconclusive as to whether the effect on fetal phenotype is due to the maternal diet itself or the maternal metabolic variables associated with obesity. The effects of maternal weight gain and diet during gestation have proved difficult to segregate in animal models due to models generally using an obesogenic diet to induce maternal weight gain and obesity. Thus, outcomes may be produced by diet, maternal obesity, or a combination of the two. While evidence is building to suggest the gestational diet may impart independent effects on offspring phenotype, the critical timing of exposure remains unknown.

Introduction

Pregnancy is a dynamic anabolic state with increased nutritional requirements to support growth and metabolism of maternal and fetal tissues, nutrient storage in the fetus, and preparation of maternal tissues for lactation. Although these additional nutrient needs may be met by increased maternal dietary intake, part of the increased demands is met by complex physiological adjustments and changes in nutrient metabolism that evolve continuously throughout pregnancy according to the changing requirements at different stages of gestation.

Metabolic adjustments depend on each nutrient and may include uptake and accretion in new tissues, deposition in maternal stores, redistribution among tissues, and increased turnover or rate of metabolism. For certain nutrients, physiological adjustments favor a more efficient utilization of the nutrient from the diet by increased intestinal absorption and/or reduced excretion through urine or the gastrointestinal tract. For each nutrient, more than one adjustment may be acting (Table 1).

Metabolic and physiological adjustments during pregnancy respond to the hormonal changes during gestation, the fetal nutrient demands, and the maternal nutrient supply through diet or mobilization of nutrient reserves. Adjustments vary widely between women depending on several factors such as lifestyle behavior, genetic background, habitual diet, use of supplements, and prepregnancy nutritional status.

Within the physiological capacity of adaptation, the developing fetus is protected from nutrient deficiency or excess in the maternal diet. However, a limit in the capacity for adjustment of the maternal organism during pregnancy may be reached depending on complex factors and interactions not yet fully studied. Limited access to a variety of foods, intense physical activity, adolescent motherhood, poor nutritional status prior to pregnancy, and environmental exposure to toxic substances (i.e., mercury, lead, pesticides, and dioxins) or infectious agents (i.e., foodborne pathogens such as listeria as well as salmonella, tuberculosis, malaria, intestinal parasites, and HIV) impose additional stress on the physiological capacity of adaptation during pregnancy. When this capacity is exceeded, fetal growth and development and pregnancy outcome may be impaired. If undernutrition or excess of certain nutrients affects the fetus, there may be short-term and lifelong adverse health effects.

Table 1 Metabolic and physiological adaptations affecting nutrition utilization during pregnancy

Adaptation	*Example of nutrients affected*
Increased tissue uptake	Amino acids, iodine, folate, iron
Redistribution among tissues	Zinc, iron, calcium, vitamin A, vitamin D, vitamin B_{12}
Increased turnover/ metabolism	Protein (amino acids), zinc, folate, calcium, iodine, vitamin D
Increased maternal stores	Fat
Increased intestinal absorption	Iron, calcium, zinc
Reduced endogenous losses	Protein (nitrogen), zinc

Changes in Maternal Physiology and Metabolism during Pregnancy

Hormonal Changes

Changes in maternal hormone secretion during pregnancy contribute to maintain the pregnancy state and to modify the utilization of nutrients (especially carbohydrates, fat, and protein) in order to stimulate maternal tissues to make greater use of lipids as energy-yielding substrates and to increase the availability of glucose, amino acids, and micronutrients for fetal growth. Hormonal changes also contribute to ensure that maternal lean tissues are conserved and spared for providing energy or amino acids for the fetus.

Soon after implantation, the corpus luteum and the placenta secrete hormones to ensure the maintenance of pregnancy and to influence metabolism in preparation for the developing fetus. Serum human chorionic gonadotropin increases rapidly during the first 2 weeks of gestation, reaches a peak at about 8 weeks, and then gradually declines but remains elevated until delivery. Serum human placental lactogen increases continuously throughout pregnancy parallel to the increase in placental mass, reaching a concentration at term about 20 times higher than before conception. This hormone affects the metabolism of carbohydrates and lipids, antagonizing the action of maternal insulin and stimulating maternal lipolysis, thus contributing to direct energy-yielding substrates to the fetus.

The corticotropin-releasing hormone (CRH) is produced by the placenta by 8 weeks after conception but remains usually undetectable in maternal serum until the last trimester of pregnancy when there is a gradual increase to about 50-fold. Placental CRH stimulates the production of fetal cortisol that in turn blocks the inhibitory effect of progesterone on placental synthesis of CRH and fetal cortisol. Maternal serum CRH is increased in preeclampsia and by maternal stress and infections and is associated with higher risk of preterm delivery.

Progesterone and estrogens serum concentrations rise progressively throughout pregnancy increasing over fivefold and tenfold, respectively, from 10 to 40 weeks of pregnancy. After 8–10 weeks of gestation, the main source of these hormones is the placenta although estrogens are also originated in the fetus and other maternal tissues. Progesterone stimulates maternal respiration and relaxes smooth muscle contributing to the atony of the uterus and the urinary and gastrointestinal tracts.

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00565-1

Estrogens (estradiol, estrone, and estriol) influence carbohydrate and lipid metabolism, increase the rate of maternal bone turnover, stimulate the conversion of maternal pituitary somatotroph cells into prolactin-secreting cells (in preparation for lactation), and help prepare the uterine muscle cells for delivery.

Blood Volume and Composition and Other Physiological Changes

As gestation progresses, several maternal organ systems adapt to the changing needs. The size of the heart increases by about 12% and cardiac output increases by about 40% in response to the increased oxygen demands. Although lung capacity is reduced by about 5% (due to elevation of the diaphragm by the enlarged uterus), alveolar ventilation increases as pregnancy progresses resulting in a more efficient gas exchange. Gastrointestinal motility is reduced, and consequently, transit time is longer allowing for increased nutrient absorption. The kidneys increase slightly in size, and renal plasma flow and glomerular filtration rate increase by about 75% and 50%, respectively, resulting in an increased urinary excretion not only of metabolic end products but also of certain nutrients. Maternal blood volume gradually expands with a modified cell and plasma composition that serves to increase the tissue supply of oxygen and nutrients and also to prepare for blood loss at delivery.

Compared to the nonpregnant state, total blood volume increases 35–40% during pregnancy, mainly by expansion of plasma volume (45–50%) and proportionally less expansion of red cell mass (15–20%). As a result of this 'hemodilution of pregnancy,' hemoglobin concentration and hematocrit values decrease especially at midpregnancy (20–30 weeks), when there is the largest increase in plasma volume, but increase slightly again in the third trimester. For these reasons, the recommended hemoglobin and hematocrit cutoff values for screening for anemia in pregnant women are trimester-specific and lower than for nonpregnant women.

Plasma volume starts to increase at 6–8 weeks of gestation, expands rapidly up to 30–34 weeks, and tends to plateau thereafter. By the end of pregnancy, the total increase in plasma volume is about 1500 ml. Red cell mass increases by about 200–250 ml during pregnancy driven by the increase in maternal erythropoietin production. The increase in red blood cell mass is greater with the use of iron supplements. Total white blood cell count increases during pregnancy although within the normal range. Neutrophils are the major type of leucocytes increased, possibly due to reduced apoptosis, and have increased oxidative metabolism. Monocyte-to-lymphocyte ratio markedly increases during pregnancy. Platelet count decreases particularly during the third trimester, a condition named 'gestational thrombocytopenia.'

Plasma concentration of total protein, particularly albumin and γ-globulin, most amino acids, some minerals, and water-soluble vitamins, decreases during pregnancy due in part to hemodilution, increased glomerular filtration rate, and/or changes in turnover or metabolism. In contrast, plasma concentration of α1-, α2-, and β-globulins, lipid fractions (particularly triacylglycerol and also VLDL, LDL, and HDL), and fat-soluble vitamins usually increases during pregnancy. Most of these changes occur during the first 10 weeks of gestation. For those nutrients that have a decreased concentration during pregnancy, reduction is much less than the 40-fold increase in plasma volume. Therefore, the total amount of energy-yielding substrates, vitamins, and minerals in the maternal circulation increases during pregnancy.

Fetal Demands

The demand for nutrients gradually evolves during gestation both in total amount and in particular nutrients required. Three main physiological stages of fetal development are usually described during pregnancy: implantation, organogenesis, and growth. Animal studies indicate that the presence or absence of certain nutrients particularly at the early stages of gestation is critical for normal development. The total amount of nutrients needed becomes critical during the second half of gestation when most of the fetal growth occurs.

During implantation and up to 2 weeks of gestation, the fertilized ovum embeds in the uterine wall and receives nutrients directly provided by the uterine secretions. At this stage, there are specific nutritional needs, but quantitative requirements are negligible.

During tissue differentiation and organogenesis, mostly occurring from 2 to 6 weeks of gestation, nutrients are provided from the maternal circulation. At this stage, lack or excess of certain nutrients can cause specific congenital abnormalities. For example, evidence from animal studies indicates that folate, vitamin B_{12}, vitamin A, and niacin deficiencies cause defects in the central nervous system; vitamin B_6 and manganese deficiencies impair neuromotor development; riboflavin deficiency affects the formation of the skeleton; and zinc deficiency or excess of vitamin A causes multiple organ malformations and embryonic death. In contrast, much less is known about the effects of specific nutrient deficiencies on organogenesis in humans. Only folate has been clearly recognized as a critical micronutrient for the prevention of neural tube defects.

During the remaining 30–32 weeks of pregnancy, most fetal growth occurs, initially by hyperplasia (rapid increase in the number of cells), later by simultaneous increase in cell size, and finally by hypertrophy (cells growing mostly in size). Critical nutrients for cell division are folate, vitamin B_{12}, and zinc, while sufficient supply of amino acids, vitamin B_6, and glucose is required for cell growth. During this rapid growth period, nutrients are delivered from mother to fetus through the placenta. Some nutrients are transferred across the placenta by simple diffusion (e.g., free fatty acids, cholesterol, and fat-soluble vitamins) whereas others by facilitated (carrier-mediated) diffusion (e.g., glucose) or active transport (e.g., amino acids, most water-soluble vitamins, calcium, iron, and zinc). In the latter case, nutrient concentrations are usually higher in fetal than in maternal circulation. Similarly to the phase of organogenesis, little is known on the effect of specific nutrient deficiencies during fetal growth in humans, although there is strong evidence that nutritional deficiency during this phase causes intrauterine growth retardation and low birth weight and increased risk of impaired immune function. However, inadequate nutrition at this stage will not cause developmental abnormalities.

Changes in Maternal Body Composition and Weight Gain

Gestational weight gain usually follows a sigmoid curve. Approximately 5% of the total weight gain occurs during the first trimester of pregnancy and the remainder 95% is gradually gained at an average rate of about 0.45 kg per week during the second trimester and 0.40 kg per week during the third trimester. The average total weight gain in full-term healthy primigravidas is about 12 kg although the amount of weight gain varies widely among women. Total weight gain is inversely related to maternal prepregnancy body mass index. Mean total weight gain during a full-term pregnancy ranges between 10 and 16.7 kg in normal weight adult women and is lower than 11 kg in overweight and obese women. Higher total weight gains normally occur in adolescent women, in thin women, and in twin or multiple pregnancies. Current recommendations of weight gain during pregnancy are set according to prepregnancy maternal weight for height categories. A normal weight gain during pregnancy is more likely to be associated with optimal reproductive outcome, fetal and infant growth, and development.

Two major components contribute to weight gain during pregnancy: the products of conception (fetus, amniotic fluid, and placenta) and the accretion of maternal tissues (expansion of blood volume and extracellular fluid, enlargement of uterus and mammary glands, and increased adipose tissue). Of the total weight gain, the fetus accounts for ~27%, amniotic fluid 6%, and the placenta 5%. Maternal tissue accretion contributes mainly with fat deposition (average 27%, although highly variable between women). The majority of the maternal fat deposited during pregnancy is subcutaneous. In healthy pregnant women, fat appears to be deposited mainly in the hips, back, and upper thighs. This pattern of fat deposition appears to be unique of pregnancy. Fat deposition occurs mainly during the first 30 weeks of gestation under progesterone stimulation. This early fat deposit acts as an energy store for late pregnancy and during lactation. The increase in fat-free mass during pregnancy represents mainly an increase in body water. The amount and pattern of gestational weight gain are strongly influenced by changes in maternal physiology and metabolism and by placental metabolism.

Nutritional Requirements during Pregnancy

Approaches for Estimating Nutritional Needs during Pregnancy

Assessment of nutritional requirements during pregnancy is challenging due to the continuous alteration in nutrient metabolism and turnover that affect concentrations in tissues and fluids and the gradual shift in the efficiency of nutrient utilization that contributes to attain homeostasis.

For most nutrients, including energy, protein, and minerals, requirements during pregnancy have been assessed using the factorial approach. This involves estimates of the total amount of the extra energy and nutrient accumulated in the mother (blood, breast, uterus, and adipose tissue) and the products of conception (fetus, placenta, and amniotic fluid) during the whole pregnancy, above the nonpregnant nonlactating state, and correction by a factor to cover for the inefficient nutrient use for tissue growth. This approach relies on indirect data and does not allow for estimates of requirements by gestational stage.

For protein and some minerals, balance studies have been used to assess nutrient retention at different stages during pregnancy. In these studies, measurement of the nutrient intake and losses from the body is done as precisely as possible during a period of time (in general during 3 weeks), and the difference is taken to indicate net retention (or loss) during the assessed period. Because not all possible sources of body losses are measured, balance studies tend to overestimate intake and underestimate losses. Also, because balance studies are carried out over short periods of time at specific stages of pregnancy, results cannot be extrapolated to the entire pregnancy.

For a few nutrients, such as folate, evidence has been obtained from experimental human studies on the amount of intake needed to attain adequate tissue concentrations (e.g., erythrocytes) and nutrient-dependent functions (e.g., enzyme activity). For many vitamins and minerals, observational studies and intervention trials have related maternal intakes to pregnancy outcomes.

Recommended nutrient intakes during pregnancy are set by expert scientific committees of different countries or organizations, based on the interpretation of the available evidence on nutritional requirements during pregnancy. The most widely used set of nutrient recommendations are those developed by the Food and Agriculture Organization/World Health Organization (FAO/WHO) and by the Institute of Medicine (IOM) for the United States and Canada (Dietary Reference Intakes, DRIs). The percent increase of recommended daily nutrient intake during pregnancy over the nonpregnant nonlactating state differs between nutrients and may differ between scientific organizations (Figure 1).

Specific Nutrient Metabolism and Requirements

Energy

Theoretical estimations of the overall energy cost of pregnancy in well-nourished women have been done based on the contribution of three main components: (1) the energy deposited as new tissue in the products of conception (placenta, uterus, amniotic fluid, fetus, mammary glands, and expansion of blood volume), approximate cost 5000 kcal; (2) the energy deposited in fat, approximate cost 36 000 kcal; and (3) the energy required to maintain the new tissues, approximate cost 36 000 kcal.

Several longitudinal studies have measured changes in basal metabolic rate (BMR), energy expenditure, and energy deposition during pregnancy in different populations, thus providing experimental evidence for estimating requirements. These studies have shown that energy requirements during pregnancy have a large variability within individuals and between populations and are influenced by several factors, including prepregnancy body weight, body mass index and body fat, maternal age, BMR, and level of physical activity.

Estimated energy requirements (EERs) during pregnancy by the FAO/WHO have been based on multiples of BMR and the level of physical activity. For each trimester of pregnancy, studies indicate that the average increase in BMR is 5%, 10%, and 25%, and the average increase in total energy expenditure (TEE) is 1%, 6%, and 17%, respectively, over prepregnancy values. EERs during pregnancy have been also derived from studies using the double-labeled water technique. EER is

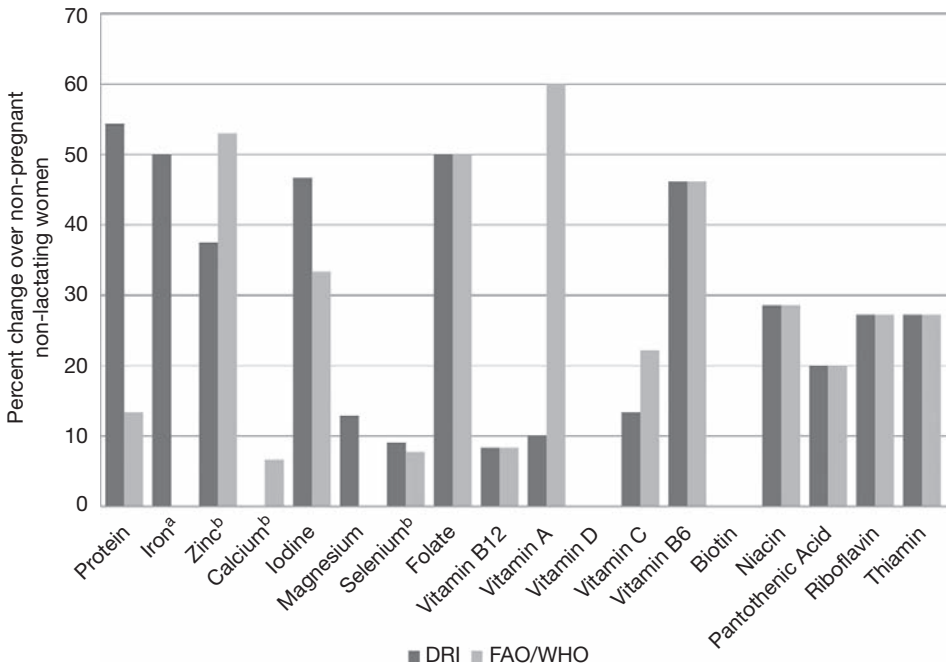

Figure 1 Percent changes in recommended nutrient intakes during pregnancy over the nonpregnant state. The [a]FAO/WHO recommends taking iron supplements up to 100 mg to all pregnant women. [b]For the FAO/WHO, percent change over nonpregnant nonlactating women was calculated considering the average recommended intake throughout pregnancy.

estimated as the sum of TEE of the nonpregnant woman plus the estimated median change in TEE of 8 kcal per gestational week, plus 180 kcal per day for energy deposition in maternal and fetal tissues during pregnancy. Taken together, these approaches translate into recommended increases of energy intake of 340 kcal per day in the second trimester and 452 kcal per day in the third trimester.

The capacity for physiological adaptation in energy metabolism during pregnancy is complex and highly variable. Adequate maternal weight gain and fetal growth are good indicators that maternal energy intake is adequately meeting energy requirements during pregnancy.

Protein

Adaptation in maternal nitrogen metabolism starts early during pregnancy and favors nitrogen conservation and protein deposition in the fetus and maternal tissues. There is a shift in the partitioning of amino acids for oxidation and protein synthesis favoring the latter. Maternal urea synthesis is reduced, therefore, with less utilization of amino acids as energy substrates. The rate of transamination of branched-chain amino acid is also reduced. During the second half of pregnancy, insulin secretion increases associated with greater insulin resistance. Thus, there is an increase in circulating glucose available for transfer to the fetus that indirectly spares amino acids for protein synthesis. Isotopic studies indicate that protein turnover increases during pregnancy and that the increase in protein synthesis is about 25% by late pregnancy compared to the nonpregnant state. There is evidence that metabolic changes in amino acid utilization during pregnancy may be limited by micronutrient status.

Using the factorial approach, the estimated total protein accretion during a full-term normal pregnancy is 925 g. Most of protein is accrued in the fetus (42%) and also in the uterus (17%), blood (14%), placenta (10%), and mammary tissue (8%). Balance studies in women before and during pregnancy indicate that nitrogen retention increases gradually during gestation particularly from the second to third trimesters. The increase in nitrogen retention during pregnancy is due to a reduction in urinary nitrogen excretion, with no change in fecal and integumental losses.

The recommended increase in protein allowance during pregnancy over the nonpregnant requirement varies (+25 g per day, the United States and Canada; +6 g per day, the United Kingdom and FAO/WHO/UNU). Most pregnant women worldwide consume at least the recommended intake. Moreover, there is little evidence that healthy women already consuming an adequate amount of protein need to consume more during pregnancy.

Iron

Pregnancy has a marked impact on iron metabolism due to the expansion of maternal erythrocyte mass that is proportional to the increased need for oxygen transport. Besides the iron need for the additional synthesis of hemoglobin (450 mg), tissue formation (placenta, 50 mg), and restitution of blood loss during delivery (250 mg), there is a need of 200–400 mg to be transferred from mother to fetus in order to ensure infant iron stores during the first months of life. Therefore, it is estimated that iron requirements over the course of pregnancy may reach 1000 mg, not equally distributed over its duration. The average requirement for iron absorption increases from

about 0.8 mg per day at early pregnancy to about 3–8 mg per day during the third trimester.

Maternal–fetal transfer of iron is especially increased during the last two-thirds of pregnancy and involves serum iron binding to transferrin receptors in placenta. Maternal serum transferrin increases almost twofold over nonpregnant values during pregnancy, possibly to facilitate iron uptake by the placenta. Hepcidin is a systemic regulator of iron metabolism that controls the efflux of iron into plasma through ferroportin regulation and therefore may have an important role on iron homeostasis during pregnancy. Liver production of hepcidin is simultaneously regulated by circulating and stored iron, erythropoietic activity, and inflammation. The limited evidence from studies during pregnancy indicates lower concentrations of hepcidin compared to the nonpregnant state and also a decrease in circulating hepcidin as pregnancy progresses with the lowest levels observed in the third trimester.

During the initial phase of pregnancy, cessation of menstrual iron losses contributes to meeting iron requirements and preserves maternal iron. Thereafter, mobilization of maternal iron stores is stimulated and theoretically could make a significant contribution. During the second and third trimesters, there is also a marked increment in the efficiency of intestinal iron absorption with an average increase of two- to threefold, or more, over nonpregnant values. It is estimated that women would need an iron store of ~500 mg at conception in order to ensure meeting the iron demands of pregnancy together with the iron supplied in the diet. However, almost half of women worldwide enter pregnancy with no iron reserves, therefore requiring increased iron intakes. The IOM recommends an increase of iron intake from 18 mg per day for nonpregnant women to 27 mg per day during pregnancy, a level difficult to achieve from food intake, therefore requiring the use of iron supplements. The WHO recommends iron supplementation 30–60 mg per day of elemental iron during pregnancy. However, recent studies indicate that the benefits of iron supplementation on maternal and infant health are inconsistent across populations and may have side effects such as reduced absorption of nonheme iron and other minerals and increased oxidative stress. Therefore, iron supplements during pregnancy may not be universally recommended.

Zinc

The additional zinc requirement during pregnancy estimated by the factorial approach is about 100 mg, more than half accrued in the fetus (57%) and the remainder in the uterus (24%), placenta (6.5%), expanded blood volume (6.5%), mammary tissue (5%), and amniotic fluid (<1%). This requirement corresponds to about 5–7% of the total body zinc in a healthy nonpregnant adult woman.

There is a physiological decline of 15–35% in plasma zinc concentration as a result of hemodilution, increased urinary zinc excretion, increased zinc uptake by maternal tissues, and transfer to fetus. However, the total amount of circulating zinc rises due to the increased blood volume and the increased (10–15%) erythrocyte zinc concentration. Transfer of sufficient zinc to the fetus is dependent on the maternal serum zinc concentrations. It appears that placenta zinc uptake adapts to fetal needs, being higher in periods of rapid growth and also when maternal zinc status is low. The efficiency of intestinal zinc absorption increases from early to late pregnancy, especially when habitual zinc intake is low. Renal zinc conservation is an additional adaptation in pregnant women accustomed to low-zinc diets.

It is estimated that an additional zinc intake of 2–10 mg per day is needed during pregnancy, depending on zinc bioavailability in the diet (FAO/WHO). The IOM recommends an additional 3 mg daily for both adult (from 8 to 11 mg per day) and adolescent (from 9 to 12 mg per day) pregnant women.

Calcium

During pregnancy, there is a marked increase in maternal calcium demand for fetal skeletal mineralization. Fetal calcium accumulation rate varies from about 2–3 mg per day in the first trimester, 50 mg per day at midgestation, to 250–300 mg per day in the third trimester. This implies in a total fetal calcium accrual of 20–30 g.

The additional calcium is obtained primarily from increased efficiency of intestinal absorption that usually doubles during pregnancy and may be more efficient when maternal calcium intake is low. Concomitantly, there is an increased expression of enterocyte Ca-binding protein. The increase in calcium absorption starts early in pregnancy and therefore precedes fetal calcium needs for bone growth. This is consistent with some calcium storage on maternal skeleton for future mobilization. Bone turnover is increased during pregnancy, as indicated by several markers of bone resorption and bone formation, especially during the last trimester. Although bone turnover may contribute to maintaining calcium dynamics, it results in very little or no net calcium loss from bones during this period. Urinary calcium excretion is increased as a consequence of the higher intestinal uptake and glomerular filtration rate. When corrected by creatinine clearance, fasting calcium excretion is normal or decreased.

Evidence from different studies indicates that the physiological adaptations for providing calcium to the fetus are largely independent of maternal calcium intake. Therefore, recommended calcium intakes during pregnancy are not increased over those for nonpregnant nonlactating women (IOM and FAO/WHO). However, special consideration should be given to adolescent mothers and women habitually consuming very low-calcium diets.

Iodine

Physiological alterations in thyroid function include the requirement of an increased production of thyroid hormone that, in turn, depends on thyroid integrity and adequate availability of dietary iodine. Regulation of thyroid function during pregnancy includes a marked increase in serum thyroxine-binding globulin, increased renal clearance of iodine, and stimulation of the thyroid gland by human chorionic gonadotropin.

Iodide (the reduced form of iodine) pool of the body is constituted by iodide from diet and from catabolism of thyroid hormones. In the nonpregnant state, and conditions of adequate intake (150 μg per day), this pool is in dynamic equilibrium with the thyroid gland and kidneys. During pregnancy, renal iodide clearance increases 30–50% and iodide requirement for thyroid hormone production increases by 50%, from the first weeks of gestation. Later in gestation, iodide is transferred from the maternal circulation to the fetus by placenta.

Increased iodide uptake and glandular hypertrophy are the main mechanisms by which the thyroid gland adapts to increased requirement and/or decreased supply.

In situations of iodine sufficiency, the thyroid gland is able to adjust hormone synthesis to the increased needs reaching a steady state, as a physiological adaptation of pregnancy. In contrast, with restricted iodine supply, pregnancy may lead to an excessive glandular stimulation. Depending on severity of iodine deficiency, pathological alterations may occur resulting in different degrees of impairment in fetal neural system development.

Iodine intake recommendation is based on estimated daily thyroid iodine uptake of ~75 μg per day by the fetus and the thyroid iodine content of the newborn, together with data on iodine balance during pregnancy and studies of iodine supplementation that prevent increased thyroid size. Compared to the nonpregnant state, both the IOM and the FAO/WHO recommend an additional intake of 70 μg per day during pregnancy.

Folate

Pregnant women have a high folate requirement as a result of increased folate utilization, catabolism, and urinary excretion. 5-Methyltetrahydrofolate (5-MTHF) is the biologically active folate metabolite that affects DNA synthesis, amino acid metabolism, and methylation of genes, proteins, and lipids via S-adenosylmethionine-mediated one-carbon transfer reactions.

Circulating 5-MTHF can be transported into cells either by the reduced folate carrier, a facilitative anion-exchange carrier, or by an endocytic process mediated by folate receptors. Folate receptors are expressed in the neural folds during the neurulation phase of embryonic development, demonstrating the importance of folate uptake for proper neural tube development. Adequate folate nutrition, especially in the periconceptional period, is thus necessary to prevent neural tube defects besides other congenital defects.

Serum 5-MTHF is the main determinant of placental transfer to the fetus. A critical concentration >7 nmol l^{-1} appears to ensure adequate folate fetal transfer. Serum folate concentrations decline in pregnant women as a physiological response to pregnancy, although mechanisms have not been fully elucidated. Erythrocyte folate concentration is an indicator of long-term folate status and tissue stores during pregnancy. A physiological decline in erythrocyte folate concentration is observed at early pregnancy followed by a slight increase at midpregnancy.

The IOM and FAO/WHO recommend an intake of 400μg dietary folate equivalents (DFEs) per day for all women of reproductive age. This is based on strong evidence that ensuring an adequate folate intake for women who are capable of becoming pregnant contributes to reduce the risk of neural tube defect occurrence. During pregnancy, both organizations recommend an additional 200 μg of DFEs daily. In the United Kingdom, recommendations are substantially lower, with an additional 100 μg per day of folate during pregnancy over the 200 μg per day recommended for nonpregnant, nonlactating women.

Vitamin B_{12}

Vitamin B_{12}, or cobalamin, is a crucial nutrient for fetal development due to its role in DNA synthesis. Maternal serum cobalamin concentrations begin to decline in the first trimester of pregnancy, more than would be expected from hemodilution alone, and continue to decrease to about half the nonpregnant concentrations until the end of second trimester. Despite this decrease, serum homocysteine is not elevated as would be expected in vitamin B_{12} deficiency. A concomitant increase in erythrocyte cobalamin and decrease in saturation of cobalamin-binding serum proteins suggest a redistribution of cobalamin during pregnancy. Transcobalamin I and transcobalamin III increase during the second and third trimesters, and transcobalamin II, considered the best biomarker of active or available B_{12}, increases sharply in the third trimester to about one-third of nonpregnant values.

During pregnancy, absorption of vitamin B_{12} remains unchanged or increased due to an increase in the number of intrinsic factor–B_{12} receptors in response to placental lactogen. Newly absorbed vitamin B_{12} is preferably concentrated in the placenta and then transferred to the fetus down a concentration gradient so that serum vitamin B_{12} concentrations in the newborn are about twice the level found in mother, although correlated with each other. Maternal liver stores contribute less to the placental–fetal transference of vitamin B_{12}.

Total fetal vitamin B_{12} requirement during pregnancy is estimated to be 50 μg, while maternal stores may reach >1000 μg in healthy women with mixed diets. The estimated deposition rate of vitamin B_{12} in fetal liver during intrauterine life is 0.2 μg per day and is the basis for current recommendations. An intake of 2.6 μg per day of vitamin B_{12} is recommended by both the IOM and the FAO/WHO during pregnancy, corresponding to an 8% increase compared to the nonpregnant state. Meeting fetal demands may be difficult for pregnant women consuming diets restricted in animal food sources as in many developing regions of the world and in the case of vegetarians.

Vitamin A

During pregnancy, an extra amount of vitamin A is required for tissue growth and also to ensure fetal stores to be used after birth. Requirements are highest during the third trimester, when fetal growth is most rapid. The absence or excess of active vitamin A metabolites (isomers of retinoic acid) at critical periods of gestation can lead to abnormal development of the embryo and the placenta.

The major maternal circulating forms of vitamin A are retinol bound to retinol-binding protein and retinyl esters packaged in chylomicrons and their remnants. Changes in maternal status and/or dietary vitamin A intake affect these circulating retinoid levels and thus the amount of vitamin A available to cross the placenta. Maternal serum homeostatic mechanisms involving lecithin–retinol acyltransferase activity and binding proteins contribute to maintain fetal acquisition of vitamin A relatively stable over a wide range of maternal dietary vitamin A intake. Maternal serum retinol concentrations <0.7 μmol l^{-1} and >3 μmol l^{-1} indicate deficiency or excess, respectively.

In less developed countries, providing pregnant women with adequate amounts of vitamin A contributes to reduce maternal and infant mortality due to infection. In contrast, in developed countries, the potential adverse effects of excessive consumption of vitamin A associated with fetal malformation are the main concern. The risk of fetal abnormalities due to vitamin A toxicity is higher during the first trimester of

gestation and associated with excessive retinol (and not β-carotene) intake from supplements.

Vitamin A requirements during pregnancy are based on adequate fetal liver vitamin A content at birth, assuming that the liver contains approximately half the body's vitamin A when liver stores are low, as in the case of newborns. Considering an efficiency of maternal vitamin A absorption of 70% and an estimated increased requirement of 50 μg per day during the last trimester, vitamin A DRI for pregnancy is increased by 10% over the nonpregnant state, totalizing 770 μg RAE (retinol activity equivalents) per day. The recommended safe intake by the FAO/WHO is increased from 500 to 800 μg RE (retinol equivalents) per day.

Vitamin D

The main circulating form of vitamin D, 25-hydroxyvitamin D, is transferred from mother to fetus through the placenta in relatively small amounts that do not appear to cause maternal depletion. Serum concentration of 25-hydroxyvitamin D does not generally change during pregnancy, although there are physiological changes affecting both transport and metabolism of vitamin D by mechanisms not fully understood. Changes include increased circulating levels of vitamin D-binding protein and 1,25-dihydroxyvitamin D, the major active vitamin D metabolite.

Compared to prepregnancy state, 1,25-dihydroxyvitamin D serum concentration increases two- to threefold starting in the first trimester and reaching a maximum in the third trimester. Although this increase is mainly due to maternal synthesis by the renal 1α-hydroxylase, there is also contribution from increased placental and decidual 1α-hydroxylase activity. During pregnancy, parathyroid hormone (PTH)–related peptide (rather than PTH), which is produced in fetal parathyroid glands and placental tissues, could be a potential signal for placental synthesis of active vitamin D and consequently for placental calcium transfer. Although closely related, the increase in intestinal calcium absorption during pregnancy cannot be explained solely by the increased 1,25-dihydroxyvitamin D because intestinal calcium absorption doubles early in pregnancy, well before the increase in free 1,25-dihydroxyvitamin D concentrations late in pregnancy.

Given that the available evidence does not suggest that pregnant women are at increased risk of vitamin D deficiency compared with nonpregnant women, recommended intakes are not increased during pregnancy compared to the nonpregnant state (IOM and FAO/WHO). However, recommended intakes of vitamin D (cholecalciferol) for nonpregnant women are set higher by the IOM (15 μg per day) than by the FAO/WHO (5 μg per day).

Conclusion

The complex physiological adjustments and changes in nutrient metabolism during pregnancy appear to be highly integrated for maintaining homeostasis and ensuring that fetal and maternal needs are met. Studies investigating these adjustments in different populations and under different conditions in relation to dietary intake have provided the basis for establishing nutritional requirements during pregnancy. However, much remains to be known on the interacting effects of factors such as nutritional status prior to pregnancy, maternal immaturity, habitual diet, physical activity, genetic background, and environmental exposure to toxic substances and infectious agents, on the capacity for physiological/metabolic adaptation during pregnancy. Understanding the limits of this capacity is crucial for warranting fetal and maternal health in the short and long term.

Preservation of Foods

EF Torres, D Rodrigo, and A Martínez, Instituto de Agroquímica y Tecnología de Alimentos (CSIC), Valencia, Spain

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Foods are perishable commodities containing enough nutrients and water to be altered by microorganisms or support deteriorative enzymatic reactions. This explains the need for and development of preservation processes. Agents that can spoil or alter foods can be divided into physical, chemical, and biological agents.

- Physical agents: Mechanical processes, temperature, dryness, and light
- Chemical agents: The Maillard reaction, lipid rancidity, and oxidation of vitamins, among others
- Biological agents: Enzymes, parasites, and microorganisms in general

Among the agents mentioned earlier, microorganisms (spoilers and pathogens) have been the prime targets of preservation processes because of the serious consequences that their presence has on human health.

Various preservation methods have been used in human history, many of them taking advantage of natural circumstances, and they have been consolidated and improved. The most common food preservation methods include salting, curing, smoking, marinating, freezing, refrigeration, drying, and heat treatment. There are now new emerging technologies that were developed toward the end of the twentieth century, being the most important high hydrostatic pressure (HHP), irradiation, and pulsed electric fields (PEF).

In this contribution, a review about concepts related to food preservation is addressed, and a brief description of some of the most important traditional and new emerging technologies is given.

Food Preservation

What does food preservation mean? Although the concept of preservation is very broad, it can be said that it consists in performing actions to maintain the desired natural properties of foods as long as possible, protecting them from pathogens and other agents responsible for spoilage, thus allowing later consumption. These actions lie squarely in the heart of food science and technology, and they are the primary purpose of food processing.

The processing and storage of food are vital for a continuous supply of nourishment during growing or production seasons and afterward. The main reasons for food processing and preservation are the following:

- To absorb agricultural surplus and reduce losses generated as a result of the highly perishable nature of foodstuffs
- To provide products with added value (vegetables and fruits, meats, eggs, and milk, among others)
- To provide variations in the diet and, in the case of fruit and vegetables, to make them available outside the growing season

Food preservation goes back to very remote times. In ancient times, salt, ice, and cold air were used to preserve food. In ancient Egypt, liquids such as oil, vinegar derivatives, and even honey were used to increase the life of foodstuffs; and salting and smoking were also part of their preservation techniques. In Persia, sugar was added to certain foods, and in Greece, the fruit and vegetable were also coated with sugar. In Gaul, the druids put fruit in baskets covered with leaves to kept them fresh longer, probably as a result of the action of CO_2 evolving from the respiration of the fruit, while in Rome, wine was preserved by adding sulfur dioxide. Between the fifteenth and the eighteenth centuries, sauces and borax were used, but it was in the nineteenth century that all the preservation technology began to develop, with the application of sulfite to meat; the use of organic acids such as boric, salicylic, and benzoic acid; and a great development the appertization invented by Nicolas Appert in 1810. Appertization was the first direct attempt by man to intentionally create a new method for preserving food. Progress was also made in the effective recognition of microorganisms as the main source of alteration of food with the discovery of bacterial spores. Appertization was the beginning of a huge industry based on the use of heat to preserve food. Canning soon became established throughout the world, although it was not until 80 years later that science started to apply it to the development of preservation procedures and their control. Until the mid-twentieth century, the main form of preservation was heat treatment, although salting, drying, fermentation, cold smoking, and other preservation methods were also used. Subsequently, other methods were developed, such as freezing, the use of modified atmospheres, aseptic food packaging, and high-temperature short-time (HTST) or ultrahigh-temperature short-time (UHT) treatments, as well as a variety of innovative technologies not based on heat, such as high hydrostatic pressure, irradiation, electrical pulses, and light pulses. Chemical preservatives and, more recently, natural antimicrobials (essential oils, polyphenols, etc.) appeared and have been used as preservatives for a long time by the food industry.

Biological Food Spoilage

Many of the microorganisms that alter food are pathogenic to humans and animals, and it is necessary to remove them or control their development throughout the food's shelf life. Microorganisms can reach food in various ways, basically before, during, and after processing.

Before processing:

- Soil, sea water, or freshwater
- Raw materials (in the field or orchard)
- During harvesting and storage

During and after processing:

- Processing equipment (blanching and peeling)
- Added ingredients (spices, sugar, and salt)
- Water used during processing
- Packaging, storage, and distribution of processed foods (cross contamination)

The organisms involved in food spoilage or that can cause or contribute to foodborne illness can be divided into the following groups:

Microorganisms:

- Yeast and mold
- Bacteria
- Viruses
- Protozoa

Insects and mites:

- Directly, by consuming foods they produce infestation
- Indirectly, through the spread of disease

Rodents:

- Directly, by consuming food
- Indirectly, by disseminating disease

From the point of view of preservation processes, bacteria are the microbial group that produces most outbreaks or sporadic cases of foodborne illness. These microorganisms can be classified by their need for oxygen as (i) aerobic, (ii) anaerobic, (iii) facultative, and (iv) microaerophilic.

In general terms, according to their growth temperature, microorganisms can be classified as follows:

(a) Psychrophilic, growth at low temperature −15 °C
(b) Psychrotrophic and mesophilic, growth at low temperatures 0–7 °C
(c) Mesophilic, growth at average temperature 20–45 °C
(d) Thermophilic, growth at optimum temperature between 45 and 80 °C
(e) Hyperthermophilic, growth at high temperature 80 °C or more

This classification is important because the growth temperature directly affects the preservation procedures, from the point of view not only of their growth capabilities but also of the heat treatment applied; because thermophilic microorganisms are more resistant to heat than mesophilic microorganisms; and so on.

Among all the microorganisms, the genus *Clostridium* and the genus *Bacillus* produce spores and have species that produce toxins harmful to humans. These are mainly the proteolytic and nonproteolytic strains of *Clostridium botulinum*, *C. perfringens*, *Bacillus cereus*, and others.

Spores of these microorganisms resist high temperatures, so they are a problem in the case of foods that receive pasteurization processes of around 90–96 °C for several minutes. After the pasteurization process, the psychrophilic and psychrotrophic strains of these microorganisms can grow at very low temperatures, even below 4 °C, and produce their toxins.

In addition to microorganisms that produce spores, there are vegetative cells, less heat-resistant than spores, which fundamentally alter food during refrigerated storage. Many of these vegetative cells are pathogenic for humans and animals and can grow at refrigeration temperatures, so their control is essential in the prevention of foodborne diseases. Among this group of organisms are *Salmonella*, *Yersinia*, *Campylobacter* spp., *Escherichia coli* O157:H7, *Listeria monocytogenes*, and *Aeromonas hydrophila*.

Certain viruses that cause foodborne illness, such as norovirus, rotavirus, and the hepatitis A virus, are becoming quite important.

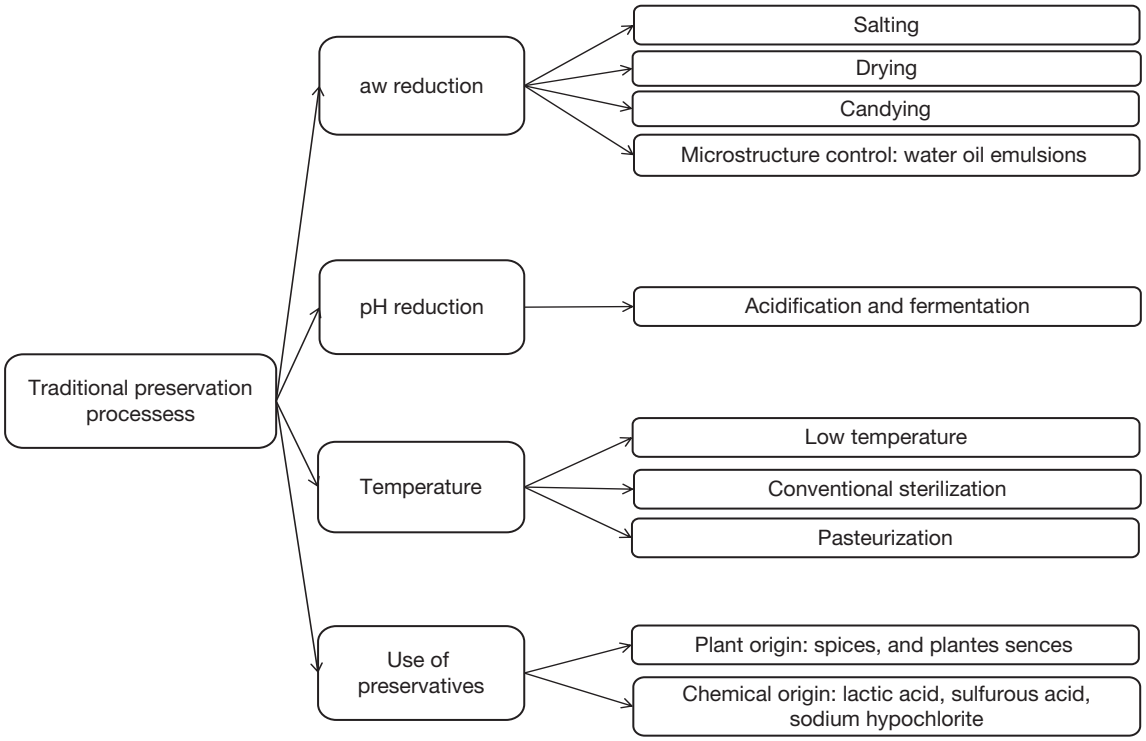
Although in the most of cases preservation processes are aimed to destroy or control pathogenic or spoilage microorganisms, preservation processes have also an important role in the inactivation of enzymes that can affect the sensorial properties of the preserved foods (color, texture, or flavor). Blanching and the conventional heat treatment applied to the foods serve also to reduce or inactivate the enzymes present in them (pectin methylesterase, peroxidase, and polyphenol oxidase, among others). In many cases, enzymes exhibit greater resistance than sporulated microorganisms; for this reason, the enzymatic inactivation is in some cases used as an indicator of the effectiveness and intensity of the heat treatment. Regarding the treatment of enzymes, it has been observed that inactivation may be affected by several factors including the composition, enzyme structure, pressure, temperature, pH time of treatment, and a_w.

Preservation Processes

The shelf life of food is increased by preservation processes. Preservation processes begin in the field through what is known as preventive measures (good agricultural practices and good hygiene practices) applicable to raw materials and the good manufacturing practices applied in the industry.

Preservation processes based on the destruction of microorganisms, including heat, biocides, and new conservation technologies, are applied in the industry. There are also procedures whose preservative power relies on slowing the growth of microorganisms, among which are low temperatures, reducing water activity, reducing pH, preservatives (natural or synthetic), and modified atmospheres. Sometimes, a combination of various preservation procedures may be used, improving the effectiveness of the preservation procedure.

Broadly speaking, these processes can be classified into traditional processes (Scheme 1), including those based on the effect of temperature, reduction of water activity or pH, and the addition of preservatives, and the so-called emerging preservation procedures. The most important forms of the latter are based on irradiation; emission of pulsed energy; the use of high pressure; new ways of applying heat and/or packaging, in addition to various antimicrobials; and applications of nanotechnology. Finally, there are combined processes or 'hurdle technologies' that combine different preservation technologies, increasing inactivation, reducing the treatment intensity of each



Scheme 1 Traditional preservation processes.

process, and thus reducing the impact of the process on the quality of the food.

The main advantages of the traditional processes are that they are economical, safe, and well established and in the case of heat treatments have a very wide application field. However, in some cases, there are some problems, such as lack of uniformity in treatment and changes that occur in chemical, physical, and nutritional properties. According to the latest market research, consumers demand 'fresh,' healthy, safe, and quickly prepared food. Given the limitations of traditional processes, especially thermal processes, and consumer demands, the future of food preservation lies in moving toward 'processing on demand,' consisting in designing a specific treatment for each food. In fact, there are foods for which traditional technologies are, and will remain, the best preservation alternative, but niche markets have appeared for emerging technologies because, when applied to certain products, they result in food that is safe from a microbiological point of view, that is healthy, and that maintains the properties of the fresh product better. These are the foods that can best meet consumer demands (Scheme 2).

A description of all preservation procedures is beyond the scope of this article. Consequently, the most commonly used methods are summarized, although technological advances are constantly being developed.

Reducing Water Activity

This mechanism for preserving food is aimed at the control of water (use of salt; drying; candying; concentration; and microstructure control, water–oil emulsion). Bacteria and other microorganisms need water to grow; thus, if there is a moisture control, the possibility of growth is reduced. The same thing happens with enzyme activity: enzyme reactions decrease when there is less free water in the medium. Consequently, dehydration is a mechanism that helps in the preservation of foods.

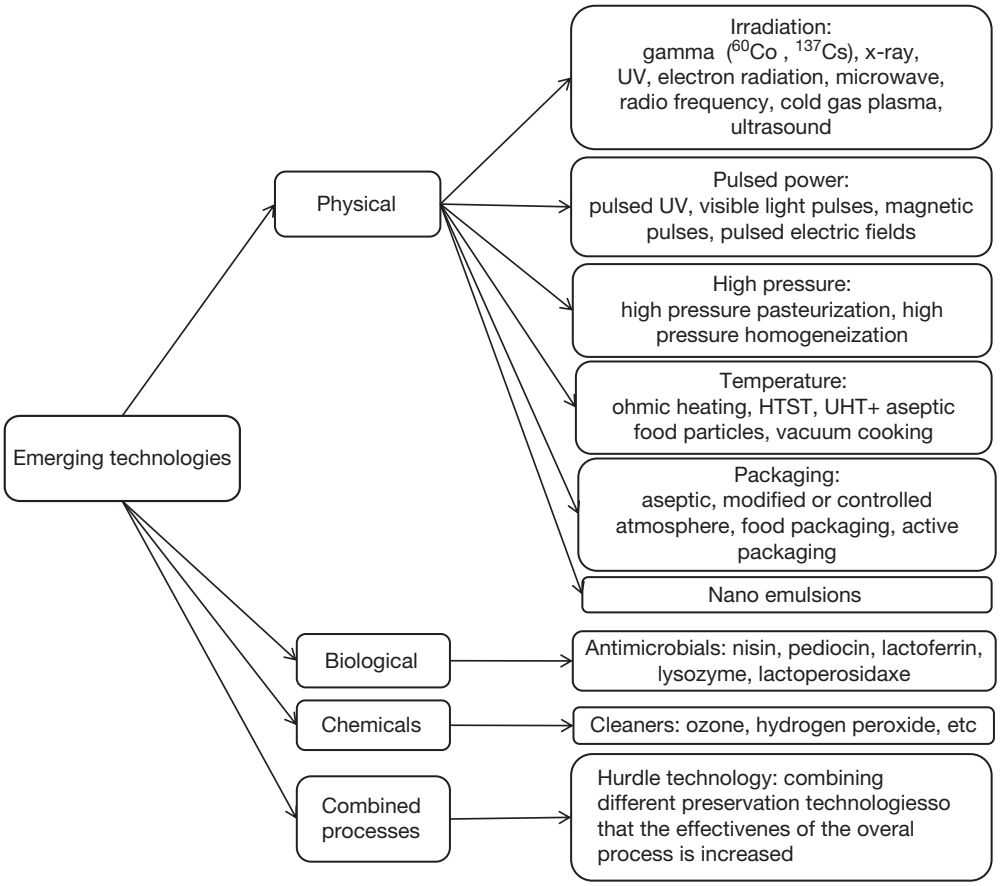
Use of Temperature to Control Microorganisms

Within the classical preservation technologies, the use of temperature to prevent the growth or activity of microorganisms and to inactivate and destroy enzymes is widespread and is one of the most common forms of food preservation. The main preservation processes based on the use of temperature are sterilization, pasteurization, cooking, freezing, and cooling.

For many years, heat treatment at high temperatures played a leading role as a preservation process. Over the years, the process has not changed, but the way in which it is used has undergone important modifications. What was initially merely a pressure cooker became a retort in its various forms, batch, continuous, and rotating and, in recent years, with heat treatment, a heat exchanger, with processes at HTST and UHT in conjunction with aseptic packaging.

There have also been changes in the way in which heat is generated, using steam, microwaves, or ohmic heating, in which the food acts as a resistance and becomes hot. It is important to point out that these treatments modify product characteristics such as taste, texture, and color to a greater or lesser extent and also increase the digestibility of components and the coagulation of protein.

Low temperatures have also been used in food preservation. This procedure has been used since time immemorial,



Scheme 2 Emerging preservation processes.

although the real development of it took place during the twentieth century. The effect of this technology is primarily based on slowing the chemical reactions and enzymatic activity inside cells. Those changes produce a limitation in the pathogenic or spoilage growth of microorganisms, slowly increasing by this way the shelf life of the products. In many cases, the growth is inhibited and the microbial concentration decreases with the storage time. Low temperatures also affect enzymes that can deteriorate foods. Low temperatures can be applied as refrigeration, which is short-term storage. In this case, the Food and Drug Administration (FDA) requires that refrigerated foods should be kept at a temperature of 4 °C or lower. Under these conditions, organoleptic and nutritive characteristics are slightly modified, the changes depending directly on the type of food, protective packaging, or treatment applied prior to storage. Freezing is the other system of preservation at low temperature. This long-term preservation method uses temperatures between −18 and −22 °C, so this technique prevents the development of spoilage and pathogenic microorganisms during the shelf life of the product.

Chemical Methods

The use of the preservative properties of many chemicals has resulted in numerous preservation methods. The main purpose in the use of chemicals is the preservation of foods by acting against microorganisms inhibiting their growth or even killing them. In some cases, chemical additives produce organoleptic changes that are pleasant for the consumer by modifying their original organoleptic properties.

Chemical preservatives (sorbic acid or benzoate) and substances with antiseptic activity can be included as methods that do not modify the sensory properties of products. Salting, curing, smoking, glazing, coating, the addition of organic acids, and fermentation processes that produce organic acids can be considered preservation methods that change the sensory properties of foods.

Owing to growing consumer concern about chemical preservatives, the industry is trying to bring to market natural antimicrobial substances from plants, animals, or bacteria that can be added to foods. Flavonoids and essential oils are compounds of plant origin that have potential as antimicrobials in the food industry. Milk proteins such as lactoferrin, lactoperoxidase, and casein have antimicrobial activity. Recently, chitosan has been gaining popularity as an antimicrobial of animal origin.

Various bacteria are being investigated in order to identify and increase the production of antimicrobials of microbial origin. Examples of these compounds are nisin, natamycin, subtilin, and plantaricin, generated by lactic acid bacteria.

Some of these natural antimicrobials are used in combination with other preservation procedures to originate hurdle technologies. The philosophy of hurdle technologies relies on

the control of microorganisms by using the addition or synergism of low doses of stressing factors.

Other chemical methods, such as ozone or chlorine, are used in the sanitation of vegetables for prepared food products.

Packaging Technologies

Packaging technologies developed rapidly during the last century. The main purpose of the package, to protect food from recontamination after being processed by other technologies, made it a preservation technology in itself.

Modified atmosphere packaging (MAP) was a great contribution to preservation processes made during the twentieth century. It is based on the preservative capability of CO_2 and a reduction in the O_2 concentration inside a package. Today, it is possible to find a great variety of vegetable, meat, fish, milk, and pasta products packed and preserved under MAP.

Various packaging systems are now being developed, such as active packaging that exhibits characteristics of absorption, retention (humidity, ethylene, oxygen, and carbon dioxide), release of components (antioxidants, antimicrobials, flavors, and preservatives), and temperature control (self-cooling and self-heating). Edible packages and intelligent packages are another step forward; the latter incorporate intelligent systems that indicate the quality and safety of the packed product, detect secondary metabolites of microbial growth, and can also have systems that monitor the temperature during production and storage, using chips, labels, or radio frequency systems.

Emerging Technologies

Among the emerging technologies, HHP is increasingly gaining more popularity as a preservation method. This technology belongs to the group of nonthermal processes, characterized by the long shelf life they provide, maintaining quality and sensory characteristics of the food. HHP now appears to be an alternative to heat treatment. This technology is being used throughout the world for the processing of fruit juices, fruit beverages, fruit purees, meat products, guacamole, and ready-to-eat foods, including dairy products. The method is based on applying pressures ranging from 100 to 800 MPa with relatively short times (from a few seconds to several minutes), combined with moderate temperature (20–50 °C). In the industry, HHP is now applied in batch processes. The resistance of microorganisms to pressurizing treatment depends directly on the type of organism and the characteristics of the matrix. In general, molds and yeasts are more sensitive to pressure, Gram-negative bacteria have a relatively medium strength, Gram-positive bacteria are among the most resistant vegetative cells, while bacterial spores require high pressures with high initial temperature to obtain significant reductions in initial concentrations. However, various germination methods prior to pressurization are now being studied in order to remove food spores. Advantages of this technology include the high nutritional quality and sensory characteristics of the products obtained, achieving sufficient microbial and enzyme inactivation at moderate temperatures. Furthermore, combinations of time, temperature, and pressure level allow the development of new products that can reach new markets.

Another nonthermal preservation technology is high-intensity PEF. This technology is based on the application of a potential difference in the food, so that an electric current is created in the product. The electric current causes a change in microbial cell membrane potential and consequently in the formation of pores in the membrane. When these pores are permanent, massive microorganism inactivation is caused by the difficulty in maintaining osmotic balance.

This technology applies electric pulses between 10 and 80 kV cm^{-1} and short treatment times between 50 and 2000 ms. There are certain limiting factors that directly affect PEF treatment: the food to be treated must comply with certain values for parameters such as pH, water activity, fat, and sugars; it is also necessary to standardize values of viscosity and electrical conductivity, because high values can cause an increased electric field that leads to a cessation of treatment.

Ionizing irradiation was considered as a promising food preservation technology. Irradiation up to 10 kGy can destroy microorganisms and bacterial spores. Irradiation is highly effective, but it has two major limitations: one is its high cost, and the other has to do with safety in the performance of the procedures. There is also some consumer concern about the consumption of foods preserved by means of this technology.

Future of Food Preservation

As new technologies are developed or the traditional ones are refined, new opportunities will be open to new products. HHP is a reality today and it is present in many preservation industries (meat, vegetables and fruits, pasta, and seafoods, among other products). Other technologies as PEF are still under development although some industrial equipment have been manufactured and are in production plants. Despite those and other advances in food preservation, heat preservation still remains as an important form of enlarging the shelf life of foods with an incredible record on food safety. Improvements on this traditional technology have permitted to produce preserved foods with better organoleptic properties than those made by using old still retorts without reducing the level of safety.

Probably, the future of food is the 'tailor-made foods' meeting the needs of some special groups of population (children, young people, and elderly). New products with new textures could be produced by using nonthermal technologies as the HHP, and new outcome technologies are being sighted and are still in its conceptualization phase.

Preservatives: Classifications and Analysis

E Mani-López, E Palou, and A López-Malo, Universidad de las Américas Puebla, Cholula, Mexico

© 2016 Elsevier Ltd. All rights reserved.

Chemical Preservatives

Chemical preservatives are defined in the Code of Federal Regulations (CFR) by the US Food and Drug Administration (FDA; 21 CFR 101.22 (a) (5)) as "any chemical that, when added to food, tends to prevent or retard deterioration thereof, but does not include common salt, sugars, vinegars, spices, or oils extracted from spices, substances added to food by direct exposure thereof to wood smoke, or chemicals applied for their insecticidal or herbicidal properties." Preservatives are used to prevent or retard both chemical and biological deteriorations of foods. The FDA includes in their list of food preservatives (21 CFR 172, subpart B) compounds with different preventive functions, such as antioxidant, color, flavor, and texture retainers, as well as antimicrobial agents. Only two functional classes of preservatives are clearly defined by the agency, antioxidant that is defined as "substances used to preserve food by retarding deterioration, rancidity, or discoloration due to oxidation" (21 CFR 170.3 (o) (3)) and antimicrobial agents as "substances used to preserve food by preventing growth of microorganisms and subsequent spoilage, including fungistats, mold and rope inhibitors" (21 CFR 170.3 (o) (2)).

On the other hand, the Food and Agricultural Organization (FAO) and the World Health Organization (WHO) of the United Nations through the *Codex Alimentarius* international food standards define preservative as "a food additive, which prolongs the shelf life of a food by protecting against deterioration caused by microorganisms" and include the following categorization: antimicrobial preservative, antimicrobial synergist, antimold and antirope agent, antimycotic agent, bacteriophage control agent, fungistatic agent, and preservative. A more specific definition is defined and established by the FAO/WHO for preservative, which only considers the biological deterioration, neglecting chemical deterioration. The approved preservatives for use in foodstuffs by two main regulatory agencies FAO/WHO and FDA are presented in Tables 1 and 2, respectively. Therefore, according to these two major regulatory agencies and their consistency in preservatives definition, preservatives in this article will refer only to chemical compounds that prevent biological food spoilage.

Classification of Preservatives

Antimicrobial agents can be classified with regard to different aspects, for example, based on their spectrum of action as bacteriostatic, bactericides, fungistatic, and fungicides; based on their origin as synthetic or natural; and based on chemical structure. Most preservatives are utilized to delay or inhibit the growth of a group of microorganisms, but there are some that are assigned to a particular microorganism, as in the case of nitrite against *Clostridium botulinum* in cured meat products, nisin against *C. botulinum* in pasteurized milk cheeses, and lactate and diacetate to inactivate *Listeria monocytogenes* in processed meats. There are not established criteria for classifying preservatives; in some cases, more than one classification is utilized according to their function, intended used, chemical structure, and origin. For example, the FAO/WHO established a classification based on their action spectrum and function. Furthermore, the FDA classifies preservatives based on their function. Some scientific reports utilize a classification based on the origin (natural or synthetic), if they want to highlight the nature of the compound. However, the classification most commonly reported in the literature is based on their chemical structure. Preservatives are classified as benzoic acid and benzoates, sorbic acid and sorbates, organic acids, sulfur dioxide and sulfites, nitrates and nitrites, nisin, natamycin, parabens, dimethyl dicarbonate, lysozyme, and miscellaneous antimicrobials.

Antimicrobial properties of preservatives depend on several factors such as antimicrobial spectrum, chemical and physical properties, concentration, and mechanism of action. Further, their activity depends on composition, pH, a_w, and storage temperature of food. Besides these factors, some other issues for choosing a preservative for use in foods must also be considered, such as genus and microorganism load, cost of preservative, and its effect on quality of the specific food. A proper assessment of these factors should be performed before choosing a preservative for a particular food. It is also necessary to revise if the preservative is permitted for use in the particular food because regulatory agencies establish restrictions. In addition, it should be reviewed the maximum permitted concentration of preservative intended to be used. Therefore, preservative maximum permitted concentrations in different kinds of food have been regulated in many countries. Regulations about maximum permitted concentrations of food preservatives are established by FAO/WHO and FDA among other agencies. Hereby, in order to assess their concentrations in foodstuffs and ensure food safety, it is important and necessary to develop effective, convenient, inexpensive, reliable, and rapid analytic methods to monitor the preservative levels in foods. A wide variety of analytic methods for determining preservatives have been developed to quantify and assess their presence in a foodstuff. These methods use the physicochemical properties of each preservative. However, before the compound or analyte of interest can be quantified, it is necessary to separate or remove it from the food matrix. The process to remove or separate the analyte depends on the composition of each food, the technique used to quantify the preservative, and the kind of preservative. Some preparatory processes for separating preservatives from a foodstuff include ultrasonication, solvent extraction, distillation, ion exchange electrophoresis, digestion, centrifugation, dilution, and filtration. Moreover, there are many methods to quantitatively determine the preservative; the most common are titration, spectrophotometry, high-performance liquid chromatography (HPLC), gas chromatography, and capillary electrophoresis (CE),

218	Methyl parahydroxybenzoate	221	Sodium sulfite
235	Natamycin	200	Sorbic acid
234	Nisin	220	Sulfur dioxide
231	Ortho-phenylphenol	339 (iii)	Trisodium phosphate
261	Potassium acetates		

among others. Procedures for both qualitative and quantitative determinations of various preservatives can be found in the Association of Official Analytical Chemists' (AOAC) Official Methods of Analysis handbooks.

Another approach to the analysis of preservatives is based on its identity and purity for which regulatory agencies established particular test methods. The FAO/WHO provides a technical sheet for each preservative, which includes its chemical name, chemical structure, physical description, level of purity, solubility, melting point, levels of metal waste, and the assay method to determine its identity and purity. Furthermore, FDA also provides several features of preservatives and test methods for identification. This information is found in the sections that describe the use of food additives and generally recognized as safe (GRAS) substances in title 21 of the CFR.

Benzoic Acid and Benzoates

The FAO/WHO defines benzoic acid as a white crystalline solid, usually in the form of scales or needles, having not more than a faint characteristic odor, with a molar mass of 122.12 g mol^{-1} and a purity of 99.5% on the dried basis, a pH of 4.0 in aqueous solution, a slight solubility in water, and free solubility in ethanol. The assay method is based on acid–base titration using phenolphthalein as an indicator. Calcium and sodium benzoate are also described.

The amount of the benzoic acid and benzoates used as preservatives during food processing is important for consumer health. Benzoic acid and benzoates are generally used to inhibit mold and yeast growth, and they are also effective against bacteria. Benzoic acid and sodium benzoate are most suitable for foods and beverages that naturally are in a pH range below 4.5 or that can be brought into this range by acidification; therefore, they have been widely used to preserve beverages, fruit products, bakery products, fish products, liquid eggs, margarine, mayonnaise, mustard, salad dressings, and sauces. The maximum concentration permissible of benzoic acid and benzoates in most foods is 0.1%. The AOAC methods for determining benzoic acid and benzoates are based on different principles, and the quantification can be performed with various equipment, which facilitates the analysis of these preservatives at different laboratories, food processors, and regulators. Table 3 presents the official AOAC methods for determining sets of benzoic acid and benzoates. These methods are based on the ability of benzoic acid and benzoates to react with certain compounds under specific condition and absorb light at a specific wavelength. To separate the benzoic acid or benzoates of food, distillation must be performed (967.15), and extraction operations should be done (983.16, 960.38, and 963.19), centrifuged and filtered (994.11), or solubilized and diluted (980.17 and 960.38). The qualitative test (ferric chloride test, 910.02) uses the ability of the benzoic acid to react with $FeCl_3$ in an alkali medium in order to produce ferric benzoate (a salmon color precipitate). The spectrophotometric techniques take advantage of benzoic acid absorbing light in a range of 265–280 nm. This same feature is used by the chromatographic methods. To determine benzoic acid by gas chromatography, it must be converted to trimethylsilyl ester.

As an alternative to the official methods of analysis, several researchers proposed improvements to the traditional methods to reduce time, reduce reagent consumption, reduce analyte separation steps, improve the detection limit, or detect more than one analyte simultaneously. For instance, HPLC to determine benzoic and sorbic acids in various food like jam, candied chestnut, carbonated drinks, black table olive, green table olive, pickles, whole meals, brown bread, and white bread using a C18 column and to detect benzoic and sorbic acid was carried out at the wavelengths of maximum absorption of the compounds, 235 and 254 nm, respectively. The detection limit was 0.19 and 0.64 mg kg^{-1} for benzoic acid and sorbic acid, respectively. In addition, they proposed a simple sample preparation, which involves homogenization with methanol and filtering. Another method consisted of a continuous system for the simultaneous determination of benzoic and sorbic acids using CE with a dynamic pH junction-sweeping strategy in liquid food with a detection limit of 0.001 mg and a very simple sample preparation, which consists in food dilution with water (100–1000 times) and filtering. They successfully analyzed fruit juices, soft drinks, soy sauces, and wines.

Table 2 Additives approved as functional class preservative and antimicrobial agents by US Food and Drug Administration (Title 21 of the Code of Federal Regulations, CFR)

Compound(s)	*Principal food applications*	*CFR designation*
Calcium disodium EDTA, disodium EDTA	Dressings nonstandardized, egg product, oleomargarine, potato salad, and salad dressing, canned kidney beans, and mayonnaise	172.120, 172.135
Dehydroacetic acid	Cut or peeled squash	172.130
Sodium nitrite, sodium nitrate	Smoked, cured sablefish; smoked, cured salmon; smoked, cured shad; and meat and meat products	172.170, 172.175
Quaternary ammonium chloride combination	Raw sugar cane juice	172.165
Benzoic acid, sodium benzoate	Beverages, fruit products, and margarine	184.1021, 184.1733
Lactic acid, lactates	Meats and fermented foods	184.1061, 184.1207, 184.1639, 184.1768
Propionic acid, calcium propionate, sodium propionate	Bakery products and dairy products	184.1081, 184.1221, 184.1784
Sorbic acid, sorbates	Most foods, beverages, wines	182.3089, 182.3225,182.3640, 182.3795
Acetic acid, acetates, diacetates	Baked goods, condiments, confections, dairy products, fats/oils, meats, and sauces	184.1005, 182.6197, 184.1754, 184.1185, 184.1721
Hydrogen peroxide	Milk, cheese and related products, and wine	184.1366
Dimethyl dicarbonate	Beverages	172.133
Methylparaben, propylparaben, heptylparaben	Beverages, baked goods, syrups, and dry sausage	184.1490, 184.1670, 172.145
Nisin preparation	Pasteurized cheese spread, pasteurized process cheese spreads, pasteurized cheese spread with fruits, vegetables, or meats	184.1538
Natamycin	Cheese	172.155
Lysozyme	Cheese, cooked meat, and poultry products	184.1550
Sulfites	Fruits, fruit products, potato products, and wines	Various

Table 3 Official methods for qualitative and quantitative determination of benzoic acid and benzoates by AOAC

Number of method	*Analytic method*	*Food*
994.11	Liquid chromatographic method	Orange juice
960.27	Titrimetric method	Milk
910.02	Qualitative tests (ferric chloride test or the modified Mohler test)	Beverages
963.19	Titrimetric method	Ketchup, jellies, jams, preserves, marmalades, cider containing alcohol, salted or dried fish
960.38	Spectrophotometric method	Ketchup, other tomato products, jams, jellies, beverages containing small amounts of alcohol, soft drinks, and fruit juices. Not applicable to solids
967.15	Thin-layer chromatographic method	Liquids, solids, semisolids, and solid–liquid mixtures
983.16	Gas chromatographic method	Apple juice, almond paste, and fish homogenate (at 0.5–2 g kg^{-1} levels) representing carbohydrate-rich, fat-rich, and protein-rich foods
980.17	Spectrophotometric method	Ground beef

Sorbic Acid and Sorbates

2,4-Hexadienoic acid and 2-propenylacrylic acid are the chemical names of sorbic acid. FAO/WHO describes it as colorless needles or white free-flowing powder, having a slight characteristic odor with a purity not less than 99.0% and molar mass of 112.12 g mol^{-1}, with a melting point between 132 and 135 °C, and being slightly soluble in water and soluble in ethanol. The assay method is based on acid–base titration using phenolphthalein as an indicator. Calcium and potassium sorbates are also described.

Sorbic acid is active against yeasts, molds, and many bacteria. Microbial inhibition by sorbate is variable and depends on species, strains, composition of food, pH, a_w, food-processing treatments, temperature of storage, and concentration of sorbate. The antimicrobial action of sorbate depends on pH and is most effective approaching its dissociation constant ($pK_a = 4.76$); however, it is possible that it has a good inhibitory effect at pH as high as 6.5–7.0, which is an advantage over other preservatives such as benzoic and propionic acids that loss their effectiveness at pH 4.5–5.5. The most commonly used forms include sorbic acid and its potassium salt. Sorbates have found wide application in various foods, including dairy products, bakery products, fruit and vegetables products, meat and fish products, beverages, food emulsions, and sugar and confectionery products. The maximum permitted concentration of sorbates for most foods is between 0.1% and 0.3%.

As already mentioned, AOAC established the official methods for the determination of sorbates in most foods; only quantitative methods are described for sorbates. In this case, the methods of analysis are based on the ability of sorbate

Table 4 Official methods for quantitative determination of sorbates by AOAC

Number of method	*Analytic method*	*Food*
971.15	Oxidation method	Cheese
974.08	Spectrophotometric method	Wines
974.10	Spectrophotometric method	Dairy products
975.10	Colorimetric method	Wines
980.17	Spectrophotometric method	Ground beef
983.16	Gas chromatographic method	Apple juice, almond paste, and fish homogenate (at 0.5–2 g kg^{-1} levels), representing carbohydrate-rich, fat-rich, and protein-rich foods

to absorb light under certain reaction conditions in a range of wavelengths ranging from 250 to 550 nm. Only one method used gas chromatography for the detection of sorbic acid. AOAC methods are summarized in Table 4. Detection methods require quantitative extraction and separation of sorbic acid from the food material without food ingredient interference. Extraction methods include acid-steam distillation, selective gas diffusion, and solvent extraction; in some foods, only filtration and dilution have been used. Extraction by steam distillation has been used extensively, but it is time-consuming; in addition, the compounds generated by the degradation of lipids in this process can cause interference in the colorimetric and spectrophotometric methods. Method 983.16 determines sorbic and benzoic acids simultaneously in fat-, carbohydrate-, and protein-rich foods and has as principle that acids are isolated from food by extraction with ether and successive partitioning into aqueous NaOH and CH_2Cl_2. Acids are converted to trimethylsilyl esters and determined by gas chromatography.

Recent proposals of new analytic methods include chromatographic methods (HPLC, thin-layer chromatography, paper chromatography, capillary chromatography, and ion chromatography). More recent approaches used chemiluminescence (CL) coupled with an automated method of analysis such as flow injection analysis using a flow-through column packed with a molecularly imprinted polymer for sorbic acid. CL detection was based on the enhancement of CL intensity of the analyte with acidic potassium permanganate with 3-o-methoxyphenyl-5-(20-sulfonophenylazo) rhodanine acting as sensitizer. This method has been probed for determined sorbic acid in milk and fruit juices. An analytic method using solvent extraction and quantitative proton nuclear magnetic resonance spectroscopy was used for the absolute quantification of sorbic acid in processed foods. The limit of quantification was 0.063 g kg^{-1} for foods and 0.0063 g kg^{-1} for beverages containing *Lactobacillus* species. More ambitious methods include the determination of nine additives in red wine with chromatography (ion-suppression reversed-phase HPLC) or determined nine preservatives in various foods by liquid chromatography–mass spectrometry, including benzoic and sorbic acids. Alternatively, new extraction methods are being developed in order to reduce cost and time of analysis like the monolith-based stir cake sorptive extraction and liquid chromatography analysis.

Organic Acids

Organic acids are referred to a specific group of short-chain acids, where acetic, citric, lactic, malic, tartaric, succinic, fumaric, and propionic acids are the most important ones. The salts of sodium, potassium, and calcium derived from these acids are also considered within the group. Only propionic acid is widely recognized as an antimicrobial agent. According to regulatory agencies (FDA and FAO/WHO), the other acids may or may not be considered as antimicrobials. These acids are considered acidulant or pH control agents, whose antimicrobial effect is due to their nondissociated form. The dissociation constants of these acids are in the range of pH 3–5; therefore, its main application is in acidic foods. Choosing an acidulant as antimicrobial agent depends on its secondary effects, because they contribute to the taste and acidity in the product. The inhibitory effect of acids depends on pH, concentration, chain length, type, microorganism, strain, and food. Organic acids are most effective in inhibiting bacteria. They have also shown inhibitory effect on yeasts and molds. Selected organic acids (acetic acid, citric acid, and lactic acid) have been used exclusively as spray sanitizers against pathogens on beef carcasses. Its application is limited by its effect on taste; however, they can be used in a wide variety of foods such as fruit products; fresh, frozen, and fermented vegetables; egg products; coffee, tea, and herbal infusions; dairy products; fish products; grain beverages; pastas; and complementary foods for infants. Most organic acids have no maximum permitted concentration, and its use is based on good manufacturing practices (GPM). Nevertheless, some acids have maximum permitted concentration for particular foods; for example, tartaric acid and tartrates must not exceed 0.4% in fruit products, propionic acid must not exceed 0.3% in whey protein cheese, citric acid must not exceed 0.3% or 0.5% in some fruit products, and fumaric acid must not exceed 700 ppm in pasta.

The various organic acids can be assayed by simple procedures. Volatile acids can be separated from foods by steam distillation and titrated for the particular acid (when one acid is present); for a mixture of acids, the distillate is separated on a silicic acid column, and the component acids can be identified by other methods. Several techniques used for the analysis of acids include spectrophotometry; potentiometry; spectrofluorimetry; HPLC; gas, paper, and thin-layer chromatography; and CE. Official methods from the AOAC to determine organic acids are presented in Table 5. Qualitative or quantitative methods can be used depending on the required degree of sensitivity.

Nowadays, HPLC is the most widely used technique in organic acids analysis due to the advantage of simplicity, short analysis time, and sensitivity. In most cases, HPLC method uses a C18 column with an acid solution as mobile phase. Organic acids are detected at wavelengths ranging from 210 to 220 nm. The sample preparation starts with homogenization followed by solvent extraction or direct dissolution in

Table 6 AOAC official methods to determine sulfites in food

Number of method	*Analytic method*	*Food*
892.02	Titrimetric method (free sulfurous acid)	Meats
961.09	Qualitative test (sulfites)	Meats
962.16	The modified Monier–Williams method (total sulfurous acid)	Food, not applicable to dried onions, leeks, and cabbage
963.20	Colorimetric method (total sulfurous acid)	Dried fruit
975.32	Qualitative test (sulfurous acid)	Food
980.17	Spectrophotometric method (sulfites)	Ground beef
987.04	Differential pulse polarographic method (total sulfites)	$\geq$10 μg total SO_2 per gram in shrimp, orange juice, peas, dried apricots, and dehydrated potatoes
990.28	The optimized Monier–Williams method (sulfites)	$\geq$10 ppm (μg g^{-1}) sulfites in foods; not applicable to dried onions, leeks, and cabbage
990.29	Flow injection analysis method (total sulfites)	$\geq$5 μg g^{-1} total SO_2 in shrimp, potatoes, pineapple, and white wine
990.30	Flow injection analysis method (free sulfite)	Wines
990.31	Ion exclusion chromatographic method (sulfites)	Food and beverages with SO_2 at $\geq$10 μg g^{-1}

the mobile phase or centrifugation and filtration. The type of separation depends on the complexity of the food matrix. This technique has been used in fruit juices, cheese, soy sauce, cider, soft drinks, salad dressings, and fresh and dried vegetables. CE is another method that is being widely utilized for organic acid analyzes. The method is relatively fast with typical analysis time of 5 min. Kits are available from a number of suppliers and contain pre-prepared reagents and standards, which provide reproducible separations. The separations are performed on standard CE equipment and capillaries, which may prevent the need to purchase specific equipment and consumables such as ion exchange chromatography systems and columns. This method has been proposed to determine organic acids in fruits, juices, nectars, wines, beer, and honey.

Sulfur Dioxide and Sulfites

Sulfur dioxide, sulfite, and metabisulfite are included in this group of preservatives. SO_2 is a broad spectrum antimicrobial to inhibit bacteria, yeasts, and molds. It is especially used in the fermentation of wine to prevent malolactic fermentation. Sulfites are used as preservatives in foods and beverages to prevent oxidation and bacterial growth. Sulfites are also used to prevent enzymatic and nonenzymatic browning in raw, dried, frozen, and canned vegetables and fruits. The Codex General Standard for Food Additives allows the use of SO_2, sulfite, and metabisulfite in the following products: fresh, frozen, fermented, and dried fruit; fruit products; fresh, frozen, fermented, canned, and dried vegetables; starches; precook pastas; fish and certain shellfish products; sugar products; herbs and spices; seasonings and condiments; vinegars; mustards; sauces; beer and malt beverages; cider; wines; water-based flavored drinks (including 'sport,' 'energy,' or 'electrolyte'); distilled spirituous beverages containing more than 15% alcohol; aromatized alcoholic beverages; and snacks. The maximum concentration permitted is in a range from 15 to 1000 ppm and depends on the product.

There are many methods for analyzing sulfites in beverages and foods, involving titration, electrochemistry, fluorimetry, CL spectrometry, colorimetric, gas–liquid chromatography, and HPLC, among others. The most commonly used techniques are based on the classic Monier–Williams method. Although this method has sufficient sensitivity, it also presents certain limitations due to the long analysis time (with important repercussions on the analytic capacity of the laboratory) and the extreme control needed in some of the analytic phases (e.g., N_2 stream adjustment). AOAC official methods of analysis for sulfites are presented in Table 6.

Faster methods are being investigated; ion exchange chromatography with column and conductivity detector has been proposed to determine free sulfites in dried fruits processed with sulfur dioxide. This method uses aqueous 0.2 N NaOH ($pH > 13$) as the solvent for standard preparation and sample extraction. Five different fruit matrices (apricot, golden grape, white peach, fig, and mango) were successfully tested and analyzed with this method. Nowadays, the most common technique proposed for determining sulfites is HPLC (reversed-phase

ion-pairing liquid chromatography with postcolumn detection or HPLC–fluorescence spectrometry).

Nitrates and Nitrites

Nitrates and nitrites are used as curing and antimicrobial agents and in cured products. Their main purpose as an antimicrobial agent is to inhibit the growth of *Clostridium botulinum* and the production of botulinum toxin in these cured products. Its use is restricted to these products. There are four permissible salts of these compounds for use in foods: sodium nitrate, potassium nitrate, sodium nitrite, and potassium nitrite. The use of nitrite and nitrate in the processing of fish products is specified in title 21 of the CFR: potassium nitrate can be used as a curing agent in the processing of cod roe, without exceeding 200 ppm in finished roe (21CFR172.160). Furthermore, sodium nitrate can be used as a preservative and color fixative, with or without sodium nitrite, in smoked, cured sablefish; smoked, cured salmon; and smoked, cured shad and in meat-curing preparations for the home curing of meat and meat products (including poultry and wild game) so that the level of sodium nitrate does not exceed 150 ppm and the level of sodium nitrite does not exceed 150 ppm in the finished product. Sodium nitrite has the same specifications as sodium nitrate. In addition, sodium nitrite could be use as color fixative in smoked, cured tuna fish products without exceeding 10 ppm in the finished product. Sodium nitrite can also be used in processing smoked chub; the maximum content in the edible portion of the finished smoked product is 150 ppm, as measured in the loin muscle. Procedures for calculating the amount of nitrite and nitrate that can be added to curing solutions and meat products are specified by the USDA.

Since control and regulation of nitrates and nitrite use in meat products is crucial to ensure consumer safety, various methodologies have been utilized to determine nitrates and nitrites, including ion chromatography, CE, differential pulse voltammetry, enzymatic reduction, and electrochemistry. The extraction of nitrate and nitrite from meat products is critical in terms of obtaining adequate recoveries and reducing possible interferences. When nitrite is added to a biological material, such as meat products, it reacts with various components present naturally in the matrix, which means that the levels of nitrite analytically detectable (known as residual) necessarily vary. Some compounds in meat products (ascorbic acid, fat, protein, etc.) that can interfere in the determination of nitrates and nitrites may be present in the extract, which is why purification or clarification steps are necessary. Several clearing techniques have been applied for the analysis of nitrite and nitrate in food, especially in meat products; these are based on deproteinization and clarifying agents, using reagents, such as potassium aluminum sulfate, borax (anhydrous sodium tetraborate), mercuric chloride, zinc sulfate, or potassium hexacyanoferrate plus zinc acetate. Other clearing techniques include active carbon or gel filtration on Sephadex G-25, the latter used for beverages only.

AOAC official methods established one method to determine nitrates and nitrites in meat (935.48 xylenol method), one method to analyze nitrites in curing preparations that includes dry cure mix and curing pickle (964.13 titrimetric method), and one method for nitrites in cured meat (973.31 colorimetric method). These methods are simple.

Nisin

FAO/WHO describes nisin A as an antimicrobial preservative with chemical formula $C_{143}H_{230}O_{37}N_{42}S7$ and molar mass of 3354.12 g mol^{-1}; it physically appears white to light brown micronized powder, is soluble in water and insoluble in nonpolar solvents, and is not less than 900 IU of nisin per milligram. The assay method consists in a bioassay that compares the activity of a standard solution against unknown sample by fluorescent light. FDA permits its use to inhibit the outgrowth of *C. botulinum* spores and toxin formation in pasteurized cheeses; its maximum concentration is determined by GMP (<250 ppm in the finished product). The Codex General Standard for Food Additives permits its use in cheeses (12.5 ppm max. level), clotted cream (10 ppm max. level), and cereal and starch desserts (3 ppm max. level). Many more applications have been suggested in foods like fresh pizza, salad dressings, soy and vegetarian products, pasteurized liquid egg, fruit juices, fish and shellfish, and meat products. Nisin antimicrobial spectrum is against Gram-positive bacteria. FDA established the quantitative method for nisin, the one designated by British Standards Institution 'Methods for the estimation and differentiation of nisin in processed cheese.' Alternatively, there are several suggested methods for quantification in foods (milk, cheese, liquid egg, canned tomatoes, and salad dressings), which include horizontal agar diffusion, immunochemistry, nisin-induced reporter gene expression, and turbidimetric bioassay. The widely used agar diffusion assay is not able to distinguish nisin from other interfering substances present in the food, causing false-positive results. Although immunochemical methods are more sensitive than the agar diffusion assay, they are not totally reliable, due to cross-reactions with compounds structurally related to nisin that can be present in the testing material.

Natamycin

Natamycin, also known as pimaricin is defined as a fungicidal antimycotic of the polyene macrolide group. It is produced by several species of *Streptomyces*. The commercial product may contain up to three moles of water. Its chemical formula is $C_{33}H_{47}NO_{13}$; its molar mass is 665.74 g mol^{-1}; it is a white to creamy-white, almost odorless, crystalline powder; is practically insoluble in water, liquid, and mineral oils; and is slightly soluble in methanol and soluble in glacial acetic acid and dimethylformamide. The assay method is by HPLC with a column packed with octadecylsilanized silica and ultraviolet detector measuring at 303 nm. FDA permitted its use in cheese in amounts not exceeding 20 ppm in the finished product. FAO/WHO permits its use in unripened, ripened, processed, analogue, and whey protein cheeses at maximum level of 40 ppm and in cured and dried non-heat-treated processed meat, poultry, and game products in whole pieces or cuts at a maximum level of 20 ppm. Other applications are suggested for natamycin in fruit juices, bakery products, olives, and wine.

FDA established as quantitative the one method designed by International Dairy Federation (IDF) Standard 140A:1992, 'Cheese and cheese rind – determination of natamycin content: method by molecular absorption spectrometry and by HPLC.' Other suggested methods are ultraviolet spectrometry, liquid chromatography, and HPLC for natamycin in cheeses.

Parabens

Methyl, ethyl, propyl, butyl, and heptyl esters of *p*-hydroxybenzoate are denominated parabens. They are odorless, almost colorless crystals or white crystalline powders. Water solubility is inversely related to alkyl chain length. The pH range of antimicrobial activity is 3–8; their antimicrobial activity is mainly against bacteria and fungi. Combinations of two or more parabens are often used since they have synergistic effects. FDA sets the maximum level of application of methyl (21CFR184.1490) and propyl (21CFR184.1670) esters of *p*-hydroxybenzoic acid at 0.1%. Both methylparaben and propylparaben are permitted as antimycotic agents in food packaging material (21CFR181.23). Heptylparaben (21CFR172.145) is also approved for use in fermented malt beverages at a maximum of 12 ppm and in noncarbonated soft drinks and fruit-based beverages at a maximum level of 20 ppm. FAO/WHO permits the use of methylparaben, ethylparaben, and propylparaben in foods. The Joint FAO/WHO Expert Committee on Food Additives (JECFA) established the assay method of methylparaben and ethylparaben as a titrimetric method. Regulatory agencies have not established an official method for its determination in foods. Nevertheless, a great number of methods are proposed to quantify parabens in foods, such as spectrophotometry, injection gas chromatography, HPLC–mass spectrometry, and CE with amperometric detection.

Dimethyl Dicarbonate

Dimethyl dicarbonate ($C_4H_6O_5$) is described by the FAO/WHO as a colorless liquid with a molar mass of 139.09 g mol^{-1} and soluble in water and miscible with toluene. The method of assay is titrimetric; dimethyl dicarbonate (DMDC) is mixed with an excess of diisobutylamine, which it reacts quantitatively. The excess of amine is backtitrated with acid. DMDC has antimicrobial activity against yeast and bacteria. FDA approves the use of DMDC in certain beverages in which the microbial population has been reduced to 500 microorganisms per ml or less by current GMP; in wine, dealcoholized wine, and low-alcohol wine at maximum of 200 ppm; and in ready-to-drink teas at a maximum of 250 ppm. For carbonated or noncarbonated, non-juice-containing ($\leq$1% juice), flavored and unflavored beverages containing added electrolytes (5–20 mequiv.l^{-1} Na+ and 3–7 mequiv.l^{-1} K+), a maximum of 250 ppm is permitted, while for carbonated, diluted beverages containing juice, fruit flavor, or both, in which the juice content does not exceed 50%, a maximum of 250 ppm. FAO/WHO permits its use in water-based flavored drinks including 'sport,' 'energy,' or electrolyte drinks and particulate drinks, coffee, coffee substitutes, tea, herbal infusions, grain beverages, cider, perry, and wines at a maximum of 250 ppm and in grape wines and mead at a maximum of 200 ppm. AOAC official methods are not available for the determination of DMDC in food. The FDA designates gas chromatography to determine DMDC.

Lysozyme

Lysozyme is defined by FAO/WHO as a polypeptide obtained from hen's egg whites consisting of 129 amino acids, having a molar mass of about 14 000 g mol^{-1} and an isoelectric point of 10.7 and possessing enzymatic activity to hydrolyze the β(1–4) linkages between *N*-acetylmuramic acid and *N*-acetylglucosamine in the outer membranes of bacterial species, in particular Gram-positive organisms, usually obtained in the hydrochloride form for food use. It is described as a white, odorless powder, as a preservative to prevent the late blowing of cheese caused by *Clostridium tyrobutyricum*, and as an assay $\leq$950 μg mg^{-1} and is soluble in water and insoluble in organic solvents and in concentrated saline solutions. The assay method is based on the changes of turbidity of a suspension of *Micrococcus luteus* ATCC 4698. Codex General Standard for Food Additives permits lysozyme use in ripened cheese, and maximum level is according to GMP, while for cider, perry, and grape wines, a maximum of 500 ppm is permitted. Several food applications have been suggested for lysozyme in meat products, dairy products, seafood, tofu, vegetables, kimchi, sake, and wine. Official methods are not available for the determination of lysozyme in foods. Recent studies show that online capillary zone electrophoresis and mass spectrometry can be used as a method for quantifying lysozyme in cheese.

Preservatives: Food Use

R García-García and SS Searle, Centro de Biotecnología FEMSA, Monterrey, Mexico; Tecnológico de Monterrey, Monterrey, Mexico

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Quality loss and spoilage of food products can be caused by a wide range of physical, chemical, enzymatic, and microbial reactions. Food preservatives are used to avoid spoilage during storage, distribution, retailing, and consumption. They are compounds that have been intentionally added to avoid deteriorative reactions and thus protect quality and extend the shelf life of foods and beverages. Preservatives are used in controlled amounts and usually at low levels, ranging from parts per million (ppm) to 1–3% by weight. Many food preservatives are multifunctional, serving to help extend shelf life by inhibiting oxidation, browning, or enzymatic reactions and to ensure microbial safety by inhibiting or killing pathogens as well as spoilage microorganisms. Food preservatives may be extracted from natural sources or synthetically produced.

Several factors have to be considered when choosing an appropriate preservative for a specific food product, including the type of microorganism present (pathogen or deteriorative), pH, composition, physical state and, product shelf life required, use, and application. It is important to also consider their possible effects altering organoleptic properties of the product like flavor or color.

Antimicrobial Agents

Microbiological damage to food products is by far the most economically and important problem related with food losses; a loss of about one-quarter of the world's food supply due to microbiological activity is estimated annually. The Food and Drug Administration (FDA) categorizes an antimicrobial agent as a substance used to preserve food by preventing growth of pathogenic and deteriorative microorganisms and subsequent spoilage. Most available antimicrobial agents do not fully inactivate microbial populations, but rather work as growth inhibitors providing inhospitable environments for microorganisms avoiding the microbial development. Antimicrobial activity of specific agents may vary widely within different food systems, thus requiring experimental validation in the food product intended for its use.

Acids are the most effective and widely used preservatives. Among the most used are the weak lipophilic organic acids such as sorbate, benzoate, and propionate or the inorganic ones such as sulfite or nitrite, all of which are most effective at pH values lower than about 5.5. There are no antimicrobial preservatives with sufficient activity at varied pH values, with the exception of parabens. Emerging concerns on the extensive use of these types of preservatives and their effects on human health as well as their inefficacy in pH levels closer to neutrality have generated a market demand for natural alternatives.

Acidulants and Organic Acids

The pH and acidity of foods play an important role in the type of microorganisms that may survive as well as their ability to proliferate and cause spoilage reactions. Microorganisms have defined pH ranges for growth and survival. Acidity in food products may be increased artificially to prevent or suppress microbial growth. Generally, spoilage bacteria and pathogens will not proliferate in pH values lower than 3 or 4, with yeasts and molds able to survive at pH values up to 2.

Acidulants and organic acids constitute the two major types of acidifying agents used to prevent food spoilage, each with different modes of action. Acidulants are acids employed to increase acidity in food products by decreasing the pH of the food matrix, whereas weaker organic acids can have an important effect in decreasing internal cytoplasmic pH. Fully dissociated acids increase proton concentrations and result in decreased pH values, negatively affecting cell walls, bacterial outer membranes, and surface membrane proteins. Protons, however, are insoluble in lipids and diffuse slowly through the phospholipid bilayers of the cell membrane, not affecting microorganisms from changes in cytoplasmic pH levels. Extracellular pH values sufficiently low to kill yeast and bacteria with acidulants would render food unpalatable, so other agents are used to effectively inhibit microbial proliferation without compromising organoleptic attributes.

Lipophilic weak acids are able to diffuse, with some actively transported through the microbial cellular membrane in their undissociated form. They have bacteriostatic and bactericidal effects below their pK values at a pH under 4.5. In the cytoplasm, at pH values near neutrality, weak acids dissociate and effectively lower cytoplasm internal pH. Changes in internal pH will cause protein misfolding, enzymatic inhibition, and metabolic alterations. Lowering internal pH also neutralizes the electrochemical gradient across the plasma membrane needed for the active transport of many essential nutrients. Alternative inhibitory mechanisms may include sequestration of metal ions and damage to membrane fluidity. Inhibition of *Clostridium botulinum* by citric acid is reversible by the addition of calcium and magnesium to the media, suggesting that inhibition was mainly as a result of the chelating properties of citric acid. For more hydrophobic acids with larger chains such as sorbic and benzoic acids, inhibitory action may be due to the effect dissolved free fatty acids have on the microbial membrane fluidity. All of these combined effects effectively control microorganism growth in foods and beverages.

The amounts required for effective antimicrobial activity vary greatly among acids. Organic acids and their salts such as benzoic acid inhibit yeast at pH 4 at concentrations of 2–6 mM, whereas acidulants, like citric acid, are required at levels of above 400 mM. The most common organic acids used as preservatives are (a) benzoates (sodium benzoate) used at concentrations from 0.01% to 0.10%, (b) sorbates (sorbic and potassium sorbate), 0.03–0.10%, and (c) propionates (sodium and calcium propionate), 0.20–0.50%. Commonly used acidulants with antimicrobial activity are acetic, citric, fumaric, lactic, and phosphoric acids. It is important to consider not only the antimicrobial properties of acidulants but also their

flavor profiles given that they are used at far greater amounts and may have a considerable effect on the palatability of the product. A combination of acidulants along with weak organic acids or their salts may be used to potentiate antimicrobial activity.

Lactic, citric, and acetic acids are permitted for their use in the European Union with the E numbers E270, E330, and E260, respectively. Lactic acid is most commonly used as a food additive in fermented meat and dairy products, carbonated drinks, dressings and sauces, and pickled vegetables. Citric acid can be found in nonalcoholic drinks, jams and jellies, sauces, cheese, and canned vegetables. Citric acid may also be used in bakery products, dry soup, or cake mixes but requires special packaging care due to its high hygroscopic properties. Acetic acid is mainly used in pickles, chutneys, sauces, mayonnaise, and dressings.

Parabens

Parabens are a group of esterified molecules of hydroxybenzoic acid at the C-4 position used as food, pharmaceutical, and cosmetic preservatives due to their antimicrobial effect. Methyl paraben occurs naturally in cloudberry, yellow passion fruit, white wine, and bourbon vanilla. Commercially used parabens are artificially synthesized through the esterification of *p*-hydroxybenzoic acid with methyl, ethyl, propyl, butyl, heptyl, and benzyl groups. While longer-chained parabens possess greater antimicrobial properties, they also exhibit decreased water solubility, thus making the shorter-chained methyl and propylparabens better suited for their application in foods.

Parabens are effective against the proliferation of yeasts and molds at much lower concentrations than weak acids, although they are less active against bacteria, especially Gram-negative. Unlike benzoic acid, from which they are derived, parabens retain their efficacy at pH levels of up to 8.0, making them a wide-spectrum antimicrobial agent and a popular choice to use in foods closer to a neutral pH. Parabens are used in cakes, pastries, pie crusts, icings, toppings, and fillings (0.03–0.06%); soft drinks (0.03–0.05%); creams and pastes (0.1%); jams and jellies (0.07%); olives and pickles (0.1%); and syrups (0.07%). Combinations of methyl and propylparabens are commonly employed to achieve better antimicrobial results.

Parabens antimicrobial activity is generally considered to be pH-independent under values of 8.0 where they are fully undissociated. No evidence has been shown linking parabens to a specific target, but experimental results suggest they act upon the cell membrane and affect the functionality of enzymes. Possible mechanisms include interactions with membrane proteins and generation of disorder on membrane lipids.

The FDA, the European Community, and the Joint FAO/WHO Expert Committee on Food Additives (JECFA) have been approved the use of parabens in food, and they are generally recognized as safe (GRAS). Parabens are rapidly metabolized without accumulating in the body, are relatively nonirritating and nonsensitizing, and present low toxicity. Recent studies have raised concerns about the use of parabens, with special focus on propylparaben as possibly having estrogenic potential; however, no conclusive evidence suggests any risk to people under current used levels.

Sulfur Dioxide and Sulfites

Sulfur dioxide (SO_2) has long been used as a food additive due to its multifunctional properties. SO_2 and soluble sulfite salts are employed as antimicrobial and antioxidant agents, enzymes, and Maillard reaction inhibitors. Sulfites are most commonly applied in drinks (alcoholic and nonalcoholic), fruits, and vegetables. In wine production, sulfites play a major role by inhibiting growth of yeast and other spoilage microorganisms, while wine yeast are relatively unaffected. Another major application is in dehydrated fruits and vegetables preventing oxidation and microbial growth.

Various similarities between sulfite salts and organic salts exist regarding their mode of action. As with organic acids, in low pH foods, sulfites are used to prevent the proliferation of yeasts and molds, and their activity is pH-dependent. Unlike organic salts and acids, sulfites are effective antimicrobial agents against Gram-negative bacteria. This advantage is employed in meat products to avoid pathogens' growth. It is important to note that the efficacy provided by sulfites' high reactivity also makes them susceptible to easy degradation. Sulfites may be rapidly oxidized into sulfates with no antimicrobial or antioxidant properties, which should be considered for shelf life evaluation. No unique cellular target for sulfites is responsible for their antimicrobial activity, but rather a combination effect over several metabolic systems.

Approved forms of sulfite additives are SO_2, sodium sulfite, sodium bisulfate, sodium metabisulfite, potassium metabisulfite, calcium sulfite, calcium bisulfate, and potassium bisulfate. Concentration of sulfite additives is evaluated in terms of SO_2 equivalents, since sulfite salts release molecular SO_2, and the concentration in foods is highly dependent on the maximum approved levels for specific products. SO_2 concentrations range from 10 ppm in wines to a maximum of 2000 ppm in dried fruits. GRAS status in the United States has been revoked for certain applications of sulfites, mostly when added to fresh products. These regulations are also prevalent in the European Union, and in the past decades, legislations controlling the approved amounts employed in different foods have been reformed internationally to lower daily intake and human exposure.

Natural Antimicrobials

The use of natural antimicrobial compounds in food has acquired great attention from the consumers and food industry. The potential negative impact of synthetic preservatives on health, the benefits of natural preservatives, and the consumers' demand for natural and minimally processed food have generated interest among researchers in the development of natural products used as preservatives. Some natural compounds with antimicrobial activity can be obtained from plants, animals, bacteria, fungi, and algae. Nisin, natamycin, and essential oils are some natural preservatives used in food processing. Nisin a bacteriocin and natamycin a polyene antibiotic are both obtained from bacteria, while essential oils are plant-derived.

Plant-derived antimicrobials

Throughout history, herbs and spices have been attributed with functional characteristics such as medicinal and

antimicrobial effects. Research in this area has proven the microbiological efficacy of many plant-derived compounds. Essential oils are considered as one of the most promising natural alternatives to synthetic preservatives. They consist of aromatic and volatile oily extracts obtained from different plant tissues, including flowers, buds, roots, bark, and leaves. Essential oils from thyme, clove, balm, ginger, oregano, rosemary, basil, coriander, citric fruits, marjoram, and lemon grass have shown a greater potential to be used as antibacterial and antifungal agents. Given that essential oils have been extensively used for centuries in food products, they are classified as GRAS and present very low risk of microorganism resistance development. Despite their approval for use in the United States as well as in Europe, currently few commercially available essential oils are marketed as food preservatives; nonetheless, their usage is expected to rise with the trending demand for natural and minimally processed foods.

Phenylpropenes and terpenoids constitute the majority of antimicrobial compounds found in essential oils, the most active being thymol, carvacrol, and eugenol. Molecular targets and mechanism of action are not yet fully understood, although many essential oil constituents have been proposed to act on the cell membrane. Aldehydes, such as cinnamaldehyde, and other nonphenolic substances may be responsible for important synergic activity as suggested by greater antimicrobial activity of crude essential oils compared to blends of their major individual components.

Concentrations needed to achieve significant antibacterial effect range between 0.5 and 20 $\mu l\ g^{-1}$ in foods and about 0.1–10 $\mu l\ ml^{-1}$ in solutions for fruit and vegetable washing. Microbial inhibition by essential oils has greatly focused on dairy and meat products where they may also impart flavor to the final product. Special considerations have to be taken when using essential oils as preservative agents. Given the hydrophobicity of many components in essential oils, application in foods with a high fat content may impair antimicrobial activity. As a result, much higher inhibitory concentrations are typically required to reproduce in food the effects observed *in vitro*. This has been reported from twofold in semiskimmed milk to 100-fold in soft cheese. In certain food products, the required inhibitory concentrations can strongly affect the product's flavor profile and even render unpalatable.

Animal-derived antimicrobials

Natural antimicrobials in animals are used as the first chemical barrier against bacterial and fungal infections. They are synthesized by all animals mostly in the form of peptides, polysaccharides, sterols, terpenes, prostaglandins, and fatty acid derivatives. Some of these compounds, such as lysozyme, chitosan, and lactoferrin, have applications in the food industry as food preservatives. Lysozyme and lactoferrin are bioactive peptides mainly extracted from hen eggs and bovine milk, respectively, whereas chitosan is a polysaccharide derived from crustacean shells and fungal cell walls.

Lysozyme is an enzyme naturally present in eggs and mammalian milk used for its bacteriolytic properties. Commercially available lysozyme is extracted from hen eggs and used as a preservative for meat and fish products, milk and dairy products, fruits, and vegetables. Lysozyme is predominantly used to prevent late-blowing defects in cheeses and has been approved by the FDA and in the European Union.

Antimicrobial activity results from lysozyme's ability to compromise Gram-positive bacterial cell walls by hydrolyzing the β-1, 4 linkages between *N*-acetylglucosamine and *N*-acetylmuramic acid from peptidoglycan. Synergic activity against Gram-positive bacteria has been reported when lysozyme is applied in combination with chelating agents (EDTA). In cheese production, lysozyme is used in concentrations of 40–500 $mg\ kg^{-1}$ of product.

Another animal-produced peptide is lactoferrin, an 80 kDa iron-binding glycoprotein, which possesses strong chelating properties. Its application as preservative has been reported in a variety of meat and dairy products. Lactoferrin is naturally occurring in mammalian milk, with concentrations in human milk of nearly ten fold the amounts found in bovine milk. Lactoferrin has strong antimicrobial activity against a wide spectrum of microorganisms such as bacteria, fungi, yeasts, and viruses. As a chelating agent, it restricts the amount of iron available for microbes in food products, resulting in decreased bacterial counts and limited growth.

The European Food Safety Authority approved the use of bovine-extracted lactoferrin in 2012, but so far, it has not received safe recognition by the FDA. Maximum levels of bovine lactoferrin for foods vary from 0.66% for baby foods, 4.0% in energy bars, 0.1% for infant formula, 0.12% for nonalcoholic beverages, 0.2% for dairy products, to 0.3% for sports nutrition beverages.

In addition to bioactive peptides, polysaccharides have gained considerable attention for their functional properties. Chitosan, a deacetylated derivative of chitin, is a natural antimicrobial agent with promising applications in the food industry as an additive or processing aid and in active packaging. Chitosan applications, however, are limited by its insolubility at neutral or higher pH. As a preservative agent, most research has focused on bioactive chitosan films alone or in combination with antimicrobials such as nisin, thymol, carvacrol, and eugenol. In winemaking, chitosan is employed to remove suspended solids, heavy metal content, and contamination microorganisms, especially *Brettanomyces*.

Chitosan is obtained from crustacean shells or extracted from the cell wall of *Aspergillus niger*. Both forms have been approved as processing aids and food additives in the European Union, the United States, Japan, Australia, and New Zealand. Antimicrobial activity of chitosan has been reported effective against spoilage yeasts and bacteria, showing stronger bactericidal effects against Gram-positive bacteria. At 0.025%, water-soluble chitosan derivatives are able to cause extensive cell surface damage *in vitro*. Applied in beverages, 0.3 $mg\ ml^{-1}$ effectively eliminated yeasts for 13 days in pasteurized apple juice.

Bacterial-derived antimicrobials

Evolutionarily, several microorganisms have developed antimicrobial defense mechanisms. Antibiotics, which have been extensively obtained from molds such as penicillin, are one of many examples. Bacteriocins are antibacterial peptides or proteins produced by lactic acid bacteria (LAB). They differ from antibiotics in their biological synthesis, application, spectrum, and mode of action. Unlike antibiotics, which are produced as

secondary metabolites, bacteriocins are peptides of ribosomal synthesis with a narrow spectrum of activity and no known toxicity. Bacteriocins possess multiple desirable properties as food preservatives. They exhibit a broad antimicrobial spectrum against spoilage and pathogenic bacteria and bactericidal activity, are inactivated by digestive proteases, and present no toxicity to eukaryotic cells. Despite a large quantity of recognized bacteriocins, so far, nisin is the only one permitted as a food preservative. Since nisin is naturally produced by starter cultures in many fermented meat products such as sausages, it has been unknowingly consumed for centuries, giving it a distinction of GRAS. Few countries have imposed maximum levels for the use of nisin at values around 10 mg kg^{-1}.

Application of bacteriocins in preservation techniques can be in the form of coculturing bacteriocinogenic LABs in food products or nisin as a food additive. LABs are utilized in table olives, sourdough, miso, sauerkrauts, refrigerated pickles, mung bean sprouts, fermented sausages, and cheese. As a food additive, nisin is used in cheeses, meat products, and kimchi. Nisin is commonly incorporated into foods as a concentrate from dairy cultures rather than a purified additive.

Natamycin, also known as pimaricin, is a polyene antibiotic produced by aerobic fermentation of *Streptomyces natalensis* used to control fungal growth with no efficacy against bacteria or viruses. Due to its extremely low solubility in water, natamycin is primarily applied as a surface preservative for cheese and meat products. Natamycin has been used for decades and is approved as a preservative agent in the European Union, Latin America, and the United States. Despite its approval in meat and cheese products in Europe, its application in the United States is limited to cheese in amounts not exceeding 20 ppm.

Polyene antibiotics damage eukaryotic cells through interactions with membrane sterols such as ergosterol. Natamycin binds irreversibly to ergosterol in yeasts and fungi, which increases permeability and results in rapid cell leakage. While fungal resistance to natamycin has been reported in research, no resistant strains have been observed from its commercial use. Natamycin may be used in hard, semihard, and soft cheeses. Its actions are to surface level and it presents very limited diffusion, allowing desired fungal species in cheese maturation such as *Penicillium* to remain unaffected. Cheese is typically immersed in a 0.2–0.4% aqueous solution before maturation. When used in meat products such as salami and other dry sausages, natamycin is commonly applied by immersion or spray with aqueous solutions of 1–4 g l^{-1}. Maximum final surface concentration for any product should not exceed 1 mg dm^{-2}.

Incorporation of antimicrobials to packaging material is considered as a promising area with major interest in the use of natamycin-based coatings. Several studies have been carried out on the potential use of natamycin, either by itself or in conjunction with organic acids or nisin, as a preservative in alginate, pectin, and other polymer films.

Antioxidants

Oxidative reactions produce substances that affect flavor, odor, and color, decreasing shelf life and consumer acceptance of food products. Oxidation may be minimized by the removal of compounds such as metals and free fatty acids, along with the protection from air and light. A more practical approach consists in the addition of antioxidants, substances employed to preserve food by retarding deterioration, rancidity, or discoloration. Enzymatic browning and lipid rancidity are the two most significant forms of oxidative problems in foods. Browning is caused by the enzymatic oxidation of phenolic compounds by polyphenol oxidase (PPO) in fruits and vegetables, whereas oxidative rancidity results from the decomposition of unsaturated fatty acids in lipid-containing foods.

Enzymatic Browning Inhibitors

Enzymatic browning in foods and beverages is a key factor contributing to quality loss. Browning is a major challenge in minimally processed vegetable products such as ready-to-use salads, fresh-cut fruit, and fresh juices. Antibrowning agents may be added to foods and beverages or used as pretreatments to prolong shelf life and avoid changes in coloration.

Browning in fruits and vegetables is caused mainly by the enzyme PPO, which in the presence of oxygen catalyzes the oxidation of *o*-diphenols to *o*-quinones. Brown pigments are produced by the polymerization of *o*-quinones. Ascorbic acid, citric acid, sodium chlorite, and chelating agents are commonly used PPO inhibitors added to foods to prevent browning. Ascorbic acid, acting as a reducing agent and a competitive enzymatic inhibitor, reduces *o*-quinones back to *o*-diphenols preventing the formation of brown pigments. Apple slices developed only moderate browning after 14 days of storing at 4 °C following a 2 min bath in a 0.5 M ascorbic acid solution, and its use in fruit-based beverages, at concentration of 0.1%, inhibits browning. Other inhibitors such as cysteine and sulfites have been reported, but their use is legally restricted.

Lipid Antioxidants

Oxidative rancidity produces low-molecular-weight compounds that negatively affect a product's odor and flavor potentially producing toxic by-products. Rancidity in foods can vary greatly, ranging from noticeable changes in flavor, loss of color and change in texture, to subtler decreased 'freshness.' Nitrites, sulfites, and synthetic phenolic compounds (SFCs) butylated hydroxytoluene (BHT), butylated hydroxyanisole (BHA), and tert-butylhydroquinone (TBHQ) are the most commonly used antioxidants in lipid-containing foods. Increased demand in natural products in addition with allergenic response to some of these agents has led to an increased use of natural antioxidants such as α-tocopherol (vitamin E), phenolic acids, phenolic diterpenes, flavonoids, and volatile oils.

Oxidation of lipids is provoked mainly from autoxidation, photosensitized oxidation, and thermal oxidation, all of which affect double bonds in unsaturated fatty acids. Once lipid peroxy radicals are formed due to heat, metals, light exposure, or reactive oxygen species, they may catalyze a free radical chain reaction. Phenolic compounds function as free radical scavengers. Each molecule of BHT, for example, is able to react with two alkylperoxy radicals, which normally act as chain propagators, thus preventing further oxidation. Phenolic

compounds are able to donate hydrogen to free radicals and remain as relatively stable radicals due to resonance delocalization by the phenolic ring. Some natural antioxidants, due to the multiple rings and arrangement of –OH in their structure, also serve as chelating agents.

Synthetic phenolic compounds

BHA, BHT, and TBHQ are the most widely used food antioxidants due to their low cost, high performance, and wide availability. They can be found in a great variety of products containing lipids. TBHQ, BHA, and BHT are approved food antioxidants in the European Union, the United States, Australia and New Zealand, and many other regions. TBHQ, BHA, and BHT can be found in oils, margarines, and fat-containing products. A major advantage in SFCs is their stability at high temperatures, retaining their antioxidant capabilities during and after baking and frying. While effective in both fats and oils, BHA and BHT are more recommended for use in fats, whereas TBHQ has a broader application in vegetable oils. Their use is highly regulated, and usually, up to 100–200 $\mu g\ g^{-1}$ of SFCs is allowed either singly or in combination.

Natural antioxidants

Compounds from natural sources used as antioxidant agents in foods include phenolic acids, flavonoids, tocopherols, and carotenoids. They inhibit oxidation by acting as reductants, chelating agents, and free radical scavengers with strong H-donating capacity. The most commonly used natural antioxidant is α-tocopherol, followed by herbs and spices with high concentrations of phenolic compounds. Vitamin E is mainly composed of α-tocopherol, a fat-soluble carotenoid with antioxidant capacity. Vitamin E adoption commercially as an antioxidant agent is extremely popular given the consumer impression of added health and wellness to food products.

Herbs with antioxidant properties are normally within the *Lamiaceae* family, including rosemary, basil, oregano, marjoram, sage, and thyme, all containing rosmarinic acid. Rosmarinic acid, a phenolic acid with 2 aromatic rings and 2 –OH groups in each ring, is capable of chelating metals and donating H+. As a free radical scavenger, rosmarinic acid is more potent than BHA, BHT, TBHQ, and α-tocopherol. Herbs' potential as antioxidants is not limited to their purified components. Polar extracts of different salvia species, including sage, have demonstrated antioxidant activities similar to BHT. For spices, oleoresins and extracted compounds show promising activity, with special focus on cinnamon, nutmeg, clove, cumin, and turmeric. These spices are rich in the phenolic acids of gallic acid and caffeic acid, as well as a wide range of volatiles like pinene, linalool, and cymene.

Conclusions

Food preservatives are an essential constituent of processed foods serving the purpose of extending the shelf life of products and preventing deterioration. While this has led to a ubiquitous use of highly characterized synthetic preservatives, governments and research centers have become increasingly concerned with their possible effects on human health. A public demand for 'more natural' preservative technologies and minimally processed foods has seen an unprecedented increase. As alternative antimicrobial and antioxidant agents are increasingly adopted and approved for their use by international regulators, some of the major challenges to arise will be focused in the discovery of broad-spectrum agents, which are able to maintain the highest standards in food safety.

Probiotics

H Kumar and S Salminen, University of Turku, Turku, Finland

© 2016 Elsevier Ltd. All rights reserved.

Introduction: Definition of Probiotics

Microbes have been part of daily diet for centuries, but the concept of 'probiotics' has evolved relatively recently. In 1907, Élie Metchnikoff, the Russian-born Nobel Prize winner, suggested the use of beneficial microbes to replace harmful microbes and pathogens in the human gut. The term 'probiotic' was extensively acknowledged in 1960 by Lilly and Stillwell, who suggested probiotics as substances produced by microorganism that promote the growth of other microbes. Fuller defined a probiotic in 1989 as "a live microbial feed supplement, which beneficially affects the host animal by improving its intestinal balance." Another definition was suggested by Havenaar and Huis in't Veld in 1992, which defines a probiotic as "a viable mono or mixed culture of bacteria which when applied to animal or man, beneficially affects the host by improving the properties of indigenous flora." Keeping all the recent developments and trends in consideration, FAO/WHO 2002 guidelines defined probiotics as "live microorganisms which when administered in adequate amount confer a health benefit on the host." Today, the question of successful fecal transplants is likely to further redefine the concept and future of probiotics as mixed cultures of microorganisms.

Common Probiotics

All probiotic strains marketed for human consumption should possess minimum properties laid down by WHO/FAO 2002, which focus on strain identification, functional characterization, safety assessment, and effective human trials.

It has been deemed desirable that probiotic isolates should be of human origin, that is, isolated from the mouth, gastrointestinal (GI) content, or feces, as these microbes could reach highest density in humans. As such, probiotics should ideally be members of normal healthy gut microbiota. For example, *Lactobacillus fermentum*, *Lactobacillus gasseri*, *Lactobacillus vaginalis*, *Lactobacillus reuteri*, and *Lactobacillus salivarius* have been isolated from the human stomach and showed promising probiotic properties. However, traditionally fermented milk and related products have also been explored for the isolation of lactic acid bacteria, bifidobacteria, and other microorganisms, including yogurt, cheese, kefir grains, Maasai milk, koumiss, and naturally fermented yak milk. Interestingly, breast milk has also been explored as a source of probiotic *Lactobacillus* spp. with immunomodulatory activity.

Conventionally, dairy products have been considered as both sources and excellent vehicles for probiotic microorganisms. Maasai milk, a traditional fermented milk from Kenya, was previously used for the isolation of probiotic *Lactobacillus* spp. that were subsequently applied as starter cultures. *Kule naoto*, or *kwerionik*, and *amasi* (*mukaka wakakora* or *zifa*), traditional fermented milks with probiotic properties, are produced and consumed in Kenya and Zimbabwe, respectively. Kefir grains are extensively used for the isolation of potential probiotic strain and in the preparation of fermented milk products. Cheeses from different countries, like Italy, Argentina, and Bulgaria, have also been used for the isolation of *Lactobacillus plantarum* strains that exhibited tolerance to relevant physiological factors, including survival in milk-based media. Yogurt is another example of traditionally prepared fermented milk product with high consumer acceptance. During the processing of yogurt, *Streptococcus thermophilus* and *Lactobacillus bulgaricus* exhibit symbiotic relationship and are considered as probiotic microbes. Industrially, the incorporation of probiotic microbes in milk or related products should not affect the major characteristics of the final products. The latter include safety, fermentability, flavor, texture, and shelf life of the formulation. Other characteristics such as the oxygen content, redox potential, and water activity are also very important to ensure the survival of probiotic microorganisms during storage. Moreover, interactions between conventional starter cultures and probiotic microorganisms, that is, synergistic or antagonistic effects, could also affect the overall sensory properties, as well as the survival of probiotic microbes, both in the product and in the human GI tract.

Apart from milk-based probiotic formulations, there are many varieties of traditional beverages used worldwide for the isolation and characterization of probiotic bacteria with specific attributes. Several of these traditional beverages are cereal based. An example is *Yosa*, an oat-based fermented cereal product that has gained widespread acceptance in the Nordic countries and provides an alternative for lactose-intolerant subjects and those who avoid animal products, soy, or milk protein. The fermented *Yosa* product has been reported to normalize bowel movements in elderly nursing home subjects. *Bosa*, a Bulgarian beverage mainly made from cereals, has been used for the isolation of *Lactobacillus* spp. *Mageu* (*amaHewu*), a traditional South African nonalcoholic drink, is made from maize porridge and is predominated by *Lactococcus lactis* subsp. *lactis*, which could be further characterized for probiotic attributes. Worldwide, many other cases where cereal-based fermented beverages have been used for the isolation of probiotic microorganisms can be found, including *Pozol* (Mexico) and *Togwa* (Tanzania). Moreover, herb- or fruit-based probiotic beverages have gained popularity. *Hardaliye* is a grape-based fermented beverage and many lactobacilli were isolated and incorporated for the standardization of its production. Other than beverage-based probiotics, there are some evidences of using meat and vegetable as potential source for probiotic microorganisms. Furthermore, *Lactobacillus plantarum* strains were isolated from Indian traditional herbal beverages, such as *Kutajarista*, for probiotic characterization.

Due to recent advancements in high-throughput technologies for microbiota analysis, a great number of studies have highlighted microbial dynamics during fermentation and the possible role of probiotic microorganisms during fermentation,

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00570-5

storage, and consumption. One illustrative example is the use of probiotic strain *Lactobacillus paracasei* IMPC2.1 during fermentation of green olives. In this fermentative process, the probiotic strains predominated in the total microbial flora and exhibited a dual role as starter and probiotic culture.

Types of Microorganisms

Lactobacillus and *Bifidobacterium* genera constitute the majority of the probiotics products available in the market at present. Moreover, most of them have a long history of safe use in food and are listed in the European QPS list and/or the US GRAS notification list as safe for specific food uses. Therefore, lactic acid bacteria and *Bifidobacterium* are probably the best models for probiotic use or health effect characterization. However, members of the genera *Streptococcus*, *Enterococcus*, *Saccharomyces*, *Bacillus*, *Escherichia*, *Propionibacterium*, and *Lactococcus* have also been explored for probiotic attributes. In each case, the assessment should start from the potential safety issues and then continue to the demonstration of efficacy and health benefits.

Lactobacillus and *Bifidobacterium*

The major *Lactobacillus* species that are considered or studied for probiotic attributes include *Lactobacillus acidophilus*, *Lactobacillus amylovorus*, *Lactobacillus casei*, *Lactobacillus crispatus*, *Lactobacillus delbrueckii* subsp. *bulgaricus*, *Lactobacillus gallinarum*, *Lactobacillus gasseri*, *Lactobacillus johnsonii*, *Lactobacillus paracasei*, *Lactobacillus plantarum*, *Lactobacillus reuteri*, and *Lactobacillus rhamnosus*. Lactic acid bacteria are acid-tolerant and fermentative in nature and have been used as starter cultures in the majority of fermented foods. Lactic acid bacteria in general have the intrinsic capacity to tolerate low pH values and high bile concentrations and to adhere to intestinal cell lines. Molecular studies have revealed that a large proportion of their genomes are attributed to sugar utilization and transportation. Additionally, intestinal adaptation is also apparent, for example, with respect to the presence of mucous-binding protein and bile salt hydrolase genes in *Lactobacillus plantarum* and adhesion protein in *Lactobacillus acidophilus*. Moreover, *Lactobacillus casei* differentially expresses genes in the mouse intestine for a better adaptability to the intestinal conditions.

Bifidobacterium spp. have also been extensively used in product formulations and probiotic applications as they share many phenotypic characteristics with lactobacilli. In comparison with lactobacilli, bifidobacteria inhabit very limited niches, such as human and animal GI tracts and, in some cases, insect intestines. The major species that were isolated and studied include *B. adolescentis*, *B. angulatum*, *B. animalis* subsp. *lactis*, *B. bifidium*, *B. breve*, *B. catenulatum*, *B. dentium*, *B. longum*, and *B. pseudocatenolatum*. Genomic studies of *Bifidobacterium* strains revealed that they can utilize a broad range of complex carbohydrates such as inulin-type fructans, arabinogalactans, arabinoxylans, and starch. Exclusive operons have been evolved for specialized purposes, as the degradation of amylopectin by *B. breve* strains and the utilization of a broad range of simple sugars by *B. dentium*. *Bifidobacterium* strains also show changes at transcriptome and proteome level in intestinal conditions or gut environment.

Strain Selection and Health Benefits

As per recent WHO/FAO guidelines 2002, probiotic properties are possibly not only species-specific but also strain-specific. Similar, but binding regulatory guidelines have been given by the European Food Safety Authority (EFSA). Therefore, health benefits conferred by one strain cannot be extrapolated to another, not even within a same species.

Probiotics are typically selected for their ability to pass through the upper GI tract (characterized by low pH and high bile salt concentrations), to colonize the intestinal epithelium, and to express antimicrobial activity against pathogens. Additionally, all initial screening and detailed characterization should follow WHO/FAO guidelines. The major steps include strain identification using molecular tools, functional characterization using *in vitro* and *in vivo* models, double-blind controlled human trials, and formulation assessment and quality control.

Highlights of the WHO Guidelines (2002)

Strain Identity

It is now widely accepted that probiotic properties are strain-specific. Therefore, in addition to identifying probiotic microorganism till genus and species level, strain identity is considered to be one of the fundamental aspects of probiotic characterization. Biochemical characterization should be supplemented with genotypic characterization based on molecular tools for strain identification or differentiation. Whole genome sequencing of probiotic strains may act as reference for validation and commercialization. Similar guidelines are also given by EFSA.

History of Safe Usage and Recommendations

Strains used for probiotic characterization should be safe in each particular application, which could in principle be ascertained by identifying the respective source of isolation and history of use. However, there were some independent reports of infections that might have been caused by administration of probiotic strains. It has been recommended that probiotic strains should also be screened for antibiotic resistance, metabolic potential, and production of mammalian toxins. In general, probiotic strains isolated from traditional food or beverages are considered to be safe because of their long history of human consumption. Nevertheless, these probiotic strains are not exempted from the WHO guidelines including *in vitro* and *in vivo* tests.

Tolerance to GI Conditions

Survivability of any probiotic strain is characterized by its ability to withstand GI conditions like acidity and high bile concentrations. Probiotic strain may also be screened for antimicrobial potential against pathogens. Many studies have highlighted secretion of bioactive factors with potential to

inhibit a broad range of pathogens. Adherence to intestinal cell lining can be determined by *in vitro* adherence tests based on various intestinal cell line models and *in vivo* by different animal models.

Human Intervention Studies

Based on animal studies, human trials have to be designed to validate claimed health benefits and their biological and statistical significances. Apart from claimed health benefits, general well-being or improvement in health condition should also be taken in account. The different phases of a clinical study include phase 1 (safety), phase 2 (efficacy), phase 3 (effectiveness), and phase 4 (surveillance of potential side effects). However, in case of foods and food supplements, slightly less regulatory framework is required (i.e., in comparison with pharmaceutical product) for the demonstration of health benefits.

Health Effects

Apart from the positive effect of probiotics on general well-being, there are several particular clinical symptoms or conditions that are reported to be beneficially affected by the use of specific probiotics. Such conditions include diarrhea, gastroenteritis, inflammatory bowel disease, irritable bowel syndrome, Crohn's disease, and alleviation of symptoms of lactose intolerance (Figure 1).

Effects on Intestinal Disorders

Probiotics find applicability in diarrheal cases that could be caused by viral or bacterial infection or could be antibiotic-associated diarrhea. It should also be noted that efficacy of probiotic strains depends on the type of diarrhea. For instance, probiotics are found to be effective against rotavirus-associated diarrhea. The major probiotic strains used for clinical applications in children belong to *Saccharomyces boulardii*, *Lactobacillus rhamnosus*, and *Lactobacillus reuteri*. For instance, some studies highlight the use of *Lactobacillus rhamnosus* GG for *Clostridium difficile*-associated diarrhea and the prevention of the onset of pouchitis.

The possible mechanism could be due to an immunomodulatory role, probably by increase in secretory IgA. Some probiotic bacteria also secrete antimicrobial peptides, that is, bacteriocins, which could inhibit the growth of certain enteric pathogens. It is also believed that probiotic microorganisms compete with pathogenic viruses or bacteria for intestinal binding sites.

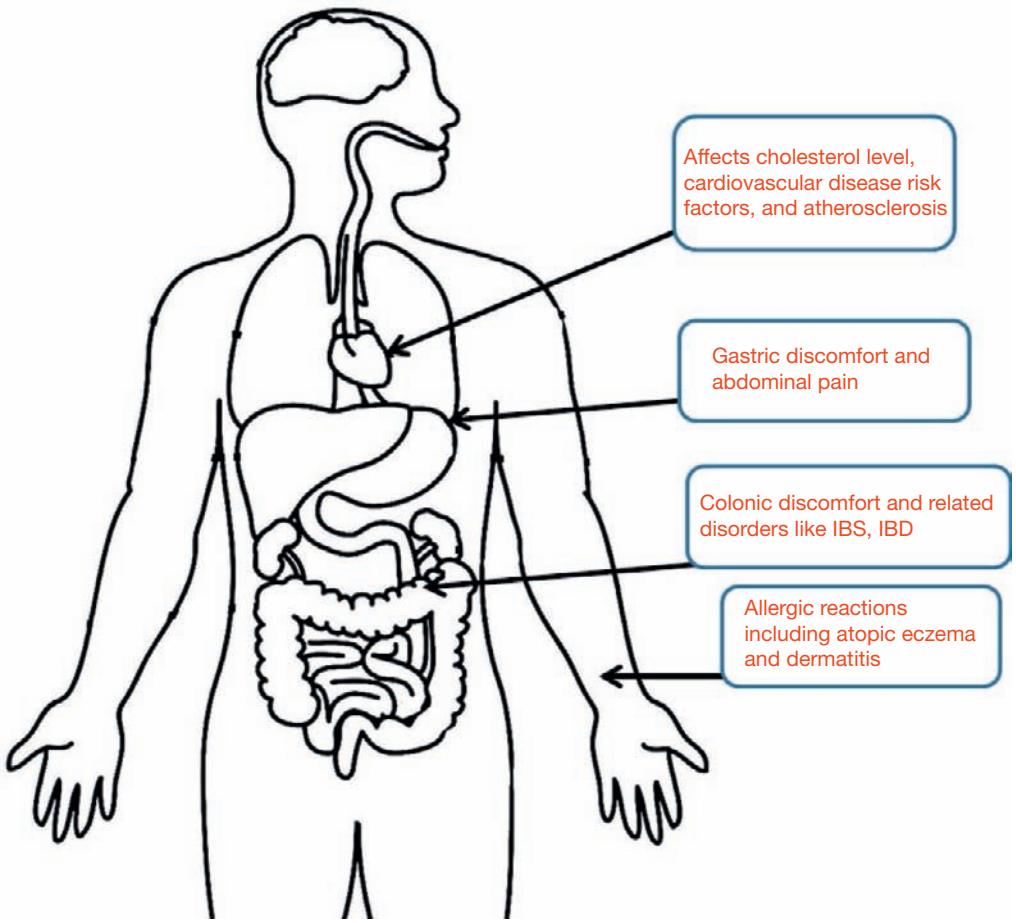

Figure 1 Major areas of studies for human health effects for probiotics: reduction of cardiovascular disease risk factors and allergies; alleviation of gastric discomfort, colonic discomfort, and related syndromes including IBS, IBD, and Crohn's disease.

Inflammatory bowel diseases, such as Crohn's disease and ulcerative colitis, are marked by high immune responses to gut microbes. Probiotics have found application in alleviating inflammatory conditions in the gut, which could be due to the stimulation of host immune response that may include immune cell proliferation, enhanced phagocytic activity, increase in secretory IgA, and shifts in overall microbial composition.

Some lactic acid bacteria, including *Lactobacillus delbrueckii* subsp. *bulgaricus* and *Streptococcus thermophilus*, also may improve lactose intolerance through the production of lactase. Therefore, fermented dairy products like yogurt are widely recommended for regulating lactose intolerance.

In case of constipation, it is believed that lactic acid bacteria secrete organic acids that modify the intestinal microbiota and increase intestinal motility due to lowering of pH or shortening of transit time.

Prevention of Allergies

Probiotics may exhibit antiallergic effects by degradation or structural modification of enteral antigens, stabilization of aberrant microbiota, improvement of the gut-barrier function, regulation of the secretion of proinflammatory mediators, and development of the immune system. Probiotic intervention studies in children have shown that there is significant reduction in cumulative incidence of eczema and IgE-associated eczema. Evidence also suggests that probiotic administration during pregnancy may reduce the risk of eczema during the first year of life. In the case of food allergies, infants that were fed with *Lactobacillus rhamnosus* GG showed an increase in tolerance to cow's milk protein. Interactions between gut microbiota and probiotics have significant roles in immune regulation and predisposition to allergy. Moreover, present knowledge suggests that singular clinical reports cannot be extrapolated for general usage or as a therapeutic alternative for allergy treatment yet. Indeed, properties are strain-specific and the exact mechanisms of action remain to be elucidated.

Anticarcinogenic Activities

Several probiotic strains belonging to *Bifidobacterium* spp. and *Lactobacillus* spp. were claimed to have anticarcinogenic, antimutagenic, and antitumorigenic activities in different animal models. Short-chain fatty acids produced by the intestinal microbiota play very important roles in the maintenance of colonic mucosal health. Yet, probiotic strains in general do not produce anticarcinogenic butyrate, in contrast to gut bacteria from the clostridial clusters IV and XIVa. The latter butyrogenic bacteria may nevertheless be stimulated by the administration of certain probiotics through cross-feeding mechanisms. Mechanism for anticarcinogenic activity of butyrate may be due to the inhibition of proliferation, induction of apoptosis, or differentiation of tumor cells. Probiotics also influence carbohydrate and protein fermentation, enriching microbiota with high saccharolytic activity and low proteolytic activity. Proteolytic fermentation end products or metabolites are potentially toxic and microbial manipulation or dietary modification toward saccharolytic fermentation is highly desirable. However, there are very few studies that claim efficacy of probiotics, prebiotics, or synbiotics with potential anticarcinogenic activity in humans.

Use of Probiotic in Controlling Blood Cholesterol

Elevated blood cholesterol levels signify increased risks for cardiovascular and related diseases. It has been suggested that incorporation of probiotics in dietary supplements may help control serum cholesterol levels. *Lactobacillus acidophilus* and *Bifidobacterium lactis* that were incorporated in yogurt may thus lower total cholesterol levels in serum. *In vitro* assays revealed that lactobacilli can precipitate cholesterol from the media and deconjugate bile salts. However, the cholesterol-lowering capacity is possibly strain-specific and, more importantly, human intervention studies are not conclusive (Table 1).

Future Developments

The market currently offers a range of probiotic-based products and formulations with varied health benefits and claims, but several challenges still remain, not in the least on the legislative level. For example, there are a number of recommendations for probiotic application by scientific societies such as the European Society of Pediatric Gastroenterology, Hepatology and Nutrition (ESPGHAN) and the corresponding society in North America (NASPGHAN) for probiotic use in treatment and prevention of specific diseases. However, in the European Union, no probiotic health claims for the general public have been approved yet. The discrepancy does not mean that probiotic products are not useful for the general population, but rather suggests that studies until now have been conducted in at risk populations or subjects with specific diseases. Further studies are thus required for the documentation of health claims. Furthermore, viability of probiotic strains to ensure adequate dosage is very important for industrial standardization. Still, food matrix composition and general processing condition are not mentioned on product labels, although they may affect efficacy, viability, or stability of probiotic strains. Encapsulation technology is very promising in maintaining the stability of probiotic strains in different food matrices. Also, the incorporation of probiotic strains should not affect overall flavor and texture of the marketed product. Therefore, it is important to meet technological and sensory demands for manufacturing probiotic-based formulations.

The efficacy of probiotics based on intervention studies should be evaluated by their clinical outcome and reduction of risk factor. In case of obesity, specific changes in gut microbiota can be promoted by probiotics, which may help in controlling fat mass and decreasing insulin resistance. Immunostimulatory activity of lactobacilli was reported to enhance immune function in case of elderly subjects. However, specific health claims of probiotics in control of obesity or immunogenicity have yet to be established. Meta-analysis of clinical trials reveals that it is extremely difficult to achieve consensus on general health claims as most trials are based on different strains or combinations of strains, used at different concentrations and in different target groups. Specific claims against major diseases, such as HIV infection or cancer, should be

Table 1 Some of the commercially available probiotic microorganisms

Probiotic strain	*Source of isolation and commercial application*	*Claimed benefits or applications*
Lactobacillus acidophilus LA-5 and *Bifidobacterium animalis* ssp. *lactis*, BB-12	LA-5 was selected by Chr. Hansen for the production of probiotic dairy products, which majorly includes infant formula, dietary supplements	LA-5 and *Bifidobacterium animalis* ssp. *lactis* BB-12 reduce diarrhea and constipation in elderly patients
Lactobacillus acidophilus NCDO 1748	Isolated from human pharynx and used in food products during 1970s. *Lactobacillus acidophilus* NCDO 1748 in fermented milk products were patented by Arla Foods	Prevents negative impact of antibiotics and immobilizes food mutagen
Lactobacillus acidophilus NCFM	Isolated at North Carolina Food Microbiology, that is, NCFM. Commercialized in supplements and fermented foods	Maintains intestinal health
Lactobacillus casei Shirota	Dr. Minoru Shirota isolated at Kyoto Imperial University's School of Medicine and later on developed fermented mild drink called Yakult	Beneficial effect on chronic constipation and short bowel syndrome (SBS)
Lactobacillus gasseri OLL2716 (LG21)	Warren and Marshall isolated in 1982 to find an alternative to antibiotic against *H. pylori* infection	Beneficial in *Helicobacter pylori* infection and gastric inflammation
Lactobacillus paracasei ssp. *paracasei*, F19	Isolated from healthy colonic mucosa. Used in fermented milk products like Cultura in Sweden and Denmark	Helps in stabilizing gut flora during antibiotic treatment
Lactobacillus paracasei ssp. *paracasei*, *Lactobacillus casei* 431	Isolated from feces of healthy child	Found effective in infant and young children diarrheal cases
Lactobacillus rhamnosus GG, LGG	Isolated from healthy human intestine and commercially available through Valio in Finland	Prevention and treatment of antibiotic-associated and traveler's diarrhea
Lactobacillus rhamnosus, GR-1, and *Lactobacillus reuteri* RC-14	GR-1 was isolated from the distal urethra of a healthy woman and RC-14 was isolated from vagina of a healthy woman	Shown significant improvement in women's urogenital health
Lactobacillus rhamnosus HN001 and *Bifidobacterium lactis* HN019	Selected from culture collection of the New Zealand Dairy Research Institute. Marketed by Danisco and by Fonterra	Beneficial in gastrointestinal diseases and have positive effect on immune health
Bifidobacterium longum BB536	Isolated from healthy infant and commercially available as Morinaga Bifidus milk	Immune stimulatory activity and stabilize gut microbiota

based on clinical trials based on large cohorts. Analysis based on biomarkers should be correlated with clinical endpoints. For example, variation in inflammatory cytokines should be backed by reduction or prevention of disease.

Probiotics have complex modes of action and can affect a number of different pathways; therefore, it is difficult to apply conventional pharmacological regulations. It becomes increasingly apparent that probiotic claims are more toward 'soft' health benefits rather than treatment of specific disease symptoms. Therefore, claims range from shortening the duration of acute diarrhea, improvement of gut well-being, immune stimulation, and control of cholesterol levels to the prevention and treatment of atopic dermatitis and eczema.

The role of gut microbiota is increasingly been recognized as one of the major factors affecting overall health status. Due to advent of 'omics' technologies, the impact of gut microbiota in different health conditions can be studied in greater detail, which will eventually lead to enhancement of our basic understanding of the microbial role in host physiology. For example, it has recently been shown that *Faecalibacterium prausnitzii* exhibits strong anti-inflammatory activity in patients with Crohn's disease, that spore-forming members of the clostridial clusters IV and XIV induce regulatory T cells in the colon and could be of therapeutic potential, and that *Akkermansia muciniphila* seems effective in controlling high-fat, diet-induced metabolic disorders. Another intriguing example is the application of fecal microbiota transplants to treat *Clostridium difficile* infections. Such studies may lead to the formulation of novel probiotics or innovative combinations of microbes that could be exploited for therapeutic utilities.

Conclusions

Recently, the field of probiotics has witnessed constant advancement with respect to product development and targeted health benefits. As such, probiotics are emerging as an alternative medicine for metabolic diseases. It seems that the whole concept of probiotics will be revisited to incorporate unconventional microbes or groups of microbes with specific health benefits. However, common probiotics are currently still predominated by members of the genera *Lactobacillus* and *Bifidobacterium*. Traditional health foods still act as major resource for the isolation and characterization of probiotic microorganisms. In the future, gut microbiota studies will lead to the design of new probiotics with proven health benefits. Importantly, probiotic strains have to be well characterized and follow guidelines set up by international organization as WHO and EFSA.

Protein Quality and Amino Acids in Maternal and Child Nutrition and Health

S Ghosh, Friedman School of Nutrition Science and Policy, Tufts University, Boston, USA

Introduction

The role of nitrogen and related compounds in life processes was first unraveled in the 1700s when French chemists identified nitrogen in air (naming it *azote*), with protein as a chemical class being identified about 50 years later. Protein is defined as a complex high-molecular-weight organic compound, consisting essentially of combinations of amino acids (AAs) in peptide linkages that contain carbon, hydrogen, oxygen, and nitrogen. Jakob Berzelius identified individual AAs as early as 1830, but it was not around the early 1900 that all the essential AAs were fully identified. Since then, considerable research on protein and AAs at the biochemical, molecular, and pharmacological levels has been undertaken, and more recently, with a better understanding of the molecular basis of the genetic coding of AA sequences, the role of protein and AAs in human health and disease is being established. While the skeletal muscle constitutes the major compartment of body proteins accounting for over 40% of the whole-body protein pool, the skin and blood proteins are also relevant.

Populations in the developing world, subsisting primarily on cereals and cereal products, are more vulnerable to protein deficits compared with those eating flesh foods. Recent food prices and financial crises have increased risk of food insecurity and hunger. Whereas energy needs may be fully met by cereals, such diets are poor not only in micronutrients but also in high-quality protein and thus have limited value in satisfying protein needs. This article presents the current understanding of protein and AA needs, their sources and production, worldwide patterns of consumption, requirements, and assessment methods and examines evidence relating protein and AA needs to health and nutrition with the aim of applying this knowledge to optimize health and well-being of human populations.

Sources and Production

From the perspective of nutritive value, dietary proteins are the source of indispensable AA and supply nitrogen for the synthesis of dispensable AAs. Indispensable AAs are those that are not produced at all or not made in sufficient amounts to support health by humans. Of the 20 AAs, 9 AAs are indispensable, one is considered as conditionally indispensable, and 10 are dispensable (Table 1).

The quality of a protein depends on its digestibility and on its indispensable AA composition, both the absolute amounts present and the proportions of the AAs. Protein-containing foods are designated as complete (high-quality) or incomplete (low-quality) on the basis of indispensable AA content. Dietary sources of animal protein such as meat, poultry, fish, and dairy products are complete proteins, while plant foods such as grains, legumes, and vegetables are incomplete proteins since they lack one or more essential AAs. The latter when consumed in specific combinations, generally cereal–legume mixes (e.g., corn and beans, rice, and lentils), provide an AA profile similar to that of a complete protein, thus the term AA complementarity. More information on food sources can be obtained from the article on protein food sources.

The capacity of food protein sources, mixed diets, or both to satisfy metabolic demand is estimated through evaluating their quality. Overall protein utilization (net protein utilization) reflects both digestibility (a function of digestion and absorption) and biological value (the degree with which absorbed nitrogen is utilized). Rat growth assays have been used to estimate protein quality in foods through the determination of the protein efficiency ratio (PER), defined as the weight gain of the test rat group divided by the protein consumed by the test group compared with a reference protein (commonly casein or egg protein). PER is based on achieved growth rate and thus has been criticized for its inability to account for protein used for maintenance purposes. Furthermore, values of PER of proteins of differing quality are not proportional to each other, that is, a PER of 2.0 cannot be assumed to be as twice as good as a PER of 1.0. Through several consultations from 1985 to 1991, a method based on measures of digestibility and AA composition, called the protein digestibility-corrected AA score (PDCAAS) method, has been adopted. The PDCAAS method is a scoring system that assesses the quality of protein in mixed diets, mixed formulations, or both based on its digestibility and essential AA composition, thus correcting for total protein and giving an estimate of 'utilizable protein.' Diets that are high in quality and digestibility such as animal-source foods are likely to have total protein and utilizable protein values closer to each other compared with those diets that are poor in quality and digestibility such as cereals and starchy food crops. It is now known that in diets in which over 50% of protein comes from cereal sources, the protein quality is relatively poor, adversely affecting biological value and protein utilization. Recent consultations have led to the recommendation of a new protein

Table 1 Indispensable and dispensable amino acids for adult mammals

Essential (indispensable)	*Nonessential (dispensable)*
Valine	Cysteine[a]
Leucine	Glycine
Isoleucine	Alanine
Threonine	Serine
Phenylalanine + tyrosine	Proline
Methionine + cysteine	Glutamic acid
Tryptophan	Aspartic acid
Lysine	Glutamine
Histidine[a]	Asparagine
Arginine[a]	Tyrosine[a]

[a]Cysteine, arginine, and tyrosine may be conditionally dispensable and histidine indispensable in infants.

quality measure called the digestible indispensable amino acid score (DIAAS). This will replace the PDCAAS and is defined as DIAAS % = 100 × ((mg of digestible dietary indispensable AA in 1 g of the dietary protein)/(mg of the same dietary indispensable AA in 1 g of the reference protein)). Further information on measures of protein quality can be obtained from the 2014 protein quality evaluation report by the Food and Agriculture Organization.

Protein and AA Requirements

Protein requirements are a function of metabolic demand reflected by maintenance (metabolic processes that utilize AA and generate N compounds excreted via urine, feces, sweat, and other miscellaneous losses), special needs (growth, lactation, and pregnancy), and the efficiency of utilization (factors related to digestion of proteins and absorption of AAs). Intakes at which balance is achieved vary within and across individuals due to variability in metabolic demand, genotype, and factors that affect phenotype and physiologic conditions (growth, pregnancy, and lactation). Efficiency of utilization (net protein utilization), dietary intakes of other nutrients, lifestyle, and environmental stress (including infection) also alter the protein requirements.

The composition and pattern of AAs in a diet are important to generate a suitable mix that will match metabolic demand for protein synthesis with other needs. AA requirements in the past were established using nitrogen balance techniques (N equilibrium defined by an intake that matched N excretion (urine + fecal + integument losses) expressed in grams of protein per kg of body weight). Presently stable isotope techniques that allow assessing protein synthesis and breakdown are used to define optimal AA and protein intakes. Carbon balance and AA oxidation methods are now recommended methods for the estimation of essential AA requirements. Compared with previous estimates, current protein requirements are lower in both adults and children; however, the requirements for AA remain the same in children and are significantly higher in adults. Effectively smaller quantities of higher-quality protein (to achieve the AA pattern) are now recommended. Protein and AA requirements as defined by the current FAO/WHO 2007 report for all age groups are provided in Table 2. For further reading on protein requirements, please refer to the article on protein requirements.

Interactions between energy deficit and protein needs also affect nitrogen equilibrium. Energy imbalance (both excess and deficit) affects body nitrogen balance. At a protein intake of 0.57 g/kg^{-1} body weight, N equilibrium is achieved if energy intake is ~10–15% above the energy requirement. Conversely, individuals with energy deficit need additional protein, and even a modest energy deficit increases protein needs by about 10%. Such fluctuations in needs are not accounted for in the estimation of normative requirements; thus, adjustments need to be made if the target population is under stress or other conditions that may increase requirements. Other possible factors that may have an impact on protein and AA needs include infections or environments where individuals have persistent immune activation. In subjects with chronic enteric infections or inflammation leading to a decline in intestinal absorptive capacity; even in the absence of overt clinical symptoms, there is still an increased demand of protein. Thus, for vulnerable populations such as women and children commonly affected by acute and chronic infections, protein and AA needs are likely to be higher than what is recommended. Growth rate (especially in length) is likely to be affected by repeated infections (bacterial and parasitic) with the long-term implications associated to stunting. These include impaired learning capacity, poorer school performance, decreased work productivity, and other functional deficits. It is known that requirements of AAs such as lysine are significantly higher in chronically undernourished adults suffering from intestinal infections.

Protein and AA Metabolism

Protein and AA metabolism is a complex system. Movement of AAs through the system includes the flow to protein synthesis and other metabolic pathways; excess AAs undergo oxidation

Table 2 Protein and amino acid requirements in children 6 months to 18 years of age

and are excreted as urea. AAs to satisfy demand are derived from dietary protein ingestion, body protein degradation, and de novo synthesis of nonessential AAs. As most of the AAs derived from protein degradation match the amount and pattern going to protein synthesis, demand is affected primarily by flow from dietary intake and de novo synthesis. Finally, the pathways of AA metabolism and interchange are critically dependent upon an adequate micronutrient status and hence upon the amount and quality of food consumed (Figure 1). The digestion, absorption, and metabolism of proteins are covered in a separate article in this volume as is the metabolism of AAs.

Global Patterns of Consumption and Access

A commonly used method to estimate nutrient availability at the global, regional, and country level is the estimation of nutrient availability using country level food balance sheets from the Food and Agriculture Organization (FAO) of the United Nations. Analyses conducted on 40 years of data from FAO (1961–2005) correcting for protein quality using the PDCAAS method show differences in the availability of energy and utilizable (good-quality) protein across regions and countries. For example, in 2005, total energy availability ranged from 2090 to 4497 kcal (2789 kcal per capita available globally) with least developed countries exhibiting the lowest levels. Regionally, Africa had the lowest availability at 2522 kcal, while countries in Northern America had the highest at 4497 kcal available per capita per day. Total protein followed total energy with a range of 53–137 g per capita available (83 g available globally), while utilizable protein (total protein corrected for AA score and digestibility) ranged from 46 to 125 g with an average of 74 g available globally. Correcting for quality of protein led to a reduction in total protein by 11% globally with as much as a 17% reduction in total protein availability in Africa (Table 3).

Examining the data for trends (1961–2005), we found that the global availability of utilizable protein (good-quality protein) has steadily increased from 57 to 74 g per capita per day (Figure 2). This increase was mirrored in Northern America, Latin America and the Caribbean, and Asia. In Europe and Oceania, utilizable protein availability has remained consistently high since 1961. In contrast, utilizable protein availability in Africa was low (47 g per capita per day) in 1961, with small gains in the following years with a per capita availability of 56 g per day in 2005. While Asian countries were below African countries with respect to utilizable protein availability from the 1960s to 1970s, the steady increase in availability in Asia is opposite to that in Africa, where there is stagnation in utilizable protein availability.

Health Effects

Clearly, there are limitations in the quality of protein available in developing country diet, which are predominantly plant- and cereal-based, and these have health ramifications. This is especially the case for infants (low-nutrient-density complementary foods) as well as foods available to pregnant and

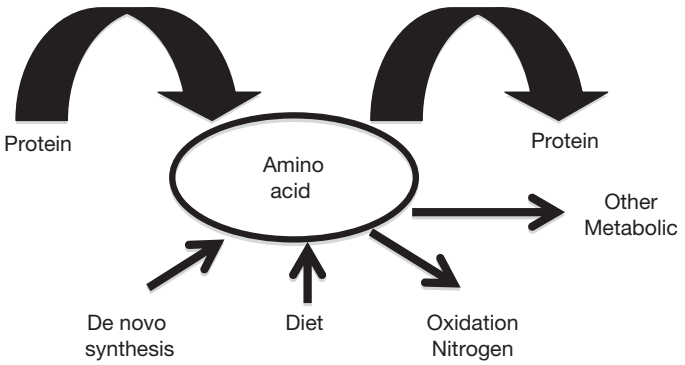

Figure 1 Protein and amino acid metabolism and interchange. Adapted from the WHO (2007).

Table 3 Comparison of protein availability across geographical regions, 2005

Country	*Total energy (kcal)*	*Total protein (g)*	*Utilizable protein (g)*[a]
World	2789	83	74
Northern America	4497	137	125
Europe	3674	115	104
Oceania	3542	116	107
Latin America and the Caribbean	3144	88	79
Asia	2550	75	67
Africa	2522	67	56

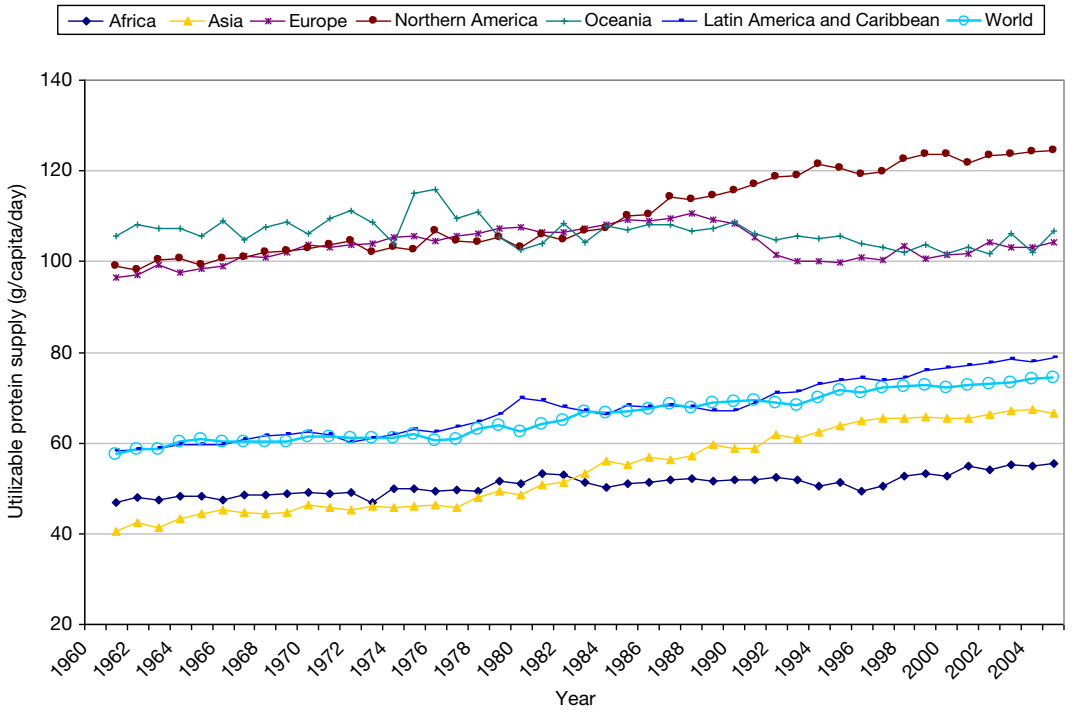

Figure 2 Utilizable protein availability across regions (1961–2005).

lactating women, preschool, and school-aged children, all of which are also low in micronutrients. The role of protein in the context of nutrition in infants and young children and maternal nutritional status and birth and pregnancy outcomes that also affect long-term growth and cognitive development in children are explored in the following sections.

Protein Effects in Pregnancy

Approximately 30 million newborns are affected by intrauterine growth retardation (IUGR, defined as being born with a birth weight under the 10th percentile of the birth-weight-for-gestational-age reference curve) in the least privileged of developing countries, with the highest prevalence in south-central Asia. Low birth weight/IUGR newborns are four times more at risk of neonatal death compared with those weighing 2500–3000 g at birth and 10 times more likely than infants weighing 3000–3499 g.

The consequences of maternal energy and protein restriction are widely documented. Maternal nutritional status has an impact on infant weight and body proportions, with low weight, height, or BMI on the mother's side being associated with lighter, shorter, and thinner babies; this has a further strong link between composition of the mother's diet and birth outcomes. Maternal protein deficiency during early or midgestation results in decreases in placental and fetal growth and may permanently retard postnatal growth and lead to permanent alterations in their structure, metabolism, and function. In vivo examination (porcine model) of the effect of maternal protein deficiency on AA availability to the fetus and potential retarded growth indicates the following: while maternal protein deficiency maintains maternal plasma concentration of AAs, it may impair placental transport of AAs from the maternal to the fetal blood with subsequent decreases in the concentrations of essential and nonessential AAs in the fetus. This could be the mechanism by which maternal protein restriction results in fetal growth retardation. More recent in vitro work using murine embryonic cells shows that AA deficiency (specifically that of lysine) increases the steady-state levels of several mRNAs (by 5- to 40-fold) that are elevated in growth-arrested cells within 24 h of exposure to AA deficiency. The provision of a high-protein diet or a diet supplemented with branched AAs to pregnant mice, in conjunction with calorie restriction, partly ameliorated the fetal growth restriction induced by the maternal calorie restriction through an increased IGF gene expression (IGF-1 and IGF-2 upregulation) in the fetal liver and was found to be independent of fetal glucose levels.

Consumption of a high percentage of energy from protein in early pregnancy is positively and significantly associated with birth weight and placental weight, an association independent of the effects of energy intake, weight gain, and confounders such as maternal age, parity, and smoking, and was specific to women who had met prespecified criteria of reliable data. For every one percent (isoenergetic) increase in protein in the diet, a 16 g increase was observed in birth weight (95% CI, 2.8–29.2 g) and a 4.2 g increase was found in placental weight (95% CI, 0.4–8.5 g). Furthermore, percent energy from carbohydrates in early and late pregnancy is negatively associated with the ponderal index. Percent of energy from dairy protein is also positively associated with birth weight and with ponderal index more strongly associated than other sources. For every 1% increase in dairy protein consumption, a 24 g increase in birth weight ($P=0.02$) and a 0.12 kg m^{-3} increase in ponderal index ($p=0.05$) have been observed. Similarly, women with high intakes of carbohydrate in early

pregnancy and low intakes of dairy protein in late pregnancy were likely to have infants that were thin at birth; women who had been low birth weight babies themselves were likely to have thin infants with the infant's ponderal index falling from 28.3 to 26.2 kg m^{-3} as the mother's birth weight decreased from 4000 to 2500 g or lower.

Several intervention studies have indicated that balanced protein and energy supplementation can affect birth outcomes and could reduce the risk of small-for-gestational age infants (as an indicator of IUGR by 32%). According to a Cochrane review of balanced protein–energy supplementation trials, providing nutritional advice to increase energy and protein intakes did not have a consistent benefit on pregnancy outcomes (5 trials with 1134 women); however, in 13 trials (4465 women) with balanced protein–energy supplementation, small increases were found in maternal weight gain and mean birth weight, with a substantial reduction in risk of Small for gestational age (SGA) births, still births, and neonatal deaths; preterm birth risk, however, was not affected. High-protein supplementation (2 trials, 1076 women) and isocaloric protein supplementation (3 trials, 966 women) led to increased risk of SGA births. Furthermore, high-protein supplementation alone or isocaloric protein supplementation may have a negative impact on fetal and neonatal outcomes. A meta-analysis has shown positive effects of balanced protein–energy supplementation on SGA births, mean birth weight, and neonatal mortality. Trials included providing nutrient supplements to pregnant women, with protein content ranging from 30 to 44 g of protein per day and contributing 25% or less to energy. The meta-analysis reports a significant reduction of 31% in the risk of giving birth to SGA infants (RR = 0.69, 95% CI 0.56–0.85) using SGA as a proxy for IUGR. Infants in the balanced protein–-energy supplementation group gained more weight compared with the control group infants, an effect that is more pronounced in malnourished women compared with those adequately nourished women. Another study providing prenatal food supplementation to undernourished or anemic pregnant women (fortified spread with peanut butter, soy flour, vegetable oil, and sugar) fortified with multiple micronutrients compared with only a multi-micronutrient supplement found improved birth length – but not weights – in the fortified supplement group. The total energy provided was 372 kcal, with 15% from protein (14.7 g of protein) and 67% from fat.

Low-protein diets, protein-restricted environments during gestation, or both could induce a nongenomic growth and adaptive response. A moderately low-protein diet (7.6% PE ratio) during gestation in rats activates a placental AA response pathway, which could be a cue for the fetus to develop an adaptive response suited to a predicted postnatal environment (a more favorable phenotype for their survival) as observed in the case of the growth of pups. Pups born to dams with a moderately low-protein diet through gestation are lighter than control pups starting from week 2 of lactation, whereas pups born to dams with a moderately low-protein diet during both gestation and lactation are significantly lighter than control pups from the 1st week of lactation. Analysis of the placental mRNA showed increases in the expression of specific genes that could be connected to the developmental capacity of the growing neonate, which may have implications in the programming of adult-onset diseases. Alterations have also been found in the expression of the liver transcriptome over three generations of offspring following a protein-restricted diet in dams (generation 0) during pregnancy; this was associated with differences in the number of genes being altered per generation, magnitude of the difference, and the distribution of up- and down-regulated genes. While not all the same genes were altered in each generation and some genes changed in the third – but not in the first – generation, all three generations had altered fasting glucose homeostasis and changes in the methylation of phosphoenolpyruvate carboxykinase promoter. The findings are indicative of the complex nature of the effects of altered nutrition (with the case in point being altered protein intakes) on the phenotype of subsequent generations of offspring. There is an association of high dietary protein intake in pregnancy (late) on infant ponderal index, later body composition, and the risk of chronic disease. In an analysis of Tasmanian Infant Health survey data, for every 10 g increase in daily maternal intake of protein during late pregnancy, a reduction in birth weight of 17.8 g was observed (95% CI: −32.7, −3.0; $p = 0.02$). Protein intake was negatively associated with ponderal index (beta = −0.01; 95% CI: −0.02, −0.00; $p = 0.01$) in large birth weight infants, but not in low birth weight infants.

Protein Effects in Infancy and Childhood

Protein and AAs in infancy and childhood play a role in growth, including muscle protein synthesis and linear growth. Studies have shown a positive impact of incorporating high-quality foods into the diets of young schoolchildren. An ecological analysis examining the relationship of stunting at the national level and protein quality and availability (in 2005) has shown that total energy, total protein, and total utilizable protein estimates are all independently and significantly associated negatively with the prevalence of stunting ($p < 0.001$). Total energy explains 41% of the variation in stunting, total protein explains 34% of the variation, and utilizable protein explains 40% of the variation in prevalence of stunting (separately). When total energy and total protein were incorporated into the model together to control for energy availability, only total energy emerged significant; however, when total energy and utilizable protein are incorporated in the model together, both are significant ($p = 0.006$ and $p = 0.017$, respectively), thus demonstrating that good-quality (utilizable) protein is a predictor of stunting controlling for energy availability.

High protein intakes (three to five times the current European requirements) are reported in children in European countries during the complementary feeding period and are indicated of having a growth stimulating role (especially that of linear growth) through effects on insulin-like growth factor-1 (IGF-1), with protein restriction leading to low levels of IGF-1 in healthy children. When older children are energy-restricted (50% reduction in intake) or protein-restricted (reducing protein from 1.0 to 0.66 g/kg^{-1} body weight per day), both forms of restriction lead to a significant decrease in nitrogen balance and decline in IGF-1 and specific IGF binding proteins. There is also a significant impact on the type and quality of protein on gene expression especially genes associated with IGF-1 and insulin-like growth factor-binding protein-1 (IGFBP-1), both of which play an important role in whole-body protein synthesis with implications for growth promotion and body

composition. High protein intake in infancy, however, could also increase BMI, early adiposity rebound, and the risk of adiposity later in life through the stimulation and subsequent release of higher levels of IGF-1. The type of dietary protein seems to have a specific stimulating effect on weight and length gain. Milk intake is positively associated with serum IGF-1 concentrations and height, suggesting a stimulating effect of milk on the hormonal pathway and subsequently on growth. Eight-year-old boys receiving a high milk intake have higher IGF-1 levels compared with boys receiving protein from meat. It is postulated that AAs, peptides specific to milk and/or other milk components (e.g.,β-lactoglobulin, α-lactalbumin, immunoglobulins, and lactoferrin) are likely to be the active stimulating components. There is a strong association between IGF-1 and body size during infancy and childhood with IGF-1 mediating a positive association between protein intake and growth. IGF-1 has been shown to regulate the partitioning of overall weight gain into linear growth compared with adiposity in infants and promote skeletal muscle formation and appears to protect against gains in BMI and adiposity (whether infants are breast-fed or formula-fed). Furthermore, there is a strong positive association between protein intake at 9 months of age and body size, height, and weight, but not percentage of body fat at 10 years of age.

There is a relationship between the quality of the protein being provided and growth patterns of infants and young children. Schoolchildren in New Guinea, receiving a regular diet (three meals of taro and sweet potato) with skim milk powder supplement (25 g protein) for 5 months, had significantly greater gains in height and weight compared with those with no milk powder supplement. Similarly, schoolchildren (in a separate study in New Guinea) provided with skim milk powder versus margarine (both isocaloric amounts) or two additional meals of taro and sweet potato daily exhibited the highest height and weight increases compared with a control group. While small weight increases did happen in the margarine group, this was accompanied by substantially higher skinfolds and the children receiving taro and sweet potato exhibited small increase in height but not to the degree of the skim milk powder group. The authors hypothesized (given the high levels of tubers in the diet) that in the case of this particular population, protein was limiting. The effect of milk-based formula has also been observed in younger children in Jamaica, where 9–24-month-olds who were initially stunted and matched (age and sex) to stunted controls were provided a milk formula for 1 year. Supplemented children gained an additional 0.9 cm and 0.31 kg during the first 6 months of the study (only), and the effects were more pronounced in younger infants than older ones. Linear growth improved in Peruvian toddlers consuming marginal diets when given complementary foods, breast milk, or animal product foods at 12–15 months of age. In toddlers with low intakes of animal product foods, breast milk was positively associated with linear growth, whereas infants with low intakes of complementary foods (of all types) benefited in length gain from having animal product foods in the diet.

Besides animal-source foods, well-formulated (e.g., cereal–legume mixture with good protein quality and a complete micronutrient profile) complementary foods also have a beneficial effect on growth patterns.

A study in Ghana found that infants receiving a cereal–legume porridge alone or with fish powder added or with a micronutrient premix added compared with those who received a cereal porridge with fish powder (no legume or micronutrients added) showed similar rates of weight and length gains and similar improvements in major indicators of iron and zinc but not iron and vitamin A stores. In contrast, nonintervention comparison infants had significantly lower Z-scores at 9–12 months of age. Another study in Ghana comparing two forms of micronutrient delivery (powders vs. tablets) to an energy-dense spread (peanut butter- and milk-based) found improved weights and lengths in infants receiving the energy-dense spread. In a study in Zambia, infants receiving a cereal–legume blend with or without amylases were found to have similar weights and heights compared with each other, and only the cereal–legume blend (with no amylase) had significantly higher length gain than the infants in the control group. Work conducted through the *Oriente* studies in Guatemala compared the skim milk-based high-protein, high-energy supplement *atole* to a nonprotein, low-energy supplement fresco with both supplements receiving additional micronutrients. The authors reported that *atole* group had greater length (2.45 ± 0.10 cm) at 3 years of age than those receiving *fresco*. The effects of protein quality on growth (height and weights) have been examined through interventions utilizing biofortified maize (quality protein maize (QPM)). A meta-analysis of randomized, controlled studies in target communities found that intake of QPM instead of conventional maize in communities where maize was the major staple food led to a 12% (95% CI: 7–18%) increase in the rate of growth in weight and a 9% (95% CI: 6–15%) increase in the rate of growth in height in infants and young children with mild to moderate malnutrition. Lysine-fortified wheat flour provided to households in China and Pakistan led to improvement in several nutrition indexes including immune parameters, iron status, and weights and heights in children under 10 years of age.

AA Effects in Infancy and Childhood

Specific AAs both indispensable and those considered 'dispensable' have also been shown to have an impact on linear growth possibly through effects on GH release. Dietary restriction of single essential AAs including leucine, lysine, methionine, and threonine decreases plasma IGF-1 production, does not affect plasma IGFBP-1 production, but does decrease its production in hepatocyte cultures. Arginine and lysine could have individual or combined effects within this mechanism via the somatotropic axis. Oral ingestion of dietary protein, AA mixtures to resemble soy protein, and arginine–lysine test drink have shown to increase growth hormone (GH) release in normal women. Soy protein ingestion has also been found to increase GH secretion (an effect similar to direct arginine supplementation); however, this effect is reduced when soy protein is ingested as part of a meal. Ingestion of soy proteins with a carbohydrate or fat alone increased secretion at the same level as soy and/or arginine alone; however, when soy was combined with both carbohydrate and fat, the effect is reduced. Peak plasma arginine concentrations were higher, indicating a role for arginine in the somatotropic activity of protein.

An association between intake of dietary protein and linear growth and high arginine intake and linear growth has been

observed in prepubertal girls over a 3-year and a 6-year follow-up period. High arginine and lysine intakes (ranging from 3.8 to 4.6 g per day) were inversely associated with fat mass index in prepubertal lean girls in both studies. This is supported by animal model studies that have found that a 1.25% L-arginine supplementation of diets in Sprague–Dawley rats leads to a reduction in retroperitoneal fat mass and an increase in lean body mass separate from the effects observed by supplementing diets with conjugated linoleic acid, another regulator of adipose tissue metabolism. Similarly, L-arginine supplementation (1.5% supplementation level) was found to shift nutrient partitioning such as promoting muscle over fat gain.

AAs and Intestinal Health

Lysine supplementation has been shown to reduce diarrheal morbidity in women and in children, as observed in studies in Syria and Ghana. Lysine supplementation (16 weeks, 1 g per day) in Ghanaian children reduced the number of days ill per child with diarrhea in the lysine group compared with the placebo group ($p = 0.034$). In addition, a significantly lower weight gain was observed in the placebo group (0.70 ± 2.18 kg) compared with the lysine group (0.87 ± 0.92 kg). The mean days ill per child with diarrhea per week was also significantly and negatively associated with weight change over the study period, when controlling for baseline weight and study group ($p = 0.04$). These findings are especially relevant from the perspective of children given that there are an estimated 5 billion cases of diarrhea in children per year, equating to at least 2.5 billion preventable deaths under 5 years of age. Every additional diarrheal episode before age 2 years contributes to stunted growth, and diarrhea is a risk factor for poorer school performance and diminished long-term cognitive function later in life. Diarrhea and protein–energy malnutrition are synergistic, especially in developing countries where cereal-based diets are marginal or deficient in protein. The effects observed on diarrheal morbidity could be due to improvement of protein status or an individual AA effect (such as lysine, tryptophan, glutamine, and arginine). The direct AA effect is a more rapid and potent mechanism. In the case of lysine, studies in rats have shown that lysine deficiency per se can strongly enhance diarrheal incidence and that lysine administration alone blocked gastric emptying and stress-induced diarrhea through a direct intestinal action on serotonin receptor 4. It is known that dietary components such as fiber can influence gut motor functions and that oral AA solutions inhibit gastrocolonic and small intestinal transit. In 'in vitro' models of rotavirus diarrhea, arginine has been suggested as a possible stimulator of protein synthesis during diarrheal episodes, and a new class of human G-protein-coupled receptor (GPRC6A) with high affinity for arginine and lysine has been described in the intestine. Protein–calorie malnutrition delays small intestinal recovery in neonatal pigs infected with rotavirus; moreover, the provision of high-quality animal plasma proteins reduces intestinal damage and reduces the effect of the rotavirus infection. Another mechanism of AA effects on diarrhea is through effects on the central and the gastroenteric systems. Lysine and tryptophan are both known to have an effect on chronic anxiety and stress in animals and humans. Lysine fortification of wheat reduces anxiety and stress response in family members of rural households in Syria with diarrheal morbidity and plasma cortisol levels reduced in women and sympathetic arousal in males. Chronic anxiety was significantly lower in men in the lysine-fortified households.

A major fuel in the gut, glutamine also becomes conditionally essential and has an impact on the immune system when the body is stressed. Glutamine supplementation improves intestinal mucosal repair and function. It has been shown to improve intestinal mucosal function and improve weight gain in HIV-positive patients with wasting and also help in rebuilding or maintaining the GI mucosal function in infectious diarrhea, cryptosporidiosis, and cholera. While glutamine itself is unstable in solution, its dipeptide form, alanyl glutamine, is stable and has been found to be well tolerated, safe, and effective in different clinical and experimental settings. Recent work in the area of HIV/AIDS indicates that indole-2,3 dioxygenase (a cytokine-inducible enzyme) contributes to enhanced tryptophan catabolism, thereby increasing immune dysregulation, accelerating disease progression, and increasing risk of other complications of HIV infection. Free glutamate is also an important signaling taste substance that facilitates efficient protein digestion, playing an important role in numerous physiological and metabolic functions such as protection and maintenance of tissue within the gastrointestinal tract. A double-blind clinical study conducted in Japan revealed that glutamate facilitates the gastric emptying of a protein-rich meal compared with a carbohydrate meal or plain water. Thus, it is suggested that free glutamate may play an important role in both protecting the GI tract and facilitating general ingestion.

Conclusion

This article provides an overview of protein and AAs, with a brief analysis of the sources of protein, their pattern of consumption worldwide, and their health effects. We also provide background on the potential role of protein and AAs within the context of food-based interventions that target maternal and child nutrition and health. Protein needs in infancy and early childhood include maintenance and growth and are the highest across all age groups in terms of g per kg of body weight. This is also the case for the AA requirements as expressed in mg per kg of body weight and the AA pattern (mg of AA/g of protein). Furthermore, additional protein needs are considerably high in gestation (especially the last trimester). A key concern identified in the setting of the current requirements is the lack of accounting for energy deficit and repeated infections, both very likely scenarios in infants transitioning from exclusive breastfeeding to breastfeeding in combination with a diet of complementary foods that are low in energy density and nutrient quality. Evidence on the effects of balanced protein and energy supplementation is moderately strong, and the impact of protein quality and quantity needs to be considered within the context of interventions that target pregnant women for prenatal services. Evidences on the specific effects of protein and AAs on infant growth and development were examined, and associations have been found between the type of dietary protein (milk vs. meat) and linear growth, and the effect of milk is said to be mediated via the GH and IGF-1. Individual AAs (arginine and lysine) and proteins (e.g., soy) are also postulated to affect GH release.

Further areas of consideration that were not covered in this article include the role of AAs in the control of stress, depression, and anxiety and effects on sarcopenia, aging, and obesity. Considerable research also exists on the role of specific AAs (such as the branched AAs) within the context of muscle protein synthesis and the role of dispensable AAs in HIV/AIDS therapy. Some nonessential AAs classified as dispensable are now being considered conditionally essential, especially when the body is under catabolic stress. Requiring further examination are the role of indispensable AAs such as lysine and the conditionality of the dispensable AAs such as arginine and glutamine within this context. The effects of individual AAs and protein have been observed on intestinal health, although more work needs to be done within the applied realm.

Protein: Digestion, Absorption and Metabolism

The Central Role of Protein in Body Metabolism

Chemically, the human body comprises protein, lipid, ash (minerals), and water, and the body's metabolism is primarily associated with the protein component, often determined as the lean body mass (LBM). Dietary protein, which provides the building blocks (amino acids) for body protein synthesis, is thus metabolically transcendental. Dietary protein is needed for body growth and for the maintenance of LBM, and because protein is central to body metabolism and because many of the noncommunicable or so-called lifestyle diseases (e.g., diabetes, hypertension, and cardiovascular disease) are ultimately related to disturbances in body metabolism, dietary protein has an important role in the maintenance of optimal body composition, muscle mass and strength, visceral-organ function, and general health.

Amino acids, released from protein during digestion in the gastrointestinal tract (GIT), are absorbed and fuel body protein metabolism. In infants and children, the amino acids are used to maintain existing protein and to synthesize new protein; this is deposited during growth, whereas in adults, the absorbed amino acids are generally used to replace amino acids that are lost from the body during metabolism. Apart from their role in body protein synthesis, amino acids also have specific metabolic roles (e.g., leucine and muscle protein synthesis; glutamine and gut energy supply; tryptophan and serotonin synthesis; and arginine and nitric oxide production). Although the demand for amino acids for these specific metabolic roles may be low quantitatively, their supply is critical to normal body function.

Twenty amino acids are needed for protein synthesis in humans. Some, referred to as the dietary essential or dietary indispensable amino acids, must normally be supplied by the diet preformed, whereas others (the dietary nonessential or dietary dispensable amino acids) can usually be synthesized by the body from other amino acids or from simpler precursors. Nine amino acids are dietary indispensable in humans (lysine, methionine, threonine, valine, isoleucine, leucine, phenylalanine, tryptophan, and histidine). It is important to note that all of the twenty amino acids participate in body protein synthesis, but in adults, 11 do not need to be supplied in the diet. These remaining dietary dispensable amino acids are arginine, proline, serine, glycine, glutamine, glutamic acid, tyrosine, cysteine, alanine, asparagine, and aspartic acid. Some amino acids, those that are normally dietary nonessential, may become dietary essential under certain metabolic conditions when the cell may not be able to synthesize them at a sufficient rate. These amino acids are referred to as being 'conditionally essential.'

Amino acids not only are used by the body to make proteins and for specific physiological and regulatory purposes but also can be catabolized to provide the body with energy. Moreover, the synthesis of body protein is energetically costly. That body protein synthesis is energy-demanding and that amino acids can be used as a substrate both for protein synthesis and for energy supply are the bases for a protein/energy interaction during metabolism. It is also important to understand that protein in the body is not a static entity, but rather body proteins are continuously being broken down and resynthesized at different rates. This is referred to as body protein 'turnover,' with synthesis, degradation, and resynthesis. The process is very significant quantitatively. In a 70 kg adult human, some 200–400 g of body protein is broken down and resynthesized each and every day. As discussed, this process is energetically costly and constitutes an important component of basal energy needs. Also, body protein turnover is not completely efficient with attendant losses of amino acids; this accompanies other losses of amino acids from the body due to other metabolic processes. A dynamic equilibrium is achieved by matching these cumulative losses of amino acids from the body with the uptake of absorbed amino acids from the diet.

An understanding of the role of amino acids and protein in protein synthesis, protein turnover, and whole body energetics gives further insight to the central metabolic role of dietary protein. Dietary protein supports LBM and a normal body weight, with higher dietary protein intakes promoting and maintaining LBM. As basal energy expenditure is related to LBM, a greater LBM at the same body weight supports a higher basal energy expenditure, which assists maintenance of body weight. Higher dietary protein intakes are also related to higher rates of body protein turnover, which in turn translate to higher energy demand, which assists with the maintenance of body weight. Dietary protein is thought to be more satiating than starch, sugars, or lipids (fats and oils), and higher protein intakes may assist in maintaining lower food calorie intakes. Also, protein and amino acids yield less energy after catabolism compared to glucose and fatty acids on a per-gross energy basis and thus provide relatively lower amounts of dietary calories per unit gross energy. All of these effects of higher protein diets underline an important role for dietary protein in promoting normal body weight and composition and in the avoidance of obesity.

Dietary Protein Digestion

Traditionally, protein digestion and amino acid absorption were considered as distinct and separate processes; it is now recognized that the breakdown of protein into smaller units and their subsequent uptake into the enterocyte with the release of amino acids into the portal blood is a highly organized and tightly integrated process. Digestion involves multiple interactions between the food matrix, itself, physical processes, and chemical processes involving endogenous mammalian and bacterial enzymes, all occurring within the complex milieu of the GIT.

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00572-9

Throughout the GIT, protein of body origin (endogenous) is either secreted or sloughed into the lumen, roughly doubling the total amount of protein available to be digested. The origins of gut endogenous proteins include enzymes, mucoproteins, sloughed intestinal cells, and proteins (e.g., albumin and immunoglobulins) that either leak or are secreted into the gut lumen from the blood. Bacterial bodies, nondietary though not strictly endogenous, are also an important component of the proteinaceous material present in the gut lumen.

Protein digestion is a remarkably efficient process. For the average Western male, around 200 g day^{-1} of protein (100 g dietary and 100 g endogenous) is effectively digested and absorbed by the enterocytes as free amino acids and dipeptides and tripeptides. Typically, around 85% of the total protein is absorbed prior to the end of the small intestine (terminal ileum), with around 30 g protein entering the large bowel. There is also extensive microbial metabolism of protein in the colon. Nitrogen derived from the breakdown of protein is absorbed from the colon in the form of ammonia, and the equivalent of around 10–20 g day^{-1} of protein is excreted as fecal nitrogen giving overall digestibility values of 90–95%. The fecal protein represents mainly the fraction of gut endogenous and dietary protein not absorbed in the small intestine, but because this unabsorbed material is used by the large intestinal microbiota for microbial growth, the fecal protein is present mainly as bacterial protein.

Protein digestion occurs throughout the GIT. Ingested food is subjected to physical breakdown by mastication in the mouth, and food is mixed with saliva and liquids, generating a food bolus that can be swallowed to enter the stomach. The lumen of this organ, moreover, also provides a medium suitable for the action of digestive enzymes. Gastric digestion involves further physical breakdown of the food and denaturation and hydrolysis of protein due to the action of gastric hydrochloric acid and the pepsins secreted by the parietal chief cells. The outcome of the gastric digestion of protein is a mixture of protein, mainly large polypeptides and some free amino acids, with virtually no amino acid absorption. The digested mixture is emptied from the stomach over time and enters the small intestine (duodenum, jejunum, and ileum), wherein further hydrolysis occurs catalyzed by a family of protease enzymes secreted by the pancreas and by enzymes localized to the intestinal cells. The latter are either secreted into the gut lumen or attached to the brush border of the intestine or are active within the mucosal cells. Small intestinal digestion is facilitated by the secretion of pancreatic bicarbonate, which neutralizes the acidic gastric chyme and establishes a pH in the intestinal digesta of 6–7. The pancreatic proteases comprise trypsin, chymotrypsin, elastase, and the carboxypeptidases A and B. The epithelial cells' brush border membrane-bound enzymes comprise a number of aminopeptidases and a carboxypeptidase and act on any oligopeptides left after pancreatic digestion. Amino acids are absorbed mainly as free amino acids, dipeptides, or tripeptides, with the peptides being acted upon by cytosolic aminopeptidases, such that amino acids are mainly absorbed into the portal blood in the free-form. It is now considered, however, that very small amounts of some peptides and protein fragments may also enter the portal blood intact. These peptides may have specific bioactivities. Protein and oligopeptides remaining undigested at the end of the ileum pass into the colon where they are subjected to extensive microbial metabolism, but amino acids *per se* are not absorbed from the human colon, at least not in nutritionally significant amounts.

Digestive enzymes are also secreted by bacteria inhabiting the GIT, and the gut microbiota undoubtedly contributes to overall gut proteolytic activity. They also make proteins more accessible to mammalian enzymes by breaking down plant fiber. Bacteria can both catabolize and synthesize amino acids and some GIT bacteria have ureolytic activity and are involved in body urea recycling. The role of bacteria in protein digestion has not been studied extensively, but it seems likely that bacterial enzymes complement, to some extent, the action of the mammalian enzymes. Bacteria, although predominantly found in the large intestine, are actually present throughout the GIT and can be intensely metabolic. The role of bacteria in supplying dietary essential amino acids to the host net of dietary supply, through microbial amino acid synthesis, is widely debated, but it is generally considered that such supply is quantitatively low.

Amino Acid Absorption

The products of protein digestion, mainly free amino acids, dipeptides, and tripeptides, are absorbed from the small-intestinal lumen by several transport mechanisms. Free amino acids are taken up by transporters located in the luminal-facing, apical membrane of enterocytes on the villi and exit the cell via basolateral membrane transporters. There are a number of brush border (apical membrane) and basolateral membrane transporter systems, specific to particular amino acids or groups of amino acids. Transepithelial movement of amino acids involves interactive participation among multiple transport systems, multiple subunits (a transporter protein encoded by a specific gene), and ion electrochemical gradients. Amino acid movement via the transport systems occurs by both secondary active transport (dependent upon ionic gradients and electrical potentials across the enterocyte membranes) and facilitated (ion-independent) transport, depending upon the system.

It is critical that the body receives a net positive flow of amino acids from the dietary proteins, and so the small intestine has the ability to adaptively upregulate its capacity for amino acid absorption. Both dietary protein intake and physiological state (influencing the amino acid requirement) may change over time in an individual, and amino acid absorptive mechanisms can adapt accordingly at both tissue and cellular levels. The combined effects of the upregulation of transporters and mucosal hyperplasia can lead to a severalfold increase in amino acid absorptive capacity in comparison with the fasting state. In addition to free amino acids, dipeptide and tripeptide products of protein hydrolysis are also transported across the apical membrane of absorptive enterocytes. In fact di- and tripeptides are absorbed to a significant extent and more rapidly than the free amino acid counterparts. Once absorbed, however, they are in the main hydrolyzed to free amino acids by the aminopeptidases in the cytoplasm of the enterocyte. The uptake of peptides is primarily due to the action of the high-capacity apical membrane Pept 1 transporter (secondary active transport), expressed throughout the small bowel, but only to a

low degree in the colon. Overall, the ability of the enterocyte to take up amino acids in the free-form and as dipeptides and tripeptides, via multiple transporters and systems, ensures an efficient absorption of the amino acids released from proteins during digestion.

Amino acids either entering the enterocyte directly or arising from intracellular peptide digestion largely pass through the enterocyte unchanged but may be used for protein synthesis within the enterocyte or be metabolized (oxidized or converted to another amino acid, metabolite, or compound). In particular, the enterocyte metabolizes amino acids such as glutamate, glutamine, aspartate, and arginine quite extensively. Following basolateral membrane transport to the interstitial fluid, amino acids move via the villus capillaries to the portal vein. The portal vein supplies the liver directly, where the amino acids may be further metabolized or transported to other organs and tissues.

Determining dietary amino acid digestibility in humans

Although dietary proteins are generally digested efficiently within the GIT, they are not completely digested and absorbed. Also, different amino acids are both released from proteins and absorbed across the intestine to different extents. It thus becomes necessary to be able to determine the digestibility (disappearance from the GIT) of dietary proteins and amino acids. Both the extent and rate of protein breakdown are a function of the amino acid sequence of the protein and various posttranslational modifications and are also influenced by the structure of the food matrix within which the protein is found. The processing, storage, and cooking of food, moreover, can lead to chemical (e.g., Maillard products or D isomers) and structural (e.g., cross-linking) changes, which can result in an impaired digestibility.

Although traditionally, the digestibility of amino acids has been determined by comparing fecal amino acid output with dietary amino acid input, this approach is now known to be inaccurate. The role of the colonic microbiota in colonic protein metabolism has been discussed earlier. The microbes may both degrade and synthesize amino acids in the large intestine, and two-thirds to three-quarters of fecal protein is actually present as microbial bodies. This means that only a small proportion of fecal amino acid excretion has any direct relationship to the flow of undigested dietary amino acids. The measurement of amino acids remaining unabsorbed at the end of the terminal ileum (posterior portion of the small intestine) is now widely recognized as generating more accurate observations of amino acid digestibility. Amino acid digestibility values determined by sampling digesta from the end of the ileum are referred to as ileal digestibility coefficients. In most simple-stomached animal species, multiple studies have demonstrated considerable differences between fecal and ileal amino acid digestibility for the same protein. For most foods and amino acids, ileal amino acid digestibility is lower than the fecal counterpart, indicating a net degradation of the amino acid in the large intestine. For some amino acids in some foods, however, a net microbial synthesis may be observed. The latter is often seen for methionine. Regardless as to whether there is a net disappearance or net appearance of an amino acid in the hindgut, fecal digestibility values are affected by the microbial metabolism of amino acids entering the colon and do not properly reflect amino acid absorption.

Although ileal amino acid digestibility provides accurate estimates of amino acid uptake from the digestive tract, its determination in humans is not straightforward. Ileal digesta can be sampled using a nasointestinal tube or directly in adult ileostomates whereby the colon has been surgically removed due to disease. Neither method can be regarded as routine or entirely satisfactory, and because of this, animal models of ileal protein digestibility have been developed. The growing pig is an established model for protein digestion in the adult human and the milk-fed piglet for human infants. Ileal digesta can be sampled directly from the ileum of an anesthetized pig or be collected from animals via surgically implanted gut cannulas. When dietary amino acid input is corrected for the total ileal amino acid output, digestibility coefficients are determined that are termed 'apparent' digestibility coefficients. This term indicates that the value is only an approximation rather than the 'true' digestibility coefficient. It is recognized that ileal digesta is a mixture of both undigested dietary protein and 'endogenous' protein that has entered the digestive tract from the animal, and this endogenous protein influences the measurement of digestibility. There are a number of ways of determining the endogenous protein, and when this is corrected for in determining digestibility, 'true' or 'standardized' coefficients of digestibility can be derived. Recommended best practice is to determine protein and amino acid digestibility using true ileal digestibility. True ileal amino acid digestibility values are available for numerous foods consumed by humans, with values ranging from around 50% to up to 95–98%. Within a protein source, the true ileal digestibility of individual amino acids can vary quite markedly.

During food processing and storage, or during the cooking of foods, some amino acids (lysine is the classic example) can undergo structural alterations. The structurally altered compounds are often not digested and absorbed and, when absorbed, are generally not utilized but are broken down and excreted in the urine. The traditional methods used for determining amino acids in food and ileal digesta can give rise to erroneous digestibility coefficients in these circumstances. During chemical analysis, the structurally altered compounds can revert back to the parent amino acid, but this occurs to different extents in food and digesta and with different foods. Because of this, specific analytic methods have been developed that determine only the structurally unaltered or available amino acid, which allows the determination of the true ileal digestibility of the structurally unaltered (available) amino acid. This can be particularly important for lysine and methionine in foods whereby protein may have been 'damaged.'

Bioactive Peptides

During dietary protein digestion, large quantities of small peptides (di- and tripeptides) and larger oligopeptides are produced within the GIT lumen. Many of these peptides possess amino acid sequences that confer bioactive functions, and some are quite resistant to digestion. The peptides may interact with mucosal cells or indeed with bacterial cells within the gut lumen and may elicit a wide variety of bioactivities (e.g., mineral-binding, cholesterol-lowering, immunomodulation,

antioxidant, antithrombotic, antimicrobial, and antifungal). It also appears that small quantities of especially the smaller peptides may be absorbed intact from the GIT and may affect body processes systemically. Larger opioid peptides are known to influence the digestive process itself through modulation of gastrointestinal motility and the stimulation of gut secretory processes. Many studies have recorded the generation of bioactive peptides during dietary protein digestion, their presence in digesta, and multiple biological effects. These bioactive peptides may have a role as complementary physiological modulators and regulators. They have been shown to be produced from the digestion of a wide variety of foods. What has not been so widely considered, however, is that the endogenous proteins entering the GIT from the body are also an important source of bioactive peptides and may provide the GIT lumen and body with a more constant and consistent supply of peptides.

Bioactive peptides are inactive within the parent protein molecule until released by enzymatic hydrolysis, generally during digestion but potentially also during food processing. Once released, the peptides are potentially capable of influencing a range of behavioral, gastrointestinal, hormonal, immunologic, neurological, physiological, vasoregulatory, and nutritional responses, and such peptides have been put forward as candidates for a variety of food and pharmaceutical applications.

There is no doubt that the generation of bioactive peptides during the normal digestion of both foods and the endogenous proteins in the GIT is an important function of proteins, and these peptides have numerous regulatory, stimulatory, and inhibitory effects. Moreover, dietary protein itself stimulates the production of gut endogenous proteins, leading to further peptide production, suggesting a highly interlinked process. Food proteins are thus far more than merely a supply of amino acids for body protein synthesis. However, the importance of the overall role of these peptides produced in the GIT lumen external to the body cells remains to be fully elucidated.

Protein Metabolism

Once absorbed, amino acids may be used for the synthesis of body protein or, in small amounts, as precursors for a multitude of nitrogen-containing compounds with unique biological activities or be catabolized with their nitrogen ultimately incorporated into urea, which is finally excreted in the urine. After deamination, the carbon skeleton from the amino acid can be oxidized to provide energy or, depending upon body energy status, can be used to synthesize fatty acids, which are stored as body lipid. The balance achieved between catabolic and anabolic pathways involving the first-limiting amino acid determines overall dietary nitrogen retention. In the growing child, there is a need for amino acids for body protein maintenance and for new tissue deposition, whereas in the adult, amino acids are needed to replace amino acids lost from the body. For pregnant and lactating women, there are additional amino acid needs for growth of the conceptus and milk production.

The absorption and metabolism of amino acids is complex and highly integrated, with continuous flux within and among body cells and within and among tissues and organs. However, it is useful to view amino acid metabolism in terms of several discrete processes that explain the utilization of amino acid postabsorption (Table 1).

Table 1 Biological processes giving rise to a requirement for absorbed amino acids in the adult human

- Integumental amino acid losses
- Gut endogenous amino acid losses
- Urinary amino acid losses
- Other miscellaneous amino acid losses
- Synthesis of nonprotein nitrogen-containing compounds
- Irreversible modification of amino acids
- Inevitable amino acid catabolism (oxidation)
- Preferential amino acid catabolism

In the adult human, relatively small amounts of amino acids are lost from the body due to the shedding of skin cells and when hair is cut or removed from the body. There is also a small loss of intact amino acids via the urine and very small losses through other miscellaneous routes. Of greater significance, quantitatively, are the losses of amino acids via the GIT. Relatively large amounts of body protein enter the GIT daily; whereas some of this material is digested and reabsorbed, considerable amounts of amino acids are catabolized in the GIT or are incorporated into microbial protein, which along with some undigested endogenous protein is lost from the body in the feces. These losses of amino acids need to be made good using absorbed amino acids from the diet, so as to maintain the body's protein mass. Amino acids are also used by the body to synthesize a wide range of nonprotein nitrogen-containing compounds essential for normal metabolic functioning (e.g., lysine for carnitine, arginine for creatinine, and methionine as a methyl donor). The use of amino acids for these purposes is usually low, though for some amino acids in some circumstances, the rate of utilization may be quantitatively significant. Also, amino acids may become irreversibly modified and thus unavailable for protein synthesis. Examples of this are the methylation of histidine and the hydroxylation and methylation of lysine. Of much greater quantitative significance than the latter two processes is the loss of amino acids due to oxidation, arising from a number of processes collectively referred to as inevitable catabolism. Inevitable catabolism refers to the oxidation of an amino acid, not for the express purpose of energy supply, but arising rather as an inevitable consequence of the action of catabolic enzymes. Even the first-limiting dietary amino acid given with a surfeit of nonprotein energy sources is subjected to a considerable degree of inevitable catabolism. Amino acids enter the body's free amino acid pool from body protein turnover and from the supply of absorbed dietary amino acids, and a proportion of the amino acid flux will be subjected to inevitable catabolism. The extent of inevitable catabolism may be affected by habitual protein intake and thus the background activity of the catabolic enzymes. First-pass intestinal amino acid catabolism may be an important contributor to inevitable catabolism, whereby some absorbed amino acids are specifically targeted for oxidation within the enterocyte. Also, it is thought that some absorbed amino acids function in having a transitory regulatory influence on body protein synthesis (anabolic drive), before being catabolized. Finally, and in situations whereby nonprotein energy sources may be limiting in terms of meeting the body's energetic needs, amino acids may be catabolized expressly to meet the energy need (preferential catabolism).

Collectively, these various biological processes translate to a metabolic requirement for amino acids, which must ultimately be met by amino acids absorbed from the diet. Many of the processes discussed earlier are affected by dietary factors. By means of example, the GIT amino acid losses are affected by the protein and fiber contents of the diet and by the presence of dietary antinutritional factors. Higher dietary protein intakes lead to higher rates of body protein turnover and likely greater fluxes of amino acids. Amino acid oxidation in the postabsorptive phase occurs at a rate determined by habitual protein intake. The kinetics of uptake of amino acids from a protein ('fast' and 'slow' proteins) can have important effects on postprandial metabolism. It is thus axiomatic that dietary amino acid requirements for the adult human at maintenance are not fixed values, but rather are diet-dependent values. This is not usually recognized in traditional tables of requirement estimates, whereby static values are prescribed.

Protein and amino acid requirements

Over the years, much work has been undertaken to determine the dietary amino acid requirements of humans, and this work has often relied on conducting nitrogen balance studies. An accurate determination of dietary amino acids in humans has proved to be elusive, and there has been much debate about the accuracy of the nitrogen balance approach. Over the last three decades, requirement estimates have been made using direct or indirect measures of amino acid oxidation. These techniques give rise to much higher estimates of amino acid requirements than the N-balance approach, but are also not without controversy related to their accuracy. The FAO, WHO, and UNU recommend 0.83 g high-quality protein per kg bodyweight as a 'safe' daily intake of dietary protein, which translates to 58 g protein per day for the reference 70 kg bodyweight man and 47 g protein per day for the reference 57 kg woman. In the United States, the approximate median intake of protein for adults (31–50 years of age) is 100 g day^{-1} for men and 65 g day^{-1} for women, suggesting a surfeit of dietary protein. In parts of the developing world, however, habitual dietary protein intakes are much lower.

Lately, research has focused on health, bodyweight management, and body function attributes as parameters to assess protein and amino acid requirements, and based on this approach, protein requirement estimates often much higher than current official recommendations are promulgated. Dietary requirements for individual dietary essential amino acids as published by the FAO, WHO, and UNU and based largely on amino acid oxidation studies are given in Table 2. As discussed, for purposes of practical necessity, single average values of requirements are given; in reality, however, there is considerable variation in requirement values due to differences among people and due to the metabolic effects of different foods and diets.

Table 2 Estimates of the daily amino acid requirements (mg kg^{-1} bodyweight) of the adult human

	FAO/WHO/UNU (2007)
Histidine	10
Isoleucine	20
Leucine	39
Lysine	30
Methionine and cysteine	15
Phenylalanine and tyrosine	25
Threonine	15
Tryptophan	4
Valine	26

Dietary Protein Quality

The extent to which amino acids present in a food can be used to meet the body's metabolic need for amino acids is referred to loosely as the food's 'protein quality.' Measures of protein quality are used for predicting the amounts of protein (first-limiting amino acid) that can potentially be utilized by a person for a particular food or protein source. They are also used to value or score proteins for trade and regulatory purposes. Essentially, protein quality evaluation aims to describe the amount of each dietary amino acid present in a food in an available (structurally unaltered) form and the amount of that amino acid, which can be absorbed from the food and based on this predict the value of the food under different conditions.

Recognizing that, in addition to serving as building blocks for body protein synthesis, amino acids also have specific physiological functions, the most recent FAO recommendations on dietary protein quality evaluation state that first and foremost, "dietary amino acids should be treated as individual nutrients and wherever possible data for digestible or bioavailable amino acids should be given in food tables on an individual amino acid basis." It is further recommended that amino acid digestibility be based on true ileal digestibility determined either in humans directly or using the growing pig as an animal model for the adult human. For foods susceptible to damage from processing, determination of the true ileal digestibility of structurally unaltered or available rather than total (conventional amino acid analysis) lysine is recommended. Also recognizing that it is important to be able to assess the contribution a food protein or mixture of food proteins makes toward meeting nitrogen and amino acid requirements, the FAO recommend a scoring procedure for proteins. Here, the predicted balance of dietary essential amino acids reaching the sites of protein synthesis is compared with the individual's ideal amino acid balance deemed to be required for body protein synthesis. The system for scoring dietary protein quality used over the last 20 years called 'protein digestibility corrected amino acid score' has been recently replaced by the FAO with a new system called 'digestible indispensable amino acid score' (DIAAS). DIAAS is defined as follows: DIAAS% = 100 × ((mg of digestible dietary indispensable amino acid in 1 g of the dietary protein)/(mg of the same dietary indispensable amino acid in 1 g of the reference protein)). Amino acid digestibility should be based on true ileal amino acid digestibility, and for processed foods, lysine availability should be taken into account. Three recommended amino acid scoring patterns (amino acid pattern of the reference protein) are given for the calculation of DIAAS, one for infants, another for young children, and another for older children, adolescents, and adults. In determining DIAAS, the ratio (described earlier) is calculated for each dietary

indispensable amino acid and the lowest value designated as the DIAAS. DIAAS can have values below or above 100%. Values above 100% are not truncated except when calculating DIAAS for mixed diets or sole source foods. A DIAAS value of 120% would indicate that the protein source supplies 120% of the individual's requirement for the first-limiting amino acid, while a value of 50% would indicate that the protein source supplies only half of the required amount of the first-limiting amino acid.

The amino acid requirements for humans of different ages and physiological states are not known with certainty. Also, there is always some degree of uncertainty in the digestible or available amino acid contents of specific foods. Because of this, DIAAS values can only be regarded as approximations or best current estimates of dietary protein quality. Other aspects of proteins, such as their ability to generate specific bioactive peptides during digestion, may also need to be considered in evaluating a protein. The 'quality' of a protein from a nutritional or physiological perspective is multifactorial, and all aspects of a protein's quality cannot be captured in a single score. Nevertheless, such scores are important for understanding a food protein's potency as a source of amino acids to meet daily metabolic amino acid requirements.

Protein: Food Sources

L Day, AgResearch Ltd., Palmerston North, New Zealand

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Food proteins have two important functions, namely, those that serve to meet essential nutritional requirements and those relating to the physicochemical properties essential for maintaining product quality. In relation to food products, proteins possess unique functionalities such as rheological properties (i.e., viscosity, hardness, and gel strength) and interfacial properties that allow stability of emulsion formation, and baking and film formation.

Production and Consumption

Protein is one of the essential macro nutrients for the human body and constitutes about half of the human body's dry weight. The different amino acids that are the building blocks of proteins are essential for human growth, tissue repair, and replacement. Protein can also serve as an energy source.

The major food sources of dietary protein are from animals and plants. Specifically, these include dairy products like milk, yogurt, and cheese; meat, poultry, and seafood; eggs; soy foods such as tofu; seeds and nuts; legumes and pulses; and grain- and cereal-based products (Table 1).

The world's supply of animal proteins as meat has shown an increase of 77% over the last 40 years, from 8 to 14.2 g/capita/day (Figure 1). However, cereals are still the major protein sources, particularly in the developing world and in Asia and Africa where cereals form the major part of staple diets. On average, cereal proteins account for 32 g/capita/day in the human diet (Figure 1).

Proteins derived from animal sources are considered to be nutritionally superior to those from plants because they contain a better balance of the dietary essential amino acids. Of these, egg and milk proteins (i.e., caseins) are frequently used as reference proteins for evaluating protein quality.

The most common sources of animal proteins for humans are in the form of meat from domesticated animal species such as cattle (beef), pigs (pork), poultry (chicken, duck, or turkey), and sheep (lamb). The production and consumption of pork and poultry meat have increased considerably over the last four decades and overtook the consumption of beef in late 1990s (Figure 2). Nowadays, poultry meat is the highest contributor to the animal protein supply for human consumption. This is probably due to the improvement in production efficiencies in intensive farming and the relatively lower cost of poultry meat compared with beef and lamb. However, the utilization and subsequent consumption of different animal species vary throughout the world due to different cultural preferences and religious beliefs.

The global per capita food supply of fish and seafood was estimated at 18.4 kg, in which fish accounted for 6.4% of the global population's intake of food proteins consumed and almost 20% of the average per capita intake of animal proteins (Figure 1).

The contribution of dairy to overall dietary protein consumption was relatively steady from the 1960s to the early 1990s but has since shown a steady increase from 7 g/capita/day in 1995 to 8.1 g/capita/day in 2011 (Figure 1). In the past, increases in demand for milk and dairy products were driven mainly by population growth, whereas they are now increasingly fueled by rising per capita milk consumption in developing countries. It may be expected that increasing income levels in Asia, particularly in China, will stimulate an increase in dairy product consumption and overall dairy protein intake.

The contribution of eggs to global protein consumption has also shown a dramatic increase, particularly over the last 20 years, from 1.7 g/capita/day in 1980 to 2.7 g/capita/day in 2011. This trend of increasing egg consumption is expected to continue with increasing world population, especially in countries with improving economies, such as China. However, total egg consumption in developed countries has actually been declining due to health concerns related to high cholesterol and fat content.

Among the cereal crops, wheat is the single most important food crop in the world. Wheat is eaten in various processed forms by more than one billion people currently and makes the largest contribution to the protein available to human beings compared with any other single food source (Figure 3). However, the consumption of wheat-based foods has decreased during the last two decades. This trend may be partly due to the increased consumption of animal proteins with increasing income levels, particularly in the Asian region. In addition, the consumption of rice is continuing to rise (Figure 3), possibly driven by the increasing popularity of Asian cuisine in Western countries and rice becoming more regularly consumed as part of the diet.

Although soybeans are one of the most important agricultural commodities, their use as a food protein source is still relatively low (Figure 3). A large amount of defatted soybean meal is produced after extraction of oil and most defatted soybean meal is used for animal feed. Only a small portion is further processed into various types of soy protein ingredients for human consumption. Thus, soybeans account for a relatively low human protein supply.

Dairy Proteins

Bovine milk serves as an important source of proteins in the human diet, in particular for infant nutrition, for much of the past century. Milk contains ~3–4.4% protein. Milk proteins are classically divided into two major groups, that is, caseins and whey proteins. Caseins are the most abundant group, which account for 80% of total milk proteins and are insoluble at pH 4.6, whereas whey proteins remain soluble at pH 4.6.

Table 1 Sources of food proteins

Sources	*Subcategory*	*Common food source*	*Protein ingredients*
Animal	Dairy	Milk, cheese, yogurt, and other dairy products	Casein and whey
	Meat, poultry, and seafood	Muscle proteins Proteins in the connective tissue, restructured products	Blood proteins, collagen, and gelatin
	Eggs		Whole egg powder, egg white, and egg yolk
Plant	Cereals	Wheat, corn, barley, oats, and rice	Wheat gluten and texturized proteins
	Legumes and pulses	Soybeans, peas, lupins, lentils, chickpeas pinto beans, kidney beans, and navy beans	Soy protein isolate, pea protein isolate, and texturized proteins
	Oilseeds	Canola, cottonseed, and flaxseeds	
	Nuts	Various ground nuts and tree nuts; raw, roasted, and salted	

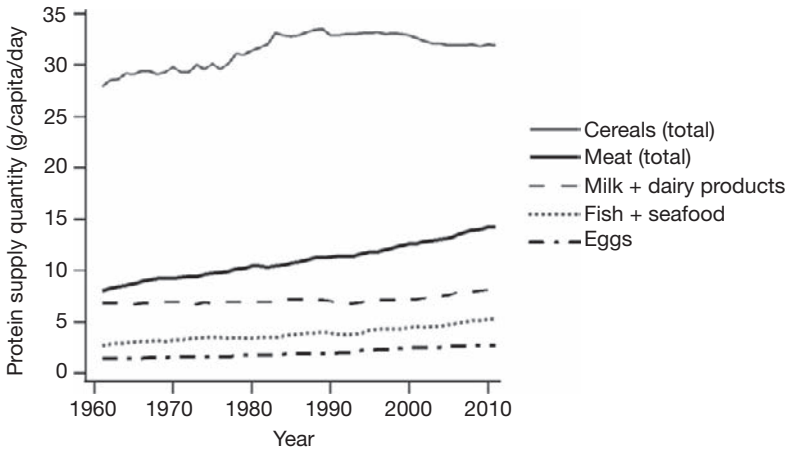

Figure 1 World protein supply quantity as food (g/capita/day) in the last four decades (1961–2011). Food and Agriculture Organisation of United Nation FAOSTAT (2014) at http://faostat3.fao.org/.

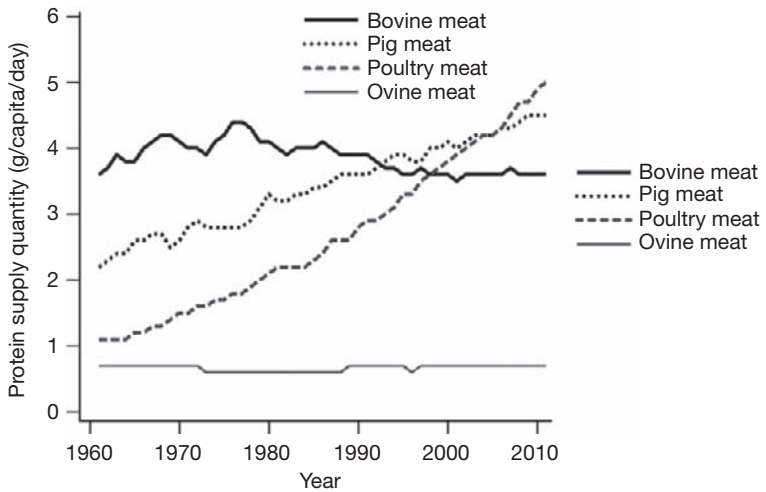

Figure 2 Changes in protein supply quantity as food (g/capita/day) from animal meat sources between 1961 and 2011. Food and Agriculture Organisation of United Nation FAOSTAT (2014) at http://faostat3.fao.org/.

Dairy proteins are also widely used as protein ingredients by the food industry in a variety of manufactured food products because they provide desirable sensory properties, physical functionalities, and nutritional values for foods.

Due to the liquid nature of bovine milk, the dairy industry has developed a range of processing technologies to fractionate, concentrate, and dry dairy proteins into an array of functional ingredients for food applications (Table 2). The most

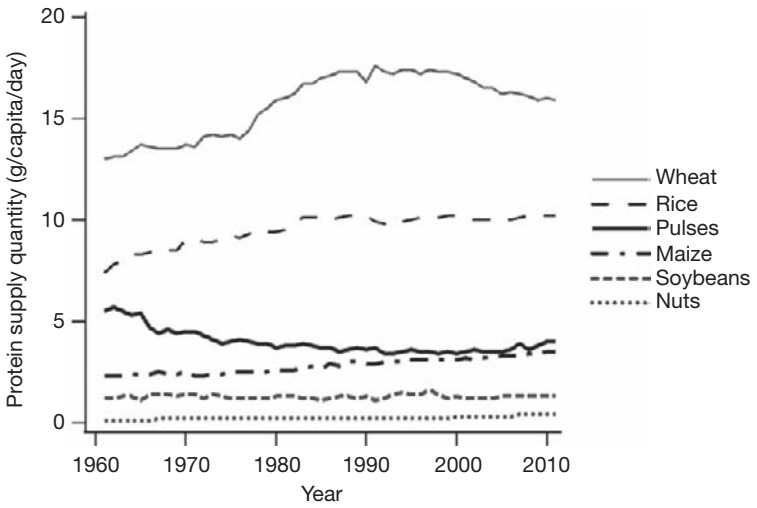

Figure 3 Protein supply quantity as food (g/capita/day) from different plant sources between 1961 and 2011. Food and Agriculture Organisation of United Nation FAOSTAT (2014) at http://faostat3.fao.org/.

Table 2 Dairy protein based ingredients and its manufacturing process and applications in food products

Product	*Protein content (%)*	*Manufacturing process*	*Food applications*
Whole milk powder			Chocolate
Skimmed milk powder	35		Chocolate
Milk protein concentrates	42–90	Membrane filtration from fresh skim milk. They contain both casein and whey protein in the same ratio as skim milk	Cheese, cultured products, dairy-based beverages, nutrition foods, weight management products, powdered dietary supplements, and sports nutrition products
Acid casein		Acidification of skim milk to pH 4.6 by adding a mineral acid or through lactic fermentation	
Rennet casein		Precipitation of skim milk through the action of microbial rennet enzymes	Processed cheese and nutritional foods
Caseinate			Beverages, food bars, soups, sauces, whipped toppings, bakery products, cultured foods, and nutritional foods
Whey protein concentrates	>80	From fresh cheese or acid whey using an ultrafiltration process	Yogurts, beverages, and dairy desserts Nutritional products and infant food
Whey protein isolates	>90		Low pH nutritional beverages, dry mix beverages, nutritional bars, protein fortified food, and sports nutrition products

frequently used technique for the dehydration of dairy products is spray drying. The purpose of dehydrating milk and dairy protein fractions is to extend the shelf life of these products for later use and reduce the cost of transportation.

Caseins

Caseins are composed of α_{S1}-, α_{S2}-, β-, and κ-casein in a percentage ratio of 40:10:40:10. Casein proteins are present in milk as self-assembled colloidal particles, commonly known as casein micelles. These micelles are in the range of 100–600 nm in diameter and provide milk with its white appearance. The casein micelle is a natural nanoparticle – self-assembled within vacuoles of the mammary epithelial cells, containing 92% proteins and 8% inorganic salts, primarily calcium phosphate, in dry weight. The major functions of the micelles are to transport proteins, calcium, and phosphate in high concentrations that would otherwise be insoluble in water and to provide adequate nutrients to young calves. The association between the mineral and protein components gives the native casein proteins their nutritional values as well as their unique functional properties that have been extensively exploited to produce dairy foods such as yogurts and cheeses.

The stability of casein micelles is due to their inherent zeta potential (~−20 mV) and from their structural steric hindrance caused by the protruding (the 'hairy' layer) C-terminal segments of glycosylated κ-casein, which prevent the close approach of nearby micelles. This creates a unique characteristic of milk in its 'white' color due to the light reflection of micelle particles. Removal of these protruding segments by

chymosin, the main enzyme present in the neonate calf stomach, results in coagulation of the modified casein micelles.

Casein is the major functional contributor in a range of dairy products. The destabilization of the casein micelles through manipulation of the pH by fermentation using bacterial cultures or enzymatically by rennet addition is an integral part in the manufacturing of the products such as yogurts and cheeses.

The casein proteins are also commercially produced as high-protein ingredients through separation from other components in bovine milk. There are three principal ways to produce casein ingredients on an industrial scale. They are isoelectric precipitation, rennet coagulation, and membrane filtration (Table 2). The isoelectric precipitation by the use of hydrochloric or sulfuric acid or by lactic acid produced by bacteria to reduce the pH of the milk to 4.6 produces the acid casein. Rennet casein is made by adding sufficient rennet to skim milk to cause it to clot. Acid or rennet casein may then be dried in a cabinet, tunnel, or spray dryer to a moisture content of 4%. The dried casein is then milled and screened to an appropriate particle size. The casein ingredients are widely used in coffee/tea whiteners, whipping powders, and imitation milks (Table 2). Rennet casein is a major ingredient in cheese analogue production.

Whole milk can also be dried to produce milk powder ingredients. Skim milk powder usually contains 35% milk protein. Milk powder ingredients are widely used for recombined milk products such as retorted or ultra high temperature (UHT)-treated long shelf life products where stability to secondary heating is paramount.

Whey Proteins

The whey from bovine milk also contains several distinct proteins. The main proteins are β-lactoglobulin (β-Lg), α-lactalbumin (α-La), bovine serum albumin, and immunoglobulin, representing approximately 0.27, 0.12, 0.025, and 0.065% in milk, respectively.

Whey proteins are highly functional and nutritional ingredients and have become increasingly valuable in formulated food products for human nutrition. There are two major types of whey protein ingredients, that is, whey protein concentrates (up to 80% protein) and whey protein isolates (90% protein). Whey proteins are manufactured as a by-product of the manufacturing of other dairy products such as cheese and casein. Low-temperature processing is needed to ensure the retention of both nutritional and functional properties because all the major whey proteins are globular proteins with defined molecular conformations that are susceptible to heat denaturation.

Whey proteins have excellent functional properties that are widely utilized in food applications such as yogurts, beverages, and dairy desserts (Table 2). They are highly soluble and able to stabilize oil/water and air/water interfaces, thus providing excellent foaming and emulsifying properties. Whey proteins can also form gels and have good water-binding properties. The excellent gelling properties of whey proteins make it an ideal gelling agent for meat products.

Whey proteins have also been increasingly recognized for their nutritional value as a superior source of protein fortification for specialized nutritional products and infant food. The nutritional value of whey proteins lies in their favorable amino acid compositions and their optimal digestibility. Whey proteins are used as a balancer for other proteins in specific nutritional applications, such as infant formula, and as a rich source of highly digestible branched-chain amino acids in sports beverages or nutritional bars (Table 2), to enhance protein synthesis in muscles, particularly after exercise.

Meat Proteins

Meat can be part of a balanced diet that contributes valuable nutrients that are beneficial to human health. Meat and meat products contain important levels of protein, vitamins, minerals, and micronutrients that are essential for growth and development of human bodies. The meat proteins, ~20% of a muscle's weight, are the major components that constitute the structure of the meat product. From a nutritional point of view, meat's importance is derived from its high-quality protein, containing all the essential amino acids and its highly bioavailable minerals and vitamins. Meat is rich in vitamin B12 and iron, which are not readily available in vegetarian diets.

Muscle proteins can be divided into three groups: myofibrillar, sarcoplasmic, and connective tissue proteins. The myofibrillar proteins account for 50–55% of the total protein. The two most abundant myofibrillar proteins are myosin and actin. They are responsible for the muscle's overall structure. The sarcoplasmic proteins account for 30–34% of the total meat protein and are soluble in water. Most of the sarcoplasmic proteins are the glycolytic enzymes, creatine kinase, and myoglobin. Myoglobin is a type of globular protein and gives meat its characteristic red color. The remaining 10–20% protein mass consists of connective tissue proteins such as collagen, reticulin, and elastin, which are all fibrous proteins.

Whole muscle meat is the food source of protein. Comminuted and reformed meat products such as burgers, sausages, and nuggets are also a common source of meat protein, although the protein content in these products is generally lower and the fat content is higher than the muscle meat cuts.

Meat protein ingredients that are derived from either meat processing by-products or lean tissue components are also used as high-protein ingredients in processed meat and other food products.

Collagen

Collagen is a family of insoluble fibrous proteins found in all multicellular organisms. It is one of the most abundant proteins in mammals, accounting for 25–30% of total body protein. It is also a major component of the skin, bone, cartilage, tendon, and blood vessels.

Collagen is a rod-shaped molecule, ~1.5 nm in diameter and 300 nm in length, consisting of three helical polypeptide chains coiled around one another into a triple-stranded superhelix stabilized by hydrogen bonds. Collagen is completely insoluble in water.

Collagen has a very unique amino acid composition and sequence. In terms of its amino acid composition, it has approximately 33% glycine, 12% proline, 11% hydroxyproline, and 11% alanine. A collagen chain has three amino acid residues per helical turn and is made up of an almost continuous repeating

of the Gly-X-Y-sequence, where X is mostly proline and Y is mostly hydroxyproline. Every third amino acid is a glycine residue, which, being small, occupies the helix's interior positions. The proline and hydroxyproline content of the collagen dictates its thermal stability.

Collagen for use in foods is extracted from bones, beef hides, pork skins, and skeletal muscle connective tissue. It is primarily used for its water-binding and gel-forming properties in reformulated meat products such as frankfurters and ham so as to increase cooking yields. Another application of collagen is in the manufacture of skinless or coextruded sausages.

Gelatin

One of the most commonly used meat protein ingredients is gelatin, a soluble protein obtained by partial hydrolysis of collagen. Gelatins are produced mainly from bovine and porcine sources; however, they can also be extracted from fish and poultry. Depending on the sources and manufacturing processes, the amino acid composition and the functional properties of gelatin can vary considerably. The content and distribution of proline and hydroxyproline are the major factors determining the physical properties of the gelatin, which in turn influence its quality and potential food applications.

Gelatin is one of the most versatile biopolymers and has numerous applications in food, confectionery, pharmaceutical, medical, and cosmetic products. The important functional properties related to the application of gelatin in food are its gel-forming, texturizing, thickening, and water-binding properties. A critical parameter for both collagen and gelatin is the helix-to-coil temperature or the denaturation temperature, which is around 36 °C. Above this temperature, all triple helical structure is lost due to the destabilization of the intra- and intermolecular hydrogen bonds leading to the unfolding of the triple helices. Below this critical helix-to-coil temperature and above the critical gelatin concentration (c*), the gelatin molecules reassemble into a network of triple helices, forming a thermoreversible viscoelastic gel upon cooling. The critical concentration and gel strength for a gelatin will also depend on factors such as the molecular weight of the gelatin, cosolutes, and pH of the solution.

It is this unique thermoreversible gelling property that makes gelatin such a useful food ingredient. Gelatin desserts and all types of jellies are examples of food products that take advantage of the thermoreversible gel formation and the 'melt in the mouth' texture of gelatin. Gelatin is also widely used in the confectionery industry. Examples of products containing gelatin are fruit gums, marshmallows, meringues, caramels, bar products, and sugar-coated candies. Gelatin can also be added to dairy products to improve the texture and reduce the secretion of aqueous whey from yogurt gels, cheese curds, and cream cheeses. Gelatin is also used in ice creams to control the size and distribution of ice crystals and thereby influence the texture, mouthfeel, and consistency of the product. In addition, gelatin is widely used in reformed meat products to bind water and meat juices and to enhance good texture and taste, in particular, as a fat replacer and/or binding agent in low-fat, low-carb, and low-calorie meat products.

From a nutritional point of view, gelatin is a good protein source that is easily digested and absorbed by the human body. However, gelatin is unusually high in the nonessential amino acids glycine and proline (i.e., those produced by the human body) while low in certain essential amino acids. The addition of gelatin in food products can increase the protein content and reduce the amount of carbohydrates, the salt content, and the amount of fat in low-fat food products.

Proteins from Seafoods

Seafood includes fish, crustaceans, and mollusks, which are considered as a low-fat and protein-rich source, as part of a healthy and balanced diet. Protein from seafood sources is of high quality, containing all of the essential amino acids in good quantity and in balanced amounts.

The amount of protein present in most fish products used for human consumption ranges from 15% to 20% on a wet weight basis (Table 3). There are no major differences between the amino acid compositions of freshwater fish and those of marine fish.

The muscle of different aquatic animals is very similar, containing similar protein and amino acid profiles. There are slight differences between fish muscle and the muscle of land animals. These are mainly associated with the differences in muscle structure required for swimming and buoyancy. Fish muscle tends to have less connective tissue than muscles from terrestrial animals, resulting in a more tender texture. About 70–80% of fish muscles are structural proteins. These structural proteins are soluble in cold neutral salt solutions of fairly high ionic strength. The remaining 20–30% contain sarcoplasmic proteins that are soluble in water and dilute buffers and a final part of the structural protein, 2–3%, being insoluble connective tissue proteins. Myofibrillar proteins are the primary food proteins of fish, comprising 66–77% of the total protein in fish meat, of which myosin comprises 50–60% of the myofibrillar contractile proteins and actin only 15–30%.

The major restructured seafood product is surimi, which is made from fish flesh by the removal of soluble protein, lipids, pigments, and other odorous compounds and with the addition of cryoprotectants, so that it can be stored in a frozen state. Currently, about 2–3 million metric tons of fish is used for surimi production. The gelling of actin and myosin on heating gives the surimi product a good resilient texture. During the

Table 3 Typical nutritional composition of fish and meat products (100 g)

Source	*Energy (Kcal)*	*Protein (g)*	*Fat (g)*
Fish	100–120	18–23	1–4
Chicken	100–160	20–25	6–15

last 10–20 years, the range of food products prepared from surimi has increased in number and quality.

Fish mince is another source of fish protein. It is a less-refined product compared with surimi. The mince retains all the flesh components, with resulting flavor and texture differences to surimi products. Fish mince is commonly used in the manufacturing of restructured products such as fish cakes and fish fingers.

Egg Protein

Hen egg is one of the most versatile foods. The hen egg, in the form of table eggs and egg products, forms an important part of the human total protein consumption. Egg products as a rich source of protein ingredients are also widely used in the food industry for their nutritional value, for their organoleptic characteristics, and mainly for their functional properties, hence their wide incorporation into manufactured food products.

Whole egg is composed of 75% water, 12% protein, 12% lipids, and about 1% carbohydrates and minerals. Proteins present in egg are distributed among the egg white and yolk. The egg white makes up ~60% of the total egg weight, of which water (88%) and protein (11%) are the major constituents. Proteins represent more than 90% of the egg white dry matter. The major proteins in egg white are ovalbumin (54%), ovotransferrin (12%), ovomucoid (11%), ovomucin (3.5%), and lysozyme (3.5%). Proteins present in egg yolk consist of lipovitellins (36%), livetins (38%), phosvitin (8%), and low-density lipoproteins (17%).

Egg white has no specific macrostructure. It is more or less a colloidal suspension of different protein constituents. They are highly functional physically and biologically and have high potential for industrial applications, if separated. Lysozyme is amongst the first egg white proteins that have been isolated and used by industry. The separation of lysozyme is achieved mainly through ion exchange chromatography due to the high isoelectric point value of lysozyme. Due to its antimicrobial activity, lysozyme is used as a natural food preservative against bacteria involved in food spoilage and food-borne disease.

Pasteurized whole egg, separated egg white, and egg yolk are further processed in liquid, frozen, or powder forms. Its foaming, emulsification, gelation, and thickening properties make egg product a universal ingredient for the food industry. Egg white is still considered as the reference for foaming properties, compared with other animal and plant protein ingredients. Both egg white and egg yolk have very good coagulation properties, when exposed to heat. Egg white, egg yolk, or whole egg is a traditional ingredient for desserts such as cakes, pastries, batter, and fresh pasta and sauces such as mayonnaise. The egg white proteins represent more than 90% of the total dry matter in egg white; thus, it is a high-quality nutritional source of protein.

Proteins from Plant Sources

Soy Protein

Although the overall contribution of soy protein in the average human diet is not as great as wheat protein (Figure 3), soy protein is, however, the most popular plant protein source to serve as an ingredient in formulated foods for their functional properties, such as water and fat binding, emulsification, foaming, and gelation. Soybeans contain ~35–40% of which 90% are storage proteins mostly consisting of β-conglycinin and glycinin. β-Conglycinin has the sedimentation coefficients of 7S, whereas glycinin has 11S. β-Conglycinin is a glycoprotein and is a trimer that consists of three subunits with molecular masses of 150–200 kDa, whereas glycinin is a hexamer with molecular masses of 300–380 kDa. Each glycinin subunit is composed of acidic (~35 kDa) and basic (~20 kDa) polypeptides, which are linked together by a disulfide bond.

The main soy protein products are soy flour, soy protein concentrate, soy protein isolate, and texturized and hydrolyzed soy proteins. Soy protein concentrate, which is produced from defatted soy flakes, after removing most of the soluble cell wall materials, has >65% protein (Table 2). Soy protein isolate, which is produced by alkali extraction and isoelectric precipitation, is the most refined form of soy protein with a protein content higher than 90%. Textured soy protein is produced by extrusion to resemble the texture of meat chunks (Figure 4). The principal function of texturized soy protein is to partially or totally replace animal proteins in various food products and is used as a protein source in vegetarian meat alternatives. Soy flour, soy protein concentrate, soy protein isolate, and their texturized products are mainly used as ingredients in formulated foods for their functional properties, such as water and fat binding, emulsification, foaming, and gelation. Common soy protein foods are soy milk that is used as a replacement for cow's milk by vegans and persons with intolerance to milk protein and tofu that is a protein curd made by precipitating the protein from soy milk.

Although traditional foods made from soybeans such as soy milk and tofu have been consumed throughout East Asia for more than 2000 years, in Western countries, soybean protein has only became an economical and high-quality vegetable

Figure 4 Texturized soy protein.

protein source for human diets during the last few decades. Soy protein ingredients have high protein levels and a well-balanced amino acid composition, which makes soy protein an important source of plant protein, with a great potential to replace meat and dairy proteins in human diets.

Wheat Gluten

The main storage protein in wheat is the gluten protein. Gluten protein is not a single protein, but a complex mixture of proteins, comprising several hundreds of polypeptides. About half of the proteins are monomeric gliadins and the other half are disulfide cross-linked polypeptides that form the polymeric glutenin fraction. The combination of these two protein fractions gives the gluten its unique physical functional property that none of other plant proteins have, that is, it forms a cohesive, viscoelastic proteinaceous network that provides the unique ability of wheat to produce leavened products. It is this precise ability of forming an insoluble protein mass when wheat flour is mixed with water that allows gluten to be separated from starch through a simple water wash process. Commercial gluten (known as vital wheat gluten) with a protein content as high as 75–80% is widely used in a variety of manufactured food products.

The major usage of gluten in Western countries has traditionally been in baked products, pasta, noodles, and breakfast cereals. In these product categories, the gluten is used to fortify flours of lower-than-desirable protein content by flour millers and bakers, in order to supplement lower-protein local wheats and to improve the quality of the flour so as to equal those with higher protein content. Gluten is attractive as a fat- and water-binding ingredient in restructured meat, fish, and poultry products. A major use of gluten in nonbakery foods is as a meat replacement in vegetarian foods and in the production of analogues of expensive foods such as seafood and crab meat, particularly in Japan. Texturized wheat protein, which is produced via extrusion, is used increasingly as plant protein to replicate the look and texture of meat products.

One major issue associated with gluten is its link with celiac disease, which is characterized by inflammation of the small intestine resulting from an inappropriate immune response to wheat gluten (and similar proteins from barley and rye). This disease can cause affected persons to lose weight and suffer from deficiencies of vitamins and minerals, which can lead to anemia and skin problems. At present, the only treatment is a strict diet avoiding all products containing gluten, and to cater for this market, other nongluten cereals or legumes are used commercially to produce gluten-free breads, pasta, flour, and other foods.

Proteins from Other Cereal Grains and Pulses

Although a variety of cereal grains are consumed as the basis of staple human diets either in the form of manufactured foods such as breads and breakfast cereals or by direct cooking of the grains such as rice, the protein content of cereal grains or the food prepared from the grains is generally low, in a range of 7–15% (Table 4). Conversely, pulses including pea, lupin, chickpea, lentil, bean, and other dry edible seeds from the pods of legume plants contain higher amounts of protein (20–36%; Table 4) compared with cereal grains and are important sources of protein in many diets around the world.

Table 4 Protein, carbohydrate, and fat content of major cereals, legumes, and oil seeds (g/100 g)

	Protein	*Carbohydrate*	*Fat*
Wheat flour	8–15	70–80	1–2
Rice	7–9	~80	~1
Maize (corn)	7–9	~75	4–5
Barley flour	10.5	74.5	1.6
Sorghum	11.3	74.6	3.3
Oats	16.9	66.3	6.9
Rye	10.3	75.9	1.6
Soybeans	36.5	30.2	19.9
Canola			
Pea	24.6	60.4	1.2
Chickpea	19.3	60.7	6.0
Lupin	36.2	40.4	9.7
Cowpeas	23.9	59.6	2.1
Lentils	25.8	60.1	1.1
Kidney beans	23.6	60.0	0.8
Broad beans	26.1	58.3	1.5
Mung beans	22.9	61.5	1.6

Flours, protein concentrates, or protein isolates have been produced from peas, chickpeas, and lupins. Pea flour is produced by dry milling of dehulled peas. Pea protein concentrate is produced by dry separation methods, whereas pea protein isolate is produced by wet processing using either alkali or acid solubilization, followed by isoelectric precipitation or an ultrafiltration process, which produces a protein fraction with a much higher protein content of 85–95%. Pea proteins have found applications in a range of food products such as cereal and bakery products, nutritional snack bars, pasta, meal replacement beverages, baby food formulations, vegetarian applications, meat, and seafood products. The increasing popularity of using pea proteins is largely due to their positive fat- and water-binding capabilities, emulsification properties, and gelation, texture, and nutritional values. Like other flours derived from pulses, chickpea flour is a potential high-protein source for use as an extender in emulsified meat products due to its superior technological functionality and minimal effects on flavor.

Lupins are nonstarch leguminous seeds with a similar protein content to soybean, at about 40%. Yellow lupins grown in Europe and South America are mostly used for animal feed. The presence of quinolizidinic alkaloids, which may be removed by soaking, prevents the direct consumption of yellow lupins as food. However, the white lupins, commonly consumed in the Mediterranean countries, are primarily grown for direct food uses. Australian sweet lupin (*L. angustifolius*) has a low alkaloid content and hence is more suitable for direct human consumption. When lupin protein is extracted, the resulting protein isolate is free of alkaloids and therefore can be used as a functional ingredient in human food. Lupin flour (i.e., free of alkaloids) and protein isolates have been successfully tested as ingredients in various food products such as in muffins in which egg and milk proteins are totally substituted, in biscuits to achieve high protein contents, and in dairy, bakery, and meat products.

Table 5 Protein, carbohydrate, and fat content of nuts (g/100 g)

	Raw			*Roasted*		
	Protein	*Carbohydrate*	*Fat*	*Protein*	*Carbohydrate*	*Fat*

Proteins from Nuts

The total protein content in nuts is relatively high, which makes them a good source of plant protein (Table 5). Peanuts, walnuts, almonds, pistachios, and cashews have the highest protein content, about 20% or higher (g/100 g raw and roasted products), followed by Brazil nuts, hazelnuts, and pine nuts in the range of 11–15%. Pecan and macadamia nuts have the lowest protein content at below 10%. However, due to their high fat content, nuts are energy-dense.

Nuts are part of the Mediterranean diet, although their average consumption is relatively low. Nuts are most commonly eaten as snacks (raw or roasted and salted). They are also used in foods such as soups, cakes, pastries, cookies, and pasta sauces such as 'pesto.'

The nutritional value of nut proteins is not very high since they are limiting in some essential amino acids, in particular lysine. Thus, for the human body to make good use of nut proteins, they need to complement other food proteins, such as pulses or other vegetable proteins in vegetarian diets, and dairy proteins in order to provide a high protein value.

Protein: Requirements

DJ Millward, University of Surrey, Guildford, UK

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Discussions in the area of nutritional recommendations are seldom without some degree of controversy, and protein is an exemplar of the difficulties and debates that can occur. The amount and type of dietary protein needed to allow optimal expression of the genome during growth and development remain poorly understood. Even the question of the nature and consequences of protein deficiency has proved controversial. For example, clinical manifestations long thought to reflect a protein deficient diet, such as edematous infantile malnutrition, have now been redefined as a reductive adaptation to a combination of infection and micronutrient deficiency. Also, there are virtually no effective markers of protein deficiency in adults. At the other end of the spectrum of public health issues, within health clubs worldwide, more money is spent on protein and amino acid supplements than on any other ergogenic aid, even though the effectiveness of such expense is poorly documented to say the least.

Values for protein and amino acid requirements derive from human and animal nitrogen (N) balance and growth studies that began early in the twentieth century and identified both estimates of dietary requirements and the pattern of amino acid essentiality. From the 1970s, research expanded to include stable isotope tracer studies of human protein and amino acid metabolism and turnover. This research has provided insight into the regulation of protein synthesis, proteolysis, and amino acid and N metabolism, in terms of quite detailed accounts of signal transduction pathways and their effectors. However, the most recent expert report from WHO on human protein and amino acid requirements concluded that, of the methodologies available, N balance (NB) remains the only available method for estimating the requirement for total protein (N); as a consequence, no current method is entirely reliable for determining the dietary requirement for indispensable amino acids (IAAs). Because of these limitations, the latest recommendations for protein and amino acid requirements are not entirely satisfactory and the nature and limitations of commonly accepted protein requirement values are by no means widely understood. In terms of the most recent appropriate research, the focus has been much more on identifying optimal protein requirements, especially for older adults. The difficulty is that virtually all new information derives from acute experimental studies of the amino acid requirements for maximizing protein synthesis in the skeletal muscle. However, the relationship with such measurements and the long-term maintenance of lean body mass in muscle and other tissues has not been established. It is the case, as indicated in Figure 1, that dietary protein intakes can vary markedly even within diets that would be judged 'healthy' and between population groups who choose plant-based rather than animal source foods. In fact, given $\geq$3-fold variation in dietary protein content indicated in Figure 1 and the fact that food energy intake can vary by up to 1.7 times due to lifestyle, overall protein intakes can vary over a fivefold range in ostensibly healthy individuals. The challenge is to identify the intake at the lower end of this range, which satisfies the criteria of a requirement value.

Terminology

Protein requirements are best discussed in terms of metabolic demand, dietary requirement, and dietary allowances. Metabolic demand is for amino acids, and the magnitude and amino acid pattern of this demand are determined by the extent of those metabolic pathways (e.g., net protein synthesis) that irreversibly consume amino acids. Thus, the demand varies with the phenotype and the developmental and physiological state of the individual. The dietary requirement is the amount of protein and/or its constituent amino acids that must be consumed in order to satisfy the metabolic demand. Because digestion and absorption may be incomplete (with dietary nitrogen (N) lost in the feces) and the absorbed amino acid pattern may not exactly match cellular needs (with some absorbed amino acid N lost as urinary N excretion), the dietary protein requirement will usually be greater than the metabolic demand. Dietary allowances are intakes derived from estimates of the average amount and between-individual variability within a population group that meets the dietary requirements of most individuals within the population. The most recent dietary allowances are those published by WHO in 2007, the values of which have been reproduced in the 2012 report of the European Food Safety Authority (EFSA).

Metabolic Demands for Amino Acids: General Aspects

Current evidence supports the representation of the metabolic demands as in Figure 2. The metabolic demand for amino acids is to maintain tissue protein at appropriate levels and to provide for all amino acid-derived metabolites and nonprotein products and any special protein needs during growth, rehabilitation, pregnancy, and lactation. Tissue proteins are diverse, including structural or fibrous insoluble types and soluble globular species, with characteristic properties and functions that are determined by their amino acid sequence. All proteins are in a dynamic state of constant turnover (i.e., breakdown to constituent amino acids and resynthesis), although for the structural proteins, this is slow or minimal. The tissue protein pool is not static even when body weight is constant, contracting and expanding in the postabsorptive and postprandial state. Nonprotein products/derivatives include nucleic acids and a diverse range of smaller molecules, such as creatine, taurine, glutathione, hormones (e.g., catecholamines and thyroxine), neurotransmitters (serotonin and dopamine), and

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00573-0

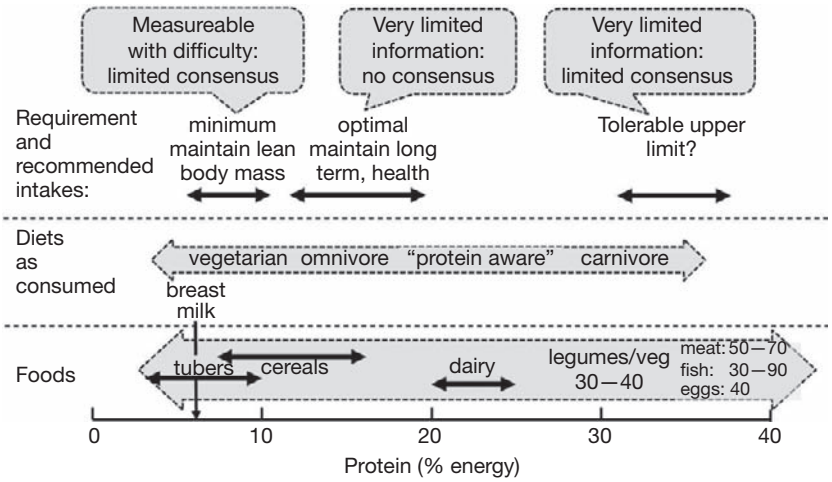

Figure 1 Protein requirements in relation to protein intakes from foods and diets.

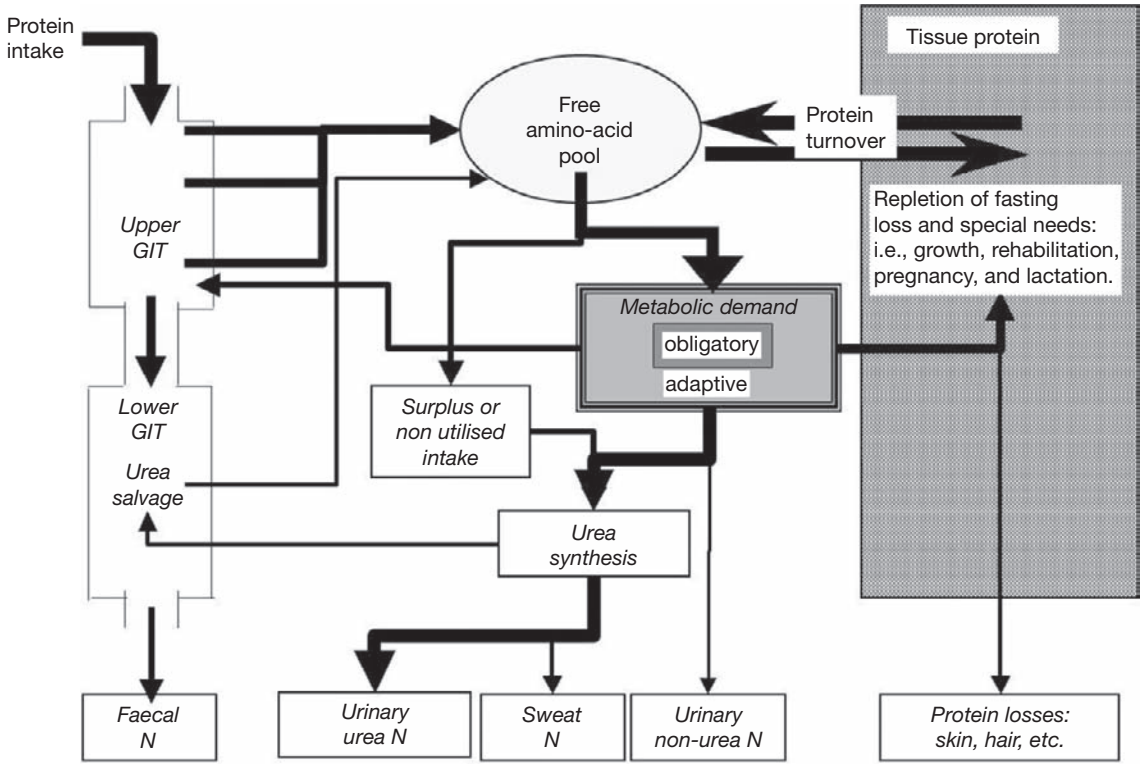

Figure 2 Schematic representation of the metabolic demands for amino acids.

nitric oxide, a key regulator of blood flow and other physiological processes.

The metabolic demand is supplied from the free amino acid pool, the size of which, for most of the IAAs, is regulated within narrow limits. This regulation involves supply from three sources: dietary proteins after digestion and absorption from the upper gastrointestinal tract (GIT), tissue protein after proteolysis during protein turnover, and urea salvage in the large bowel. Within the free amino acid pool, there are also interconversions of several of the dispensable amino acids (DAAs), especially during transfer between organs and in the course of amino acid absorption from the GIT. Removal of free amino acids occurs by reactions in which they act as substrates, and these reactions are shown as three pathways, one of which is the metabolic demand. This pathway involves a number of irreversible pathways, including net protein synthesis, and other irreversible metabolic transformations of individual amino acids. The second and quantitatively largest pathway is the removal for protein synthesis during protein turnover. At N equilibrium, because turnover involves the reversible removal of amino acids, with replacement through proteolysis, it does not exert a net metabolic demand (other than for those amino

acids irreversibly modified during or subsequent to protein synthesis). The third pathway is the irreversible removal of amino acids by oxidation and N excretion provoked, for example, by the transient increases in some or all free amino acids after a protein meal. This would represent an inefficient utilization. Although amino acid oxidation and urea synthesis are assumed to be irreversible, this is not entirely true because of urea salvage in the lower GIT. Thus, the rate of urea synthesis is usually in excess of the rate of urea excretion because some urea enters the large bowel and is hydrolyzed by bacteria. Most of this N is utilized by bacteria, and since little is lost as fecal N, it is eventually returned to the systemic pool as ammonia and amino acids after bacterial death and proteolysis, including some IAAs. Although the extent and nature of this salvaged urea N are poorly understood, ammonia predominates and this contributes to the *de novo* synthesis of DAAs.

The metabolic demand for amino acids appears to involve obligatory and adaptive components. The obligatory component for subjects at equilibrium (i.e., maintenance) comprises conversion of some individual amino acids into important metabolites that are further transformed into nitrogenous end products, mainly urea and other compounds in urine, feces, or sweat, as well as net synthesis of proteins lost from the body as skin, hair, and any other secretions including those within the upper GIT such as mucin proteins lost into the large bowel. These diverse biological demands for amino acids for maintenance represent an essential but probably quite small intrinsic metabolic demand for an equivalent amount of protein. The magnitude of this maintenance component is assumed empirically to be equal to the obligatory nitrogen loss (ONL) – that is, the sum of all N losses from the body observed in subjects fed with a protein-free but otherwise nutritionally adequate diet after 7–14 days. By this time, N losses have declined to a stable and reproducible low level with the subjects losing body protein at a constant daily rate. In normal adults, the daily obligatory urinary, fecal, and subcutaneous and other N losses are approximately 33, 12, and 7 mgN kg^{-1}, respectively (i.e., 52 mg kg^{-1} day^{-1}), in total equivalent to 0.33 g protein/kg/day tissue protein mobilized to meet such demands. The ONL is a function of body weight and, as far as is known, varies little with age. After adaptation to a protein-free diet, net tissue proteolysis is assumed to provide for the nonprotein components of the obligatory demand at a rate determined by the metabolic consumption of the rate-limiting amino acid (the amino acid with the highest ratio of molar proportion in the metabolic demand to molar proportion in protein). Because the obligatory metabolic demand is for a mixture of amino acids with a profile that is unlikely to match that of tissue protein, the actual N content of the metabolic demand is likely to be less than that indicated by the ONL (i.e., less than an equivalent of 0.325 g protein/kg/day). This is because all amino acids mobilized to provide for the metabolic demand must be oxidized and will contribute to the N excretion, whereas only some of them will serve useful functions. The evidence for this is the lowering of the ONL in response to feeding selective amino acids, such as threonine, tryptophan, and methionine. In addition to these metabolic demands for maintenance, any net protein synthesis associated with growth, pregnancy, and lactation also constitutes an obligatory metabolic demand.

The adaptive component of the metabolic demand represents amino acid oxidation at a rate varying with the habitual protein intake. Although this aspect of amino acid metabolism is not well understood, it is likely to occur because humans grow slowly or maintain constant weight on diets that may contain protein considerably in excess of minimum needs. Thus, in order to be able to rapidly dispose of excess protein and maintain the very low tissue concentrations of those amino acids that may be toxic at higher concentrations, that is, the branched chain (e.g., isoleucine), aromatic (e.g., phenylalanine), and sulfur amino acids (e.g., methionine), the capacity of the pathways of oxidative amino acid catabolism adapts (increasing their maximum initial velocity of enzymatic reaction $\{V_{max}\}$), enabling them to operate at the appropriate rate set by habitual protein intakes. Crucially, the adapted rate of amino acid oxidation changes minimally with feeding and fasting and changes only slowly in response to a change in dietary protein intake level. This has two main consequences.

First, because the adaptive rate of amino acid oxidation continues to some extent into the postabsorptive state, there are postabsorptive losses of tissue protein and N excretion – that is, a diurnal cycle of postabsorptive losses and postprandial gains with an amplitude that increases with the increasing habitual level of protein intake as shown in Figure 3. As such, the adaptive metabolic demand includes a component of net protein synthesis that repletes postabsorptive losses. The magnitude of this varies in a complex way with eating pattern and with the amount and quality (amino acid score) of the habitual protein intake.

Second when intake falls below habitual intake, mobilization of tissue protein occurs with a negative NB for as long as it takes to adapt amino acid oxidation rates to the lower level of intake. This was previously identified as the labile protein reserves. It can be assumed that for intakes greater than the minimum protein requirement (MPR), full adaptation to the new level will include not only a change in the adaptive metabolic demand to match intake but also repletion of most tissue N lost during the adaptive transition, that is, a period of positive NB.

The main practical implication of this adaptive metabolic demands model is that the true MPR will be that associated with the lowest possible adaptive metabolic demand. It is not known with any certainty how long such adaptation would take, but the limited existing evidence suggests it is considerably longer than the 2-week periods employed in short-term balance studies. This implies that short-term balances, from which our estimates of the MPR derive, may overestimate the value. It also means that some of the variability in protein requirements between studies may reflect variable completeness of adaptation to the test diets.

The Amino Acid Pattern of the Metabolic Demand: Plant Versus Animal Sources

With continuous and extensive amino acid interconversion, the pattern of amino acids in dietary protein need not exactly match the amino acid pattern of the demand. This is because some amino acids are dispensable and can be replaced by sufficient total amino acid N supplied from other amino acids or sources of nonessential N such as ammonium

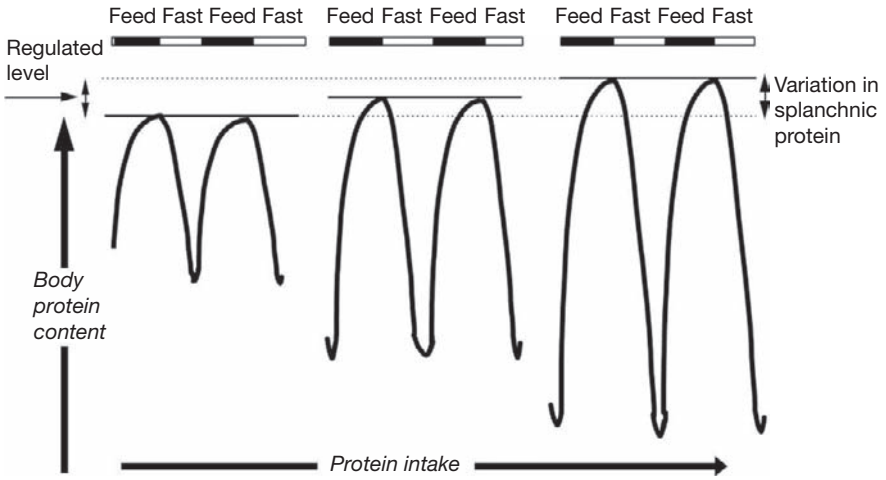

Figure 3 Balance regulation throughout the diurnal cycle with increasing habitual protein intakes.

compounds. These amino acids include aspartic acid, asparagine, glutamic acid, alanine, and serine. However, there will be a minimum dietary requirement for other amino acids, that is, those amino acids that cannot be formed from other amino acids and are therefore classified as indispensable. These are histidine, isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine. In addition, some amino acids are formed only slowly from other amino acids and become indispensable under specific physiological or pathological conditions. These are the conditionally IAAs, for example, cysteine, tyrosine, glycine, arginine, glutamine, and proline.

However, the definitions 'dispensable' and 'indispensable' for amino acids need to be interpreted with care. It might be assumed that excess IAAs can provide nonessential N after their carbon skeletons are oxidized. In fact, it has long been known that dietary amino acid mixtures rich in IAAs like egg protein are less effective in meeting the demand than mixtures with added nonessential N. Such diluted mixtures will maintain overall balance with lower levels of IAAs. This indicates that the demand includes an absolute need for nonessential N, which is less efficiently provided for by the oxidation of excess IAAs than by the DAAs. The metabolic basis of this demand for nonessential N is poorly understood.

There is a widespread view that there are significant differences in the relative nutritional value (quality) of plant compared with animal protein sources in human nutrition, mainly because of relative deficiencies of some IAAs. This view, which almost certainly overestimates the extent of any such differences, derives from studies that assessed the quality of dietary proteins in animal growth assays. In such assays, marked differences are observed between animal and many individual plant protein sources. For example, compared with animal source proteins, cereal proteins generally have low levels of lysine and in some cases tryptophan because of the structure of the main storage proteins – the prolamins, for example, gluten in wheat and zein in maize. In legumes, while the main storage proteins, the globulins, contain much higher levels of lysine than cereals, they often have relatively lower levels of the sulfur amino acids, methionine, and cysteine. These differences influence their individual performance in animal growth trials identifying them as lower-quality proteins. However, when different plant protein sources are combined in these assays, such as cereals and legumes, near maximal growth can be observed. This gave rise to the concept of 'complementation,' in which the appropriate balance of essential amino acids is provided from combinations of plant proteins.

It is now recognized that in human nutrition, with the rapid growth of the newborn infant slowing markedly after weaning, the nutritional demand for IAAs for tissue growth becomes a minor component of the metabolic demand after the first year of life. Little of the metabolic demand for amino acids is generated by protein turnover because of amino acid recycling. Some net protein synthesis is associated with skin and hair growth and with gastric secretions (e.g., threonine-rich mucus glycoproteins) that pass into the colon to be utilized for bacterial metabolism and with the postprandial replacement of postabsorptive tissue protein losses as shown in Figure 3. The metabolic demand for maintenance of normal function and composition is a poorly understood pattern of amino acids utilized in the various metabolic pathways other than protein synthesis. It has long been known, however, that this pattern differs from that required for growth (the tissue protein pattern) and contains a much lower overall amount of IAAs. The currently recommended amino acid pattern for human adults, the maintenance pattern, contains 28% IAAs compared with 42% in tissue proteins. Furthermore, nitrogen balance studies of different plant protein sources have consistently failed to show marked differences between plant-based and animal protein-based diets. Indeed long-term studies of healthy active adults on diets where wheat provided most of the protein have shown that body composition and physical fitness is maintained over periods of several months. This means that protein quality in terms of the amino acid profile may be less relevant in human nutrition, at least after the first few years of life when the rapid growth of infancy has subsided.

In fact, it is likely that the main difference between animal and plant dietary protein sources reflects the lower digestibility of some plant protein sources due to a combination of tough

plant cell walls that reduce the accessibility of plant proteins to digestive enzymes and antinutritional factors that can inhibit digestion.

In the opinion of this author, the currently accepted amino acid pattern of the maintenance requirement for IAAs defined in the 2007 WHO report is not entirely satisfactory. This is because each value is the average of several values that derive from different methodologies. These vary considerably, over a twofold range in the case of lysine, for example. This means that considerable uncertainty remains about the amino acid requirement pattern, which is used currently to judge the quality of dietary protein sources.

Nitrogen Balance

NB studies have been central to the definition of protein requirements within a model of nutrient balance: that is, a protein intake that balances all losses observed in a healthy, weight-stable subject. N is the proxy measure of protein intake and losses, and health is identified only in terms of an appropriate lean body mass at a healthy body weight. Thus, the MPR is determined as the intake for N equilibrium (zero balance), as indicated in NB studies. There are no other measureable physiological or biochemical indicators of health that are exclusively and unequivocally indicators of protein intake and no disease states that have been identified as having a quantifiable relationship with protein intakes.

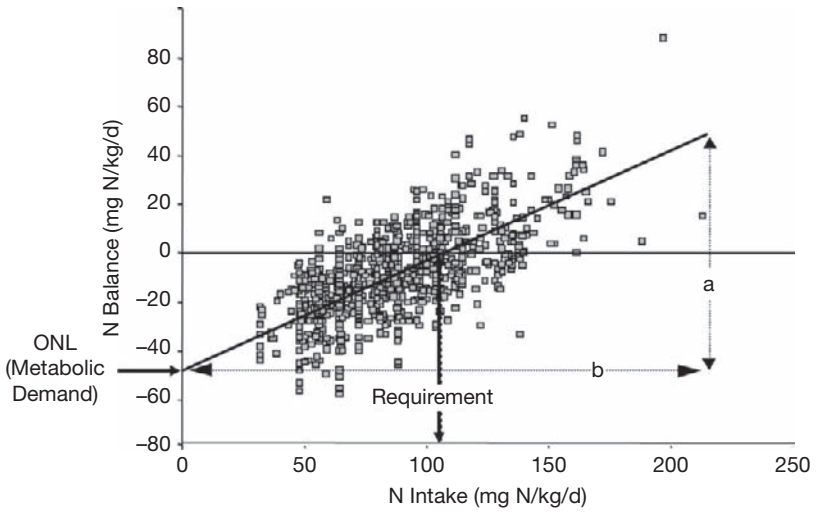
The aim of NB studies is simple – to define the relationship between intake and all losses (urinary, fecal, and surface – mainly sweat, skin, hair, breath ammonia, nail clippings, etc.) in subjects fed with three or preferably more intake levels, usually at or below the expected intake for equilibrium. This allows the intake (I), which matches all losses (L), and maintains N equilibrium to be identified as the requirement (R). Thus,

$$\text{when } I = R, \quad \text{balance} = I - L = 0$$

As indicated previously, the lowest level of losses observed, the ONL, equates to a daily loss of about 0.33 g protein/kg/day. When such subjects are refed with protein, losses of body protein decrease as the dietary protein provides for some of the metabolic demand. However, the apparent efficiency of utilization of dietary protein to meet the metabolic demand is much $<100\%$ so that N losses increase with intake and the required intake for balance is more than the ONL. The literature on human NB studies has been assessed in a meta-analysis, with all the reported individual balance points and the analytic principle shown in Figure 4. The protein intake that will balance all losses and produce N equilibrium, the maintenance requirement, is identified by linear regression of balance against intake, as intercept/slope. The currently accepted maintenance requirement for adults ($0.66\,\text{g}\,\text{kg}^{-1}\,\text{day}^{-1}$) is the median value of all individual subject linear regressions of the three or more levels of protein intake. Although the majority of the studies were young men studied with animal proteins, some studies with mixed plant proteins, with women, and with older adults were included. However, no significant influences of sex, age, or dietary protein source were observed. Subsequent NB studies examining age and sex specifically have confirmed that these factors do not influence the MPR.

Inherent Difficulties with N Balance Studies

This apparently simple – but laborious – approach is in fact beset with a large number of quite serious problems, as listed in Table 1. Because balance is a small value compared with the much larger values of N intake and N excretion, there is a lack



Balance = e x intake-ONL
(e = efficiency of utilisation = Δbalance(a)/Δintake(b))

Balance = 0.47.intake – 48.1mgN/kg/d
Requirement = intake for zero balance = ONL/e
= 105mgN/kg/d = 0.66g protein/kg/d

Figure 4 Meta-analysis of N balance studies: individual balance points and principle of analysis.

of precision in its measurement with considerable overall error. The various systematic errors mean that balance may be overestimated, often with unrealistic positive balances (protein gains) at high intakes. In practice, prediction of a zero balance–intake intercept is made from a few balance points by linear regression. Of the various difficulties relating to the design and interpretation of NB studies, the most important are (a) ensuring subjects are at energy balance, (b) allowing sufficient time for adaptation of amino acid oxidation rates to the change in protein intake, and (c) interpreting the slope of the regression as a true measure of the efficiency of protein utilization.

Energy Balance and N Balance

Body protein equilibrium is influenced by energy intake, with excess leading to weight and lean-tissue gain and with inadequate energy intake leading to weight loss, with the protein intake diverted to oxidation as an energy source. Thus, the protein requirement for N equilibrium is a function of energy balance and the actual influence is quite marked. According to one analysis of NB on intakes of energy (EI; kcal kg^{-1}) and N (NI; mg N/kg), NB = 0:171NI + 1.006EI – 69:13, implying that the intake for N equilibrium (the requirement) will vary from 1.4 to 0.32 g kg^{-1} day^{-1} according to whether energy intakes are equal to the resting metabolic rate (RMR) or equal to twice the RMR. In fact, most (85%) of the estimated between-individual variability used to calculate the safe protein intake shown in Figure 5 could be accounted for by an error of only ±10% of basal metabolic rate (BMR) in estimating the true energy needs of a subject. Such errors might not be observed in terms of weight change during the few days in which NB is measured. It is highly likely that many of the positive NBs shown in Figure 4 reflect excess energy intake. This dependence of NB on energy intake raises difficult and currently unanswered questions about whether the protein requirement should be defined in terms of a specified energy intake level, to maximize dietary protein utilization. For example, for populations with low-protein staples, the consumption of more energy would allow body protein equilibrium to be achieved: this could, however, predispose to obesity if energy expenditure is insufficient to match the increased intakes. In any case, the extent to which variation in energy intakes at energy balance (i.e., with increasing levels of physical activity) influences NB is unknown.

Table 1 Potential problems relating to N balance methodology

Imprecise: Balance is small difference between two much larger amounts
Systematic errors: Intake overestimated, loss underestimated due to difficulty of accounting for all losses:
Skin surface and secretions
Loss of N_2 gas
Expired ammonia
Endogenous NO production gives urinary nitrate, fecal ammonia, and nitrite (not always measured)
Changing size of the body urea pool
Design: Balance influenced by
dietary energy intake and physical activity
extent of adaptation of amino acid oxidation
Analysis: Linear regression slope markedly underestimates efficiency of utilization

Adaptation to Changes in Protein Intake

With the metabolic demand for amino acids including both fixed and variable demands, the relationship between intakes and balance will be a function of time and the rate of adaptation. This is undoubtedly why the determination of human protein requirement by NB has proved to be so difficult. Thus, when protein intake changes, the metabolic adjustments involved with matching amino acid oxidation and urea excretion rates to the new intakes take considerable time to adapt to the new level of intake. In practice, most balance studies are short-term, with dietary periods of 2 weeks at each intake studied and with diet periods randomized to minimize metabolic carryover of prior diets. The actual time taken for complete adaptation is poorly understood, but it is likely to be much longer than the 2 weeks usually allowed for in balance studies. While 2 weeks allows N excretion to stabilize in

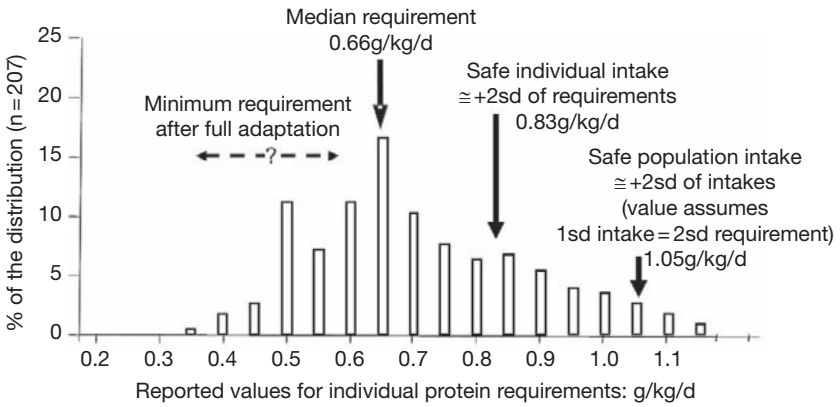


Figure 5 Distribution of reported values for the protein requirements showing values for safe individual and population intakes. The bars are the distribution of individual values of intakes for N equilibrium expressed as protein equivalents ($n = 224$ individual subjects from $n = 32$ studies, after a 5% trim of outliers), from a meta-analysis of N balance data. The minimum requirement after full adaptation is not known but likely to be less than the median value within the range shown.

subjects fed with a protein-free diet while establishing the magnitude of the obligatory N losses, it appears that this adjustment to a protein-free diet, an extreme metabolic change, occurs more rapidly than the adjustment from one intake to another. The evidence suggests changes in N excretion continue over several months after reduced protein intakes. Incomplete adaptation to a reduced intake at the end of a 2-week dietary change will result in a more negative NB, increasing the apparent protein requirement.

Adaptation and the Efficiency of Protein Utilization

While considerable NB studies have been performed in healthy adults, there are only a limited number of studies in any other population group, for example, children and pregnant and lactating women. In these cases, protein requirements have been derived with a factorial model in which the special needs for growth, pregnancy, and lactation have been calculated and added to the maintenance requirement derived for adults, which is assumed to be the same in these other populations. Calculation of the additional special needs involves adjusting measured rates of protein deposition, in children or during pregnancy, or rates of breast milk production, by an efficiency factor to determine the extra dietary intake necessary to meet the special needs. Historically, these efficiency factors were decided somewhat arbitrarily at 0.7. However, in the recent WHO report, much lower specific values were chosen from the slopes of the linear regressions of the limited NB studies reported for the different population groups. As discussed in the succeeding text, the calculated special needs added to the maintenance requirement are now much larger than previously identified.

Clearly, most balance studies are performed with high-quality protein sources, and this raises the question as to why protein utilization should be so inefficient in healthy adults. In fact, direct studies of the efficiency of utilization of proteins with ^{13}C-1 leucine oxidation (leucine labeled on its 1-carbon with the stable isotope, carbon-13) balance studies have shown that the true efficiency of utilization of dietary protein is as would be expected, that is, 95–100% for milk and high-quality proteins and lower (60–70%) for wheat. The shallow slope (low efficiency) of the NB regression has been explained in terms of the adaptive metabolic demand, which results in an increasing demand above the ONL (the intercept) with increasing intakes. This means that the slope underestimates the actual efficiency of utilization and it is consequently incorrect to evaluate the balance data in terms of an efficiency of utilization. The slope of the regression is only of value in terms of defining the intake for equilibrium (i.e., the requirement = intercept/slope = intake for zero balance). The consequence of this conceptual error is that the special needs for children and pregnant and lactating women are all overestimated in the current WHO report and these values have been adopted by other international and national bodies that invariably tend to adopt the WHO values.

Dietary Protein Allowances for Individuals and Populations

NB studies aim to determine both an individual MPR and a recommended allowance for protein, which, if consumed by any individual, would be associated with a very low risk of deficiency (deficiency = an intake < requirement). As shown in Figure 5, the average or median requirement is the midpoint of the range of individual requirements (0.66 g kg^{-1} day^{-1}). The safe individual intake (recommended nutrient intake in the United Kingdom) is calculated from the interindividual variability of the distribution of requirement values, as the 97.5th percentile, nominally the average + 2 SD, that is, 0.83 g kg^{-1} day^{-1}. Thus, any individual receiving such an intake will have a very low (<2.5%) risk of deficiency (defined as an intake < requirement). However, it is not generally appreciated that the safe intake for a population will differ from the safe individual intake. This is because the safe population intake needs to take into account the distribution of individual intakes as well as requirements. Because the variability of intake is usually greater than that of the requirement, the safe population intake is greater than the safe individual intake, usually approximating to the average requirement + 2 SD of intakes or plus 3–5 SD of requirements (i.e., 1.05 g kg^{-1}/day^{-1}). This does not mean that every individual in the population should consume the safe population intake; it means merely that the mean intake should be at least this level. In fact, the average or median requirement can be used to judge the adequacy of the population intakes. This is because, on the assumption that intakes and requirements are not correlated, the prevalence of deficiency approximates to the proportion of the population with intakes below the average requirement. For a population within which the median intake equates to the safe population intake, this proportion would be about 2.5% (this is called the 'cut-point' method of calculating the approximate deficiency prevalence).

A tolerable upper limit (TUL) has not been identified for protein, but the evidence suggests that intakes of three to four times the safe individual intake are consumed without obvious harm. This would suggest as shown in Figure 1 that the TUL may be quite high (e.g., ≈35% protein energy) and certainly higher than the value of 2 × safe intake often assumed in the past.

The serious implication of lack of complete adaptation in short-term multilevel balance studies is that because of the very wide range of protein intakes in the human diet, mainly through variable meat intake, the apparent requirement indicated in a study may still reflect the prior habitual diet: that is, the actual metabolic demands are higher than minimum levels because the adaptive component of amino acid oxidation remains influenced by previous intakes. This may explain the very wide range of reported apparent requirements shown in Figure 5 from below 0.4 to >1.1 g protein/kg/day. If adaptation, rather than variation in actual protein requirements, does account for the variability, then a quite different analytic model would be implied in which the MPR and safe intake are much lower. In this case, risk of deficiency for fully adapted individuals would remain low until intakes fall to quite low levels. Such adaptive models pose difficult questions for public health nutrition.

Protein Requirements for Growth and Special Needs: The Factorial Model

As indicated earlier, for infants, children, adolescents, and pregnant and lactating women, protein requirements are derived by a semifactorial model in which the requirement

comprises the components of the metabolic demands shown in Figure 2, identified as maintenance (the adult MPR identified as the intake for N equilibrium as discussed earlier), plus special needs. Special needs, that is, growth in children, the products of conception in pregnancy, milk production during lactation, and catch-up growth during nutritional rehabilitation, are calculated from measured rates of protein deposition (or secretion) adjusted with an assumed efficiency of dietary protein utilization to meet these amounts. In practice, the amounts of protein deposition, or milk protein secretion, are known reasonably accurately.

Infants, Children, and Adolescents

The main components of the safe individual intake during growth and development as reported in the recent WHO report are shown in Figure 6. The requirements include maintenance, assumed to be the adult MPR for all age groups, and growth. This is derived from measured rates of protein accretion in infants and children adjusted for an efficiency of utilization of 58%, derived from the slope of NB studies in children. To account for interindividual variability, the safe intakes include the addition of 2 SDs for maintenance and dietary growth needs, calculated from a coefficient of variation (CV) that is the weighted mean of the CVs for maintenance and growth. Overall, the safe intake falls from 1.31 g kg^{-1} day^{-1} at 6 months to 0.83 g kg^{-1} day^{-1} in adults.

Pregnancy and Lactation

The values reported by WHO allow for protein retention in the products of conception and in the maternal tissues associated with an average gestational weight gain in healthy women of 13.8 kg; this has been estimated from body composition analyses and for the increased maintenance costs of the increased body weight. The efficiency of dietary protein utilization to meet these growth costs is assumed to be 42%, a value observed in NB studies in primiparous teenagers, and the safe intake is calculated assuming a CV of 12%. This equates to additions of 0.7, 9.6, and 31.2 g protein per day. Lactation requirements are 19 g day^{-1} for the first 6 months and 12.5 g day^{-1} after this time; these values derive from the demand, observed as average milk protein output of well-nourished women breast-feeding adjusted for an efficiency of utilization of 47% as observed in NB studies in adults.

Uncertainty About and Safety of Requirements for Growth and Special Needs

Because the values selected for the efficiency of dietary protein utilization are very much lower than would be expected, the requirements for growth, pregnancy, and lactation are much higher than would be if more physiologically realistic values were used. This means that there are uncertainty and controversy about these requirement values.

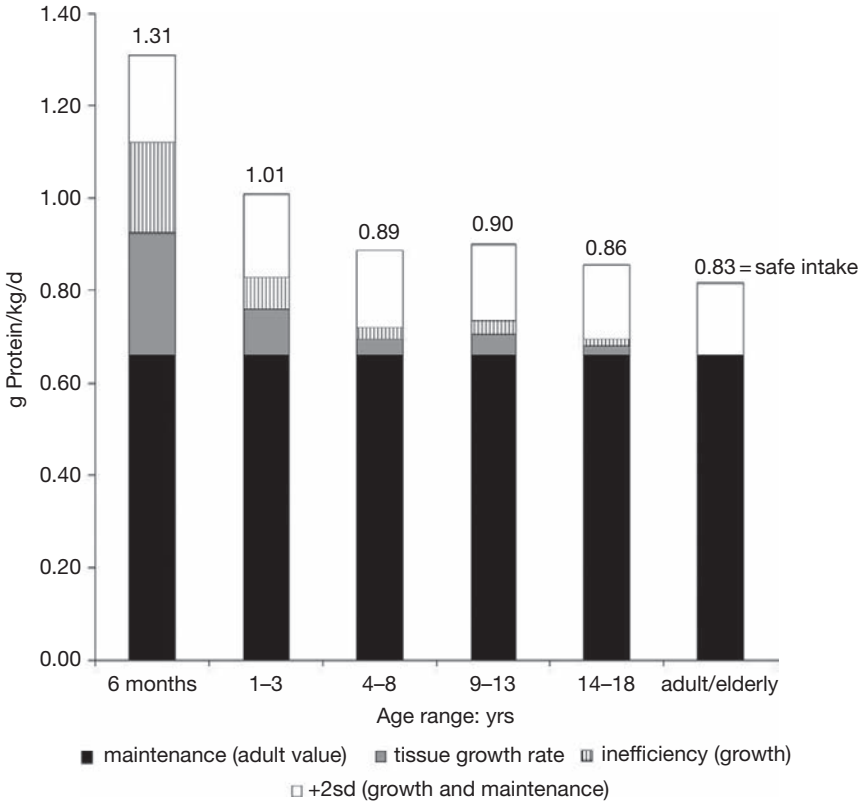

Figure 6 Factorial estimates of protein requirements throughout the lifecycle. Overall values are averages of the separate values for boys and girls.

Clearly, any argument that the true adult MPR may be less than the median value of 0.66 g kg^{-1} day^{-1} with a value toward the lower end of the distribution shown in Figure 4 will also apply where the adult maintenance value is used in the factorial calculation (i.e., child growth and pregnancy). This means that for children and adolescents, the true MPR values are likely to be lower than values shown in Figure 6. However, it is the case that the factorial model used for children was evaluated in the WHO report by modeling the values from birth to 6 months of age against protein intakes of healthy breast-fed infants. This indicated that the factorial model predicted a safe protein requirement value that is similar to, but lower than, the 'crude' breast milk protein intake at all ages, which is what would be expected given that breast milk intakes from healthy mothers can be assumed to be adequate. However, in this modeling, the values for maintenance were 12% lower (0.58 rather than 0.66 g kg^{-1} day^{-1}) and the efficiency of protein deposition assumed to be 14% higher (66% rather than 58%), so that at 6 months, the safe intake was identified as 1.14 g kg^{-1} day^{-1} compared with 1.31 g kg^{-1} day^{-1} as shown in Figure 6. This 15% overestimation is probably acceptable, however, given that utilization of protein from a mixed diet after weaning is likely to be less efficient than during breast-feeding. It is also the case that any need for dietary protein to provide an anabolic drive on linear growth is not included in the factorial model for children. Taken together, this means that there is little reason to be concerned about any overestimation of the protein requirements for children.

In the case of pregnancy, however, there is every reason to be concerned that the requirement has been seriously overestimated. This is because of evidence that excessive protein intakes in pregnancy, including high-protein supplements, can have adverse effects on pregnancy outcomes. Thus, if any additional dietary protein intakes are recommended for pregnant women, these should comprise extra intakes of a normal healthy diet. In the WHO report, advice is given that the additional protein during pregnancy should consist of additional normal food, rather than high-protein supplements. During the third trimester, an extra 31 g day^{-1} of protein would represent an extra 3.6 MJ of a mixed diet assuming it contains 15% protein energy. This is considerably more additional energy than is recommended at this stage of pregnancy by any agency. Indeed, given the concern for adverse influences of overweight and obesity on pregnancy outcomes and given that pregnant women often have successful pregnancy outcomes without any increase in food intake, it is likely that this amount of additional food would result in excessive weight gain. On this basis, it is clear that these new WHO requirement values for pregnancy need a serious review.

Optimal Protein Intakes and Implications of Adaptation for Nutrition Policy

In general, protein requirements serve two purposes. One is as a basis for prescription (i.e., advice on safe diets through recommending appropriate dietary intakes). Adaptation implies a low – but difficult to define – MPR. Indeed, since natural diets, providing sufficient energy and other nutrients, usually provide considerably more than the minimal amount of protein, the magnitude of the MPR becomes to some extent an issue of scientific curiosity only. Formulation of policy in relation to prescriptive matters will inevitably and correctly be most concerned with satisfying the upper range of demands for protein and, where there is uncertainty, include positive margins of error. In this case, it is arguably unwise to adopt an adaptive model and reduce the MPR, even if agreement could be reached on the likely lower limit of adaptation. Indeed, an adaptive model does not imply that protein is an unimportant nutrient for the maintenance of human health and well-being, but rather that indicators other than balance (N, protein, or amino acid) need to be identified. Thus, the most relevant measure is an optimal requirement allowing balance and supporting both optimal body function and minimum risk of chronic disease as shown in Figure 1. There is increasing experimental evidence for the potential benefit of protein intakes considerably higher than the current MPR for bone health in the elderly and epidemiological evidence for benefit with respect to hypertension and ischemic heart disease. However, such influences are unproven, with no plausible mechanism identified in the latter cases. In any case, there are no quantifiable indicators. This results in a dilemma for those attempting to frame prescriptive dietary guidelines. From this perspective, it is probably wise to retain current values as an operational expedient (at least those that are safe) until it becomes possible to quantify the benefits (and any risks) of protein intakes within the adaptive range.

The other purpose of requirement recommendations is as a diagnostic indicator of deficit risk, often within an epidemiological context in which population groups rather than individuals are considered. In this case, indicators used to estimate prevalence of disease states or deficit risk are carefully chosen so as to strike an acceptable balance between false positives and false negatives. The main implication of adaptation for estimating risk of deficiency as intakes fall to less than requirement levels is a dramatic reduction in the prevalence of risk for most populations compared with that assessed according to the traditional model, which does not account for adaptation. This occurs because the requirement and intake can be assumed to be correlated and because the actual MPR and safe intake calculated from it will be lower. As in the prescriptive context, this low risk of deficiency applies only to that of being unable to maintain NB after full adaptation with otherwise nutritionally adequate diets satisfying the energy demands. Nutritionally adequate diets containing protein intakes at such low levels are likely to be very rare, and whether such populations enjoy optimal protein-related health in terms of immune function, bone health, or any other function is a separate issue and needs to be addressed as such. From this perspective, it follows that maintenance of NB can no longer be used as a surrogate of adequate protein-related health and that current lack of quantifiable alternative indicators is no excuse for ignoring the issue of adaptation.

Proteins in Foods

Proteins are one of the major compound classes in raw agricultural materials (e.g., milk, eggs, soy, and cereals) as well as in meat and fish products. The proteins present in raw products serve different purposes, related to the structure and properties of the proteins. The first distinguishing feature of proteins is their solubility. This was used in the classical separation of wheat proteins by Osborne. The milled wheat can be sequentially extracted by water, 5% NaCl, and 70% ethanol to yield the albumin, globulin, and prolamin fractions. The remaining alcohol-insoluble fraction contains the glutelins, which combined with the prolamin fraction are referred to as gluten. For milk whey, obtained after the removal of the caseins (either by chymosin or by precipitation at pH 4.6), a similar separation of proteins is obtained by increasing the concentration of ammonium sulfate. The globulins precipitate in 50%, and the albumins in 100% $(NH_4)_2SO_4$. Proteins that are insoluble in aqueous solutions often have the function to provide structure (e.g., myosin in muscle tissue). Soluble proteins such as found in milk are often used for metabolic purposes (e.g., enzymes, transport proteins, and nutrition). In addition to proteins, which are polymeric chains of amino acids or polypeptides, there are also free amino acids and oligopeptides present in food raw materials. It is important to note that while up to 300 different natural amino acids have been identified, only 20 amino acids are commonly included in the protein amino acid sequence.

The most common sources of proteins that are used as ingredients in food products are milk, egg(white), and soy. In addition to these traditional protein sources, research is done to develop the potential of other protein sources, such as alternative leguminous seeds (e.g., pea), potato, or algae. The composition of these food materials is reported in Table 1.

Chemistry of Proteins

Food proteins are an essential component of the diet needed for the survival of animals and humans. Their basic value in nutrition is to supply adequate amounts of needed amino acids.

Proteins are a major source of energy, nitrogen, and essential amino acids, which are essential to human health, but which the body cannot synthesize.

The proteins are present in natural products in what is called their native structure. For globular proteins, this means that the proteins have a more or less spherical shape, where the more hydrophobic amino acids are buried in the interior, while the charged and polar amino acids are mostly present on the solvent exposed surface of the proteins. During processing, different reactions can occur that change the properties of the protein. These are (1) denaturation, which means a transition from the native (globular) state to a different folding state, (2) hydrolysis of the peptide bonds in the proteins, and (3) chemical reactions to the side chains of amino acids. Denaturation occurs, for instance, during the boiling of an egg and can be used to make aggregates or gels. The hydrolysis of proteins is often used to reduce allergenicity or to improve digestibility. Chemical side reactions, such as the Maillard reaction, can be positive with respect to technofunctional properties (e.g., solubility) but may negatively affect digestibility.

In addition to the natural presence in food raw materials, proteins are often extracted from such materials to be added in processed food products (e.g., bread, ice cream, and mousse). In these applications, the proteins do serve not only as source of essential (and other) amino acids but also as ingredients to give products a desired structure (e.g., gels, emulsions, or foams).

Alteration of the chemical structure of food proteins can be caused by deteriorative reactions arising during processing and storage and by modifications with chemical or enzymatic reagents intentionally done to alter the properties of the proteins. The application of chemical and enzymatic methods intentionally to modify chemical and functional properties of food proteins has a long history of usage, as illustrated by the enzymatic modification of milk proteins to produce yogurt and cheese.

The Maillard reaction, which was first observed by the French chemist, Louis-Camille Maillard (1912), is probably one of the best-known reactions of proteins in the processing, drying, and storage of foods containing both proteins and carbohydrates. It is known as nonenzymatic browning, resulting from the reaction between the carbonyl group of a carbonyl compound (usually glucose, fructose, or pentose) and the amino groups of proteins. Glycation results in the formation of stable compounds through the Amadori rearrangement, which further evolve in other degradation products. Several reaction factors, such as temperature, time, pH, water activity, intrinsic properties of protein, and sugar composition, influence the yields and types of the Maillard reaction products and consequently physicochemical, structure, and functional properties of modified food proteins. Moreover, the Maillard reaction alters the nutritional content of the proteins, mostly depleting lysines, which, in later stage of Maillard reaction, are modified to generate compounds such as lysinoalanine, furosine, and carboxymethyllysine.

Protein cross-links form an interesting subset of the Maillard reaction products since, in addition to the loss of essential amino acids such as lysine, proteins can be cross-linked to form aggregates, which are thought to be less accessible to digestive enzymes reducing the digestibility of the proteins.

Chemical methods of derivatization that have been reported in the literature include (a) acylation (acetylation and succinylation) or alkylation of amino groups; (b) esterification or amidation of carboxyl groups; (c) acylation or electrophilic substitution of phenolic groups; (d) oxidation or alkylation of sulfhydryl, thioether, imidazole, or indole groups; (e) oxidation or reduction of disulfide groups; and

However, most of these chemical modifications are not approved or acceptable for the modification of proteins that are intended for human consumption. Notable exceptions are oxidizing and reducing agents, such as sulfite, hydrogen peroxide, ascorbic acid, and cysteine, which are commonly used for food protein modification, for example, in controlling dough properties in the baking industry. In addition, acid or alkali treatments are currently being used for the purpose of deamidation or peptide bond cleavage to produce hydrolysates.

In contrast to chemical modification, enzymatic modification is generally considered to be milder, more specific, and less prone to yield undesired side reactions. Furthermore, enzymes can possibly be inactivated after the desired functional property has been achieved, leading to better control of the final product quality.

Proteolysis, or hydrolysis of the peptide bond, is probably the most common application of enzymatic modification of proteins. A variety of enzymes from microbial, animal, and plant sources are commercially available for the modification of food proteins, with different specificities and sites of action. The optimum degree of hydrolysis depends on the desired product, with limited proteolysis being used to enhance functional properties such as emulsification, foaming, or curd formation, while extensive proteolysis yielding amino acids and peptides used to produce flavor hydrolysates (in combination with the Maillard reaction) or predigested nutritional products for feeding or for individuals who have protein hypersensitivity, gastrointestinal disorders, or other special medical concerns. Proteolysis, besides decreasing the molecular weight, also increases the number of ionizable groups and can expose hydrophobic groups, which can change physical or chemical environmental interactions. However, the hydrolysis conditions need to be controlled to avoid excessive protein hydrolysis that can impair functionality and cause unfavorable effects, such as the production of bitter-flavored peptides.

Nutritional Quality of Proteins

The basic function of proteins in human nutrition is to provide the adequate amount of the amino acids needed for the synthesis of our own proteins. The nutritional value of the proteins is related to several different parameters: amino acid composition, ratio of essential amino acids, the susceptibility to digestion by the enzymes during gastrointestinal passage, and modifications introduced during food processing in the amino acids. The different sources of proteins highly differ in the nutritional quality of the provided proteins. Although amount can vary according to metabolic state, age, sex, diet, and health conditions, roughly speaking, the amount of proteins required by young adult males is 0.6 g kg^{-1} body mass. This number anyway is highly theoretical, since it refers to 'ideal' proteins having a perfect amino acid composition and being perfectly digestible. If the intake is based on proteins having not a perfect amino acid composition (which is almost always the case), this number must be raised to 0.8 g kg^{-1}, and if the average digestibility (which of course most of the time is far from perfect) is also taken in consideration, a more realistic value of 1 g kg^{-1} body mass should be considered.

Among the 20 amino acids found in proteins, some of them are released and used as such, since the human metabolism cannot synthesize them. Others can be further metabolized obtaining nitrogen compounds useful as building blocks of the amino acids that human metabolism can synthesize. The amino acids that the human metabolism cannot synthesize and thus must be introduced with the diet are histidine, isoleucine, leucine, valine, phenylalanine, tryptophan, methionine, threonine, and lysine. They are named essential amino acids. Other amino acids that are not considered essential, in the sense that the human body can synthesize them, can nevertheless be obtained only by metabolic conversion of essential amino acids and not really synthesized from scratch, like cysteine (obtained by methionine) and tyrosine (obtained by phenylalanine). These amino acids, together with some other amino acids, are considered to be 'conditionally' essential, since they are usually not essential, but they can become essential in certain conditions, like growing children or in the presence of metabolic disease. The conditionally essential amino acids are tyrosine, arginine, cysteine, glycine, glutamine, proline, serine, and tyrosine. This only leaves alanine, aspartic acid, and glutamic acid as truly dispensable amino acids.

In proteins, the greater the prevalence of essential amino acids is, the greater their nutritional value, but also, the distribution of the single essential amino acids is of paramount importance. Proteins that are deficient in one or more essential amino acids, even if rich in all the others, are considered to be

of poor quality. The essential amino acid that has the lowest abundance in specific proteins as referred to an ideal abundance is often named the 'limiting' amino acid. Tryptophan and lysine are limiting in corn, lysine in wheat and other cereals, and methionine in soybean and legumes.

There are many available methods to estimate the nutritional quality of proteins, aimed at determining the net biological use of a protein as related to the amount consumed and its quality. Some are based on the composition, like the chemical score for single essential amino acids (the mg of that amino acid in 1 g of a test protein as related to the mg of the same amino acid in a reference protein), and some on *in vivo* trials, like the protein efficiency ratio (the ratio between the weight gain and the protein consumed).

Before a protein can be used as nutritional source of amino acids, it must be digested, that is, it must be susceptible to hydrolysis to single amino acids by the enzymes present in the gastrointestinal tract. Resistance to digestion of course lowers the nutritional value of a protein, by lowering the amount of essential amino acids available for the human metabolism. The food matrix is further complicating this picture, since the matrix can both affect the susceptibility of proteins to be digested by the gastrointestinal enzyme, as well as the availability of released amino acids to be absorbed. The presence of protease inhibitors, amylase inhibitors, lectins, phytates, and tannins can thus impair the true nutritional value of proteins ingested, as compared to the theoretical one in the absence of these compounds.

Food processing can both improve and reduce the nutritional value of proteins, depending on the type of food and processing. Highly proteolyzed foods, such as cheese, usually have an increased nutritional value due to the increased digestibility due to the presence of 'predigested' proteins. On the other side, processes that destroy essential amino acids can have an impairing effect on the nutritional value of a proteinaceous material. In particular, extreme pH values or heat treatments highly affect the nutritional value of proteins. These conditions can trigger the Maillard-type reactions involving amino groups or oxidative degradations of sensitive amino acids. Racemization can also occur, as well as the formation of cross-linked amino acids. Lysine, methionine, and tryptophan are particularly sensitive to degradation. Lysine easily reacts through the primary amine side chain, particularly in the presence of carbohydrates; methionine easily undergoes oxidative degradation; and tryptophan is very sensitive to acidic pH in combination with extreme heat.

In order to be considered a good source of proteins, a food must contain large amounts of high-quality, easily digestible proteins. According to the FAO/WHO standards, white egg and milk whey proteins are considered to be the most optimal protein source when looking at nutritional characteristics also including digestibility. For this reason, egg proteins are often used as reference in all methods for evaluating the nutritional properties of proteins. Also, meat is usually considered to be an optimal source of good amounts of high-quality proteins, but in this case, the true availability of amino acids is often hampered by digestibility issues. Some plant proteins (soybean, peas, and beans) have interesting nutritional characteristics when considering protein amount, quality, and digestibility, even if certain essential amino acids are usually limiting (cysteine, methionine, tryptophan, threonine, and lysine).

Besides basic nutrition properties, proteins can have a role in satiety (they are reported to induce satiety more efficiently than other food compounds, although the issue is still controversial). Proteins can also be a source of peptides having biological properties. A huge amount of literature exists on positive biological properties of peptides, such as antihypertensive, anti-inflammatory, opioid, calcium-binding, antibacterial, and antioxidants. Some peptide sequences can actually escape digestion and be absorbed as such, suggesting that these functions might also be exerted *in vivo*, even if often the amount absorbed is very low. Despite the relevance of the subject and the extensive researches done, the issues about resistance, absorption, distribution, and biological effects of food-derived peptides are still a matter of much debate.

Allergenic properties of food proteins are specifically treated in another chapter.

Technological Quality of Proteins

Proteins are major structural components of many natural foods, often determining their overall texture, for example, tenderness of meat or fish products. Isolated proteins are often used in foods as ingredients because of their unique technofunctional properties, that is, their ability to provide desirable appearance, texture, or stability. Typically, proteins are used as gelling agents, emulsifiers, foaming agents. Some food proteins are enzymes that are capable of enhancing the rate of certain biochemical reactions. These reactions can have either a favorable or an unfavorable effect on the overall properties of foods. Protein functional properties are attributed to both intrinsic (molecular structure and composition) and extrinsic (temperature, pH, and environmental chemicals) factors. When these factors are changed, food proteins' structure is modified and functional properties vary accordingly.

Proteins isolated from different sources (e.g., milk, eggs, and soy) are often added in food products to form and stabilize certain textures of the food, such as foams, emulsions, or gels. It is important to note that such protein preparations are never pure. Typically, they contain many different types of proteins. For instance, milk contains whey proteins and caseins. In each class, again, a subdivision of proteins is made (e.g., β-lactoglobulin and α-lactalbumin). Each individual protein can be present in different states. This may be due to genetic variation (β-lactoglobulin A and β-lactoglobulin B), posttranslational modification (i.e., phosphorylation and glycosylation), or processing (i.e., heat-induced unfolding and aggregation). In addition, due to processing, chemical reactions may have taken place such as the Maillard glycation (nonenzymatic) and decarboxylation.

Protein preparations are sold as concentrates or isolates. The distinction is often based on the isolation procedure and the resulting differences in protein purity. Concentrates contain 35–80% protein. Isolates contain 80–95% protein. The remaining part may contain fat but mostly contains carbohydrates. Due to the variation in protein content, composition, and the state of the protein, even seemingly similar protein isolates (such as whey protein isolates) may show a large variation in their technofunctional properties, that is, their ability to form and stabilize foams, emulsions, or gels. The first characterization of protein ingredients is often done by determining the solubility of the material, perhaps as function of the pH. Since proteins contain

both acidic and basic amino acid side chains, the charge of the protein changes from positive at low pH values to zero (at the isoelectric point) to negative at high pH values. Proteins usually have lowest solubility around the isoelectric point, since the absence of electrostatic repulsion will not counteract the hydrophobic attraction. However, whey proteins can be obtained from milk after acid precipitation of the caseins at pH 4.6. In this case, the caseins do precipitate, while the whey proteins stay in solution, even though for all the proteins the pH is close to their isoelectric point. After heat treatment, the proteins may unfold (and partially refold), after which hydrophobic groups that were previously buried in the protein interior became exposed. This increased hydrophobicity results in a higher attraction between proteins and consequently a lower solubility. Unfolded whey proteins, for instance, can be separated from the native whey proteins by precipitation at the isoelectric point.

For foams and emulsions, again, the charge of the proteins and the exposed hydrophobicity seem to be dominant factors that determine the ability of the proteins to adsorb to the air–-water or oil–water interface. This adsorption results in an increase in surface pressure and surface dilatational modulus. These properties have been typically related to increased stability of foams and emulsions. However, recently, it has become apparent that for certain systems (e.g., heated lysozyme), the interfacial properties of several samples may be similar, while the foam properties are very different. Consequently, the determination of the technofunctional properties of proteins is still best tested under the conditions and the system that most closely reflects the final application. In addition, it is very important to realize that there may be changes in the protein structure that can influence the observed behavior. Many proteins do not occur as single polypeptide chains, but have a so-called quaternary structure. β-Lactoglobulin, for instance, occurs mostly as a dimer, and soy glycinin occurs as a hexamer of a disulfide bridge-linked subunit consisting of an acidic and a basic polypeptide chain. In both cases, changes in pH, temperature, or ionic strength can result in the dissociation of the quaternary structure. In addition to these changes in the protein state, it is of extreme importance to realize that the presence of nonprotein compounds also has a significant effect on the properties of the protein isolate or concentrate. Partly due to the name, people are lead to believe that the properties may be attributed to the protein part, but carbohydrates and phenolic compounds can also have significant effects. For instance, the presence of salt in the protein isolate can result in changes in the ionic strength of the protein solution when protein solutions are prepared at different concentrations. Such effects are often overlooked. Based on the wide variety of properties observed even in seemingly similar protein ingredients, any comparison of functionality between proteins from different sources should be considered with appropriate care. It may be that while testing a whey protein isolate, a soy protein isolate, and a caseinate in one case, the whey protein isolate seems best, while with another set of samples, the soy protein isolate is best.

Analysis of Proteins

w?>Food analysts are interested in knowing the total concentration, type, molecular structure, and functional properties of the proteins in foods. The first and most relevant information on protein content in a given food is of course the crude amount of proteins. This is usually done by methods determining the nitrogen content, since, among the three major classes of macronutrients (proteins, fats, and carbohydrates), the nitrogen atom is contained almost exclusively in proteins. Also, the most relevant methods are those that analyze the whole product, without extractions, and that can handle solid materials, in order to minimize or even skip the sample preparation. Among them, Dumas and Kjeldahl methods are the most widespread ones.

The Kjeldahl method, developed in 1883 by a brewer named Johan Kjeldahl, is usually considered to be the standard method of determining the total protein content. A food is completely hydrolyzed by boiling in concentrated acid so that it releases all protein nitrogen in the form of ammonia, which can then be determined by a suitable titration technique. The amount of protein present is then calculated from the nitrogen concentration of the food. The same basic approach is still used today, although a number of improvements have been made to speed up the process and to obtain more accurate measurements. Because the Kjeldahl method does not measure the protein content directly, a conversion factor (F) is needed to convert the measured nitrogen concentration to a protein concentration. A conversion factor of 6.25 (equivalent to 0.16 g nitrogen per gram of protein) is used for many applications; however, this is typically not correct. Each protein has a different conversion factor depending on its amino acid composition.

The Kjeldahl method is widely used internationally and is still the standard method for comparison against all other methods. Its universality, high precision, and good reproducibility have made it the major method for the estimation of protein in foods. However, it does not give a measure of the true protein, since all nitrogen in foods is not in the form of protein, so a slight overestimation is generally the rule.

Recently, an automated instrumental technique has been developed that is capable of rapidly measuring the protein concentration of food samples based on a method first described by a scientist named Dumas over a century and a half ago. A sample of known mass is combusted in a high-temperature chamber, leading to the release of gasses (including N_2 deriving from proteins) whose thermal conductivity is measured, allowing to determine the amount of nitrogen. As with the Kjeldahl method, it is necessary to convert the concentration of nitrogen in a sample to the protein content, using suitable conversion factors, which again depend on the precise amino acid sequence of the protein.

The Dumas method is nowadays competing with the Kjeldahl method as the standard method of analysis for proteins for some foodstuffs, since it has the advantage of being much faster than the Kjeldahl method, it does not need toxic chemicals or catalysts, it can handle many samples at time, and it is easy to use. On the other hand, the Kjeldahl method is much better for inhomogeneous samples and can analyze larger samples sizes.

Besides these two, a number of methods based on UV–vis spectroscopy have been devised in order to measure protein concentration after extraction from a food matrix. These methods either use the natural ability of proteins to absorb light in the UV–visible region of the electromagnetic spectrum or chemically or physically modify proteins in order to make

them absorb light in this region. One example is the direct measurement at 280 nm, which is used for proteins that contain tryptophan and tyrosine, which absorb ultraviolet light strongly at this wavelength. Another possibility is the use of compounds that bind proteins making them absorbing in the UV–visible region: the biuret method (based on Cu^{2+} complexes), Lowry method (based on the biuret and the Folin–Ciocalteu phenol reagent), and methods based on anionic dyes. In all these methods, the quantitation is obtained by calibration with a reference protein, typically bovine serum albumin (BSA). However, the response factors for different proteins may be different from that of BSA, giving inaccurate results. In addition, hydrolyzed proteins do not bind the compounds in the same way as full proteins, again altering the results. Furthermore, the reagents used to bind proteins might bind to other matrix components, giving rise to unreliable results.

UV–visible techniques are fairly rapid and simple to carry out and are sensitive to low concentrations of proteins. However, it is necessary to use dilute and transparent solutions, which contain no contaminating substances, which absorb or scatter light at the same wavelength as the protein being analyzed. The need for transparent solutions means that most foods must undergo significant amounts of sample preparation before they can be analyzed, for example, homogenization, solvent extraction, centrifugation, and filtration, which can be time-consuming and laborious. In addition, it is sometimes difficult to quantitatively extract proteins from certain types of foods, especially after they have been processed, so that the proteins become aggregated or covalently bound with other substances. As a consequence, while the Kjeldahl method and increasingly the Dumas method have been officially approved for a wide range of food applications, only a small number of applications of UV–visible spectroscopy have been officially recognized.

Besides bulk protein content, food analysts are also often interested in the type of proteins present in a food, because each protein has unique nutritional and physicochemical properties. Gel electrophoresis techniques, such as typically one-dimensional (1-D) SDS-PAGE or 2-D electrophoresis, provide a nice overview of the complexity of the protein mixtures. Individual proteins are usually visualized by staining with Coomassie blue or silver and possibly identified by immunoblotting procedures or by mass spectrometry. The analysis of single proteins can be also performed by chromatographic methods by exploiting the different affinities of different proteins for the solid matrix. Ion-exchange chromatography and reversed-phase chromatography are the most used general methods, although hydrophobic interaction chromatography and Hydrophilic Interaction Liquid Chromatography (HILIC) are also used. Size exclusion chromatography is also largely used, although more for preparative purposes.

Amino acid analysis is used to determine the amino acid composition of single proteins and protein mixtures and also to determine the true protein amount in a mixture in a way that is independent from the Kjeldahl and Dumas determination, albeit more cumbersome. A protein sample is first hydrolyzed (e.g., using a strong acid) to release the amino acids, which are then separated by using chromatography, typically ion exchange (as such), or reversed-phase chromatography (after derivatization).

The differences among proteins in their physicochemical properties, such as size, charge, adsorption characteristics, solubility, and heat stability, can also be exploited to isolate individual proteins from a complex mixture. Many separations are done by exploiting differences in their solubility in aqueous solutions. Proteins can be selectively precipitated or solubilized by altering the pH, ionic strength, dielectric constant, or temperature of a solution. Some examples are salting out, isoelectric precipitation, solvent fractionation, and denaturation.

In the salting out, proteins are precipitated from aqueous solutions when the salt concentration exceeds a critical level. Ammonium sulfate $(NH_4)_2SO_4$ is commonly used because it has a high water solubility. The protein of interest can be then separated by centrifugation.

The isoelectric point (pI) of a protein is the pH where the net charge on the protein is zero. Proteins tend to aggregate and precipitate at their pI because there is no electrostatic repulsion keeping them apart. Proteins have different pI's because of their different amino acid sequences (i.e., relative numbers of anionic and cationic groups), and thus, they can be separated by adjusting the pH of a solution.

The solubility of a protein depends on the dielectric constant of the solution that surrounds it because this alters the magnitude of the electrostatic interactions between charged groups. As the dielectric constant of a solution decreases, the magnitude of the electrostatic interactions between charged species increases.

In the solvent fractionation, by adding water-soluble organic solvents, such as ethanol or acetone, it is possible to decrease the dielectric constant of the aqueous solution and indeed favor the protein isolation by precipitation.

Finally, many proteins are denatured and precipitate from solution when heated above a certain temperature or by adjusting a solution to highly acid or basic pH. Proteins that are stable at high temperature or at extremes of pH are most easily separated by this technique because contaminating proteins can be precipitated while the protein of interest remains in solution.

Introduction to Proteomics

The term and concept of proteomics were introduced by Marc Wilkins et al., in the 1990s, the term proteome referring to the entire protein complement expressed by a genome or by a cell or tissue type.

One main difference between the concepts of genome and proteome is that the proteome varies in different cell types, from tissue to tissue, and it changes during development and under different conditions, but the genome does not. Moreover, the number of proteins in a proteome can exceed the number of active genes due to alternative gene splicing and posttranslational modifications (PTMs). Proteomic analyses were initially based on protein separation by two-dimensional electrophoresis (2-DE) on polyacrylamide gels (isoelectric point (pI) and molecular mass) followed by image analysis of the gels in order to catalog all the resolved spots to form reference maps. Initially, the analyses were mostly descriptive: for example, one could analyze the 2DE protein maps of the control and the case samples (e.g., a biopsy from the liver of animals fed with diet A and another from animals fed diet B) and examine the differences, which often required multivariate data analyses. This approach, the most frequently used in the early 1980s, was mainly descriptive and the results were lists of differentially present spots, whose pI and molecular mass had been estimated and cataloged as present, absent, increased, or decreased intensity in relation to the issue under study (type of diet, disease, etc).

The proteome, the total protein content of one particular biological system, is highly dynamic and constantly changes according to different stimuli. Proteomics includes not only the structural and functional knowledge of proteins but also the study of their modifications, the quantification of their abundance, the interactions between them, and the study of their localization.

A general challenge for proteomic analyses is the large complexity of the protein mixtures, which usually is accompanied by a wide range in their relative abundances. Therefore, the comprehensive characterization of complex proteomes often necessitates their fractionation into less complex subproteomes (selecting proteins with similar characteristics or with similar abundances). The integration of the subproteomes will then give a picture of the total proteome of the complex sample. The complexity presented by most proteomes makes the need for further technical advances in the near future clear.

What Do You Need in Your Lab to Work in Proteomics?

The provision of a proteomics lab includes expensive instruments for protein separation and fractionation, imaging, robotics sample preparation, mass spectrometers, computers, advanced software, and expert personnel in such processes and results interpretation or management. Furthermore, electrophoretic, liquid chromatographic, and mass spectrometry (MS) apparatuses require accessory material and facilities such as gas supply, fume cupboards, thermostatic baths, centrifuges, air-conditioned rooms, vacuum pumps, and sonication baths, without which it would be impossible to prepare the sample in good conditions to be analyzed using that instrumentation. Table 1 compiles the most important material needed for each proteomic step in the proteomic workflow.

However, it must be kept in mind that a good sample is the most valuable item for the analysis, and it is easy to forget that the protein extraction from their source and the subsequent fractionation or purification steps are the most important processes in the procedure. Indeed, that is the starting point, to ensure that the relevant proteins or peptides have been successfully extracted and will be characterized.

What Proteomics Can Do

Depending on the general objectives of the study, proteomics can be used to identify and characterize a given protein, to study variations in the proteome caused by stimuli (differential proteomics), or to study the functional interactions between different proteins and the networks to which the proteins belong to (functional proteomics).

Protein Identification and Characterization

MS is the method of choice for the identification and characterization of proteins. The analysis of any kind of proteome usually relies on one or several separation steps followed by MS analysis. MS experimental data are compared with the data included in protein sequence databases using appropriate software, known as search engines, of which Mascot, SEQUEST, and ProFound are the most frequently used. Matches are scored and the peptide or protein with the best score may be assigned to the experimental data after a judicious probabilistic calculation is made by the selected program.

Table 1 Major lab requirements for proteomic workflow

Proteomic step	*Instrumentation*	*Fungible material*	*Reagents*
Protein extraction and solubilization	Homogenizers, tissue disrupters, vortex, mortars, liquid nitrogen, centrifuges	Glasses, tubes, balances, freezers, automatic pipettes, test tubes	Protease inhibitors, detergents, chaotropes, reducing agents, TCA, ethanol, commercial extraction kits, commercial cell lysis kits, commercial fractionation kits, commercial cleanup kits, reduction–alkylation kits, devices to avoid high-abundance proteins and to concentrate low-abundance proteins (i.e., phosphoproteins)
Protein quantitation	UV–Vis, NanoDrop, spectrophotometer, fluorometer, centrifuge	Quartz or glass cuvettes, disposable pipettes, tubes	Protein commercial assay reagents. Protein standards
Electrophoresis	Power supplies, thermostatic baths, vertical or horizontal electrophoretic systems, IEF cells	Bottles, test tubes, glass plaques, combs for sample deposition, separators	Precast gels; acrylamide/bisacrylamide; electrophoresis buffers; ampholytes; urea; molecular weight and isoelectric point protein standards; protein stains: Coomassie, silver nitrate, commercial dyes. Others: methanol, acetic acid, ethanol, detergents, DTT (dithiothreitol), ammonium persulfate, sodium thiosulphate
Protein digestion	Incubator, ultrasonic sound, pressure-cycling technology, vacuum concentrators	Low-peptide-bound plastic or glass material, pipettes, filters, tubes	Trypsin, V8 enzyme, lysine-C, cyanogen bromide, other proteases, TCEP (tris 2-carboxyethyl-phosphine hydrochloride), IAA (iodoacetamide), C18 cleanup devices
MALDI-TOF–MS	MALDI mass spectrometer	Low-peptide-bound plastic or glass material, pipettes, filters, MALDI target plates	C18 reversed-phase resin beds; alpha-cyano-4-hydroxycinnamic acid (a-cyano or CHCA) and 3,5-dimethoxy-4-hydroxycinnamic acid (sinapinic acid or SA), 2,5-dihydroxybenzoic acid (DHB) and 2-(4-hydroxyphenylazo) benzoic acid (HABA), 2,6-dihydroxy acetophenone, and ferulic and caffeic acids. Peptide standards
LC–ESI-MS/MS	Micro-HPLC, UPLC, autosampler, and mass spectrometers with electrospray ionization	Columns, syringes, bottles, peak tubing, micropipettes	C18 reversed-phase resin beds, CAN acetonitrile, FA (formic acid), TFA (trifluoroacetic acid), peptide standards, AQUA™ peptides, helium supply, nitrogen supply
Software	Image analysis; protein database; protein identification, quantification, monitoring, and *de novo* sequencing analysis	Good resolution monitors, robust computers and servers	Examples of patented and public software: PdQuest™, UniProt, ExPASy, SEQUEST™, Mascot, X! Tandem™, Trans-Proteomics Pipeline, MaxQuant, OpenMS, PeptideAtlas, MRM Atlas™, Progenesis™, DeNovoX™, PEAKS™, Spectral Libraries, Skyline, R-statistical software, Spotfire®

In the peptide mass fingerprinting (PMF) approach, the protein previously isolated (usually, but not only by 2-DE) is enzymatically digested. The masses of the peptides obtained from the MS spectrum are the data used for the identification. Another approach, known as peptide fragmentation fingerprint, uses tandem mass spectrometry (MS/MS) fragment ion data from one or more peptides, allowing the sequencing of the peptide(s) and thus yielding the unambiguous identification of the protein. Alternatively, MS/MS fragment ion data from the whole protein can be used in a similar way, in the approach known as top-down proteomics. For all these approaches, the sequence(s) of protein(s) under study must be contained in the database. However, if the protein is absent from the database, identifications can still be made if homologous proteins, usually from related species, are present in the database. When the experimental sequence remains unassigned, the peptides must be sequenced *de novo*, meaning that the MS/MS spectrum has to be interpreted manually or by computer-assisted identification of the fragmented ions whose mass differences correspond to the residue masses of the amino acids.

Proteins can suffer PTMs in response to a wide range of extra- and intracellular signals, or as a result of processing treatments, as may be a frequent case in food products. PTMs play crucial roles, since they alter the protein activity, localization, or stability. More than 300 different types of PTMs are known, although only few of them are being extensively investigated, such as phosphorylation, acetylation, glycosylation, and oxidation. The mass shift in the modified amino acid with respect to the unmodified one is the basis for the detection and characterization of PTMs by MS. However, since PTM peptides are usually present in very low amounts when compared to non-PTM peptides, modification-specific enrichment techniques, such as antibody-based affinity enrichment, special chromatographic procedures, or chemical tagging, are needed.

Differential Proteomics

Proteomes are highly dynamic. Protein patterns change from cell to cell or tissue to tissue, through cell and organism cycles, and in response to different environmental stimuli. Quantitative information at the protein level, such as the relative abundance in a specific protein in different samples, or the absolute amount of the protein, turns out to be very helpful when looking for differences between different conditions (e.g., control vs case). Relative quantification can be achieved with different methodologies, which can be classified as gel-based, label-based, and label-free approaches. In gel-based methods, the protein spots from different samples are compared after 2-DE. The samples to be compared may be run either in different gels or, alternatively, in the same gel after being differentially labeled (technique known as difference gel electrophoresis, DIGE). DIGE allows the comparison and quantification of the proteins contained in up to three different samples, and it increases the confidence in terms of detection and quantification of differences in protein abundance, in addition to reducing the number of gels needed per experiment.

Other label-based methods relay in the relative quantification of peptides labeled with the different isotopes of the same chemical element (i.e., isobaric tags for absolute and relative quantification (iTRAQ), ^{18}O). Peptides or proteins previously labeled using a mass tag that has been introduced metabolically, enzymatically, or by a chemical reaction produce differences in the intensity of the signals obtained from the MS or MS/MS readout, based on the intensity ratio of heavy to light isotope in the peptide pairs.

Finally, label-free approaches avoid using labeling and stable isotopes. The protein amount is calculated based on the MS-derived ion current signal of the peptides/proteins or on the number of identified MS/MS spectra (spectral count) for the protein. However, the absolute quantification of proteins needs isotopically labeled synthetic peptides as internal standards for each targeted protein. Quantitative proteomics methodologies have been greatly improved with the introduction of selected reaction monitoring (SRM), a high-sensitivity LC-MS/MS acquisition mode that is commonly used to verify and validate candidate biomarker proteins.

Functional Proteomics

Most proteins work in close collaboration with other proteins and molecules and are assembled in dynamic complexes. Functional proteomics deals with the integrated analysis of the functional interactions between different proteins and the networks made up by them. Thus, the term interactomics refers to the discipline that studies the interactions between a specific protein and the others, or between a protein and other molecules, and the consequences of these interactions. In this transition from structural to functional proteomics, different platforms are being developed and not all of them are MS-based: protein microarrays, yeast two-hybrid assay, phage display, affinity pull-down, and capture compound MS are some of them.

Activity-based proteomics is another area related to functional proteomics, studying the specific activities of the proteins in a sample, such as their function and inhibition. Activity-based protein profiling uses small-molecule probes to label and analyze active enzymes in lysates, cells, and whole organisms. MALDI imaging MS, a new imaging modality that allows mapping proteins within a tissue section, has turned out to be a relevant tool for functional proteomics, since the location of the different protein isoforms can help to understand their roles.

Proteomic Workflow

As stated earlier, the analysis of the proteome is commonly done after one or several sample preparation steps. As already mentioned, a great challenge for MS technology is the complex nature and highly dynamic range of proteomes. This makes it convenient to select extraction protocols that allow the enrichment in the proteins of interest. Partial purification, depletion of the high-abundance proteins, and selective enrichment of those in low abundance are some of the common protocols when working with complex samples. At this point, two different proteomic workflows can be followed: *bottom-up* or *top-down* as shown in Figure 1.

Using the classical workflow, referred as the bottom-up approach, the protein/s of interest is converted into peptides using enzymes such as trypsin, and the peptides produced are analyzed by MS. For that reason, this approach is sometimes

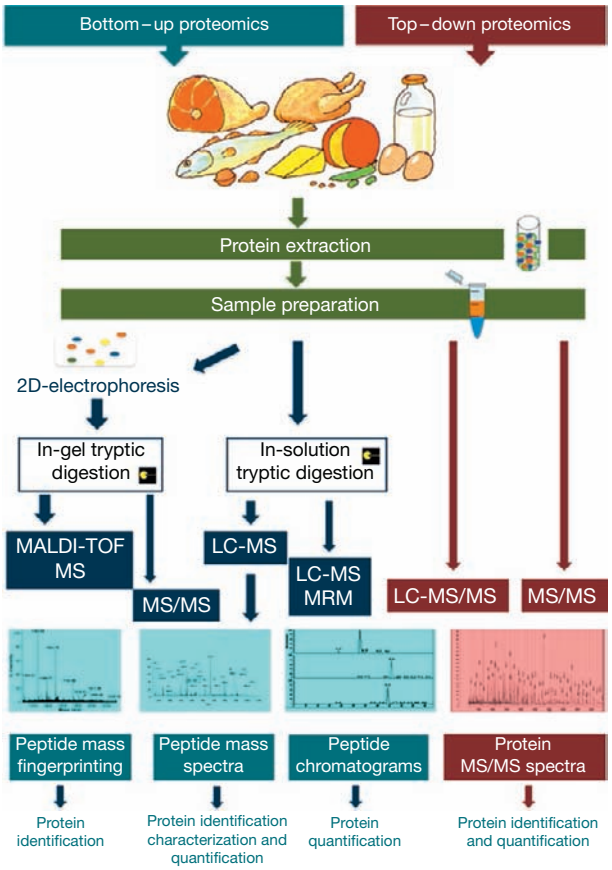

Figure 1 Proteomic workflows commonly used in food technology research.

known as peptide-based proteomics. Bottom-up approaches can be further divided depending on whether the fractionation steps are performed before (at the protein level) or after (at the peptide level) the enzymatic digestion. The former strategy has its more representative example in the use of the gel-based 2-DE technique, where proteins are separated according to their pI and molecular mass, so that protein spots can be individually excised from the gel and digested into peptides that are analyzed by MS. It must be noted that proteins may comigrate, and it is not infrequent to find that one single spot in a gel contains more than one protein or peptide.

In an alternative bottom-up approach, also referred as *shotgun proteomics*, the protein mixture is enzymatically digested without previous fractionation, and the resulting mixture of peptides separated by reverse-phase (RP) HPLC or UPLC coupled to an ESI tandem mass spectrometer. However, the chromatographic separation of peptide mixtures becomes very complex, and usually, the peak capacity of one-dimensional chromatography is not enough for highly complex protein samples. Therefore, multidimensional liquid chromatography coupled to mass detection is widely used. Separations combining strong cation exchange chromatography, or based in the isoelectric points of peptides (OFFGEL), are usually combined with RP separations.

Top-down proteomics uses intact, isolated, and undigested proteins for direct fragmentation by MS/MS. The fragment ions produced are used to reconstitute amino acid sequences by any of the methods previously described. Top-down proteomics is possible thanks to the high mass accuracy and resolution attainable with Orbitrap or FTICR mass spectrometers.

MS Analysis

MS analysis relies on the ionization of analytes at an ion source (i.e., ESI and MALDI) and the separation of the analyte ions according to their mass to charge (m/z) ratio at one or several mass analyzers (i.e., quadrupole (Q), ion trap, time of flight (TOF), and FTICR). Subsequently, a detector registers the ion current coming from the analyzers and generates the corresponding mass spectrum. Applying a variety of bioinformatics tools to the analysis of the mass spectra obtained, it is possible to obtain information about the peptide sequence and its abundance.

MS techniques provide valuable mass data from peptides and proteins and can be used for PMF identification of an isolated protein, to measure the exact mass of a whole protein, or for the selected ion monitoring (SIM) quantification method. Nevertheless, most of the protein identifications are produced nowadays using hybrid mass spectrometers. These instruments combine different types of analyzers, such as Q, TOF, linear ion traps (LIT), or any of the high-resolution instruments (Orbitrap or FTICR). Some examples are triple quadrupole (QQQ), quadrupole-time of flight (Q-TOF), tandem time of flight (TOF–TOF) and, for high resolution, Q or LIT coupled with either Orbitrap or FTICR. MS/MS or even more MS stages (MSn) are possible with these instruments. This means that a specific peptide (in bottom-up approaches) or protein (in top-down approaches) can be isolated and fragmented (MS/MS) using different activation approaches (e.g., collision-induced dissociation, CID; higher-energy collisional dissociation, HCD; and electron transfer dissociation, ETD) to obtain the fragment ions needed for their identification. Using ion traps, the fragmentation cycle (precursor isolation, activation, and analysis of the produced fragments) can be repeated several times selecting specific fragments from the previous cycle (MSn).

Several data acquisition approaches are possible depending on the nature and the stage of our research. The approach known as data-dependent analysis (DDA) is the most frequently used when the objective is to study the highest possible number of proteins present in the sample. This method consists on the MS/MS fragmentation of the most abundant ions detected during a survey MS scan, and it is often followed by discovery analyses, where a massive identification of proteins is pursued, and quantitative data can also be obtained from the MS/MS spectra using a proper methodology such as chemical isotopic labeling or spectral counting. However, the detected peptides are biased towards those coming from high-abundance proteins. To avoid this, one can use the data-independent analysis acquisition mode, where, instead of selecting one specific ion for fragmentation, all peptide ions present at a time in the mass analyzer are fragmented. This latter approach is currently growing due to recent advances introduced in MS instruments, such as elevated-energy MS (MSe) and sequential window acquisition of all theoretic mass spectra acquisition modes (where multiplexed fragmentation spectra are obtained), and in spectral deconvolution software.

When previous information about the m/z of the proteins/peptides under study is available, data can be obtained using several acquisition modes included under the term-directed analysis. Directed analyses focus on specific ions selected by the operator, thus increasing reproducibility, sensitivity, and selectivity. They can be used to identify, monitor, and quantify low-abundance peptides not detected in DDA analyses, in acquisition modes such as SIM or selected MS/MS ion monitoring, where only the selected m/z values are detected or fragmented, respectively.

Finally, when the m/z of both the precursor ion and one or several product ions are known, a targeted proteomic analysis can be made using the SRM scanning mode. The high-sensitivity LC-MS/MS acquisition mode, usually performed on QQQ instruments, is the gold standard method for the quantification of proteins and is commonly used to verify and validate candidate biomarker proteins in a hypothesis-driven approach following a discovery study. Absolute quantification can be achieved in SRM using isotopically labeled synthetic peptides as internal standards for each targeted protein.

Proteomic Studies on the Main Food Groups

Cereals, Fruits, Wine, and Beers

Proteomic studies on cereals focus on relevant biological aspects that go from assessing biodiversity, to (1) crop improvement, authenticity, and nutrition assessment; (2) the characterization of seed development, germination, and growth; (3) responses to stress (biotic and abiotic); (4) mapping organelle proteomes and secretomes (secreted proteins); (5) the screening of transgenic plants (e.g., nutritional and safety assessment of transgenic plants); (6) food safety proteomics; and (7) the identification

of proteome characteristics that keep a relationship with grain quality. Technically, there is a need for improvements in sample preparation methods (for tissue and organelle isolation) and protocols for protein extraction, separation, and detection of proteins, PTMs, and the redox proteome (related to protein oxidoreduction and the characterization of the redox control systems). The methods used include MALDI-TOF–TOF, ESI-MS/MS and multidimensional protein identification technology, isotope-coded affinity tags, and iTRAQ protein separation.

Proteomic studies on fruits (tomato, grape, citrus, prunes, and apples) have mostly focused on maturing and ripening processes, and most species seemed to share profiles involving sugar and oxidative metabolism and stress responses, but there is still a clear need for further studies to optimize the quality and nutritional value of the fruits.

In wines and beers, the proteinaceous material is made up of native, denatured, chemically modified, and partially hydrolyzed proteins and peptides. Many of the proteomic studies aim at characterizing their quality (formation of haze, protein denaturation, aggregation, and precipitation) and safety (detection of allergens that may originate in the fruit or be formed during processing and of hordeins and gliadin-like proteins in beer, which make the product unsuitable for celiacs). Combinatorial peptide ligand library (CPLL) technology (to detect very low-abundance proteome), nano-LC–ESI-MS/MS, and competitive ELISA assays using specific antibodies have been used to detect traces of harmful proteins in these beverages.

Other relevant properties examined include how changes in the proteome may be affected by adaptation to different stresses and during berry ripening (i.e., the induction of antioxidant proteins; changes in amino acid, proteins, and energy metabolism; and production of by-products and changes in structural proteins) and the influence of these changes on the product's nutritional value. Both the abundance and the PTM of some proteins (disulfide bond reduction, partial proteolysis, glycosylation, and phosphorylation) seem to be of high relevance for the quality of the beverages.

The yeasts used to produce the beverages have a large impact on their quality and have been subject to proteomic studies: most of the changes in yeast proteomes affect proteins involved in stress responses; glycolysis and ethanol production; glycerol, carbohydrate, and amino acid metabolism and protein degradation (most of which were upregulated); and nucleotide metabolism and protein synthesis (most of which were downregulated).

Dairy Products and Eggs

Milk is one of the important biological fluids and contains considerable amounts of nutrients. All types of milk and derivatives contain proteins in colloidal dispersion as micelles, fats in emulsified globules coated with a membrane, and easily digested minerals, vitamins, and other components. The application of proteomics tools to milk research took place in the 1990s, and while the major protein components of human, and animal and particularly bovine milk were biochemically characterized two decades ago, the analyses of the less abundant milk proteins have only just recently been reported for bovine and porcine milk and included with the human data in the PeptideAtlas repository. Significant advances have been made in (1) the detection and identification of new proteins, in particular minor proteins or proteins located in subcellular compartments such as the milk fat globule membrane; (2) variations in the protein profiles depending on the mammalian species or on the stage of lactation; and (3) PTMs (e.g., glycosylation and phosphorylation), which occur at extremely high frequency, either naturally or induced by processes such as lactosylation.

The proteomic milk workflow includes essential prefractionation steps and strategies for every milk fraction (Figure 2) (caseinomics, milk fat globule proteins, and whey proteins), although other recently strategies such as ion exchange and SDS-PAGE-based protein fractionation have been also described. From the food composition, nutrition, and technology perspective, proteomics has been applied to the dairy industry in every phase and product obtained from raw milk in order to enhance their quality and safety and the knowledge about milk protein functionality. Regarding product safety, mayor and minor allergenic milk proteins have been detected with different proteomics tools and classical strategies. Proteomics has been used to study milk adulteration, bacteriologic characterization, protein modifications due to processing (including yogurt and cheese production), and aspects related to milk quality and functional properties.

Most of the proteomic studies on eggs have targeted hen eggs and their allergenicity, changes during storage, and characterization of proteins in the white, yolk, and eggshell using CPLL.

Meat Products

Meat being a major source of proteins in the human diet, proteomics has been applied in meat research from many different perspectives. The investigations have been related to factors influencing sensory quality properties, mainly juiciness, flavor, and tenderness. These properties are closely related to the proteolytic state and degree that in turn are dependent on pre- and postmortem processes taking place in the carcass. Many works monitor skeletal muscle biochemistry and physiology of different animal farm species using proteomics methodologies including glycolytic and proteolytic pathways by 2-DE and

Figure 2 Milk essential prefractionation steps for proteomic analysis.

MALDI-TOF–MS. Alternatively, as manufacture and storage of meat products involve different and sophisticated processes affecting the integrity of their proteins, proteomics contributes to understand and resolve many of the protein modifications and is becoming a valuable tool to identify a large amount of proteinaceous biomarkers related to safety, such as protein oxidation, microbiological contamination, adulteration by growth promoters, and authenticity. However, the main proteomic work about meat products has been carried out in meat from farmed species such as beef, veal, poultry, rabbit, and, the most studied, pork.

Seafood

Seafood comprises a large number of very heterogeneous species and products, and that heterogeneity has been an impediment to the application of proteomics technologies to seafood research because the databases have been and are still scarce. Fortunately, basic studies on model animal species such as zebra fish and on relevant commercial species (carp, salmon, and eel) are contributing to increase the number of sequenced proteins from aquatic organisms. The main issues addressed by proteomics of seafood products include quality (influence of the feed composition, fish welfare, capture method, and handling and storage on the quality of the fillet), safety (identification of allergens and spoilage microorganisms and of exposure to contaminants and biotoxins), authentication, and fish processing monitoring (e.g., changes happening during surimi manufacture, ice and frozen storage, and high-pressure treatment).

Bioactive Compounds

In opposition to toxic compounds, bioactive compounds are substances, or compounds, that have a biological activity with positive direct effects on living organisms (e.g., cholesterol-lowering or anti-inflammatory activities). Bioactive compounds are present in foodstuffs of both plant origin and animal origin and may have different nature: lipids, vitamins, carbohydrates, phenolic compounds, and evidently proteins, peptides, and amino acids. Protein bioactive sequences are normally quiescent within the parent proteins. Active peptide fragments are released from their matrix via proteolytic digestion by means of gastric, fermentative, enzymatic, and other chemical processes. The most representative bioactive peptides from food proteins are angiotensin-converting enzyme inhibitory peptides with antihypertensive action and opioid, antioxidative, and immunomodulating peptides.

Proteomic studies on bioactive peptides are still scarce, but they are increasing rapidly through the application of both traditional and high-throughput electrophoretic and MS methodologies, such as microchip electrophoresis or nano-LC–Q-TOF, ICP-MS, and 'precursor acquisition independent from ion count and imaging' coupled with bioinformatics and genomics database in order to characterize those bioactive substances.

From Proteomics to Systems Biology

The significant technical improvements in analytic methods for proteomics have gone hand in hand with significant advances in genomics, transcriptomics, metabolomics, and other -omic approaches, and this has generated an enormous amount of very valuable data that can no longer be processed by traditional statistical methods or classical multivariate data analyses. Fortunately, these analytic improvements have found a counterpart in comparable developments in computer sciences, and the vast amount of information provided has led to redefinition of proteomics. For example, Patterson and Aebersold defined it in 2003 as "the systematic study of the many and diverse properties of proteins in a parallel manner with the aim of providing detailed descriptions of the structure, function and control of biological systems in health and disease." What is interesting in this last definition is the inclusion of the term 'biological systems,' which indicates the shift that has taken place in the last decade from the analyses of the function and interactions of single components towards a holistic approach focusing on how biological systems function and interact as whole entities.

To take into use this new way of understanding proteomics and its role in nutrition and health requires first the delimitation of which is the biological system under study (it may be a cell or a metabolic route, but also a person) and then, considering the system in a holistic manner, the application of tools that come from a variety of disciplines (such as mathematics, physics, computer science, and control systems engineering). These new tools are essential to map the interactions between the individual constituents of the system. The concept of systems biology was introduced as a distinct discipline in the 1960s, and it has been increasingly used ever since.

Systems biology requires the knowledge and the data produced within experimental biology (including proteomics techniques) and mathematical modeling to identify the relationships between the data. Computational technology and numerical techniques are used to simulate complex biological networks. The information gained from simulations can then be used to design targeted and more efficient *in vivo* and *in vitro* experiments (lowering the cost of the study and use of experimental animals), to further improve the model. The final goal is to understand the processes, mechanisms, and principles of the system, and this in turn may help to predict the outcome and to control the system.

Proteomics is one of the main set of tools (together with genomics, metabolomics, lipidomics, and other high-throughput analytic techniques) that have become essential in systems biology studies.

Application of Systems Biology to Nutritional Science

Nutritional science deals with the organism's responses to the diet. It includes studies not only on the nutrients themselves but also on molecular interactions, metabolic and signaling pathways, physiology, pathology, and toxicology. As in other disciplines, it became clear that the application of the systems concept and modeling were necessary to expose and understand the intricate interrelationships between the diet and its result on the organism and also to perform quantitative or semiquantitative studies. One major challenge is that a model on nutrition must contribute to understanding the relationship between nutrition and health, but this relationship occurs at

different organizational (e.g., biochemical and cellular interactions and metabolic routes) and temporal (e.g., from immediate responses to the intake of a given nutrient to the response after a chronic ingestion of deficiency in the diet) levels. Even though the level of complexity is enormous and currently no single mathematical model can integrate all the information available and generate all the possible knowledge, it is possible to develop suitable computational models based on the use of the virtual patient concept, together with accurate phenotyping and the development of biomarkers generated from the -omics techniques. Then, all these data must be integrated at multiple organizational levels and timescales.

The application of proteomics in a systems approach to nutritional sciences and human health has been used to study the relationships between muscle proteomics and obesity and type 2 diabetes (T2D) (by 1DGE and LC-MS/MS), urinary proteomics in type 1 diabetes versus T2D (by CE, LC-MS/MS), plasma proteomics after folic acid supplementation (2DGE and LC-MS/MS), plasma proteomics in T2D, serum proteomics after fish oil supplementation, adipocyte proteomics after energy restriction, and peripheral blood mononuclear cell proteomic response after flaxseed and after soy-isoflavone supplementations (by 2DGE and MALDI-MS).

Any systems-based nutrition study must first define the system under study (cell, tissue, organ, and individual) and then determine which information should be obtained from the system (proteomics, behavior, genetic makeup, and cholesterol levels) and the interactions among component (e.g., how the fat content in the diet influences the cholesterol level in an individual with genotype X and a proteome Y in the tissue Z). Then, a model needs to be constructed for the system to explain and help understand the interactions between the different data. Finally, the model needs to be improved with further data and finally validated.

Needless to say, we are still far from having a complete model integrating all the components and interactions relevant to human nutrition and health that must also take into account individual differences, that is, taking into account gene expression–nutrient interactions. But, eventually, we will get there.

Pulsed Electric Fields

JÁ Guerrero-Beltrán, Universidad de las Américas Puebla, Puebla, Mexico
J Welti-Chanes, Centro de Biotecnología FEMSA, Tecnológico de Monterrey, Monterrey, Nuevo Leon, Mexico

© 2016 Elsevier Ltd. All rights reserved.

What Are Pulsed Electric Fields?

High-energy pulsed electric fields (PEFs) deliver high-energy discharges at very short periods. Low-voltage energy from the DC power supply is transformed to high-intensity pulsed fields. The high-intensity energy is stored in capacitors to be discharged to the target at different electric strengths (20–80 kV cm^{-1}) and times (<1 s), which depend on the purposes to be attained in the food. The food is passed between two electrodes, hosted in a chamber, which could be of different designs; the high-intensity pulses are discharged to the food mainly for inactivating microorganisms and enzymes. Supposedly, the food's physicochemical, nutritional, and sensory characteristics should be kept as those of fresh products during delivery. However, attention should be paid since the PEF processing may increase temperature suddenly and fast; therefore, a combination of the type of food, electric fields, processing times, flow rate, and refrigeration systems should be taken into account for delivering foods maintaining their nutritious and sensory characteristics similar to fresh foods.

PEF Production

Circuits for generating high-energy electric fields are simple. Different types of pulses can be produced by the PEF system, namely, square wave, exponential decay, oscillatory, or bipolar pulses (Figure 1). However, the square waves and exponential decay pulses are the more commonly used and they are produced differently. The exponential decay pulses are produced in the circuit formed by a DC power supply, a bank of capacitors connected in series with a charging resistor, and a discharge switch to deliver the high-energy pulses to the treatment chamber hosting the food. On the other hand, the square wave pulses, which are more energetic, are produced in an array of capacitors, inductors, and switching devices.

Pulse Generation and Treatment Chambers

The PEF treatment chambers are the heart of the PEF system. There, pulses are delivered to the food passing between two electrodes. There are different designs. Figure 2 illustrates a batch treatment chamber (a) and two continues chambers (b, c). Caution should be paid since a breakdown may occur if the electric field strength exceeds the food electric strength; as a result, sparks produced may damage the electrode's surface.

In a simplest pulse-forming system, an electric strength (E) between two points is created when an electric potential difference (V) crosses two points separated by a nonconductive material, which is directly proportional to V and inversely proportional to the distance (d):

$$E = \frac{V}{d} \quad [1]$$

In a coaxial treatment chamber, the electric field varies according to the radial distance from the inner electrode:

$$E = \frac{V}{r \ln\left(\frac{R_2}{R_1}\right)} \quad [2]$$

where r is the distance to measure the electric field and R_1 and R_2 are the radii of the inner and outer electrodes, respectively. The charged capacitors (C_o), where the high energy γ is loaded before being delivered to the treatment chamber, are discharged (Figure 1) through the resistor (R); therefore, the voltage through the food decreases exponentially with a pulse width (τ):

$$R = RC_o \quad [3]$$

The treatment time (t) is obtained taking into account the pulse width and number of pulses (n):

$$t = n\tau \quad [4]$$

The discharge of pulses to the food and its control are controlled by a computer coupled to the pulse generator.

Energy and Temperature Release

The energy requirements and temperature rise during a PEF treatment are complicated. For a single-pass process with no recirculation, the energy (Q) released during the capacitor discharge (C) at the charged voltage (V) would be

$$Q = \frac{1}{2}CV^2 \quad [5]$$

Ideally, the total capacitor energy is discharged to the treatment chamber. However, only part of the total energy is set to the food and this defines the maximum voltage in the treatment chamber:

$$V_{Chamber} = V_{Charging}\frac{R_{Chamber}}{R_{Total}} \quad [6]$$

As a result, the pulse energy dumped to the chamber is

$$Q_{Pulse} = \frac{1}{2}\frac{R_{Ch}}{R_T}CV^2 \quad [7]$$

During the delivery of energy to the food, throughout the process, the food temperature increases due to ohmic heating. The heating of food product is

$$Q = mC_p\Delta T \quad [8]$$

where m is the mass, C_p is the specific heat capacity of the food product, and ΔT is the rise of temperature. In a continuous PEF system, the pulse energy is

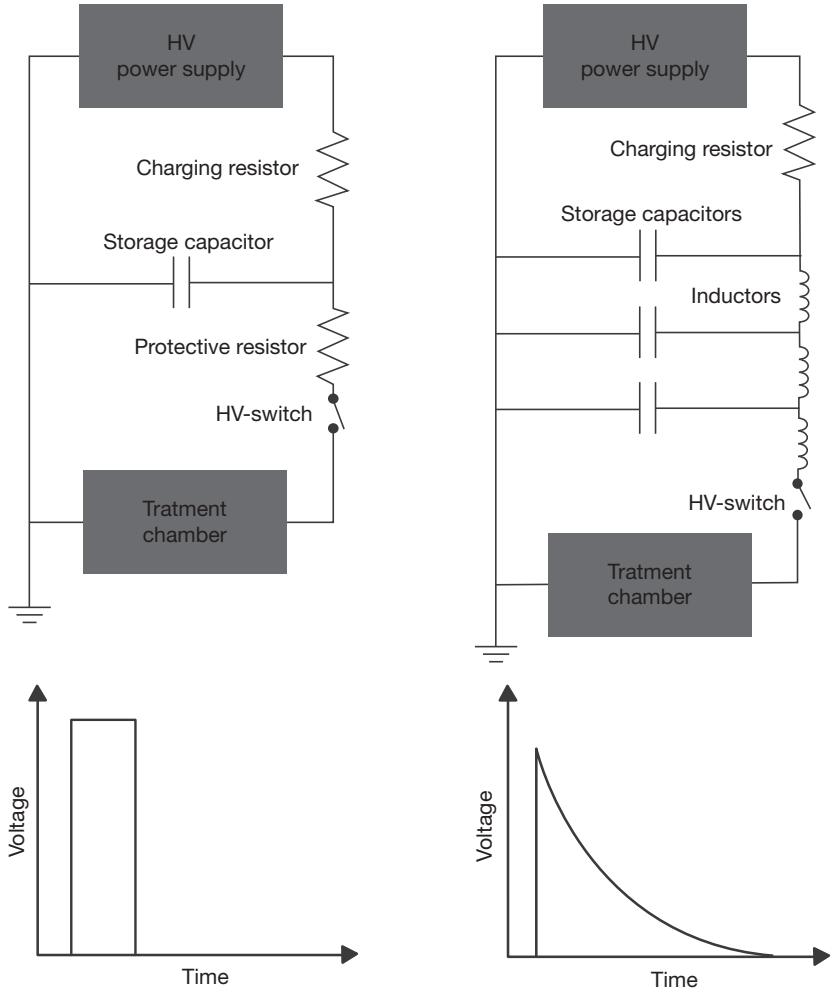

Figure 1 Exponential decay and square wave pulse generation.

$$Q_{\text{Pulse}} = \frac{\rho v C_p \Delta T}{f} \quad [9]$$

where ρ is the density, v is the flowing volume per second, and f is the frequency of pulses.

What PEF Are Used for?

The PEF technology is used for treating foods with different purposes. The microbial and enzymatic inactivation is of paramount importance to deliver microbiological and physicochemical safe food products to consumers. PEF technology is used for inactivating pathogenic and spoilage microorganisms, and the effect on all of them will depend on the treatment (electric field intensity (E), pulse width, treatment time (the number of pulsed (n) per the time of each pulse), t, temperature, pulse shape and pulse polarity, microorganism (type, concentration, growth phase), and medium characteristics (pH, preservatives, conductivity, and ionic compounds)). PEF is also valuable for inactivation of enzymes such as pectin methyl esterase, polygalacturonase, polyphenol oxidase, peroxidase, and lipoxygenase found in fruit and vegetable juices and alkaline phosphatase, protease, and lipase in milk.

PEF Effect on Cells

Electroporation (Figure 3) is the phenomenon in which electric field is applied to biological cells. The number of pores formed around the cell membranes, due to the electric field, depends on the medium and on the PEF variables – electric field strength, pulse intensity, pulse width, pulse number, and processing time – and the type and strain of microorganism and size and geometry of cells (Figure 4). Electroporation may compromise cells at different levels; therefore, electric field strength higher than 2 kV cm^{-1} generates irreversible recovery in microbial cells and more than 14 kV cm^{-1} is required for plant cells.

Microbial Inactivation Modeling

Microbial inactivation can be described using different mathematical models. The type of model used will depend on the

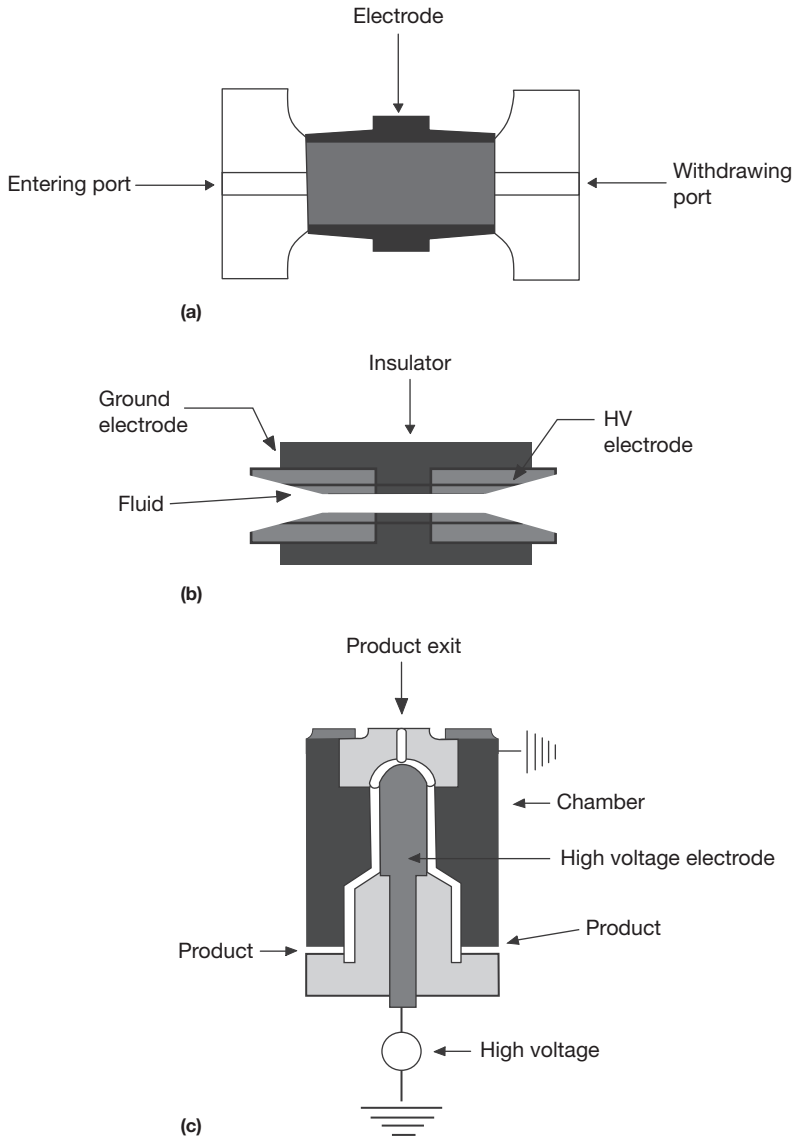

Figure 2 Batch parallel plate (a), cofield continuous (b), and concentric cylinder continuous treatment chambers (c).

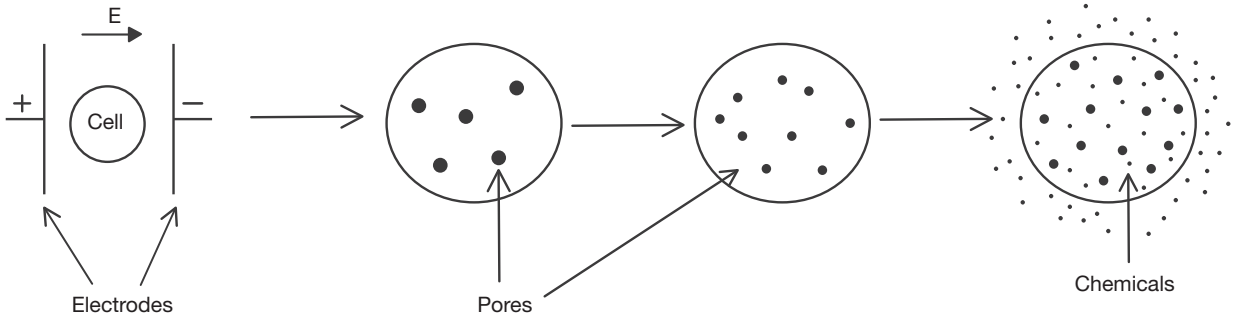

Figure 3 Electroporation of cells.

manner the microorganism is being injured along the time of treatment or any other variable used in the PEF methodology. Some models used for describing the microbial load survivals are as follows:

- First-order kinetics model

$$\log\left(\frac{N}{N_0}\right) = -kt \qquad [10]$$

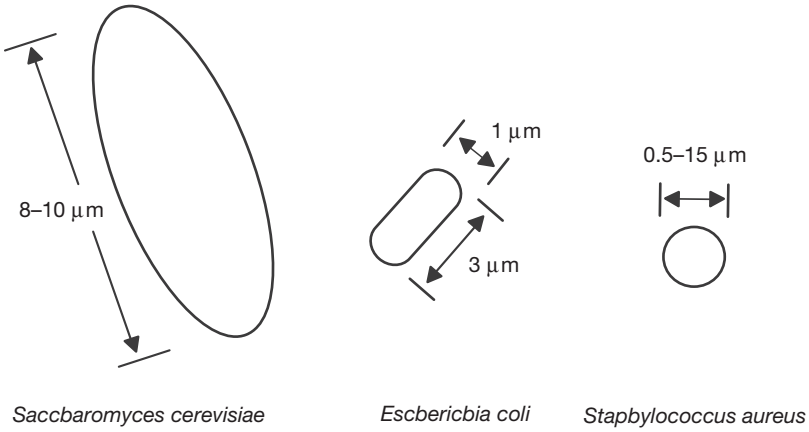

Figure 4 Microorganism size and geometry.

- Weibull distribution

$$\frac{N}{N_0} = e^{-(bt)^a} \quad [11]$$

- Log-logistic distribution

$$\log\left(\frac{N}{N_0}\right) = \alpha + \frac{\omega - \alpha}{1 + e^{[4\sigma(\tau - \log t)]/\omega - \alpha}} \quad [12]$$

- Modified Gompertz equation

$$\log\left(\frac{N}{N_0}\right) = Ce^{-e^{BM}} - Ce^{-e^{B(t-M)}} \quad [13]$$

- General model

$$s = \left(\frac{t}{t_c}\right)^{-\left(\frac{E-E_c}{K}\right)} \quad [14]$$

where N is the microbial load after some treatment (CFU ml^{-1}); N_0 is the initial microbial load; t is the time (product of the number of pulses and pulse width); k is the inactivation rate constant; a and b are the shape and scale constants, respectively; α and ω are the upper and lower asymptotes, respectively; σ is the maximum slope of the survivals curve; τ is the logarithm of time at the maximum slope; C, B, and M are constants; s is the survival fraction; E is the electric field strength; and E_c, t_c, and K are constants evaluated experimentally or empirically.

PEF Effect on Enzymes

Enzymes found in foods can be inactivated by applying PEF. Some enzymes could damage the food systems and some of them are only part of the product metabolism and non-dangerous; however, unwanted enzymes should be inactivated or depleted to ensure an adequate food product shelf life. The PEF effect on enzymes may depend on the electric conditions. In most of the cases, a high amount of enzyme was inactivated; however, in some cases, no inactivation or an increased activation was observed. PEF electric conditions for treating foods with the aim of affecting enzymes are higher than for inactivating microorganism. The levels of field strength that have been applied range from 10 to 87 kV cm^{-1} for several times or pulse number for attaining some purpose in a food system, model food systems, or in solutions. Since enzymes are proteins, denaturation may occur due to PEF effects on the structure. In a general way, the mathematical models reported to describe microbial inactivation are similar for describing the enzymatic inactivation.

Effect of PEF Treatment on Functional, Nutritional, and Sensory Properties

Functional compounds such as antioxidants found in foods could be altered after PEF treatment. Many fruit and vegetable products have phenolic compounds, vitamins, pigments, and other chemical compounds found in essential oils of parts of plants. These types of compounds may remain unaltered, depleted, or increased in the food product after PEF treatment, which will depend on the treatment conditions. In some cases, phenolic compounds are depleted after PEF treatment (apple juice) for accomplishing the microbial or enzymatic inactivation or increased when the objective is disintegration of cells for increase the liberation of them (anthocyanin of grapes and their products) or increase such as in the case of soy milk. Carotenoids and vitamin C could decrease. Therefore, antioxidant capacity related with those compounds may decrease or remain in the food product after PEF treatment as the thermal treatment does.

In general, the sensory characteristics of foods remain unchanged when there is no increase in temperature during PEF processing at different treatment conditions. Milk, orange juice, and cranberry juice, just to mention some, have been evaluated for their sensory characteristics after PEF treatments. In all cases, no significant sensory changes were noticed.

PEF Food Safety Features

Foodborne diseases and rotting of foods due to microorganisms can be controlled by applying PEF to foods. Food spoilage microorganisms and pathogens can be decreased or eliminated due to impairment of their normal metabolic functions. PEF methodology has been used for processing foods or model

solutions with pathogens such as *Staphylococcus aureus*, *Listeria monocytogenes*, *Escherichia coli*, *Salmonella dublin*, *Salmonella enteritidis*, *Escherichia coli* O157:H7, *Bacillus cereus*, *Yersinia enterocolitica*, *Clostridium tyrobutyricum* (spores), and *Pseudomonas aeruginosa* and spoilage microorganisms (or fermenters) such as *Corynebacterium* spp., *Xanthomonas maltophilia*, *Lactobacillus delbrueckii*, *Bacillus subtilis*, *Saccharomyces cerevisiae*, *Listeria innocua*, *Leuconostoc mesenteroides*, *Zygosaccharomyces bailii*, *Lactobacillus brevis*, *Lactobacillus plantarum*, and *Lactobacillus plantarum*.

What Types of Foods Are Treated with PEF?

The PEF technology is used for treating liquid and solid or semisolid foods. For instance, for liquid foods, orange juice and apple cider and juice are two of the more studied products by researchers in PEF as well as milk and other fluid products such as liquid egg; tomato, grape, mango, and cranberry juices; and beer. The disintegration of vegetable cells is another field of study for improving the liberation of the cell content, such as fruit or vegetable juices or other high-value products from cells.

PEF-Treated Liquid Foods

Due to the chamber's design and PEF system, most of the treated foods are liquids. The electric system (high-voltage pulse generator) consisting of the high-energy reservoirs which are delivered throughout the treatment chamber (electrode system) to target the liquid food which is flowing throughout the chamber as well. Hence, a number of liquid foods have been treated by the PEF technology, bringing microbiological and physicochemical safe and nutritious with good sensory quality products. Milk, egg, fruits, and vegetables and their products have been the most PEF-studied products alone or in combination with other preservation factors.

PEF-Treated Solid and Semisolid Foods

As mentioned earlier in the text, cells from solid foods such as plants can be treated to ease the liberation of valuable chemicals. However, food products other than those from plants could be also PEF-treated to accomplish other purposes. However, foods such as meat and fish do not resist electric field strengths beyond 10 kV cm^{-1} because their texture may change. Such low-electric field intensities are not enough for inactivation of microorganisms or enzymes for delivering satisfactory PEF-treated foods. PEF treatment has been used to electroplate cell from herbs for improving the extraction of essential oils.

Final Remarks

Even though the PEF technology has been studied for more than one decade, more research is required for processing and delivering physicochemical and microbiological safe food products with good sensory characteristics to consumers.

Quality Control in Food Processing

R Karoui, Université d'Artois, Lens, France

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Food processing refers to a series of actions involved in the preparation and preservation of a food supply by some continuous operation or treatment to achieve as a goal a safe, high-quality product with extended shelf life. Changes occurring in foods could be of two types: deterioration and spoilage. The former involves changes in quality induced by physicochemical and/or biochemical reactions taking place with or without the intervention of a physical environment (CO_2, O_2, light, temperature, etc.), while the latter refers to changes in quality due to action of biological agents such as bacteria, molds, and yeasts. These changes induce modifications in the quality characteristic of foods at the macroscopic (sensory and rheology), molecular (protein–protein, protein–lipid, and protein–water interactions), and microscopic levels.

Food control is defined as a mandatory regulatory activity of enforcement by national or local authorities to provide consumer protection and ensure that all foods during production, handling, storage, processing, and distribution are safe, wholesome, and fit for human consumption; conform to safety and quality requirements; and are honestly and accurately labeled as prescribed by law.

Quality control is not an optional extra in food processing, neither is it something that is only done by large manufacturers. It is an essential component of any food processing business. The purposes of quality control are to:

- protect the customers from dangers (e.g., contaminated foods) and ensure that they get the weight and quality of food that they pay for;
- protect the business from cheating by suppliers, damage to equipment (e.g., stones in raw materials), and false accusations by middlemen, customers, or suppliers;
- be sure that food laws operating in a country are complied with.

The determination of the quality of food products during processing is a critical attempt due to the presence of and interaction between different components (e.g., proteins, lipids, and carbohydrates). These interactions influence the quality of food products. The quality of foods could be determined by several analytical methods including microscopic, physical (sizes, weight, density, etc.), physicochemical (pH, vitamin content, fat content, etc.), microbiological, rheological (firmness, elasticity, fragility, etc.), sensory (appearance, taste, flavor, texture, etc.), etc. Among these methods, the physicochemical methods are most commonly used. Although heavy, these techniques are considered among the most interesting ones for the determination of the quality of food products during processing. With regard to rheological methods, they are being used to determine the texture of food products (firmness, adhesivity, gumminess, etc.).

However, most of the previously mentioned techniques are tedious and destructive and time-consuming and require highly skilled operators. As technology advanced, food processing technology also geared up to meet productivity, quality, safety, and economic requirements. Objective testing of quality attributes like odor and taste is difficult to carry out by subjective methods. Present-day technology continues to develop and use various modern tools for both monitoring and control of the various food quality parameters. In addition, the variation in texture properties of food products depends strongly on their structure. Recently, more attention has been paid to the development of noninvasive and nondestructive instrumental techniques such as infrared, fluorescence, nuclear magnetic resonance, and Raman spectroscopy. These techniques are fast, of relatively low cost, and environmentally friendly and provide a great deal of information with only one test, making them suitable for on-line and/or at-line process control. In addition, spectroscopic techniques often require little or no sample preparation and are relatively easy to operate.

This article will provide a comprehensive overview of the applications of different analytical techniques (i.e., physicochemical, rheological, fluorescence, and infrared), in combination with multivariate data analysis, to determine the quality of food products (Figure 1). Actual examples illustrating the utilization of these techniques in both laboratory and industrial environments will be discussed as well as their advantages and disadvantages.

Physicochemical Methods

The physicochemical properties are considered as an important tool to determine the quality of food products (Table 1). Indeed, food products may be altered by several factors related to the area of production and characteristics of the production systems, such as feeding, microbial contamination, and the technological process.

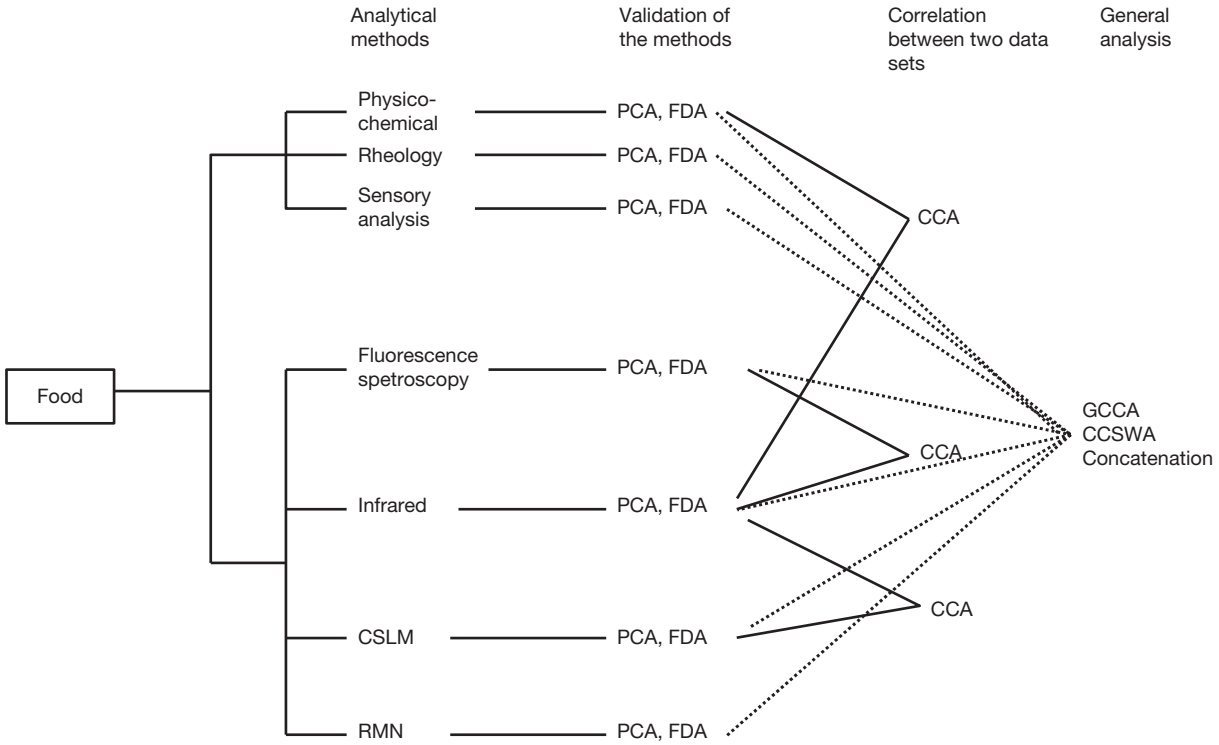

Figure 1 Different analytical techniques coupled with chemometric tools used for the evaluation of food quality. CCA, canonical correlation analysis; CCSWA, common component and specific weight analysis; CSLM, confocal scanning laser microscopy; FDA, factorial discriminant analysis; GCCA, general canonical correlation analysis; NMR, nuclear magnetic resonance; PCA, principal component analysis.

The physicochemical characteristics of semiskimmed UHT milk kept at different storage temperatures (4, 20, and 40 °C) for up to 6 months were investigated. No change for milk samples stored at 4 and 20 °C even after 6 months was found in contrast to those kept at 40 °C where, on the one hand, a gradual drop to pH 6.21 was observed compared with freshly processed UHT milk presenting a pH of 6.7 and, on the other hand, an increase in noncasein nitrogen content with the increase of storage temperature (i.e., 3.54, 3.87, and 5.47 g kg^{-1} for milks kept at 4, 20, and 40 °C).

The impact of milk maturation on the physicochemical characteristics in three different conditions was studied. Full cream milk samples collected from the evening milking were stored in the farm and delivered to the cheese factory in churns or in thermos-regulated tanks at a temperature not lower than 18 °C. The natural creaming (10–12 h overnight) was performed in a traditional large flat vat or in thermos-regulated large flat vats at ∼15 °C. Compared with full cream milk, skimmed evening milks showed lower values of casein and casein number and higher contents of whey proteins. Recently, the physicochemical characteristics of raw bulk milk samples kept at different conditions have been investigated: 12, 24, 36, and 48 h at 4–6 °C and 8–10 °C and 12 and 24 h at 13–15 °C. A significant increase in pH value was observed in the first 12 h of storage, regardless of the considered temperature. No significant change of milk samples kept at 13–15 °C during 24 h was observed, whereas a gradual decrease of this parameter was noted during the first 36 h of milk samples stored at lower temperatures (4–6 °C and 8–10 °C) due to the dissociation of calcium from the casein micelle, which increased milk pH.

The impact of technological process on the formation of biogenic amines in fish products has been investigated by several authors. The effect of different freezing treatments on the formation of biogenic amines of cultured bighead carp heads was investigated. Fish heads were packaged in polyvinyl chloride bags and kept randomly at two temperatures −40 and −18 °C during 3 months. After being stored for 3 months, fish heads were moved to boxes and stored in refrigerated chambers at 4 °C. Among the eight biogenic amines investigated in this study (i.e., tryptamine, phenylethylamine, putrescine, cadaverine, histamine, tyramine, spermidine, and spermine), spermine and spermidine were found to be the two major amines present in fish head samples attaining levels of, respectively, 56.9 and 11.1 mg kg^{-1} after 18 days storage. One of the main conclusions of this study was that freezing treatments had a significant lower value of spermine and spermidine than the fresh ones.

Although the physicochemical analyses are considered as reference methods providing accurate and reliable results on quality and authenticity of fish samples, they are time-consuming and need a lot of pollutant reagents, are relatively expensive, cannot be utilized at-/on-line, and involve the use of chemicals and trained labor.

Rheological Methods

Rheology is the study of deformation and flow of matter. Foods can be classified in different ways, such as solids, gels, homogeneous liquids, and suspensions of solids in liquids and

Table 1 Some examples of destructive and nondestructive methods used for quality assessment of food products

	Analysis	*Examples of most used methods*	*Approximate percentage (wet weight basis)*
Destructive methods	Moisture and total solids	Over drying methods Distillation procedure Chemical method (Karl fisher titration) Refractometer	Wheat flour: 10.3 Milk: 88 Egg: 75.3 Honey: 17.3

emulsions. Many of the food products exhibit both viscous and elastic properties and can be described as viscoelastic materials. In contrast, if fluids contain dissolved low-molecular-weight compounds (e.g., sugars) and no polymer or insoluble solids, they may show Newtonian behavior.

Processed foods may be viewed as edible structures that are created as a result of the responses of proteins, polysaccharides, and lipids in aqueous media to different processing methods, such as thermal processing, homogenization, and other physical treatments. Most, if not all, of those responses are physical in nature. The measured rheological responses are those at the macroscopic level. However, they are directly affected by the changes and properties at the microscopic level. Thus, it would be helpful to understand the role of structure of foods on their rheological behavior. Rheological properties are based on flow and deformation responses of foods when subjected to normal and tangential stresses.

Texture is a very important quality parameter of food products and it is of interest to producers, processors, and consumers. Since rheology represents the properties and characteristics of both liquid and solid foods, in strict terms, texture is the rheology related to solid foods, while viscosity is the rheology related to fluid foods. Changes occurring in heated UHT milk with low levels of calcium chloride addition ($\leq$20 mM) have been monitored. One of the main conclusions of this study was that the addition of 10–20 mM $CaCl_2$ caused thickening and/or gelation of milk heated at 70 °C. Some authors have monitored during ripening at 4 °C (5 days, 8, 16, and 24 weeks) the rheological properties of cheddar-like cheese made from caprine milk collected at different lactation periods and found that a minimum of 8 weeks of aging was needed to stabilize the cheese texture.

Regarding fish and fish products, the impact of smoking and freezing–thawing treatments on the rheological properties of fish samples has been determined and the obtained results indicated that hardness, gumminess, and chewiness decreased within 5 days of storage.

In a different approach, the incorporation of specific probiotic bacteria, together with selected additives, has been conducted. The whey cheeses have been produced with probiotic bacteria from combinations of bovine whey and milk, following protein denaturation at 90 °C; they were subsequently

inoculated at 10% with the previously mentioned strains and homogenized and additives such as salt and sugar were then incorporated. The resulting solid matrices were stored at 7 °C for up to 21 days. Their results showed that whey cheeses inoculated with *L. casei* were always more elastic and viscous than those inoculated with *B. animalis*. Other research studies determined the impact of cream heat treatment prior to butter manufacturing as well as the fluctuation of temperatures during storage. The obtained results showed that low cooled cream maturation significantly increased the storage modulus (G′) from 0.30 to 0.38 MPa compared to butter produced from nonmatured cream. One of the main conclusions of this study was that cooled cream maturation did not cause any changes in the rheological profile, while fluctuating temperatures significantly affected the G′.

Rheology measurements avoid the high costs of highly trained personnel and do not suffer from fatigue or adaptation as sensory evaluation could do. However, some artifacts such as slippage and sampling procedure could occur during the measurements since solid food products samples could present different dimensions during the application of rheological methods inducing difference in rheological values.

Front-Face Fluorescence Spectroscopy

Fluorescence spectroscopy is a rapid, sensitive analytical method for characterizing molecular environments of food products. Fluorescence is the light emission subsequent to absorption of ultraviolet or visible light of a fluorescent molecule or substructure, called a fluorophore. The fluorophore present naturally in food products absorbs energy in the form of light at a specific wavelength and liberates energy in the form of light emission at a higher wavelength.

With classical right-angle fluorescence spectroscopy, the measurements are carried out in dilute solutions where the absorbance is below 0.1. At a higher absorbance rate, a decrease of fluorescence intensity and a distortion of emission spectra are observed due to the inner filter effect. To overcome such problems, front-face fluorescence spectroscopy (FFFS) was developed where only the surface of the material is illuminated and examined. To minimize artifacts generated by the photons of excitation reflected from the sample, the emitted photons are collected at an angle between 30° and 60° to the surface of the sample; this technique allows a quantitative investigation of fluorophores in powders as well as in concentrated or even opaque samples.

The potentiality of fluorescence spectroscopy coupled with multivariate statistical methods to characterize milk samples collected from different manufacturers and stored at four different temperatures (i.e., 4, 22, 35, and 50 °C) for 8 weeks has been determined. To extract information from the fluorescence spectra, the authors have applied multivariate statistical methods, that is, principal components analysis (PCA), to the different acquired spectra (i.e., Maillard products, tryptophan, and riboflavin). One of the main conclusions of this study was that FFFS could be used as a tool for monitoring changes occurring in milk samples during storage. In another study, FFFS has been utilized to monitor structure during milk acidification kinetics of skimmed milk samples at two coagulation temperatures (30 and 40 °C). For each coagulation temperature, synchronous fluorescence spectra were recorded in the 250–500 nm excitation wavelength range using offset of 80 nm between excitation and emission monochromators during 300 min coagulation kinetics. By applying PCA to the spectral data sets, the authors pointed out the impact of the coagulation temperature on the molecular structure and the interaction between the different macromolecules present in the coagulum, which was confirmed after by others who assessed to determine the effects of heat treatment (60 and 80 °C during 20 min) and rennet-induced coagulation temperatures (30 and 40 °C). One of the main conclusions reached was the clear discrimination observed between (i) raw milks and heated milks and (ii) milks renneted at 30 °C and those renneted at 40 °C. These results were recently confirmed by others who also succeeded to discriminate milk samples according to heating (72–120 °C).

Recently, some authors have determined using the emission spectra of vitamin A the impact of heat treatment on the evolution of fluorescence spectra. As shown in Figure 2, heat

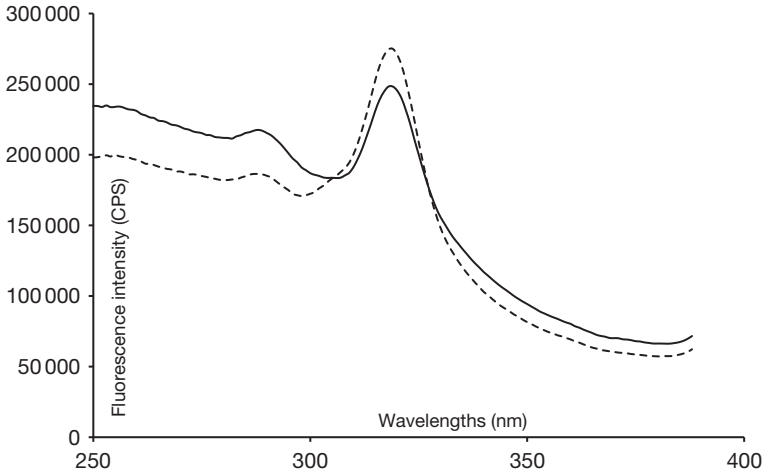

Figure 2 Evolution of vitamin A spectra acquired on milk samples after heating at 55 °C (---) and 75 °C (___) during 10 min.

treatment induced a decrease in the fluorescence intensity at both 320 and 290 nm since milk samples heated at 75 °C for 10 min presented the lowest intensity compared with milk samples heated at 55 °C during the same time.

Regarding cheeses, the impact of technological process on the molecular level of both the external and central zones of 15 different soft cheeses (i.e., two traditional soft cheese varieties and one stabilized soft cheese variety) has been investigated. By applying a series of chemometric tools, the authors succeeded to discriminate cheeses according to their manufacturing process and sampling zone. The obtained results were confirmed after by others who monitored changes occurring in Cantal cheeses throughout ripening period (30, 120, and 200 days) using synchronous fluorescence spectra. A clear differentiation between cheeses according to their ripening stage was observed since 100% of correct classification was obtained; the authors have attributed this trend to the modifications occurring in the physicochemical properties of cheese matrix.

Reported studies on the use of FFFS as a method to monitoring fish and egg freshness are scarce. The impact of storage conditions on the evolution of fish and egg freshness has been monitored. The shape spectra of egg and fish samples illustrated some differences according to storage time. By applying factorial discriminant analysis (FDA) to the NADH data sets acquired on fish samples, correct classification amounting to 92% has been obtained. The authors concluded that NADH spectra could be considered as fingerprints that may allow discrimination between fresh and aged fish fillets. The same research group has later succeeded using FFFS to differentiate between fresh and frozen–thawed fish samples. By applying PCA to the normalized NADH spectra, a clear discrimination between fresh and frozen fish samples was observed, which was confirmed by FDA model since complete (100% and 100%) correct classification was obtained for the calibration and validation data sets, respectively.

As illustrated earlier, the environment of intrinsic fluorophores recorded on food products contains valuable information regarding the composition and nutritional values of food products. The huge potential for the application of fluorescence spectroscopy combined with multivariate statistical analyses could be an alternative to the destructive techniques for the evaluation of food products quality. The principal advantages of fluorescence spectroscopy are its rapidity and specificity since this technique is considered to be 100–1000 times more sensitive than other spectrophotometric techniques. However, the major disadvantage of fluorescence is its strong dependence on light scatter and environmental factors such as temperature, pH, and viscosity.

Infrared Spectroscopy

The infrared region comprises that part of the electromagnetic spectrum in the wavelength range varying between 780 and 100 000 nm and is divided into near-infrared (NIR) region (780–2500 nm) and mid-infrared (MIR) region (4000–400 cm^{-1}). Absorptions in the fingerprint region are mainly caused by bending and skeletal vibrations, which are particularly sensitive to large wave number shifts, thereby militating against unambiguous identification of specific functional groups.

Sixteen semihard cheeses varying in their protein (20.2–24.1%), fat (23.7–31.1%), and dry matter (50.2–57.9%) contents were sampled at different ripening times (1, 21, 51, and 81 days) and analyzed by MIR. To extract information from the MIR spectral data sets, PCA was applied to the 1700–1500 cm^{-1} spectral region, and the similarity map showed incomplete differentiation between the investigated samples. By combining mid-infrared and fluorescence spectra using canonical correlation analysis, a clear discrimination of cheese samples has been obtained. One of the main conclusions of this study was that the protein network characteristics of the ripened cheeses were found to be related to the initial composition of young (1-day-old) cheeses. The authors suggested that FT-MIR and fluorescence spectroscopies provided a common description of cheese samples throughout ripening, allowing their potential use as tools for providing useful information related to protein structure in cheese.

In a similar approach, some authors have used FT-MIR to monitor the ripening process of camembert soft cheeses at different ripening stages (i.e., after 10, 13, 15, 17, 20, and 27 days). No changes were observed in the case of core samples, although those collected from under the rind did show some spectral modification throughout the ripening period studied.

Regarding meat and meat products, the potential of FT-MIR has been explored for the analysis of comminuted beef meat contaminated at low spoilage levels. Using the 1500–700 cm^{-1} spectral region, the developed models were found to be not accurate. Another application related to authentication issues of red seabream was performed by others who conducted a study to determine whether VIS/NIR spectroscopy in a reflection mode could differentiate fresh fish samples from frozen–thawed ones. By applying PCA to the spectral collection, a clear differentiation between frozen–thawed samples and fresh ones was observed. The obtained results confirmed previous studies that succeeded by using FT-MIR to differentiate between fresh and frozen–thawed fish samples in the 3000–2800 cm^{-1}. By applying FDA to this spectral region, 100% and 87.5% of correct classification was obtained, respectively, for the calibration and validation data sets.

Regarding cereal products, some authors have applied NIR and MIR spectroscopy to study dough proofing, after mixing. On the basis of these studies, the authors concluded that FT-IR spectroscopy revealed information about the relative importance of protein and starch moieties during proofing.

In another study, infrared has been used to determine the effect of heat treatment on the quality of apple juice samples. The authors have applied a series of chemometric tools, and correct classification in the 77.2–100 range has been found depending on the technique used (NIR or MIR).

The infrared technique provides more information compared to traditional ones, as it allows simultaneous identification of quantitative and qualitative changes of various chemical components (proteins, fat, water, etc.) involved in the determination of food quality. The use of MIR is characterized by a high repeatability and very easy sampling. However, the disadvantage of infrared technique is its inability to measure molecules with very low concentrations. Moreover,

the strong absorptions of water due to the O–H bending band could obscure potentially useful absorptions from protein for foods containing high level of water content.

Conclusion

During the past decade, a considerable interest has been paid to determine food product quality. Food quality could be determined by different analytical techniques. Nowadays, the need for rapid analytical techniques to determine quality and authenticity is greater than ever. Recently, a considerable effort has been made by researchers to explore the possibilities of using spectroscopic techniques for the determination of the quality of food products. These techniques as depicted in this article are mostly of relatively low cost and can be applied in both fundamental research and the factory as on-line sensors for dairy process monitoring and product quality assessment.

Introduction

Quinoa, *Chenopodium quinoa* Willd., is an Amaranthacean, stress-tolerant plant cultivated along the Andes for the last 7000 years, facing highly different environmental conditions ranging from Bolivia, up to 4.500 m of altitude, to sea level, in Chile. Quinoa, called 'the mother grain,' constitutes a strategic crop with potential to contribute to food security and sovereignty due to nutritional quality, genetic variability, adaptability to adverse climate and soil conditions, diversity of methods of use, and low production cost.

The nutritional benefits and agricultural versatility of quinoa have been stressed by the United Nations Food and Agriculture Organization (FAO). The expansion of the crop from South America to other continents supports that it is a crop with high potential to contribute to food security in various regions worldwide, especially in those countries where the population does not have access to protein sources or where production conditions are limited by low humidity, reduced availability of inputs, and aridity. After the submission of the report 'Quinoa: An Ancient Crop to Contribute to World Food Security' in July 2011 by the Regional Office for Latin America and the Caribbean to the 37th FAO Conference in support of the declaration of the 'International Year of Quinoa,' 2013 was declared the International Year of Quinoa.

Its grains have higher nutritive value than traditional cereals, and it is a promising worldwide cultivar for human consumption and nutrition. Quinoa has been called a pseudocereal for botanical reasons but also because of its unusual composition and exceptional balance between oil, protein, and fat. Quinoa is the only plant food that contains all the essential amino acids, trace elements, and vitamins and contains no gluten. Essential amino acids are found in the core of the grain, unlike other cereals, like rice or wheat, in which they are located in the hull. Quinoa is an example of a 'functional food' that aims at lowering the risk of various diseases. Functional properties are given also by minerals, vitamins, fatty acids, and antioxidants that can make a strong contribution to human nutrition and health, particularly to protect cell membranes, with proven good results in brain neuronal functions. Its minerals work as cofactors in antioxidant enzymes, adding higher value to its rich proteins. Quinoa also contains phytohormones, which offer an advantage over other plant foods for human nutrition.

Furthermore, the crop has a remarkable adaptability to different agro-ecological regions. It can grow at relative humidity from 40% to 88% and withstands temperatures from −4 to 38 °C. It is a highly water-efficient plant, is tolerant and resistant to lack of soil moisture, and produces acceptable yields with rainfall of 100–200 mm. There are more than 3000 varieties or ecotypes of quinoa both cultivated and wild, which can be grouped in five basic categories according to the altitudinal gradient: ecotypes from sea level, the valleys, the Yungas, the salt flats and the Altiplano (high plain). Although the main producers are Bolivia, Peru, and the United States, quinoa production is expanding to other continents, and it is currently being cultivated in several countries in Europe and Asia with good yields.

Quinoa, like other Andean grains, has traditional and nontraditional uses as well as value-added industrial innovations generated through research that are now commercially available.

Sources and Production

The quinoa (a dicot plant) is not a true grain, like cereal (monocot) grains; it is rather a fruit, so that it has been called a pseudocereal and even a pseudo-oilseed. This is also because of its unusual composition and exceptional balance between oil, protein, and fat. Quinoa is a drought-tolerant crop that has low water requirements, although yield is significantly affected by irrigation. Quinoa can be seen as an oligocentric species with a broad center of origin and multiple diversification.

As a plant, quinoa grows three to seven feet high and produces a small, flat, circular-shaped seed. It has been considered 'one of the world's most perfect foods.' Compared to other cereal grains, it is higher in protein content (14–18%) and has a nutritionally attractive amino acid balance. The seed is high in lysine, methionine, and cysteine, making it complementary to both other grains and to legumes, which are deficient in these nutrients. It also has higher levels of energy, calcium, phosphorus, iron, fiber, and B vitamins than barley, oats, rice, corn, and wheat.

The seeds have a bitter saponin in the outer coat that must be removed before consumption. They can be washed or milled to remove the seed coat, adding to the total cost of the final product. On average, quinoa yields 5.8% oil by weight.

Quinoa production is in a process of expansion into different geographic areas of the planet due to its extraordinary adaptability (Figure 1). Quinoa is grown mainly in cool mountainous regions because air temperatures above 90–95° cause sterility of the pollen. Although most quinoa is still grown in South America, it is also cultivated in the United States, China, Europe, Canada, and India. It is also cultivated experimentally in Finland and the United Kingdom. Increasing amounts are being exported to the developed world like Europe and the United States. Quinoa has been cultivated since the early 1980s and commercially produced since the mid-1980s in the Colorado Rockies, especially in the San Luis Valley. Production has also been attempted in California, New Mexico, Oregon, and Washington. Until 2008 the production of Bolivia and Peru accounted for 90% of world quinoa production. Following them are the United States, Ecuador, and Canada with about 10% of global production volumes. Quinoa is also cultivated in England, Sweden, Denmark, the

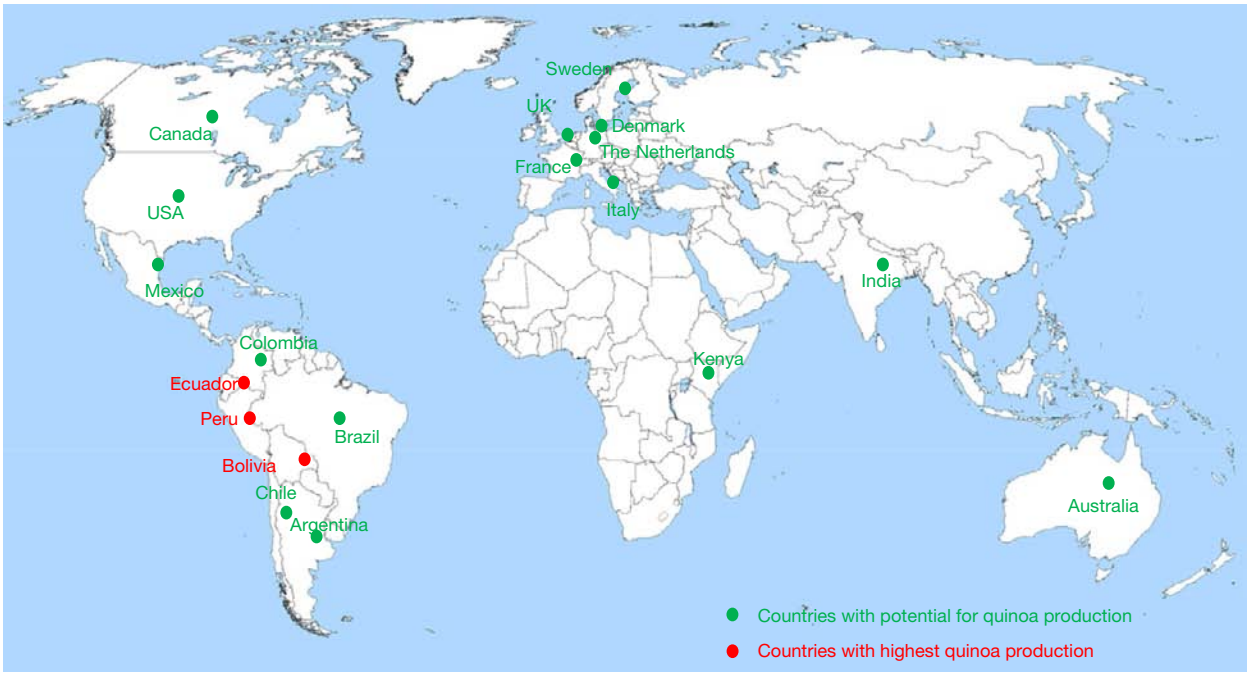

Figure 1 Geographic distribution of quinoa production worldwide. Adapted from FAO (2011). Quinoa: an ancient crop to contribute to world food security. Regional Office for Latin America and the Caribbean. http://www.rlc.fao.org/en/publications/quinoa-ancient-crop-food-security/.

Netherlands, Italy, and France. Recently France has reported an area of 200 ha with yields of 1080 kg ha^{-1}, and Kenya has shown high seed yields (4 ton ha^{-1}). In the Himalayas and the plains of Northern India, the crops can develop successful and with high yields. In tropical areas such as the savannas of Brazil there has been experimental quinoa cultivation since 1987 reportedly obtaining higher yields than in the Andean area. In Europe quinoa was introduced in England in the 1970s, and later research projects focussed on its production for humans and/or as a fodder crop under temperate conditions. Quinoa production has increased in the last 20 years, especially in Bolivia. The main producing countries are Bolivia, Peru, and Ecuador, which in 2007 produced 61 490 tons, up from 19 000 tons in 1973. During 2007 quinoa production was 34 000 tons in Peru, 26 800 tons in Bolivia, and 690 tons in Ecuador. Most quinoa consumed in the United States is imported from South America. Current estimates of US production are minimal, at less than 10 000 pounds. According to the FAO, world production of quinoa in 2012 was 82 510 metric tons (MT) on 102 745 ha. Peru produced 44 210 MT in 2012 on 38 495 ha followed by Bolivia with 37 500 MT on 63 000 ha. The price of quinoa has increased dramatically over the past 10 years due to high demand by the United States and European consumers. Higher prices that help farmers can also adversely affect local Andean consumers. Poor people in Bolivia and Peru have less access to quinoa, a traditional and healthy component of their diet. The higher price might force them to shift consumption to other types of food, as has been reported in Bolivia. Bolivia is the largest exporter of quinoa in the world followed by Peru and Ecuador. In 2009 Bolivia exported a value of over US $43 million. The major importers of Bolivian quinoa grain are the United States (45%), France (16%), the Netherlands (13%), Germany, Canada, Israel, Brazil, and the United Kingdom. In 2007, Peru exported volumes somewhat greater than 400 MT of quinoa grain with values equivalent to US $552 000. In 2008 Ecuador showed similar export levels: 304 MT worth US $557 000.

Value-Added Uses

Quinoa, like other Andean grains, is used in many different ways. It has traditional and nontraditional uses as well as value-added industrial innovations generated through research that are now commercially available (Table 1).

Quinoa can be eaten as a rice replacement, as a hot breakfast cereal, or boiled in water to make infant cereal food. The seeds can even be popped like popcorn. Seeds can be ground and used as flour or sprouted. The sprouts need to get green before they can be added to salads. Quinoa is made into flour for baked goods, breakfast cereals, beer, soups, pastas, desserts, and even livestock feed (Figure 2). Quinoa flour can be mixed with maize or wheat flour. Several levels of quinoa flour substitution have been reported, for instance, in bread (10–13% quinoa flour), noodles and pasta (30–40% quinoa flour), and sweet biscuits (60% quinoa flour), to obtain products of acceptable quality. Quinoa flour can be also drum-dried and extruded, providing products with good physical, sensorial, and nutritional qualities. Solid-state fermentation of quinoa with *Rhizopus oligosporus Saito* provides a good-quality tempeh. The seeds are used boiled like rice or used to thicken soup or as porridge. Quinoa flour was made into noodles. Such a use is, however, complicated due to the bitter taste of the seeds because of their saponin content, which forms a soapy solution in water. The seeds can be boiled, added to soups, or even

Table 1 Traditional, nontraditional, and industrial uses of quinoa

Traditional uses
Quinoa soup: Cooked quinoa with meat or dried meat, tubers, and vegetables
Lawa: A semithick porridge-like preparation with raw flour, water with lime, and animal fat
P'esque: Quinoa grain cooked with water, without salt, served with either milk or grated cheese
Kispiña: Steamed buns of different shapes and sizes
Tacti o tactacho: Fried buns, a kind of doughnut made with flour and llama fat
Mucuna: Steam-cooked balls made from quinoa flour with seasoning in the center
Phiri: Roasted and slightly dampened rough quinoa flour
Phisara: Lightly roasted and cooked quinoa grain
Q'usa: Quinoa chicha, a macerated cold drink
El Ullphu, *Ullphi*: Cold drink prepared with roasted quinoa flour diluted in water with sugar added
Kaswira de quinua: Flattened bread fried in oil, made with katahui (lime) and white quinoa
Kaswira de ajara: Flattened bread fried in oil, made with lime and black quinoa or ajara
K'api kispiña: Steamed bun, made with quinoa ground in a K'ona and cooked in a clay pot
Turucha quispiña o Polonca: Large steamed breads, made with katahui and quinoa
Mululsito quispiña: Steamed bread, made with katahui and quinoa flour, cooked in a clay pot
Quichi quispiña: Steamed and fried bread, made with katahui and quinoa flour, fried in a pan
Juchacha: Andean soup based on ground quinoa and katahui, with roasted barley flour
Chiwa: Young leaves of quinoa used as a vegetable in the preparation of soups and salads
Nontraditional uses
Gluten-free goods, pasta, cakes, tawas, pancakes, doughnuts, juice, api, bread, biscuits, confectionary, chili, and nectar
Industrial and other potential uses
Cosmetics, pharmaceuticals, and other uses

Source: FAO (2011). http://www.rlc.fao.org/en/publications/quinoa-ancient-crop-food-security/.

fermented. The cooked seeds have a nutlike flavor and remain separate, fluffy, and chewy. Quinoa breads and flours are popular products for their gluten-free, high-protein qualities. The plant is sometimes grown as a green vegetable, and leaves are eaten fresh or cooked. The leafy plant materials can be used for human consumption or for livestock feed. Leaves, like the seed, can also be cooked, made into a spinach-like dish, or served raw in a salad. Tonics, puddings, and syrups can also be prepared from the leaves. The foaming qualities of saponin are sometimes used to produce a frothier chicha. In industry, saponins from quinoa have multiple purposes. They are used as soap for washing hair or clothes, in a compound for a fire extinguisher, or in photo processing. Dried stalks of the plant are used as fuel or may be used in preparing bleach or dyes.

Future uses of quinoa can be wide ranging, like textured and fermented products. There are many ways in which it can be consumed: cooked, flour, extruded. Quinoa meat substitute has been introduced in Europe. There are several developments with quinoa flour at a smaller scale, like bread, cookies, muffins, pasta, snacks, drinks, flakes, breakfast cereals, baby foods, beer, diet supplements, and extrudates. Extruded corn grits–quinoa blends that had high-protein quality and solubility and an acceptable sensory evaluation have been obtained. Gluten-free quinoa spaghetti was developed and a product obtained without loss of solids and acceptable weight and volume increase on cooking, whereas the adhesiveness of the cooked product was not very high.

Quinoa flour does not have good baking properties like wheat gluten proteins. The wheat proteins are able to form a viscoelastic network when flour is mixed with water to form dough, and these viscoelastic properties allow the use of wheat to produce bread and other processed foods. The enzyme transglutaminase is promising for developing a protein structure. Use of the enzyme reduced the polypeptides of the low-molecular-weight fractions and the soluble protein fractions when producing pasta. There are some gluten-free products without good baking properties for celiac groups, and quinoa provides an opportunity to develop gluten-free cereal-based products. It has been proven that quinoa can be used to make novel, healthy, extruded, snack-type food products. It produces a good product with maximum expansion, minimum density, a high degree of gelatinization, and a low water solubility index.

Chemical, Nutritional, and Health-Related Aspects of Quinoa

Quinoa seeds are a complete food with high nutritional value due mainly to their high content of good-quality protein. There is an extensive literature on quinoa seeds and flours covering different aspects, including the composition of reserves, chemical characterization of proteins, fatty acid composition of the oils, mineral content, and functional and nutritional values (Table 2).

Biopolymers are found in specific parts of the grain. Starch granules occupy the cells of the perisperm, whereas lipid bodies, protein bodies with globoid crystals of phytin, and proplastids with deposits of phytoferritin are the storage components of the endosperm and embryo tissues. The embryo that surrounds the perisperm is dicotyledonous and is part of the bran fraction of the seed; it is high in proteins and lipids and contains most of the ash, fiber, and saponins. The shape of quinoa seed is similar to a flattened sphere; their mean equivalent diameter varies from 1.4 to 1.6 mm. Carbohydrates, proteins, and lipids are the main components of the seeds, and they are mostly responsible for the functional properties that have made them new ingredients in the development of new products.

Proteins

The mean protein content reported in the literature for quinoa seeds is 12–23%. Compared to cereal grains, the total protein content of quinoa seed (16.3% dry basis, db) is higher than that of barley (11% db), rice (7.5% db), or corn (13.4% db) and is comparable to that of wheat (15.4% db). Quinoa contains relatively minor proteins compared to legume seeds. Relative to cereal grains, quinoa proteins are particularly high

Figure 2 Assorted quinoa-based products (a) and loaves, slices, and magnified crumb grain of breads made of wheat:rye (50:50, w:w) (left) and wheat:rye:quinoa (50:50:5, w:w:w) (right) flours (b).

Table 2 Chemical, functional, and nutritional composition of flours from wheat (*Triticum aestivum*) and quinoa (*Chenopodium quinoa* Willd.) (mean of three replicates ± SD)

Parameter	*Quinua*	*Wheat*
Moisture (g/100 g flour, as is)	12.05 ± 0.36^a	14.32 ± 0.32^b
Fat (g/100 g flour, as is)	3.44 ± 0.19^b	1.34 ± 0.09^a
Ash (g/100 g flour, as is)	2.10 ± 0.10^b	0.54 ± 0.06^a
Protein (g/100 g flour, as is)	11.32 ± 0.16^a	12.11 ± 0.21^b
Insoluble fiber (g/100 g flour, as is)	9.13 ± 0.96^b	1.28 ± 0.09^a
Soluble fiber (g/100 g flour, as is)	5.37 ± 1.03^b	0.91 ± 0.09^a
Total dietary fiber (g/100 g flour, as is)	14.5 ± 0.98^b	2.19 ± 0.09^a
*Digestible carbohydrates (g/100 g flour, as is)	57	70
Water holding capacity 3000 rpm (g water/g flour)	1.57 ± 0.09^b	0.84 ± 0.06^a
Water holding capacity 5000 rpm (g water/g flour)	1.16 ± 0.06^b	0.61 ± 0.09^a
Fat adsorption capacity (g/g)	1.2 ± 0.10^a	1.38 ± 0.12^a
Foam capacity (ml)	3 ± 1^a	14 ± 2^b
Foam stability 30' (%)	100 ± 7	36 ± 2^a
Foam stability 60' (%)	100 ± 4^b	36 ± 3^a

Within each row of single flour samples, values with different letters differ significantly from each other ($p < 0.05$).

Source: Collar, C. and Angioloni, A. (2014). Pseudocereals and teff in complex breadmaking matrices: impact of lipid dynamics on the bread functional and nutritional profiles. *Journal of Cereal Science* **59**, 145–154, with permission from Elsevier.

in lysine, the limiting amino acid in most cereal grains. Their essential amino acid balance is excellent because of a wider amino acid range than in cereals and legumes, with higher lysine (5.1–6.4%) and methionine (0.4–1%) contents. Quinoa proteins have higher histidine content than barley, soy, or wheat proteins, whereas the methionine and cysteine content of quinoa is adequate for children (2–12 years old) and adults, it is similar to that of barley and soy, and lower than the amounts in wheat. According to the FAO/World Health Organization (WHO), suggested requirements for 10-year-old children, quinoa proteins have adequate levels of aromatic amino acids (phenylalanine and tyrosine) and similarly in histidine, isoleucine, threonine, phenylalanine, tyrosine, and valine contents. By comparison, lysine and leucine in quinoa seeds are limiting amino acids for 2- to 5-year-old infants or children, whereas all the essential amino acids of this protein are sufficient according to FAO/WHO suggested requirements for 10- to 12-year-old children. In comparison,100 g of quinoa contains nearly fivefold lysine; more than double isoleucine, methionine, phenylalanine, threonine, and valine; and much larger amounts of leucine (all essential amino acids along with tryptophan) than 100 g of wheat. In addition, it also exceeds wheat, in some cases by triple, in the amounts of histidine, arginine, alanine, and glycine as well as containing amino acids not present in wheat such as proline, aspartic acid, glutamic acid, cysteine, serine, and tyrosine (all nonessential amino acids).

Bioavailability of lysine in quinoa is very high, whereas in wheat, rice, oats, millet, and sesame it is significantly lower. Quinoa also contains interesting amounts of phenylalanine, threonine, and tryptophan. Other amino acids present in quinoa but uncommon in other cereals are aspartic acid, glutamic acid, cysteine, serine, and tyrosine.

The protein digestibility or bioavailability (true digestibility) of quinoa's amino acids varies depending on the variety and the treatment they are subjected to. Comparative studies carried out by FAO/WHO using the balance method in rats ranked the values of true digestibility of protein in three ranges: high digestibility from 93% to 100% for animal foods and soy protein isolate; intermediate digestibility values of 86–92% for polished rice, whole wheat, oatmeal, and soy flour; and low digestibility of 70–85% for corn and different types of pulses including beans and lentils. According to this classification, quinoa grain is in third position, that is, with low digestibility.

Active biopeptides have been obtained from quinoa by enzymatic hydrolysis, and it has been suggested that short-chain peptides are more active than long-chain peptides. Low-molecular-weight peptides possess higher potential than high-molecular-weight peptides as antihypertensive agents or as compounds that reduce the amount of free radicals.

Fats

Quinoa contains from 2% to 10% fat. The study of 555 accessions of the Bolivian quinoa collection found that the fat content ranged from 2.05% to 10.88% with an average of 6.39%. Quinoa's fat content is very valuable due to its high proportion of unsaturated fatty acids. These values from quinoa germplasm are expected in the extraction of fine vegetable oils for culinary and cosmetic uses. The relatively high amount of oil in quinoa, a very understudied aspect of the crop, makes it a potential source for oil extraction. Studies carried out in Peru to determine the fatty acid content of quinoa found that the highest percentage of fatty acid in this oil is omega-6 (linoleic acid), 50.24%, very similar to the values found in corn germ oil, which has a range of 45–65%. Omega-9 (oleic acid) is second in quantity, accounting for 26.04% of quinoa oil. The values found for omega-3 (linolenic acid) are 4.77%, and palmitic acid accounted for 9.59%. In addition a small proportion of fatty acids such as stearic acid and eicosapentaenoic acid were also found. The composition of these fatty acids is very similar to corn germ oil. Quinoa helps reduce low-density lipoprotein cholesterol in the body and raise high-density lipoprotein cholesterol due to its omega-3 and omega-6 content. In some cases, 82.71% of fatty acids in quinoa oil are unsaturated.

Carbohydrates

The carbohydrate (by difference, db) content of quinoa sees is comparable to that of barley and rice. Starch is the major component of quinoa carbohydrates, and it is present between 32% and 69.2%. Besides, total dietary fiber of quinoa is near that of cereals (7–9.7% db), and the soluble fiber content is reported between 1.3% and 6.1% db. There is about 3% of simple sugars, mostly maltose, followed by D-galactose and D-ribose, and also fructose and glucose.

Carbohydrates play a basic nutritional function, and they may have different physiological health effects, such as provision of energy, effects on satiety/gastric emptying, control of blood glucose and insulin metabolism, protein glycosylation, and cholesterol and triglyceride. Carbohydrates from quinoa can be considered a nutraceutical food because they have beneficial hypoglycemic effects and induce lowering of free fatty acids. Studies made in individuals with celiac disease showed that the glycemic index of quinoa was slightly lower than that of gluten-free pasta and bread. Besides, quinoa induced lower free fatty acid levels than gluten-free pasta and significantly lower triglyceride concentrations compared to gluten-free bread. *In vitro* digestibility of raw quinoa starch was reported at 22%, whereas that of autoclaved, cooked, and drum-dried samples was 32%, 45%, and 73%, respectively. Saponins did not affect the digestibility of the starch. The total dietary fiber content in quinoa flour is affected by thermal treatment, whereas the insoluble dietary fiber fraction does not change with heat treatment.

Fiber accounts for 6% of the grains' total weight, and quinoa intake therefore promotes intestinal transit, regulates cholesterol, stimulates the development of beneficial bacterial flora, and helps prevent colon cancer. It has a high percentage of total dietary fiber, which makes it an ideal food for helping to eliminate toxins and waste products that can damage the body. It therefore acts as a purifier of the body. It produces a feeling of fullness. Grains in general, and quinoa in particular, have the ability to absorb water and stay longer in the stomach, and in this way fullness is achieved with a low volume of food.

Minerals

If a comparison is made between wheat, corn, rice, barley, oats, rye, triticale, and quinoa, quinoa stands out for its high content

of calcium, magnesium, and zinc. Quinoa is a food rich in calcium, which is easily absorbable by the body (containing more than four times that of corn, almost triple that of rice, and much more than wheat), and quinoa can therefore help to prevent decalcification and osteoporosis. Calcium is responsible for many structural functions of hard and soft tissues of the body as well as the regulation of neuromuscular transmission of chemical and electrical stimuli, cell secretion, and blood clotting. Thus calcium is an essential component of the diet. The recommended daily intake for calcium is 400 mg day^{-1} for children 6–12 months to 1300 mg day^{-1} for adults and is covered with an average consumption of food from 800 to 1000 mg day^{-1}. Quinoa provides 114–228 mg day^{-1}, with a calculated average of 104 mg/100 g of edible portion. The calcium content of quinoa is between 46 and 340 mg/100 g of dry matter. Quinoa contains three times more than wheat and five times more than rice, whereas corn lacks this mineral completely. It contains twice the potassium amount of wheat, four times more than corn, and eight times more than rice. Magnesium is also in much higher amounts than in the other three grains. An adult male of 70 kg contains about 20–28 g of magnesium and the recommended daily intake is about 300–350 mg day^{-1} for adults. Quinoa contains 270 mg/100 g of dry matter. Figures ranging from 170 to 230 mg/100 g of dry matter are presented. Magnesium is a component and activator of many enzymes, especially those that convert energy-rich phosphates. It is also a stabilizer of nucleic acids and membranes. Quinoa almost doubles the amount of zinc found in wheat and is four times that of corn, whereas rice does not contain this mineral. The zinc content of an adult male weighing 70 kg is 2–4 g. Zinc acts on the synthesis and degradation of carbohydrates, lipids, proteins, and nucleic acids. If the body can make use of 20% of the zinc available in food, recommended intakes are 8.3 mg day^{-1} (children under 1 year), 8.4 and 11.3 mg day^{-1} (preschool and schoolchildren), 15.5 and 19.5 mg day^{-1} (adolescents), and 14 mg day^{-1} (adults). Therefore, an intake of between 6 and 20 mg day^{-1} is sufficient, and in this sense, quinoa provides 4.8 mg/100 g of dry matter.

Vitamins

The vitamin content (mg/100 g) of quinoa seeds is also valuable because quinoa seeds have high levels of vitamin B_6 (0.487) and total folate (0.184), whose amounts in 100 g can cover the requirements of children and adults. The riboflavin content in 100 g (0.30–0.32) contributes 80% of the daily needs of children and 40% of those of adults. The niacin content (1.24–1.52) does not cover the daily needs, but is beneficial in the diet. Thiamin values in quinoa (0.29–0.36) are lower than those in oats (0.763), but those of niacin, riboflavin, vitamin B_6, and total folate are higher than in oats and barley.

Other Bioactive Components in Quinoa

Recently, much attention has been given to naturally occurring antioxidants, which may play an important role in inhibiting both free radicals and oxidative chain reactions within tissues and membranes. Pseudocereal seeds and sprouts show relatively high antioxidant activity. The antioxidant activity of various extracts from quinoa (Japan) and from its relative Amaranthus were foundto be different.. Quinoa presents higher antioxidant activity than amaranth using different methodologies: ferric reducing/antioxidant potential, 2,2-azinobis(3-ethylbenzothiazoline 6-sulfonate) and 2,2-diphenyl-2-picryl-hydrazyl. Antioxidant activity of quinoa might be of particular interest to medical researchers and needs further attention regarding its utilization as a natural potent antioxidant. Quinoa seeds from different origins show different isoflavone concentrations, particularly daidzein and genistein. These hormones are implicated in plant physiology (protection from pathogens, from UV light and nitrogen-limited soils) and could be recognized by alpha- and beta-receptors of estrogens in humans. These endoplasmic reticulum-linked receptors are implicated as inhibitors of tyrosine kinase enzymes and as antagonists of vessel contraction. They also reduce arterial resistance, benefit bone density, and stimulate osteoprogerin secretion by osteoblasts, in addition to their antioxidant properties. Saponins are strongly bitter-tasting, surface active compounds with a structure consisting of a steroid or triterpenoid aglycone and one or more sugar chains, which are present in quinoa seeds at significant levels. Saponin levels in different quinoa varieties vary within the range 0.01–4.65%. Due to the bitter taste imparted by saponins, quinoa seeds are normally processed by means of abrasive dehulling or water extraction to remove the outer layers of the seeds where saponins are concentrated, which in turn causes a reduction in the vitamin and mineral content. Although traditionally considered as antinutrients due to their mineral binding activity, recent research has shown that saponins may have anticarcinogenic and cholesterol-lowering properties.

Functional Properties of Quinoa

Some functional properties of quinoa flour have been described, mainly solubility, water-holding capacity, gelation, foaming, and emulsifying capacity (Table 2). Solubility is related to the hydrophilic–hydrophobic balance of the proteins and the thermodynamics of its interaction with the solvent. It has been found to have solubility values of about 15–52%, corresponding to minimum solubility at pH 6 and maximum at pH 10. The solubility values of quinoa flour in the acid pH region imply that the protein may be useful in the formulation of beverages, dehydrated soups and sauces, and low-acid foods. Quinoa flour may not be a good gel-forming agent. However, it was observed that the addition of different salts at low concentration (0.5%) improved the gel-forming property of quinoa, and this effect was better with KCl. The other functional properties measured in quinoa flour are those related to surface tension, like foaming and emulsifying capacity. Quinoa has a low-foaming capacity and stability, and salt addition may improve this property, but high concentrations around 10% are not useful for human consumption. Water and oil absorption are good, enhancing the potential of quinoa seeds in human food and formulations like beverages, sauces, desserts, and sausages.

Conclusions

The outstanding physicochemical, nutritional, and functional properties of quinoa have been emphasized and currently rediscovered by modern scientific approaches. Its uses account for traditional and nontraditional food and industrial applications. The need for intensive cultivation of quinoa should be stressed and encouraged, as it could meet the quality and quantity requirements by the food industry. Quinoa could play a key role in the nutritional behavior of either developing countries or the developed world. In the Andean countries, quinoa crops could play an important role in their economies in the future, giving a new export market, as well as in national subsistence. In addition, quinoa could be a strategic crop used to complement the diet in rural/marginal regions where energy–protein malnutrition affects most of the population of the developing countries. Quinoa, as the 'mother grain,' represents an exotic and healthy rediscovery (gluten free) in the developed world. Bitter seed coat saponins, although probably giving slower speed to quinoa recovery, might now be helpful for its 'take-off' among farmers for a broader range of consumers, as such saponins also have important agropharmacological and cosmetic industrial uses. From the point of view of vegetarian consumers, quinoa in combination with other cereals might easily replace meat, with a great future in modern, conscient, and more ecological food habits. Functional properties given by strongly active compounds like minerals, vitamins, fatty acids, and antioxidants make of this small and noble grain a strong contribution to human nutrition, particularly for all cell processes requiring antioxidant protection of membranes, like neuronal activity, with minerals and amino acid contents with potential implications for aiding memory and lowering anxiety under stressful conditions.

Rapeseed Oil/Canola

NAM Eskin, University of Manitoba, Winnipeg, MB, Canada

Introduction

Canola and rapeseed belong to one of the most widespread and diverse cultivated plants known as the *Brassica* genus. The development of canola from rapeseed originated in Canada and is often referred to as *Canada's Cinderella* crop. Prior to World War II, rapeseed was totally unknown to Canada as well as North America. The first recorded planting of rapeseed in Canada occurred in Saskatchewan during the 1930s by an immigrant farmer from Poland, Fred Solvoniuk, with seeds he received from a friend back in Poland. The seeds were from *Brassica campestris* (now known as *Brassica rapa*) and adapted well to the soil condition in western Canada. The oil from rapeseed proved invaluable during World War II as it was an excellent lubricating oil for marine engines. No other oil adhered to the metal surfaces of the marine engines under the extreme heat and steam conditions better than rapeseed oil. Because of the blockade of Europe and Asian sources of rapeseed oil, a high priority was given by the Canadian government for the commercial production of rapeseed in Canada. In order to meet the desperate shortage of rapeseed oil, rapeseed was also imported from Argentina of the type *Brassica napus*. After the conclusion of the war and with the conversion of ships to diesel engines, the demand for rapeseed oil decreased precipitously. Possible alternative food uses were sought for rapeseed oil. However, these proved unsuitable because of the oils' green color, sharp taste, and very high erucic acid content. Nothing was done until the late 1950s when several plant breeders in Manitoba and Saskatchewan conducted groundbreaking work on rapeseed that would change the landscape of Canadian agriculture in the prairies. This article will discuss the development of canola oil, its composition, processing, and functional and health properties that make it the second most important oilseed crop in the world.

Conversion of Rapeseed to Canola

Rapeseed suffered from two basic problems that limited its use for human or animal consumption. Firstly, the oil was very high in erucic acid, a C22:1 fatty acid that was found to cause heart lesions in several animal models. Secondly, the meal was high in glucosinolates, which limited its utilization for animal feed. Consequently, there was a need to drastically reduce the level of erucic acid level in rapeseed oil (which ranged from 40% to 70% of the total fatty acids) and glucosinolates in the meal. This challenge was undertaken by the outstanding work of two Canadian plant breeders, Dr. Baldur S. Stefansson and Dr. R. Keith Downey, who both developed rapeseed varieties that were low in erucic acid and glucosinolates. This resulted in the Canadian government placing a maximum of 5% erucic acid in rapeseed oils for use in foods. The permitted level for erucic acid was further reduced to 2% in both Canada and the United States in 1985. The stellar work by both these breeders earned them the title of 'fathers of canola,' which led to the development of a multibillion dollar canola oilseed industry with hundreds of thousands of jobs created in Canada and around the world. Not to be forgotten is the important contribution of Dr. Frithjof Hougen, a professor at the University of Manitoba, whose analysis of the canola varieties and crosses for erucic acid using gas chromatography (GC), a Nobel-winning development in science that occurred at this time, made the achievements by Dr. Stefansson possible. A key discovery in the development of canola was an important discovery by Dr. Downey and his graduate student that genotype of the developing embryo controlled erucic acid rather than the maternal plant. This meant that seeds from the same plant could actually differ in erucic acid content. The development of low-erucic-acid varieties was accelerated using the 'half-seed method' to measure the erucic acid content. A very low-erucic-acid sample was finally identified in *B. campestris* by Dr. Downey and grown into a new plant using the half-seed technique. This resulted in the release of the first low-erucic-acid variety of *B. campestris* in 1971. Attention was then focused on reducing the glucosinolate content in the seed. Using a new GC method for measuring glucosinolates, Dr. Stefansson developed the first zero-erucic acid, low-glucosinolate *B. napus*, Tower. This was followed by the release of a corresponding zero-erucic acid, low-glucosinolate *B. campestris* variety, Candle, which was far better suited to northern growing conditions than Tower.

The successful development of double-low rapeseed varieties from *B. napus* and *B. campestris* necessitated their differentiation from the high-erucic-acid and high-glucosinolate rapeseed varieties. In 1978, the Western Canadian Oil Crushers' Association trademarked the new double-low rapeseed varieties as canola, a contraction of Canada and ola, meaning oil, which was later transferred to the Canola Council of Canada (previously known as the Rapeseed Association of Canada). The official definition for canola is the seed from *B. napus* (L.) or *B. rapa* (L) that

produces an oil that contains less than 2% erucic acid, and solid component of the seed must contain less than 30 μmol of any of a mixture of 3-butenyl glucosinolate, 4-pentenyl glucosinolate, 2-hydroxy-3-butenyl glucosinolate, and 2-hydroxy-4-pentenyl glucosinolate per gram of air-dried, oil-free solid.

Since rapeseed was not a traditional food of the United States, canola had to convince the US Food and Drug Administration (FDA) that it was safe for humans. Luckily, the large number of nutritional studies conducted in Canada and other countries combined with the endorsement by the American Heart Association of canola oil, due to it being very low in saturated fatty acids (SFAs), led to the successful granting of generally regarded as safe status by the FDA in 1985. In Europe, it took longer to convert the high-erucic-acid rapeseed varieties to the low-erucic-acid varieties, which are now referred to as low-erucic-acid rapeseed or LEAR.

After palm and soybean oil, canola oil is now the third-largest oilseed crop worldwide with Europe accounting for 63% of world production and Canada 31%.

Composition of Canola Oil

Fatty Acids and Triacylglycerols

Canola oil comprises around 44% of the total seed and is composed mainly of triacylglycerols (TAGs), which account for 94–99% of the total oil. Table 1 illustrates the fatty acid changes occurring when the high level of erucic acid (C22:1) in rapeseed was reduced in canola oil and replaced by substantial increases in levels of C18 fatty acids. The most notable difference was a substantial increase in oleic acid (C18:1) from 14.8% in rapeseed oil to 61.6% in canola oil followed by linoleic acid (C18:2), which almost doubled to 27.7% in canola oil. Of particular note was the very low level of SFAs (7%) in canola oil, which made it quite unique among the other edible oils. Canola oil was also very high in linolenic acid (Ln,C18:3, 9.6%) making it similar to soybean oil, although the latter has much higher SFAs (14.9%) and linoleic acid (L,53.3%) and much lower oleic acid (O, 23.8%).

Table 1 Fatty acid composition of canola oil (w/w%)

Fatty acid	*Canola oil*	*Rapeseed*
C14:0	0.1	–
C16:0	3.6	4.0
C18:0	1.5	1.0
C20:0	0.6	0.6
C22:0	0.3	1.0
C24:0	0.2	0.3
Saturated	*6.3*	*7.1*
C16:1	0.2	0.3
C18:1	61.6	14.8
C20:1	1.4	10.1
C22:1	*0.2*	*45.1*
Monounsaturated	*62.4*	*69.7*
C18:2n−6	27.7	14.1
C18:3n−3	9.6	9.1
C18:3n−6		*1.0*
Polyunsaturated	*31.3*	*23.2*

Source: Adapted from Przybylski and Eskin (2011).

The marked reduction in erucic acid (C22:1) in canola oil resulted in substantial changes in the types and location of fatty acids in the TAG molecules. TAGs are esters of glycerol with three molecules of fatty acids, with each fatty acid located at one of the three positions in the molecule referred to as *sn*−1, *sn*−2, and *sn*−3. The higher amounts of linoleic acid in canola oil replaced erucic acid in the *sn*−1,3 positions in the TAGs. Regular canola oil was also reported to be composed of five main TAG molecules ranging in decreasing order from triolein (OOO), linoleo-diolein (LOO), linoleno-diolein (LnOO), dilinoleo-olein (LnLnO), and linoleno-linoleo-olein (LnLO).

As will be discussed in the processing section, the commercial processing of canola oil is designed to remove all those minor components that have a detrimental effect on its stability. These include free fatty acids, phospholipids, chlorophyll, oxidized products, and trace metals. Thus, top-quality commercially refined canola oil is composed mostly of triacylglycerols (96–99%) with less than 0.1% free fatty acids. The main minor components naturally in canola oil are tocopherols, as these serve as very efficient antioxidants and are usually related to the content of unsaturated fatty acids, particularly linoleic and linolenic acids. There are four isomers of tocopherols, with the greatest degree of antioxidant activity following the order $\delta > \gamma - > \beta > \alpha$. The main ones in canola oil are γ- and α-tocopherols. Other minor components include phytosterols as well as the pigments, chlorophyll, and carotenoids.

Canola oil processing

The processing of canola oil is similar to most edible oil processing operations and is designed to remove deleterious minor components. The ultimate goal is to produce as pure a solution of TAGs as possible, which is essentially what is in the bottle of vegetable oil purchased in the supermarket. Each source of edible oil, including canola oil, is unique and requires some process modifications as one process does not fit all oilseeds. These differences are often subtle but extremely important for the particular type of oil processed.

Flaking, Cooking, and Pressing

The mature and cleaned canola seeds are very small ranging from 2 to 3 mm in diameter. In order to release oil, the cell wall must first be broken down by passing through a set of rollers. Further treatment with rollers continues rupturing of the cells, which allows the oil to be released and coalesce into larger particles. At this stage, the changes on surface of the flaked seed are minor as they still appear fairly dry. The canola flakes are then cooked and held at 85–95 °C for a short period of time to inactivate the enzyme myrosinase and prevent it from hydrolyzing glucosinolates. Some of the hydrolyzed products may contain sulfur, which could have a deleterious effect on the flavor and odor of finished canola oil. Following cooking, the canola flakes are transferred to a screw press. This applies pressure to the canola flakes and removes 60–70% of the total oil leaving behind a press cake.

Solvent Extraction

The residual press cake, containing the remaining oil (39–40%), must be subjected to solvent extraction with *n*-hexane. Concerns to minimize the use of n-hexane have led to using alternative

solvents such a mixture of 2-methylpentane, 3-methylpentane, hexane, and a small amount of other solvents sometimes referred to as 'isohexane.' Countercurrent solvent extraction of the press cake will remove most of the residual oil leaving the cake with as much as 25–35% solvent. Total removal of this solvent is achieved by then subjecting the press cake to countercurrent steam flows in a desolventizer toaster vessel to make the cake meal solvent-free for use for feed.

Degumming

The solvent extracted oil is then mixed with the screw-pressed oil. The combined oil, known as the crude oil fraction, contains phospholipids. Because phospholipids are gums that are hydrophilic, that is, water-soluble, so they can be treated with steam by degumming. This process effectively removes the phospholipids, which can be then added back to the meal or press cake. If mineral salts, particularly calcium and magnesium ions, are extracted with the oil during the extraction and pressing processes, they can make the phospholipids nonhydratable. A super-degumming process using a small amount of citric acid (1500–2500 ppm) at 50–65 °C is available in canola plants to chelate the nonhydratable phospholipids so that they can now be removed from the crude oil along with the hydratable phospholipids. Another reason for removing most of the phospholipids is that they are very high in polyunsaturated fatty acids (PUFAs) and would oxidize readily causing the oil to become rancid.

Canola Oil Refining

The crude-degummed oil now undergoes refining to remove free fatty acids, any phospholipids still remaining, color bodies, iron and copper, and in the case of canola oil also any sulfur compounds. In the traditional alkali-refining process, there are at least five major steps.

Acid Pretreatment

The first step involves heating crude-degummed canola oil to 50–60 °C while at the same time injecting 300–2000 ppm phosphoric acid into the oil followed by mixing vigorously. Once the nonhydratable phospholipids are acidified, they can then be separated. In addition to phospholipids, chlorophyll as well as prooxidants iron and copper are also removed.

Neutralization

The free fatty acid content of the oil as well as the amount of phosphoric acid added will determine the amount of sodium hydroxide added to neutralize the oil. The level of sodium hydroxide added will vary between 8% and 12%. To ensure complete saponification of these fatty acids, however, further alkali may be required. The overall result is that some triacylglycerols are hydrolyzed by sodium hydroxide to produce glycerol and fatty acid salts or soaps.

Soapstock Removal

Further reduction of the soapstock from the oil is achieved by washing with water at 85–95 °C. Citric or phosphoric acids may also be added to the remaining oil to remove any traces of soapstock.

Drying Oil

This is achieved by agitating the oil at 105 °C until the oil is dried.

Physical Refining

An alternative to alkali refining is to use steam distillation directly to remove free fatty acids from canola oil. This process, known as physical refining, is carried out on canola oil after it is acid-degummed and bleached in a specially designed deodorizer. It is more environmental-friendly than alkali refining by avoiding the production of soap and the disposal problems associated with the latter.

Bleaching

Once the canola oil is refined and dried, it then undergoes bleaching. The bleaching process is primarily geared to reducing and removing chlorophyll from canola oil. Acid-activated bleaching absorbent or bleaching clay is used to absorb chlorophyll as well as any phosphatides still remaining after degumming, color pigments, metal ions, magnesium, calcium, iron, and any oxidized fatty acids such as peroxides. Of these minor components, chlorophyll reduction is the primary goal as unless removed it can act as a prooxidant making the oil rancid. Consequently, the level of chlorophyll must be reduced to less than 30 ppb (parts per billion).

Deodorization

Until fairly recently, hydrogenation was regularly carried out after bleaching to reduce the PUFAs and enhance the oxidative stability of canola. This practice has since been discontinued due to the formation of *trans*-fatty acids, which have been shown to be deleterious to human health. Consequently, following bleaching, the oil is now subjected to steam distillation at very high temperatures (240–270 °C) under vacuum (3–8 mmHg). Under these deodorization conditions, any free fatty acids or off-flavor products are completely removed from the oil. The final product is a bland oil to which citric acid (0.005–0.01%) is added to chelate any residual trace metals to prevent oxidation.

Cold-Pressed Canola Oil

In Europe, there is an increasing niche market in virgin cold-pressed canola oil. It simply involves extracting the oil by screw pressing. There is no further treatment of the oil, so it is important to select top-quality canola seeds. Cold pressing is normally

carried out in small- and medium-sized plants, and the oil yields obtained are much lower at around 75–85% of the oil produced from the traditional oil-refining plants. Once the oil is collected, it is cleaned, by removing any particles of seed material, and then carefully stored to minimize loss of quality. Virgin cold-pressed canola oil represents a small but expanding niche market, particularly in Germany, and has slowly been developing in North America for the health food market.

Functional Properties

Canola oil accounts for 50% of all edible oils consumed in Canada. Around 65% of canola oil produced in Canada is exported for use in salad oils and dressings, soft and hard margarines, and baking shortenings. It is a natural salad that generally remains clear at refrigerated temperatures.

The high level of linolenic acid (C18:3) in canola makes it very susceptible to oxidation. Generally, the more double bonds a fatty acid has, the greater is the rate of oxidation. For example, linoleic acid (C18:2) with 2 double bonds oxidizes 25 times faster than oleic acid (C18:1) with one double bond. In the case of the more PUFA, linolenic acid (C18:3) with three double bonds, it oxidizes twice as fast as linoleic acid. Consequently, linolenic acid oils, such as canola and soybean oils, were generally subjected to light hydrogenation that added hydrogen to saturate the double bonds and reduce the level of linolenic acid. The overall effect was to enhance the shelf life and frying life of the oil by preventing oxidative rancidity. Unfortunately, this process, in addition to saturating some of the natural *cis*-double bonds, also resulted in the formation of *trans*-fatty acids. The *trans*-double bond behaved like a saturated bond so that the oil became solid by a combination of newly saturated and newly *trans*-double bonds. The recognition of the deleterious effects of *trans*-fatty acids has essentially removed hydrogenation as a safe process for edible products. An alternative to hydrogenation is to develop tools that will block the formation of linolenic acid and produce canola oil with much lower levels of this PUFA. This resulted in the release of a more stable canola oil, high-oleic-acid canola oil, in 2012. This oil is used extensively in commercial deep frying by food service establishments in North America and has excellent stability. While oleic acid accounts 80% of the total fatty acids, linoleic and linolenic acids account for around 23–27% and 3% for linoleic and linolenic fatty acids in high-oleic-acid canola oil, respectively. In addition to its enhanced frying stability, it is also used extensively as an ingredient in foods.

Health Aspects

The fatty acid composition of canola oil makes it quite unique nutritionally (Table 1). It has very low levels of SFAs, very high amount of monounsaturated fatty acids (MUFAs), and significant levels of the PUFAs, linoleic and linolenic acids, as well as substantial amounts of tocopherols (700–1200 ppm) and phytosterols (0.53–0.97%). This combination has made canola oil extremely healthy because of these cardioprotective substances. Early understanding of the cardioprotective effects of fatty acids was based on the P/S ratio, the ratio of PUFAs (P)/SFAs (S), which suggested you need twice as much P to S to prevent your cholesterol levels from increasing. This ratio proved too limited and oversimplified as it ignored the fact that not all SFAs raised cholesterol and did not take into account the role of the MUFA, oleic acid. This view changed drastically when it was shown that MUFAs were as effective as PUFAs in lowering blood total and low-density (LDL) cholesterol and that they contributed to cardiovascular health in contrast to some of the SFAs. Thus, MUFAs were subsequently shown to exert cardiovascular benefits by regulating plasma lipids and lipoproteins, the susceptibility of LDL lipoproteins to oxidation, and insulin sensitivity. The combined benefits of these canola oil components on the biomarkers of cardiovascular health (total cholesterol and LDL cholesterol) resulted in the following qualified claim for canola oil authorized by the US Food and Drug Administration in 2006: "Limited and not conclusive scientific evidence suggests that eating about 1½ tablespoons (19 gram) of canola oil daily may reduce the risk of coronary heart disease due to the unsaturated fat content in canola oil. To achieve this possible benefit, canola oil is to replace a similar amount of saturated fat and not increase the total number of calories you eat in a day."

A recent study by Jenkins and coworkers in Canada examined the combination of linolenic acid, MUFA in canola oil as part of a low-glycemic-index diet on participants with type 2 diabetes. The test diet, 4.5 slices of canola oil-enriched whole wheat bread, was provided as a supplement and contributed 31 g canola oil or 14% of the total dietary calories of a 2000 cal diet. The control diet supplement was 7.5 slices without canola oil. The canola oil-enriched low-glycemic-index diet improved glycemic control, particularly for those with high systolic blood pressure. Overall, a greater reduction in the Framingham CVD risk score (FRS) was reported for the test diet. FRS is based on a long-term and ongoing cardiovascular study of 5209 adult residents in Framingham, Massachusetts, started in 1948 and now in its third generation of participants. It is a gender-specific algorithm for estimating the 10-year cardiovascular risk for an individual based on total cholesterol, HDL cholesterol, smoking, and systolic blood pressure.

DHA-Enriched High-Oleic-Acid Canola Oil

Plant breeders have been developing new varieties of canola, such as low linolenic acid and high oleic acid, that improve oxidative stability. Because of the increase in metabolic syndrome (a cluster of conditions that increase the risk of heart disease, stroke, and diabetes) and the prevalence of coronary heart disease, breeders have focused their attention on developing canola oil varieties with unique fatty acids such docosahexaenoic acid (DHA), an invaluable $n-3$ fatty acid with important cardiovascular benefits. The deficiency of DHA in North American diets led to a recent multicenter randomized controlled human clinical trial conducted in Canada and the United States using a novel DHA-enriched high-oleic-acid canola oil. Consumption of the DHA-enriched high-oleic-acid canola oil was found to improve HDL cholesterol (the good cholesterol), triglycerides, and systolic blood pressure and reduce FRS compared to other oils with varied unsaturated fatty acid composition.

Conclusion

The conversion of high-erucic-acid rapeseed oil to canola oil had a dramatic effect on the economics of Canadian agriculture. It not only made Canada a major producer of oilseed for the world market but also provided employment for hundreds of thousands of people both in Canada and around the world. The oil also had a unique fatty acid profile that made it one of the healthiest oils by lowering cholesterol and improving heart health. New breeding developments introducing new varieties of canola with even lower levels of SFAs as well as the presence of important fatty acids such as gamma linolenic acid and DHA that may further improve cardiovascular health.

Introduction

Raspberries are an aggregate fruit commonly grown and consumed throughout the Northern Hemisphere and, as members of the rose family, are closely related to blackberries and other brambles or caneberries. Although many species and types of raspberries exist, red and black are the most common. Here, we discuss the origins and traditional uses of raspberries, raspberry biology, specific raspberry species and varieties, raspberry production, raspberry nutrient composition, and the potential effects of raspberries on health.

Raspberry Origins and Traditional Uses

Raspberries belong to the rose family (Rosaceae) and the genus *Rubus*, which also includes other brambles or caneberries, such as blackberries, dewberries, and boysenberries. It is thought that the scientific name for red raspberries (*Rubus idaeus*) came from Mount Ida in Turkey because of the myth that Greek gods went there in search of berries and came back with raspberries. There is a belief that Romans cultivated raspberries in the fourth century and that raspberries appeared in gardens across Europe by the 1500s. Throughout their long history of consumption, various parts of the plant have been used not only as food but also as medicine. The raspberry fruit and raspberry leaves and blossoms have been used for medicinal purposes for many centuries. Raspberry leaves have been used traditionally to treat gastrointestinal disorders, respiratory disorders, heart problems, the flu, fever, and diabetes and to treat morning sickness and to aid with labor. Raspberry leaves were also traditionally used to promote sweating, urination, and bile production. Red raspberry leaves have been applied directly to treat sore throat symptoms and skin rashes. Raspberry blossoms were used to make eye ointments or to treat stomach ailments. Some of these traditional uses are now being investigated using modern scientific methods (see the section '**Raspberry Health Effects**').

Raspberry Biology

Raspberries are woody shrubs that have a perennial root system and long, thin stems or canes, which are biennial. This means that while roots grow year by year, the canes have a 2-year life span. Raspberry plants produce a number of new canes, known as primocanes, each year. The second-year canes are called floricanes. Some raspberry varieties are known as primocane-fruiting, while others are known as floricane-fruiting. Primocane-fruiting raspberry plants can produce a limited number of flowers and fruits the first year, from late summer to fall, and then produce a second, larger crop of berries from floricanes in the second year. In contrast, floricane-fruiting raspberry canes produce no fruit in the first year. Instead, floricane-fruiting plants produce only nonfruiting primocanes in the first year. These nonfruiting primocanes emerge from crown buds or adventitious roots (roots that emerge from aboveground stems). Nonfruiting primocanes grow rapidly during spring and early summer and then form flower buds in the fall of the first year. Buds on the nonfruiting primocanes break and plants produce leaves, flowers, and new, fruiting canes (floricanes) in the spring of the second year. After fruiting, the floricanes on floricane-fruiting plants senesce and die.

In addition to primocane- and floricane-fruiting types, raspberry plants can also be characterized by the amount of support their canes need to remain off the ground. Keeping raspberry canes off of the ground helps to prevent disease by keeping the berries dry. It also makes machine harvesting or handpicking raspberries easier. Raspberries are hand-harvested for fresh market and can be machine-harvested for processing. Machine harvesting is accomplished by tall tractors that straddle raspberry rows and shake the berries off of the canes using long, flexible plastic rods. The berries that are shaken off of the canes land on conveyor belts that transport them into boxes or baskets for storage. Based on how much support is needed, raspberry plants are classified as erect, semi-erect, or trailing type. Just as it sounds, the erect and semi-erect canes do not require support. The trailing type of canes, however, requires a stake or trellis system for support.

Like blackberries, boysenberries, and the other so-called caneberries, raspberries are not considered true berries. Instead, they are classified as 'aggregate fruits,' because they are composed of 75–125 small fruits, called drupelets. **Figure 1** shows the characteristic aggregate form of the 'berries.' When the fruit ripens, an abscission (separation) layer develops between the fruit and the 'receptacle' (a fingerlike projection that attaches them to the plant during ripening). When the ripe raspberry fruit is removed from the plant, the receptacle is left behind, resulting in a hollow fruit. This is one of the physical characteristics that differentiates raspberries from blackberries. Blackberries do not develop an abscission layer in the same way as raspberries do and are, therefore, not hollow. Raspberry fruits undergo color change as they ripen due to the degradation of chlorophyll and accumulation of the anthocyanins that are primarily responsible for the red to dark purple colors of the ripe fruits. Raspberry fruits are highly perishable, with a shelf life of 3–6 days at 0 °C and 90–95% relative humidity. Therefore, raspberries need to be handled properly so the respiration rate is reduced and shelf life can be extended as much as possible. The fact that fresh market berries must be harvested by hand, along with their limited shelf life, may explain their high price, relative to other commonly sold fresh fruits.

Figure 1 Black raspberries at various stages of ripeness.

Raspberry Species and Varieties

More than 200 raspberry species have been identified. Raspberry fruits can have several colors including red and yellow (both *R. idaeus*), purple (*R. neglectus*), and black (*R. occidentalis*), but red raspberries are the most widely grown type. Black raspberries are a distant second. Red raspberries are more widely grown than black raspberries because they are generally more disease-resistant and more productive than black raspberry plants. Raspberry breeding experienced major advances in Britain in the nineteenth and early twentieth centuries. Red raspberries cultivated in North America before 1800 originated in Europe. In 1866, the US-developed cultivar Brinckle's Orange was released. Cultivars such as Latham, Newburgh, and Chief were also developed during the twentieth century. Primocane-fruiting raspberries were bred, and cultivars such as Heritage, Amity, and Autumn Bliss were released. Currently grown floricane-fruiting red raspberry cultivars include Claudia, Emily, Encore, Esta, Lauren, Prelude, and Qualicum, and primocane-fruiting cultivars include Autumn Bliss, Autumn Britten, Caroline, Dinkum, Heritage, Josephine, and Polana. Fewer black raspberry cultivars have been developed compared with red raspberries, primarily due to the greater popularity of the red varieties. Currently, popular black raspberry cultivars include Allen, Black Hawk, Bristol, Jewel, Mac Black, and Munger. There are currently established breeding programs in 21 countries, so that raspberries with enhanced disease resistance (fungal diseases and viral diseases transmitted by aphids are major concerns) or desirable traits (e.g., thornless canes or larger, sweeter berries) can be produced.

Raspberry Production

Raspberries are grown worldwide, primarily in the Northern Hemisphere, although there is some commercial production in Chile. Fresh market raspberries are grown to be bright and glossy, whereas raspberries destined for processing are selected for their color intensity. Black raspberries are grown to be dark purple so that they can be used for their natural colorant properties. Frozen seedless raspberry puree can be used as a base for products such as ice cream and sorbet. Raspberry juice can be mixed into many beverages to enhance flavor and color and to balance sweetness and tartness in mixed fruit beverages. Machine-harvested raspberries can be processed for fruit juice, puree, jam, jelly, concentrated syrups, dried forms, individually quick frozen units, and frozen bulk fruits. According to the FAO (the Food and Agricultural Organization of the United Nations), Russia is the number one raspberry producer in the world, followed by Serbia, Poland, and the United States. Russian production in 2010 was reported to be 125 000 metric tons, one and a half times greater than that of either Serbia or Poland and four times greater than that of the United States. Serbia is the world's top raspberry exporter, followed by Russia and Poland. In recent years, raspberry production has increased markedly. Worldwide raspberry production and total production area increased from 320 861 metric tons and 63 762 ha in 1995 to 543 421 metric tons and 100 556 ha in 2011, respectively.

According to USDA National Agricultural Statistics Service data, 31 400 metric tons of red raspberries and 1000 metric tons of black raspberries were produced in the United States in 2012, with an estimated total worth in excess of $220 million. Of these, 590 metric tons of red raspberries and 23 metric tons of black raspberries were sold for fresh market purchase. Freezing (whether into individually quick frozen berries or into solid blocks) represents 50% of the processed raspberry market in the United States, followed by juice and puree. In the United States, raspberry production is dominated by three Western states, Washington, California, and Oregon. In 2010, Washington state produced 61 million pounds ($50 million) of red raspberries, while Oregon produced 5 and 1.8 million pounds of red and black raspberries, respectively. California produced 81 million pounds of raspberries ($200 million). About 95% of raspberries produced in the United States in 2001 were processed and only about 5% were sold for fresh market purchase. Despite the large quantity of raspberries produced, the United States imports raspberries from Canada, Mexico, and Chile. This may be due partly to the proximity of these countries (raspberries have a very short shelf life) and in the case of Mexico and Chile, may also be due to the availability of fresh berries in winter months. With regard to processed berries, about 40% of raspberries and blackberries processed in the United States are ultimately used for preserves, jam, and jelly, followed by bakery products (25%), individual quick frozen products (18%), juices and extracts (7%), ice cream and yogurt (5%), and canned berries (5%). In summary, raspberry production and their monetary value are increasing worldwide and most raspberries are processed, rather than eaten fresh. This raises the question of how the nutrients found in the fresh berries are affected by the various types of processing.

Raspberry Nutrient/Phytonutrient Composition

A variety of nutrients and other potentially beneficial compounds are found in raspberries, including vitamins,

essential minerals, fatty acids, and dietary fiber. These nutrients not only determine the fruit's health properties but also can affect their flavor, texture, and appearance. As with other fruits, water is the major constituent of raspberries. Sugars, in particular glucose and fructose, and citric acid are the major soluble solids. The sugar-to-acid ratio is important to the taste of raspberries and thus for consumer acceptance. Fruits grown in mild, dry summers (daytime temperature around 77 °F or 25 °C) have the best sensory characteristics in that they are sweeter, less acidic, and have more aroma and intense color than raspberries grown in other conditions. The *Rubus* species are the sources of the water-soluble vitamins C and folic acid and the fat-soluble vitamins A and E. Depending on the type of soil in which they are grown, they contain minerals, including calcium, magnesium, manganese, and selenium. They are also rich in soluble fibers, such as pectin. Although nutrient content is influenced by many factors, one cup of raspberries, on average, provides 54% of the daily recommended value (DV) of vitamin C, 12% DV of vitamin K, 6% DV of folate, 41% DV of manganese, 7% DV of magnesium, 5% DV of potassium, and 32% of the DV of dietary fiber. Raspberries are low in total calories, containing 52 cal, on average, in a 100 g serving or ~120 cal per cup.

In addition to their nutrient composition, raspberries are an excellent source of nonnutrient phytochemicals, also known as 'nonessential' nutrients, because they are not technically necessary to sustain life but may communicate health benefits if consumed in the right amounts. Berries contain a variety of monomeric and polymeric phenolic compounds. Monomeric compounds found in raspberries include flavonoids, phenolic acids, and carotenoids. Polymeric raspberry compounds include ellagitannins, gallotannins, and proanthocyanidins. Flavonoids are a diverse group of over 6000 compounds that includes anthocyanins and flavanols. Anthocyanins are of particular interest in raspberries, since they provide a red to purple color and may be some of the most 'bioactive' in terms of potential anticancer and other health effects. Depending on the cultivar, cyanidin 3-glucoside, cyanidin 3-sambubioside, and cyanidin 3-sophoroside have all been reported as major anthocyanins in red raspberries. Black raspberries contain the anthocyanins cyanidin 3-sophoroside-5-rhamnoside, cyanidin 3-sambubioside-5-rhamnoside, and cyanidin 3-rutinoside. Carotenoids such as lutein, zeaxanthin, b-cryptoxanthin, and a- and b-carotene are also present in raspberries. The importance of carotenoid pigments is most evident in yellow raspberries (which are an albino form of the red raspberry), where the red to purple anthocyanin pigments are absent. Although carotenoid colors are typically masked by anthocyanins, they do contribute to the aroma of raspberries via the formation of compounds known as ionones and damascenones. Interestingly, ethyl formate, one of the principal flavor components in raspberries, was detected at the center of the Milky Way galaxy, proving once and for all that raspberry flavor is out of this world. Table 1 gives a general summary of the nutrient/phytonutrient contents reported in raspberries. It is important to keep in mind that, as indicated previously, the nutrient content varies based on the type of raspberry in question and its degree of ripeness, length of storage, degree of processing, etc.

Table 1 Approximate raspberry nutrient/phytonutrient content by percent

Nutrient/phytonutrient	*Reported content*
Water	86%
Fiber	6.5%
Sugars	4.4%
Organic acids (primarily citric acid)	1.5%
Protein	1.2%
Lipids	0.7%
Total minerals (ash)	0.5%
Ellagitannins	0.1%
Anthocyanins	0.1%
Salicylates	<0.1%

Raspberry Health Effects

As mentioned previously, raspberry leaves and fruits have been used as part of traditional medicines to treat a wide range of illnesses for millennia. In contrast, the study of the health effects of raspberries by modern science is relatively new, going back only to the early 1980s. These newer studies have identified potentially beneficial compounds and chemical properties in raspberry plants and have examined raspberry's health effects in cell culture, in animal models, and, to a limited degree, in humans. Based on these newer studies, raspberries and the compounds contained in them have been reported to possess a wide variety of potential benefits, including anticancer, antidiabetic, antiobesity, antihypertensive, anticoagulant, anti-inflammatory, antiviral, antidepressant, and neuroprotective effects. The weight of evidence for most of these effects is weak, relying primarily on cell culture or animal models. The strongest evidence presented so far relates to the cancer preventive (chemopreventive) effects of black raspberries in humans. These effects are influenced by raspberry variety, growth, storage, and processing conditions and by individual differences in the genetics and intestinal flora of the consumer. While raspberries may provide health benefits, a number of outbreaks of foodborne illnesses have also been linked to fresh and frozen raspberry consumption. This section examines the potential health benefits of raspberries and weighs these benefits against the risk of foodborne illnesses that may be associated with their consumption.

The recognized leaders in the area of cancer chemoprevention with raspberries are Dr. Gary Stoner and his colleagues. The groundbreaking work done by Dr. Stoner and his collaborators at the Cleveland Clinic at Ohio State University and his current work at the Medical College of Wisconsin have shown that raspberries are highly effective chemopreventive agents in cell culture and in animal models. More importantly, the information gathered from cell culture and animal models is now being translated into human clinical trials. His primary focus in human studies has been on cancers of the digestive tract. The first step in these types of food-based human studies is to assure that no harm results from the amount of a food or food components consumed. Some of his early work in human trials indicated that the black raspberry constituents ellagic acid and anthocyanins were found in blood and urine after large amounts (equivalent to about 1 pound of fresh berry consumption per day) of

freeze-dried black raspberry slurry were consumed by human volunteers over several days. It also indicated that even this large amount of berries was well tolerated when the freeze-dried berries were reconstituted in a small amount of water and consumed as a slurry. Studies by other researchers have indicated that the majority of anthocyanins consumed are rapidly absorbed and rapidly cleared from the body but that some are absorbed and remain in the tissues for extended periods.

Dr. Stoner's work examining the preventive effects of whole raspberries against digestive tract cancers in humans has included studies of oral, esophageal, and colon cancer. An oral cancer prevention trial conducted by his lab showed that the anthocyanins in black raspberry-based mouth rinses are taken up by human oral tissue and metabolized by it. They are also metabolized by bacteria present in the mouth. Individuals differ in the way that this metabolism occurs, which may, in turn, alter their risk for oral cancers. Raspberries have been reported to affect antioxidant measures in patients with Barrett's esophagus, a precancerous condition that can lead to esophageal cancer in humans. Some of his most recent work, which involved feeding freeze-dried black raspberry slurries to colon cancer patients, indicated that raspberries have the ability to beneficially affect tissue- and blood-based markers in colon cancer. Blood samples taken from colon cancer patients indicated that there were positive changes in the plasma levels of granulocyte–macrophage colony-stimulating factor and interleukin 8, two blood markers associated with cancer growth. Consumption of black raspberry slurries was also associated with the methylation of tumor suppressor genes in cancerous colon tumors of human subjects. Gene methylation is important because it can determine whether a gene is 'turned on' or 'turned off.' Turning 'on' tumor suppressor genes in tumor cells can cause them to die off. In addition to work with whole, freeze-dried berries, Dr. Stoner's group also examined the effects of black raspberry extracts. A black raspberry extract was found to reduce polyp formation in the colon by 59% in human patients with familial adenomatous polyposis, a genetic condition that dramatically increases the risk of developing colon cancer. Although some effort has been made to identify an 'active ingredient' in black raspberries, one of the unique aspects of this work is the apparent success achieved with whole berries.

Despite the success of the 'whole food approach,' a number of compounds present in raspberries have been identified as important to their health effects, including anthocyanins, ellagitannins, and salicylates. There is some evidence that the dark purple pigment compounds, anthocyanins, may be the active anticancer ingredient in the black raspberries. It is also possible that any health benefits provided by raspberries may result from a combination of compounds (anthocyanins, ellagic acid, etc.) or metabolites of multiple compounds (e.g., the ellagic acid metabolites, urolithins, that are discussed later in this section) contained in the raspberry fruit. Salicylates are similar to aspirin in chemical structure and have similar anti-inflammatory and pain-relieving effects. While it would be premature at this point to say that raspberries have cancer preventive effects in humans, the results of preliminary clinical trials examining the chemopreventive effects are encouraging and warrant further study.

One area of recent research interest has been the realization that because freshly harvested, unprocessed, or minimally processed berries are alive and biochemically active, they can respond to environmental stimuli. It has long been recognized that phenolic compounds, like flavonoids, are produced by plants as a stress response to factors such as sunlight, heat, drought, and pests. Man-made stresses, such as radiation, ultrasound, or high pressure, can increase the level of potentially beneficial compounds. One study reported that gamma-irradiated raspberries showed significant decreases in bacterial and fungal content and increased the phenolic and antioxidant properties. A loss in firmness appeared to be the only negative effect observed. Irradiation of raspberries may, therefore, have two benefits: one with regard to increased content of phenolic compounds and another with regard to decreased bacterial load and enhanced food safety. Ultrasound, at both low and high frequencies (20 and 986 kHz, respectively), was shown to increase the content of potentially beneficial compounds in raspberry puree. At the lower frequency, total phenol content, antioxidant content, and anthocyanin content each increased by 10% or more. At the higher frequency, only total phenol content increased. With an improved understanding of the ways in which raspberries respond to specific types of stresses, it may be possible to maximize the production of specific compounds, thus standardizing and maximizing the content of potentially beneficial compounds or biological effects.

Antioxidant activity has been used extensively as a marketing tool for raspberries and may also influence their health effects. Antioxidants are compounds that can react with and inactivate highly unstable molecules known as free radicals or that prevent the formation of free radicals. Total phenolic content, which is a measure of a whole food's chemical reducing capacity, is closely related to antioxidant activity and, in raspberries, to anthocyanin content. Some essential nutrients contained in raspberries, such as vitamin C and other 'nonessential' nutrients, including flavonoids and carotenoids, possess antioxidant properties. Antioxidants may play a role in reducing the risk of chronic diseases, such as cardiovascular disease, cancer, and diabetes via the prevention of oxidative stress and effects on cell signaling. Raspberries have been reported to possess greater antioxidant properties than strawberries, kiwi, broccoli, leeks, apples, and tomatoes. Recently, questions have been raised about whether antioxidant properties alone can communicate any health benefits. For this reason, the USDA has decided to remove their oxygen radical absorbance capacity database from their website. Despite the changing views over the importance of antioxidant properties in relation to direct health effects, it is clear that many foods, like raspberries, with proved health benefits also possess significant antioxidant activity. In addition, antioxidants may indirectly benefit health by acting as natural 'preservatives' for other food components, protecting them from destruction by processing and storage.

Microbial flora and their interaction with the foods we eat have now been recognized as one of the most significant contributors to health, for both positive and negative reasons. Raspberries are no exception. One of the most intense areas of investigation has focussed on nutrient absorption and how nutrient and nonnutrient compounds are metabolized to other compounds not only by human digestion but also by the trillions of microbes present in the human gut. It is well known that only a very small percentage of flavonoids,

carotenoids, and other 'nonessential' nutrients are absorbed by the body, such that they are detectable in blood or urine after a berry-containing meal. Research interests are now beginning to examine whether the microbial metabolites of 'nonessential' nutrients, rather than the compounds found in food, may be the active compounds that may influence disease prevention. One example that illustrates this idea is the conversion of raspberry ellagitannins to ellagic acid and ellagic acid to urolithins by intestinal bacteria. Depending on the type of raspberry and its degree of ripeness, raspberries contain varying levels of ellagitannins and ellagic acid (pale, unripe raspberries contain more ellagitannins and less anthocyanins than ripe raspberries). Ellagitannins are not absorbed by the body and ellagic acid is only poorly absorbed. Urolithins are relatively well absorbed compared with ellagic acid. Urolithins are formed from the breakdown of complex ellagitannins to ellagic acid. In this way, raspberries are analogous to pomegranates, walnuts, and muscadine grapes, in that they are all sources of ellagitannins that may be converted to urolithins by intestinal microbes. Urolithins may be responsible for some of the antioxidant, anti-inflammatory, and anticancer effects attributed to ellagitannins and ellagic acid.

Despite all of the reported health benefits of raspberries, there are also risks associated with their consumption. These risks are related primarily to foodborne illnesses but may also be associated with pesticide application and heavy metal contamination. Raspberries can serve as vectors for foodborne illnesses, particularly in fresh or fresh frozen berries. Raspberries have been associated with norovirus, hepatitis, and *Cryptosporidium* outbreaks. The most thoroughly studied and frequently reported foodborne illness associated with raspberry consumption is norovirus. Typical norovirus symptoms include short-term bouts of vomiting and diarrhea. While rarely fatal, the symptoms of this viral illness can be quite severe. Raspberries may be contaminated with norovirus in the field, during picking and handling, or during packaging and freezing processes. For this reason, every effort must be made to assure that not only the berries but also the workers, the processing machinery, and the packaging be norovirus-free. Interestingly, some black raspberry compounds may have both antibacterial and antiviral effects. Although it is clear that raspberries can be sources of foodborne illnesses, it is unclear whether individuals who eat contaminated raspberries are more or less likely to become ill than if they consumed other foods (i.e., do the potential antimicrobial effects of berries have any real benefits in terms of decreasing food poisoning incidents?).

In addition to microbial safety, chemical contamination and allergies to raspberry proteins can also affect raspberry safety. Depending on the types of minerals found in the soil in which they are grown, raspberries may contain metals, including chromium, cobalt, and lead, each of which may be toxic at high levels. The issue of metal contamination is not unique to raspberries but certainly deserves consideration. Strawberries, blueberries, and raspberries contain similar proteins that may act as allergens in sensitive individuals. This means that those who are allergic to one of these berries may be allergic to all of them. Some individuals are also sensitive to salicylates. Whether the issue is microbial food safety, environmental contamination, or food allergies and sensitivities, the most important question regarding the safety of raspberries is whether the potential health benefits of eating raspberries outweigh the potential risks. Given that raspberry-related foodborne illnesses, metal contamination, and allergies appear to be relatively rare events, the answer would seem to be that the benefits do outweigh the risks.

As with other fruits, one of the primary issues with raspberry's health effects is their availability and expense relative to other foods. From 2003 to 2004, 87% of fruits in the United States were consumed in the homes of the buyers. The total US consumption of fruits is 9.65 g day^{-1}. American male adults from 40 to 59 years old have the highest consumption of fruits. Higher educated families have a higher consumption of fruits than families with lower education levels. Caucasians eat more fruits than all other races. Underweight children eat more fruits than children in other weight classes. Since many of the human studies conducted with raspberries have subjects consuming the equivalent of a pound of berries per day in freeze-dried form, this presents two problems. The first is the cost of consuming one pound of berries per day. The second is the need to consume either a pound of fresh berries or the equivalent (about 45 g or 2 oz) in order to reap the potential benefits of the berries. For this reason, research to determine the active ingredients in raspberries is important, because it may allow for the consumption of a much smaller amount a material, if daily dosing is needed.

Summary

Raspberries have a long history of human consumption and cultivation in what is now Europe. Today, world raspberry production is focussed in Eastern Europe and Russia, with Russia being the leading producer. Various species of raspberries may produce red, yellow, purple, or black fruit. Of these, red raspberries are the hardiest and most commonly grown. Only a small percentage of raspberries are consumed fresh. Most raspberries are frozen or processed into jams and other products. Raspberries are sources of essential vitamins and minerals and 'nonessential' compounds that may benefit health. In addition to the use of raspberry fruit as food, many parts of the raspberry plant have also been used for medicinal purposes. Although not conclusive, recent human studies suggest that raspberries may show promise in cancer prevention. Although raspberries are generally considered to be 'healthy' foods, they can also be sources of foodborne illnesses if contaminated in the field or during processing and storage. Future research will continue to produce new varieties of raspberries and to examine their potential health effects.

Renal Function and Disorders

GPS Shantha, The Wright Center for Graduate Medical Education, Scranton, PA, USA
LJ Cheskin, Johns Hopkins Weight Management Center, Baltimore, MD, USA

© 2016 Elsevier Ltd. All rights reserved.

Background

The kidneys are bean-shaped retroperitoneal organs located in the paravertebral gutters. The kidneys are highly vascular organ systems and they receive 20% of the cardiac output. They are supplied by the right and left renal arteries, which are direct branches from the abdominal aorta. The main functions of the kidney include the following:

- *Excretion of metabolic end products*: They play a key role in excreting products of protein breakdown most notably urea, toxin excretion, and excretion of drugs and metabolites.
- *Maintenance of body homeostasis*: They regulate body fluid volume, osmolarity, acid–base balance, and electrolyte balance. Electrolytes regulated by urinary excretion include sodium, potassium, chloride, calcium, magnesium, and phosphate.
- *Production of hormones and enzymes*: Renin and erythropoietin are the hormones produced by the kidney. Renin is produced by granular cells of the juxtaglomerular apparatus. Renin acts on a plasma globulin called angiotensinogen and converts it to angiotensin. Angiotensin is a potent vasoconstrictor and plays a key role in blood pressure and sodium regulation. Erythropoietin is produced by the renal cortical interstitial cells and stimulates maturation of erythrocytes in the bone marrow.

Body Fluid Composition

The human body is largely made of water. But the quantity of water is variable depending on the fat mass. Adipose tissue is low in water content. An obese individual may have a lower water content compared to a nonobese individual. Similarly, women have lower water content (55%) compared to men (60%). Simple bedside estimates for body fluid compartment volumes are as follows:

Total body water (liters) = 60% × body weight
Intracellular water (liters) = 2/3 of total body water
Extracellular water (liters) = 1/3 of total body water
Plasma water (liters) = ¼ of extracellular water
Blood volume (liters) = plasma water/(1 − hematocrit)

Basic Structure of a Nephron

Please refer to Figure 1 for a basic structure of a nephron. Structurally, each kidney is composed of 1 million filtering units called nephrons (Figure 1). Each nephron comprises a glomerulus, proximal convoluted tubule, loop of Henle, distal convoluted tubule, and collecting duct. The renal artery is a direct branch of the abdominal aorta. Then, the renal artery branches into the lobar, the interlobar, and then the arcuate arteries, which further branch into the afferent arterioles that take blood to the glomerulus and form the glomerular tuft of capillaries. From the glomerular tuft of capillaries arise the efferent arterioles, which join the arcuate vein, then the interlobar vein, and finally the renal vein, which joins the inferior vena cava. The uniqueness of this system is that the glomerular tuft of capillaries gives rise to the efferent arteriole rather than a venule. The resistance offered by this efferent arteriole increases pressure within the glomerular capillaries aiding in ultrafiltration where fluid and electrolytes are filtered out of the glomerular capillaries into the Bowmen's capsule.

Glomerular Ultrafiltration

Substances encountered by the glomerulus are broadly divided into large molecules (>60 000 Da molecular weight), middle molecules (between 500 and 60 000 Da), and small molecules (<500 Da). The large molecules are usually immunoglobulins and are not filtered by the kidney. This is considered an evolutionary protective mechanism to retain immunoglobulins in the body. Small molecules usually are nitrogenous waste products that are highly water-soluble and are easily filtered. They can be easily dialyzed when the kidney is diseased. The middle molecules are uremic toxins and drug haptens that resist filtration via the glomerulus. Accumulation of these middle molecules is considered the predominant reason for uremic symptoms such as nausea, vomiting, and lack of appetite. Dialyzing these middle molecules, though possible, is difficult.

The rate at which blood is filtered in the glomerulus is called the glomerular filtration rate (GFR). GFR is the most commonly used marker to denote kidney function in clinical practice. GFR can be accurately assessed by measuring the clearance rate of a solute that has a constant concentration in the blood, which is filtered but neither reabsorbed nor secreted. Inulin clearance measured by infusing inulin at a rate so as to maintain a constant blood concentration is an accurate method to assess GFR. But this technique is not commonly used in routine clinical practice considering the hassle that goes with infusing inulin. The commonest and easiest method to estimate GFR is to use creatinine clearance. Creatinine is endogenously produced, filtered in the glomerulus, and not reabsorbed and we have assays to easily measure creatinine. Hence, it fits most criteria for the solute that will make an ideal ultrafiltrate. However, creatinine is secreted by the peritubular capillaries, and hence, creatinine clearance potentially overestimates actual GFR by 10–15%. There are two general methods of estimating creatinine clearance: (1) Direct measurement: from a 24 h urine collection assessing the quantity of creatinine excreted over a 24 h period. Though considered accurate, the technique is cumbersome and not used in regular

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00589-4

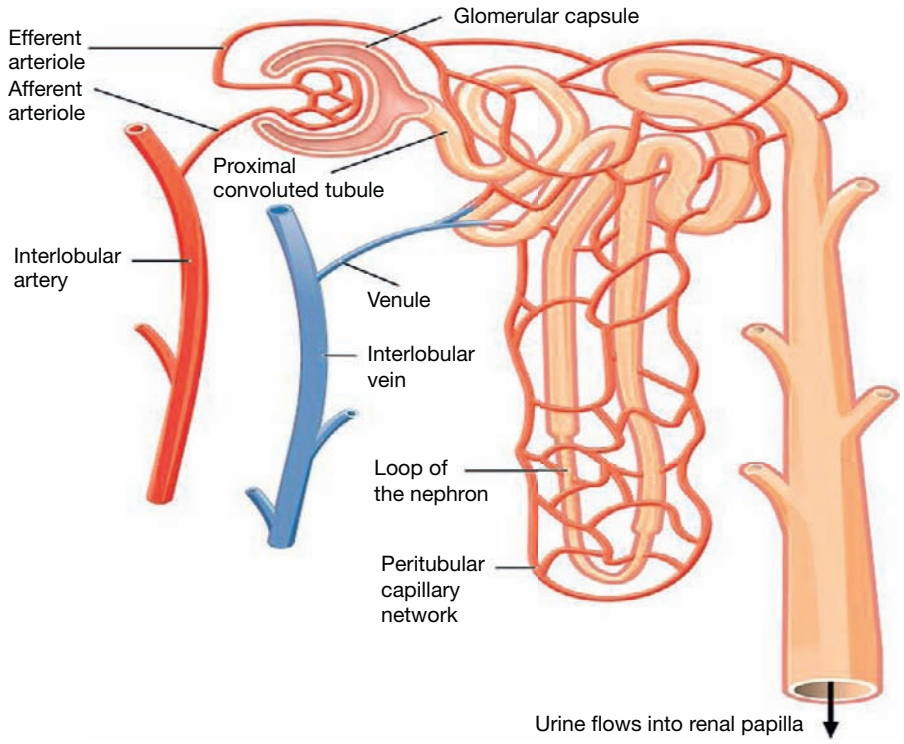

Figure 1 Microscopic structure of a nephron.

clinical practice. (2) Estimated glomerular filtration rate (eGFR). There are multiple formulas to assess eGFR. Broadly, they are classified into creatinine-based equations and cystatin-based equations. Common creatinine-based equations are (1) the Cockcroft and Gault equation, (2) Modification of Diet in Renal Disease (MDRD) equation, and (3) Chronic Kidney Disease Epidemiology Collaboration (CKD-Epi) equation. Creatinine-based equations, though clinically applicable and inexpensive, may overestimate GFR as discussed earlier. Also, these equations have not been validated for use for ages >75 years. The most valid among these is the CKD-Epi equation:

$$\text{eGFR} = 141 \times \min(SCr/k, 1)^{a} \times \max(SCr/k, 1)^{-1.209} \times 0.993^{\text{Age}} [1.018 \text{ if Female}] \times [1.159 \text{ if Black}]$$

Cystatin alone or cystatin combined with creatinine-based estimated GFR prediction has been found to perform optimally for GFR estimation.

Irrespective of the method used, eGFR has been shown to predict outcomes that include cardiovascular events, stroke, incident diabetes, and mortality. Further, rate of eGFR decline has been identified to predict future events better than a single measure of GFR.

Tubular Reabsorption and Tubular Secretion

Tubular reabsorption is the process by which there is movement of solute or water from tubular lumen to blood. This is the predominant process in the renal handling of Na^+, Cl^-, bicarbonate, water, glucose, amino acids, protein, phosphate, calcium, magnesium, urea, uric acid, and other molecules. Tubular secretion is the process of movement of solutes from the blood or the renal tubular cell interior to the tubular lumen. Secretion is important in the renal handling of hydrogen ion, potassium, ammonium ion, and a number of organic acids and bases. Briefly, the glomerular filtrate passes through the proximal convoluted tubule. Here, water, sodium, chloride, amino acids, and sugars are reabsorbed by active transport mechanism involving Na/K-ATPase pump. Nearly 90% of NaCl and water reabsorption happens in the proximal convoluted tubule. Also, in the proximal convoluted tubule, secretion of organic ions and drugs happens. Then, the filtrate passes through the loop of Henle where passive movement of NaCl and water happens from the tubular lumen to the tubular cells and then to the tubular interstitium. Then, at the distal convoluted tubule, further reabsorption of NaCl and water happens. The remaining filtrate comes out as urine. Understanding these absorption sites is important to understand diuretic action. Osmotic diuretics inhibit Na and water reabsorption at the proximal tubule. Loop diuretics like furosemide act at the ascending loop and inhibit the sodium potassium cotransporter. Thiazide diuretics inhibit Na/Cl^- cotransporter at the distal convoluted tubule. Amiloride blocks epithelial sodium channel at the collecting duct.

Acid–base balance

An arterial pH lower than 7.36 is considered as acidemia and a pH more than 7.44 is considered alkalemia. The blood pH is determined by the ratio of serum bicarbonate concentration and the PCO_2. When a metabolic disorder decreases the serum bicarbonate (metabolic acidosis) or increases serum bicarbonate (metabolic alkalosis), compensatory PCO_2 response follows the same direction as the bicarbonate. In a patient with metabolic

acidosis, the PCO_2 falls approximately 1.2 mmHg for every 1 meq l^{-1} reduction in serum HCO_3 concentration. In a patient with metabolic alkalosis, the PCO_2 raises by 0.7 mmHg for every 1 meq l^{-1} increase in serum HCO_3 concentration. In acute respiratory acidosis, for every 10 mmHg increase in PCO_2, the serum HCO_3 increases by 1 meq l^{-1}, whereas in chronic respiratory acidosis, for every 10 mmHg increase in PCO_2, the serum bicarbonate increases by 3.5–4 meq l^{-1}. In acute respiratory alkalosis, for every 10 mmHg increase in PCO_2, the HCO_3 increases by 2 meq l^{-1}, whereas in chronic respiratory alkalosis, for every 10 mmHg drop in PCO_2, the HCO_3 decreases by 4–5 meq l^{-1}. Metabolic acidosis is broadly divided into two types: (1) raised anion gap metabolic acidosis and (2) normal anion gap metabolic acidosis. The anion gap is the difference in the measured cations (positively charged ions) and the measured anions (negatively charged ions) in serum, plasma, or urine. Raised anion gap acidosis happens when acid accumulates in the body. Examples of raised anion gap metabolic acidosis include lactic acidosis, diabetic ketoacidosis, kidney disease, toxic alcohol ingestion including methanol and ethylene glycol, and salicylate poisoning. Normal anion gap metabolic acidosis happens due to loss of body reserves of bicarbonate. Normal anion gap acidosis happens in conditions like diarrhea and renal tubular acidosis, conditions associated with bicarbonate losses. Metabolic alkalosis happens secondary to hydrogen ion loss in the gastrointestinal track or the urine. Common causes include removal of gastric contents via vomiting or nasogastric suctioning and use of loop and thiazide diuretics. Respiratory acidosis happens in chronic obstructive pulmonary disease and secondary to respiratory muscle fatigue, conditions associated with CO_2 retention. Respiratory alkalosis happens in conditions associated with CO_2 washout secondary to hyperventilation. Examples include anxiety and panic attack, acute asthma, and hyperventilation.

Nutritional Management in Kidney Disease

Acute kidney injury

Acute kidney injury (AKI) represents a syndrome of acute derangement in kidney functions and usually reversible decline in GFR. The causes for AKI include (a) prerenal causes (due to hypovolemic states such as acute hemorrhage, diarrhea, and gross insensible losses such as burns), (b) intrinsic renal vascular disease (includes acute insults such as small vessel vasculitis, microangiopathies such as thrombotic thrombocytopenic purpura, and chronic vascular insults such as hypertensive nephrosclerosis), (c) intrinsic glomerular diseases (includes primary glomerulonephritides or secondary to paraneoplastic and drug-induced or systematic rheumatologic etiologies), (d) intrinsic tubular/ interstitial (the commonest being acute tubular necrosis), and (e) obstructive nephropathy (includes urolithiasis, prostate disease, and retroperitoneal fibrosis).

Nutrition in AKI

Nutrition in AKI is an important component in the management:

(a) *Energy requirement*: Though requirements may vary, the general consensus is a calorie requirement of 25–30 kcal kg^{-1} day^{-1}.

(b) *Protein requirement*: Increases with severity of illness and initiation of dialysis. Nondialysis patients require 0.8–1.2 g kg^{-1} of protein a day and the critically ill require 1.2–1.5 g kg^{-1} per day or more. Also, enteral nutrition is preferred compared to parenteral nutrition as evidence supports the survival benefit of enteral nutrition over parenteral nutrition.

(c) *Vitamins and mineral requirement*: Patients with AKI receiving renal replacement therapy (RRT) have low plasma levels of vitamin C, thiamine, and folic acid compared to patients with AKI who do not need RRT. The significance of these deficiencies and outcomes upon replacement of these nutrients are unknown. Hypocalcemia is common among patients with AKI, the causes being increase in serum phosphorus levels caused by reduced GFR, skeletal resistance to parathormone, and decreased synthesis of 1,25(OH)2D3. Treatment of hypocalcemia depends on the severity and symptoms. In asymptomatic cases, correction of hyperphosphatemia with use of phosphate binders will correct serum calcium spontaneously. Patients with symptomatic hypocalcemia and a serum phosphorus between 8 and 10 should be dialyzed to correct hypocalcemia and hyperphosphatemia. Intravenous therapy with calcium chloride or calcium gluconate is only indicated in the presence of life-threatening hypocalcemia characterized by tetany, confusion, seizures, and QT interval prolongation in electrocardiogram.

(d) *Sodium and potassium requirement*: Sodium and potassium are restricted depending on urinary excretion, edema, serum sodium levels, and dialysis needs. During the oliguric phase of acute kidney injury, sodium and potassium may be restricted to 500–1000 mg per day and 1000 mg per day, respectively.

Chronic kidney disease

Chronic kidney disease (CKD) is defined as the presence of kidney damage or decreased kidney function for 3 or more months irrespective of the cause. The time duration of 3 months is necessary to differentiate AKI from CKD.

Nutrition Assessment in Patients with Chronic Kidney Disease

Nutrition assessment is a major component of kidney disease management. There is no single measure to assess malnutrition in a patient with kidney disease. The following criteria have been proposed to identify kidney disease-related protein energy wasting:

Serum chemistry

- Serum albumin < 3.8 g dl^{-1}
- Serum prealbumin < 30 mg dl^{-1} (transthyretin) (applicable only for patients on maintenance hemodialysis since the serum levels may vary depending on GFR in patients with CKD stage 2–4)
- Serum cholesterol < 100 mg dl^{-1}

Body mass index (BMI)

- BMI < 23 kg m^{-2}

- Unintentional weight loss over time: 5% over 3 months and 10% over 6 months
- Total body fat percentage < 10%

Muscle mass

- Muscle wasting: reduction in muscle mass by 5% over 3 months or by 10 % over 6 months
- Reduced midarm muscle circumference area (>10% reduction in comparison to 50 percentile of reference population)
- Creatinine appearance

Dietary intake

- Unintentional low dietary protein intake $<0.80\ g\ kg^{-1}\ day^{-1}$ for at least two months for dialysis patients or $<0.6\ g\ kg^{-1}\ day^{-1}$ for patients on CKD stages 2 to 5
- Unintentional low dietary energy intake $<25\ kcal\ kg^{-1}\ day^{-1}$ for at least 2 months

At least three out of the four listed categories (and at least one test in each of the selected categories) must be satisfied for the diagnosis of kidney disease-related PEW. Optimally, each criterion should be documented on at least three occasions, preferably two to three weeks apart. In short, PEW may be suspected if the serum albumin is $<3.8\ g\ dl^{-1}$, serum prealbumin $<30\ mg\ dl^{-1}$, and serum cholesterol $<100\ mg\ dl^{-1}$.

Nutrition Management of Patients with CKD

(a) *Energy requirement*: Though energy requirement largely depends on metabolic demand depending on the stage of CKD, 25–30 kcal $kg^{-1}\ day^{-1}$ is acceptable energy requirement in CKD.

(b) *Protein requirement*: Kidney Disease Improving Global Outcomes (KDIGO) guidelines recommend protein restriction of 0.6–0.8 $g\ kg^{-1}$ in predialysis patients. However, the benefit of protein restriction in patients receiving maintenance dialysis is unclear. Protein intake <0.6 or >0.8 $g\ kg^{-1}$ did not show any significant benefit in terms of reduced CKD progression or mortality benefit. Protein restriction in CKD patients with nephrotic range proteinuria is unclear. Evidence-based recommendations in this subgroup are scanty, though it is generally believed that protein restriction of 0.8 $g\ kg^{-1}\ day^{-1}$ may be safe in this subgroup.

(c) *Sodium requirement and potassium requirement*: The 2012 KDIGO guidelines recommend sodium intake of $<2\ g\ day^{-1}$ in all adult patients with CKD and a potassium intake of 40–70 mEq day^{-1} (1500–2700 mg day^{-1}).

(d) *Calcium, phosphorus, and vitamin D*: Hyperphosphatemia, hypocalcemia, and hypovitaminosis D are the abnormalities commonly noted in patients with CKD. KDIGO guidelines recommend a moderate phosphate dietary restriction of 900 mg day^{-1} in patients with CKD. The target serum phosphorus goal in CKD patients is between 3.5 and 5.5 mg dl^{-1}. If dietary restriction fails to correct phosphorus to normal levels, then phosphate binders are indicated. Calcium generally corrects with use of phosphate binders. Calcitriol or activated vitamin D deficiency is common in CKD. CKD patients with parathormone levels (PTH) > 300 pg ml^{-1} should receive calcitriol according to KDIGO guidelines. Oral doses of calcitriol (0.5–1.0 μg) or doxercalciferol (2.5–5.0 μg) can be given two or three times weekly. Alternatively, a lower dose of calcitriol (0.25 μg) can be administered daily. The goal of therapy is to keep PTH to a target range of 150–300 pg ml^{-1}.

Dietary Management of Renal Stones

In general, increased fluid intake is associated with reduced recurrence of kidney stones. The exact quantity of fluid intake needed to achieve this remains unclear. One study noted that the maintenance of urine output $>2\ l\ day^{-1}$ decreases recurrence of kidney stones. Another study showed that an increase in urine output of 320 ml day^{-1} from baseline was associated with a decreased incidence of kidney stones, thereby emphasizing the concept that any increase in fluid intake decreases risk for recurrent kidney stones. Grapefruit juice is associated in observational studies to be associated with increased risk for kidney stones, whereas coffee, tea, and alcohol lower risk for kidney stones. Lowering animal protein intake, increasing consumption of fruits and vegetables, lowering sodium intake (80–100 meq day^{-1}), a normal calcium intake (1200 mg day^{-1}), and decreasing sucrose and fructose intake decreased risk for stone formation.

Nutrition and Its Effects on Kidney

Obesity and kidney disease

Obesity has become a pandemic. Obesity adversely affects multiple morbidities that in turn result in deranged kidney functions. Obesity increases risk for hypertension, diabetes, and metabolic syndrome, which are all risk factors for CKD. Data from the Framingham Offspring Study showed the independent association of obesity and kidney disease in spite of adjustment for the confounders such as hypertension, diabetes, and metabolic syndrome. Focal segmental sclerosis and obesity-related glomerulopathy are two specific types of kidney diseases that are known to be independently associated with morbid obesity. An interesting observation in the association between obesity and kidney disease is the obesity paradox observed in patients with ESRD and receiving hemodialysis. Obese ESRD patients (BMI > 30) have better survival when compared to ESRD patients with BMI < 30. Though the exact mechanism is not known, the malnutrition–inflammation complex syndrome (MICS) has been indicted in this association. Nonobese ESRD patients are at increased risk for malnutrition. Malnutrition is known to be associated with systemic inflammation in this group, which increases risk for cardiovascular disease and all-cause mortality.

Common Food Stuffs and Effect on Kidney (Coffee, Tea, Alcohol, Tobacco, and Chocolate)

The association between coffee, tea, and kidney disease is unclear. Small studies have reported an increased GFR with

increasing coffee and tea intake, but the effect of this increased GFR associated with coffee intake on cardiovascular and mortality outcomes is unknown and yet to be studied. Alcohol consumption, especially moderate–excess consumption, has been shown to decrease risk for kidney disease. Several observational studies and a large meta-analysis confirmed these results. The exact mechanism underlying this association is unknown and patient characteristics that promote heavy alcohol consumption are suspected to confound this association. Randomized studies assessing this association are lacking and may not be viable considering the ethical issues surrounding the conduct of such a randomized trial. Tobacco in any form increases risk for incident CKD and is associated with CKD progression. Molecular evidence and small observational studies on healthy individuals show a protective effect of chocolate on kidney functions. However, the effect of chocolate on incidence of CKD, progression of CKD, cardiovascular, and mortality outcomes is unknown and needs to be studied.

Weight Loss Diets and Effect on Kidney

As discussed earlier, patients with MICS have increased risk for kidney disease, but those attempting intentional weight loss have decreased incidence of kidney disease. The Look AHEAD (Action for Health in Diabetes), a randomized controlled trial that assessed weight loss in patients with diabetes, showed that in a median follow-up of 8 years, intensive weight loss efforts decreased both CKD incidence and progression, hence alluding to a need to consider intentional weight loss as a adjuvant to other efforts to prevent CKD. There are many diets and medications claiming to achieve effective weight loss in obese patients. Weight loss diets and medications that aid with weight loss are unlikely to adversely affect kidney functions in healthy individuals with no prior kidney disease. However, the use of these modalities is not recommended in patients with existing kidney disease because most weight loss diets recommend high protein intake (some as high as 1.9 g kg^{-1} day^{-1}), which can have deleterious effects on kidney functions in this group of obese people with existing kidney disease.

Introduction

'Vitamin A' is the collective term for compounds that show the biological properties of retinol, including visual function and maintenance of epithelial tissues. This classification includes retinol (vitamin A alcohol), retinyl esters (vitamin A esters), and retinal (vitamin A aldehyde and retinaldehyde). Retinoic acid (vitamin A acid) is included, even though it does not sustain visual function, because it has been found to be the active metabolite that carries out many of the functions of vitamin A. These are isoprenoid compounds, having in common a polyene chain attached to a trimethyl-substituted cyclohexenyl ring (Figure 1). The term 'retinoids' refers to all compounds, natural or synthetic, that show some biological activity typical of vitamin A, such as promoting differentiation of cells; but not all retinoids can support all the functions of vitamin A, such as vision. Vitamin A compounds are not found as such in plant tissues, but rather are characteristic of the animal kingdom; the notable exception is 13-*cis* retinal, which serves as a chromophore in the purple membrane of certain halobacteria.

Vitamin A deficiency is still a major public health problem especially in developing countries, although much progress has been achieved during the past 50 years. It has been estimated that some 127 million preschool children have vitamin A deficiency and more than 6 million women develop night blindness during pregnancy.

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00591-2

Major Dietary Sources

Provitamin A carotenoids from plant sources are the major source of vitamin A for much of the world's population. These are provided by green leafy vegetables (GLV) and by orange-yellow fruits. Provitamin A carotenoids arise mostly from plant products: β-Carotene is the most active precursor of vitamin A and is widely distributed in plants, but other carotenoids (such as α-carotene and β-cryptoxanthin and β-apo-carotenals) can be important sources of vitamin A from particular foods. Other carotenoids, such as lycopene and xanthophylls (including lutein and zeaxanthin), are major carotenoids in some foods and can have other important physiological functions, but they have no provitamin A activity in higher animals. Biofortified foods with enhanced β-carotene content have been produced by conventional plant breeding (e.g., maize, carrots, and cassava) or by genetic engineering (golden rice).

Good food sources of preformed vitamin A (as retinyl esters) include liver, fish liver oils, egg yolks, and fortified foods (such as milk and breakfast cereals in the United States). Human milk is a very important source of vitamin A for the breast-fed infant. Other foods, such as sugar, monosodium glutamate, and cooking oils, are used as vehicles for fortification in other settings. Retinyl esters, for example, retinyl acetate and retinyl palmitate, are more stable chemically than is free retinol and hence are used in food fortification and food supplementation. The relative importance of these sources of vitamin A is very dependent on diet, that is, on agricultural, cultural, and behavioral patterns.

Typical estimates of absorption efficiency of preformed dietary vitamin A are 70–85%. Estimates of carotenoid absorption are usually much lower but are confounded by slow intestinal absorption and rapid metabolism; there is considerable species variability in absorption efficiency and in metabolism of carotenoids. Animal feeding studies show that the biological matrix of food carotenoids has profound effects on their bioavailability.

Metabolism, Storage, and Excretion

The importance of vitamin A in multiple physiological pathways is reflected in the redundancy of mechanisms for interconverting its forms and transporting it. This brief article cannot give full justice to these complementary pathways; the reader is referred to the Supplemental Reading for details.

Since both vitamin A and carotenoids are lipids, intestinal micelle formation with bile acids is essential for their absorption. Human subjects with impaired bile acid formation or flow (e.g., with biliary atresia) may require intramuscular supplementation with vitamin A and the other fat-soluble vitamins. Within the intestinal lumen, vitamin A esters are hydrolyzed to free retinol, which is absorbed as such; free retinol and carotenoids apparently are taken into intestinal cells by membrane-bound lipid transporters. Provitamin A carotenoids, such as β-carotene, are often cleaved within intestinal cells; this metabolism is predominantly by central cleavage (mediated by the enzyme carotene 15,15′-monooxygenase, CMO1 – formerly called carotene 15,15′-dioxygenase), although asymmetrical cleavage followed by chain shortening may play a role. Retinal, the final product of carotenoid cleavage, is enzymatically reduced to retinol. Free retinol is mostly reesterified within the intestinal cells, although some may be released as such into the blood circulation (Figure 2). The physiological ligand for this esterification process seems to be retinol bound to an intracellular retinol-binding protein (CRBP II, molecular weight approximately 14 600 Da, one of several small intracellular retinoid-binding proteins); the primary retinyl ester-synthesizing activity transfers fatty acid from phosphatidylcholine (lecithin retinol acyltransferase (LRAT)), although an acyl-coenzyme A-dependent esterifying activity (acyl-CoA:retinol acyltransferase (ARAT)) is also present.

Regardless of their dietary source, the retinyl esters are transported in the core of chylomicra in the lymph from intestinal cells. After removal of triacylglycerols by lipoprotein lipase as the lipoprotein particles circulate through peripheral tissues, the chylomicron remnants are rapidly taken up by

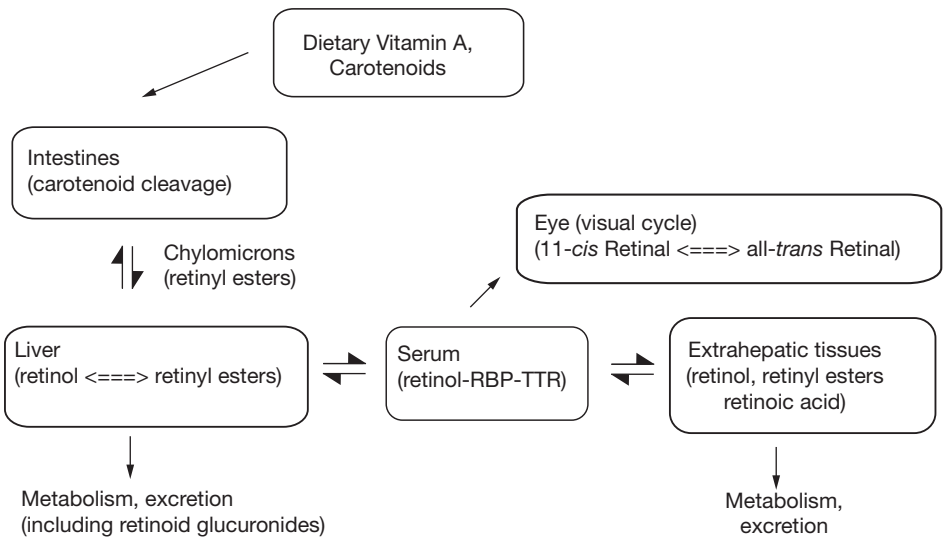

Figure 2 Metabolic interconversions of vitamin A forms.

hepatocytes in the liver, and the vitamin A esters are converted to retinol by retinyl ester hydrolase there. The resulting retinol is then either reesterified (primarily by LRAT, although ARAT activity may be important at high retinol concentrations) and stored in the liver or released into the plasma as a complex with plasma retinol-binding protein (RBP; also called RBP4). The two cell types involved in liver vitamin A metabolism are the hepatocytes (parenchymal cells) and the lipocytes (also called stellate cells, Ito cells, or fat-storing cells). The hepatocytes are the major site of RBP synthesis and retinol-RBP release; some retinyl esters are also found here. The lipocytes store retinyl esters in cytoplasmic lipid droplets, which also contain triacylglycerols and some cholesteryl esters within a phospholipid coat. After requirements of other tissues have been satisfied, vitamin A is stored in the liver, typically 50–80% of total body vitamin A in the well-nourished individual. Vitamin A in excess of immediate requirements is stored in the liver as esters of long-chain fatty acids (Figure 2); the ratio of liver retinol to retinyl esters decreases as total liver vitamin A increases, but typically, 95% of total liver vitamin A is present as the esters. Retinyl palmitate is the primary ester in the livers of most species, although significant amounts of other esters are found (especially oleate and stearate), and the liver retinyl ester composition can be affected by dietary fatty acid composition. Other organs, such as kidney, testes, and adrenal glands, also contain detectable retinyl esters. The concentration of retinyl esters in adipose tissue is low, but the significant mass of adipose tissue in the human body can account for a substantial amount of total vitamin A storage. The efficiency of liver storage of vitamin A is particularly noteworthy in the polar bear, where concentrations as much as 36 μmol g^{-1} (10 380 μg g^{-1}) of liver have been reported. Typical values for human liver vitamin A (autopsy specimens) are 0.44–0.74 μmol g^{-1} (126–211 μg g^{-1}) in the United States of America.

Because most forms of vitamin A are hydrophobic, the transport, metabolism, and function of vitamin A are dependent on a series of binding proteins, each specific for its ligand and tissue. Intracellular binding proteins serve as transporters and chaperones (CRBP forms for retinol, CRABLP and interstitial retinoid-binding protein (IRBP) forms for retinal, and CRABP forms for retinoic acid). Retinol-RBP is the major form of transport from liver to peripheral tissues; gene knockout studies have shown that delivery of retinyl esters via lipoproteins may be adequate for maintaining vitamin A in some tissues but that retinol delivered via RBP is essential under conditions of stress. Although the transport of vitamin A from other tissues back to the liver may be via retinyl esters transported by lipoproteins (normally present at about 5–10% the serum concentration of retinol-RBP), transport via retinol on RBP synthesized in the outlying tissues may be an important pathway (mRNA for plasma RBP has been detected in a number of other tissues in addition to liver). Plasma RBP typically has molecular weight of approximately 21 000 Da in mammalian species; the complete amino acid composition has been determined for several species, and the gene from some species has been cloned. RBP binds retinol with 1:1 stoichiometry. The hydrophobic retinol molecule fits into a 'barrel' within the protein, shielded from interactions with the aqueous environment. Holo-RBP, in turn, binds transthyretin in plasma (TTR; formerly called prealbumin); a TTR tetramer can bind up to four molecules of RBP. Usual concentrations of human plasma RBP are 1.9–2.4 μM (40–50 μg ml^{-1}); typically, total circulating RBP is 80–90% saturated with retinol ligand. Although retinol, retinal, and retinoic acid bind to RBP with similar affinity, retinol is present in highest concentrations in plasma and is the predominant ligand. Retinyl esters have much less affinity for RBP and are transported by serum lipoproteins instead.

The release of holo-RBP from liver hepatocytes is carefully controlled to maintain levels of circulating retinol within narrow limits, but the mechanism of this control is not yet clear. In the absence of adequate vitamin A, apo-RBP accumulates in the liver hepatocytes, ready to be released as soon as vitamin A is available (i.e., the basis of the relative dose response (RDR) assay for vitamin A deficiency, as discussed in the succeeding text). Clearly, this mechanism has developed because of the dichotomy of vitamin A action: vitamin A is essential, in small amounts, for proper differentiation and maintenance of epithelial cells, but excesses of vitamin A are toxic and must be avoided by the organism. A cell surface receptor, STRA6, facilitates the uptake of retinol from plasma RBP in tissues that are heavily dependent on retinoids; STRA6 may be coupled with intracellular LRAT to trap vitamin A as retinyl esters within cells.

Some studies have suggested linkage between RBP (known as RBP4 in this context) and obesity, diabetes, and insulin signaling. It has been proposed that activation of the JAK/STAT cascade by RBP-retinol, via a peroxisome proliferation-activated receptor (PPAR β/γ), upregulates target genes including those that control lipid homeostasis and inhibition of insulin signaling.

Retinol can be reversibly oxidized to retinal (vitamin A aldehyde) by aldehyde dehydrogenases (either cytosolic or microsomal) and retinal can be reduced back to retinol; retinal can be oxidized to retinoic acid by aldehyde dehydrogenases, but retinoic acid cannot be converted back to the other forms. Thus, retinol, retinyl esters, and retinal have equal biological activity because they are freely interconverted; retinoic acid fills some (but not all) of the functions of retinol, but it and its derivatives are not stored. Concentrations of retinoic acid are carefully regulated, by regulation of both production and catabolism. Not surprisingly, genetic expression of many of the enzymes involved in retinoid metabolism is regulated by retinoic acid (see succeeding text). Typical human serum concentrations of retinoic acid are 5–10 nM (1.5–3 ng ml^{-1}), compared with typical retinol concentrations of 1–2 μM. Retinoic acid presumably can be transported in plasma by albumin as well as by RBP. Retinoyl β-glucuronide and retinyl β-glucuronide (formed in the liver from retinoic acid and retinol, respectively) are secreted into the bile but can be hydrolyzed and reabsorbed in the intestine (enterohepatic circulation); both these compounds have vitamin A activity in a variety of tests, are found in human blood, and may have regulatory roles in vitamin A function.

In rats and mice, catabolism of vitamin A occurs by oxidation of the cyclohexenyl ring (particularly at the 4-position), epoxide formation at the 5,6-positions, hydroxylation of the ring methyl groups, and chain shortening. A set of cytochrome P450 enzymes (CYP26A1, CYP26B1, and CYP26C1) are primarily responsible for catabolism of retinoic acid, although

other cytochrome enzymes can also be involved. All-*trans* retinoic acid induces its own catabolism by upregulating CYP enzymes. The resulting metabolites are generally inactive, although some may have a little biological activity. These more polar retinoids are excreted in the urine and in the bile.

The rat has served as a valuable model for vitamin A metabolism in the human, particularly for aspects that cannot be studied readily in humans. Mathematical modeling of kinetic studies carried out in rats has shown that there is extensive cycling of liver vitamin A stores and extensive recycling of vitamin A between liver and other tissues; this assures an ample supply of retinoid to tissues in response to immediate needs. Kinetic models of human vitamin A metabolism are consistent with these findings.

Functions in the Body

Vision

The major roles of vitamin A are (a) in vision and (b) in control of gene expression (including differentiation of epithelial tissues, support of reproductive functions and the immune system, and a host of other systems). Metabolism of vitamin A in the retina of the eye is unique, in keeping with the unusual role of vitamin A in that tissue. Vitamin A is stored in the retinal pigment epithelium as retinyl esters. All-*trans* retinyl esters are simultaneously hydrolyzed and isomerized to 11-*cis* retinol by an isomerohydrolase enzyme (RPE65) that uses the free energy of hydrolysis of the retinyl esters to drive the isomerization reaction. 11-*cis* Retinol, a compound unique to the eye, is then oxidized to 11-*cis* retinal by an alcohol dehydrogenase. 11-*cis* Retinal is transferred from the pigment epithelium cells to the rod cells by IRBP, a distinct binding protein (MW 140 000). In the rod cells, 11-*cis* retinal binds (as a Schiff base with the ε-amino group of a specific lysine residue) to the protein opsin to form the visual pigment, rhodopsin. When a photon of light is absorbed by a rhodopsin complex, the 11-*cis* retinal is isomerized to all-*trans* retinal and released from the protein complex; the resulting conformation change of the protein initiates a cascade of reactions, resulting in a neural signal to the brain. The protein opsin is then available to bind another molecule of 11-*cis* retinal for another round of the visual cycle. The all-*trans* retinal that was released from the protein complex is transferred back to the pigment epithelium via IRBP, enzymatically reduced to all-*trans* retinol, and esterified again. In contrast to the high turnover rates of vitamin A in other tissues, vitamin A in the eye is highly conserved, with little leakage back to the liver. Prolonged vitamin A deficiency, however, leads to reduced sensitivity to light, usually first noted as impaired vision at night (night blindness). These effects of vitamin A deficiency are generally reversible by subsequent vitamin A supplementation.

In a very different role of vitamin A in the eye, the cornea depends on vitamin A for proper cell differentiation and for secretion of protective glycoproteins. In vitamin A deficiency, these tissues lose integrity and are susceptible to attack by opportunistic bacteria; such attack may result in permanent scarring and permanent vision loss. These effects of vitamin A deficiency, unlike those in the retina, may not be reversible by subsequent vitamin A supplementation. Such vitamin A-dependent corneal degeneration (given the general name 'xerophthalmia') accounts for an estimated 500 000 new cases of blindness in preschool children in the world each year.

Control of Gene Expression

Many functions of vitamin A are the result of its regulation of gene expression, mediated via retinoic acid. To date, more than 500 genes, with a great variety of functions, are known to be under control of retinoic acid; proteomic analyses have revealed unanticipated targets. The dominant nuclear receptor proteins responsive to retinoids are RAR (retinoic acid receptors), RXR (retinoid x receptors), and PPAR. The three RAR forms (RARα, RARβ, and RARγ) are activated by all-*trans* retinoic acid. The three RXR forms (RXRα, RXRβ, and RXRγ) initially were believed to be activated by 9-*cis* retinoic acid, but intracellular concentrations of this retinoid are generally undetectably low; however, some synthetic analogs ('rexinoids') and various other natural lipids are effective ligands. RARs form heterodimers with RXR to bind to a specific retinoic acid response element (RARE) in the control element of a gene; RXR can form homodimers or heterodimers with a variety of nuclear receptor proteins (vitamin D receptors, thyroid hormone receptors, and PPARs, among others) (**Figure 3**), providing an exquisite mechanism for control of multiple cellular pathways.

In addition to these genomic, transcriptional roles of retinoic acid, function of some proteins can be controlled via retinoylation, covalent addition of retinoic acid to a protein via a thioester bond. These modifications are cell-specific and posttranslational. Effects apparently include cell differentiation, cell growth, and steroidogenesis.

Human Health

Infection and Disease

From the early days of vitamin A research, it was observed that vitamin A-deficient animals are more susceptible to disease. Supplementation of children with vitamin A reduces the severity of measles and diarrhea (although vitamin A supplementation may not reduce the incidence and duration of diarrhea). Supplementation of measles patients with vitamin A (200 000 international units (IU), i.e., 60 000 μg of RE, 209 μmol) during infection reduces hospital stay and mortality rate and is now recommended by WHO in communities where vitamin A deficiency is prevalent. On the other hand, infectious diseases such as measles, chickenpox, and respiratory diseases can lead to vitamin A deficiency. Currently, it is not believed that vitamin A supplementation can provide any benefit for other respiratory diseases (non-measles pneumonia). The mechanistic role of vitamin A status in tuberculosis, malarial infection, and HIV infection is not clear. However, it has been shown that vitamin A public health programs can have a tremendous impact on child morbidity and mortality in developing countries.

The mechanism(s) by which retinoids affect the immune system have not yet been delineated, but it seems safe to assume that control of gene expression is involved. In at least

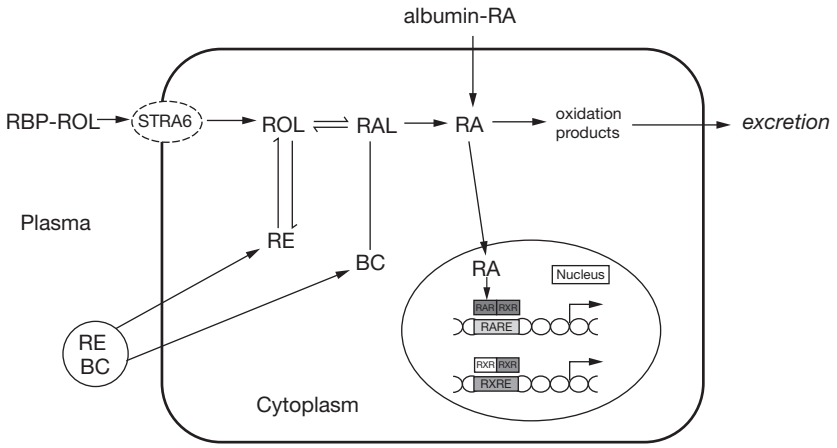

Figure 3 Intracellular metabolism and nuclear mode of action of retinoids. ROL, retinol; RAL, retinal; RA, retinoic acid; RE, retinyl esters; BC, β-carotene; RBP, plasma retinol-binding protein; STRA6, cell surface receptor for retinol-RBP; RAR, retinoic acid receptor; RXR, retinoid X receptor; RARE, retinoic acid receptor element; RXRE, retinoid X receptor element.

some experiments, the function of vitamin A can be filled by all-*trans* or 13-*cis* retinoic acid, consistent with current knowledge of retinoids and gene expression. Both antibody-mediated and cell-mediated immune responses are reduced in vitamin A deficiency. Interpretation of human studies of the relationship between vitamin A status and immune response is complicated by the fact that RBP is an acute-phase protein; the release of retinol-RBP from liver and thus plasma retinol concentrations (often used as a convenient measure of vitamin A status) fall during infection even in vitamin A-replete subjects.

Dermatology

One of the first pharmaceutical applications of retinoids was the use of 13-*cis* retinoic acid (isotretinoin, Accutane) to combat cystic acne, ichthyosis, and follicular keratosis; 13-*cis* retinoic acid promotes CRABP II mRNA expression and inhibits sebaceous gland size and activity. Routine use of 13-*cis* retinoic acid, however, is restricted because of dangers of teratogenicity. The process of keratinization (differentiation and maturation) of skin cells is affected both by deficiency and by excess of retinoids. Retinoids are now used clinically to treat psoriasis, ichthyosis, Darier's disease, and other disorders of keratinization, acne, and photoaged skin. 3,4-Didehydroretinol (dehydroretinol or vitamin A_2) and its esters, as well as trace amounts of retro-retinoids, are found in human skin (more so in epidermis than in dermis) as well and may have specific roles there. Synthetic retinoids, such as etretinate and the ethyl ester of the arotinoid TTNPB (Figure 1), as well as the naturally occurring retinoyl β-glucuronide, have been developed in attempts to reduce the toxicity of the naturally occurring retinoic acids without losing efficacy. Retinol (or retinyl esters) is frequently used as an ingredient in skin lotions.

Cancer Prevention and Treatment

At times, there has been great interest in retinoids for the prevention and treatment of cancer. They can inhibit cell transformation and tumor development in a variety of cell and animal models, but the effects are not uniform with all malignancies. In general, it seems that retinoids may not prevent initiation of tumors, but more likely interfere with the promotion process. They exert these effects by modulating growth, differentiation, and apoptosis of cells; most, if not all, of these effects may be explained by the role of retinoids in control of gene expression.

Retinoids have been tested against a variety of cancers in human and animal studies. *N*-(4-Hydroxyphenyl)-retinamide (4-HPR; fenretinide) has been tested clinically for the prevention of recurrence of human breast cancer; although results are promising, some toxicity (owing to interference with normal retinol metabolism) has been observed. Incidence of skin tumors associated with xeroderma pigmentosum is reduced by treatment with 13-*cis* retinoic acid. Perhaps the most dramatic application is the use of retinoic acid (tretinoin) against promyelocytic leukemia; this disease results from a chromosomal translocation producing the fusion of the RARα gene with the PML gene to produce an oncogene and responds well to high doses of all-*trans* retinoic acid.

Requirements and Recommended Intakes

Vitamin A deficiency is still a significant public health problem in many parts of the world, especially in young children because they are born with low body stores of vitamin A (placental transfer is limited). A variety of public health interventions are used to combat vitamin A deficiency, including dietary diversification (increased consumption of GLV and orange-yellow fruits and vegetables), food fortification, biofortification with provitamin A carotenoids (as mentioned earlier), and supplementation (periodic dosing with vitamin A in oil).

Liver concentrations provide the best estimate of vitamin A status. Human liver specimens can be difficult to obtain, but analysis of autopsy specimens can be useful in evaluating the vitamin A status of a population. As indicated earlier, serum retinol levels are maintained nearly constant (via an as-yet unclarified mechanism) and are not generally useful in

assessing vitamin A status, except when liver vitamin A reserves fall well below 0.07 μmol g^{-1} (20 μg g^{-1} of liver). Serum (or plasma) retinol levels are normally 1–2 μM (290–570 ng ml^{-1}) across a wide range of mammalian species.

Because liver concentrations of vitamin A are not readily measured, and serum retinol values are not an adequate indicator of an individual's vitamin A status, several indirect methods have been developed. Conjunctival impression cytology (CIC) evaluates the development of squamous metaplasia (enlarged epithelial cells) and loss of goblet cells from the conjunctiva of the eye by histological examination of cells transferred from the cornea to filter paper. The relative dose response (RDR) depends on the release of retinol-RBP from the liver into the serum after a large oral dose of vitamin A (typically, 450 μg of retinyl acetate in human studies); as described earlier, apo-RBP accumulates in the liver in vitamin A depletion. The RDR is calculated as

$$\text{RDR} = \{(A_5 - A_0)/A_5\} \times 100\%$$

where A_5 represents the serum retinol concentration at 5 h after the oral dose and A_0 represents the fasting serum retinol concentration at the time of the dose. Studies in both humans and rats indicate that an RDR value greater than 20% indicates liver vitamin A reserves less than 0.07 μmol g^{-1} (<20 μg g^{-1} of liver), that is, inadequate vitamin A status. The RDR assay requires, of course, that the oral dose be absorbed normally (an intramuscular injection has been used in human subjects with impaired absorption) and that protein metabolism is normal: protein deficiency or zinc deficiency or liver cirrhosis impairs the dose response. An alternate approach, the modified relative dose response (MRDR), uses the vitamin A analog 3,4-didehydroretinol (vitamin A_2, a form found in some freshwater fish and found in very low levels in human skin). The ratio of vitamin A_2 to vitamin A_1 in serum retinol at 5 h after an oral dose is used as a measure of vitamin A status, with high values indicating poor vitamin A status. Chlorinated vitamin A analogs have been used in a similar fashion. The RDR and MRDR, as well as CIC, have been used successfully in human population studies. Isotope dilution of tracer-labeled vitamin A (radioactive or stable-isotope labeling) has been used to estimate human vitamin A status, and recent developments in mass spectrometer technology are making this technique more useful.

Because of confusion among the various units for presenting vitamin A values, the concept retinol equivalent (RE) has been proposed. One RE equals 1 μg of all-*trans* retinol, either free or as the retinyl component of a retinyl ester; 1 RE = 3.33 IU of vitamin A, or 3.5 nmol of retinol or retinyl ester. Although the exact vitamin A value of carotenoids depends on several factors, the RE was defined as 6 μg of all-*trans* β-carotene or 12 μg of other provitamin A carotenoids (10 IU of provitamin A carotenoid). To account for updated findings on provitamin A value of carotenoids, the retinol activity equivalent (RAE) has been defined more recently as 1 μg of all-*trans* retinol, 12 μg of all-*trans* β-carotene, or 24 μg of other provitamin A carotenoids.

Nutritional requirements for vitamin A have not been well defined because of the diversity of vitamin A functions. In animal studies, intakes of 3–8 RE per day per kilogram of body weight (10–28 nmol $day^{-1}kg^{-1}$ of body weight) cure deficiency symptoms, and intakes of 30–60 RE per day per kilogram of body weight (100–210 nmol $day^{-1}kg$ of body weight) produce optimal growth. Kinetic studies of vitamin A metabolism in rats show that irreversible loss of vitamin A is decreased on low vitamin A intakes. Studies on vitamin A requirements have not yet addressed functional criteria such as immune function and control of genetic function.

Recommended intakes of vitamin A (preformed plus provitamin A carotenoids) are given in Table 1. Because of differences in assumptions, recommendations by the WHO/FAO are slightly different from the Canadian/US recommendations.

Toxicity

Numerous cases of human vitamin A toxicity have been reported (and doubtless many go unreported), owing to either acute (single or a few large doses ingested over a brief period of time) or chronic intake (moderately high doses taken frequently for periods of months or years). Acute toxicity in human adults is reported from doses of 300 000–10 000 000 RE (1000–35 000 μmol); chronic doses of 15 000–300 000 RE (50–1000 μmol) have produced hypervitaminosis A. Symptoms include headache, vomiting, diplopia, alopecia, dryness of mucous membranes, desquamation, bone abnormalities,

and liver damage. However, single oral doses of 60 000 RE in oil have been successfully used in vitamin A intervention programs for preschool children, with transient toxic symptoms observed in no more than 3% of subjects. Massive doses of β-carotene are not toxic, but may be less efficiently absorbed and used than vitamin A itself. (Conversion of provitamin A carotenoids is reduced when vitamin A status is high.) Rodent animal models have been extremely valuable in elucidating vitamin A requirements and metabolism, but the rat seems to be much less susceptible to hypervitaminosis A than is the human.

The toxic effects of high vitamin A intakes are mediated by serum retinyl esters; retinol-RBP concentrations are maintained at normal levels in hypervitaminosis A, but serum retinyl esters are markedly elevated, bypassing the normal homeostatic controls on vitamin A transport. Some carnivores, including the dog, are unusual in having high fasting levels of serum retinyl esters, presumably reflecting differences in lipoprotein metabolism in these species; the implications of this for vitamin A metabolism and for resistance to hypervitaminosis A are not clear.

The most tragic consequences of excessive vitamin A intake are teratogenicity (specifically, malformations of the cranium, face, heart, thymus, and central nervous system) and embryotoxicity. Acidic retinoids such as those that have been used in dermatology are particularly potent, as they can attain high serum levels and can readily pass the placental barrier. Although large intakes of vitamin A itself (>7500 RE day^{-1}, 26 μmol day^{-1}) early in human pregnancy can cause birth defects (probably because of metabolism of retinol to retinoic acid), serum concentrations of retinol and retinyl esters are normally maintained at moderate levels during pregnancy. It is assumed that these teratogenic effects are related to the important role of retinoids in the differentiation of cells and that these effects are mediated via the nuclear receptor proteins. (Interestingly, the retinoid β-glucuronides are much less teratogenic than retinoic acid.) In view of these teratogenic effects occurring at less than 10 times the recommended daily intakes, a consensus of several professional organizations is that women should avoid vitamin A supplements during the first trimester of pregnancy and that subsequent supplements, if taken at all, should be prudently limited to 8000 IU day^{-1} (2400 μg RE, 8.5 μmol), although 10 000 IU (3000 μg RE, 10 μmol) appears to be safe.

Future Directions

The pathways by which vitamin A is needed for vision and for control of gene expression have been elucidated. It is possible that new roles for vitamin A and retinoids will be discovered. The molecular role of vitamin A in immune function remains to be explained. Many aspects of vitamin A metabolism (including the mechanisms maintaining plasma concentrations of retinol-RBP) need further clarification. A current pressing need is improved methods for assessing human vitamin A status so that nutrition intervention programs can be more efficiently targeted; it seems likely that functional assays of vitamin A status (based on gene expression) will be developed. Such functional assays of vitamin A status will also lead to better estimates of vitamin A requirements and dietary allowances.

Introduction

Vitamin A is a fat-soluble micronutrient required in small amounts for embryonic development and for maintenance of nearly all tissues throughout the life span. The chemical and physical properties of vitamin A are major determinants of its metabolism, and they also dictate the procedures used for its determination. The International Union of Pure and Applied Chemistry specifies that "the term vitamin A should be used as the generic descriptor for retinoids exhibiting qualitatively the biological activity of retinol. This term should be used in derived terms such as vitamin A activity, vitamin A deficiency, vitamin A antagonist." The term retinoid, which is now commonly used to describe vitamin A and its metabolites and analogs, was coined as a generic term to cover a large number of synthetic analogs that have structural similarity to retinol, but not necessarily vitamin A activity.

Vitamin A in foods is found two forms. Certain carotenoids, also known as provitamin A, are present in foods of plant origin and, when ingested, as a precursor for the conversion to vitamin A in vertebrate tissues. Retinol and its esterified form, retinyl ester, which are also known as preformed vitamin A, are present in certain foods of animal origin. Much of the retinol or retinyl ester that is used as a component of feedstuffs, special diets, and formulas and for the fortification of foods is of synthetic origin, identical chemically to the vitamin A in foods. This article will focus on retinol and retinyl esters because these are the two major forms of vitamin A in foods and tissues. While the vitamin A metabolites retinal and retinoic acid are both extremely important physiologically, neither are quantitatively significant forms in the diet. *In vivo*, the function of retinyl esters and retinol appears to be exclusively to serve in the storage and transportation of vitamin A, which can be converted to these active metabolites in appropriate tissues.

Specific Forms of Vitamin A

Retinol

Retinol, Figure 1(a), is a lipid alcohol of empirical formula $C_{20}H_{30}O$ and molecular mass 286.44 g mol^{-1}. Although the first report of the biological requirement for vitamin A was published in 1913, it was not until the 1930s that the structure of retinol was known and its complete chemical synthesis was accomplished. A Nobel Prize in Chemistry was awarded to Paul Karrer in 1937 for his research that elucidated the structures of retinol, β-carotene, and other vitamins. Purified retinol is crystallized as a pale-yellow solid. The retinol molecule is composed of three parts, an ionone ring; a conjugated, methyl-substituted side chain; and a terminal hydroxyl group (Figure 1(a)). If retinol is produced by the metabolism of β-carotene, then its ring will be a β-ionone ring. However, some foods such as carrots contain a portion of carotene, as the α-carotene isomer (structurally α, β-carotene) and the ring of the retinol produced by its metabolism may be in the α-configuration, with the double bond between carbons 4 and 5.

The double bonds of retinol are generally in the all-*trans* configuration. While *cis* double bonds at position 9 or 11 are known to exist, such isomers are mainly found in the metabolites of retinol, such as 11-*cis*-retinal. The system of conjugated double bonds in the retinoid structure allows for very efficient absorption of light in the UV range (see the section 'Spectrophotometry of Vitamin A'). This intrinsic absorptive property is critical to the visual function of retinal *in vivo*. Light absorption is also the basis of many of the methods used for the detection and determination of retinol and related metabolites in various analytic procedures.

In vivo, the properties of retinol are modified by their interactions with specific proteins and lipid-containing structures. Retinol present in plasma is bound to a specific transport protein, retinol-binding protein (RBP), while retinol present within the cytoplasm of cells is mostly bound to one of several specific intracellular RBPs. The retinol molecule, being lipophilic, is 'membrane-seeking,' and thus, in the absence of sufficient binding capacity by these proteins, the retinol molecule can intercalate into the membrane phospholipid bilayer. Various adverse effects including membranolytic properties on the cell's plasma membrane and intracellular organelle membranes have been described.

Other forms of vitamin A found in nature include 3,4-dehydroretinol, a form present in tissues of freshwater fish and also produced *in vivo* in skin. The isomer of retinol, α-retinol, is present in some foods and has been described as having partial vitamin A activity.

Retinyl Esters

Retinyl esters are the most abundant form of vitamin A in most tissues and the form often used in preparing diets, supplements, and fortified foods. In a retinyl ester, the C-15 alcohol group of retinol is esterified with a fatty acid, usually a long-chain aliphatic acid such as palmitic acid. Esterification increases the lipophilicity of the retinyl ester molecule significantly, with retinyl palmitate being more lipophilic than, for example, retinyl acetate. Purified retinyl palmitate is a very viscous oily compound and dark red-orange in color. The empirical formula and molecular mass of retinyl palmitate are $C_{36}H_{60}O_2$ and 525 g mol^{-1}, respectively. The esterification of retinol improves its stability toward oxidation.

In vivo, retinyl esters are usually found dissolved in other neutral lipids. In plasma, retinyl esters constitute a minor component of the core lipid of plasma lipoproteins. In cells, retinyl esters are found within lipid droplets admixed with triglycerides and cholesteryl esters. Most of the data available on retinyl esters are from studies in rats and some from human tissues that, in general, show a similar pattern of esters among tissues. In the

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00590-0

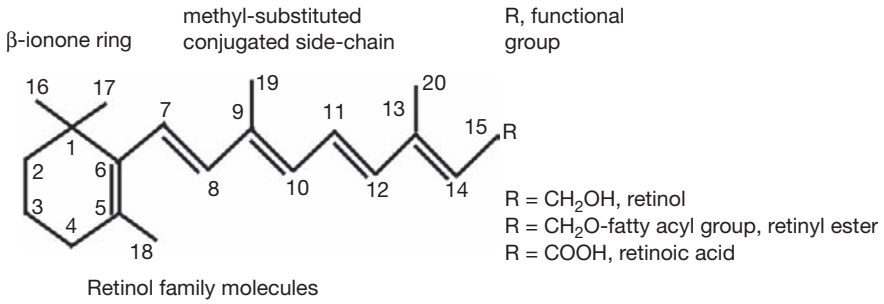

Figure 1 All-*trans*-retinol illustrating the IUPAC numbering system.

liver, where the majority of vitamin A is stored, retinyl palmitate and some retinyl stearate are the predominant retinyl esters, mostly contained in vitamin A-containing lipid droplets within the cytoplasm of hepatic stellate cells. In chylomicrons, which are formed during vitamin A absorption, retinyl palmitate, retinyl stearate, and retinyl oleate are predominant, while in milk, the variety of retinyl ester species was broader and included medium-chain fatty acid esters of retinol. Other organs that have significant stores of retinyl esters include the kidney and lung, although their concentrations are generally lower than those in the liver, while numerous other tissues may contain even lower concentrations. The retinal pigment epithelial cells of the retina comprise a concentrated, but small, retinyl ester pool. Although these patterns are common in the rodent and appear similar in humans, several interesting species-related differences have been reported. For example, some carnivores store more vitamin A per g weight in the kidney than in the liver. Dietary vitamin A intake is an important determinant of vitamin A concentrations in most tissues.

Retinal

Retinal is a metabolite of retinol, formed by the oxidation of the C-15 alcohol group. It is also the first metabolite of β-carotene cleavage that is formed by oxidative cleavage of the C-15,15′ double bond. Except for the aldehyde group, the structure of retinal is identical to that of retinol. Its empirical formula is $C_{20}H_{28}O$ and molecular mass 284.4 g mol^{-1}. Through redox reactions that are catalyzed by different enzymes, retinal can be either reduced to form retinol or oxidized to form retinoic acid. The reductive reaction appears to be predominant, as feeding retinal results in an increase in the concentration of retinyl esters in vitamin A-storing tissues. Normally, however, the concentration of retinal is very low, even undetectable, in most tissues because all-*trans*-retinal is present only transiently as a metabolic intermediate. In the retina, however, the concentration of retinal, in the form of the 11-*cis* isomer, is relatively high. Most of this 11-*cis*-retinal is bound as a Schiff base to one of the visual pigment proteins, either rhodopsin, which is a major constituent of the outer membrane disks of rod cells, or one of the iodopsins in the outer membrane disks of cone cells. The binding of 11-*cis*-retinal serves to sequester retinal within the protein structure in a manner that shifts the wavelength of maximal light absorption from 365 nm, as found for 11-*cis*-retinal in organic solvent, to higher wavelengths for rhodopsin, 500 nm, and for each of the three major cone pigments, resulting in selective 'tuning' of the red, green, and blue cone cells for their specific color vision. During the process of phototransduction, also known as photobleaching, 11-*cis*-retinal becomes released from the visual pigment proteins and then is regenerated through a series of reactions referred to as the visual cycle. This cycle involves the metabolism and isomerization of the retinoid and then the binding, again, of newly generated 11-*cis*-retinal with a visual pigment protein.

Retinoic Acid

All-*trans*-retinoic acid (vitamin A acid) was first reported in 1946. It is a crystalline yellow solid of empirical formula $C_{20}H_{38}O_2$ and molecular mass 300.0 g mol^{-1}. The UV absorption properties of retinoic acid are similar to those of retinol, but the absorption maximum is slightly redshifted to ~345 nm, and, due to the carboxylic acid nature of the molecule, the absorption spectrum is sensitive to changes in pH.

In plasma and cells, retinoic acid is typically present at much lower concentrations than either retinol or retinyl ester. Similar to fatty acids, retinoic acid binds to albumin in plasma. Essentially, all of the biological functions of retinol, except for its role in vision, can be replaced by retinoic acid. This was first shown in studies in which retinoic acid was fed to vitamin A-deficient rats, which thereafter resumed growth and were generally healthy. However, visual function was still impaired after retinoic acid treatment, indicating that *in vivo* there is no mechanism for the reduction of retinoic acid to retinal.

The functions of retinoic acid *in vivo* are mediated to a significant extent through its binding to nuclear receptor proteins known as retinoic acid receptors (RARs), RAR-α, RAR-β, and RAR-γ, which are transcription factors. A larger number of genes, estimated at over 300, are responsive to retinoic acid under physiological conditions, with most showing increased but some decreased transcriptional activity in the presence of retinoic acid. Well-defined DNA sequences, known as retinoic acid response elements, have, however, been characterized for only a small proportion of these genes. Receptors may also be involved in indirect mechanisms, such as through protein–protein interactions and nongenomic mechanisms.

Oxidized Metabolites

The retinoid structure is subject to oxidation by several types of enzymes, including cytochromes P450 that introduce epoxide,

hydroxyl, and keto groups onto the ring structure or the side chain of the molecule, creating molecules that are referred to collectively as polar metabolites. The polar metabolites of retinol and retinoic acid have been found. While their function is still debatable, it is generally thought that they are formed as elimination products during the normal metabolism of vitamin A, especially when higher amounts of retinol are consumed or after pharmacological administration of retinoic acid. Very polar metabolites, which are soluble in aqueous media, can be formed by the addition of groups such as glucuronic acid, forming retinyl or retinoyl β-glucuronide. Polar and aqueous-soluble metabolites are found physiologically in bile and are excreted mainly in the feces and, in lesser quantity, in urine.

Vitamin A for Use in Foods and Supplements

Stability. For use in the food industry, vitamin A is added as carotene or as retinol or retinyl ester. Antioxidants may be added to vitamin A premixes. Such compounds are butylated hydroxyanisole, butylated hydroxytoluene (BHT), and tocopherols (vitamin E). Chelators may be added to bind trace metals (especially iron and copper) that accelerate the degradation of vitamin A. Gelatin and food starches may be added to commercial preparations of vitamin A as carriers and/or to improve stability. The stability of vitamin A is also adversely affected by acidity, and below a pH of 5.0, vitamin A is very unstable. Thus, compounds that maintain a neutral pH are likely to improve the stability of vitamin A. Carotenoids and vitamin A compounds are easily degraded by light, oxidants, and heat. Therefore, they should always be stored in the cold under conditions that exclude light and air (see succeeding text). This is especially true for any reference standards, which should be checked periodically for quality.

Preparations Used Specifically for Vitamin A Supplementation

Certain specialized preparations of vitamin A have been used for various purposes, especially for supplementation in populations with a low intake of vitamin A.

Vitamin A capsules

Vitamin A in the form of retinyl palmitate is the major form that has been used for reducing vitamin A deficiency in at-risk populations. Because retinol is stored in the body as retinyl ester, which can be hydrolyzed to release retinol as needed, it is possible to deliver a relatively large dose of vitamin A, but below an amount that would result in acute toxicity, on a periodic basis. Doses equal to 100 000–200 000 international units, 30–60 mg of retinol, in the form of retinyl ester, given at 4–6-month intervals, have been shown to reduce morbidity and mortality in children and pregnant women. Capsules have been designed to provide this quantity of vitamin A for use in public health programs. The supplement is packaged into small single-dose gel caps that protect the vitamin A from light.

Vitamin A admixed with other ingredients

The topic of micronutrient supplementation of foods, including fortification with vitamin A, was reviewed by a United Nations Advisory Group on Nutrition in 1998. A general approach to micronutrient supplementation for vitamin A has been its addition to products that are widely used in a population, consumed in rather standard quantities, of low cost, and amenable to appropriate packaging and distribution. Examples include vitamin A fortification of monosodium glutamate, an approach used in Indonesia, vitamin A-fortified sugar as produced and tested in Guatemala for reduction of vitamin A deficiency, and vitamin A-fortified margarine in the Philippines.

Spectrophotometry of Vitamin A

UV Light Absorption Properties

Retinol possesses a very characteristic UV absorption spectrum. The spectrum is slightly influenced by the solvent in which the molecule is dissolved but altered rather markedly when retinol is bound to proteins such as RBP. Most published data are for all-*trans*-retinol dissolved in either absolute ethanol or hexane (petroleum ether). In these solvents, the UV absorption maximum is at 324–326 nm. There is a slight shoulder at ~318 nm, and the absorption drops off significantly at wavelengths above the maximum. Thus, determining the UV absorption spectrum using a spectrophotometer that can scan from ~260 to 400 nm, through a UV-transparent cuvette or flow cell, such as quartz, will give a good first indication of the purity of a preparation. If the oxidation product, retinal, is present, then the absorption will be increased at wavelengths above the UV maximum for retinol, as the spectrum for retinal is much stronger at these higher wavelengths. There should be no absorption of retinol above 395 nm.

Determination of Mass Using Extinction Coefficients

Because the researcher is often dealing with small amounts of retinol or retinyl esters, the most accurate means of determining the quantity or concentration is by using spectrophotometry, rather than by attempting to weigh the sample. When using larger quantities, determination by weighing may be suitable. However, spectrophotometry has the additional advantage that the retinol solution can be kept out of the air, in the dark, and in the presence of a suitable antioxidant, if desired. The extinction coefficients for retinol and its major metabolites are shown in Table 1. For retinol, the molar extinction coefficient (value for the absorption of a 1 M solution under standard conditions in a 1 cm light path) is 52 770 in ethanol and 51 770 in hexane. Absorption maxima and extinction coefficients for a variety of other retinoids, including both naturally occurring forms and numerous synthetic analogs, can be found in references such as by Furr et al.

Because the molar extinction coefficients for retinoids are relatively high, it is necessary to dilute the stock sample(s) before reading on a spectrophotometer. Solutions must be diluted into the low micromolar range to give a suitable reading. For example, using a 1 cm cuvette, a 1.0 μM solution of pure retinol in ethanol is expected to have an absorbance reading at 325 nm of 0.527, which is within the range of good sensitivity for spectrophotometry. After reading to

Table 1 Maxima of absorption spectra and molar extinction coefficients of retinol, retinyl esters, and selected biological metabolites of vitamin A

Analyte	*Solvent*	*Maximum absorbance (nm)*	*Molar extinction coefficient ($mole^{-1}\,cm^{-1}\,l$)*
All-*trans*-retinol	Ethanol	325	52 770
All-*trans*-retinol	Hexane	325	51 770
α-Retinol	Ethanol	311	47 190
All-*trans*-retinyl palmitate	Ethanol	325	49 260
All-*trans*-retinal	Ethanol	383	42 880
11-*cis*-retinal	Ethanol	380	24 935
All-*trans*-retinoic acid	Ethanol	350	45 300
All-*trans*-retinoyl β-glucuronide	Methanol	360	50 700
All-*trans*-retinyl β-glucuronide	Methanol	325	44 950

Data from Furr et al. (1994), where data for many nonbiological retinoids can also be found.

determine the experimental absorbance, the Lambert–Beer law (absorbance = molar extinction coefficient × path length (cm) × concentration, M) can be applied to calculate the exact concentration of the diluted material. The dilution factor is then applied to calculate the exact concentration of the stock solution. Before using retinol, the solvent can be evaporated under inert gas, nitrogen or argon, and a suitable vehicle added to achieve the desired concentration. The vehicle selected might be ethanol or dimethyl sulfoxide if the purpose is to add retinol to aqueous media, for example, for a cell culture experiment, or it might be an oil or purified triglyceride for the addition of retinol to a diet or for oral administration.

Handling and Determination of Vitamin A

Storage

Crystalline retinol should be stored in a tightly capped vial, either low-actinic red or brown glass or clear glass wrapped in foil, after introducing a stream of nitrogen just long enough to evacuate the air, at −20 °C or lower, inside a desiccator or within a tightly capped container containing a desiccant such as calcium chloride. Purging the sample or the secondary container with nitrogen may also help to stabilize the compound during storage.

Retinyl esters can be stored neat (dry), provided they are kept cold and protected from air and light. Retinyl ester is also a suitable material for the preparation of retinol, by hydrolysis, when small quantities are needed, as for research purposes.

Liquid stock solutions can also be stored for a relatively long time, provided they are protected from light, heat, and oxygen. For research purposes, it is often convenient to store retinol as a solution in organic solvent, with ethanol being preferred because it is less volatile than hexane. In the author's laboratory, we typically prepare retinol beginning with a high-quality commercial retinyl ester, which is very stable on storage, and then generate free retinol by saponification. The nonsaponifiable lipid fraction containing the retinol is isolated by partition extraction into hexane. The hexane is evaporated under nitrogen, and ethanol is then added to prepare a stock solution at a concentration of about 3–10 mM, stored in the dark at −20 °C, purged of air. When retinol is needed for an experiment, we then dilute the sample and determine its UV spectrum and concentration, as described in the preceding text, and then dilute the retinol to the desired concentration in a solvent of choice for the experiment to be conducted.

Retinol has been reported to be stable for years in plasma or serum in samples stored at −70 °C. Due to the UV sensitivity of retinoids, care should also be taken to prevent light exposure when collecting tissues, transferring and storing samples, and weighing them for analysis. The problem is most severe for samples that contain small amounts of vitamin A compounds or samples that are of small size so that light may more readily penetrate them.

Room lighting can be controlled by using a yellow or red light source that does not emit UV light or, alternatively, placing a UV filtering material over the ambient lights. The author's laboratory has used plastic sheets of UV filtering material, cut to fit over the overhead lighting fixtures, and has found that this is sufficient for blocking UV light for most work with vitamin A, such as for the analysis of plasma and most tissues.

Determining Vitamin A in Samples by Extraction, High-Performance Liquid Chromatography, and UV Detection

Numerous published methods provide details, and thus, only some of the principles of analysis and examples are discussed here. Analysis generally consists of five sequential processes: (1) denaturation of the matrix (foodstuff, plasma, or tissue) to liberate the retinoid and solvent extraction to obtain the broad class of lipids containing the vitamin A for analysis; (2) partitioning or transfer of the retinoid into a solvent that is ideal for high (or ultra)-performance liquid chromatography (HPLC or UPLC); (3) an HPLC separation step capable of resolving the molecular species of the retinoids to be detected; (4) detection, usually done on-line, using UV, fluorescence, or mass spectrometry for analysis; and (5) finally, the processing of the resulting data for quantification, usually accomplished by integration of the peaks using various software. Because few biological molecules possess both the lipophilicity and absorption characteristics of retinol, it often is possible to determine retinol levels in foods, plasma/serum, or tissues even in the presence of other molecules, like vitamin E or β-carotene, which are generally coextracted into organic solvents in the initial separation but later can be resolved by HPLC and further defined by differences in their light absorption characteristics. Several methods have been described for the simultaneous analysis of retinol, carotenoids, and vitamin E in various matrices.

Solubility

Retinyl esters are maximally soluble in hexane, petroleum ether, or another highly nonpolar solvent, while retinol and retinoic acid are most soluble in organic alcohols such as ethanol or methanol. When considering solubility, it is important to consider the entire lipid in the sample. For example, the solubility of vitamin A in extracts of lipid-rich adipose tissue or lipoproteins may be limited by the other lipid components of these materials.

The initial denaturation step typically uses an organic alcohol capable of denaturing proteins and of solubilizing the total lipids in the sample. Methods for the initial denaturation/extraction of tissues, such as liver tissue, include maceration in ethanol, lyophilization followed by extraction, and grinding the wet tissue with anhydrous sodium sulfate to remove water, followed by several extractions with a mixture of organic solvents such as hexane, ethyl acetate, dichloromethane, and methanol. Some methods use ethanol for the denaturation step followed by the addition of water and partitioning from 50% ethanol to hexane to extract (partition) the neutral lipids, which include retinyl esters, retinol, and other lipids such as triglycerides, cholesteryl esters, cholesterol, and tocopherol. Other methods, usually used for plasma, are based on the use of a more polar solvent initially, such as acetonitrile or dichloromethane/methanol, followed by centrifugation to eliminate protein residues from the organic phase that can be used directly for HPLC. The choice of method is largely determined by the type of sample, and, for each new type of sample, a recovery test should be conducted using one or more 'spiked' samples to which a known amount of the analyte of interest, or a very similar compound as surrogate, has been added, in comparison with the same sample without this addition.

Retinol and retinyl ester separation and detection

For separation, most methods are based on reversed-phase HPLC in which the column matrix (stationary phase) is nonpolar and the solvent (mobile phase) is relatively more polar. Common combinations are an octadecylsilyl, octyl, or phenyl stationary phase and either ethanol, methanol, or acetonitrile mixed with a small percentage of water, for the elution of retinol and similar molecules. Solubility is also an issue regarding the choice of mobile phase used for HPLC. The polarity of the mobile phase may need to be reduced (e.g., to 100% methanol) for the elution of the less polar molecules including retinyl esters. Even within the class of retinyl esters, the molecular polarity of various esters differs in a systematic way by fatty acyl chain length, and the methods used for retinyl ester separation, for example, for a complete analysis of milk, may need to be modified to account for this.

Detection may be either at a single wavelength or at dual or multiple wavelengths simultaneously, such as by using a photodiode array detector. For serum retinol, generally monitoring at 325 nm is sufficient. Mass spectrometry is not necessary for routine retinol or retinyl ester determination but it may become necessary if the study has used a heavy isotopic compound and isotopic enrichment must be determined. Integration is generally based on peak area after subtraction of suitable background and is generally automated within the analytic software of the HLPC or UPLC instrument.

Application to determination of plasma or serum retinol

For retinol in plasma, either plasma (anticoagulated) or serum is acceptable, and results are similar. Several approaches for retinol analysis are possible, and the first choice to be made is whether to measure the retinol fraction, without use of saponification, for example, alkaline hydrolysis. The second choice is to saponify and then measure the total retinol in the sample, which will include both the unesterified retinol and whatever fraction is present as retinyl ester. As plasma total retinol is generally >90% unesterified, free retinol and total retinol are generally similar, but in a sample collected postprandially, the retinyl ester may increase especially if a meal or diet high in vitamin A has been consumed. The third option is to measure both the unesterified retinol and retinyl ester in the unsaponified sample; this is feasible but it substantially increases the run time and thus the amount of solvent that is required. Reversed-phase HPLC is the separation method of choice. Either an internal standard method or external standard method can be used. We prefer the internal standard method because it eliminates the need for transferring precise volumes of solvent after the internal standard is added. The internal standard should be a material that is not present endogenously in the sample, but that has essentially identical extraction characteristics as retinol, and that will separate from retinol on the HPLC system that is used. Either a synthetic derivative of retinol, tocol, or potentially another UV-absorbing compound can be used as the internal standard. Reference materials suitable for use in the analysis of human plasma are available, such as SRM 968d from the National Institute of Standards and Technology, and can be used for external validation for retinol and several other plasma lipid analytes. Alternative methods are under development, especially for use in field studies. A portable fluorometer was compared with HPLC, with adequate correlation, for serum retinol analysis in a field survey situation.

Retinol in other tissues

For tissues other than plasma, or for samples of diet, feed, etc., it is important to consider the matrix (tissue or sample type – whether fibrous, easily homogenized, etc.) and the approximate concentration of retinol that is expected. For tissues that can easily be macerated, it may be preferable to pulverize/grind a weighed portion of tissue in absolute ethanol, which may contain 1 mg ml^{-1} of BHT as antioxidant, in a glass tube, using either new tubes or acid- or ethanol-washed tubes. For tougher tissues such as the lung or muscle, the same procedure may be used but the tissue may be minced beforehand, ground for a longer time, or mechanically disrupted in the solvent with a tissue homogenizer. For adipose tissue, due to the high level of total fat, it may be necessary to add another low-polarity miscible solvent such as benzene to the ethanol for complete extraction of the tissue lipids; this should be determined on trial samples beforehand. In the experience of the author's laboratory with tissue retinoid analysis, recoveries were better using direct extraction into ethanol, either by tissue maceration or mechanical homogenization, than after use of a traditional chloroform/methanol extraction method with washing. For analyzing vitamin A in diets, a sufficiently large sample should be taken, sampling from different batches or lots of the feed for the most accurate sample, and then, if the diet is pelleted, it

should be finely ground beforehand. A small weighed amount is then transferred to a glass tube and extracted with ethanol. Extraction from ethanol into hexane is as previously described. Samples of hexane are then taken for the evaporation of solvent and preparation of the sample for analysis by HPLC.

Retinyl esters

In tissues that contain retinyl esters, it is likely that several different esters may be present. For some of these esters, there is no commercially available retinyl ester to use in coelution studies in order to identify the peak. The synthesis of specific standards is an option, and acyl chloride- or acyl anhydride-based methods have both been used; these standards can be purified and kept frozen as reference materials. However, our experience has shown that the order of retinyl ester peak elution is quite reproducible, since it is based on polarity, and, therefore, if a standard method is used, the order of elution will be the same each time, and thus, comparison with published chromatograms in which multiple retinyl ester standards have been adequately identified may be sufficient to make a reasonable identification of each retinyl ester peak. In most tissue samples, retinyl palmitate and retinyl stearate will constitute the major peaks, and since retinyl palmitate is available commercially, it can be used in a comigration study to identify this major peak. In reversed-phase chromatography, the order of elution is retinol (and internal standard, if added), followed by a long elution time before retinyl esters are eluted. Generally, a gradient to a less polar mobile phase is used to speed up the elution of the retinyl esters and sharpen their peaks. Several minor esters of retinol may appear before a larger peak of retinyl palmitate and, following that, retinyl stearate. If retinyl oleate is present in the sample, it may migrate with or as a shoulder on the retinyl palmitate peak. Retinyl esters can be identified provisionally by comparison of the mass of retinol in a saponified sample with the sum of the masses of eluted retinyl esters. The UV absorption spectrum of retinyl esters and their molar (but not mass) extinction coefficients are essentially identical to the spectrum and extinction coefficient of retinol. The use of a photodiode array detector to determine the absorption spectrum of each peak can be very helpful in identifying whether or not a peak is a retinyl ester.

Analysis of retinal and retinoic acid

These compounds are not dietary components per se, and thus, their analysis is almost always performed on tissues, cultured cells, or reaction mixtures after *in vitro* assays. Retinoids such as retinal and retinoic acid require a similar but yet somewhat different approach from retinol for their determination, both because they are sufficiently different in polarity and because they are relatively reactive.

Retinal, as an aldehyde, is intrinsically reactive with amines, and methods have been developed to extract retinal and form a derivative by reaction with hydroxylamine or an acylhydroxylamine such as ethylhydroxylamine. The hydroxylamine is added to cleave the Schiff base of retinal with proteins, such as rhodopsin, or to derivatize free retinal in organic solution. The retinal oxime that is formed is much more stable than retinal and can be extracted and analyzed by HPLC. The oxime formed will represent the isomers present in the sample. *Syn*- and *anti*-conformers are formed for each geometric isomer of retinal, but they can be added up to represent the total amount for each isomer.

Although retinoic acid is a qualitatively important metabolite, it is generally present in low concentrations, for example, in the nanomolar range in plasma, as compared with retinol, which is in the micromolar range. An issue for analysis is the existence of several isomers, including all-*trans*, 9-*cis*, and, potentially, di-*cis* isomers of retinoic acid. Since all of the isomers share the same molecular weight, their separation on HPLC is very challenging and is necessarily based on small differences in polarity due to the conformational change caused by isomerization. Methods have been developed to separate these forms by liquid chromatography with quantification by mass spectrometry, in which the different fragmentation patterns of the *cis* and *trans* isomers aid in separation, identification, and quantification. Extra care is needed in preparing samples to prevent the isomerization of the native forms during processing.

Rheological Properties of Food Materials

B De Cindio, N Baldino, D Gabriele, and FR Lupi, University of Calabria, Arcavacata di Rende (CS), Italy

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Rheology is a science dealing with the mechanical properties of materials, with a particular emphasis on those showing a complex behavior that cannot be classified as a Newtonian liquid or an elastic solid. Constitutive equations and mechanical models are the main objective of this science, the cradle of which is polymer science. Rheology has become more and more important for foods because they usually show a complex mechanical behavior ranging from simple liquid (fruit juices, tapered water, beverages) to hard solids (candies, dry fruits). This specific behavior of foods, is due to the existence of an internal structure, operating at supramolecular dimension, and the mechanical properties exhibited by the material mainly depend on it; consistency, hardness, and viscosity, for instance, are fully determined by the extension and strength of this network. This structure is what is perceived by consumers and is better called 'texture.' It is something different from what is usually assumed as chemical structure because it is linked directly to consumer perception, more than to the presence of micro- or macrocomponents. Even flavor is determined by this structure because its release is according to its diffusivity in the food matrix. In turn, the process conditions are capable of controlling the material parameters, which allow the food to be produced with the desired 'texture.' Food rheology has the objective to make a bridge between texture and the chemical structure because rheological parameters are defined on a macroscopic scale, and from this point of view they are strictly linked to texture, but they are determined by the strength and extension of the internal network.

Because food properties are a combination of different contributions that can hardly be reduced to simple rheological parameters such as viscosity or elastic modulus, food rheology has been widely approached in a rather empirical way. Consequently, an incredible amount of experimental or imitative devices and fitting models have been proposed even though poor theoretically. In the last few decades the requirement of quality products has become more exacting to remain competitive; therefore researchers have been asked to tackle food production using a higher degree of technology and science. Consequently, the use of rheological techniques has also increased. Fitting equations and empirical or imitative devices are increasingly substituted by fundamental measurements and rheometers in industrial use. This has been possible because, despite apparent big differences, common aspects and features can be easily recognized, and consequently, foods can now be classified as a unique material class to which similar theoretical models and experimental techniques apply: material properties will differ only for their intensity. It should be admitted, however, that there is still a trend to approach this task in an empirical way both experimentally and theoretically; therefore, in the following, the two approaches called 'diversifying' and 'unifying' are both detailed.

Finally, it should be observed that the unifying approach is very helpful in process design, particularly when producing new products of a desired texture, whereas the diversifying approach allows only the final product properties to be determined.

Diversifying Approach

This approach has been used for many years and was necessary to tackle rheological characterization when the availability of instruments was very poor and very expensive. Any food is considered as a single system, and properties are found by iterating a simple test several times to find an acceptable result. The experimental solutions are based on experience and linked to technological or consumer evidence. This way to operate can be very helpful for well-consolidated productions, but it is useless for new products and process design because, as already stated, it needs a lot of measurement to be reliable.

Experimental Aspects

There are an incredible number of experimental devices measuring the mechanical properties of foods in an empirical fashion. The difficulty to have a complete assessment of the rheological parameters has driven researchers in the past to find rather empirical solutions to characterize foods, instead of using well-defined physical parameters. One of the most used classes of these devices is the 'penetrometer' based on the physical idea that the material, according to its structure, can more or less resist the penetration of a solid rod or needle. Thus, several geometries such as cylinders, cones, flat disks, or spheres are used. The penetration depth under a fixed applied force is an empirical easy way to measure food consistency. Very similar to those apparatus are 'compressimeters,' the difference being that the material is compressed, avoiding penetration. If a cylindrical tool is forced on a material, the resulting compression is proportional to the dimension of its base area (Figure 1(a)); on the contrary, if it penetrates there is the additional contribution of the lateral surfaces, and if this so-called shear deformation, defined as the deformation occurring when two parallel surfaces move one in respect to the other, is dominant, obviously, its contribution is proportional to the contact perimeter (Figure 1(b)). Because during penetration the active surface is changing, the experimental data are often reported in terms of 'yield value,' computed as the depth penetration obtained under a given force for a given time. Yield value, often defined as force minimum value needed to start flowing, is then associated with a perceived assessment: low values are associated with soft, just pourable materials, middle values to spreadable materials, and high values to hard ones.

To measure flow properties of consistent materials sometimes a squeezing flow apparatus is used. In this device

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00592-4

the testing material is put between two plates that are pushed one against the other at constant velocity causing the squeezing out of the material (see Figure 2). The data are reported as the measured load to maintain a constant velocity versus the height of the gap. Of course, a sudden increase of the load is found as far as the height becomes smaller. In Figure 2 the squeeze of a biscuit dough is shown, from which it is possible to obtain a sort of measurement of its resistance to flow.

Another very popular apparatus, is the so-called back extrusion device that seems to be very helpful to determine the viscosity of soft materials. In fact, the material is put into a cup and then is forced by a plunger to flow out at constant velocity through the narrow annular gap between cup and plunger (Figure 3(a)). The resistance to flow can be assumed as a sort of empirical viscosity. This test is very helpful when treating with rather liquid dough; as an example the results obtained for a batter dough are shown in Figure 3(b), where the values of the measured force are plotted versus the cell height.

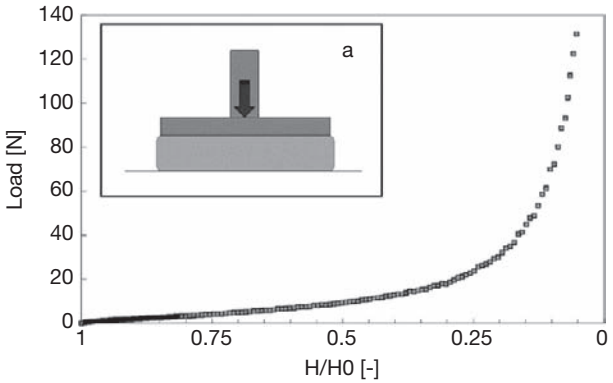

Figure 1 Sketch of compressimeters (a) and penetrometers.

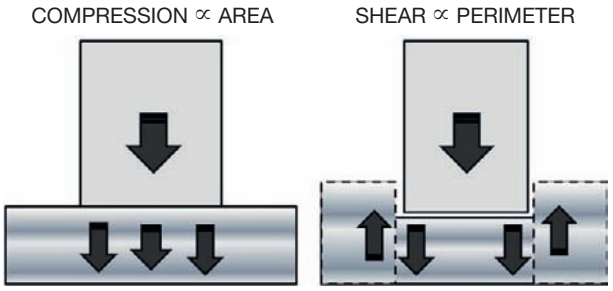

Figure 2 Squeezing flow: sketch of the device (a) and experimental data for a biscuit dough (b).

Special attention has been dedicated to dough characterization due to its importance in several foods. There are many devices used in the different applications. Farinograph, amilograph, mixograph, Brabender mixer, extensimeter, and Chopin alveograph are well-known devices widely used in the industry. However, despite their specific importance in several uses and the availability of a rather great amount of industrial data, they are very empirical, and consequently they need a lot of measurement to be well standardized. The Brabender mixer is very useful to establish the so-called rheological optimum of a dough. With this device the mechanical power adsorbed during water mixing is measured and a power versus time plot is obtained (Figure 4). During the experiment the power grows due to the increase of the consistency, attaining a maximum within a couple of minutes and falling down more or less significantly. The so-called Brabender units (BUs) are defined as a measuring scale of mechanical power, and a value of 500 is taken as reference for optimum rheological behavior. Three parameters are considered to qualify flours: development time (time needed to reach 500 BU), stability (time interval between the initial exceeding of 500 BU and before the falling down), and relaxing degree (difference between BU peak and BU value after 10 min). Strong flours are characterized by a small degree of relaxation and are stronger when the 500 BU are achieved in shorter times. Weak flours show significant values of the degree of relaxation. A strong or weak flour is preferred according to the use considered. In conclusion, one should admit that this apparatus is useful to determine the amount of water needed to form an optimal rheological dough.

Because doughs are subjected to processes implying extension, another apparatus is often used to measure the processing capability of different flours. 'Chopin alveograph' is a very popular device that consists of blowing a dough sheet to

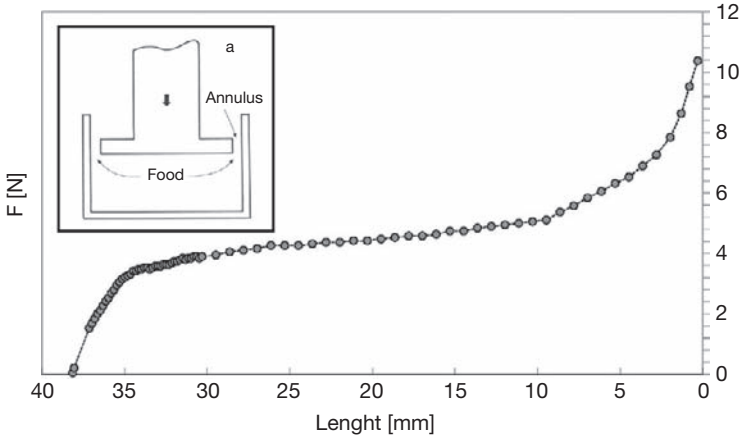

Figure 3 Back extrusion: sketch of the device (a) and experimental data for a batter dough.

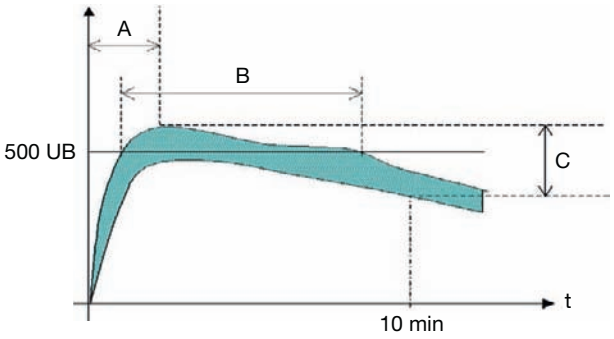

Figure 4 Measurement by a Brabender mixer: force versus time plot.

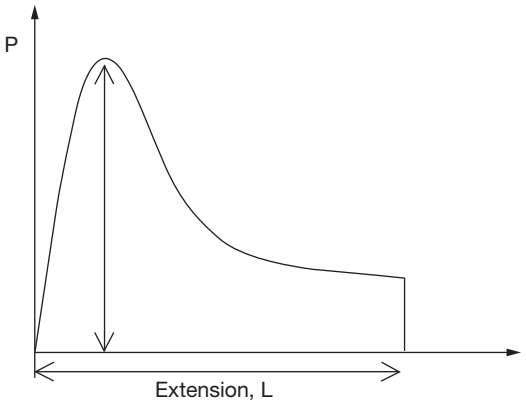

Figure 5 Measurement by a Alveograph apparatus: pressure versus extension plot.

make a bubble and measuring both pressure and extension continuously up to rupture. The shape of the resulting force versus extension plot (Figure 5) has been standardized to define some empirical parameters whose result is very helpful to address flours to different uses. Terms such as short or long flour are associated with the value of the rupture extension L, whereas strong or weak are associated with the maximum pressure P exhibited during the experiment. Even though the experimental procedure is scientifically rather questionable, an optimized ratio between P and L, based on experience, is found useful for industrial uses. For instance, based on experience, a biscuit dough is expected to have a lower P and a greater L to facilitate leavening and bubble growth, whereas a French bread should require shorter L and higher P.

It must finally be recalled that there are also a great number of devices built on an imitative base. For instance, the so-called texturometers are built to make a compression cycle that imitates human mastication. In this way the mechanical response is associated with the first and the second bite, and a qualitative measurement for the hardness, fracturability, and adhesiveness of foods can be obtained.

Theoretical Aspects

Diversifying approach theories mainly stand on data fitting being absent from any sort of generality. Rheological behavior is considered to come from the combination of three basic mechanical elements: an elastic spring, a Newtonian dashpot,

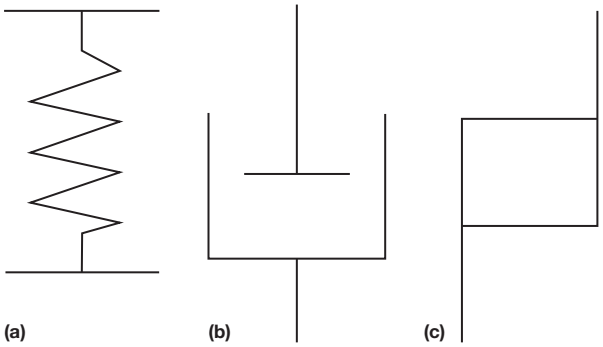

Figure 6 Basic mechanical elements: elastic spring (a), viscous dash pot (b), and plastic body (c).

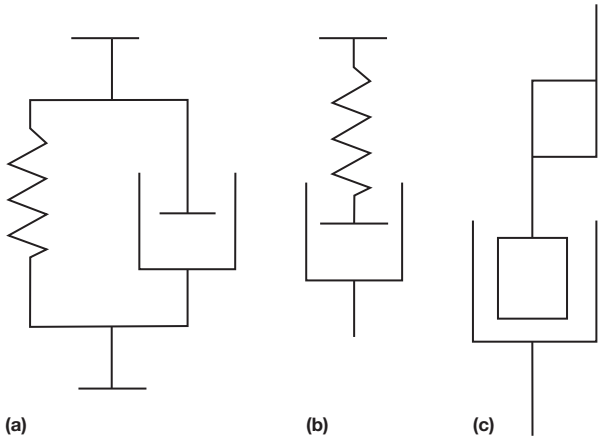

Figure 7 Combined mechanical elements: Maxwell element (a), Voigt element (b), and viscoplastic element (c).

and a plastic body (Figure 6). For instance, if the elastic element is combined with the dashpot in a serial fashion, the so-called Maxwell element is obtained, which when subjected to a fixed deformation over time relaxes the acting force. Viscoelastic behavior is well represented by this combination (Figure 7(a)). On the contrary, when the assemblage is parallel, the so-called Voigt element is obtained that, again, represents viscoelasticity but when subjected to a constant stress, defined as the force divided the area of the surface on which it acts (Figure 7(b)). The yield stress, that is, the minimum stress necessary to flow, is modeled by a friction element and takes the viscoplasticity into account (Figure 7(c)). It is possible to propose more complex combinations to fit data with the aim to separate the contributions of single components. For instance, in the case of ice cream, the contributions to the mechanical behavior of ice and fat crystals, of stabilizers, of air bubbles, of proteins can be split into elastic and viscous elements. The quantities of different ingredients in any given recipe is assumed to be a function of their contribution to the proposed mechanical model. This approach, although to some extent fascinating, seems rather questionable because of the excessive number of parameters and because the same result can be obtained by a simple numerical fitting technique.

Because a lot of rheological measurements are done with simple rheometers based on the application of selected shear

deformation rates and geometries, numerous rheological fitting equations are found that define some rheological parameters. The most-used monodimensional fitting equations are Newtonian fluid and Power law fluid. For instance the Power law equation assumes that the measured shear stress, that is, the tangential force divided by its application surface, is proportional to a power of the deformation rate: If the value of the power is 1 the behavior is Newtonian and a constant viscosity is found. Some examples of data usually found are reported in Table 1. It clearly appears that the greater is *K*, the greater is the perceived consistency, but also that *n* gives an idea of the resistance to flow at different shear rates.

Unifying Approach

The deepening knowledge of food behavior and the availability of more sophisticated but less expensive devices to measure mechanical properties has allowed researchers to collect foods in a unique frame to find both experimentally and theoretically unique solutions. This in turn has had a positive effect on food product design responding to the actual requirement of more complex systems, especially those addressed to new uses, such as healthy foods, baby food or foods for the elderly, nutraceutics, controlled release foods, and so on. In these cases it is necessary to predict the rheological properties for a proper design of the production process.

Table 1 Power law fitting parameters for foods

Food	n	K *(dynes* s^n *cm^2)*
Tomato purée	0.55	10.80
Apricot purée	0.31	200
Applesauce	0.64	5.0
French mustard	0.40	334
Tomato ketchup	0.28	187
Guar gum (1.5%)	0.16	464
Xanthan gum (1.2%)	0.26	39.8
Sweetened condensed milk	0.83	36

Experimental: Rotational and Oscillatory Shear Flow

Two rheological functions characterize complex materials: non-Newtonian viscosity and viscoelastic moduli. Viscosity is measured by rotational devices as the ratio of the measured stress to the applied shear velocity of deformation. The difference with the diversifying approach is essentially the use of rotational rheometers with specific standard geometries like cone-and-plate, plate and plate, and coaxial cylinders. Applied kinematics control allows the measurement of physically well-defined properties. The experimental test is done at different shear rates, and a so-called flow curve is obtained giving the shear viscosity as a function of the shear rate. In principle also the normal stresses difference should be measured, but up to now there have not been any suitable instruments capable of reliable measurement. Often, a pseudoplastic behavior is exhibited, which means that the shear viscosity decreases when the shear rate is increased; more rarely the opposite dilatant behavior is observed in foods. The flow curve is usually reported as shear viscosity versus deformation rate, and often fitting is done using a power law equation or a cross equation. Often food viscosity shows a constant value at low shear rates called zero shear viscosity, then it decreases, sometimes attaining another constant value at high shear rates. This latter is interpreted as the material resistance to flow when the internal structure is completely destroyed. In Figure 8 the shear viscosity of a chocolate sample is shown.

When fitting is done with the power law, the value of the constant *K* is interpreted as the measure of the consistency of the considered food, whereas the value of the power *n* is linked to the rate of destruction of the internal structure. In Table 2 the most-used models are reported.

Another rotational test is the creep test, consisting of applying a constant force and measuring the resulting deformation: the rheological parameter is the compliance defined as the deformation divided by the applied stress, the force per unit of surface. When compliance is not determined by the applied stress, a linear behavior is evidenced, and compliance assumes the meaning of a material property: Very often the linearity range is limited to very low stresses. In this test the material always starts to show a solid behavior and at long times can

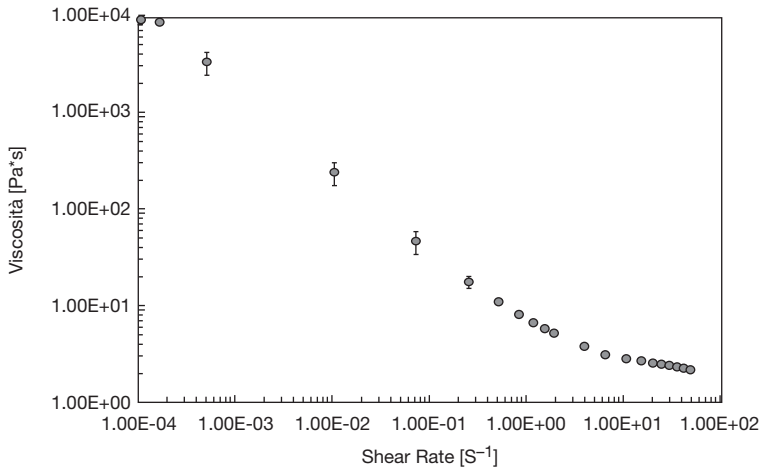

Figure 8 Flow curve of a chocolate sample.

exhibit a liquid-like behavior if the slope becomes constant, the reciprocal of this being viscosity, or a solid-like effect when the slope is zero. The test is very useful to measure yield stress because the transition between no flow and flowing is evidenced by the slope change.

To get more information about food behavior, creep is often followed by a creep recovery following the sudden removal of the applied force. If the deformation, called in this case shear strain, is reported versus time, the mechanical response of the material may be interpreted as an instantaneous strain just at beginning when the stress is applied, followed by a primary creep and a secondary one when the relationship becomes linear. At this time the applied stress is removed with the consequence of an instantaneous recovery, followed by a time-dependent recovery, finally ending, after some time, with a permanent strain. The test depends on the applied stress, and any different shown behavior may be linked to specific material parameters. Semolina dough creep and creep recovery test is shown as an example in Figure 9.

It should be noticed that from a theoretical point of view, the aforementioned parameters are rheological properties according to the deformation history; therefore they can be used strictly only when the material is subjected to an equivalent flow or deformation. This can be overcome by measuring equilibrium properties. The solid–liquid characteristics at equilibrium are measured by applying small oscillation shear deformation in the linear region and measuring the phase angle δ of the mechanical response respect to the applied deformation. Because an ideal solid is characterized by a phase angle 0° whereas a liquid will show phase angle 90°, the measure of δ will give the relative weight of the two behaviors. Usually the mechanical response is reported as the specific force divided by the deformation called modulus and is subdivided into two contributions called G', storage modulus, and G'', loss modulus. G' is associated with elastic (solid) behavior, whereas G'' is associated with the liquid one. A sketch of a typical viscoelastic response is shown in Figure 10, reporting, in a log–log plot, the values of the two dynamic moduli against the oscillation frequency. At low frequencies liquid behavior prevails with respect to the solid behavior, whereas at high frequencies the contrary occurs. The cross frequency is assumed as a rough measure of the material inversion behavior.

It is worth noting that seldom do foods show that sharp viscoelastic behavior, and often a linear behavior of both dynamic moduli G' and G'' in a log–log plot is observed within a large range of frequencies. This specific behavior is associated with the mechanical properties of a macrostructure spread into the material that contributes to solid–liquid characteristics according to its strength and extension. Typically foods show values of G' at most one decade higher than G''.

Table 2 Shear stress models

Model	$\tau(\dot{\gamma})$
Power law	$\tau = k\dot{\gamma}^n$
Cross	$\tau = \eta_\infty\dot{\gamma} + \frac{(\eta_0 - \eta_\infty)\dot{\gamma}}{1 + (\lambda\dot{\gamma})^{1-n}}$
Casson	$\tau^{1/2} = \tau_y^{1/2} + \eta_\infty^{1/2}\dot{\gamma}^{1/2}$
Carreau	$\tau = \eta_\infty\dot{\gamma} + \frac{(\eta_0 - \eta_\infty)\dot{\gamma}}{\left(1 + (\lambda\dot{\gamma})^2\right)^{\frac{1-n}{2}}}$
Herschel–Bulkley	$\tau = \tau_y + k\dot{\gamma}^n$

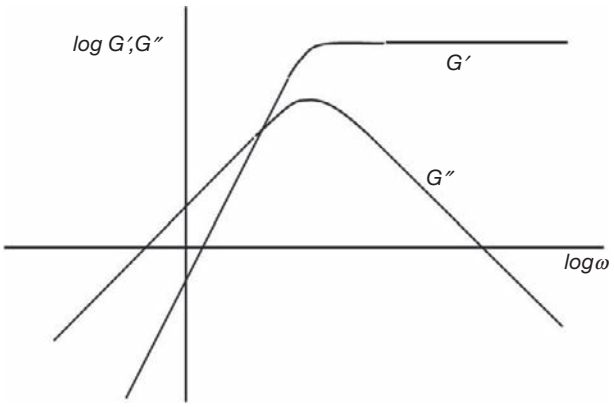

Figure 10 Small amplitude oscillation dynamic moduli G' and G'' versus oscillation frequency for a linear viscoelastic material.

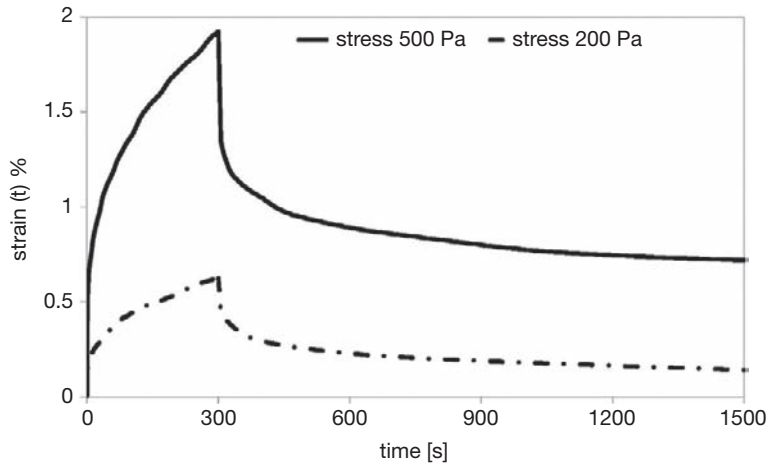

Figure 9 Nonlinear creep and creep recovery test of a semolina dough for pasta making.

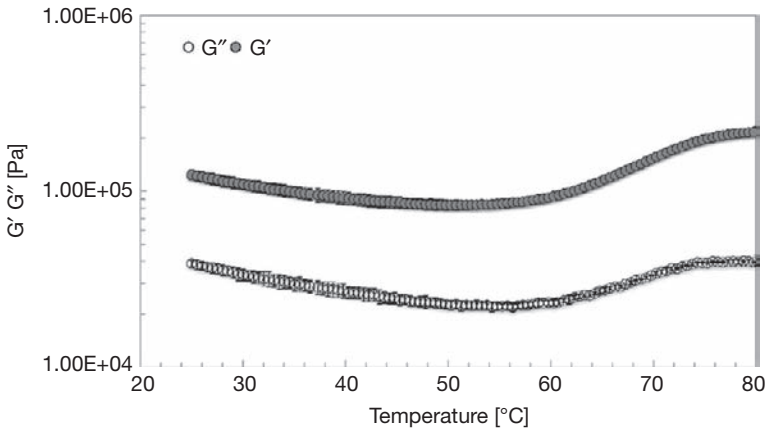

Figure 11 Dynamic moduli G' and G'' at 1 Hz versus temperature for a semolina dough sample.

In addition, a test can be carried out at a fixed frequency, usually 1 Hz, changing temperature by a suitable ramp, usually 1 °C min^{-1}, with the aim to show the structural changes that can occur. In Figure 11, for instance, the values of G', G'' are shown in the case of a semolina dough. It clearly appears that both G' and G'' moduli decrease by increasing temperature up to 60°, where protein and wheat coagulation occurs, with the consequence of a sudden and relevant increase of both moduli. The material becomes harder, and both moduli G' and G'' may become an order of magnitude higher than those shown by the dough.

Coming back to flow curves, they are very important in process design because in many operations shear flow is dominant, and shear viscosity must be determined in a large range of shear rates. To do this, different tests must be used. In fact, shear creep test is capable of covering a low rate of deformation because it is possible to apply a stress as low as possible depending on the used rheometers. For a large shear rate of deformation, a shifting technique may be adapted from polymer science using the complex dynamic modulus defined as the square root of the sum of the squares of G' and G'' and assuming that oscillation frequency is equal to shear rate.

Viscoelastic and Weak Gel Theoretical Models

A network operating at supramolecular scale and changing according to applied deformation is a well-accepted rheological model. The continuum medium is modeled as a series of topological points (entanglements) linked each to the other with strands. When applying a deformation rate, if the system remains at equilibrium (small amplitude oscillation), the number of strands and entanglements remain dynamically constant. The applied deformation is transferred from the continuum to the network in an affine way, so that what is applied to the continuum contour applies identically to the discrete network. To write the constitutive equation, some additional hypothesis is necessary regarding the dynamic and kinetic behavior of nodes and strands, the relationship between stress and deformation, the link between material parameters, and the node concentration. The interactions present in foods are rather weak when compared to chemical bonds because they are essentially van der Waals and London forces, hydrogen bonds, and so on; consequently, the network is temporary and very sensitive to deformation. A linear viscoelastic model seems to be a good approximation to represent the rheological behavior of these systems by assuming that at equilibrium the entanglements form or disappear with the same velocity, their number (network connectivity) remaining constant. By assuming a Gaussian distribution of the rheological units (nodes and strands), the effect superposition principle can be used at any time to evaluate their contribution to the total stress. It should be noted that when the behavior is solid-like, the stress will not change with time, whereas solid–liquid behavior is characterized by a relaxation following the imposition of the deformation. Materials can exhibit several different relaxing mechanism that contribute separately to their mechanical response and that can be summed in accordance with an assumed suitable distribution. Usually a so-called relaxation time spectrum $H(\lambda)$, a sort of distribution of the different relaxing mechanism, can be used to represent the modulus decreasing mechanism with time at any assumed relaxation time λ. The time-dependent modulus $G(t)$ is then obtained by means of the effect superposition principle summing all the mechanism, that is, integrating over λ if an infinite number of relaxation times is considered. This model implies that at low frequency the material should show a liquid behavior (G' proportional to the square of the frequency and G'' to the frequency) and at high frequency behaves as a solid (G' constant and G'' proportional to the reciprocal of frequency) as sketched in Figure 10; at a given frequency a cross between G'' and G' occurs, this latter thereafter becoming definitively greater. Sometimes it is possible to find also a solid behavior at low frequency then an extraelastic modulus G_E term can be added to take into account this effect. This is ascribed to the possible existence of a permanent cross-linked network with fixed node. In conclusion, in accordance with the viscoelastic network model, the rheological properties of foods are the relaxation spectrum $H(\lambda)$ and the elastic modulus G_E that can be obtained by G' and G'' measurement.

To find the relaxation spectrum this model requires the inversion of the integral defining the spectrum, and this is easily done if the liquid behavior is attained. This means that at the lowest frequencies experimentally tested it is necessary to find that the modulus G'' is proportional to frequency and G'

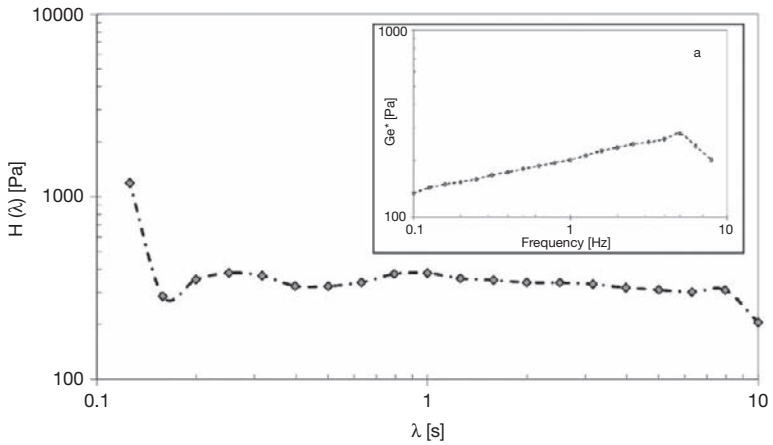

Figure 12 Rheological characterization of a yogurt sample by relaxation spectrum (a) and apparent elastic modulus.

to the square of frequency. It is a common experience that when considering foods, this occurs only for very liquid systems; on the contrary, a constant slope of both moduli G' and G'' is evidenced. However, if the relaxation spectrum is computed in these conditions, it is necessary to define an apparent elastic modulus G_E^* that, depending on the applied frequency range, allows to take into account the approximation. The two parameters $H(\lambda)$ and G_E^* are shown in the case of a yogurt (Figure 12). It must be noticed that if the frequency range is increased, the value of G_E^* decreases. From a physical point of view, G_E^* represents the mechanical response of a part of the network assumed to be permanent in the time window considered.

More recently another approach has been proposed that seems to be more realistic for foods. The viscoelastic network model is taken from polymer theories that consider bonds so strong that the strand will never break, therefore the rheological properties stand only on the variation of the entanglements that can break and be reformed as a function of the applied deformation. In equilibrium the number of entanglements remains constant. When considering foods, according to the weakness of the forces involved, it appears that the strands are more likely to break than the nodes. This means that the behavior is always solid-like, but the value of G' decreases linearly with frequency in a log–log plot with a slope ranging from 2 to 0. The limiting value 2 refers to a viscoelastic liquid, whereas the value 0 refers to a viscoelastic solid. Therefore this slope is a measure of the weakness of the network. From the cooperative flow and the gel theories, it has been possible to propose a new model called 'weak gel' that has become very popular in the last decade to interpret food rheological properties. Weak gel is a two-parameters model stating that the value of the complex modulus G^*, defined as the square root of the sum of the squares of the two dynamic moduli G' and G'', is proportional to a power of the applied frequency. The proportionality constant A can be related to the strength of the network and the reciprocal of the power $1/z$ to the extent of the network. Often, because the value of G'' is smaller than G', the complex modulus is approximate to the latter. This model is very simple because it requires only two parameters avoiding to invert the integral. From a physical point of view this means that foods are considered weak solids at least within the time range considered.

Table 3 Weak gel parameters for jams at 25 °C

Jam	z	A *(Pa)*
Apricot	4.17	686.4
Cherry	6.72	479.6
Strawberry	6.33	522.8

Table 4 Temperature dependence of cherry jam weak gel parameters

Temperature (°C)	z	A *(Pa)*
25	6.72	479.6
40	7.41	323.1
60	3.92	85.0
80	4.72	84.9

The weak gel model, for instance, may be very useful in the product design of jams. The choice depends on the rheological matching between the product and the jam, taking into account the temperature behavior due to the cooking in an oven. In fact, krapfen are filled and therefore they need a jam capable of flowing and diffusing into the product during cooking, whereas cakes are covered with a top layer that should remain sticky over its surface. The rheological behavior of jams is consistent with a weak gel model. The values of the two parameters are reported in Table 3. Apricot jam shows a smaller network extension but a rather strong strength, whereas cherry and strawberry jams show larger extension and less strength. The temperature dependence of A and z is quite different because apricot jam is very stable, whereas strawberry jam becomes very liquid. Cherry jam has a particular behavior showing a minimum of the network extension (Table 4). This information suggests to use apricot jam as topping and strawberry jam for filling. Some active rheological ingredients may be added to the original recipe to vary these conditions.

Conclusions

The unifying approach is justified by several cases of experimental evidence out of the results obtained that clearly demonstrate the possibility of defining a unique class of materials. The majority of foods, when subjected to small oscillatory deformation, show similar features: G' values increase with the oscillation frequency and decrease when increasing the applied deformation. There is always a nonzero value of G'', and it is approximatively within one decade less than G'. When high deformations are applied, the following characteristics are often found: stress overshoot in starting shear, plasticity, thixotropy, elongational viscosity, syneresis, and low mechanical stresses. In this respect, from a rheological point of view, foods are very similar but differ each from the other only in the intensity of their properties. The main result is therefore that so far the structure present in the food can be fully measured by a unifying rheological approach, but it should be admitted that the link between texture and structure is still too weak and has to be developed to produce predictive models. The weak gel model is the closest to achieving this result and is very interesting not only due to the theoretical aspects, but also because of the few parameters involved. Actually the equilibrium behavior seems to be understood enough to allow a link to be made between chemical structure, process, and ingredients. This, in turn, allows the making of good rheological process models very useful for designing and controlling industrial product, but on the contrary, the link between texture and rheology is still suffering from a lack of suitable parameters that define attributes and descriptors closer to reality, even though in this matter some progress has been made.

Introduction

Rum is an alcoholic beverage resulting from the distillation of fermented raw materials with high sugar contents. Its alcohol content varies from 35% to 54%V V^{-1}, measured at 20 °C. The various legislations of the countries where the beverage is produced determine the minimum alcohol content rum must have. For example, in Brazil, the legal contents range from 38% to 54%V V^{-1}; in Venezuela, the amount is 40%V V^{-1}; in Colombia, it is 50%V V^{-1}; in Cuba, it is not <35%V V^{-1}; and in Spain, the minimum is 37.5%V V^{-1}. For some special types of rum, such as those produced in the Canary Islands (Spain), the minimum content permitted is 30%V V^{-1}.

Rum-producing areas are mainly found in both the Spanish- and Portuguese-speaking regions of the Caribbean, as well as in areas of English and French influence, although there is a rum-producing tradition in the Spanish provinces of Granada, Malaga, and the Canary Islands. Generally speaking, areas where sugarcane has traditionally been grown are also rum-producing.

Although rum is one of the so-called congeneric beverages, that is, it has a distinctive aroma achieved during fermentation and distillation, it also has the requirement to be aged in oak barrels for a period ranging from a few months to several years, or even decades. Depending on the country of origin, other types of wood such as cherry can also be used. After aging, the rum finally acquires its final organoleptic characteristics.

The techniques involved in the production of rum can be summarized in the following stages: (1) harvesting and preparation of the raw material, (2) fermentation of the raw material, (3) distillation, (4) aging, and (5) standardizing and preparation for bottling.

Characteristics of the Raw Material

Rum must be made using sugary raw materials, usually supplemented with nutrients necessary for the initial fermentation.

The juice of sugarcane is used as the sugary raw material, as well as molasses and/or other by-products of the production of sugar from sugarcane, although molasses is the most commonly used. As a by-product of sugar production, molasses found its principal use in the making of rum. Its use in beverage production began over 300 years ago. The British Crown even passed the Molasses Act of 1733, which it imposed in all its possessions in the New World, in an attempt to exclude competition from other Caribbean regions.

In the process of sugar production, molasses consists of inorganic and organic by-products, left when most of the water (in several stages) and finally the sucrose has been extracted from the juice (*guarapo* in Cuba). Molasses is a high-density, viscose liquid, characterized by its sugars, total solids, and ash contents. The physical, chemical, and physicochemical characteristics of sugarcane molasses have an important effect on the resulting rum.

Generally speaking, sugarcane syrup mainly consists of water and sugars, such as sucrose and glucose, with smaller amounts of fructose. In an alkaline medium, fructose can produce furfural and hydroxymethylfurfural, which disrupts fermentation, and are therefore undesirable.

In addition to sugars, other elements and compounds are also present, such as metallic cations (potassium, calcium, sodium, magnesium, iron, zinc, and manganese as macrominerals and copper, iodine, cadmium, chrome, molybdenum, nickel, and vanadium as microminerals), anions (chloride, sulfate, nitrate, nitrite, and phosphate), nitrogen-containing organic compounds (glutamic acid, aspartic acid, valine, arginine, leucine, peptides, colorants, pyrazines, and pyrroles), organic acids (citric acid, malic acid, lactic acid, aconitic acid, propionic acid, and butyric acid), phenolic compounds (such as p-coumaric acid, ferulic acid, and syringic acid), fatty acids, and vitamins (biotin, pantothenic acid, inositol, thiamine, nicotinic acid, and pyridoxine). It should be pointed out that organic nitrogen is responsible for the formation of higher alcohols (such as isoamyl and isobutyl) during fermentation, which is not entirely desirable.

Many of the foregoing compounds, such as vitamins and minerals, are required for the metabolism of sugars during alcoholic fermentation. Although these nutrients are found both qualitatively and quantitatively in the molasses, other nutrients not found in molasses must be added. This is the case for inorganic nitrogen, which is rapidly assimilated and must be supplied to complete fermentation. Likewise, the addition of sulfur as a sulfate is recommended for the synthesis of the amino acids required by the yeasts, as well as phosphate.

Water and microorganisms, such as yeast and bacteria, are also essential for fermentation, but are present in molasses. Water is the medium in which other components are dissolved and it is indispensable for fermentative reactions. Yeast and bacteria are naturally present in molasses and play a fundamental role, inducing fermentation, and thereby a factor in the production of light or heavy rum, depending on the type and species of microorganism involved. The yeasts responsible for the fermentation of rum molasses must be able to generate a high degree of ethanol and the desired, balanced content of aromatic compounds. Table 1 summarizes some of the most common genera and species of yeast and bacteria found in molasses.

Apart from the bacteria naturally present in molasses, selected cultures of other bacteria may be added at the start of fermentation, mainly types of *Clostridium*, which can improve the development of alcoholic fermentation by acting in synergy with the yeast (*Saccharomyces cerevisiae*), as well as producing volatile acids (e.g., butyric acid) characteristic of heavy rums.

Alcoholic Fermentation in Rum Production

Fermentation is a metabolic process in which chemical changes take place in an organic substrate under the action of

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00598-5

cellular enzymes, typically in the absence of oxygen. It is characterized by being highly exothermic and the incomplete oxidation of large quantities of the original substrate.

In the case of alcoholic fermentation, the initial substrates are fermentable sugars such as glucose and fructose, and the end products consist mainly of ethyl alcohol, smaller amounts of other congeneric products, and the large-scale release of CO_2 (Figure 1).

In order for alcoholic fermentation to commence, a number of requisites must be met for both the raw materials and the conditions under which fermentation is to take place. One of these factors is the sugar content and both intrinsic and extrinsic nutrients found in the molasses. Other factors within the control of the rum producer are temperature, fermentation duration, the pH, the predominant type of yeast during fermentation, and the density of the medium (Table 2).

With the exceptions of temperature and fermentation duration, all these factors must be adjusted in the molasses prior to fermentation. Correspondingly, the molasses is diluted to the appropriate density to avoid malfunction of the fermentation apparatus. Particles in suspension are precipitated with aluminum sulfate; nutrients added, such as nitrogen (urea or ammonium salts) and phosphorus; and the pH adjusted with phosphoric and/or sulfuric acid. If selected yeasts or bacteria are to be added, pasteurization may be used to ensure the elimination of autochthonous microbial flora that might compete with the added flora and reduce their output. The characteristics of commercial yeast strains should promote the appropriate development of fermentation, such as high fermentation velocity, ethanol tolerance, high-temperature acidity, and osmotic pressure, as well as alcoholic output and the production of appropriate aromatic compounds. It is now also thought very desirable for these yeasts to have a 'killer' capacity, by controlling the development of other undesirable yeasts during fermentation.

In order to accelerate the start of fermentation, a mixture known as 'bottom of the vat' may be prepared at 4–10%V V^{-1} with yeasts selected from the molasses. This preferment is added to the vat and, when fermentation begins, diluted

a.a, absolute alcohol.

molasses is gradually added to avoid excessive temperature buildup. Although the preferred temperature for fermentation is 21 °C (Table 2), the temperature range is quite wide, depending on the type of rum produced. For example, for light rums, temperature can vary from 28 to 33 °C, while for heavy, Jamaican-type rums, the range is from 30 to 33 °C, and cases have been recorded of fermentation at 37 °C. The production of dark or heavy rums always involves the use of higher temperatures and fermentation durations (Table 2), with even the possible addition of the 'dunders,' which are the nitrogen-rich residues or lees from previous distillations.

Just as there are nutrients in molasses that encourage alcoholic fermentation, other constituents may have the opposite effect. Compounds, such as hydroxymethylfurfural (≥0.05% V V^{-1}), butyric acid (≥0.1%V V^{-1}), valeric acid (≥0.1% V V^{-1}), and minerals, such as silver, arsenic, barium, mercury, lithium, nickel, osmium, lead, selenium, and tellurium (≥100 mM), can delay or even inhibit alcoholic fermentation. Acetic acid can affect yeast activity, modifying their tolerance to both alcohol and temperature. The higher the concentration of this compound, the lower the alcohol tolerance of the yeast, up to a maximum of 1%V V^{-1}, where tolerance is zero. Similarly, at a concentration of 1%V V^{-1}, the critical temperature of yeast falls to 26 °C, in comparison to a 42 °C maximum for some yeast in the absence of acetic acid.

Once alcoholic fermentation has begun, and the alcohol concentration has reached 3.5–4.5%V V^{-1}, the sugar has fallen below 6 g 100 ml^{-1}, and the fermentation temperature is below 30 °C, the *Clostridium* culture is added. The most efficient culture has a bacterial (*C. saccharobutyricum*) to yeast ratio of 1:5. The bacteria accelerate the formation of alcohol during fermentation and encourage the formation of a balanced aromatic profile. The function of other bacteria is not clear.

Table 4 Influence of pH on alcoholic fermentation

Product (g 100 l^{-1}a.a)	*pH 3*	*pH 4*	*pH 5*	*pH 6*	*pH 7*
Ethanol	171.0	177.0	173.0	161.0	150.0
CO_2	181.0	190.0	188.0	177.0	161.0
Glycerol	6.2	6.6	7.7	16.2	22.2
Acetic acid	0.5	0.7	0.8	4.0	8.7
Lactic acid	0.8	0.4	0.5	1.6	1.9

a.a, absolute alcohol.

The major end products of alcoholic fermentation are ethyl alcohol and CO_2. A number of other compounds, known as congeneric compounds, are also formed. These have an important effect on the bouquet of the rum, although others are present in the raw material. The congeneric compounds are mainly glycerol, *n*-propyl alcohol, organic acids (acetic and lactic), higher alcohols (isoamyl and isobutyl), aldehydes (acetaldehyde), esters (ethyl acetate), and fatty acids. The production of congeners is closely related to the type of yeast and the predominant pH during alcoholic fermentation. Tables 3 and 4 provide some examples of the foregoing.

A rest period of 24–40 h after the conclusion of fermentation is recommended to increase development of the rum's bouquet. Low fermentation temperatures and low pH values toward the end of the process likewise encourage the concentration of esters. It is also thought that significant concentrations of a higher alcohol, such as *n*-propanol, are the result of high concentrations of glutamic acid in the molasses.

Different fermenting systems are used in the production of rum. Discontinuous systems are commonly used in the closed batch and Melle–Boinot variants (Figure 2). These are closed processes in which the preferment and nutrients are added at the start of fermentation, allowing incubation to take place under optimal conditions. When the desired state has been reached, the fermentation vessel is emptied and cleaned and the process repeated. Multiple-stage continuous fermentation systems are also used, where the nutrients and preferments are continuously added and ferment is withdrawn from the vat or bioreactor. Conditions are thus kept uniform throughout the fermentation vessel, with a balance between nutrients, microorganisms, and desired end products obtained (Figure 3).

After the completion of fermentation, and before distillation commences, the fermented mass or wash (*batición* in Cuba) is left to stand in order for the yeast to settle at the bottom. Suspended insoluble matter is separated by centrifuge.

Distillation in Rum Production

After fermentation, the next stage is distillation. Its modern expression evolved variously in different geographic production areas. However, the industrial revolution brought about the most important change in distilling, allowing highly homogeneous beverages to be produced regardless of year, raw material, etc. A better understanding of chemistry, and especially the principles

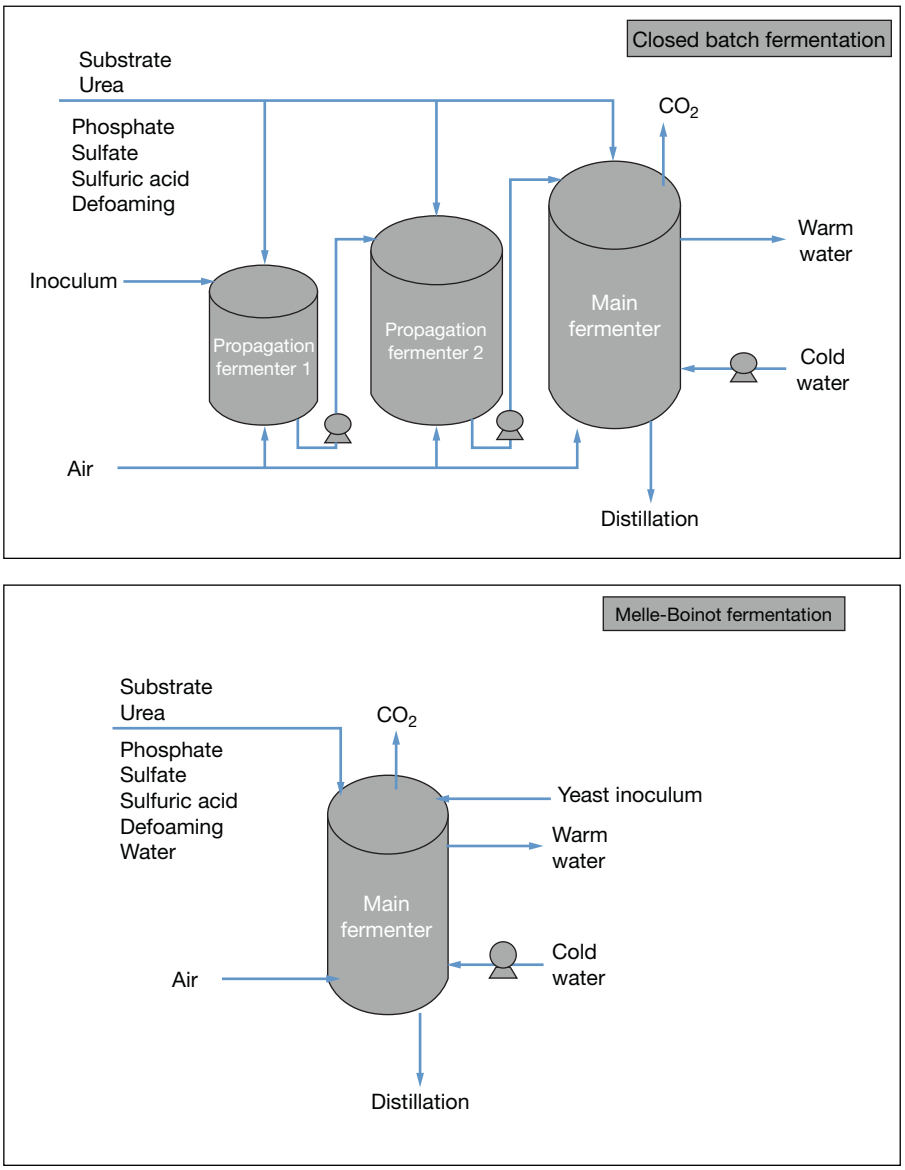

Figure 2 Discontinuous fermentation systems in rum.

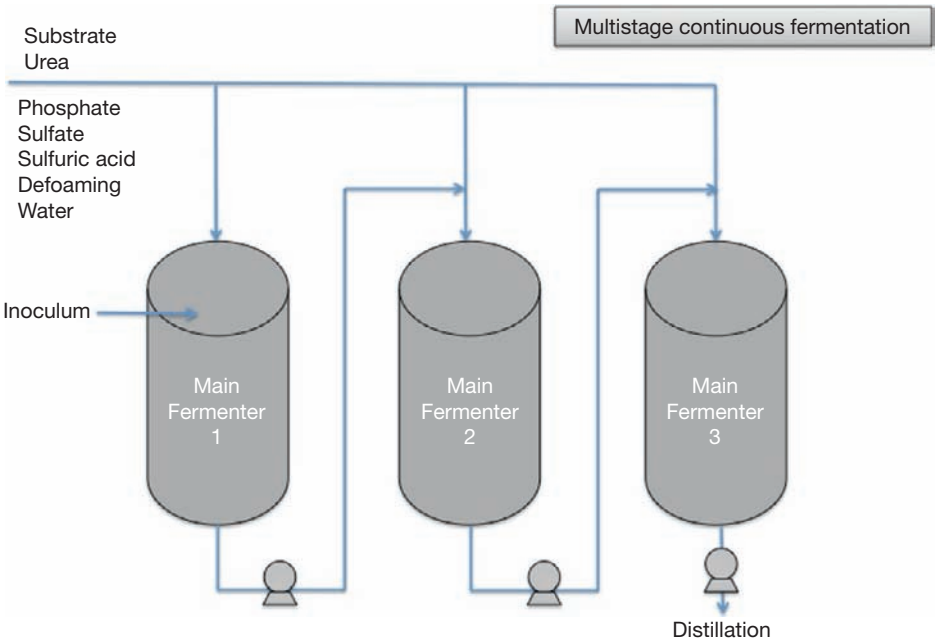

Figure 3 Multiple-stage continuous fermentation system in rum.

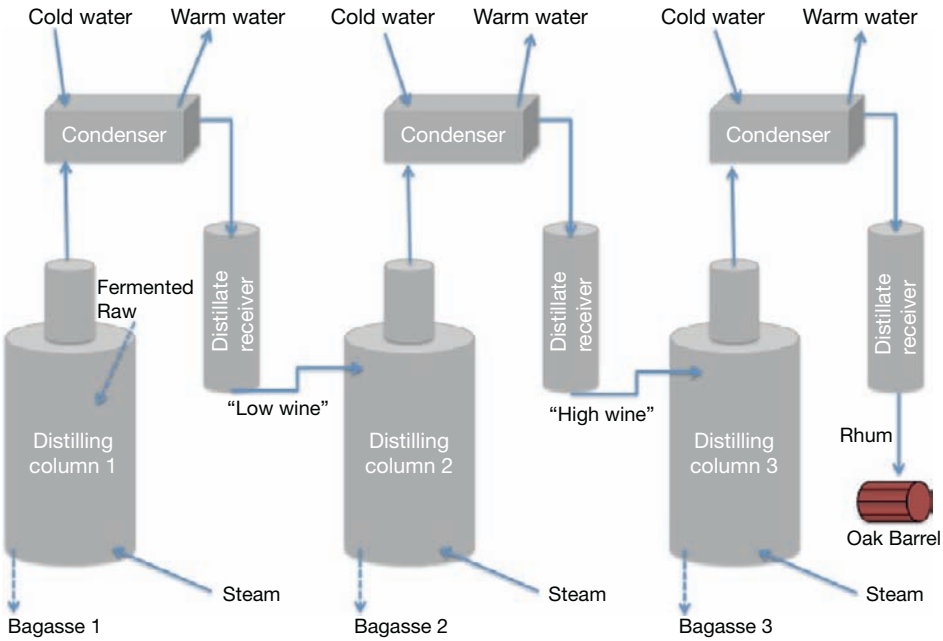

Figure 4 Batch distillation system in rum.

of evaporation and condensation, altered rum production forever.

Generally speaking, the term 'distillation' is applied to processes of vaporization, by which compounds removed with steam are recovered during condensation. More specifically, the constituents of a liquid mixture are separated by partial vaporization, and there is separate recovery of the steam and waste. Most of the volatile components of the initial mixture pass into the steam, while the less volatile constituents concentrate in the remaining liquid. In this way, the alcoholic and aromatic products of yeast fermentation (secondary aroma), as well as those from molasses (primary aroma), are separated, selected, and concentrated. Rum is made using either simple, discontinuous, batch distillation or continuous distillation in a single or multiple (3–5) column system.

Simple, discontinuous, or batch distillation (Figure 4) is used in French and English areas of the West Indies and in Brazil for heavy rums. It is typically a relatively simple,

low-cost, flexible system, producing high-quality rum, although production costs are high. A typical installation is similar to a simple pot still with three stages. The mixture to be distilled is pumped into a copper distillation vessel, from which the distillate obtained, known as 'low wine,' is collected in a second vessel where another distillation takes place, producing 'high wine.' The heads and tails of the second distillation are discarded and only the heart (middle cut) of the high wine is distilled to produce rum. The head fraction of the high wine is obtained at temperatures below 78 °C and is rich in very volatile substances such a methanol, acetone, acetaldehyde, and ethyl acetate. The tail fraction is the last to be obtained, at temperatures above 82 °C. It consists of the components with the highest boiling point: higher alcohols, furfurals, and aromatic compounds. These could impair the aromatic characteristics of the distillate if their recovery is prolonged, leading to high contents in the final product. The central fraction is collected between 78 and 82 °C and consists mainly of ethyl alcohol and desirable congeneric compounds, reaching an alcohol content of 90–95%V V^{-1}. The master distiller's skill consists in knowing how to collect only the central of the three fractions, determining when they begin and end. This ensures the absence of undesirable alcohols and the presence of a high percentage of aromatics, although correction can be carried out to obtain pure ethanol. Correction processes enrich alcoholic vapors by passing them countercurrent through liquids descending from the upper parts of a column. Inside the column, the vapors exchange heat and mass with the liquid and eventually condense upon leaving the column with partial reflux. This 'washes' components with highest boiling point out of the rising vapor flow. At the same time, some the compounds with low boiling point are lost.

Variations in continuous distillation are suitable for large-scale production (~10 000 l in 24 h), with consequent savings in fuel and time. However, a significant disadvantage is the inability to obtain a suitable degree of splitting. An installation of this type, which avoids the disadvantage, consists of a distilling column, a rectifying column, one or more purifying columns, and three or more condensers (Figure 5). The end product is complex, with alcoholic strength of 40–70%V V^{-1} and important amounts of aldehydes, acids, esters, higher alcohols, etc., and is known as *liquor*.

Distillation contributes decisively to the volatile composition of the rum distillate. For example, heating promotes oxidation, esterification, and partial dehydration, giving rise to new compounds, with an increase in the concentration of aldehydes, ethyl acetate, and other esters, as well as furfural. Sugarcane ferments (worts) contain very little furfural, but it can appear due to the dehydration of pentoses and pentosans during distillation. A wort with higher sugar contents and more acid gives rise to a higher furfural content in the distillate. Similarly, an increase in acetaldehyde content is due to the incomplete oxidation of ethyl alcohol. Acetaldehyde can also react with ethanol to produce acetal.

Another important consideration in the production of rum, and of any distilled beverage, is the presence of methanol. Because of its nerve toxicity, distillation is adjusted to keep its concentration very low in the final distillate. Methanol is metabolized by the liver to formaldehyde and subsequently to formic acid. The latter can be excreted (via urine) or oxidized to CO_2. Approximately 3–5% is eliminated in unmetabolized form via the kidneys and lungs. The minimum lethal dosage is 100 mg Kg^{-1} body weight (ranges from 20 to 100 ml methanol).

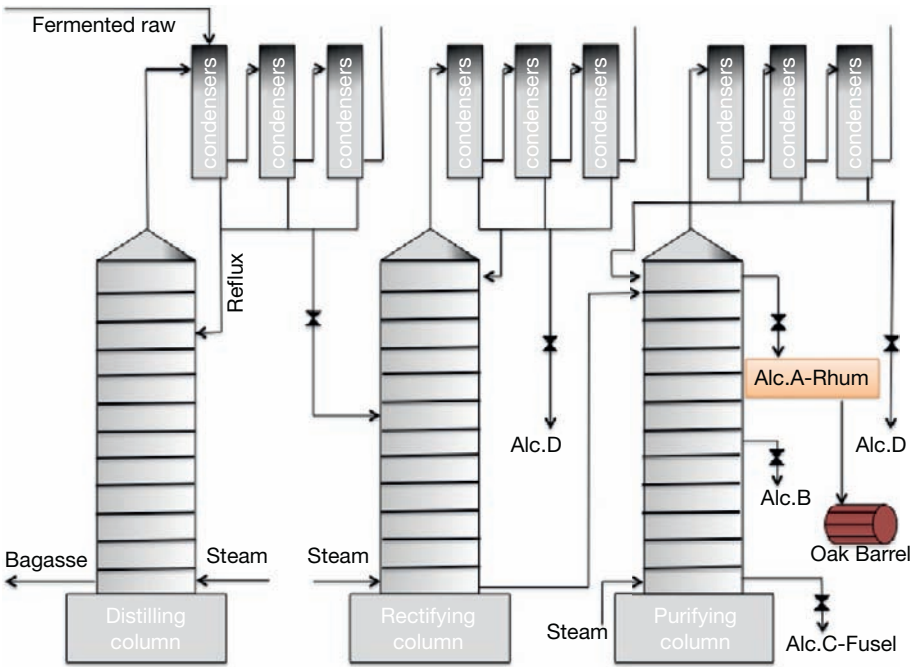

Figure 5 Continuous distillation system in rum. *Alc.A-Rhum*: The finest alcohol and used for rhum elaboration; *Alc.B*: Fine alcohol but not used for rhum elaboration; *Alc.C*: Fusel alcohol rich in superior alcohols and not used for rhum elaboration; *Alc.D*: The worst alcohol in distillation and not used for rhum elaboration.

In order to ensure the minimal concentration of methanol in the distillate, systems can be used consisting of columns that leach methanol by trichloroethylene in the liquid–vapor phase. Different regulations in rum-producing countries set maximum limits for the presence of methanol. In Cuba, for example, the maximum is set at 10 mg 100 ml^{-1}, and in the European Union and other Caribbean nations, it is 30 mg 100 ml^{-1}.

Another manner of purifying rum is by using activated carbon. This is a porous adsorbent, consisting mainly of carbon, with a high adsorption capacity for gaseous substances as vapor or in solution. This is the result of a particular thermal treatment known as activation, which increases the specific surface of the carbon and donates high porosity. The use of this product with rum decreases its acidity, as well as its phenol, ester, and fatty acid contents. It also creates a slight decrease in higher alcohol contents and eliminates lactones. If necessary, it can also have a bleaching effect.

Aging of Rum

Aging of rum involves storage in white oak barrels (cherry being used in some regions), the duration depending on the quality and type of product desired, with the aim of improving its sensory attributes. This improvement is the result of a number of transformations that take place between components of the distillate and those of the wood. These involve reactions between different compounds of the distillate, reactions between substances extracted from the wood and their oxidation, and reactions between the original compounds, extracted compounds, and those formed previously. The most influential reactions during aging are those of esterification, oxidation, and the decomposition of lignin.

Esterification depends on alcoholic strength, acid content, temperature, and duration, while oxidation is more intense at the start of the aging process. This results because of the large amount of oxygen dissolved during preceding stages. Oxidation begins by affecting the components of rum, with an increase in aldehydes and acetic acid, and over time, it also affects wood components.

The most common wood used for aging rum is oak (*Quercus*). The most widely used species are white oaks (*Q. alba*, *Q. minor*, *Q. platanoides*, *Q. iberica*, *Q. longipes*, *Q. robur*, and *Q. canariensis*) because of their excellent porosity and the contribution they make to the aromatic composition of rum, providing both volatile and nonvolatile compounds. The main role of most of the nonvolatile compounds is to act as precursors in the formation of flavorants during contact of the oak with the alcoholic beverage, whereas the volatile compounds can make direct contributions to the taste and bouquet of the rum.

Oak wood contains cellulose (40–45%), hemicellulose (20–25%), lignin (20–33%), and a heterogeneous group of soluble compounds (2–10%). The latter are important, as they can donate the characteristic color and smell of wood. This large group includes resins, volatile oils, terpenes, fatty acids, carbohydrates, polyhydric alcohols, nitrogenous compounds (proteins and alkaloids), phenolics, and inorganic components.

The decomposition of lignin (Figure 6) causes the appearance in the distillate of compounds such as coniferaldehyde and sinapaldehyde and their derived acids and aldehydes. These have an important role on the organoleptic characteristics of the rum. The longer the aging, the higher the presence of these compounds in the distillate, although extraction also depends to a large extent on the age and usage of the barrel. The same is true of other wood extractives, such as tannins and oak lactones. Similarly, the intensity of the scorching of the barrel's inner surfaces, part of its construction, also has an effect on the compounds that originate from the wood.

Although compounds that originate during aging have some active participation in its sensorial characteristics, oak lactones are possibly the most important. The two oak lactones recognized in rum are oak *trans*-lactone and oak *cis*-lactone. The

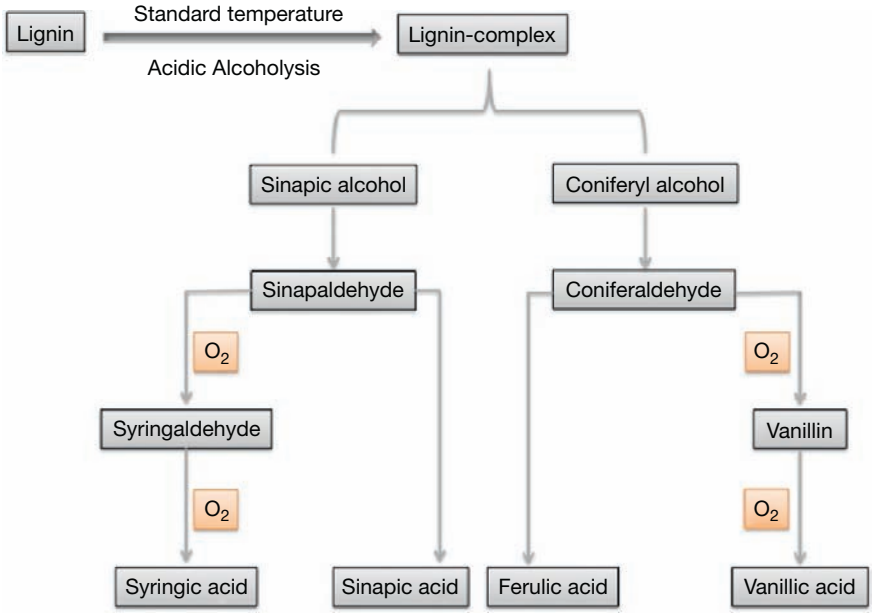

Figure 6 Decomposition of lignin.

former gives off aromatic notes of grass, straw, spices, a slight smell of firewood, and a moderate smell of coconut, while the second smells of cinnamon and strongly of coconut. The lactone contents of rum depend on the species of oak and the intensity of charring during construction. The species with highest lactone contents are Romanian and French oaks, while American oaks, which are the species used primarily for rum aging, have medium contents. The lowest concentration of lactones is found in Japanese oak, which is hardly ever used. The heavier the barrel charring, the higher the oak lactone contents. The maximum charring duration is 15 min (heavy charring). For light rums, barrels may be only lightly toasted, or not at all. Charring has several effects on wood composition: thermal decomposition of polyoxides, creating furanic aldehydes; thermal decomposition of lignin, creating volatile phenols, aldehydes, and phenolic acids; thermal decomposition of tannins, creating gallic and ellagic acids; and thermal decomposition of lipid components, creating lactones.

An important question regarding rum aging is evaporative loss. This depends on several factors, such as the density of the barrel wood, the evaporation area per unit volume, the humidity of the air in the storage area (70% is considered optimum for balance), ambient temperature, airtightness of the barrels, and the intensity of inner surface charring. Loss can be up to 12% per year, with a decrease in compounds such as ethanol, acetaldehyde, n-propanol, ethyl acetate, isobutanol, isoamyl acetate, isoamyl acid, ethyl caproate, and acetic acid.

The oak wood used in aging can have different morphological characteristics that can have an effect on the end product. The capacity of the barrels is usually 200 l or 450 l, which determines the contact surface of the distillate with the wood. In a 200 l barrel, the area of wood per liter of distillate is 90 cm^2, while for a 450 l barrel, the area is only 60 cm^2. This means that one or other type of barrel will be chosen, depending on the desired type of rum and aging period. The higher the contact surface, the more intense the organoleptic characteristics of the rum, and therefore, aging time in the barrel will tend toward the legal minima, whereas in a barrel with lower contact surface, aging times will increase for similar organoleptic results.

The barrels are stacked in different ways depending on the characteristics of the storage area. The most usual arrangements are known as *solera* and racks (Figure 7), each of which has its advantages and disadvantages. For example, the solera arrangement, also known as *solera gallega* in Cuba, has the advantage of economy of setup but is more awkward to work with. The rack arrangement has the advantage of improved barrel support, but it is expensive and complex to set up, sometimes requiring the use of forklift trucks to move the barrels.

The traditional arrangements for barrel storage (*solera* and racks) are the most common, but they have their disadvantages: large warehouses required to keep the barrels, the limited availability and cost of barrels, evaporative loss during aging, deterioration of warehouses and barrels, periodic reactivation of the barrels, and treatment of new barrels before use for aging.

In an attempt to reduce the effects of the foregoing, nontraditional aging systems have come into being. These aim to reduce evaporative loss and accelerate the aging process. To this end, these new aging techniques must achieve rapid extraction of oak compounds by the hydroalcoholic mixture, improve the conservation and increase the original volatile substances, and provide adequate oxidation of the components extracted from the wood and those present in the rum. Some of these nontraditional techniques include the use of oak extracts, oak wood chips, treatment with oxygen or ozone, the application of electrical currents to the distillate, and the application of nonionizing radiation. The most effective of these techniques are those using extracts and chips of oak wood. The others are of dubious utility.

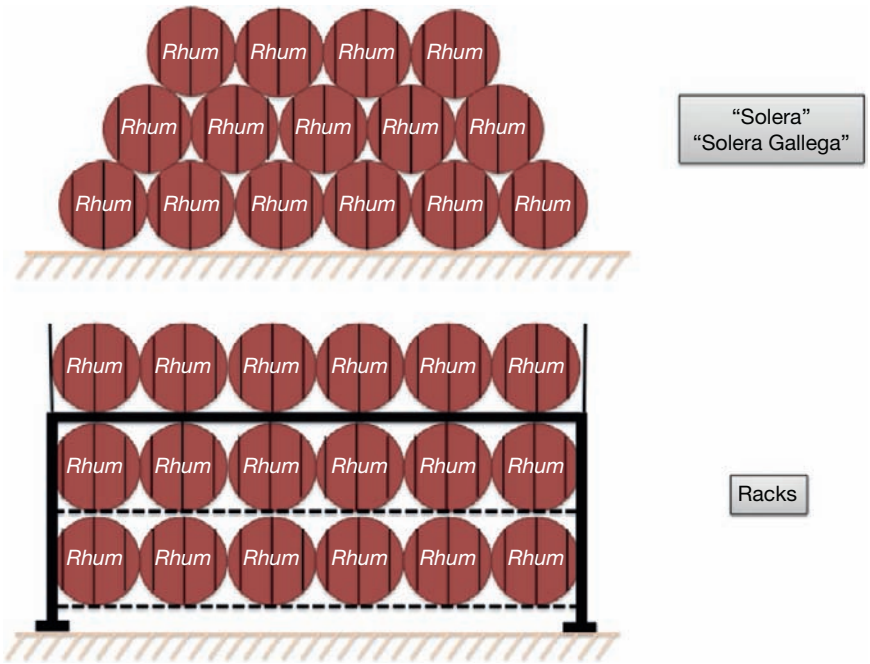

Figure 7 Most usual arrangements for aging of rum.

Final Treatments of Rum

At the conclusion of the desired aging process, and taking into account the change in alcoholic strength that may have occurred, the rum has to be diluted to the final strength permitted by the regional legislation. Adjustment of the alcoholic strength must be carried out with suitable water that does not contaminate the taste or smell of the rum. The same goal can also be achieved using rums of different alcoholic strengths to make a blend of the desired strength.

Other factors, such as the variation in the raw material, growth conditions of the sugarcane, the strain of yeast, and the techniques of distillation and aging, can lead to the same rum not always presenting homogenous characteristics. Standardizing the final rum is an important part of the producer's job. It can be achieved by blending different distillates with different characteristics from different barrels, ages, amounts of distillate, and aging processes or by using small amounts of additives that do not interfere with the product's character but provide it with an easily identifiable personality. The use of coloring syrup and caramel (E-150) is very common to standardize rum color, which can range naturally depending on aging from amber to mahogany color. The use of polysaccharides as coloring is not without risk, considering that if they have an unsuitable isoelectric point or they are not alcohol-resistant, they may precipitate. This can be avoided by the addition of alcohol prior to use, in order to ensure their suitability and stability. White or almost colorless rums can be made by decoloration with activated carbon.

The use of *solera* aging methods, similar to those used in the production of Sherry wines or Sherry brandy, can also help to standardize rum. This is the method used for rum made in Motril (Spain).

Having adjusted the alcoholic strength and blending, a number of operations are necessary before bottling to assure that the rum remains a clear, bright liquid, attractive to the end consumer. One of these operations is to allow it to rest for a variable period (from 48 h to 15 days), in order for sedimentation to eliminate components adversely affected by a change in solubility, the formation and sedimentation of some less soluble compounds, and the homogenization and balance of its blended aromatic components. Cold or coagulating agents are commonly used at this stage to achieve faster sedimentation.

Finally, the beverage is clarified using a filter system using diatomaceous earth or cellulose plates.

At present, the bottling process is no different to any other beverage. Modern machines fill and close the glass bottles, some of which can inject an inert gas (nitrogen) into the neck of the bottle to improve conservation of the beverage.

General Types of Rum

Heavy or Strong Rum

Maturation: charred oak or cherry. Aging time: 10 or 12 years up to 15 years. Final alcoholic strength: 40–60%V V^{-1}. Color: variable (colorless/amber/mahogany color). Additional coloring: caramel. Bleaching where necessary: active carbon.

Light or Smooth Rum

Maturation: oak or cherry, even uncharred. Aging time: short periods. Final alcoholic strength: 40–60%V V^{-1}. Color: variable (colorless/amber/mahogany color). Additional coloring: caramel. Bleaching where necessary: active carbon.

Commercial Types of Rum

White

These are clear, dry, light rums, although their alcoholic content is the same as in others. The liquor produced by the distilleries is colorless, so it could be said that white rums are the basis of the industry. Contact with the oak wood during aging gives the rum a slight amber color, which is eliminated by active carbon filtering before marketing, although some producers bottle without filtering, retaining the name of white rum. Due to its short aging (sometimes only 1 year), this is the cheapest rum with most neutral flavor and is therefore preferred for mixing and cocktails.

Dorado, Gold, or Ambré

It is similar to white rum, but with a more or less intense amber color. Because of its longer aging than white rum and lack of filtering, it has a more intense flavor due to the higher congeneric contents. Caramel is sometimes added to accentuate the color.

Black or Dark

They are heavy rums with strong body. Most are produced in pot stills and therefore retain a strong taste of molasses. The dark, almost black color is obtained by the addition of coloring to intensify the amber color acquired in the barrel. The main producing countries are Jamaica and Barbados. The Demerara variety is a dark rum produced in the Demerara River basin in Guyana.

Spiced or Flavored

In this category, the rum is blended with various extracts to give extra flavor. Both fruit flavors (orange, lemon, banana, pineapple, coconut, etc.) and spices (vanilla, nutmeg, cinnamon, etc.) are used. White rum is normally used for the fruit flavors, while gold or aged rums are used for spiced flavors.

Overproof

These are generally white rums bottled at an extremely high alcoholic strength (100 or more degrees British proof). There are no differences between British and Canadian overproof rums.

Premium

Premium rums are those in which aging and blending have been taken to the maximum degree of quality without economic loss. The term 'premium' is frequently used only for publicity purposes. Rums produced in small quantities for one

Guatemala	Light rum	Zacapa
Guyana	Demerara Courante	El Dorado, Dos Maderas, XM, Wood's, Lam's
Haiti	Simple distillation rum Double distillation rum	Clairin, Barbancourt
Jamaica	Light rum Blended rum Heavy rum (wedderburn, plummer)	Appleton, Capitán Morgan, Myer's, Lemon Hart
La Martinica	Heavy rums	Bardinet, Grappe Blanche, Clement, Gran Arome, Saint James, Negrita, Bacardí, Bailly, Duquesne
La Barbada	Light rum	Mount Gay, West Indian Rum, Barbados Dt.
The Philippines	Light rum	Pandy, Tanduay
Puerto Rico	White label Golden label	Bacardí, Boca chicacarioca, Don Q, Mérito, Ronrico, Matusalem, Bellows
Spain	Pale rum (light) Honey rum (sweet)	Montero, Bacardí, Bermúdez, Larios, Guanche, Aldea, Tropicana, Negus, Negrita, Bunti, Pujol
Trinidad	Light rum	Bacardí
Venezuela	Light rum	Aniversario, Cacique, Pampero, Santa Teresa, Estelar, Real Caruano

reason or another are special cases and may be meant for private consumption or special occasions.

Production Areas

Rum-producing areas coincide with the regions where sugarcane is grown. This mainly includes practically all of America, where Christopher Columbus introduced sugarcane from Andalusia. Apart from America, sugarcane is still grown in some parts of Europe, specifically southern Spain and the Canary Islands. There is also a small production of rum in the Philippines, doubtless the result of its colonization by Spain. Table 5 summarizes the different areas and countries where rum is produced.

Riboflavin: Physiology

HJ Powers, University of Sheffield, Sheffield, UK

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Riboflavin (7,8-dimethyl-10-ribityl-isoalloxazine) is the generic term used for the water-soluble vitamin B_2 but chemically describes the free-form of riboflavin. Derivatives of riboflavin, which are functionally important to humans, are riboflavin phosphate, also called flavin mononucleotide (FMN), and flavin adenine dinucleotide (FAD). Intracellularly, riboflavin is converted to FMN by ATP: riboflavin 5-phosphotransferase (flavokinase; EC 12.7.1.26); and FMN is converted to FAD by ATP: FMN adenylyltransferase (FAD pyrophosphorylase; 2.7.7.2). FAD and FMN are tightly bound, either covalently or noncovalently, at the catalytic site of numerous enzymes.

Dietary Sources and Patterns of Consumption with a Global Perspective

Riboflavin is distributed widely in foods, as free riboflavin or the derivatives FMN and FAD. In Western diets, milk and milk products generally make the largest contribution to dietary intakes; fortified cereals, meat, and fish make a useful contribution too. The fortification of some grain products with riboflavin means that certain breads and breakfast cereals are very good sources of this vitamin. Yeast extract such as Marmite can also be a very good source, even though generally consumed in small amounts.

Studies worldwide indicate that riboflavin intakes are likely to be low in populations consuming diets low in dairy and meat products. Although there are several reasons why individuals and communities consume dairy- and meat-poor diets, low income is a central determinant. However, even in resource-rich countries, riboflavin deficiency is prevalent in some groups, notably adolescents, which might be causally linked to a decline in the consumption of milk and dairy products. Although vegetarian diets can be nutrient-dense, riboflavin intakes have been reported as being lower in vegetarians than nonvegetarians in some settings.

Bioavailability, Transport, Metabolism, and Excretion

Most riboflavin is present in foods bound as FAD and FMN with small amounts as free riboflavin. Milk and eggs differ from most foods in that they contain riboflavin bound to specific binding proteins, but there is no evidence that this influences bioavailability. To be available for absorption, FAD and FMN in food are hydrolyzed in the intestinal lumen by phosphatases, releasing free riboflavin, which is transported into the enterocytes of the small intestine by an active, carrier-mediated process. The transport process is saturable at about 30 mg in a single meal. Flavokinase in the intestinal mucosa phosphorylates intracellular riboflavin, so that much of the riboflavin entering the plasma does so as FMN. Kinetic modeling following ingestion of stable isotope-labeled foods suggests that a large fraction of newly absorbed riboflavin is removed from the circulation on first-pass metabolism by the liver. Although the main site of absorption is the proximal small intestine, there is some capacity for absorption from the colon, so that riboflavin synthesized by colon microbiota may be an important source of this vitamin. Bioavailability is not known to differ between food sources, although this has been the subject of limited research activity.

Riboflavin is carried in the plasma bound to albumin and to certain immunoglobulins, which can also bind FAD and FMN. Recent data show that about 70–75% of total riboflavin in the plasma is present as FAD, 5–10% as FMN, and 15–20% as free riboflavin.

Uptake into tissues occurs by carrier-mediated diffusion of riboflavin, which is phosphorylated intracellularly to FMN and then to FAD, which constitutes the great majority of intracellular flavins. Very little intracellular riboflavin occurs in the free-form. FAD and FMN that are not bound to protein are hydrolyzed to riboflavin, which diffuses rapidly out of cells and is excreted. Evidence suggests that flavin-dependent enzymes show a differential response to progressive reduction in dietary riboflavin that is also tissue-specific. Generally, it appears that tissue concentration of FAD is conserved at the expense of riboflavin and FMN.

As riboflavin intake increases, there is a point at which urinary excretion increases markedly; this occurs at a daily intake of around 1.0 mg and is generally understood to reflect tissue saturation. About 25% of urinary riboflavin is as free-form. Riboflavin-8-α-histidine and riboflavin-8-α-cysteine may appear in the urine as a result of the metabolism of enzymes containing covalently bound FAD or FMN. The activity of hepatic cytochrome P450-linked mixed-function oxidases generates 7-hydroxymethylriboflavin and 8-hydroxymethylriboflavin, which may also appear in the urine.

Biological Function

Redox Reactions in Intermediary Metabolism

Attention has been drawn to the remarkable versatility of the flavoproteins, attributed to the wide variation in redox and electronic states in which the isoalloxazine ring of flavins can exist. Flavins act as electron carriers in a diversity of redox reactions important to intermediary metabolism. Notably, steps in the cyclical β oxidation of fatty acids and oxidation steps of the tricarboxylic acid cycle utilize FAD as an electron acceptor in two-electron transfer reactions. In the process, the substrate is oxidized, often to form a carbon–carbon double bond, and the flavin is reduced. FAD functions as an electron carrier in the iron–sulfur flavoprotein of the mitochondrial electron transport chain. Riboflavin is thus essential for energy

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00594-8

generation in the aerobic cell through oxidative phosphorylation, and a lack of riboflavin compromises cellular energetics. Riboflavin-deficient mice exhibit impaired hepatic oxidative metabolism, and rats fed with a diet deficient in riboflavin show a reduction in the activity of flavin-dependent mitochondrial enzymes. Riboflavin-depletion of cultured cells leads to a decrease in ATP generation.

Disulfide oxidoreductases: FAD is also integral to a group of flavoproteins that contain an active disulfide site; these enzymes catalyze reduction of a disulfide group with the concomitant oxidation of reduced nicotinamide adenine dinucleotide phosphate (NADPH). They include glutathione reductase, which is used as the basis of a functional assay for riboflavin status, and the associated generation of reduced glutathione has important antioxidant function. Lipoamide dehydrogenase and thioredoxin reductase also fall into this group.

Flavin oxidases: Flavin oxidases catalyze reactions in which the flavin is reduced by dehydrogenation of the substrate, reactions that involve an intermediate substrate–flavin adduct. D- and L-amino acid oxidases fall into this category. Reoxidation of the reduced flavins generates a flavin semiquinone radical and superoxide, which react further to generate perhydroxy radicals.

Other flavoproteins: Other flavoproteins include NADPH oxidase (the respiratory burst oxidase), important in the cytotoxic action of macrophages, and flavin-dependent mixed-function oxidases, which are active in the metabolism of xenobiotics.

Methylenetetrahydrofolate Reductase

FAD is a coenzyme for methylenetetrahydrofolate reductase (MTHFR), which is central to the function of the methyl cycle, which drives the very many and diverse methylation reactions in humans. Methionine is the direct precursor of *s*-adenosylmethionine, which serves as the methyl donor for numerous substrates including DNA, phosphatidylethanolamine (to form phosphatidyl choline), and guanidinoacetate (to form creatine). All methyltransferase reactions generate homocysteine, a sulfur-containing amino acid that is not incorporated into protein. Homocysteine remethylation to methionine depends on 5-methyltetrahydrofolate as the methyl donor, generated in a reaction catalyzed by MTHFR. Factors associated with a diminished MTHFR activity can lead to elevated plasma homocysteine concentrations. Riboflavin was identified as a factor influencing plasma homocysteine concentration in the Framingham Offspring Cohort. Plasma homocysteine concentration is responsive to riboflavin intake, but only in individuals who are homozygous for the relatively common MTHFR C677>T polymorphism.

Dietary Requirements for Riboflavin

Dietary requirements are variously expressed as dietary reference values (DRVs) in the United Kingdom, dietary reference intakes in the United States, and population reference intakes in Europe. In all cases, the intention is to convey need in terms of a daily intake that will satisfy the needs of the majority of the population, excluding those with particular requirements because of disease or metabolic abnormality. For riboflavin, values have been set between 1.0 and 1.6 mg day^{-1} for adults, varying according to the scientific body making the recommendations. There is no clear functional outcome associated with intakes less than recommendations; in the United Kingdom, requirements were based in part on the relation between riboflavin intake and urinary excretion. An inflection, at which urinary excretion increases sharply, thought to reflect tissue saturation with flavins, occurs at an intake of about 1.0 mg.

Because of the central role of riboflavin in energy-generating metabolism, riboflavin requirements are sometimes expressed on the basis of energy intake. However, in view of the wide range of riboflavin reactions unrelated to energy generation, it is difficult to justify this approach.

Consequences of Low Intakes

Prevalence of Deficiency Globally

At very low intakes of riboflavin, clinical signs of deficiency may occur, including lesions at the corners of the mouth (angular stomatitis) and at the margins of the lips (cheilosis), desquamation of the tongue, and a general seborrhoeic dermatitis. However, these clinical signs may also occur in association with other B vitamin deficiencies and cannot be considered specific for riboflavin. Clinical signs of deficiency are rare in Western countries but relatively common in some low-income countries, with some evidence of seasonal variation in incidence. The relation between dietary intake of riboflavin and appearance of clinical symptoms of riboflavin deficiency may be confounded by other dietary factors and by local infection, and the absence of clinical symptoms does not necessarily reflect adequate riboflavin status.

Biochemical riboflavin deficiency is usually assessed by measurement of the activity of FAD-dependent glutathione reductase, measured in red blood cell hemolysates. The activity of erythrocyte glutathione reductase is measured before and after the addition of the coenzyme FAD, and the ratio of the two activities (FAD-stimulated/FAD-unstimulated) is expressed as an activation coefficient, EGRAC. This test is very sensitive to changes in riboflavin intakes at the lower end of the intake range. An EGRAC value of >1.30 is the most commonly used cutoff for biochemical riboflavin deficiency. The detail in the conditions used in the EGRAC assay can have an important influence on the assay results, and this must be borne in mind when making comparisons between data describing prevalence of riboflavin deficiency in different populations.

Biochemical deficiency based on the EGRAC test has been reported in many countries and is not confined to low-income regions or populations. A high prevalence of deficiency has been documented in, for example, Gambia, India, Taiwan, Ivory Coast, and the United Kingdom. Deficiency is often associated with a low dietary intake of milk and dairy products and meat. Deficiency occurs across life stages from infancy to old age.

Many studies of the prevalence of riboflavin deficiency, particularly those conducted in low-income countries, are reliant on estimates of dietary intake. Compared with national or WHO DRVs, there is a high prevalence of inadequate intake of

riboflavin in many regions of the world, including China, Iran, several countries in Africa, and India.

However, despite evidence for low intakes and biochemical riboflavin deficiency across many regions of the world, there is still an incomplete understanding of the functional consequences of low intakes of riboflavin and poor status.

Growth

Impaired growth is a well-established hallmark of riboflavin deficiency in animals, presumed to be due to effects on energy-generating steps in metabolism and an associated reduction in ATP generation. Frank riboflavin deficiency in humans generally occurs in association with other micronutrient deficiencies, making it difficult to ascribe symptoms to riboflavin specifically. Certainly, while poor growth in association with low riboflavin intakes is common in many low-income countries, this is likely to be the result of inadequate intakes of several essential nutrients.

Lipid Metabolism (Organic Acidurias)

Much of the research into the effects of low riboflavin intakes on lipid metabolism and associated disorders has been conducted in animal models of deficiency. Rats fed a riboflavin-deficient diet exhibited altered fatty acid profiles in hepatic lipids, notably an increase in 18:2$n-6$ and a lower 20:4$n-6$. Feeding a riboflavin-deficient diet to weanling rats impaired β oxidation and led to the abnormal urinary excretion of dicarboxylic acids. Gene defects in humans, leading to flavin-dependent acyl-CoA dehydrogenase deficiencies, are associated with defects in fatty acid metabolism and organic aciduria, accompanied by a range of clinical abnormalities. People carrying these defects are responsive to high doses of riboflavin. Whether there is broader relevance to humans is unclear; β oxidation of fatty acids seems not to be impaired in riboflavin-deficient infants.

MTHFR Activity, Homocysteine Concentration, and Disease Risk

Riboflavin is one of several B vitamin determinants of plasma homocysteine concentration, which may be important because elevated plasma homocysteine concentration has been linked with a greater risk of coronary heart disease, stroke, hypertension, and some other conditions. There does however remain considerable uncertainty about the cause–effect relationship of some of these associations, which seem particularly weak when publication bias is taken into account.

The homocysteine-lowering effect of riboflavin seems largely confined to people with a reduced activity of MTHFR, and this seems to have particular functional relevance to hypertension and hypertensive disorders. A graded association between blood pressure and the MTHFRC677<T polymorphism has been reported across different populations, and evidence is accumulating to suggest that riboflavin supplementation, even at rather modest doses, can lower blood pressure in individuals with hypertension who also have the MTHFR C677T genotype.

In addition to its coenzyme role in MTHFR, riboflavin status may influence flux through the methylation cycle, through effects on the metabolism of vitamin B_6, which is essential for the metabolism of homocysteine to cystathionine, via transsulfuration. Interconversions of vitamin B_6 metabolites are influenced by riboflavin through the activity of flavin-dependent enzymes.

Cardiovascular Disease

Paradoxically, although riboflavin has the potential to generate free radicals on exposure to UV light, it is also known to have antioxidant properties. The action of flavin reductase on riboflavin generates dihydroriboflavin, which can reduce heme proteins containing ferric iron. This is potentially important because of the pro-oxidant activity of heme iron. This is thought to explain protective effects of riboflavin administered either *in vivo* or to tissues *ex vivo*, in three models of tissue damage – ischemia-reperfusion injury, activated complement-induced lung injury, and brain edema following hypoxia reoxygenation. However, although effects in animal models of tissue injury appeared promising, there has been little to suggest an application in humans. A small study showed that supplementation of patients with B-group vitamins immediately following an acute ischemic stroke mitigates oxidative damage; the supplement included riboflavin, folate, vitamin B_6, and vitamin B_{12} and so the effect cannot be ascribed solely to riboflavin.

Vision

There is a long history of reports of corneal vascularization, corneal opacity, and cataracts in animals fed with diets low in riboflavin. Whether there is a human corollary is not clear. Several studies have examined a possible relationship between cataracts in elderly people and riboflavin status; results are suggestive that higher riboflavin intake is associated with a lower risk of development of nuclear lens opacities and cataract. A long-term supplementation of riboflavin and niacin to elderly people in Linxian, China, was associated with a lower prevalence of cataract, but the study design does not make it possible to ascribe effects to riboflavin alone. Recent attention has been focused on the therapeutic role of flavins in corneal disorders. The nonenzymatic oxidation of reduced flavins leads to the production of reactive oxygen species, including superoxide. This potentially damaging reaction has been shown to have protective benefits when applied to the cornea, as the free radicals generated are thought to increase cross-linking of collagen molecules the cornea, which increases the biomechanical strength of the cornea. The treatment consists of the ultraviolet-A irradiation of riboflavin-soaked cornea; the riboflavin undergoes autoxidation, with the generation of superoxide and other radicals, which initiate the cross-linking. Results in patients have been so successful that treatment with riboflavin in its role as a photosensitizer has become standard treatment for progressive conditions of the cornea, such as keratoconus.

Iron Metabolism/Anemia

Suggestions of a mechanistic link between riboflavin metabolism, iron handling, and anemia date back to the 1950s, when riboflavin-responsive anemia was reported in humans. Subsequently, several groups conducted investigations in various animal models of riboflavin deficiency, which collectively confirmed that riboflavin depletion can lead to disturbances in iron handling. The mobilization of iron from the iron storage protein, ferritin, requires a reductive step, and this can occur through nonenzymatic reduction (e.g., by ascorbic acid) and by the activity of FMN:NADH-linked oxidoreductase (EC.1.5.1.42), which is riboflavin-dependent. Riboflavin deficiency in animals impairs iron mobilization from ferritin in the gastrointestinal mucosa, placenta, and liver, indicating a possible role for riboflavin in iron absorption, maternofetal transfer, and mobilization of iron from hepatic stores.

The relevance of these studies to humans has been the focus of some research endeavor in different populations. Findings from a large cohort in China show that low riboflavin intake is associated with an increased risk of anemia at the 5-year follow-up. An interaction between iron intake and riboflavin intake was apparent, such that when riboflavin intake was adequate, there was no relation between iron intake and anemia. Correcting a deficiency of riboflavin has been shown to improve hematological status in school-age children, pregnant women, and men, the effect being most convincing when marked riboflavin deficiency and poor hematological status exist at baseline. Understanding of the mechanisms of such associations, or response to riboflavin supplements, is incomplete; while it can be shown that riboflavin deficiency in animals impairs iron absorption, results of human studies of riboflavin and iron absorption have been less consistent. Findings from human studies can be more readily explained by an effect of correcting riboflavin deficiency on mobilization of iron from stores than by effects on iron absorption.

Gastrointestinal Structure and Function

There is a small but persuasive body of literature suggesting that riboflavin status influences aspects of gastrointestinal development. Riboflavin-deficient rats exhibit a number of disturbances to the normal structure and kinetics of the cells of the duodenum. Effects include crypt hypertrophy, a decreased villus number, and an enhanced rate of transit of cells along the duodenal villi, all of which would be expected to have a downstream effect on nutrient absorption and nutrient loss from the gastrointestinal tract. This may be a contributing factor to the well-established effects of riboflavin deficiency on growth. The human corollary is less clear, but there is some evidence that poor riboflavin status is associated with morphological disturbances to duodenal crypts and altered proliferative activity.

Cancer

Evidence for causal links between low riboflavin status and increased risks of cancer is rather limited. There has been long-standing interest in a possible link between low riboflavin intake and increased risk of esophageal cancer, with plausible mechanisms relating to effects of riboflavin deficiency on epithelial integrity and function. Early interest was based on epidemiological studies of micronutrient deficiencies and prevalence of esophageal cancer in Iran and South Africa. Subsequently, particular attention has focused on China and Iran, countries with a high prevalence of esophageal cancer and evidence for low dietary intakes of riboflavin. Most studies were case–control studies or cross-sectional studies and generally supported an inverse association between riboflavin intake and risk of this cancer. A large multinutrient supplementation trial in Linxian, China, showed a modest benefit on precancerous cell changes, but evidence from randomized controlled trials for a beneficial effect of riboflavin on incidence of esophageal cancer or progression of precancerous lesions is lacking. A case-control study nested in the large EPIC cohort (European Prospective Investigation into Cancer and Nutrition) revealed an inverse association between plasma concentrations of flavins and risk of colorectal cancer. There is modest evidence to associate low riboflavin concentrations in the circulation and tissue with increased risk of cervical cancer and also with an increased likelihood of cervical cell infection with the causal agent, human papillomavirus; this warrants further investigation. Other smaller studies of riboflavin and colorectal cancer risk have generally generated null findings.

Neurological Function

Severe riboflavin deficiency in rats and chickens can lead to neurodegeneration, in some cases linked with peripheral nerve demyelination. This may arise from impaired energy generation and deranged lipid metabolism, but this remains conjectural. Evidence of neurodegeneration in humans, arising from riboflavin deficiency, is lacking. There are a few isolated case histories describing neurological impairment in association with riboflavin deficiency, in some cases responsive to high doses of riboflavin. A group of rare and complex childhood-onset motor neurone diseases, called Brown–Vialetto–Van Laere syndrome, has been causally linked with a mutation in the gene SLC52A2, which encodes a riboflavin transporter RFVT2. Recent evidence suggests that high-dose riboflavin supplements can ameliorate some of the clinical and biochemical features and slow progression of the condition. A tenuous link has been proposed between poor riboflavin status and Parkinson's disease, with reported partial recovery of some motor functions in response to high-dose riboflavin, but this needs to be substantiated.

Physicochemical Characteristics

Riboflavin, the prescribed name for vitamin B_2 by the IUPAC–IUB, is the biologically active component of the prosthetic group of flavoproteins. Older designations are lactoflavin, ovoflavin, and uroflavin, which originated from the first isolation. It comprises a tricyclic, nitrogen-containing ring system, chemically defined as a substituted isoalloxazine with a ribitol side chain at N_{10}. With the systematic nomenclature, the molecule is named as 7.8-dimethyl-10-(1-D-ribityl)-benzo[g]pteridin-2,4-dion. The empirical formula is given as $C_{17}H_{20}N_4O_6$ with an MW of 376.36 (Figure 1). The substance is a yellow to orange-yellow powder and crystallizes in sharp, optically active needles, melting under decomposition at ~275–282 °C. The optical rotation is $[\alpha]_D^{25} = -112°C$ to $-122°C$ (c = 50 mg in 10 ml 0.02 N alcoholic NaOH). Riboflavin is sparingly soluble in water with a yellow-green fluorescence, very sparingly soluble in ethanol and insoluble in other organic solvents. It is readily soluble in dilute alkali, but rapidly deteriorated, being accelerated by light. In neutral or acid solutions, it is more stable even against heat and oxygen. Nevertheless, all operations with riboflavin solutions should be handled in the dark or at red light.

Light sensitivity of the flavins has also consequences for the stability of vitamin B_2-containing foods. In milk stored under day light, the riboflavin content is dropping off by more than 80% within hours. Processing losses in foods are given with ~20%.

Light exposure of alkaline solutions decomposes riboflavin to lumiflavin (7,8,10-trimethylisoalloxazine); in neutral or acidic solutions, the blue fluorescent lumichrome (7,8-dimelthylalloxazine) is formed (Figure 2). Riboflavin is found in free-form only in the retina of the eye, in whey, and in urine. In other biological systems and tissues, the predominant forms are flavin mononucleotide (FMN) or riboflavin phosphate and flavin adenine dinucleotide (FAD). Free riboflavin and FMN-monosodium salt are the most important commercial products. FMN and FAD are effective as coenzymes or prosthetic groups in more than 100 enzymes in the plant and animal kingdom. The accepted designation for both compounds is incorrect, because FMN is not truly a nucleotide and FAD not a dinucleotide. The designations arose from the discovery of riboflavin and have been adopted ever since. Pure riboflavin was first isolated from yeast, egg white, and whey in 1933 (Kuhn and Wagner-Jauregg). Simultaneously, the so-called yellow coenzymes were discovered in yeast (Warburg and Christian), which could be identified as FMN. FMN is considerably more soluble in water than riboflavin. Its solubility in organic solvents as well as its stability against heat and light exposure is comparable to riboflavin.

The flavoproteins FMN and FAD belong to the enzymatic class of oxidoreductases. The conjugated structure of the pteridine moiety of the basic molecule determines its coloring and light absorbance in the UV and visible spectrum. Absorbance maxima of the flavins are listed in Table 1. The catalytic hydrogen transfer in the flavin enzymes takes place at both conjugated bound N_1 and N_5 atoms of the isoalloxazine molecule. The oxidized form of the flavoproteins, the flavoquinone, is thereby reversibly reduced to the colorless flavohydroquinone or leucobase (see Figure 1). The absorbance is lost, because double bonds are dissolved. As an intermediate product during this reaction, a sequinone radical is formed. During the redox process, the flavin molecule changes its conformation, which is planar in the oxidized and folded in a butterfly configuration in the reduced state.

The characteristic yellow-green fluorescence of riboflavin and FMN in aqueous solutions exhibits maximal intensity at pH 6–7. The fluorescence of FAD is about 10–20% of that of riboflavin with the same spectral distribution but exhibiting a maximal intensity at pH 3. The fluorescence of flavins is quenched when bound to proteins. The irradiation products of the flavins are also fluorescing, and their spectrum is shifted to the blue (lumichrome) or green (lumiflavin) spectral range. For quantification of riboflavin, particularly the conversion to lumiflavin, measurement of its fluorescence intensity in chloroform solutions is used (ex 270 nm, em 418 nm).

Content and Reactions in Food

Content

Riboflavin belongs to the group of water-soluble vitamins and is generally referred to as vitamin B_2. Riboflavin is an important compound of a healthy diet and is widely distributed in animal and vegetable foods. Protein-rich foods of animal origin are as rule considerable sources of this vitamin with good bioavailability. Particularly rich in riboflavin are offal, such as the heart, liver, and kidney, and eggs and dairy products, mostly as FMN and FAD. Of special importance for the dietary habits in Western countries are milk, dairy products, and meat, despite of a medium content of riboflavin. If those are omitted from the diet, problems may arise to cover an adequate vitamin B_2 intake for human beings (Table 2). Furthermore, riboflavin is used as a safe coloring agent for some processed foods and pharmaceuticals and is included in nutrient supplements. Meat, fish, and dark green vegetables contain also significant concentrations of riboflavin. Milk and cheese are in agreement with their content of riboflavin products for which light-induced quality deterioration is now widely recognized to be the result of riboflavin photosensitizing.

Stability of Riboflavin

Riboflavin and its physiological compounds are relatively stable during thermal and nonthermal food processing and

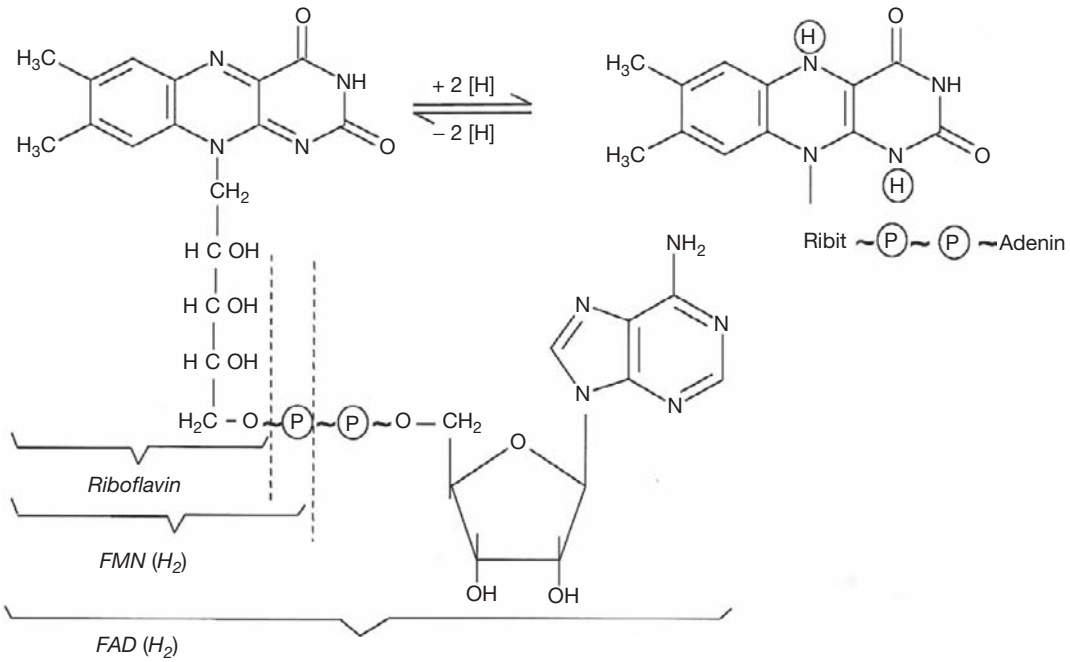

Figure 1 Riboflavin and its coenzyme forms.

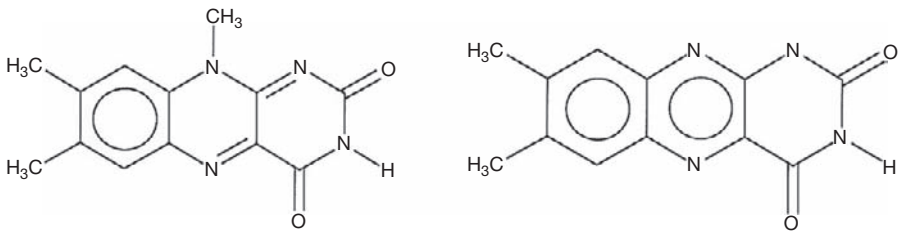

Figure 2 Photolysis products of riboflavin.

storage, in the absence of light even at high temperature. But they are very unstable to light even at room temperature. Particularly, aqueous solutions of these substances are sensitive to UV and visible light, and they are degraded through a variety of reactions resulting in a number of photoproducts under aerobic and anaerobic conditions. The major photoproducts obtained through normal photolysis of riboflavin in aqueous solvents include formylmethylflavin, lumichrome, lumiflavin, and 2,3-butanedione. With multicomponent spectrometric methods, several further photoproducts are to be identified. Lumichrome is the major product under neutral or acidic pH; lumiflavin is formed in basic pH; 2,3-butanedione is the major volatile compound with a typical buttery odor. Lumichrome and lumiflavin are formed from unstable diradical excited triplet riboflavin by dealkylation; 2,3-butanedione is produced from the reaction between electrophilic singlet oxygen and electron-rich riboflavin. The kinetics of riboflavin photolysis under light exposure and in the pH range of 1–12 indicate that riboflavin has maximum photostability around pH 5–6. Mostly destructive to riboflavin is exposure to light with wavelength of its absorption maximum at 450 nm.

Reactions of Riboflavin as a Photosensitizer

Riboflavin and other flavins are efficient photosensitizers, inducing oxidative damage to light-exposed food and several food compounds. When exposed to light of wavelength 420–560 nm, the absorbed energy does excite riboflavin to triplet state. Riboflavin can accept or donate two hydrogen atoms and acts together with lumiflavin as efficient photosensitizer. These so-called sensitized photoreactions are typical for foods and essentially involve two pathways. Direct interaction of the excited sensitizer with food compounds initiates radical processes through electron transfer or hydrogen abstraction and is known as a type 1 photo-oxidation. This mechanism is favored under low oxygen pressure and is, for example, responsible for light-struck flavor formation in beer. Under aerobic conditions, excitation energy is preferably

Table 1 Physicochemical data of flavines

Property	*Riboflavin*	*Riboflavin-5-phosphate-Na (FMN-Na)*	*Flavinadenindinukleotide-Na$_2$ (FAD-Na$_2$)*
Molecular weight	376.36	478.34	829.6
Melting point	278–282 °C (decomposition)	280–290 °C (decomposition)	
Solubility	Readily soluble in dilute alkalis (decomposition) Sparingly soluble in water (70–100 mg l^{-1}, 27 °C)	Soluble in water at pH 7 (30 g l^{-1}, 25 °C)	Soluble in water
	Very sparingly soluble in ethanol (45 mg l^{-1}, 27 °C)	Very sparingly soluble in ethanol	
	Insoluble in acetone, chloroform, ether, benzene		
Absorbance (UV/vis)	223, 267, 374, 444 nm (0.1 N HCl)		
Fluorescence	Yellow-green fluorescence of aqueous solutions at pH 6–7 (ex. 444 nm, em. 530–565 nm)		ex. 400–500 nm, em. 530 nm
Stability	In neutral and acidic medium relatively stable against heat and oxygen. Rapid photolysis by UV- and visible light to blue fluorescent lumichrome (acidic and neutral solutions) or yellow-green fluorescent lumiflavin (alkaline solutions). After reduction by dithionite, Zn-HCl, sodium hydrosulfite, etc., reversible conversion to leucoflavin (dihydroflavin)

transferred to oxygen to generate singlet oxygen, the pivotal intermediate in a type II photo-oxidation. This reaction is responsible for oxygenation of unsaturated fatty acids in vegetal oils causing high peroxide values and eventually rancidity, while attack of amino acid residues in dairy proteins may give rise to sulfury and potato-like off-flavors. Both photo-oxidation pathways induced by triplet-excited riboflavin lead to premature aging or spoiling of foods and beverages. Photosensitizing of riboflavin causes production of reactive oxygen species such as super oxide anion, singlet oxygen, hydroxyl radical, and hydrogen peroxide. Radicals and reactive oxygen species accelerate the decomposition of food compounds

as amino acids, proteins, lipids, carbohydrates, and vitamins and cause significant alterations of nutritional value of foods. Carbohydrates are less sensitive to riboflavin-photosensitized oxidation than proteins, lipids, or vitamins. Exposed to visible light, riboflavin acts as a potent photosensitizer in food and beverages presenting a risk for their stability. Decomposition of the nutrients depends on the wavelength and energy of light, the concentration of oxygen and riboflavin, and the presence of activating or inactivating compounds. Riboflavin is an excellent photosensitizer for singlet oxygen formation and a superb reactant for singlet oxygen, with the reaction rate of 1.01 ± 10^{10}/M/s. The triplet-excited state of riboflavin is relatively long-living and as a biradical a very powerful oxidant compared to ground state riboflavin, leading to direct oxidation of most types of biomolecules.

Riboflavin Losses in Dairy Products

Due to the relative heat stability, only minor vitamin B_2 losses occur during processing. Likewise, the pasteurization of milk in the absence of light causes losses of $< 10\%$. On the other hand, exposure of dairy products to day light may result in a remarkable decrease of the riboflavin content being dependent on the surface exposed. In milk stored under daylight, the riboflavin content is dropping off by more than 80% within hours with both lipids and proteins being oxidized under photosensitized conditions. The photodegradation leads to the formation of carbonyl compounds such as pentanal, hexanal, heptanal, 2-nonenal, 2,4-nonadienal, and 2,4-decadienal all attributed to lipid photo-oxidation. The chemical reaction between methionine and singlet oxygen, which has been formed by riboflavin photosensitization, produces dimethyl-disulfide, which is responsible for the sunlight flavor of milk. In an actual study, it could be demonstrated that photodegradation of riboflavin in milk may be considerably reduced by the addition of small amounts of gum arabic microcapsules, avoiding large losses in the nutritional value of milk.

Riboflavin Losses in Beer and Cereals

Light exposure of beer generates an obnoxious off-flavor after a complex interplay of light, excited riboflavin, isohumulones and sulfur-containing amino acids, peptides, and proteins. The radical chemical degradation path of these compounds results in 3-methylbut-2-ene-1-thiol, the main off-flavor compound that characterizes light-exposed beers with the trivial name of skunky thiol. Vitamin losses occur also during the milling process of cereals. White flour with a low extraction rate contains about one-third of riboflavin of the whole grain flour.

Photodegradation of Amino Acids and Vitamins

The deactivation of triplet-excited state riboflavin by several food components leading to photodegradation of nutrients in food, beverages, and model solutions is described in actual studies. For instance, the amino acids cysteine, histidine, methionine, tyrosine, and tryptophan are rapidly photodegraded in aqueous solutions in the presence of triplet exited riboflavin. These amino acids are the primary targets of photochemical oxidation in proteins.

Both fat-soluble and water-soluble vitamins are sensitive to photo-oxidation as sensitized by riboflavin. The vitamins ascorbate, folate, thiamine, and pyridoxal phosphate deactivate triplet-excited riboflavin and are photodegraded as well as vitamins A and D3 and tocopherols in aqueous solutions. A good photostability in the presence of riboflavin was demonstrated for the vitamins biotin and niacin. Carotenoids seem to reduce the formation of triplet-excited riboflavin through an inner filter, which protects these substances against the riboflavin-induced photosensitizing damage.

How to Prevent Reactions

Polyphenolic compounds are efficient antioxidants with strong free radical scavenging ability. It was demonstrated that the plant polyphenols rutin and catechin, several flavonoids, and phenolic compounds present in beverages quench the triplet-excited state of riboflavin and protect the beverages that contain these compounds from light-induced off-flavor formation.

Methods of Determination

In earliest reports, the most frequently applied assays of flavins as vitamin B_2 active components made use of the direct fluorimetric assay of the intact flavins or after hydrolysis to FMN or free riboflavin. Alternatively, the lumiflavin method based upon the conversion of the chloroform-insoluble riboflavin into chloroform-soluble lumiflavin after photodegradation in alkaline solution was used, despite a transformation rate of only 60–70%. Currently, microbiological assays and high-performance liquid chromatography (HPLC) procedures with enhanced sensitivity are widespread utilized (see also **Table 3**).

In principle, riboflavin is extracted from dry materials by autoclaving in 0.1 N HCl for 30 min or on water bath for 1–2 h. By using acid extraction, flavins are released from their protein binding and FAD and FMN are converted to free riboflavin. In protein-rich materials, the acidic extraction may be followed by enzymatic hydrolysis for complete liberation of the flavins. It is of importance to carry out all operations relating to the extraction and quantitation of flavins and riboflavin under subdued light and in brown or dark vessels.

An optimal extraction procedure applicable for microbiological or HPLC determination of thiamine and riboflavin has been worked out by the European Measurement and Testing Program. The steps of the extraction are detailed in autoclaving, incubation with takadiastase, and filtration.

For biological samples, such as plasma/serum, the preferred extraction medium is 5–10% trichloroacetic acid, which is suitable for denaturing the relatively weak protein binding while keeping the phosphorylated forms intact.

Direct Fluorimetry

Direct measurement of the native fluorescence of riboflavin may be applicable for pharmaceutical preparations or food samples with a relatively high vitamin content. After acid extraction, the remaining proteins are removed by precipitation at pH 4.5. Interfering substances are subsequently oxidized with potassium permanganate and the excess oxidant

Table 3 Methods of riboflavin determination

Method	*Principles*	*Specials*	*Detection limits*
Direct fluorimetry	Fluorescence measurement of riboflavin at 440 (ex)/565 (em) nm	Conversion of FAD and FMN to riboflavin by acidic hydrolysis	0.1 μg B_2/g sample
Lumiflavin method	Fluorescence measurement after irradiation at pH 10–12 (ex 450, em 513 nm)	Lumiflavin is separated by chloroform extraction	0.02 ng B_2
Microbiological assay	Turbidimetric measurement of bacterial growth response dependent on the B_2 content	Interference of growth response with nutrients/food components	0.1–0.5 ng B_2
HPLC analysis	Separation of flavins on RP-C_{18} materials with aqueous/organic solvents and fluorimetric/UV detection	Differentiated analysis of flavins, combined analysis with other B vitamins	0.21 ng riboflavin 0.89 ng FMN 11.15 ng FAD 0.02 ng B_2 (precolumn irradiation to lumiflavin)

destroyed with hydrogen peroxide or sodium bisulfite. The fluorescence of the clear sample solution, commonly spiked with riboflavin as an internal standard, is registered by difference measurement before and after reduction of riboflavin with sodium bisulfite to the leuco form for correction by unspecific fluorescences (ex = 440 nm; em = 565 nm).

The detection limit of this method is about 0.1 μg riboflavin per gram sample. The direct fluorimetry of flavins had been adopted by the US Pharmacopoeia for the riboflavin analysis in tablets and injections and by the AOAC for the riboflavin determination in foods, as in milk-based formulas.

Lumiflavin Method

By this method, riboflavin is photodegraded in alkaline solution at pH 10–12 to the stronger fluorescent lumiflavin (ex = 450 nm; em = 513 nm). This reaction is specific for riboflavin since other flavins interfering with riboflavin fluorescence are not converted into lumiflavin. Lumiflavin is separated from riboflavin and other fluorescent substances by extraction with chloroform. The transformation into lumiflavin is not quantitative and ranges between 60% and 70%. Reliable results can actually only be obtained by comparison with a riboflavin standard under identical irradiation conditions for sample and standard solution.

While the original lumiflavin method is sparsely used, the principal methodology was applied to HPLC analyses of the riboflavin content in foods with detection limits of 0.02 ng riboflavin per injection.

Microbiological Assay

Besides bioassays, as chicken and curative rat growth tests, microbial assays belong to the first widely used test methods measuring the biological activity of preparations containing total vitamin B_2. The most frequently used test organism is *Lactobacillus casei* subsp. *rhamnosus* (ATCC No. 7469). The sensitivity limit is indicated to be 0.5 ng riboflavin absolutely. Occasionally, other test organisms are proposed such as *Enterococcus faecalis* (ATCC No. 10100) and *Leuconostoc mesenteroides* (ATCC No. 9135) with enhanced sensitivity of 0.1 ng ml^{-1} riboflavin. The microbiological assay with *L. casei* is approved by the AOAC International Methods for the riboflavin determination in vitamin preparations. Growth response of bacteria is proportional to the riboflavin content of the medium and measured turbidimetrically. Earlier techniques determined metabolically formed lactic acid by titration. However, comparisons of turbidimetry after 16 h incubation obtained results that agreed with those obtained by titration of lactic acid after 72 h. Thus, the turbidimetric measurement is at present preferred in view of its shorter incubation time and easier handling.

The growth response of lactobacilli differs significantly between free riboflavin and FMN and FAD. Acidic or enzymatic treatment is therefore needed for releasing and converting the flavins into riboflavin as described under methods of determination, followed by adjustment of the extract to pH 4.5 before incubation. In case of enzymatic release using takadiastase or clarase, it has to be considered that some enzyme preparations contain variable traces of riboflavin.

Starch, glycogen, free fatty acids, and other lipids and protein degradation products can interfere with the test by either stimulating or inhibiting the bacterial growth. Lipids in a relevant content can be removed either by filtration or by ether or petroleum ether extraction before hydrolysis. Proteins are precipitated at pH 4.5 and starch is split by the acidic or enzymatic hydrolysis step. As with the other analytic procedures, the microbiological test has also to be done under subdued light. Of importance is that the used glass vessels do not release any traces of alkali and should thus be cleaned with acid before use, because the flavins are alkali-sensitive. Hence, it is advisable to dissolve riboflavin standards in 0.02 M acetic acid.

An optimal extraction procedure applicable for microbiological or HPLC determination of thiamin and riboflavin has been worked out by the European Measurement and Testing Program. The steps are detailed in autoclaving in 0.1 N HCl at 121 °C for 30 min and adjusting thereafter to pH 4.0 with 4 M sodium acetate buffer (pH 6.1), addition of takadiastase (0.1 g g^{-1} sample), incubation at 37–45 °C (18 h), filtration, or centrifugation after cooling.

HPLC Procedures

HPLC methods enable separate quantification of individual flavins or simultaneous analysis of riboflavin including FMN

and FAD. A broad variety of HPLC techniques are described, varying the column material, mobile phase, separation mode, and detection system as well. Of the numerous analytic and technical variations communicated during the last 20 years, the separation techniques can be categorized as follows:

Reversed phase C_{18} materials are utilized as stationary phases in most cases, combined with aqueous/organic mobile phases on the basis of water, methanol, acetonitrile with or without phosphate, or acetate buffer in an isocratic mode. Rarely, ion pair chromatography with sodium salts of hexane or heptanesulfonic acid in the mobile phase (ion interaction chromatography) was utilized; in some cases, the separation of riboflavin and flavins was accomplished with gradient elution technique.

Ion-pair HPLC seems more favorable only when riboflavin is determined simultaneously with other B vitamins (e.g., B_1, B_6, niacin, folic acid, and B_{12}), because this technique results in better peak shapes.

Retention times of vitamin B_2 active compounds are between 5 (FAD) and 20 (riboflavin) minutes. Fluorescence monitoring is preferred for detection; UV or visible absorbance detection at 270 or 446 nm is restricted to early HPLC analyses or measurements of pharmaceuticals and enriched foods. Limits of fluorescence detection at 450/520 nm (ex./em.) for the native flavins were given to 0.55 pmol (0.21 ng) riboflavin, 1.96 pmol (0.89 ng) FMN, and 14.19 pmol (11.15 ng) FAD. In an earlier HPLC method, the detection limit could be increased to 0.02 ng riboflavin/injection by irradiation of the sample extract and conversion of the extracted riboflavin to lumiflavin prior to HPLC separation.

A specific and sensitive UHPLC/LC-MS method was developed for the simultaneous determination of riboflavin and pyridoxine in infant food.

In principle, extraction techniques and sample cleanup suitable for HPLC analysis resemble those used for quantitation by the other methods discussed. Mostly, vitamin B_2 active substances are released from the food matrix by autoclaving with 0.1 N mineral acid (HCl or H_2SO_4) followed by enzymatic digestion with papain, takadiastase, or claradiastase. Solid-phase cleanup procedures on C_{18} materials or Florisil are often used for support prior to injection. The extraction procedure is guided by the analytic aim, whether the total riboflavin content, that is, the sum of FAD, FMN, and free riboflavin, shall be determined or the differentiated quantitation of FAD and FMN in addition to free riboflavin is strived for. Treatment with potassium permanganate can be omitted, because possibly remaining extraneous fluorescent substances are chromatographically separated.

The combined acid and enzymatic hydrolysis is advantageous particularly for foods with high starch or protein content to liberate the bound flavins. Occasionally, autoclaving with dilute mineral acid is incomplete, particularly for the conversion of FMN to riboflavin, as indicated by the appearance of an FMN peak in the following chromatogram. Additionally, FMN may be partially converted during acid hydrolysis to biologically active isomeric riboflavin phosphates, which are separated from FMN by HPLC analysis and remain neglected for the calculation of total riboflavin. The combination of acidic and enzymatic digestion is thus advisable prior to HPLC analysis for the determination of total riboflavin. When using this extraction procedure and following HPLC analysis, the riboflavin content of various foods such as breakfast cereals, porridges, milk, and milk products correlated well with the microbiological assay using *Lactobacillus casei*. The simultaneous determination of FAD and FMN besides free riboflavin needs nondegradative techniques, such as extraction of flavins by methanol/dichloromethane followed by partitioning with citrate buffer (pH 5.5) or extraction with 6% formic acid containing 2 M urea. The HPLC separation and quantitation of the flavins was accomplished by using internal standards (7-ethyl-8-methyl-riboflavin, sorboflavin isoriboflavin, nicotinamide, and others). This analytic device enabled the flavin analysis (FAD, FMN, and riboflavin) of milk and dairy products, fruits and vegetables, meats, and cereal products. In many cases, HPLC methods were developed for the simultaneous or sequential determination of riboflavin and thiamin in foods. Both vitamins are extracted by a common procedure using acidic and enzymatic digestion.

For biological samples, as blood or plasma/serum, the preferred extraction medium is 5–10% trichloroacetic acid, which is suitable for denaturing the relatively weak protein binding while keeping the phosphorylated forms intact. In this way, flavins in whole blood can be analyzed by isocratic RP-HPLC against an external standard. A compilation of usual HPLC procedures is listed in **Table 4**. An overview on methods of riboflavin determination can be taken from **Table 3**.

European Standard Method

The European Technical Committee for Standardization (CEN/TC 275) specifies a method with the title "Foodstuffs: Determination of vitamin B_2 by high performance liquid chromatography and fluorescence detection." The document number is DIN EN 14152:2014, the publication date is 2014-08, the original language is German, and the responsible standards committee for food and agricultural products is NA 057-01-13 AA: Vitamins and Carotenoids.

The 'Deutsches Institut für Normung e.V. (DIN)' is the responsible committee for the standardization in the field of food as well as in the agricultural sector.

This method has been validated in two interlaboratory studies. The first study was for the analysis of samples of milk powder and pig's liver ranging from 1.45 to 10.68 mg/100 g. The second study was for the analysis of samples of tube feeding solution, baby food, powdered milk, meal with fruits, yeast, cereal, and chocolate powder ranging from 0.2 to 87.1 mg/100 g. Vitamin B_2 is the mass fraction of total riboflavin including its phosphorylated derivates.

In this European norm, riboflavin is extracted from foods after acidification, followed by an enzymatic dephosphorylation. The quantification takes place with subsequent HPLC separation, fluorimetric detection, and extern standards.

Rice: Role in Diet

BO Juliano, University of the Philippines Los Baños campus, College, Laguna, Philippines

Commercial Importance, Global Distribution, and Varieties

Rice is the most important crop in terms of total developing world production (480×10^6 tonnes of rough rice in 2012) and numbers of consumers (3.5 billion) dependent on it as a staple food. It is grown in over 100 countries in every continent (except Antarctica) from 53° N to 40° S and from sea level to an altitude of 3 km. In 2012, total production was 697×10^6 tonnes of rough rice with Asia accounting for $149/158 \times 10^6$ ha world area for cultivation; mean rough rice yield was 4.40 tonnes ha^{-1}. About 90% of the world's rice is grown and consumed in Asia across 200 million rice farms, most of which are smaller than 1 ha. The major rice producers in 2012 were China, India, Indonesia, Bangladesh, Vietnam, and Thailand.

Rice can grow in upland (aerobic) and flooded (anaerobic soil) conditions with air channels connecting to its roots. In 2010–12, about 57% of total rice cultivation was irrigated, 31% rain-fed lowland, 9% upland, and 3% flood-prone wetland corresponding to total rough rice production of about 75% (irrigated), 19% (rain-fed lowland), 5% (upland), and 1% (flood-prone wetland). Since rice-growing area is shrinking, rice production must keep up with the annual increase in consumption through increased yield.

Rice is mainly *Oryza sativa* L. with some *Oryza glaberrima* L. grown in West Africa. It is estimated that there are about 100 000 rice varieties, but only a small proportion are cultivated. These vary in grain weight, size and shape, translucency, degree of dormancy, longevity and seedling vigor, and pigmentation (none, to red, to purple–black). More than 75% of Asia's rice area is planted with semidwarf plant type with erect leaves. These newer, improved varieties have a similar yield potential to the first commercial variety (IR8) but have a better resistance/tolerance to biotic and abiotic stresses. Although essentially self-pollinated, three-line cytoplasmic male sterile hybrids and two-line thermogenic male sterile hybrids have been grown successfully in China with increased yields. Complete sequencing of the rice genome in 2002 has accelerated the use of molecular markers in breeding for yield, for abiotic and biotic stress tolerance, and, lately, for grain quality.

Structure of the Rice Grain

The rice grain (rough rice or paddy) consists of an outer protective covering (hull or husk) and the edible rice caryopsis or fruit (brown, cargo, dehulled, or dehusked rice) (Figure 1). Brown rice consists of the outer layers of pericarp, seed coat, and nucellus; germ or embryo, which are the maternal tissues; and the endosperm. The endosperm consists of the aleurone layer and the starchy or inner endosperm. Pigment is confined to the pericarp, but there are varietal differences in the retention of pigment with the degree of milling. The aleurone layer encloses the embryo.

The inedible hull constitutes 16–28% (mean 20%) of rough rice weight. Brown rice consists of 1–2% pericarp, 4–6% aleurone plus nucellus and seed coat, 1% embryo, 2% scutellum, and 90–91% endosperm. The aleurone and embryo cells are rich in lipid bodies (spherosomes, 0.2–1.5 μm) and in protein bodies (aleurone grains containing inclusions of phytic acid bodies or globoids (1–3 μm)).

The endosperm cells are thin-walled and packed with amyloplasts containing polyhedral compound starch granules (3–9 μm). Protein occurs mainly in the form of large (1–2 μm) and small (0.5–0.8 μm) spherical protein bodies and crystalline protein bodies (2–4 μm). Spherical protein bodies (PB I) are rich in prolamin (alcohol-soluble protein), while crystalline protein bodies (PB II) are rich in glutelin (alkali-soluble protein). High night ripening temperatures increase the PB II/PB I ratio. Spherosomes are present in the subaleurone or the two outermost cell layers of rice endosperm. High night ripening temperatures also reduce linoleic acid content of rice lipid.

Grading, Handling, and Storage

There is no international standard for milled rice size and shape. The International Rice Research Institute (IRRI) uses the following scale for size: extra long >7.50 mm, long 6.61–7.50 mm, medium 5.51–6.60 mm, and short <5.50 mm. For grain shape, based on the length–width ratio, the following scale is used: slender >3.0, medium 2.1–3.0, bold 1.1–2.0, and round ≤1.0. Grades are based on grain size and shape, degree of milling, percentage of head or whole-grain milled rice, immature grains, damages (discolored) and heat-damaged grains (chalky grains, red grains, and red-streaked grains), aroma, and organic and inorganic extraneous matter.

An important property of harvested grain is its moisture content: 14% on a wet-weight basis is considered a safe storage value. Grains become susceptible to fissuring from moisture adsorption stress below the critical moisture content (12–16%), depending on the variety. Aging of sun-/oven-dried rough rice for up to 2 months after harvest at ambient temperature (>15 °C) improves milling yields and makes milled rice expand more during cooking and become more flaky, with fewer soluble solids. Heating during grain drying accelerates aging.

About 20% of rice is consumed parboiled. Parboiling consists of boiling or steaming steeped aged rough rice until the hull starts to open and then cooling and drying the gelatinized grain. Diffusion of bran B vitamins into the endosperm occurs during parboiling, but with some heat decomposition, and many antioxidants are destroyed. Mycotoxins are a potential problem in parboiled rice.

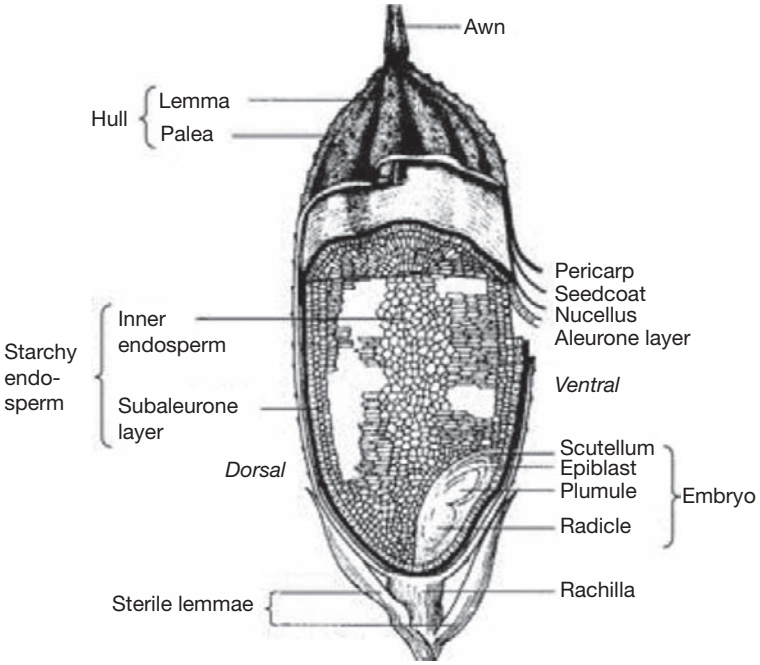

Figure 1 Longitudinal section of the rice grain. Reproduced from Juliano, B. O. (1984). Rice starch: production, properties and uses. In: Whistler, R. L., BeMiller, J. N. and Paschall, E. F. (eds.) *Starch chemistry and technology*, 2nd ed., p. 509. Orlando, FL: Academic Press, with permission.

Milling involves dehulling followed by removal of the outer 7–10% of the brown rice, by either friction or abrasion, removing most of the pericarp, seed coat, nucellus, aleurone layer, and the germ. In Engelberg mills, hull and bran are removed simultaneously with high grain breakage. In modern cone mills, milling is done in several steps with tempering between steps to minimize breakage. Many modern mills have also shifted to milling at >14% moisture to minimize breakage and use moisture to treat the rice (through hollow shafts) during milling to soften the bran and improve surface gloss.

Only about 4–5% of the world's rice production enters the international market. The major rice exporters in 2012 were Thailand, India, Vietnam, the United States, and Pakistan. In 2012, the major rice importers were Nigeria, China, Iran, the Philippines, Iraq, Saudi Arabia, Ivory Coast, and Malaysia.

Chemical and Nutritional Composition

Protein: Rice has one of the lowest protein contents (7%) among the cereals. The bran layers and embryo are richer in nonstarch constituents than the milled (white) rice (Table 1). The major nutritional advantage of brown rice, over milled rice, is its higher content of B vitamins and dietary fiber. Although higher in minerals, bran phytic acid forms complexes with minerals and proteins, reducing their bioavailability. Thus, the available iron (milligram per meal) is similar in brown and milled rice meals, but brown rice is probably higher in zinc (milligram per meal) than milled rice. The energy content of brown rice and bran is higher than milled rice, owing to the higher fat content. Rice contains no vitamin A, C, or D.

Although cereal proteins are deficient in lysine, rice protein has one of the staple foods having highest lysine contents, corresponding to an amino acid score of 65% in milled rice, based on the World Health Organization (2007) amino acid requirement pattern for 1–2-year-old children (5.2% lysine as 100%, Table 2).

The solubility fractions of milled rice proteins are about 15% albumin–globulin (water- and salt-soluble), 20% prolamin (PB I, alcohol-soluble), and 65% glutelin (PB II, alkali-soluble). Bran proteins are 66–98% albumins. Prolamin is poor in lysine, but rich in sulfur-containing amino acids. The high lysine content of rice protein is due to the low prolamin content. From studies funded by the United Nations University/FAO/WHO, the mean safe-level protein requirements of rice-based diets are 1.02 g protein per kilogram body weight per day in adults and 1.38 g protein per kilogram body weight per day in preschool children, while safe-level protein requirements are 0.85 g protein per kilogram body weight per day for adults and about 1.00 g protein per kilogram body weight per day for preschool children. Organic rice contains less protein than conventionally grown rice because of reduced nutrients from organic fertilizer.

Energy digestibility is higher in milled rice than in brown rice because of the reduced dietary fiber and phytic acid, as verified by the poor energy digestibility of rice bran (Table 2). The true digestibility (TD) of milled rice protein is also higher than brown rice, but the biological value (BV) is lower, resulting in similar net protein utilization (NPU). Bran protein has a lower TD, but a higher BV than brown and milled rice proteins. The amino acid score corrected for TD in rats, proposed by the Food and Agriculture Organization as a protein quality index, shows similar values to NPU for rice proteins. Black or purple rice has a lower NPU (72%) than brown rice and higher phenolics level (0.6%, anthocyanin) than red rice (NPU 83% and 0.2% phenolics, proanthocyanidins) and nonpigmented rice (NPU 97% and ≤0.02% phenolics), but these milled rice have identical NPUs. Japanese cooked milled rice protein has

Table 1 Comparison of nutrient composition of brown rice, milled rice, and rice bran

	Amounts (per 100 g)		
Property	*Brown rice*	*Milled rice*	*Rice bran*

O. and Maniñgat, C. C. (1982). Protein and energy utilization of rice milling fractions by rats. *Qualitas Plantarum Plant Foods for Human Nutrition* **31**, 371–376.

lower cysteine and slightly higher TD in rats than indica rice protein (tropical as compared with japonica, temperate, or Japanese rice). Rice complements legumes (deficient in sulfur-containing amino acids) in amino acid composition for human diets.

Cooking and parboiling reduce the TD in growing rats by 5–15%, with a corresponding increase in BV, but little change in NPU. However, lysine digestibility remains close to 100%, while cystine digestibility drops to about 82%. The fraction that remains in the feces, as fecal protein particles, represents

the lipid-rich core of large PB I, with less than 1% lysine in the protein, but is rich in cystine. PB II is readily digested.

Rice is hypoallergenic, but some individuals are allergic to the 14–16 kD alpha-amylase/trypsin inhibitor and 33 kD Oryza glyoxalase 1. Both allergens are still active in cooked milled rice.

Starch: Starch varies in apparent amylose content (true amylose plus long-chain amylopectin as determined by iodine colorimetry in acetate buffer pH 4.5): waxy 0–2%, very low 2–10%, low 10–20%, intermediate 20–25%, and high >25%, all on a milled rice dry-weight basis since the 1950s. Actual amylose content values, measured using differential scanning calorimetry (by melting or crystallization enthalpy of amylose–lysolecithin complex), are slightly lower and closer to values determined using iodine colorimetry (ammonium buffer pH 9) (low 10–17%, intermediate 17–22%, and high >22%).

Rice starches also differ in gelatinization temperature, the point when granules start to swell irreversibly in hot water: low 55–70 °C, intermediate 70–74 °C, and high >74 °C. Gelatinization temperature correlates positively with cooking time.

The glycemic index of cooked brown rice tends to be lower than cooked milled rice owing to the greater amounts of phytic acid and fiber in brown rice, but only in waxy and low-amylose content rice. Brown and milled rice have similar glycemic index in intermediate- and high-amylose content rice. Among cooked milled and brown rice, glycemic index decreases with increasing amylose content regardless of the cooking method. With high amylose content, glycemic indexes are lower in those cooked in excess water; when cooked in a rice cooker with the same water–rice ratio and cooking time, low-gelatinization temperature rice has a higher glycemic index than intermediate-gelatinization temperature rice. Processing, including parboiling, tends to reduce the glycemic index. Resistant starch *in vivo*, as determined in ileostomy patients, is ≤5% and may not be as discriminating as glycemic index for humans. Short-term satiety has been found to be similar in milled and brown rice cooked to the same hardness by adjusting water content, regardless of amylose content.

Rice bran: The use of rice bran and brown rice in cereal products has increased in recent years owing to its recognition as a whole grain and hypocholesterolemic effect of the unsaponifiable fraction (up to 4.4%) of bran oil, which contains gamma-oryzanol (cycloartenol, 24-methylene-cycloartanol, and campesterol esters of ferulic acid), tocopherols, and tocotrienols, an analog of tocopherol (vitamin E). Defatted bran has no hypocholesterolemic activity, unlike in oats where the active component is soluble β-glucan. Inactivation of antinutrition factors – trypsin inhibitor, oryzacystatin, and hemagglutinin–lectin – and lipase and lipoxygenase, which are concentrated in rice bran by heat treatment (including cooking) and extrusion, improves the shelf life of bran and its nutritional value to poultry. In contrast, phytic acid is heat-stable and, in rice bran and brown rice, has been reported to have some activity in preventing/reducing the risk of colon cancer. Phytic acid content of rice bran is the highest among cereal brans (3–8% phytic acid).

The major fatty acids of rice oil are palmitic, oleic, and linoleic. Essential fatty acid content of rice oil is 33.4% linoleic acid and 1.6% linolenic acid. Levels of oryzanol, tocopherols, tocotrienols, and unsaponifiable matter differ among crude rice bran oils, and oryzanol, tocopherols, and tocotrienols may be reduced by up to 90% by conventional refining and deodorizing. These antioxidants seem to be lower in Philippine rice than rice grown in the United States.

Breeding for improved nutritive value: Breeding efforts to improve the nutritional value of rice grain include a higher micronutrient density (higher iron, zinc, and vitamin A), low phytic acid (high inorganic phosphate) content, low prolamin content, elimination of lipoxygenase-3 activity and allergenic globulin, and transgenic rice endosperm with provitamin A (β-carotene) (golden rice 2), soybean glycinin, or ferritin genes. Efforts to increase protein content from 7% to 9% at IRRI in 1966–79 were not successful.

Processing and Food Uses

The mean worldwide per capita consumption of milled rice was 53 kg year^{-1} in 2009. It was 77 kg in Asia, 31 kg in South America, 21 kg in Africa, 14 kg in Oceania, 9 kg in North and Central America, and 5 kg in Europe. Per capita rice consumption was highest in Southeast Asia at 129 kg year^{-1} followed by South Asia at 71 kg year^{-1}. In 2009, more than 3.5 billion people depended on rice for more than 20% of daily energy. Rice provides more than half the daily energy for about 520 million people in Asia, most of them being poor to very poor.

There are various ways of cooking milled rice. In tropical Asia, rice is prewashed to remove dirt, which reduces B vitamins and fat content. Presoaking for 30 min reduces cooking time (particularly of parboiled and brown rice). Rice can be cooked in the amount of water it will absorb or boiled in excess water and the cooking water discarded. Steaming is used in Indonesia and elsewhere for waxy rice. Oil or ghee may be added in the Middle East, which reduces surface stickiness. Enriched rice premixes, containing iron and B vitamins resistant to washing, have been developed, but are not popular because of the additional expense; the enriched rice can be readily distinguished from ordinary rice.

Rice amylose content correlates positively with water absorption and volume expansion during cooking in the amount of water it will absorb and with hardness of boiled rice. South Asian consumers prefer high-amylose content, intermediate–high-gelatinization temperature (>70 °C) rice, while Southeast Asians prefer intermediate-amylose content, intermediate-gelatinization temperature rice. *Japonica* (temperate) short-grain rice, preferred in Japan, Korea, Taiwan, and northern China, are mainly low amylose content and low gelatinization temperature (≤70 °C), with some having an intermediate amylose content in Europe. Only in Laos and north and northeast Thailand is steamed waxy (glutinous) rice consumed as a staple.

The low- and intermediate–high-gelatinization temperatures result from differences in proportion of debranched amylopectin with chain lengths less than 24 glucose units: low-gelatinization temperature rice contain more of the shorter chains. Increased numbers of longer chains raise not only gelatinization temperature but also the staling of cooked starch. Among waxy and low-amylose content rice, low-gelatinization temperature rice is softer when cooked than those with high gelatinization temperatures (intermediate gelatinization temperature is rare at low amylose content), but intermediate-gelatinization

temperature rice is softer when freshly cooked rice than low-gelatinization temperature rice. High-amylose content rice, with a high content of long-chain amylopectin (blue staining with iodine), has a hard gel consistency because long-chain amylopectin behaves like amylose. Native long-chain amylopectin crystallizes from water-saturated 1-butanol only after debranching with isoamylase.

For some rice products, specific amylose content is preferred. Freshly, well-milled rice is preferred for rice products with a prolong shelf life, minimizing rancidity in the stored products. Parboiled rice should be aged with high or intermediate amylose content, whereas extruded and flat noodles use mainly aged, high-amylose content, low-gelatinization temperature rice. Rice with a low gelatinization temperature is better for rice puddings, breads and cakes, and beer adjuncts. Waxy and low-amylose content rice is preferred for rice wines (for a higher ethanol yield) and in frozen sauces, desserts, snacks, and sweets, because of the slower staling rate. Rice crackers are prepared from waxy and nonwaxy rice. Parboiled rice is preferred over raw rice for *idli* (pudding) and *dosai* (cake) with rice-black gram usually fermented at a 3:1 weight ratio. The thermophysical properties of starch, such as glass transition temperature, gelatinization temperatures, enthalpy of raw starch, staled amylopectin melting (45–60 °C), amylose-lipid complex I (<100 °C) and II (>100 °C) melting, and staled amylose melting (>130 °C) of gelatinized starch, affect the properties of rice products in addition to the amylose–-amylopectin ratio and protein content.

Specialty rice includes Italian Arborio rice for risotto, waxy rice (sweet rice with an opaque grain), Thai Jasmine rice (aromatic low-amylose content long grain), and Punjab Basmati (aromatic intermediate-amylose content long grain, which elongates when presoaked). 2-Acetyl-1-pyrroline is the first major aroma components to be identified in raw and cooked aromatic rice; others are being characterized. Endosperm 2-acetyl-1-pyrroline, which is bound to starch and more persistent, requires higher extraction temperatures than the free form, which is volatile at room temperature and lost during storage.

Rice: Types and Composition

PS Panesar and S Kaur, Sant Longowal Institute of Engineering and Technology, Longowal, India

Introduction

Rice (*Oryza sativa* L.), a member of family Poaceae and subfamily Oryzoidea, is one of the major staple foods consumed by 70% of the world's population and occupies one-fifth of the total land covered under cereal crops. The importance of rice has been recognized for many centuries and rice is also known as 'dhanya,' which means the sustainer of the human race. It is not only used as a foodstuff but also is an ingredient in medicines and cosmetics and has a role in crafts and religious ceremonies. The adaptation of rice cultivars to wide climatic conditions has led to the development of thousands of varieties having diverse quality features in terms of physical, cooking, eating, and product development characteristics. Rice is also known as model crop due to fully sequenced genome, relatively small genome size, significant level of polymorphism, and large amount of well-conserved genetically diverse material. It gives unique opportunities to researcher for studying its varietal difference and history of crop improvement using different approaches. In natural form, rice is obtained as a paddy, which is further processed to get different forms (brown, milled, parboiled, enriched, etc.) depending on health issues and consumer choice. Many research efforts including genetic engineering have been put forward to improve the productivity and nutritional composition of rice.

Morphology and Taxonomy of Rice

Rice is an annual plant that can grow to 3.3–5.9 ft tall having long, slender leaves, and flowers are produced in branches bearing pendulous inflorescence. The edible seed is a grain that is a fertilized and ripened ovule containing a live embryo capable of germinating to produce a new plant. Grain is mainly composed of the ripened ovary, the lemma and palea, the rachilla, the sterile lemmas, and the awn, where lemma and palea along with their associated structures constitute the husk. The embryo present on ventral side of the spikelet next to the lemma contains the embryonic root, and the rest of the grain consists of edible portion, that is, the endosperm. The taxonomy of rice is given in Table 1.

Rice Forms and Nutritional Composition

Multilevel processing categorized rice into different forms, which include paddy rice (kernels are present inside the hull), brown rice (husk being removed), milled or white rice (bran layers being removed), parboiled rice (rice gone through steam-pressure process before milling to increase head rice recovery and vitamin content of milled rice), precooked rice (cooked and dehydrated rice after milling to reduce time required for cooking), and enriched rice (a blend containing ordinary milled rice and a small percentage of fortified rice with vitamins and iron content slightly above the level present in brown rice).

Rice is mainly composed of carbohydrates as energy source followed by fat. The carbohydrate in rice is mainly in the form of starch, which exists as either amylose or amylopectin. Amylopectin contains branches and is less resistant to digestion, whereas amylose is a straight chain molecule and harder for the digestive system to break up. It is also a good source of the B vitamins, thiamine, riboflavin, and niacin but contains little to no vitamin C or D or β-carotene (precursor of vitamin A). The amino acid profile of rice is high in glutamic and aspartic acids but low in lysine.

Rice Husk

Rice husk, a by-product of the rice milling industry, offers the valuable nutritional advantage, as it contains an antioxidant defense system to protect the rice seed from oxidative stress. The major phenolic compounds present in husk are ferulic acid and p-coumaric acid along with isovitexin, a potent antioxidant.

Brown Rice and Rice Bran

Brown rice is unmilled and a whole grain form of paddy with mild and nutty flavor. Brown rice and milled rice have similar amount of calories as well as carbohydrates. However, during the milling process, dietary fibers, minerals, and B vitamins present in the bran are stripped off. The rice bran fraction contains 12–13% oil and highly unsaponifiable components (4.3%). The oil fraction contains tocotrienols, gamma-oryzanol, and β-sitosterol, which play an important role in lowering of the plasma levels of the various parameters of the lipid profile. The main antinutritional factors concentrated in the bran are phytate, trypsin inhibitor, oryzacystatin, and hemagglutinin–lectin. The interesting feature related to mineral content of rice bran is its low sodium and high potassium content, which may be a useful supplement in diets for hypertensives.

Milled Rice

The milling and polishing process to get white milled rice results in the loss of some important nutrients. The highly milled white rice have reduced protein, mineral, and lysine content, and the zinc concentration remains half as compared with brown rice. However, the consumption of milled rice is generally more acceptable than brown rice due to difficult digestion, high cooking time, and the need for more water for cooking, and more importantly, the color and texture of cooked brown grains are not attractive to the consumers.

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00596-1

The major use of milled rice is in daily meals, breakfast cereals, snacks, desserts, pet foods, and brewing.

Parboiled Rice

Parboiled rice (converted rice) has been reported to be nutrient-dense. During the processing (soak and steam the rice kernels under intense pressure) method, many of the nutrients from the rigid outer hull go to the inner part of the kernel, and the hull falls off. The end product (parboiled rice) is enriched with plenty of vitamins and minerals and is very low in the glycemic index. The parboiling has been mainly done to drive nutrients, especially thiamin, from the bran to endosperm, and the parboiled rice is 80% nutritionally similar to brown rice. Thus, parboiled rice is found to be a better source of fiber, calcium, potassium, and vitamin B_6 than milled white rice. They are used as refrigerated and frozen products, salads, health food products, snacks, and breakfast cereals.

Enriched Rice

During milling process, many nutritional components have been stripped off in bran, and the consumption of highly milled white rice results in nutritional deficiencies. To overcome the problems, different types of enriched white rice have been developed with fortification of lost components including thiamine, riboflavin, iron, niacin, pantothenic acid, vitamin B_6, calcium, and folate. The two commercially adopted techniques for rice enrichment are powder enrichment and whole grain enrichment. The stability of added nutrients may be varied by the method adopted, utilization and storage washing, and cooking conditions.

Colored Rice

The nutrient content of rice suggests that the nutritional value of rice varies based on a number of factors as shown in Figure 1. The nutritional content also depends on the color of the grain. Scientists have found that the color of rice is basically due to the compounds it contains as in purple rice, hydrophilic antioxidants represent a greater portion than the lipophilic antioxidants. Furthermore, studies showed that most of the useful substances are found in the inner part of the purple rice bran. Similarly, black rice and red rice contain pigments that reduce atherosclerosis development and cholesterol levels, which are however absent in milled white rice.

Cultivation of Rice

The genus *Oryza* has 21 wild and 2 cultivated species, that is, *Oryza sativa* (Asian rice) and *Oryza glaberrima* (African rice). The varieties belonging to *O. sativa* spp. are grown across the world, while the cultivation of the *O. glaberrima* has been confined to Africa. *O. glaberrima* varieties are fast being replaced by the *O. sativa* due to weed tolerance, pest resistance, and fast maturing growth attributes of later varieties. Based on the number of morphological, physiological, biochemical, and molecular traits, Asian rice cultivars are broadly classified into two major subspecies, that is, *Oryza sativa japonica* and *Oryza sativa indica* as shown in Figure 2.

In addition to these major varieties, the minor groups include aus cultivars of India and Bangladesh, ashinas varieties of Bangladesh, and aromatic basmati varieties of India. These groups may be further subdivided into more types like aromatic and nonaromatic, waxy, and nonwaxy based on their distinct features. Each type of rice cultivars have different markets and within each type are special quality demands for specific uses.

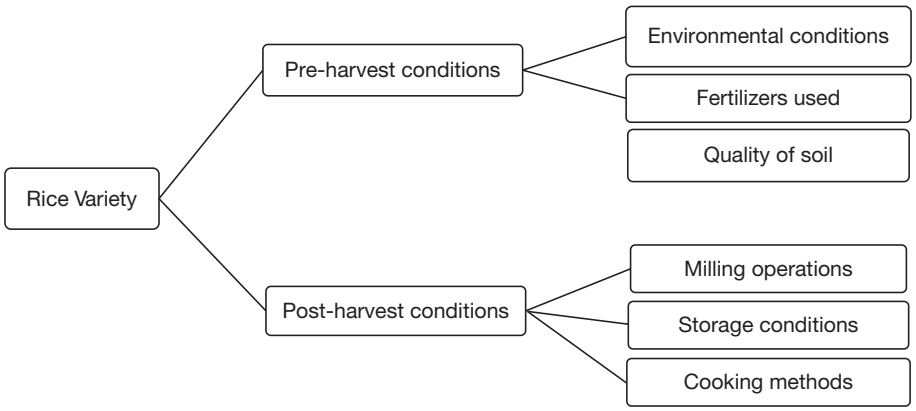

Figure 1 Different factors influencing nutritional composition of rice.

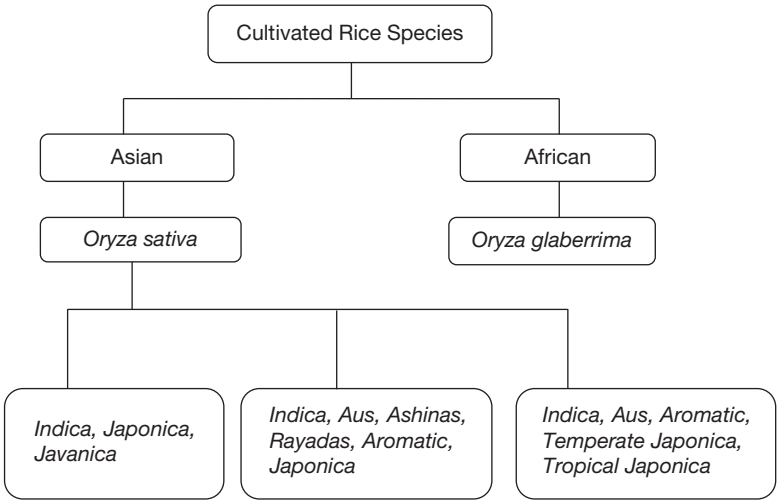

Figure 2 Classification of cultivated rice species.

Rice Varieties

With its long history of cultivation and selection under diverse environments, rice acquired wide adaptability, enabling it to grow in a wide range of environmental conditions. About 40 000 rice varieties and 500 000 accessions of rice genetic resources are conserved all over the world. The largest six gene banks are in Asia and together conserve around 70% of the total world rice germplasm. They are the International Rice Research Institute (IRRI) in the Philippines, National Bureau of Plant Genetic Resources (NBPGR) in India, Institute of Crop Germplasm Resources (CAAS) in China, China National Rice Research Institute (CNRRI), National Institute of Agrobiological Sciences (NIAS) in Japan, and Rural Development Administration (RDA) in the Republic of Korea.

Rice varieties are often classified into different groups on the basis of morphological, geographic, and quality variations, which are discussed in the succeeding text.

Japonica Rice

Japonica is one of the two major ecogeographic races of *O. sativa* (*O. sativa* japonica) from northern and eastern China and grown extensively in some areas of the world. It is found in the cooler zones of the subtropics and in the temperate zones. Japonica grains are short and roundish, do not shatter easily, and have 0–20% amylose content (AC), with awnless to long-awned spikelets. The two main categories of Japanese rice are ordinary rice (uruchimai) and glutinous rice (mochigome). Uruchimai is widely grown and is the staple foodstuff of the Japanese diet with short translucent grains and has sticky texture. Glutinous rice are short, round, and opaque grains with greater stickiness upon cooking but firmer and chewier texture when consumed.

Indica Rice

Indica rice is the other of the two major ecogeographic races of *O. sativa*. It is the major type of rice grown in the tropics and subtropics. They grow mostly in the Philippines, India, Pakistan, Java, Sri Lanka, Indonesia, central and southern China, and African countries. Indica grains are long to short, slender, and somewhat flat, and the spikelets are awnless. Indica grains shatter more easily and have 23–31% AC. The diverse ecological situations in areas of rice cultivation have given rise to the different ecospecific rice varieties of indica group with specificity for season, situation, and system.

Aromatic Rice

Aromatic rice constitute a small but special group of rice, which are considered best in quality. These varieties have long been popular in the Orient and are now becoming more popular in Middle East, Europe, and the United States. The fragrant rice other than basmati are found in different parts of the world. Basmati is one of the most well-known varieties of aromatic rice. It is cultivated in India, along with *Chinoor*, *Shakarchini*, and *Kalanamak*, among numerous other varieties. Basmati rice is different from other aromatic rice varieties because of the aroma and postcooking elongation attributes. No other rice has these combined characteristics. The other distinct characteristics of basmati rice include extra long, slender grain, lengthwise excessive elongation on cooking, and soft and fluffy texture of cooked rice grain. Studies on the unique quality traits of basmati rice found their gene expression only when they are grown in the northwestern foothills of the Himalayas in the Indian subcontinent. Due to the geographic specific manifestation of quality features, basmati is now a geographic indication belonging to a specific geographic area in the Indian subcontinent grown by farmers of Punjab region of India and Pakistan and Haryana and Uttar Pradesh regions of India for more than 250 years.

Similarly, jasmine rice, known as Thai fragrant rice (originally from Thailand), possesses long grain and has a nutty aroma and a subtle pandan (*Pandanus amaryllifolius*) like the flavor caused by 2-acetyl-1-pyrroline (2-AP). The grains will cling when cooked, though they are less sticky than other rice as they have less amylopectin. It is also known as Thai Hom Mali and has a very high glycemic index of 109, which is more than pure glucose.

In the United States, several companies have bred specific cultivars of aromatic rice, including wild pecan and Wehani rice. Wild pecan has a rich, nutty flavor and aroma, whereas Wehani smells like popcorn and is gray in color and the grain splits on cooking. These cultivars were developed in response to increasing consumer demand for this rice.

Glutinous Rice

This group of rice varieties is also famous as sticky rice or waxy rice. This rice is mainly grown in the regions of Southeast and East Asia. The grains have opaque grains and very low AC and are sticky when cooked. Amylopectin is responsible for the sticky quality of glutinous rice. Like all types of rice, glutinous rice does not contain dietary gluten (i.e., glutenin and gliadin) and should be safe for gluten-free diets.

Rice Grain Quality

The quality of rice grain assumes greater importance because most of the rice produced is cooked and consumed as a whole kernel, whereas the percentage of rice converted into flour or flakes is very small. The genetic diversity among rice cultivars from quality point of view can be assessed in three broad categories, that is, physical qualities, processing qualities, and nutritional qualities. The shape and size of grain, chalkiness, and alkali spreading values are considered under physical qualities. Alkali spreading value involves the treatment of rice grains with dilute alkali, which results in disintegration of starch molecules. The waxy and low-amylose-containing grains disintegrate fast as compared with high-amylose-containing rice grains. The change in shape of grain and its disintegration level are recorded on seven-point scale on the basis of which gelatinization temperature is calculated. Milling, cooking, and textural and thermal attributes are considered as processing qualities, which are in turn greatly influenced by AC and gelatinization temperature. The nutritional qualities of different rice grains depend upon protein, carbohydrate, starch, ash, fat, mineral, vitamin, and amino acid contents.

Milling yield is one of the most important criteria of rice quality especially from a marketing standpoint. A variety should possess a high turnout of whole grain (head) rice and total milled rice. Milling yield of rough rice is the estimate of the quantity of head rice and total milled rice that can be produced from a unit of rough rice. Thus, the milling quality of rice may be defined as the ability of rice grain to stand milling and polishing without undue breakage to yield the greatest amount of total recovery and the highest proportion of head rice to broken rice. The three main dimensions (length, width, and thickness) of paddy grains are useful in selecting sieve separators to calculate surface area and volume of kernels, which are important during modeling of grain drying, aeration, heating, and cooling and further in designing particular equipment for handling and storage of grains. Densities of different types of cereal grain kernels are of paramount interest in breakage susceptibility and hardness studies. The parameters related to the frictional properties (angle of repose and coefficient of friction) of cereal grains on different surfaces are very helpful in design of hoppers based on the flow ability of agricultural grains and also in safe designing of equipments related with processing, moving, and storage of grains.

Physical Parameters of Milled Rice

The rice grain length, width, and weight mainly determine the physical quality of rice grain. The classification of rice quality is based on the length of grain, that is, short, medium, and long grains. Grain shape is an important agronomic trait in cereal crops because it is directly or indirectly related to the quality and quantity of grain products. Moreover, grain size and shape are the first quality characteristics considered in developing new varieties. The length to breadth ratio ranging from 2.5 to 3.0 is widely acceptable, and the grain length >6 mm is preferred. The size and shape of the rice grain may vary from one group to another group of different regions. Some groups prefer short grains, some prefer medium grains, and mostly, the peoples like long, slender grains in Indian subcontinent regions and in international market. Medium and short grains are preferred by the peoples of South Asian regions. Thus, components of appearance traits are one of the first criteria for rice quality that breeders consider in developing new varieties for open release and commercial production.

The length to width ratio is also an important aspect to determine the shape of the variety, whereas grain weight gives the information about the size and density of the grain. The density of different rice grains affects the cooking quality.

Chemical Parameters of Milled Rice Grains

The most important quality criterion based on chemical characteristics of rice grain and flour of different cultivars is moisture, carbohydrate, protein, fat, crude fiber, and ash contents. The moisture content during storage showed changes with the length of storage and the temperature of storage. Proteins and starches are the two major components of rice, with approximately 8% and 80% composition, respectively. Rice protein is more nutritious because of its higher lysine content than any other cereal proteins. Micro-Kjeldahl analysis and different methods are used to determine the protein content in rice. Fat is the main source of food energy, which, rather than giving energy, helps in the absorption of fat-soluble vitamins. Rice contains very low amount of fat, but cooked brown rice contains higher fat contents than white rice.

Cooking and Textural Properties

The rice produced in different parts of world varies significantly in composition and cooking quality. Genetic and environmental factors are mainly responsible for the variation in composition and cooking quality of rice. Consumer preference regarding cooking attributes of rice grains may vary from region to region. Japanese like sticky rice, while Italians consume short-grain variety, which releases starch during cooking, making a creamy and smooth risotto, Americans prefer a semi-milled long-grain rice or even brown rice, Asians predominantly prefer spicy and scented basmati/jasmine rice, and the people of Indian subcontinent prefer a well-milled white rice. Cooking and eating characteristics are largely determined by the properties of the starch that makes up 90% of milled rice. Gelatinization temperature, AC,

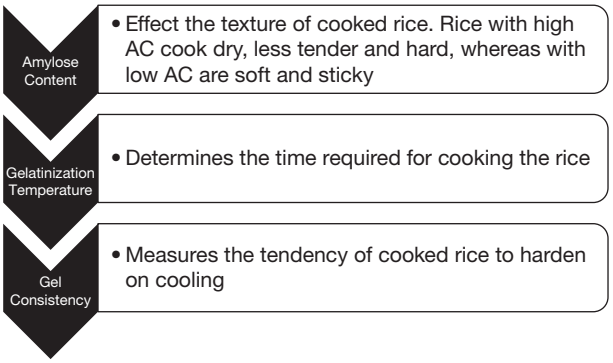

Figure 3 The effects of amylose content, gel consistency, and gelatinization temperature on cooked rice grains.

and gel consistency are the important starch properties, which influence cooking and eating characteristics as shown in Figure 3.

Amylose content

AC is considered as the most important character for predicting rice cooking and processing behavior. Many of the cooking and eating characteristics of milled rice are influenced by the ratio of two kinds of starches, that is, amylose and amylopectin. Amylose is the linear fraction of starch in the nonglutinous varieties, whereas amylopectin, the branched fraction, makes up the remainder of the starch. Amylose is almost absent from the waxy (glutinous) rice cultivars that do not expand in volume, are glossy and sticky, and remain firm when cooked. High-amylose-containing rice grains show high volume expansion and a high degree of flakiness. They cook dry, are less tender, and become hard upon cooling. Rice grains with intermediate AC cook moist and tender and do not become hard upon cooling. Rice varieties are grouped on the basis of their AC into waxy (0–2% AC), very low (3–9% AC), low (10–19% AC), intermediate (20–25% AC), and high (>25% AC).

Gelatinization temperature

Different diffusive processes like heating, water uptake, and swelling of the rice particles take place during cooking of rice grains. Starch granules are heated in water beyond a critical temperature; the granules absorb a large amount of water and swell to many times their original size. Over a critical temperature range, the starch granules undergo an irreversible process known as gelatinization, which is marked by crystalline melting, loss of birefringence, and starch solubilization. As soon as the temperature rises above the gelatinization temperature, the starch granules begin to swell and viscosity increases. The gelatinization temperature provides an indication of the minimum temperature required to cook for a given rice sample. The gelatinization temperature of rice varieties may be classified as low (55–69 °C), intermediate (70–74 °C), and high (>74 °C). The gelatinization temperature can be estimated by an alkali digestibility test in which the degree of spreading value of individual milled rice kernels in a weak alkali solution (1.7% KOH) is very closely correlated with gelatinization temperature. Rice with low gelatinization temperature disintegrates completely, whereas rice with intermediate gelatinization temperature shows only partial disintegration. Rice with high gelatinization temperature remains largely unaffected in the alkali solution.

Linear elongation of rice on cooking is one of the major characteristics of good rice. Some varieties expand more in size than others upon cooking. Lengthwise expansion without increase in girth is considered a highly desirable trait of rice. Soaked milled rice of high gelatinization temperature elongates less during cooking than rice of low and intermediate gelatinization temperature. Thus, gelatinization temperature correlates positively with grain elongation. However, gelatinization temperature does not correlate with the texture of cooked rice.

Gel consistency

The texture of cooked rice grains is mainly dependent upon the AC; however, the cohesiveness, tenderness, color, and gloss of cooked grains are greatly based on gel consistency, when the AC is high. Varietal differences in gel consistency exist among varieties of similar AC. The gel consistency test is based on the consistency of the rice paste, which is different among varieties with high AC. It measures the tendency of cooked rice to harden when it cools down. In gel consistency test, test tubes containing rice grain powder (100 mg), ethyl alcohol (95%), thymol blue (0.025%), and potassium hydroxide (0.2 N) are heated in a vigorously boiling water bath for 8 min. The test tubes are removed from the water bath and left to stand at room temperature for 5 min. The tubes are cooled in an ice water bath for 20 min and laid horizontally on a laboratory table lined with millimeter graphing paper. The total length of the gel has been measured in mm from the bottom of the tube to the gel front. This test separates rice grains into three categories:

1. Very flaky rice grains with hard gel consistency (length of gel, 40 mm or less)
2. Flaky rice grains with medium GC (length of gel, 41–60)
3. Soft rice grains with soft gel consistency (length of gel, more than 61 mm)

Cooked kernel elongation

The elongation ratio and elongation index are the important cooking quality traits of rice and are much preferred by the consumers. The quality of cooked rice grain is mainly associated with its length wise expansion as compared with its widthwise expansion. Aromatic long-grain basmati rice are known for their pleasant aroma and extra elongation on cooking with least breadthwise swelling. It has been also observed that if rice elongates more lengthwise, it gives a finer appearance, whereas it gives a coarse look if it expands girthwise.

Aroma

The aroma of rice plays a role in its consumer acceptability, and it draws a premium price in certain specialty markets. Most of the high-quality preferred varieties in major rice growing countries are aromatic in nature. Jasmine rice from Thailand, basmati rice from Pakistan and India, and Della rice from the United States are the main sources of aromatic imports. The scent of aromatic rice is a highly heritable trait and reportedly is under the control of one to four genes, depending on the population studied. More than 100 compounds that

contribute to the aroma of rice have been identified. Some of these volatile compounds contribute to consumer acceptance of certain type of rice, whereas other compounds contribute to consumer rejection. The popcorn-like smell of aromatic rice stemming primarily from its 2-AP content is considered desirable by many consumers.

Global Distribution of Rice

Rice is the world's leading food crop, cultivated over an area of about 155 million hectares with a production of about 596 million tons (paddy). In terms of area and production, it is second to wheat. Maximum area for rice cultivation is found in Asia, with India having the largest area (44.8 million hectares) followed by China and Indonesia. In respect to production, India ranks second with 131 million tons of paddy next to China (200 million tons of paddy). In regard to average yield per hectare, Egypt ranks first followed by the United States. The leading countries producing rice crop are Japan, Brazil, China, India, Indonesia, Bangladesh, Vietnam, Thailand, Myanmar, and the Philippines. The details about milled rice production and consumption in tons at international level have been given in Table 2.

There are major world markets for rice in terms of quality, definite varieties, and processing types. The long-grain, higher-quality rice is sold mostly in Europe and the Middle East, the medium-quality long-grain in the deficit countries of Asia, the short-grain product in various special demand areas, the high-quality parboiled rice in the Middle East and Africa, and the lower-quality parboiled rice in special markets in Asia and Africa. Aromatic rice is demanded mostly in the Middle East, and glutinous rice meets the needs in Laos with smaller volumes to other countries.

Table 2 Statistical data on milled rice production and consumption in different countries

Countries	*Production (2013–14)*	*Consumption (2013–14)*
Bangladesh	34 200	34 700
Brazil	8500	7800
Burma	11 000	10 250
Cambodia	4900	3800
China	144 000	147 000
Egypt	4850	4000
India	108 000	98 500
Indonesia	37 700	40 300
Japan	7720	8150
South Korea	4220	4497
Nigeria	3100	3350
Pakistan	6200	5900
The Philippines	11 700	12 925
Thailand	21 100	10 600
Vietnam	27 850	20 600
Others	38 183	58 212
Subtotal	473 223	473 187
The United States	6038	3657
World total	479 261	476 844

Rice Biotechnology

The rapid increase in global population and the ever-increasing demand for food force the researchers, industrialists, and government authorities to fulfill the demanding gap. This situation is true also to rice as it is a significant source of calories for half of the world. As a result, rice is receiving considerable attention by plant breeders who are using both conventional and transgenic techniques to increase rice yield and quality.

International Rice Genome Sequencing Project has developed and analyzed a complete, highly precise sequence of the rice, and the project came out with many prominent attributes of rice genome: the genome size is 389 Mb, sequencing covered 95% of the total genome including all of the euchromatin, two complete centromeres, and 37 544 nontransposable element-related protein-coding sequences, and 2859 genes were found to be unique to rice. It has recognized 80 127 polymorphic sites that can distinguish between two cultivated rice subspecies, *O. sativa japonica* and *O. sativa indica*. Along with the identification of genes, single-nucleotide polymorphisms and simple sequence repeats were additionally identified, which in the future will pick up the pace in improvements of rice production.

Some of the important interventions of biotechnology in rice (in terms of health) are as follows.

Nutritional Rice Varieties

Golden rice is a genetically modified variety of *O. sativa*, which has been developed to biosynthesize β-carotene, a precursor of vitamin A, in the edible parts of rice. The research was conducted with the goal of producing a fortified food to be grown and consumed in areas with a shortage of dietary vitamin A, a deficiency that is estimated to kill 670 000 children under the age of 5 each year. Golden rice was created by transforming rice with only two β-carotene biosynthesis genes:

1. *psy* (phytoene synthase) from daffodil (*Narcissus pseudonarcissus*)
2. *crtI* (carotene desaturase) from the soil bacterium *Erwinia uredovora*

The original golden rice was called SGR1, and under greenhouse conditions, it produced 1.6 $\mu g\ g^{-1}$ of carotenoids.

To improve the nutritional quality, the major focus is on developing rice varieties with provitamin A and high iron and zinc content in the polished grain. Biotechnology techniques such as plant transformation offer great opportunities for increasing the amounts of trace metals in the endosperm. Different types of genes (OsNAS2, SoyFer, TOM1, HvNAS1, etc.) have been used for rice biofortification, and these genes are encoding metal chelators and metal transporters, Fe storage protein (ferritin), and phytase.

Improvement of Quality Traits in Rice

The quality of grains is a major concern for consumers, which generally preferred long, nonsticky, and aromatic rice. Many traits related to the quality of cooked rice grains have been mapped, and genes/QTLs have been reported for AC, gel consistency (chromosome 6), kernel length after cooking, and

aroma (chromosome 8). Similarly, many QTLs have been reported for head rice recovery, protein content, grain length, and grain length to breadth ratio.

Expression of Human Proteins in Rice

Genetic modifications have been done in rice varieties to express lactoferrin and lysozyme proteins, which are usually found in breast milk and human serum albumin. These proteins have many medicinal benefits including antiviral, antibacterial, and antifungal effects. Grains of rice containing these proteins can be used as a component in oral rehydration solutions to treat diarrheal diseases and anemia.

Allergen-Free Rice

Rice seed proteins contain antigens that provoke allergic responses in some individuals with food allergy, particularly in those with cereal allergy. These antigens are responsible for clinical symptoms such as eczema and dermatitis. An attempt has been made to develop allergen-free rice variety by repressing the formation of high-molecular-weight allergen compounds.

Conclusions

The production and consumption of rice are variable at a global scale based on its forms, varieties, geographic origin, climatic conditions, and choice of consumer. The demand of rice is expected to be higher in the future to keep in pace with increasing population. Thus, technologies like biofortification and genetic modifications in rice are advancing at a rapid rate to make scientific progress, which would lead to both nutritional and economical benefits in rice-consuming countries.

Risk Assessment of Foods and Chemicals in Foods

SM Barlow

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Risk assessment has been defined by the International Programme on Chemical Safety in 2004 as

> A process intended to calculate or estimate the risk to a given target organism, system, or (sub)population, including the identification of attendant uncertainties, following exposure to a particular agent, taking into account the inherent characteristics of the agent of concern as well as the characteristics of the specific target system.

Risk assessment of food and food ingredients can range from assessment of the effects on health of whole foods and food ingredients, such as macro- and micronutrients, to individual chemical substances or physical agents such as radionuclides or foreign bodies present in food. The focus of this article is on individual chemical substances, such as food additives, processing aids, migrants from food contact materials, residues of plant protection products (pesticides) and of veterinary products, and undesirable contaminants originating from the natural or man-made environment. Risk assessment of novel foods and genetically modified (GM) foods has also become an important activity.

There is also increasing attention by public health bodies on the effects of the diet as a whole and of macroingredients in food on human health, particularly on serious, chronic, and prevalent conditions such as cardiovascular disease, diabetes, and cancer. Microbiological contamination of food is also an important and frequent cause of ill health. Both of these topics are beyond the scope of this article.

Risk assessment of individual chemical substances in food that are derived from products deliberately added to food or applied to food, crops, or food-producing animals (e.g., food additives, food packaging, processing aids, pesticides, and veterinary products) usually relies on information obtained from *in silico*/bioinformatic approaches, *in vitro* laboratory tests, and *in vivo* testing in laboratory animals. Similar approaches are used for the assessment of GM foods but with lesser emphasis on laboratory animal tests and greater emphasis on the characterization of the GM element(s). For common food contaminants (e.g., mycotoxins, heavy metals, and persistent organic pollutants), there are often human data available in addition to laboratory-derived data. Risk assessment of the diet or macroingredients is usually based on human epidemiological studies and observations.

General Principles of Risk Assessment as Applied to Food

The scientifically based process of risk assessment utilizes the following steps: hazard identification, hazard characterization, intake/exposure assessment, and risk characterization. This four-step paradigm for a systematic approach to risk assessment is widely adopted throughout the world by risk assessment bodies, such as the Joint FAO/WHO Expert Committee on Food Additives (JECFA), the European Food Safety Authority (EFSA), and the US Food and Drug Administration.

Hazard Identification

Hazard identification is the first step in the risk assessment process. It identifies the types of adverse health effects that a chemical or physical agent may exert. The aim is to identify potential hazards to humans that the presence of a substance in food may pose. Potential hazards can be identified from data including *in silico* analysis of structure–activity relationships, read-across from toxicity data on closely structurally related substances, laboratory studies on the substance itself and *in vitro* or *in vivo* studies in laboratory or farm animals, human and domestic animal case reports, and other human observations and epidemiological studies.

Risk assessors consider all of the available data on chemical structure, physicochemical properties, kinetics and metabolism of the ingested substance in the body, and toxicity of the substance. In this manner, as much information as possible is assembled on the nature and severity of any toxic or adverse health effects observed, the affected target organs and/or tissues, and, if toxicity is evident, any information that may be available on the mode of action of the substance.

Hazard Characterization

Hazard characterization is the second step in the risk assessment process. It involves the qualitative and, where possible, the quantitative evaluation of the adverse health effects that have been identified in the first step. For chemicals, this is sometimes termed dose–response assessment. It describes the relationship between the magnitude of the administered dose of (or exposure to) a chemical and the incidence and/or severity of an adverse health effect. Where possible, risk assessors will try to identify from the range of studies available a dose or exposure below which no adverse effects have been observed.

During hazard characterization, each effect identified will be assessed for human relevance. Some effects observed in animal studies are not considered relevant for humans (e.g., the accumulation of alpha-2-microglobulin resulting in nephropathy in the kidney with exposure of rodents to hydrocarbons, adrenal medullary hyperplasia and neoplasia in rodents treated with large amounts of nondigestible substances, and the particular sensitivity of cats to hematologic effects from propylene glycol). Usually, a critical effect of potential relevance to humans will be identified. The critical effect is the first significant adverse effect that appears as dose or exposure is increased. This generally forms the focus of the risk assessment, but other identified adverse effects occurring at

higher doses may also need to be considered (see section 'Risk Characterization').

For most types of toxic effect, it is generally considered that there is a dose/exposure below which adverse effects will not occur (i.e., a threshold) in animals or humans. For toxic effects with a threshold, a no-observed-adverse-effect level (NOAEL) or a no-observed-effect level can usually be identified from animal studies. NOAEL is the preferred term used nowadays because it indicates that the effect observed at doses higher than the NOAEL is considered adverse and relevant to humans. Whether or not the NOAEL closely approximates the true threshold for the onset of a toxic action of a particular substance in the system or species under investigation depends very much on study design aspects, such as the duration of the study, the number of animals or human subjects per dose group, the dose intervals selected, the range of the toxicity parameters investigated, and the sensitivity of the methods used to detect changes in the body.

For chemical substances, the aim of hazard characterization is to identify, if possible, a numerical reference point or point of departure (POD) from which a health-based guidance value (HBGV) can be derived at the final risk characterization stage. The reference point or POD is often the NOAEL. If an NOAEL cannot be identified, it may be possible to identify the lowest-observed-adverse-effect level (LOAEL), which can then be used as the reference point or POD. More recently, risk assessors have introduced an approach in which the dose–response data for each potentially critical effect are mathematically modeled to derive a 'benchmark dose' (BMD) for a particular incidence of effect. The incidence selected is usually near the lower end of the observed range of data (e.g., a 5% or 10% incidence) and is termed the benchmark response. To allow for uncertainty, the computed lower 95% confidence limit on the modeled BMD (BMDL), rather than the BMD itself, is normally used as the reference point or POD for derivation of an HBGV. The critical effect to be taken forward for the risk characterization is usually the effect with the lowest BMDL. The use of the BMD approach is considered preferable nowadays to the NOAEL approach because it makes best use of the available dose–response data and is not unduly influenced by the dose interval selection.

For some types of toxic effect, such as genotoxicity or cancer caused by a genotoxic mode of action, it cannot be assumed that a biological threshold exists. For these types of effect, it is assumed that there is some probability of harm at any level of exposure. In the case of substances that are avoidable in foods (e.g., a proposed food additive, pesticide, and veterinary drug), which are shown to be genotoxic *in vivo*, a decision may be taken not to allow their use. In other cases, in which an unavoidable substance in food (e.g., a contaminant) is shown to be both genotoxic and carcinogenic, the BMDL derived from animal cancer bioassays may be used as the reference point or POD for risk characterization.

Intake/Exposure Assessment

Intake/exposure assessment is the third step in risk assessment, in which the known or anticipated extent of human intake of, or exposure to, the substance is determined. Quantitative determinations are essential for full risk assessment, but if data are sparse, as may be the case with contaminants, a qualitative assessment may be the best that can be achieved. Intake is the term usually applied when considering macroingredients or whole foods. Exposure is the preferred term when considering chemical or physical agents. In the case of chemical substances present in food, through either deliberate addition or application to food or their unintentional presence in food, exposure assessment takes into consideration the following information:

- Occurrence and concentrations of the chemical in the various foods in the diet
- The consumption patterns of the foods containing the chemical
- The likelihood of consumers eating large amounts of the food(s) in question (high consumers)
- The likelihood of the chemical being present in these foods at high levels

Single-point estimates of intake/exposure are of limited value because they do not reflect the likely range across the population. Normally, exposure assessors will provide a range of intake/exposure estimates (e.g., for average consumers and for high consumers), which will usually also be broken down by the subgroup of the population (e.g., infants, children, and adults).

Exposure estimates should, ideally, take into account not only exposure from food sources but also exposure to the same substance from all sources, by all routes and pathways. This is termed an aggregate exposure assessment. However, detailed information on other sources may often be lacking. For a comprehensive risk characterization, an estimate of total systemic exposure may be needed, particularly where nonfood sources make a significant contribution to overall exposure.

Risk Characterization

Risk characterization is the final step in the risk assessment process. All the data from the preceding three steps of hazard identification, hazard characterization, and intake/exposure assessment are assembled to provide a qualitative and, where possible, quantitative description of the probability of occurrence of adverse health effects in the population as a whole and/or in subgroups of the population, under different exposure scenarios. Risk characterization should include a narrative description of the nature and severity of any adverse effects. In considering risks to human health, a distinction is usually made between toxic effects and intolerance reactions such as pain and diarrhea from osmotic effects of polyol sweeteners or from consumption of bulky fibrous ingredients. Toxic effects are always taken into account when setting an HBGV, whereas intolerance reactions may not be, but may require a narrative warning.

The risk characterization advice should be in a form that is suitable to enable risk managers to make decisions about any necessary actions that may need to be taken to protect the population from ill health. Most importantly, risk characterization should include a clear description of the assumptions and uncertainties in the available data on hazards, dose–response, and exposure, including data gaps and any uncertainties in the derivation of an HBGV. Consideration of

any assumptions and uncertainties is a key aspect for risk management decision-making, particularly in cases where risk management actions may be indicated. Where risk management actions may need to be taken to avoid or reduce exposures, the risk characterization may usefully include the assessment of the effect on exposure of different scenarios for risk reduction.

Risk assessment is usually carried out by toxicologists, nutritionists, and exposure experts and requires a scientific background. Risk assessors advise and interact with risk managers who have the responsibility for ensuring that the food supply is safe and that consumers are not put at risk. Ideally, risk characterization should be based on quantitative information, but where this is not possible, advice can be given in a qualitative form.

Qualitative advice

Qualitative advice may include, for example, that the available data indicate that there are no human health concerns, or there are no toxicological concerns (or no safety concerns), even at high exposure levels. Alternatively, qualitative advice may need to state limitations, such as, for example, that there are no concerns from exposure to a particular substance used in a specified way up to a specified concentration in food. If the available data indicate that there are or would be human health concerns arising from certain exposures or particular uses in some or all sectors of the population, then qualitative advice should make clear the circumstances under which adverse effects could occur. When it is not possible to give a precise estimate of probability of occurrence of adverse effects on health, narrative guidance, based on professional judgment, is helpful for risk managers.

Quantitative advice

Quantitative advice may include the derivation of an HBGV and information on whether current population or subpopulation exposures are below or above the HBGV. Alternatively, quantitative advice may provide estimates of the level of risk at different exposures.

Health-based guidance values

HBGVs are levels of human exposure, which may be experienced over a lifetime, that are considered to be without appreciable risk to health. An HBGV for a chemical that is deliberately added to food or is applied to food crops or food-producing animals is termed acceptable daily intake (ADI). For chemicals not deliberately added to food, such as contaminants, the terms tolerable daily intake (TDI) and reference dose are preferred. For some chemicals, for which cumulative exposure causing a chronic toxic effect is the critical effect, the HBGV is set as a weekly or monthly intake, rather than a daily intake. For pesticides and veterinary products, in addition to an ADI, it may also be necessary to set an acute reference dose to cover possible acute effects from exposures to high amounts over a short period (24 h). This particularly applies to those chemicals whose mode of action as a pesticide or veterinary medicine is to inhibit acetylcholinesterase, as this effect is often seen at low exposure levels.

HBGVs, such as ADIs and TDIs for substances with toxic effects that are expected to have a threshold, are set by application of an uncertainty factor (UF), also known as a safety factor, to a reference point or POD; suitable PODs are the NOAEL, and, if the BMD approach has been used, the BMDL. An HBGV is calculated as follows:

$$\text{HBGV} = \frac{\text{POD (i.e., NOAEL or BMDL)}}{\text{UF}}$$

A default overall UF of 100 (10×10) has been routinely used for many years when extrapolating from animal data to humans, comprising a factor of 10 to cover possible interspecies variation and a factor of 10 to cover possible human interindividual variation. It was originally proposed in the 1950s, on an empirical basis, and has largely stood the test of time. Each of the subfactors of 10 can be further subdivided into toxicokinetic (TK) and toxicodynamic (TD) components. TK data describe the behavior of a chemical in the body; TD data describe the sensitivity of the target organs/tissues to toxicity. The default factors for TKs and TDs are as follows: interspecies variation, 4.0 for TKs and 2.5 for TDs, and human interindividual variation, 3.16 for TKs and 3.16 for TDs. If the data on a particular chemical are sufficient, they may allow replacement of some or all of the default UFs for TKs and TDs by specific, observationally derived values, known as chemical-specific adjustment factors. If the data used to derive an HBGV are from human studies, then the default UF of 10 for interspecies variation is not utilized.

If an LOAEL rather than an NOAEL is used as the reference point or POD, then it is usual to incorporate an additional UF (e.g., a factor of 2), in addition to the default UF of 100, giving an overall UF of 200. Similarly, some risk assessors may use additional UFs, ranging up to 10, to take account of gaps in the underlying toxicology database (e.g., absence of a reproductive study) or to extrapolate from subchronic to chronic exposure duration.

While the utilization of UFs in derivation of HBGVs is intended to take account of interspecies differences and human interindividual differences in TKs and TDs, it does not necessarily take account of specific medical conditions or all genetic differences in metabolic capacity. When it is known that a subgroup of the population with a specific metabolic condition may be at risk from exposure to a particular substance, then that substance may still be permitted in food, accompanied by an appropriate warning, as is the case for the intense sweetener, aspartame, for which those with phenylketonuria are advised to avoid.

HBGVs are normally set based on a single critical effect (see section '**Hazard Characterization**'), which will normally be the effect observed at the lowest dose across a range of studies. However, since HBGVs are derived by dividing the NOAEL or BMDL by an appropriately selected UF, there may be occasions when another toxic effect is first observed at a dose higher than that for the originally identified critical effect but requires the application of a higher UF, resulting in a lower HBGV. Thus, risk assessors may sometimes need to consider more than one toxic end point for a substance.

Once an HBGV has been set for a particular substance, the final task in the risk characterization is to compare the population exposure estimates with the HBGV. If all exposure estimates are below the HBGV, then the substance may be permitted for use in food, or if it is already in use, or it is a

contaminant, this indicates that risk management actions are not needed. If any of the exposure estimates exceed the HBGV, then that is an indication that risk management actions may be needed.

Margin of exposure approach

In the case of a substance for which the toxicity is considered to have a threshold, but for which some data are missing and so it may be inappropriate to set a numerical HBGV, the margin of exposure (MOE), also sometimes called the margin of safety (MOS), between an NOAEL or an LOAEL and the known or estimated human exposure can be calculated to provide guidance for risk managers. The MOE/MOS would be accompanied by a narrative describing the potential impact of the missing data on the risk assessment.

The MOE approach is also used for substances with toxic effects that are considered not to have a threshold, such as genotoxicity or carcinogenicity with a genotoxic mode of action. In such cases, the setting of HBGVs is not appropriate. Substances that are genotoxic and/or genotoxic carcinogens are not normally permitted in food unless they are unavoidable. In the case of genotoxic substances that have been tested in animal carcinogenicity bioassays, the data from such assays can be used to estimate the MOE between the BMDL value for the critical tumor site(s) and the known or estimated human exposure levels. The MOE is calculated as follows:

$$\text{MOE} = \frac{\text{BMDL}}{\text{Human exposure}}$$

MOEs of 10 000 or more generally indicate low health concern as the probability of the substance causing genotoxic damage or cancer is considered to be very low. MOEs of less than 10 000 will usually trigger risk reduction measures. MOEs of under 100, as, for example, in the case of acrylamide in food, would be considered to require urgent risk reduction measures.

Cumulative Risk Assessment

It has long been recognized that simultaneous exposure to more than one substance, as opposed to exposure to a single substance, may have an influence on the resulting toxicity of any of the substances involved. Substances that are very closely structurally related may have similar toxicities and, for food additives, this has been recognized by the allocation of group ADIs for such substances. In the case of dioxins and dioxin-like polychlorinated biphenyls, which are ubiquitous contaminants in the environment and thus present in food, a similar approach has been adopted of assessing the potential combined health effects from multiple exposures to closely related substances with similar toxic effects. For this, the concept of toxic equivalency factors has been developed, which allows comparison of the relative potency of different chemicals within the group on the same target and allows a combined HBGV to be set for the group.

Other substances that are not particularly closely related in structural terms may nevertheless exert their toxicity by a common mode of action. For example, various pesticides have a common mode of action to inhibit acetylcholinesterase, which forms the basis not only of their insecticidal activity but also of their toxicological activity. For such groups of substances, it is now recognized that a cumulative risk assessment is required. Cumulative risk assessment is the analysis, characterization, and possible quantification of the combined risks to health from aggregate exposure to multiple agents or stressors. During the last decade or so, regulatory authorities, such as the US Environmental Protection Agency and EFSA, have provided guidelines for the conduct of cumulative risk assessments.

Risk Assessment Approach for Substances with No Toxicological Data

An approach for the assessment of ingested substances of unknown toxicity was developed in the 1980s and 1990s, known as the Threshold of Toxicological Concern (TTC) approach. It has been further developed in recent years and is now widely used for substances for which toxicity data are few or completely lacking and for which human exposures are known to be low. It is particularly useful for low-level contaminants in food, on which risk assessment advice may be needed urgently but for which few toxicological data exist. It has also been used to assess substances migrating into food from food contact materials and to evaluate the acceptability of flavoring substances in food.

Application of the TTC approach requires only knowledge of the chemical structure of the substance concerned and information on human exposure. The exposure estimate(s) should include any likely high exposure. The approach uses generic human exposure threshold values (also called TTC values) for substances grouped according to their chemical structure and likelihood of toxicity. A range of TTC values have been developed covering both cancer and noncancer end points. A very low TTC value is used for substances that are genotoxic or have a structural alert for genotoxicity, and four higher TTC values are used for substances not likely to be genotoxic, which cover possible toxic effects that have a threshold. The TTC values have been derived using existing, published, toxicological information on substances that have been tested in animals in the past.

If the estimated human exposure to an untested substance is below the TTC value that is relevant for the structural class of the substance, it can be concluded with reasonable confidence that there is a low probability of adverse health effects. The TTC approach can be used to obtain a first approximation of risk or may be used (e.g., in the case of flavoring substances) to conclude that toxicity testing is not necessary. If estimated human exposure is above the relevant TTC value, then that is an indication that toxicity data would be needed for a reliable risk assessment.

Risk Assessment Approaches for Specific Food Categories

Micronutrients

In the case of essential vitamin and mineral micronutrients, HBGVs for the amounts needed to maintain good health

are set. These are variously termed guideline daily amounts, recommended daily amounts, recommended daily allowances, dietary reference intakes, or dietary reference values. The physiological requirements for a micronutrient may differ depending on the age group or physiological condition (e.g., pregnancy). Accordingly, guidance values are set for different age groups. In addition, some nutritional and risk assessment bodies set upper limits or tolerable upper intake levels (ULs), above which toxicity may occur. The UL is defined as the maximum level of total chronic daily intake of a nutrient (from all sources) judged to be unlikely to pose a risk of adverse health effects to humans. Unlike HBGVs for other chemicals that are deliberately added to food, such as ADIs, which may be 100-fold lower than the overall NOAEL derived from animal toxicity studies, for micronutrients, there may only be a narrow margin (<10) between the amount required to maintain good health and the UL, with a similar narrow margin between the UL and the onset of toxicity in humans. This situation is due to the essential nature and the inherent biological activity of micronutrients, but the ULs are set, where possible, on the basis of human data. High safety margins are not attainable.

For micronutrients, risk assessment advice may also include the discussion of risks to health from exposures that are below the minimum daily requirement and might result in adverse health effects because of deficiency, as well as the possible toxicity risks from exposures that are above the ULs.

Novel Foods

Novel foods are foods or food ingredients that are not yet consumed on a wide basis by any population or by a proposed target population. Examples include foods, such as fruits, with a history of use in some countries but not hitherto consumed widely by the target population or novel sources of oils, proteins or enzymes, and other substances that can be isolated from plants, microorganisms, fungi, or algae.

Risk assessments of novel foods usually use traditional foods and ingredients as reference points and focus on the differences between the novel food and the traditional food. This approach uses the 'substantial equivalence' concept, which aims to show that there is substantial similarity between the novel food and its relevant traditional counterpart, whose safety is accepted. Under this approach, a systematic comparison of the information available on the compositional analysis and nutritional and toxicological characteristics of the novel food and its traditional counterpart is undertaken. From this, any additional information that may be required to reach a view on whether the novel food would be safe for consumption is identified. That information may or may not involve biological or toxicological testing. Since these are whole foods, risk assessment advice is normally of a qualitative nature, offering advice on whether consumption can be expected to be as safe as the traditional counterpart or can reasonably be expected to result in no harm to health. In some instances, if there are particular molecular structures within the food that are novel, these may have been tested for toxicity and may provide data suitable for quantitative advice within the overall risk assessment.

GM Foods

Risk assessment of GM foods follows a similar approach to that for novel foods, using comparisons of the GM food with relevant traditional counterparts that have a history of safe use. It aims to identify intended and unintended differences and/or lack of equivalences between GM foods and their comparators, taking into account the range of natural variation. For GM plants, assessment of composition and phenotypic and agronomic characteristics and assessment of the genetic modification process and of the resulting introduced genetic trait, including its expression and stability, are key aspects. The majority of GM foods involve the addition of one or more novel proteins; thus, the focus of the risk assessments is on the novel proteins and their potential for toxicity, including allergenicity. Toxicological evaluation of GM foods normally includes laboratory animal testing, the extent of testing required differing under different legislative jurisdictions. Allergenicity evaluations may involve comparison of amino acid sequence homology of the novel protein with that of known allergens (followed up by specific serum screening if there is homology with known allergens), assessment of pepsin resistance, and *in vitro* digestibility tests. A nutritional assessment is also carried out. Risk assessment advice is usually of a qualitative nature.

Enzymes

Enzymes (GM or non-GM) can be used as food additives and as food processing aids. Risk assessment of enzymes requires information on the source material for the enzyme, which may be animal, plant, or microbial, usually some toxicity data, such as genotoxicity and subchronic toxicity, allergenicity assessment (as for a novel protein of a GM food), and exposure information. Risk assessment advice will usually be of a qualitative nature.

Engineered Nanomaterials

The use of engineered nanomaterials (ENMs) in food is in its infancy, but it is anticipated that formulations of many types of substances that are deliberately added to food, used on food or feed crops, or used in food packaging may in the future contain ENMs. Soluble ENMs that have conventional-form equivalents, which have been toxicologically tested, do not require testing because they will revert to the conventional substance on solubilization, and risk assessment can be done by read-across. Risk assessment of substances that are in the form of insoluble ENMs involves additional considerations to those for substances in the conventional form. These include technically difficult characterizations of the nature of the ENM before it is added to food and when it is in a food matrix or in body tissues and fluids and in the material used for toxicological testing. Additional complications of the risk assessment include the interpretation of toxicity studies, given current uncertainties about the validity of testing ENMs in *in vitro* and *in vivo* systems that were originally developed for the testing of substances in conventional chemical forms.

Foods with Inherent Toxicity

Natural toxins are found inherently in some foods of plant and animal origins. Examples include naturally occurring toxins in certain species of mushrooms and berries and in plants that may be used in herbal remedies or plant-based food supplements. Some plant-based foods may also be toxic if they are not processed or cooked appropriately before consumption (e.g., pulses or sprouts from pulses containing lectins that cause gastrointestinal symptoms and cassava and sorghum that release cyanide from cyanogenic glycosides). In some plant-based foods, the level of inherent toxins may build up if they are stored inappropriately for long periods (e.g., glycoalkaloids in sprouting and green potatoes). Foods of animal origin that may be inherently toxic include shellfish that may contain toxins that cause amnesia, paralysis, and other forms of neurotoxicity, various species of reef fish that may contain ciguatoxin that causes gastrointestinal and neurological symptoms, and puffer fish containing the neurotoxin tetrodotoxin.

The risks from consumption of such foods are well documented. Local knowledge of the problems associated with inherently toxic foods and ways of avoiding toxicity generally means that risk assessment is not necessary. In the case of fish and shellfish toxins, regular monitoring of the frequency of occurrence and of occurrence levels may be necessary for ongoing risk assessment.

Saccharin – How Sweet It Is

C Fitch, West Virginia University, Morgantown, West Virginia

© 2016 Elsevier Ltd. All rights reserved.

Introduction

For as long as man has inhabited this Earth, he has been enchanted by foods that taste sweet. In nature, a sweet taste in foods typically indicates higher energy concentration than those foods that do not taste sweet. Saccharin ($C_7H_5NO_3S$) is a chemical compound that is 300 times sweeter than table sugar (sucrose), yet provides no energy. It is in a class of compounds known as nonnutritive sweeteners (NNS) or intense sweeteners for their ability to impart a sweet taste with little to no energy. These compounds have been extensively studied for their effects on human health, yet experts continue to debate their safety.

History

Saccharin, the oldest NNS, was discovered by accident in 1879. Constantin Fahlberg was working on coal tar derivatives in the laboratory of Ira Remsen at Johns Hopkins University. One evening, after a long day of work in the lab, he ate dinner without first washing his hands. He noticed an unusually sweet taste on a roll that he was eating and then on his napkin and a cup. He ran back to the lab and tasted all the vials, beakers, and dishes that he had been using until he identified the source in a beaker in which o-sulfobenzoic acid had reacted with phosphorus, chloride, and ammonia, producing benzoic sulfimide that he called saccharin. Fahlberg and Remsen published an article describing methods of synthesizing saccharin with a taste that was sweeter than cane sugar. A few years later, Fahlberg left Remsen's lab without notice and applied for German and American patents for a new method to produce greater quantities of saccharin at lower cost. He began marketing saccharin in New York City where it was used for many purposes including as a treatment for headaches, nausea, and corpulence, a preservative in canning, and a sweetener for coffee or tea for people with diabetes. Fahlberg touted it for its ability to provide sweetness without spoilage or adverse health effects.

By 1906, Americans were wary of the food industry and the safety of their food so Congress passed the Pure Food and Drug Act in an attempt to regulate the nation's food supply. Responsibility for enforcing the law fell to the US Department of Agriculture, Bureau of Chemistry, led by Harvey Wiley. Wiley sought to ban saccharin, not because he deemed it unsafe, but because it was being used in commercial food production to replace the more expensive agricultural product, cane sugar. His efforts were not successful, largely, perhaps, because President Theodore Roosevelt opposed him. The president used saccharin to manage his weight, at the recommendation of his physician. By 1911, saccharin was considered to be an adulterant and was prohibited from use in processed foods. Its use was to be limited to those with a medical need, but it was still available for purchase by the public at drug stores and pharmacies. A sugar shortage during World War I and again during World War II led to a marked increase in the use of saccharin as a sugar substitute. As the United States recovered from WWII, dietary patterns began to change and there was a greater interest in modifying caloric intake. Saccharin, the only NNS on the market, became more popular as a method of decreasing calories without giving up the sweet taste.

In 1958, Congress passed the Food Additives Amendment to the Federal Food, Drug, and Cosmetic Act, which gave the US Food and Drug Administration (FDA) responsibility for evaluating the safety of food additives. This amendment required that all new food additives undergo a strict premarket approval process unless the substance is generally recognized as safe (GRAS) among experts qualified by training and experience to evaluate its safety under the conditions of its intended use. Food additives were defined as any substance that results, directly or indirectly, in its becoming a component of food. At the same time, Congress passed the Delaney Clause, which stated that no food additive would be deemed safe if it is found to induce cancer when ingested by man or animal and prohibited the FDA from approving such food additives. Food ingredients that were in common use prior to 1958 were listed as GRAS and were not considered food additives; saccharin met that criterion.

In 1970, a study from the University of Wisconsin reported a higher incidence of bladder cancer among rats that consumed saccharin daily, and the FDA removed it from the GRAS list. In 1977, a study out of Canada indicated that rats exposed to very high doses of saccharin over two generations had significantly higher rates of bladder cancer than rats that were not exposed. The FDA moved to ban saccharin under the provisions of the Delaney Clause. This resulted in a massive public campaign to persuade Congress to intervene. Although the evidence to support a ban was limited, the interpretation of the Delaney Clause was that no risk of cancer, no matter how remote, was

acceptable in a food additive. Marketers of saccharine framed the public debate as overreach by big government to deprive the public of their right to self-determination. Congress received more than 1 million letters opposing a ban on saccharin. They placed a 2-year moratorium on the ban and passed the Saccharin Study and Labeling Act of 1977 that required all products containing saccharin to include a warning on the label stating "Use of this product may be hazardous to your health. This product contains saccharin which has been determined to cause cancer in laboratory animals." Saccharin was delisted as a food additive in Canada, although limited access was maintained for saccharin as a tabletop sweetener and the European Commission Scientific Committee on Food restricted the acceptable daily intake (ADI) of saccharin. The unintended result of the proposed ban was a large increase in the purchase of saccharin by American consumers.

Safety studies on saccharin continued over the next several years and the moratorium on the proposed ban in the United States was renewed several times. The American Medical Association, Council on Scientific Affairs, and Division of Drugs and Technology supported the moratorium and its extensions until (1) stronger evidence of saccharin's carcinogenicity was forthcoming or (2) an alternative nutritive or NNS becomes approved. Studies showed a clear dose–response relationship between saccharin exposure during weaning and bladder cancer in male rats with 1% (equivalent to 500 mg kg^{-1} body weight per day) identified as the dose at which there were no observed adverse effects. However, these results could not be replicated in other animal models. Epidemiological studies were inconclusive, but those that controlled for other variables related to bladder cancer showed no consistent dose–response relationship with saccharin. Case–control studies showed no increased risk of bladder cancer related to the use of saccharin. The Danish population that was born during WWII, when the use of saccharin was high, showed no evidence that saccharin exposure *in utero* was associated with an increased risk of bladder cancer during the first 35 years of life.

The National Institute for Environmental Health Sciences determined that the mechanism by which saccharin caused bladder cancer in rats was unique to male rats that had been exposed to saccharin over two generations and was related to changes in rat bladder tissue that were seen with sodium saccharin and with high doses of other sodium salts. An increased risk was not seen in other animal models, and human studies had not shown an increased risk for cancer related to saccharin consumption in amounts that were relevant to people. In 1991, the FDA formally withdrew its recommendation to ban saccharin, although by this time, there was an NNS alternative, aspartame, on the market. In 1990, the UK Committee on Toxicity of Chemicals in Food, Consumer Products and the Environment reviewed the studies on saccharin and recommended a full ADI of 0–5 mg kg^{-1} body weight. In 1997, the European Commission Scientific Committee on Food did the same. On 15 May 2000, saccharin was removed from the list of suspected carcinogens, and on 21 December 2000, President Clinton signed legislation removing the warning label. In 2006, Health Canada notified stakeholders that they intended to propose regulatory changes that would allow saccharin to be used as a food additive.

Sources and Production

Saccharin is used in more than 100 countries around the world. Its use has been approved by numerous regulatory bodies including Health Canada, the Joint Expert Committee on Food Additives of the World Health Organization and the Food and Agriculture Organization of the United Nations, the European Union Scientific Committee on Food, and the USFDA. To put the assessment of health risk in perspective, it is important to understand the approval process for food additives in the United States. A manufacturer that wants to market a new food additive must assemble and present to the FDA all required safety data relevant to the proposed use of the additive in accordance with safety guidelines published by the FDA. The FDA considers probable intake, cumulative effect from all uses, and toxicological data required to establish safety. Data should include pharmacokinetics and metabolism to evaluate absorption, tissue distribution, metabolic pathways, and rate of elimination of the substance and any metabolites. Toxicity studies include short-term and subchronic toxicity tests with rodents, subchronic and long-term toxicity tests with nonrodents, reproductive and developmental toxicity tests, and tests of carcinogenicity.

The approval process is based on three safety concepts. The first concept is the highest no-effect level – that is, the highest level or threshold of intake at which no adverse effect occurs in the most sensitive of animal studies. The second safety concept is the acceptable daily intake (ADI). ADI is calculated from the highest no-effect level, given a 100-fold safety factor: tenfold because the studies were done in animal models and tenfold to account for genetic variation. ADI is set as the highest no-effect level divided by 100 and expressed as mg per kg body weight. The ADI represents an amount that is considered safe to consume every day over the course of a lifetime. The final safety concept is the estimated daily intake (EDI), which is derived from the amount of the additive to be added to foods assuming 100% replacement of sugars and other sweeteners and the typical consumption of those foods by people of different ages and health status. The EDI generally overestimates consumption because it assumes that the new additive will replace all sweeteners on the market (100% market penetration). The ADI is compared with the EDI to confirm that the ADI is well in excess of the EDI. If the EDI is determined to exceed the ADI, there may be limitations placed on the use of the additive. Once a food additive receives final approval, that approval is published in the Federal Register and the FDA may request additional data on consumption or other safety data during the post-market period.

In the United States, the FDA has approved saccharin, ammonium saccharin, calcium saccharin, and sodium saccharin as food additives on an interim basis pending additional studies (21CFR180.37, revised April 2014) and with some restrictions. The ADI is 5 mg kg^{-1} body weight and is based on the highest no-effect level in rat studies. It is approved for use in beverages not to exceed 12 mg per fluid ounce, in processed foods not to exceed 30 mg per stated serving size, and as a tabletop sweetener not to exceed 20 mg saccharin per teaspoon of sugar sweetening equivalency. Diet soft drinks often contain a blend of saccharin and aspartame and provide

8 mg saccharin in one 12 ounce serving. A 70 kg person would have to drink 15 12 ounce cans of diet soda or use 30 individual packets per day to reach the ADI.

Saccharin is produced for commercial use in Asia, Europe, and the United States, but China is the largest manufacturer and exporter of saccharin. In 2005, China produced 22 850 tons; 19 000 tons was exported. Two methods are used to produce saccharin. Most manufacturers use the Remsen–Fahlberg process in which toluene is treated with chlorosulfonic acid to produce ortho- and para-toluenesulfonyl chloride. The resulting product is treated with ammonia to separate the two isomers. Ortho-toluenesulfonamide is oxidized and heated to produce saccharin. The only producer of saccharin in the United States uses the Maumee process that begins with methyl anthranilate, a substance occurring naturally in grapes. Methyl anthranilate or anthranilic acid successively reacts with sodium nitrate, sulfur dioxide, and chlorine to produce 2-chlorosulfonylbenzoic acid methyl ester. In the presence of ammonia, this is converted to its amide that is de-esterified to yield saccharin. Saccharin alone does not dissolve well in water, so it is often converted to its sodium or calcium salt.

Patterns of Consumption

Saccharin and other NNS are used in human consumption to provide sweetening without sugar. Sugar has several important functions in food preparation including binding water to inhibit microbial growth, adding texture or volume, supporting the growth of yeast for leavening, and enhancing crystallization. Saccharin cannot replace sugar for any of those functions; it can only replace the sweetening power of sugar. In fact, because it is so much sweeter than sugar, it is used in very small quantities, and when packaged as a tabletop sweetener, it is usually mixed with a bulking agent to approximate the same volume that sugar would provide for the comparable sweetness.

Perception of sweet taste begins on the tongue and soft palate where taste receptors interact with food or beverages. Taste receptor cells are organized into taste buds that are distributed along the tongue. The sweet taste receptor is a heterodimeric G protein-coupled receptor composed of subunits T1R2 and T1R3, which have multiple active sites. These receptors respond to sugars (sucrose, fructose, galactose, glucose, lactose, and maltose), amino acids (glycine and D-tryptophan), sweet proteins (monellin and thaumatin), and NNS (acesulfame potassium, aspartame, cyclamate, dulcin, neotame, saccharin, and sucralose). Saccharin may also bind with bitter taste receptors on the same taste buds. After binding to taste receptors, a cascade of chemical changes translates the stimulus through the nervous system to the perception of sweet taste in the brain. The transduction of sweet taste from sugars uses cyclic AMP as a second messenger, and the pathway for nonsaccharide sweeteners such as NNS uses inositol 1,4,5-trisphosphate (IP3). Both mechanisms work through calcium ion channels and exist in the same taste receptor cells. Synergy exists among sweeteners because different sweeteners bind different subunits of the taste receptor. Binding a single subunit activates the sweet response, whereas a second sweetener binding a different subunit enhances the response. Saccharin is often used in combination with other sweeteners to enhance the sweet response making it possible to achieve a more palatable product with the use of less sweeter volume.

Saccharin sweetens with little bulk, is stable during storage, and maintains its sweetness on heating. Saccharin and its salts are used in a variety of foods, beverages, pharmaceuticals, and cosmetics, and saccharin is available as a tabletop sweetener in powder, tablet, or liquid form. It is used in fruit juices, soft drinks, and beverage bases or mixes. In foods, it is used in processed fruits, gelatin desserts, confections, jams, toppings, sauces, and dressings. It is used in chewing gum, toothpaste, and mouthwash. Manufacturers who used NNS in their products are required to include them in the list of ingredients, but they are not required to list the amount with the exception of saccharin. Saccharin is restricted so the amount must be listed on the label. Some diet soft drinks contain saccharin, often in combination with acesulfame potassium or aspartame.

Estimating the usual intake of an individual is difficult because of inherent weaknesses in dietary intake methodology. People who answer questionnaires or surveys about their usual food intake tend to overestimate intake of foods perceived as high value and under report intake of low-value foods. People who record their intake in real time often change their usual intake during the reporting period (which is one reason that recording food intake is often used as a weight management tool). When reading studies that describe usual intake, it is important to consider the limitations of the data collection methods. A 2006 review of intake studies from around the world indicated that the average intake of saccharin was well below the ADI in almost all groups. The only exception in this review was a study of children with diabetes in Sweden that showed a very small number of the highest consumers took in about 125% of ADI. The data were collected using a food frequency questionnaire and assuming the maximum permitted saccharin concentration for each product category – considered by the authors to be a worst-case scenario. A survey in a region of India, also published in 2006, showed heavy use of saccharin in products that were popular with children including ice candy and crushed ice. Overall, children aged 6–10 years who had the highest consumption of ice candy and crushed ice exceeded the ADI for saccharin by 50% and adults with the highest intake of other food products containing saccharin exceeded ADI by 37%. Reports of saccharin intake that exceeds the ADI are very rare and limited to the highest consumers of saccharin-containing products.

In the United States, it is estimated that more than 6000 products contain NNS, with sucralose, acesulfame potassium, and aspartame being the most frequently used. The most common source of NNS in the United States is carbonated beverages, and NNS intake is typically estimated based on reported intake of beverages and foods that contain NNS. However, exact formulations are proprietary and subject to change based on market forces, making it difficult to estimate exposure of any specific NNS. Data from US nutrient monitoring systems were used to locate items that contained NNS on food composition tables to estimate *per capita* use of NNS. In 2004, about 15% of people in the United States used any NNS.

By 2010, that increased to 20%, most as sugar-free beverages. Low-calorie beverages accounted for about 19% of beverage intake by children aged 2–18 years and about 32% of beverage intake among adults aged 19 years and older.

Availability, Absorption, and Metabolism

Saccharin is almost completely absorbed from the gastrointestinal (GI) tract and not metabolized; it is rapidly excreted, unchanged, by the kidneys. When radiolabeled sodium saccharin was given to rats and monkeys at a dose of 40 mg kg^{-1} orally, ~99% was recovered in urine after 96 h of collection, most within the first 24 h, and < 1% was recovered in bile. Daily oral doses of up to 500 mg sodium saccharin given to monkeys over 2 years had no effect on metabolism of a single dose of radiolabeled saccharin. There was no evidence of metabolites, leading to the conclusion that saccharin is not metabolized in rats or monkeys. Experiments in human volunteers given saccharin intravenously or orally confirmed that it was not metabolized and was rapidly excreted in urine.

Health Effects

The safety of saccharin has been studied extensively, in part because of its controversial history. It is used around the world as a low-cost, readily available sugar substitute. There is wide agreement among experts that it does not increase the risk for cancer. Nevertheless, questions of safety persist – related not to the risk of cancer, but to the risk for obesity and diabetes. How could a substance that is not metabolized contribute to obesity and diabetes? Hypotheses include binding sweet taste receptors on the GI tract, discrepancies in learned relationships between sweet taste and energy delivery, and alterations in gut microbiota.

Duodenal cells express the G protein-coupled receptor, gustducin, T1R2, T1R3, and other taste transduction elements. Sugars and sweeteners in the GI tract bind to taste receptors and induce secretion of glucagon-like peptide-1 (GLP-1) and glucose-dependent, insulinotropic peptide (GIP), which regulate the expression of sodium–glucose cotransporter 1 (SGLT1). SGLT1 actively transports glucose and sodium into the enterocytes. GLP-1 and GIP are rapidly destroyed by hydrolysis, but some may be absorbed into the bloodstream to act as systemic hormones. GLP-1 stimulates insulin release, inhibits glucagon secretion, reduces gastric emptying, and augments feelings of satiety. Animal studies have shown that NNS stimulate the release of GLP-1 and GIP, although the magnitude of the increase varies among the different NNS. Some have hypothesized that this increase in glucose uptake and concomitant release of GLP-1 stimulate insulin release that lowers blood glucose, increasing appetite, leading to increased weight gain. However, studies in human subjects have not consistently shown that NNS increase GLP-1 or serum concentrations of glucose or insulin.

Another hypothesis states that consuming sweet-tasting foods that do not deliver the expected caloric load interferes with learned responses that normally contribute to glucose and energy homeostasis and lead to increased rates of weight gain. To test the hypothesis, male rats were supplemented with yogurt containing saccharin or glucose. Those in which the sweet supplement was not associated with increased calories (saccharin) consumed more total calories and gained more weight and adipose tissue. The changes were attributed to reductions in energy expenditure and a decreased ability to compensate for energy intake from other sweetened foods in the diet. The researchers concluded that saccharin stimulated food intake by reducing the ability of rats to regulate energy balance in the presence of caloric-sweetened foods. Other researchers have reported increased weight gain, but no increase in energy intake in rats supplemented with saccharin compared to rats supplemented with sucrose.

A newer hypothesis states that saccharin induces glucose intolerance by altering gut microbiota based on studies in wild-type and germ-free mice from one laboratory. The researchers fed mice with a high-fat diet supplemented with saccharin equal to 5 mg kg^{-1} body weight. After 5 weeks, the saccharin-supplemented mice had higher serum glucose concentrations at 90 and 120 min and higher area under the curve (AUC) after an oral glucose tolerance test compared to control mice. Fecal microbiota differed in saccharin-fed mice compared to control. After treatment with antibiotics to destroy gut bacteria, the differences in glucose tolerance disappeared. Seven healthy human volunteers were fed with saccharin equal to 5 mg kg^{-1} body weight in three divided doses daily for 5 days. Four of the seven had poorer glycemic response (defined as higher AUC on glucose tolerance test) after the saccharin supplement compared to before, while the other three volunteers showed no change. Fecal microbiota differed in those that responded to saccharin compared to the nonresponders at the beginning of the study and changed over the course of the study. No change was seen in the microbiota of nonresponders. The researchers concluded that NNS consumption in mice and humans enhances the risk of glucose intolerance, possibly due to increased glycan degradation pathways that have been linked to increased energy harvest.

Studies in Humans

Clearly, humans eat differently from other animals and humans who use NNS do so for different reasons including to limit carbohydrate intake, limit intake of added sugars, or manage weight. If the use of NNS has the opposite effect of making weight management more difficult, many people would stop using them. Understanding the relationship between NNS and factors related to weight management and other health effects is critical, but research is complicated. There are a number of different NNS in use, preferences for one NNS over another change over time, and many low-calorie products use one or more NNS. There is no indication that saccharin has different effects than other NNS, so this section includes information on health effects of NNS in general and on saccharin specifically when information is available.

The use of NNS should lead to an energy deficit by replacing sugar in foods or beverages, but animal studies seemed to indicate that animals compensated for the energy deficit by increasing intake of other sweetened foods. One question is whether NNS affect appetite, hunger, and satiety differently than sugars do in humans. Studies to answer that question

typically involve providing preloads with different energy contents and measuring energy intake in the following meal or meals. If NNS affects satiety differently than sugar does, subjects should report greater feelings of hunger or appetite and should compensate for the lower-energy preload by eating more at subsequent meals. Studies that used food as the vehicle for NNS showed compensation for about one-third of the energy deficit over the next 24 h. When the vehicle was a beverage, only about 15% of the deficit was made up over the next 24 h, meaning that NNS were effective in reducing energy intake when substituted for sugar. Studies that specified saccharin as the NNS showed no increased food intake or appetite in human subjects. An analysis of evidence by the Academy of Nutrition and Dietetics concluded that saccharin did not increase food intake or appetite and substituting saccharin for sugar-sweetened products in a form that is lower in energy can result in modest energy savings.

Randomized controlled trials (RCT) are considered the gold standard of experimental design because they compare an intervention with a control and minimize bias by randomly assigning subjects to treatment arm and blinding researchers and subjects to assignment. A recent meta-analysis of 15 RCT that examined the effect of NNS on body weight and composition in a total of 1951 subjects noted a small decrease in body weight (−0.8 kg, 95% CI −1.17, −0.43) among all ages with significant decreases in body mass index, waist circumference, and fat mass. Most RCT replaced sugar-sweetened beverages (SSB) with beverages sweetened with NNS as the intervention. RCT have not shown any significant differences between the effects of NNS and control on glycemic response in people with or without diabetes.

Although considered the gold standard for medical research, RCT have limitations in public health research. They cover a limited time frame and use a research team to provide support to subjects. Consequently, the results may not be generalizable to other groups and they are too short to determine changes in long-term outcomes such as development of chronic disease. Population studies and long-term outcomes require prospective cohort studies. These are studies that follow a group of individuals with many similarities and few differences over longer periods of time to measure differences in the outcomes of interest and to determine if those differences in outcomes are related to ways in which the individuals differ. Prospective cohort studies that examined differences in the use of NNS and body weight, weight change, and obesity-related diseases have had mixed results. In some studies, higher use of NNS has been associated with a higher risk for obesity and diabetes. However, studies that controlled for other differences that would affect risk have not found an association between NNS consumption and obesity or obesity-related diseases, leading many to conclude that the measured association was due to reverse causality – as people begin to gain weight, they may use NNS in an attempt to manage their weight. A meta-analysis of nine prospective cohort studies showed a small increase in BMI (0.03 kg, 95% CI 0.01, 0.06) but no significant increase in body weight or fat mass. Well-controlled prospective cohort studies that examined relationships among NNS and risk factors for diabetes and cardiovascular disease have not shown an increased risk of adverse effects from NNS consumption, and a long-term study of previously obese people who have maintained significant weight loss shows that the majority consume NNS-sweetened beverages.

There is consensus among experts that added sugar in the diet and consumption of SSB are associated with increased weight gain and greater risks for obesity, diabetes, and metabolic syndrome. Although NNS can replace the sweetness of sugar without energy and can provide a calorie-free beverage to replace SSB, there is no consensus as to their overall health effects. Despite a lack of consensus, many health experts support their use as a replacement for sugar in the diet. In a combined scientific statement, the American Heart Association and the American Diabetes Association state that NNS could facilitate reductions in added sugar intake, thereby resulting in decreased total energy and weight loss/weight control and promoting beneficial effects on related metabolic parameters.

Conclusion

Saccharin has been used to replace the sweet taste of sugar for many years in many countries. Overall, the evidence supports its safety when consumed within guidelines.

Salad Crops: Dietary Importance

MK Rana, CCS Haryana Agricultural University, Hisar, India

© 2016 Elsevier Ltd. All rights reserved.

Introduction

A large number of vegetables that are consumed raw (without cooking) are considered to be salad crops. They are attractive and seasonal and are valued for their succulence, bulk, and nutritional importance in the human diet. Eaten regularly, these foods help keep the body healthy because they contain fiber along with minerals, vitamins, and phytochemicals – regular consumption of which helps reduce the risk of cardiovascular disease, diabetes, and some cancers.

Types of Plant in Salad Category

Because a vast number of salad vegetables are being cultivated and consumed globally, these vegetables need to be categorized in such a way that information about them can be readily gathered. By virtue of their raw consumption, one option is to classify salad vegetables according to the part consumed (Tables 1–3).

Nutritional and Dietary Significance

Salad vegetables are considered to be protective because they are rich in minerals, vitamins, fiber, and natural phytochemicals, which have a key role in maintaining good health. Salad crops are inexpensive and easy to grow, and they have relatively a long period of harvest and storage. Because of their high fiber content, these vegetables promote digestion and help prevent constipation. Most leafy vegetables, such as celery, cabbage, Chinese cabbage, lettuce, parsley, rhubarb, and spinach, are characterized by having a high water and cellulose content (a result of their succulence and bulk).

In salad vegetables, carbohydrates consist of starches and sugars that are easily available to the body. Vegetables also provide small quantities of unsaturated lipids that contain essential fatty acids, such as linoleic (omega 6), linolenic (omega 3), and arachidonic acids, which are required for normal growth and maintenance of the body. Salad crops provide sundry proteins, which are analogous to animal protein in terms of their amino acid make-up. Most proteins consist of enzymes, thus, plant leaves are the actively metabolizing organs. This protein content is more absolute (containing nine essential amino acids) than proteins derived from seeds; thus, consumption of leafy salads could make a major contribution toward the optimum health of an individual.

Salad crops ranking highest in vitamin A content are: carrot, turnip greens, spinach, mustard, and dandelion (Tables 4–6). Artichokes rank seventh, based on mineral and vitamin content. Spinach, kale, and collard contain more minerals and vitamins (especially vitamin A, calcium, phosphorus, and iron) than many other salad crops. A single serving of these vegetables meets the adult daily requirement for vitamins A and C, as well as 13% of the total calcium requirement (Table 1).

Beetroot (*Beta vulgaris* var. crassa) is rich in carbohydrates, protein, calcium, phosphorus, iron, and vitamins A and C. The tops of beetroot and Swiss chard are excellent sources of vitamins A and B_2, and are a good source of vitamin B_1. Beet leaves are particularly valued for calcium, iron, B group vitamins (especially riboflavin), ascorbic acid, and vitamin K content – because they are all excellent source of vitamin K_1 (5–16 $\mu g\, g^{-1}$). They also supply iron, manganese, zinc, and copper as well as appreciable quantities of protein, which is rich in essential amino acids (especially in lysine).

Broccoli (*Brassica oleracea* var. italic) is the most nutritious of the mustard family (Cole crops) because it contains relatively more minerals (especially calcium and iron), and vitamins. Its secondary inflorescence is characterized by higher dry matter, vitamin C, chlorophyll, β-carotene, carotenoids, and by low levels of nitrates. In comparison to other Cole crops, Brussels sprouts (*Brassica oleracea* var. gemmifera) have more protein and carbohydrates. Except for vitamin A and calcium, Brussels sprouts are comparable with broccoli; however, for most of the parameters measured, the leaves are better than the sprouts. Cabbage (*Brassica oleracea* var. capitata) is rich in carbohydrates, protein, minerals (such as calcium, phosphorus, potassium, sulfur, and iron), vitamins A and C, thiamine, riboflavin, and – above all – fiber. The young green heads are higher in vitamin A than older white cabbage. Like other Cole crops, cabbage contains glucosinolates (i.e.,sinigrin, progoitrin, and glucobrassicin). The peculiar flavor of cabbage is due to sinigrin, which contains sulfur. Chinese cabbage (*Brassica pekinensis* and *Brassica chinensis*) is rich in thiamine, riboflavin, and carotene. It contains more vitamin C than lettuce. Among the organic acids, citric acid is highest in Chinese cabbage. Kohlrabi (*Brassica oleracea* var. gongylodes) contains more sugars than broccoli. Besides carbohydrates, kohlrabi is rich in vitamins A, B_3, B_5, B_6, B_9, and C, as well as calcium, phosphorus, magnesium, potassium, sodium, iron, and chlorine. It is also superior to turnip and rutabaga, but is similar to red cabbage.

Carrot (*Daucus carota*) roots contribute a significant proportion of the daily requirement for vitamin A. In addition to vitamins and minerals, carrot roots are an important source of dietary fiber. They are rich in sucrose, having ten times more sucrose than glucose and fructose. The highest score for sweet taste is obtained in carrots grown at low temperatures; bitterness (terpenes) and sugar increases with the temperature. Terpenes suppress the perception of sweetness, but terpinolene decreases with increasing temperature, and probably has only a minor role in masking the sweet taste.

The leaves of celery (*Apium graveolens* var. duke) are a rich source of flavonoids, such as zeaxanthin, lutein, and beta-carotene, and are a good source of vitamin A. The herb is also

Table 1 Botanical names, common names, and edible plant parts of vegetables/salad crops

Common name	*Botanical name*	*Family*	*Edible plant part*
Horsetail family			
Water fern	*Ceratopteris thalietroides* (L.) Brongn	Parkeriaceae	Young leaf
Vegetable fern	*Diplazium esculentum* (Retz.) Swartz	Polypodiaceae	Young leaf
Onion family			
Chive	*Allium schoenoprasum* L.	Alliaceae	Leaf
Chinese chive	*Allium tuberosum* Rottler ex. Sprengel	Alliaceae	Leaf and immature flower
Lily family			
Asparagus	*Asparagus officinalis* L.	Liliaceae	Shoot
Carpetweed family			
New Zealand spinach	*Tetragonia tetragoniodes* (Pall.) O Kuntze	Aizoaceae	Tender shoot and leaf
Carrot family			
Chervil	*Anthriscus cerefolium* (L.) Hoffm	Apiaceae	Leaf
Celery	*Apium graveolens* L. var. dulce (Mill.) Pers		Petiole leaf
Celeriac	*Apium graveolens* L. var. rapaceum (Mill.) Gaud.		Root, leaf
Fennel	*Foeniculum vulgare* var. azoricum (Miller) Thell.		Leaf
Florence fennel	*Foeniculum vulgare* var. dulce Fiori		Leaf base
Parsnip	*Pastinaca sativa* L.		Root, leaf
Parsley	*Petroselinum crispum* (Mill.) nym. var. crispum		Leaf
Turnip-rooted parsley	*Petroselinum crispum* (Mill.) nym. *Tuberosum*		Root, leaf
Italian parsley	*Petroselinum crispum* (Mill.) Nym. Var. neapolitanum		Leaf
Sunflower family			
Endive	*Cichorium endiva* L.	Asteraceae	Leaf
Chicory	*Cichorium intybus* L.		Leaf
Indian lettuce	*Lactuca indica* L.		Leaf
Asparagus lettuce	*Lactuca sativa* L. var. asparagina Bailey		Stem
Head lettuce	*Lactuca sativa* L. var. Capitata L.		Leaf
Romaine lettuce	*Lactuca sativa* L. var. longifolia Lam.		Leaf
Dandelion	*Taraxacum officinale* Wiggers		Leaf, root
Mustard family			
Curled mustard	*Brassica juncea* (L.) Czernj. and Coss. var. crispifolia	Brassicaceae	Leaf
Small leaf mustard	*Brassica juncea* (L.) Czernj. and Coss var. foliosa		Leaf
Gemmiferous mustard	*Brassica juncea* (L.) Czernj. and Coss. var. gemmifera Lee & Lin		Stem and axillary bud
Involutes mustard	*Brassica juncea* (L.) Czernj and Coss. var. insoluta Yang & Chen		Leaf
Wide petiole mustard	*Brassica juncea* (L.) Czernj. and Coss. var. Patipa Li.		Leaf
Rutabaga	*Brassica napus* L. var. napobrassica (L.) Reichb.		Root and leaf
Chinese kale	*Brassica deracea* L. var. alboglabra Bailey		Young flower stalk and leaf
White cabbage	*Brassica oleracea* L. var. capitata L.		Leaf
Portuguese cabbage	*Brassica oleracea* L. var. Costala DC		Leaf and inflorescence
Brussels sprouts	*Brassica oleracea* L. var. gemmifera Zenk.		Axillary bud
Konlrabi	*Brassica oleracea* L. var. gongylodes L.		Enlarged stem
Broccoli	*Brassica oleracea* L. var. italica plenck		Immature flower stalk
Spinach	*Brassica perviridis* Bailey		Leaf
Chinese cabbage	*Brassica rapa* L. var. Pekinensis (Lour.) Olsson		Leaf
Garden cress	*Lepidium sativum* L.		Leaf
Water cress	*Nasturtium officinale* R. Br.		Leaf
Buck wheat family			
Rhubarb	*Rheum rhabarbarum* L.	Polygonaceae	Petiole
Valerian family			
Italian corn salad	*Valerianella eriocarpa* Desv.	Valerianaceae	Leaf
European corn salad	*Valerianella locusta* (L.) Laterrade em. Betcke		Leaf

rich in many vital vitamins, including folate, riboflavin, niacin, and vitamin C. Fresh celery is an excellent source of vitamin K. The herb is a very good source of potassium, sodium, calcium, manganese, and magnesium. Its leaves and seeds contain many essential volatile oils, which include terpenes, limonene (75–80%), and the sesquiterpenes such as β-selinene (10%) and humulene.

Chicory (*Chihorium intybus*) is low in saturated fat and very low in cholesterol. It is also a good source of thiamine, niacin, and zinc, and a very good source of dietary fiber vitamins A, C,

Chicory	*Cichorium intybus*	Compositae
Cress	*Lepidium sativum* L.	Cruciferae
Dandelion	*Taraxicum officinale*	Compositae
Garlic	*Allium Sativum*	Alliaceae
Lettuce	*Latuca sativa*	Compositae
Mustard	*Brassica juncea*	Cruciferae
Onion	*Allium cepa group*	Alliaceae
Endive	*Cichorium endiva*	Compositae
Parsley	*Petroselinum crispum*[a] *var. neopolitanim*	Umbelliferae
Watercress	*Irorippa nasturtium var. aquaticum.*	Cruciferae
Flowers		
Cauliflower	*Brassica oleracea* var. botrytis	Cruciferae
Artichoke (globe)	*Cynara scolymus*	Compositae
Fruits		
Immature		
Cucumber	*Cucumis sativus* L.	Cucurbitaceae
Mature		
Tomato	*Lycopersicum esulentum*	Solanaceae

[a]Recently assigned to the genus, *Carum;* hence variety now recognized as *Carum petroselenum* var. *neopolitanum*.

"All the salad vegetables belong to the Angiospermae and Dicotyledonae except onion, which belongs to subclass Monocotyledonae".

E, B_2, B_3, B_5, and B_6, as well as calcium, iron, magnesium, phosphorus, potassium, copper, and manganese. One cup (29 g) of chicory greens contains 108% of the RDA of vitamin K and a third of the RDA for vitamin A. Other active compounds in chicory are inulin, sesquiterpene lactones, fat, mannitol, and latex. Constituents include fructan, sesquiterpene lactones, alpha-amyrin, taraxerone, baurenyl acetate, and β-sitosterol.

Chives (*Allium schoenoprasum*) are very low in energy (30 kcal/100 g leaves), but surprisingly high in vitamin A (4353 IU/100 g leaves), which is significantly more than any other Alliaceae plants. Its green leaves contain other flavonoid-phenolic antioxidants, such as carotenes, zeaxanthin, and lutein, as well as flavonoids and dietary fiber (2.5 g/100 g leaves). Like other alliums, they also possess thiosulfinites (diallyl disulfide, diallyl trisulfide, and allylpropyl disulfide), which are converted to allicin by an enzymatic reaction when the leaves are crushed. Fresh chives are a rich source of vitamin K (212.7 μg/100 g greens) and folate (105 μg/100 g leaves). Leafy greens contain essential minerals, such as calcium, iron, magnesium, phosphorus, potassium, zinc, copper, manganese, and choline, as well as vitamins, including thiamine, niacin, pantothenic acid, riboflavin, pyridoxine, and vitamin C.

Dandelion (*Taraxacum officinale*) greens are very low in energy (providing just 45 cal/100 g), saturated fat, and cholesterol. They are a good source of dietary fiber. Fresh dandelion provides vitamin A (10 161 IU/100 g), which is one of the highest sources among culinary herbs. Its leaves are rich in flavonoids such as β-carotene, α-carotene, lutein, cryptoxanthin, and zeaxanthin. The herb is a good source of potassium, calcium, manganese, iron, and magnesium. It is also rich in many vitamins, including folate, riboflavin, pyridoxine, niacin, vitamin E, and vitamin C. Dandelion is probably the richest herbal source of vitamin K.

Endive (*Cichorium endivia*), commonly known as escarole, is one of the richest sources of vitamin A, C, *etc*. and it is one of the very low calorie (17 kcal/100 g leaves) leafy vegetables. It contains B-group vitamins such as folate, pantothenic acid, pyridoxine, thiamine, and niacin, and is also a good source of manganese, copper, iron, potassium, calcium, chlorine, magnesium, phosphorus, zinc, copper, and sulfur. It is an excellent source of fiber and carotene. Endive provides several other important nutrients such as omega-3 and omega-6 fatty acids.

Fennel (*Foeniculum vulgare* var. dulce Alef) is very low in energy (31 kcal/100 g bulb). It contains a generous amount of fiber (3.1 g/100 g), very little fat, and no cholesterol. Its flavor is due to a high content of essential oils (anethole, estragole) and fenchone (fenchyl acetate). The bulb contains several vitamins, including pantothenic acid, pyridoxine, folate, niacin, riboflavin, and thiamine (in small amounts), as well as vitamin C (12 mg/100 g bulbs) and a small amount of vitamin A. The bulbs have good levels of potassium (414 mg/100 g) and a small amount of copper, iron, calcium, magnesium, manganese, zinc, and selenium.

Kale (*Brassica oleracea* var. acephala) contains oxalates, which are naturally occurring substances that interfere with the absorption of calcium. Thus, kale should not be consumed with calcium-rich foods. Like other mustard family plants, it also contains health-promoting phytochemicals (quercetin sulforaphane and indole-3-carbinol), which reduce the risk of some cancers and cardiovascular disease. It is a rich source of β-carotene, lutein, and zeaxanthin, and is rich in vitamin A and vitamin K. The leaves contain vitamin C (120 mg/100 g) and are a notable source of niacin, pyridoxine, thiamine, pantothenic acid, etc. as well as minerals such as copper, calcium, sodium, potassium, manganese, phosphorus, and iron.

Mustard greens (*Brassica juncea*) contain an array of nutrients, including carbohydrates, sugars, soluble and insoluble fibers, minerals (calcium, potassium, phosphorous, sodium, and magnesium), vitamins (vitamin A and C), fatty acids, and amino acids. However, the nutritional values differ from species to species.

Parsley (*Petroselinum crispum*) is an excellent source of vitamins K (1640 µg/100 g) and C, as well as a good source of vitamin A, folate, and iron. The herb is also a good source of potassium (100 g providing 554 mg (12%) of daily requirements), calcium, manganese, and magnesium. Parsley is also rich in vitamins (pantothenic acid, riboflavin, niacin, pyridoxine and thiamin, and vitamin E) as well as zeaxanthin, lutein, and cryptoxanthin. It contains no cholesterol or fat, but is rich in essential volatile oils (myristicin, limonene, eugenol, and alpha-thujene) and flavonoids (apiin, apigenin, crisoeriol, and luteolin).

Spring or Welsh onions (*Allium fistulosum*) are very low in energy (31 kcal/100 g leaves) and contain many noteworthy flavonoids, minerals, vitamins, and dietary fibers. Their leafy greens also contain ascorbic acid (vitamin C), pyridoxine, folate (64 µg/100 g fresh leaves), niacin, riboflavin, and thiamine. In fact, spring onions are one of the richest sources of vitamin K (207 µg/100 g greens). In addition, this salad crop is

a good source of copper, phosphorous, magnesium, potassium, chromium, iron, manganese, and calcium. They contain vitamin A (997 IU/100 g) and other flavonoids such as carotenes, zeaxanthin, and lutein. Being leafy-greens, spring onions contain more plant-derived antioxidants than other Allium members, like the onion, shallot, etc. Spring onions contain thiosulfinates antioxidants – albeit less than garlic – and are a source of flavonoids (such as quercetin), and contain allyl propyl disulphide.

Turnip (*Brassica rapa* var. rapa) greens are a good source of protein, thiamine, niacin, pantothenic acid and phosphorus, and are a very good source of dietary fiber, vitamins A, C, E, and K, riboflavin, pyridoxine, folate, calcium, iron, magnesium, potassium, copper, and manganese; but they are very high in sodium. One cup of cooked greens provides carbohydrates (4.4 g), protein (1.2 g), dietary fiber (3.5 g), vitamin C (27 mg), folate (118 μg), potassium (203 mg), about 20 kcal, and calcium (137 mg), which is about four times more calcium than cabbage and about twice that of mustard greens.

Watercress (*Nasturtium officinale*) contains many natural phytonutrients, including *isothiocyanates*. It is thought to be one of the most nutrient dense foods. The leaves and stem contain gluconasturtiin, a glucosinolate, as well as vitamin C (47 mg/100 g leaves). It is an excellent source of vitamin K (100 g/100 g), vitamin A, and flavonoids including beta-carotene, lutein, and zeaxanthin. It is also rich in riboflavin, niacin, pyridoxine, thiamine, and pantothenic acid. Further, it is also a rich source of minerals such as copper, calcium, potassium, magnesium, manganese, and phosphorus.

Industrial Use

Vegetables are less acidic than fruits. Hence, vegetables are classified as low acid foods. A wide range of microorganisms are able to grow on moist, low-acid products which may lead to spoilage and/or food poisoning. To prevent spoilage, vegetables can be processed with heat to destroy bacteria, or preserved using pickling, salting, fermenting, or drying to inhibit bacterial growth. Care is needed while processing low acid commodities to minimize the risk of pathogenic bacteria consumption.

The continuous supply of fresh and processed vegetables in markets globally indicates the economic importance of the vegetable industry, and the contribution of vegetables to dietary requirements. With the expected increase in population, vegetable crops will continue to comprise a major part of the agricultural economy. For example, dehydration of onion bulbs is an important industry in the United States – especially in California. Asparagus, tomatoes, lettuce, cucumber, and carrot are produced and processed worldwide. Sauerkraut is the primary processed product prepared from cabbage. Some cauliflowers, cabbages, rat-tail radishes, turnips, and carrots are canned. Large quantities of chives are sold to processors and, sometimes, their chopped leaves are mixed with cottage cheese for the retail market. A fermented Korean dish called kimchi includes either Chinese cabbage or radish along with hot pepper, garlic, and other ingredients. The juice of a tropical carrot is used to prepare kanji (a fermented product) which is an appetizer consumed before meals in India.

Because of the different growing and harvesting seasons of vegetables globally, the availability of fresh vegetables differs greatly in different parts of the world. Processing can transform vegetables from perishable produces into durable foods with longer shelf lives, thereby aiding in the global distribution of many vegetables. The goal of processing is to deter microbial spoilage and natural deterioration of the plant cells. Techniques include blanching, dehydrating, canning, freezing, fermenting and pickling, and irradiation.

After proper washing, vegetables are blanched in hot water at 88 °C for 2–5 min, or with steam at 100 °C for 30 s to 1 min. Blanching inactivates the enzymes responsible for discoloration.

It also reduces the number of organisms and renders the vegetables flaccid for easier packing. For some vegetables, blanching also serves as a way to remove/reduce strong flavor(s). After blanching, vegetables are cooled rapidly in cold water to retain quality. The vegetables are then ready for:

- *Dehydration*: Drying is the oldest method of preserving vegetables. Water is removed by applying heat from the radiant energy of the sun or electric heaters. Some vegetables are blanched before they are dried and some are dried directly in sunlight. Removing water reduces the volume, making storage and transportation convenient, as well as reducing the risk of microbial growth. New drying techniques, including tunnel, vacuum-, drum-, spray-, and freeze-drying, are very sophisticated. Although freeze-drying produces outstanding quality, it is costly and not widely used.
- *Canning*: Keeping vegetables in metal cans or glass jars is a key processing method, which is useful particularly in developing countries where refrigeration is restricted. Vegetables are cut into pieces, packed in cans, and subjected to heat treatment to make them sterile. Processing targets the inactivation of heat-resistant spore-forming mesophilic bacteria. The temperature and time used for canning varies with the size and other characteristics of the vegetables as well as heat transferring principles. After heat treatment, the containers are hermetically sealed while hot to create a vacuum when they are cooled to room temperature. Canned vegetables can be stored at ambient room temperature for years; however, the slightest defect in the process will result in swelling of the cans during storage. In most cases, this is caused by the formation of gas from chemical reactions between the metal cans and their contents. Alternatively, insufficient heat may not destroy bacterial spores. Canned vegetables may be inferior in quality (less nutritious) to fresh and frozen products because of the conditions during processing.
- *Freezing*: Frozen vegetables have outstanding quality. Indeed, some frozen vegetables may be superior in flavor and nutritional content than fresh produce. Vegetables can be stored longer when frozen because temperatures below 0 °C remove not only limit bacterial growth but also reduce the water available. Most vegetables are blanched at 90–100 °C for 1–5 min before freezing to inactivate the enzymes and reduce bacterial load. Various freezing techniques (blast, plate, belt-tunnel, fluidized-bed, cryogenic, and dehydration) are used for the preservation of vegetables. Advances in packaging materials and techniques have led to bulk frozen products being stored in large retortable pouches.
- *Fermented and pickled vegetables*: Low pH has been used to preserve vegetables for centuries. In both fermented and pickled vegetables, acid is used to preserve the products. Varieties used for fermentation or pickling may not be the same as fresh market vegetables. Due to the acidic environment, fermented and pickled vegetables need less heat treatment before being placed in containers. Cabbage, cucumbers, cauliflower, carrots, beans, sweet peppers, onions, and radishes, are salted (dry, e.g., cauliflower) or soaked in brine (wet, e.g., cucumber) prior to preservation. The temperature of fermentation is generally 20–25 °C.
- *Irradiation*: Ionizing radiation, mostly gamma rays, has been used in several countries to preserve vegetables. The practice is common for preventing deterioration in potato, onion, garlic, ginger, and arum during long-term storage. Vegetables treated with a low dose of ionizing radiation are safe, but consumers are still concerned about this processing technology and, generally, it is not accepted.

Use in the Home as Raw or Industrially Processed Food

Freshness is the key to crisp and tasty salads. Salad crops are largely consumed raw. They are attractive and have value in their appetizing succulence, bulk, and nutrient content. Celery, lettuce, onions, and tomatoes are the most important salad crops available throughout the year; but carrots, cauliflower, cucumbers, radishes, and turnips are also used for preparing pickles.

Artichokes are the edible, immature flowers of a cultivated thistle, but they may also be consumed after boiling or steaming. Some people appreciate eating it raw, when it is young enough. Artichoke hearts are canned, frozen, marinated, or kept in oil. Pulp, paste, and purees are also available. The carbohydrate inulin, in Jerusalem artichoke tubers, yields fructose after hydrolysis and has been examined as a dietary treatment for diabetes mellitus.

Cabbage (*Brassica oleracea* var. capitata) is used in the frozen food industry for preparing salad. Chinese cabbage is used raw in salads, cooked as greens, or fermented (e.g., kimchi). Sauerkraut is the product of the lacto-fermentation of cabbage. Many traditionally fermented food items (kraut, ketchup, pickles, etc.) do not undergo lactic-acid-producing fermentation, but are instead preserved with vinegar, enhanced with sugar, and pasteurized. The health benefits of lacto-fermentation have, therefore, been lost in the industrialized use of vinegars and pasteurization. An increasing number of retailers now carry lacto-fermented products, but these need to be refrigerated during storage.

Celery, chervil, leeks, and tomato are used in soups and stews. Celery is a staple in professional kitchens around the world, adding a crunch when raw and a distinct, yet mellow flavor when cooked. Celery and radishes are used to make banh mi bun (a sandwich and a popular snack food in traditional Vietnamese cuisine). Rhubarb and tomato are also used for preparing sauces. Fringed-leafed endive, parsley, chervil, chicory, leeks, and fennel leaves are used for flavoring and garnishing. Cucumber, cabbage, lettuce, radish, and turnip are fermented to dill and sour pickles, salt stock, sauerkraut, sauerriipen, lettuce kraut, and pawtsay. These foodstuffs are more palatable than their raw forms. Chervil is an herb that is processed lightly to retain its fresh green appearance, as well as its distinctive aroma. It is used with other food items such as dairy products, herb mixtures, instant meals, and marinades. Purées and passatas have become major tomato products as ketchup, juice, puree, paste, sauce, and pickles.

Chicory roots are dried, roasted, and ground for use as a coffee substitute or blended in with coffee. Rhubarb is prized

for its use in pies, tarts, sauces, wines, and even tanning hides. A relative of the globe artichoke, a leafy plant known as cardoon is used for its edible roots (or more often its petioles), which may be cooked or eaten raw in salads. Appealing to the eye and nose, parsley may be used both on and in most foods, except sweets. It can be utilized as both a seasoning and a garnish in soups, salads, fish, meats, and vegetables.

Toxic Substances

Vegetables are the most abundant foodstuffs on earth, and are rich in minerals and vitamins. Raw vegetables are enzyme-rich and widely believed to aid digestion. However, the digestive system of many people is too weak to digest raw vegetables. For many, excess gas, bloating, and abdominal pain are common reactions after eating raw vegetables. This is most likely because of cellulose, a fiber that is poorly digested by humans. Though fiber has little nutritional value, it is important for our intestinal health, in particular for forming a healthy stool. But, unlike cows and other ruminants, humans do not have the enzymes necessary to properly digest the fiber in vegetables. Cellulase, produced by some intestinal bacteria, digests cellulose into sugars that can be absorbed. Fermenting raw vegetable is also a problem, because this breaks down (or predigests) the fiber. When consumed in excess, even beneficial substances can produce harmful effects, whilst some toxic compounds can be tolerated at low concentrations.

In adapting to their environment, plant foods have developed various repellent structures (e.g., spines), odors, bitter flavors, and toxins. Characteristics like flavor and nitrate content may also need to be assessed. Several reports have indicated that ingested nitrates may be converted to carcinogenic nitrosamines. Asparagus contains saponins and cholinesterase inhibitors. The rhubarb and sorrel leaves have a high oxalic acid content, and should not be consumed. White oca tubers also contain oxalic acid, which combines with metals (i.e., calcium) in the body to form oxalate crystals. These crystals can irritate the gut and kidneys. Many greens contain oxalic acid, which binds iron and calcium from within the body or from other food sources. Cooking can destroy the oxalic acid. Vegetables that contain oxalic acid include spinach, chard, parsley, chives, purslane, rhubarb, and beet greens. Raw potatoes contain hemagglutinins, which disrupts red blood cell function. Some raw mushrooms (e.g., edible white mushrooms) contain toxic substances such as agaritine – a suspected carcinogen. These substances are heat sensitive and neutralized by cooking.

On the other hand, while eating cruciferous vegetables is important, these vegetables contain natural goitrogens that can block the production of thyroid hormones. These chemicals are released when the raw vegetable is chewed or the intestines break down vegetables that are only lightly steamed. Thus, some vegetables should only be consumed in large quantities after cooking. Perhaps more importantly, cruciferous vegetables are a rich source of iodine, which is essential for thyroid function. By steaming, goitrogens can be reduced by 30–90%, while the iodine is largely retained.

Glucosinolates present in mustards can cause digestive disorders. Parsley and celery contain psoralens and terpenoids which have been linked with dermatitis. Lettuce is known to be a nitrate accumulator, and spinach contains oxalic acid, saponins, and tends to accumulate high levels of nitrates. These nitrates can interfere with blood oxygen transport, or can form nitrosamines, which are carcinogenic. Significant toxins are listed below:

Name of crop	*Toxins*	*Name of crop*	*Toxins*
Artichoke	Grosshemin	Garden beet	Malonic acid
Asparagus	L-Arginine	Lettuce	Lactucin and lactucopicrin
Brown mustard	Progoitrin	Mustard	Gluconasturtiin
Cabbage	Glucocapparin (progoitrin)	Parsley	Malonic acid
Cabbage leaves	Spirobrassinin	Parsnip	Xanthotoxol
Celery	Xanthotoxin	Rhubarb	Oxalic acid
Chicory	Cichoralexin	Spinach	Coumestrol, histamine, and oxalic acid
Fennel	Anethole

Salad Crops: Leaf-Type Crops

MK Rana, CCS Haryana Agricultural University, Hisar, India

© 2016 Elsevier Ltd. All rights reserved.

Leafy salad vegetables, also known as potherbs, greens, vegetable greens, leafy greens, or salad greens, are among the most important and universally used vegetable crops grown globally and available throughout the year. They are valued for their appetizing succulence, bulk, and nutrients. These vegetables, as a natural group, have mostly crisp, tasty, and tender edible leaves and have become a staple food. As a result, the acreage under leafy salad crops has expanded to a remarkable degree over the past few decades, making these crops an important segment of agricultural and marketing industries.

Leafy salad vegetables are plants the leaves of which are eaten as vegetable. Nearly a thousand species of plants with edible leaves are known. These vegetables most often come from short-lived herbaceous plants, such as lettuce, which contains many nutrients, especially vitamin K because phylloquinone is involved directly in photosynthesis, which can lead leafy salad vegetables to interact significantly with the anticoagulant warfarin. Leafy salad vegetables are low in energy and fat and high in protein, dietary fiber, iron, and calcium and very high in phytochemicals, such as vitamin C, carotenoids, lutein, folate, magnesium, and vitamin K.

Nearly all vegetables can be consumed raw, but only few are commonly referred to as salad crops, and, of these, only a few are considered as leafy salad based on the criterion that the leaves alone are consumed. Leafy salad crops have been defined as those crops from which the leaves are harvested for use as raw vegetable. However, most of these crops are considered high-risk vegetables since their leaves and petioles are susceptible to attack by pests, poor production and handling systems, and environmental extremes over which growers may have little or no control.

The major leafy salad crops are endive (*Cichorium endivia* L.); lettuce (*Lactuca sativa* L.) and a number of lesser vegetables used primarily for salads, flavoring, or garnishing foodstuffs; Brussels sprouts (*Brassica oleracea* var. *gemmifera*); cabbage (*Brassica oleracea* var. *capitata*); celery (*Apium graveolens*); celtuce (*Lactuca sativa* var. *asparagina*); chervil (*Anthriscus cerefolium*); chicory (*Cichorium intybus*); Chinese cabbage (*Brassica rapa* subsp. *pekinensis* and *B. rapa* subsp. *chinensis*); collard greens (*Brassica oleracea*); dill (*Anethum graveolens*); garden cress (*Lepidium sativum*); kale (*Brassica oleracea* var. *acephala*); mustard (*Brassica juncea*); parsley (*Petroselinum crispum*); sorrel (*Rumex acetosa*); summer purslane (*Portulaca oleracea*); Swiss chard (*Beta vulgaris* var. *cicla*); turnip greens (*Brassica rapa* var. *rapifera*); and watercress (*Nasturtium officinale*). These salad crops thrive best during cooler and moist seasons and do not tolerate hot weather.

Global Distribution, Commercial Importance, and Varieties

Brussels sprouts (*Brassica oleracea* var. *gemmifera*) are believed to have been cultivated in Italy during the Roman times and possibly as early as the 1200s in Belgium. They were cultivated first in Belgium (hence Brussels sprouts) as early as 1587 with their introduction into the United States in the 1800s. Brussels sprouts were grown in California during the early 1900s. With the development of frozen food industry in 1940s, Brussels sprout production in California increased to its highest levels over the next 20 years. This crop has been grown near Brussels (BE) for hundreds of years and is an important vegetable in most European countries, particularly the United Kingdom. Outside of Europe, the importance of the crop is reduced, although Australia and California grow the crop widely. Brussels sprouts are a very good source of many vitamins, especially vitamin C and folate. They, along with other cruciferous vegetables, have been shown to have protective effects against certain types of cancer, as they contain many different ingredients that are believed to help prevent diseases.

The word cabbage (*Brassica oleracea* var. *capitata* L.) is thought to derive from the French caboche, meaning head. One of the oldest recorded vegetables, cabbage was mentioned in early literature and was probably in use as early as 2000 or 2500 BC. The Romans introduced it to Europe where it was bred into the form recognized today. Explorers in the seventeenth and eighteenth centuries included cabbage in ships' stores because of the high vitamin C content, which helped stave off scurvy. By this time, a pickled form was popular in Europe and the French from the Alsace area gave it the name Choucroute (sauerkraut). Cato advised eating cabbage soaked in vinegar before embarking upon an evening of heavy drinking and the accepted remedy for a Roman hangover was simply more cabbage consumption. Caesar's armies carried cabbage with them and not only used it for food but also bound wounds with the leaves to reduce infection. Cabbage has antibacterial properties and reduces inflammation. Cabbage is easy to grow and stores well, and a single serving of cabbage contains nearly half of the daily vitamin C requirement as well as significant levels of manganese, iron, and vitamin B_6. It is high in dietary fiber and low in energy, which makes it an ideal food for those seeking to lose weight.

Beet greens (*Beta vulgaris* var. *crassa*) are the leafy tops of beetroot, which evolved from wild sea beet, a native of coastlines from India to the United Kingdom and the ancestor of all cultivated forms of beet. Sea beet was first domesticated in the eastern Mediterranean and Middle East, although only the leafy salad was eaten when the Romans began to cultivate it. Apicius, the renowned Roman gourmet, recommended it in salad with a dressing with mustard oil and vinegar in his book *The Art of Cooking*. In the early times, it was used to treat a range of ailments including fevers, constipation, wounds, and various skin problems. At that time, the roots were long and thin like a carrot. The rounded root shape that we are more familiar today was not developed until the sixteenth century and became widely popular in Central and eastern Europe 200 years later. Many classic beetroot dishes originated in this region, including the famous beetroot soup, known as borscht.

Chinese cabbage (*Brassica rapa* subsp. *pekinensis* and *B. rapa* subsp. *chinensis*, $2n = 20$) is a native to China and has been cultivated since the fifth century. It was introduced to the United States in the late nineteenth century and is grown throughout the year in California, Florida, and Hawaii. It is increasing in importance in European countries, notably the United Kingdom, France, and Germany. Two more or less distinct species are grown, namely, pe-tsai (*B. rapa* subsp. *pekinensis*) and pak choi (*B. rapa* subsp. *chinensis*). Varieties include Shantung cabbage, chefoo cabbage, pekin cabbage, chou de Chine, and celery cabbage. Of the two types of Chinese cabbage, *B. rapa* subsp. *pekinensis* (napa cabbage) and *B. rapa* subsp. *chinensis* (bok choi), the Pekinensis group is more common, especially outside Asia, such as napa cabbage (large white vegetable) and Baguio petsay or petsay wombok (Chinese white cabbage). Pekinensis cabbage has broad green leaves with white petioles, tightly wrapped in a cylindrical formation and usually forming a compact head. As the group name indicates, this is particularly popular in northern China, around Beijing (Peking). The Chinensis varieties do not form heads, but have smooth dark green leaf blades forming a cluster reminiscent of mustard or celery. Chinensis varieties are popular in southern China and Southeast Asia. Increasingly, they are grown in northern Europe because they are winter-hardy. Linnaeus originally classified this group as its own species under the name *Brassica chinensis*. However, Chinese cabbage used for salad is a term covering a variety of greens used in Chinese cuisine. In the West, this is commonly known as napa cabbage, which has a mild, almost sweet flavor that complements strong-flavored ingredients.

Celery (*Apium graveolens*) is an herb widely cultivated for its edible swollen leaf stalks. It is available in green and white forms. Celeriac (*Apium graveolens* var. *rapaceum*) is a variety of celery with an edible tuberous base to the stems. Celery was first cultivated as a medicinal crop as early as 400 BC in Egypt and the Roman Empire. The Greeks used it to make a celery wine called selinites. Crowns made of celery stems and leaves were awarded to winners of athletic games at the Isthmus of Corinth. Celery is believed to be originally from the Mediterranean Basin. Ancient literature documents that celery was cultivated for medicinal purposes in this region before 850 BC. The claimed medicinal values were probably attributable to its volatile oils, contained throughout but mostly in the seeds. During ancient times, Ayurvedic physicians used celery seed to treat cold, flu, indigestion, arthritis, and liver and spleen ailments. Woven garlands of wild celery have been found in early Egyptian tombs. The Romans valued celery more for cooking than for religious reasons, although much superstition was also connected with it: celery was thought to bring bad fortune under certain circumstances. Although celery is thought to be from the Mediterranean, indigenous wild relatives of celery are found in southern Sweden, the British Isles, Egypt, Algeria, India, China, New Zealand, California, and the southernmost portions of South America. The Italians domesticated celery as a vegetable in the seventeenth century. Early celery had a tendency to produce hollow stalks. Growers found that the naturally strong flavor could be diminished if grown in cooler conditions and blanched, not cooking in boiled water, but the practice of pushing earth up around the stalk base to prevent sunlight from turning the stalks green. There are two types of stalk celery varieties, namely, (i) self-blanching or yellow and (ii) green or Pascal celery. In North America, green stalk celery is preferred and mainly eaten raw although it is also eaten cooked. In Europe and the rest of the world, self-blanching varieties are preferred. Celeriac is very popular in Europe where it is eaten cooked or raw.

Chervil (*Anthriscus cerefolium*) has a long history, as do many herbs. It was once called myrrhis, because the volatile oils extracted from the plant resembles myrrh in both fragrance and taste. Chervil symbolizes new life and is linked to Easter ceremonies in Europe. During the Middle Ages, it was used to cure hiccups, a remedy that still survives today. For thousands of years, the young green leaves of chervil were used as a tonic. Chervil, dandelion, and watercress combined were used to combat vitamin and mineral deficiencies. Native to Europe, it was spread abroad by the Romans. Chervil is native to Europe and it was cultivated first in England in 1597 and in America by 1806. The origin of salad chervil is the region of southeastern Europe and western Asia.

Cress is also known as peppergrass or garden cress and is grown as a salad crop all over the world. It is native to Iran and Europe. From Persia, it spread to India, Egypt, and Greece. It was mentioned by Xenophobe in 400 BC and has been cultivated in England since 1548. It grows wild and is cultivated in the United States and elsewhere. There are four cultivars: (i) common, (ii) curled, (iii) broad-leaved, and (iv) golden.

Chicory (*C. intybus* L., $2n = 2x = 18$), also known as French endive, witloof, witloof chicory, and succory, is an important salad crop. The first mention of chicory culture was in 1616 in Germany. It is one of the oldest recorded plants and a native to northern Africa, western Asia, and Europe. Its cultivation is thought to have originated in Egypt. Medieval monks grew chicory in Europe and it was brought to North America in the 1700s. Chicory has been a popular coffee substitute or an ingredient in coffee in France since around the 1800s. It tends to be the preferred coffee substitute, and in some circles, it is used even when coffee is available and cheap. One historical and cultural example of its use as a coffee substitute was found in New Orleans, which was a major consumer of coffee prior to the Civil War. Today, chicory remains a popular coffee replacement or flavoring in New Orleans, and New Orleans coffee typically refers to chicory coffee. 'Radichetta' and 'Rosso di Verona' are the principal chicory cultivars in the United States and Italy, respectively. 'Penninck,' 'Christaens,' 'Mueninck,' and 'Van Espen' are Belgian cultivars, while 'Normato,' 'Malina,' 'Bubbal Blank,' and 'Slusia Meilof' are Dutch cultivars. Flambor, Bergere, and Zoom are chicory hybrids. In a study to assess the best cultivar for forcing, Tardivo and Mitado gave the highest yield and best quality produce. Best forced under a hydroponic system in terms of yield and quality were Tardivo, Mitado, F_1 hybrids Nunhems 825-76 and Nunhems 820-76, Zoom, Alvaro, and Barola. With very early forcing, Daliva was outstanding; Arnova, Zoom, Mitiva, and Wivro gave the next highest yield.

Collard (*Brassica oleracea* var. *acephala*) is a headless form of cabbage. It bears the same botanical name as kale, from which it differs only in leaf characters. Its leaves are much broader without frill and resemble the rosette leaves of head cabbage. Lower leaves are harvested progressively. While collard has a medium green color, smooth texture, and an oval shape, kale

has dark grayish green broad leaves with a crinkled texture. On flavor scale, collard is several times milder than kale, a strong bitter vegetable. Historians surmise that it was growing wild in Asia Minor, now Turkey, as well as in Greece along the Mediterranean long before recorded history. Collard, a type of kale, has remained almost the same for about 2000 years. The plant is a source of nutritionally important minerals and vitamins A and C.

Kale (*Brassica oleracea* var. *acephala*, $2n = 18$), also a nonheading type of cabbage, is a hardy plant and grown as food and fodder. It is closely related to wild cabbage, and most forms bear a rosette of leaves at top of the stem. There are various types of kale, but curly leaf kale is grown for human consumption. Its cultivation probably began seven millennia ago; the Greeks grew it as early as 600 BC. Eighty varieties from 17 countries were studied and classified into marrow-stem kale, leafy kale, thousand-headed kale, and curly kale. It is an excellent source of vitamins A, C, and K; a good source of calcium; and a source of some folate and potassium.

Endive (*C. endivia* L., $2n = 2x = 3x = 18, 36$) is an annual or biennial salad crop. It is believed to be a native of Egypt or India and indigenous to eastern Mediterranean areas and may have originated from the cross *C. intybus* × *C. pumitum*. The Egyptians used it during the early periods and it was brought to Europe in the thirteenth century. Its cultivation began in England in 1686 and in France in 1826 and was recorded first in the United States in 1806. Endive is an especially popular salad vegetable in Europe, and its popularity has increased in the United States. Endive is classified into two general groups, namely, (i) the curled- or fringe-leaved cultivars and (ii) the broad-leaved cultivars. The green curled 'Ruffec,' 'Deep Heart Fringed,' 'Green Curled Pancalier,' and 'White Curled' are curled- or fringe-leaved types. The varieties representing broad-leaved class are 'Broad-Leaved Batavian,' 'Full Heart,' 'Batavian or Escarole,' and 'Florida Deep Heart.'

Lettuce (*Lactuca sativa* L.) is a popular leafy salad crop, grown throughout temperate, tropical, and subtropical climates and is of great commercial importance. Its cultivated and wild species are native to Europe and Asia and have been in cultivation for the last 2500 years. Evidence suggests it was cultivated before 4500 BC. The Portuguese and British introduced lettuce to India in the sixteenth century. The crop spread throughout the Mediterranean region during the Greek and Roman eras and from there to the rest of Europe and the New World by 1494. Lettuce is available in different forms, namely, romaine, iceberg, oakleaf, and mâche. Romaine lettuce is high in vitamin A and provides some folate. Leaf lettuce has a softer texture than romaine, a crunchy variety used in Caesar salads. The darker the leaf, the more nutrients it contains, meaning red-leafed varieties are more nutritious than green. In the United States, four types of lettuce are grown, and each is recognized as a subspecies or botanical variety, namely, (i) head type, *L. sativa* var. *capitata*; (ii) curl leaf type, *L. sativa* var. *crispa*; (iii) cos or romaine, *L. sativa* var. *longifolia*; and (iv) asparagus type, *L. sativa* var. *asparagina*. Six morphological types of commercial cultivars are available, namely, crisphead, butterhead, cos, leaf, stem, and Latin. The crisphead type is the most common in the United States. About 70% of US crisphead lettuce is produced commercially in California, 16% in Arizona, and rest in other states. Butterhead and cos (Romaine) are popular in northern and southern Europe. The US crisphead cultivars are usually large, heavy, brittle-textured, and tightly folded and have a green outer and white or yellowish inner leaves. This type is becoming increasingly popular in the United Kingdom and Spain and, in the latter case, as a winter crop for export to the United Kingdom. Crisphead lettuce is often called iceberg lettuce, but this is somewhat misleading since there is also a crisphead cultivar called 'Iceberg.' Most of the important commercial varieties are the crisphead class; the best-known are New York 515; Imperial 44, 152, 456, 615, and 847; Great Lakes; and Pennlake. Big Boston, White Boston, May King, Salamander, and Wayahead are the best-known varieties of butterhead type but have relatively little commercial importance. Black-Seeded Simpson, Early-Curled Simpson, Grand Rapids, and Slow Bolt are the main varieties of leaf or bunching lettuce. Paris white (white cos) and Dark Green are the cos-type varieties. 'Great Lakes' (head type) and 'Chinese Yellow' (loose-leaf type) cultivars are commonly grown in India. 'Imperial 859' and 'Slow Bolt' are also improved cultivars of lettuce.

Mustard (*Brassica juncea*) is native to Central Asia and the Himalayas with secondary centers in India and eastern China. White mustard (*Sinapis alba*), black mustard (*Brassica nigra*), and Ethiopian mustard (*Brassica carinata*) are commercially important in many parts of the world and grown all over the world for a variety of uses. They are common in the United States, Canada, and the United Kingdom and most other European countries, India, China, and Southeast Asian countries. The inner leaves are milder and best suited for salad use. There are two principal salad or greens cultivars, namely, 'Florida' (broad leaf) and 'Southern' (giant curled leaf), which are grown in the United States. Mustard greens have scalloped edges and come in red and green varieties. They have a peppery taste and give off a mustardy smell during cooking.

Parsley (*Petroselinum crispum* (Mill.), $2n = 2x = 22$) is native to the central Mediterranean region (southern Italy, Algeria, and Tunisia). The name is derived from the Greek meaning rock celery and it is a relative of celery. Parsley was popular in early times among the Greeks and Romans. Its value was reputed to be in aiding digestion and suppressing odors of onion and wine. It has been in cultivation for over 2000 years. It was introduced to the United Kingdom from Sardinia in 1548 and to the United States in 1806. It is produced commercially in Texas, California, New Jersey, Florida, and New York. The ancient Greeks associated parsley with death, as it was supposed to have sprung from the blood of Archemorus, whose name means 'forerunner of death.' Homer tells of chariot horses being fed parsley by warriors prior to battle in the hope of making the animals more fleet of foot. Generally, the Romans did not eat parsley but they did wear its garlands on their heads during feasts to ward off intoxication. It was kept away from nursing mothers because it was thought to cause epilepsy in babies. Five types of parsley cultivars are available, namely, (i) plain-leaved, (ii) celery-leaved or Neapolitan, (iii) curled, (iv) fern-leaved, and (v) turnip-rooted type. The curled type is common in the United States where plain and turnip-rooted parsley is also grown. The best-known varieties are Moss, Extra Double Curled, Fern-Leaved, Curled Dwarf, Evergreen, Extra Triple Curled, and Plain and Dark Green Italian. Morgo was developed in Sweden, and

'Hamburg' is the only turnip-rooted cultivar. Curly-leaf parsley is often used as a garnish. In Central and eastern Europe and in western Asia, many dishes are served with fresh green chopped parsley sprinkled on top. Root parsley is very common in Central and eastern European cuisines, where it is used as a snack or a vegetable in many soups, stews, and casseroles.

Swiss chard (*Beta vulgaris* var. *cicla*), also called silver beet, is a green leafy biennial vegetable originally from Sicily. It established a place in kitchen gardens in England and America in the 1830s. Indeed, its first notice in American agriculture is Baltimorean Gideon Smith's letter of 30 October 1829 announcing receipt of seeds from Europe and his later reports about plantings, published in *The American Farmer*. Horticulturist Robert Buist was its primary antebellum promoter and it first found popularity in the Philadelphia area. As late as the 1850s, it remained a special plant. Broader cultivation came after the American Civil War. In the nineteenth century, chefs often separated the midrib from the leaves and prepared it like asparagus. Similar to beets with a flavor that is bitter, pungent, and slightly salty, it is truly one of the vegetable valedictorians with its exceptionally impressive list of health-promoting nutrients. Swiss chard along with kale, mustard greens, and collard greens is one of several leafy green vegetables often referred to as greens. It is a tall leafy green vegetable with a thick crunchy stalk that comes in white, red, or yellow with wide fanlike green leaves. Both the leaves and stalk of chard are edible, although the stems vary in texture with the white ones being the most tender. It is a good source of vitamins A and C. Swiss chard contains oxalates, which are slightly reduced by cooking but bind to calcium, a concern for people prone to kidney stones.

Watercress (*Nasturtium officinale*), which is unique among the vegetables, as it commonly grows in flowing water as a wild plant, is believed to be native to the eastern Mediterranean and Europe. In cool regions of the world, it grows wild in streams but it is also found growing wild above 1500 m in the Himalayas of Nepal and hilly areas of the United States, especially in Virginia, Maryland, and Pennsylvania. It is also grown in California and Europe. It was cultivated in England for the first time in 1808 and in France in 1811. According to Howard and Lyon, watercress formed one of the tributes to the high Kings of Erin (Ireland) during the Dark Ages. The first large-scale cultivation of watercress was suggested to have occurred in southern Germany, near Erfurt, in around 1750. Large-scale cultivation in England and France, to supply the markets of London and Paris, started in the early nineteenth century. It is a peppery nutritious vegetable, which is often used in sandwiches and salads. An elongating shoot induces vigorous basal branching to produce a sward crop. Repeated cutting leads to increased branching and as many as ten crops may be harvested in a year. Watercress enjoys worldwide distribution and, when grown commercially outdoors, it is planted in beds covered with slowly flowing, clean water. There are two main cultivars, namely, (i) 'Green Cress' (diploid and fertile) and (ii) 'Brown Cress' or 'Winter Cress' (triploid and sterile).

Morphology and Taxonomy of the Edible Parts

Dwarf varieties of Brussels sprouts have short stems, <50 cm long. 'Improved Long Island,' 'Catskill,' 'Early Morn Dwarf Improved,' and 'Friither Zwerg Kvik' are the most important varieties. In dwarf cultivars, sprouts are of medium size and the distance between sprouts is short. 'Bedfordshire'; 'Cambridge No. 1, 3, and 5'; 'Irish Elegance'; and 'Sherradian' are some of the important cultivars grown in the United Kingdom and Ireland. Early cultivars such as 'Breda' (the Netherlands), 'Weibulls Rapid' (Sweden), and 'Wilhelmsburg' (Germany) have light green sprouts. Late hardy cultivars include 'Red Vein,' 'Hild's Idea,' 'DeRoshy Amager,' and 'Polarstjernen.'

An improved Chihili (Michihili), the most common variety of Chinese cabbage, is uniform in size with heads around 46 cm long, 10 cm thick, and cylindrical in shape with a tapered tip. The outer foliage is dark green, inner leaves blanched, and the midrib white and broad. 'Won bok' with light green leaves is a very old Chinese cultivar. Pe-tsai resembles cos lettuce but produces a much larger, elongated, and compact head, and the leaves are slightly wrinkled, green, thin, and much veined. The midrib is broad and light in color. Pak choi resembles Swiss chard in its habit of growth. The leaves are long, dark green, and oblong or oval and do not form a solid head.

Endive grows as a loose head of leaves, which are strongly ruffled and serrated. The outer leaves are green and bitter, but the inner leaves are light green to whitish. In the case of Radichetta chicory, the leaves are dark green, narrow, and notched, and the Italian cultivar is red and nonforcing type. Endive is a plant with numerous radical leaves, which are smooth, lobed, and more or less deeply cut, spreading into a rosette, and the stem is hollow (50 cm to >1 m high), ribbed, and branching.

Kale produces edible inflorescence like cauliflower and broccoli. The most popular varieties of kale in the United States are Dwarf Blue Scotch and Dwarf Green Scotch.

The cultivated lettuce (*Lactuca sativa* L.) is related to wild lettuce (*Lactuca serriola*), a common weed in the United States. Heading lettuce was first described as cabbage lettuce in 1543. It forms a rosette of large, longish leaves, which are somewhat spoon-shaped and more or less toothed at the edges. From the center of rosette springs a nearly cylindrical stem, which narrows very rapidly and branches at about one-third of its height. It is furnished with clasping leaves, which encircle the stem and become narrower as they approach the top.

Mustard (*Brassica juncea*), a member of the cabbage family, is used both as a salad and as a green vegetable. In addition to being grown for its seeds, white mustard may be grown as a salad plant, cover crop, and green manure. Although principally an oilseed crop, it is commonly grown as a leafy vegetable in northern parts of India, China, and tropical and subtropical regions. 'Ford Hook Fancy,' 'Ostrich Plume,' and 'Southern Giant Curled' are the popular varieties of *Brassica juncea* grown in the United States. The basal rosette leaves vary in form, while the stem leaves are mostly intact. Leaves are large, broadening toward the apex, and have smooth or curled margins. 'Florida BroadLeaf' is a vigorous, large, and erect plant, with large, thick, broad, oval leaves with toothed margins. 'Southern Giant Curled' (curled leaf) is large and upright, with large leaves and curly margins.

Parsley forms a rosette of divided leaves on a short stem. The most common and attractive is the curled leaf-type containing three subtypes, namely, (i) doubled-curled, (ii)

evergreen, and (iii) triple-curled. The degree of leaf curling, coarseness of the leaf, and plant growth habit distinguishes these subtypes. The plain leaf parsley (Dark Green Italian) has deeply cut leaves but no curling or fringing. Double-curled lettuce has a stem 30.5 cm tall with compact and very dark green leaves, which are finely cut, deeply curled, and frost-resistant. Evergreen leaves are coarsely cut, while extra triple-curled leaves are finely cut and very closely curled. The triple-curled variety has closely curled shorter leaves. Plain leaf types include plain (singles) and have flat leaves. The leaves of the Dark Green Italian cultivar are heavy and glossy green.

Watercress (*Lepidium sativum* L.) has three sections, namely, (i) an aerial stem portion with an apex leaves but no roots that is projecting above the water, (ii) a stem portion beneath the flowing water that has foliage and a system of adventitious roots that arise from the leaf axils and remain free in water, and (iii) normal roots. Watercress leaves are pinnately compound with 3–11 leaflets, rounded or oblong, slightly fleshy, and with smooth margins. Cress is a much-branched annual with linear leaves. The moss curled (curled) variety is branching, dark green, and with a mild but distinct flavor.

Postharvest Handling and Storage

Baskets are used to pick and carry Brussels sprouts to the packinghouse. Individual boxes are wrapped with a transparent film, which is useful in preventing moisture loss. The optimum storage conditions for Brussels sprouts are 0 °C temperature and 95–98% relative humidity, which keep them in marketable condition for about 3–5 weeks. At −2 °C, sprouts can be stored for a longer period. A controlled atmosphere (CA) of 2.5–5.0% O_2 and 5–7.5% CO_2 is helpful in maintaining Brussels sprouts at 5 or 10 °C, but not at 0 °C. Oxygen levels $< 1\%$ can cause internal discoloration.

Cabbage heads are harvested with a sharp-edged sickle, leaving a couple of leaves below the head intact, which provide a degree of protection for the base of the head. For prolonged storage, due care is exercised to prevent injuries arising from bruising. Healthy heads are packed in perforated polyethylene bags and stored at low temperature soon after harvest. Refrigeration at 1.6 °C and low relative humidity are needed to control the growth of pathogens. The lower the temperature, the longer their shelf life, but freezing reduces quality. Solid heads are more susceptible to freezing injury than firm heads. A storage temperature of 0 °C with 98% relative humidity is recommended for storage up to 6 months. The prevention of moisture loss is essential during storage. Slight reductions in weight loss and retardation of senescence, such as yellowing, toughening, and loss of flavor, are major advantages for CA storage of cabbage. White cabbage stores well in 5% O_2 and 2.5–5% CO_2. If oxygen levels are near zero or CO_2 is maintained at 15% or higher for 1 month, the internal leaves of cabbage discolor even though the external leaves are normal. Some cultivars are grown for off-season marketing. These cultivars can be maintained in acceptable condition for 2–3 months and up to 6 months, with the use of modified atmosphere storage (1% O_2 and 5% CO_2 at 0–1 °C temperature and 98–100% relative humidity). All cole crops should be stored in an atmosphere free from ethylene to avoid premature senescence and tissue injury.

Chinese cabbage is harvested by hand at the base, and the outer, diseased, or injured leaves trimmed off. The head should be packed loosely and preferably upright. The vegetable can be stored at 0 °C coupled with 95% relative humidity for several weeks. A temperature of 0 °C coupled with 98% relative humidity is optimal for maintaining a marketable state for about 4–6 months. Spacing among containers in storage should be allowed for air circulation. A low concentration of oxygen is reported to be beneficial in extending the storage life.

Chicory is harvested when the heads are compact, bright, and well sized. The plants are cut at the base, and damaged or diseased leaves are trimmed. The trimmed heads are washed and cooled by vacuum or hydrocooling to 0 °C temperature before being packed in layers in wire-bound crates, cartons, or baskets for transit. They are stored at 0 °C and 90–95% relative humidity for 2–3 weeks. Chicory can be stored for a longer period with crushed ice in and around the packaging.

Endive and escarole are leafy salad greens not adapted to long storage. Even at 0 °C, they cannot be expected to be kept satisfactorily for more than 2–3 weeks. Vacuum or hydrocooling can help in maintaining a fresh appearance. They can be kept for longer if stored with crushed ice in or around the packaging. The relative humidity should be above 95% to prevent wilting.

Lettuce harvesting begins as soon as the plants reach acceptable size and it should be completed before the leaves become tough and bitter or the seed stalk starts to bolt. Lettuce grown for the market must be allowed to grow to full size and develop a solid head. For home use, it is often harvested before the head is fully developed. The heads are hand-cut just below the lowest leaf. Loose and damaged leaves are removed and the product is washed prior to packaging. Most commonly, lettuce is packed in cartons and vacuum-cooled soon after harvest. Lettuce intended for longer storage should be packed in perforated plastic films in cartons or crates with liners to maintain a high humidity. It is advisable to trim unfolded leaves before packing, as these are not needed to maintain quality and retailers discard wrapper leaves. Removing wrapper leaves at harvest and wrapping the heads with plastic film reduces injury during packaging. Shed packaging of two to six dozen heads of lettuce in wooden crates with ice has yielded to dry packing of 24 heads in fiberboard containers. Polyethylene-lined packaging reduces decay by 30–40%, compared with open polyethylene bags. Mechanical injury is one of the major causes of loss of quality and waste in unwrapped lettuce. Packaging of romaine lettuce in unsealed polyethylene-lined (0.04 mm thick) packaging causes a marked decrease in decay during storage in spite of high relative humidity. The beneficial effect of packaging has been attributed to high CO_2 and low O_2 levels in the package because of respiration. Lettuce should be precooled to −1 °C and stored at 0 °C and 98–100% relative humidity early after harvest. The rate of general deterioration at 15 °C is about 2.5 times greater than that at 0 °C. Precooling is commonly accomplished by vacuum cooling. To aid vacuum cooling, clean water is sprinkled on lettuce heads prior to carton closure if they are dry and warmer than 25 °C. Lettuce is highly perishable and deteriorates rapidly with increasing temperature. The respiration rate increases rapidly and storage decreases concomitantly as the storage temperature

increases over the range from zero to 25 °C. Leaf lettuce respires at about twice the rate of a head lettuce. Lettuce is not stored for a long period although it can be stored for 3–4 weeks at 0 °C if it arrives in good condition. It can be kept for about twice as long at 0 °C as at 3–4 °C. Lettuce is easily damaged by freezing, and thus, all storage must be above the highest freezing point (−0.2 °C). CA is of limited use in storing lettuce. Oxygen about 3–5% and CO_2 1.5% are recommended to prevent russet spotting and butt discoloration. Lettuce is sensitive to high CO_2 and low O_2; oxygen below 1% and CO_2 above 2.5% are injurious to lettuce. Problems, such as russet spotting, bacterial soft rot, and CO_2 injury, can cause serious losses. Kinetin application delays chlorophyll losses and slows down the increase in abscisic acid content. Application of gibberellic acid (10 ppm) and cytokinin isopentenyladenine (0.1 ppm) 2 days before harvest can delay senescence effectively.

In the case of mustard, small bundles made after discarding old and diseased leaves are handled like other greens at 0 °C. It is commonly shipped in package under ice to maintain freshness. Quality is retained so long as wilting is prevented.

Because of the high rate of respiration, broccoli and kale are prone to rapid desiccation. Therefore, it is important to cool rapidly to low temperatures under high humidity until the commodity is consumed.

Parsley can be harvested over a long period by cutting outer, larger leaves only and tying it in bunches for market. The leaves can be packed loose or bunched after being washed thoroughly and before packing into crates. Crushed ice is usually placed in the packing and shipment made under refrigeration to distant markets. Much of the crop is supplied to restaurants and hotels or dehydrated. At 0 °C and high humidity, parsley can be held for 2 months in storage.

The top 15 cm watercress shoots are harvested and precooled with ice water and shipped using refrigerated vehicle. Its leaves are highly perishable and need prompt handling and refrigeration after harvesting. When it is handled inappropriately, the leaves become slimy. Watercress should be precooled using either hydro- or vacuum cooling and stored at 0 °C with high relative humidity (95–100%). It is bunched and packed in alternate layers with flake ice and kept cool during shipment by spraying with cold water and/or ice. Watercress at 0 °C and high relative humidity in waxed cartons with top ice can be held for up to 2–3 weeks. A similar storage life is possible using permeable polyethylene crate liners and package icing to minimize wilting. Naked bunches are highly perishable even at 0 °C and may be kept only for 3–4 days. The use of polyethylene film liners may be justified to prevent moisture loss under some circumstances.

Feeding the Future

The common root and tuber crops (potato, cassava, sweet potato, and yams) play a critical role in providing needed calories to the food-insecure of the developing world. The global population, as estimated by the United Nations, exceeded seven billion in October of 2011 with projected current growth to nine billion by the year 2050. The Intergovernmental Panel on Climate Change, a global consortium targeting a scientific and socio-economic understanding, predicts future stresses on human communities, agricultural production, and natural ecosystems by threat of increased climatic temperatures, drought, and flooding. As a result, agricultural systems will be under pressure to produce more under suboptimal conditions and climatic stress. Root and tuber crops have tremendous satiating power through their capacity to thrive in marginal growing environments. However, ensuring global food security goes beyond providing needed calories. Root and tuber crops, like cassava, can provide a medley of phytonutrients and phytochemicals. According to the Food and Agriculture Organization (FAO), globally, 870 million people, or one in eight, suffer from malnutrition and undernutrition. In addition, the FAO has stated that root and tuber crops, grown in over 140 countries, are capable of delivering the needed calories and many essential nutrients to the undernourished.

Root and tuber crops are produced, processed, and consumed in ways as unique as each urban and rural culture where they are cultivated. Rural consumers are those who grow, on a substance level, much of the food they rely on to meet nutritional needs. Urban consumers, those who purchase the majority of their food from producers, have developed a preference for root and tubers based on convenience and purchasing power. Rural consumers typically produce their own food and trade with surplus for additional income as compared to urban consumers who purchase food. The nutritional importance of a food for a given population can be evaluated, according to the FAO, by considering its contribution to the total energy supply, taking into account the availability of the food and total available energy for a given population. Measured nutritional value of starchy foods depends on nutrient content, starch properties, antinutritional factors, and toxic substances. Nutritional availability, digestion, and absorption from root and tuber crops can be impacted by cultural practices, storage conditions, and processing. Technological advances have been shown by researchers to allow for the rapid characterization of nutritional properties, allowing for improved health benefits through these crops.

The Consultative Group on International Agricultural Research (CGIAR) is a global partnership uniting organizations engaged in research for a food-secure future. The 15 CGIAR research centers, each with a specific crop mandate, focus on reducing rural poverty, increasing food security, improving human health and nutrition, and ensuring more sustainable management of natural resources. Root and tuber crops are the source of most daily carbohydrate intake for large populations globally; therefore, three CGIAR centers carry mandates focused toward their development: the International Center for Tropical Agriculture (CIAT) in Colombia, the International Institute of Tropical Agriculture (IITA) in Nigeria, and the International Potato Center (CIP) in Peru. CIP was established as a root and tuber research and development center originally focused solely on the potato due its global nature of production and the ability to produce more dietary calories and protein than any other staple crop. Research efforts at CIP have since been broadened to include root crops due to their critical role in the developing world and global agricultural systems. Research has shown that root and tuber crops are capable of growing with limited inputs and in marginal conditions providing one of the cheapest sources of calories and vital nutrients. Preempting a global food crisis will require adaptation of current agricultural systems beyond simply producing dietary calories. Collaborative research efforts, such as those modeled by the CGIAR system, between agronomist, biologist, entomologist, nutritionists, and social scientist must be conveyed all the way to the farmer to carry the needed impact.

Production and Processing

Root and tuber crops function as a dietary foundation supporting those most affected by hunger within the developing world. Foods eaten regularly in quantities that constitute a dominant part of the diet (major source of energy and nutrient needs) are considered food staples. Globally, according to the FAO, four of the top ten food staples are root and tuber crops with potato just behind the major cereal grains of maize, wheat, and rice. In many resource-poor and developing areas, food cultivation requires crops capable of performance in marginal soils, those supplemented with limited inputs. Excluding the potato, root and tuber crops are grown almost exclusively in the highly variable environments of the tropics.

Industrial production and processing of root and tuber crops is challenging due to the unique and often ununiformed physiological shape of the roots and tubers produced. Differences in root and tuber shape can largely be associated to the variable environments in which they are grown. The same phenoplasticity allowing these crops to thrive across contrasting environments may limit their use in large-scale commercial production; however, this adaptive trait is critical in feeding those struggling in developing nations.

Crop breeding is based on selection of hybrids evaluated for desired traits. Crosses are made between parental lines with

different and hopefully complementary genes in hopes of deriving progeny capable of outperforming either parent. The breeding process requires extensive time and efforts, making the development of new cultivars challenging. The danger of vegetative propagation, such as that in root and tuber crops is a challenge, as breeders must keep ahead of rapidly changing plant pathogens capable of devastating the needed harvest. Farmers are at the mercy of changing plant diseases given its ability to impact an entire crop lacking in genetic diversity.

The potato is the world's most productive crop when considering the needed inputs in comparison to the total caloric output. Potato consumption has more than doubled since 1993 with a global production of over 335 million metric tonnes a year. China leads the global potato harvest followed by India and Russia. Potato cultivars that have been adapted for large-scale production typically have shallow root systems to facilitating harvest yet limit their ability to access lower soil profiles containing water and nutrients. The potato tuber is an enlarged portion of the stolon that forms in response to hormones triggered by temperature and day length. Tubers grow rapidly once initiated although high temperatures can negatively impact formation.

In commercial production, potatoes are planted in hills or raised beds to optimize water drainage and uniformity of irrigation. Potatoes can be grown on a variety of soils contrasting in water holding capacity. Ideal soils would be those of good structure and drainage allowing root aeration limiting the impact of root disease. Soil pH can range from 4.5 to 8.5; however, 5.5–7.0 is ideal for production and nutrient uptake.

In North America, the potato season begins in March or April with the preparation of seed for planting in April or May. The growing season spans from around April to October with harvest beginning in late July. Once planted, initiation of sprouting and emergence will occur 15–30 days following planting. Stolon initiation begins at the same time of emergence; tubers will initiate 15–30 days following emergence. Filling of tubers begins around 45–90 days following emergence. Tuber development, plant maturation, and harvest will range from 90 to 120 days following emergence.

Early blight (*Alternaria solani*) and late blight (*Phytophthora infestans*) are potato fungal pathogens that can negatively impact crop production if not managed correctly. Additional efforts to control pests such as the aphids and psyllids are critical to reduce crop damage. Nematodes can have an equally devastating effect on overall production if not suppressed through simple crop rotation.

Patterns of Distribution and Consumption

Tuber crops constitute a considerable part of the world's food supply and are a valuable source of animal feed. On a global basis, ~45% of tuber crop production is consumed as food, with the remainder used as animal feed or for industrial processing for products such as starch and distilled spirits.

The pattern of tuber crop utilization varies considerably among countries. In the developing countries (with the exception of China and Brazil), relatively small amounts (<20%) are fed to livestock. Most of the remainder is used locally as food. The relatively high cost of transportation and processing, as well as the time needed in food preparation, makes unprocessed tuber crops less attractive to urban consumers.

The consumption of tuber crops in developed countries is considerably smaller, but their use as animal feeds is higher. A small proportion of tuber crop production (<5%) is traded internationally. More than two-thirds of those exports come from developing countries. Apart from cassava, only potatoes are traded internationally mainly among developed countries.

There are considerable differences in the agroclimatic conditions suitable for the production of tuber crops. Cassava is cultivated across a range of agroclimatic conditions from sea level to 1800 m and from areas with as little as 500 mm of rainfall to tropical rain forest areas. Potatoes, on the other hand, are considered to be a high-latitude/high-altitude crop, originating in the Andes, but now grown in a range of environmental conditions, including irrigated production in Latin America, Asia, and portions of Africa.

Sweet potato originated in the Americas (as did cassava and potato), and it too is grown over a considerable range of latitude and elevation (up to 2500 m). Conversely, yams have a relatively narrower range of production, being mainly confined to the tropical regions throughout the world from sea level to 1400 m.

The dozen or so lesser known Andean root and tuber crops vary considerably in their ranges of adaptation and tolerance to environmental conditions. They are primarily considered to be medium- to higher-elevation crops of moderate temperature regimes and water requirements.

Health Benefits

As with all crops, nutritional content in tubers can vary greatly depending on the varieties cultivated and management practices used during production. Furthermore, the preparation and cooking of tubers may alter their nutritional content. Vitamin, mineral, and fiber content can change by peeling, or cooking. With these caveats in mind, the values discussed should be considered averages.

Tuber crops are some of the richest sources of starch and dietary fiber. Research has shown that many varieties of potato also contain a melody of vitamins and minerals. Potatoes, yams, and sweet potatoes provide around 70–100 calories per 100 g serving, while cassava has nearly twice the calories of potatoes, perhaps highest for any tropical starch-rich tuber (100 g providing 160 calories). Tubers are good sources of vitamin B complex such as pyridoxine (vitamin B_6), thiamin, niacin, pantothenic acid, and folates. Furthermore, fresh potato along with its skin is a good source of antioxidants. Most tubers contain adequate amounts of many essential minerals like iron, manganese, magnesium, phosphorous, copper, and potassium (Figure 1). Colored potatoes like red and russet potatoes contain adequate amounts of vitamin A and antioxidant flavonoids.

Sweet potatoes are an excellent source of flavonoid phenolic compounds such as beta-carotene and vitamin A. In fact, their vitamin A content is among the highest in the root-vegetable categories. Sweet potato leaves are more nutritious than the tuber itself. Weight per weight, 100 g of fresh leaves contains more minerals than the tuber.

Figure 1 Nutrition facts of selected root and tuber crops. Nutritional values represent an uncooked serving size of 100 g. Nutrient data were sourced from the USDA National Nutrient Database. *Percent daily values (%DV) are for adults or children aged 4 or older and are based on a 2000-calorie reference diet.

Like all tubers, cassava is low in fats and protein. Nonetheless, it has more protein than that of other tropical food sources like potatoes and yams. As in other roots and tubers, cassava is free from gluten. Young tender cassava (yuca) leaves are a better source of dietary proteins and vitamin K.

Toxic Substances and Antinutritional Factors

Tuber crops contain small amounts of potential toxins and antinutritional factors such as trypsin inhibitors. Apart from cassava, which contains cyanogenic glucosides, cultivated varieties of most edible tubers do not contain any serious toxins. Wild species may contain toxins that must be correctly processed. These species are useful in times of food scarcity, and local people have developed techniques for detoxifying the roots before consumption.

Cassava Toxicity

The main toxic principle, which occurs in varying amounts in all parts of the cassava plant, is a rather stable cyanogenic glycoside. Researchers have shown that if absorbed from the gut to the blood as the intact glycoside, it can be excreted unchanged in the urine without causing any harm. However, it can liberate cyanide in the gut during digestion. The range of cyanogen content of cassava varies greatly between varieties and also with environmental and cultural conditions. The concentration of the cyanogenic glycosides of cassava increases from the center of the tuber outward; in general, the cyanide content is substantially higher in the cassava peel.

Traditional processing techniques practiced in cassava production are known to reduce cyanide in tubers and leaves. Drying is the most ubiquitous processing operation in many tropical countries. Sun drying has been shown to eliminate more cyanide than oven drying and soaking followed by boiling is better than soaking or boiling alone.

Nutritional Bioavailability

Biofortification is the process by which necessary daily micronutrients are delivered to the diet through food crops. Plants are versatile biochemical factories, capable of synthesizing a nearly full complement of essential dietary micronutrients. Regrettably, the plant-based foods most abundantly consumed by at-risk populations contain levels of several micronutrients that are insufficient to meet minimum daily requirements. Furthermore, often these nutrients are unevenly distributed among plant parts exacerbating the problem. Biofortification efforts are directed toward increasing the levels of specific, limiting micronutrients in edible tissues of crops by combining crop management, breeding, and transgenic approaches.

Global economists from the Copenhagen Consensus Center have deemed plant biofortification as one of the preeminent global challenges faced today. Furthermore, the economists predicted tremendous benefits compared to costs associated with developing this technology. Perhaps, the greatest challenge may be to get producers and consumers to accept biofortified crops and increase their intake of the target nutrients. With the advent of good seed systems, the development of markets and products, and demand creation, this can be achieved.

There are numerous examples of biofortification strategies that have been successfully implemented with tuber crops. Zn fertilizers have been used with potato varieties to increase Zn accumulate in their edible portions. Traditionally, white or yellow sweet potato varieties are grown and eaten in Africa, but these provide little, or no, vitamin A. Orange sweet potato has now been conventionally bred, not only to provide more vitamin A but also to be high-yielding and drought-tolerant. Utilizing transgenic approaches, researchers have developed 'golden potatoes' where carotenoid levels of 114 $\mu g\,g^{-1}$ dry weight and beta-carotene of 47 $\mu g\,g^{-1}$ dry weight were obtained. Similarly, it has been suggested biofortifying cassava with provitamin A (converted in the body to vitamin A) could significantly improve nutrition and overall health, especially among poorer communities.

Food scientists have shown that most crops are deficient in one or more essential amino acids that cannot be synthesized *de novo* by humans; for example, legumes tend to lack methionine and cysteine, whereas grains tend to be deficient in lysine and threonine. Plant biologists have used various methods to increase essential amino acids in these plants. For example, research has shown that expression of storage proteins, which contain high levels of desirable amino acids, has raised protein content in potatoes.

Plant calcium transporters within the cell have also been manipulated to increase calcium levels in potatoes by transgenic approaches. Researchers at Texas A&M University have modified potatoes expressing high levels of a deregulated transporter to accumulate almost threefold more calcium in the edible part compared to control plants, without perturbing growth, development, or fertility, under controlled lab conditions (Figure 2).

As mentioned at the onset of this section, traditional breeding approaches will find widespread acceptance and can be used to enhance the nutritional qualities of foods. However, breeding alone will not be an adequate approach because of the limitations of particular plant species.

Summary

Root and tuber crops are calorie- and nutrient-dense foods with a potential to mediate future food insecurities. Additionally, technology is focusing on improving the nutrient content and yield of these crops. Flexible growing requirements in conjunction with the ability to produce in marginal environments afford these crops an important role in feeding the world's poor.

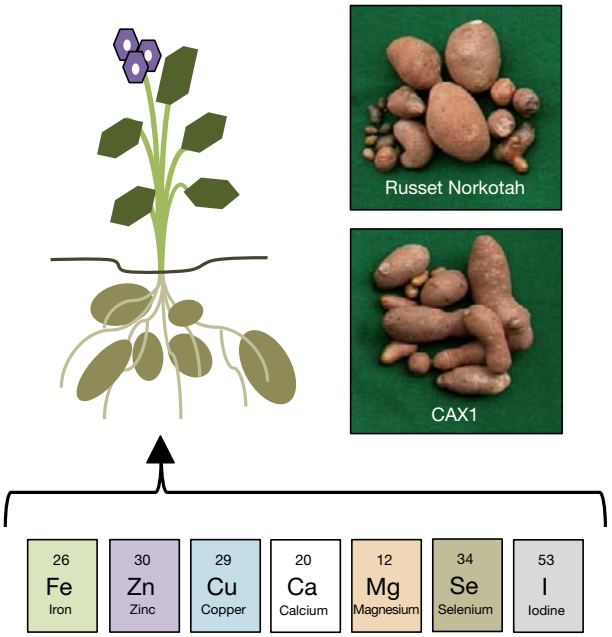

Figure 2 Target nutrients for crop biofortification. Researchers have demonstrated the capacity of Russet Norkotah potato tubers expressing the *Arabidopsis* H^+/Ca^{2+} transporter sCAX1 contain up to threefold more calcium without impacting growth or yield.

Salad Crops: Stem-Type Crops

MK Rana, CCS Haryana Agricultural University, Hisar, India

© 2016 Elsevier Ltd. All rights reserved.

Among the leaf-stem type of salad crops, celery (*Apium graveolens*) is the most important. Other crops in this group are American wintergreen (*Gaultheria procumbens* L.), asparagus (*Asparagus officinalis*), baby corn (*Zea maize* var. crassa), broccoli (*Brassica oleracea* var. italica), dandelion (*Taraxacium officinale* Wig.), Florence fennel (*Foeniculum officinale* D.C.), globe artichoke (*Cynara scolymus* L.), kohlrabi (*Brassica oleracea* var. gongylodes), oca (*Oxalis tuberosa* Molina), and parsnip (*Pastinaca sativa* L.). These crops are consumed in different forms, especially in temperate countries.

Global Distribution, Commercial Importance, and Varieties

American wintergreen (*Gaultheria procumbens* L.) belongs to Ericaceae family, and Gaultheria was named after Dr Gaultheria, a physician in Quebec (CA) in about 1750. Its tender leaves and stems are consumed widely in America and other Western countries as well as in Asia and Australia.

Asparagus (*Asparagus officinalis*) is native to Europe and Asia. Its varieties produce green and purple spears. Forcing the plants with the exclusion of light produces white spears, which are very popular in Europe. Green asparagus is commonly canned and is most popular in the UK.

Baby corn (*Zea mays* var. saccharata or rugosa), a form of maize, is an important and popular vegetable, especially in the United States. Maize is an ancient crop, as revealed by cob remnants dating to about 5000 BC found at the Tehuacan cave excavations in Mexico; domestication is estimated to have begun about that time. Baby corn is most popular in Western countries, where it is imported from developing countries—mainly Thailand.

Broccoli (*Brassica oleracea* var. italica) is usually harvested when the curd is compact and immature. The name broccoli refers to the young shoots that develop in some species of the genus *Brassica* (*brocco* is an Italian word for shoot). Broccoli is believed to be the ancestor of cauliflower. Broccoli is gradually becoming a popular vegetable in other parts of the world. A favorite of Americans, broccoli is of commercial importance to the United States. A large portion of the United States' yield goes to the freezing industry. The top broccoli-producing states are California, Arizona, and Texas. In the US, it is also known as Italian broccoli, pointing to its origin. Italian green sprouting and calabrese are its most popular varieties. Strains of Italian green sprouting (midway, green mountain and grand central) are the early and medium-maturing type, which are dark bluish green and produce large compact heads and lateral shoots after the central head is cut. The cultivar De Cicco is light green in color and produces abundant lateral shoots; it is the main winter broccoli grown in Texas.

Celery (*Apium graveolens* L.) comprises three distinct cultivated varieties. They are grown in different parts of the world for different economic purposes. Based on the botanical part of the plant consumed, these varieties are classified as:

- *Apium graveolens var. dulce, common name celery*: develops succulent, solid petioles that are used mostly raw as salad
- *Apium graveolons var. rapaceum, common name celeriac or root celery*: characterized by the development of hypocotyls, or root tissue, and mostly consumed cooked in stews and soups or grated on salad
- *Apium graveolens var. secalinum, the common name smallage or leaf celery*: leafy, slender and often hollow petioles, its leaves are used as a condiment, garnish and for medicinal purposes.

The genus *Apium* is spread worldwide, particularly in the Mediterranean basin, Australia, New Zealand, South Africa, and South America. Among 14 species of *Apium*, graveolens is the only one to be cultivated. Argentina and Chile are the countries that are richest in *Apium* species. Celery is important in Europe and America. Its habitat extends southwards from Sweden to Algeria, Egypt, and Abyssinia. In Asia, the habitat is from the Caucasus (Bluchistan) to the mountains of India. Wild celery can be found in damp or marshy areas of various European countries, Egypt, and parts of Asia. It was first used as a medicinal plant and as food in AD 1500. Homer's *Odyssey* mentions celery grown in 850 BC, but this early form (later called smallage) was a leafy, pungent, and bitter plant used exclusively in medicines. Celery was demonstrated as a vegetable in Italy in the sixteenth century. At this time, the first report of the three horticultural varieties appeared. Selection for solid and succulent petioles resulted in celery types, whereas selection for enlarged hypocotyls gave rise to celeriac type. Celery is a popular crop widely cultivated throughout the world. The use of celery began in the eighteenth century and its use as a vegetable in the United States was recorded in 1806. It is used in mixed salads or as an appetizer. It is often stuffed with cream cheese or peanut butter. The petioles are sometimes cut up and served as a cooked vegetable, although its use is declining. In the US, a large part of the celery crop is consumed in its raw state; however, a considerable quantity is used in vegetable juices, soups and stews, and as a cooked vegetable. In the 18th century, two varieties of solid stem Italian celery were available in France, that is, solid celery and striped rose. In 1875, Chemin selected a line known as solid golden white celery, which became the variety Paris golden yellow—a self-blanching type. In 1884, Pascal selected a green celery line from this variety, which is known in the seed trade as Pascal celery. In 1887, both varieties were introduced to North America under the names white plume (the self-blanching type) and giant Pascal (the green type).

The word dandelion comes from the French phrase *Dent de Lion*, meaning lion's tooth—reflecting the jagged shape of the leaf. It is a great favorite in Europe and to a lesser extent in the United States. Previously, it was considered a noxious weed,

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00786-8

but cultivated species are now available. The cultivated dandelion has been developed from the wild species (*Taraxacum officinale*), a member of the Compositae family. Its leaves are used raw in salads or cooked as greens. The flowers can be fermented to produce wine and the roots may be used as a coffee adulterant similar to chicory roots.

Fennel is produced commercially in the United States. Most fennel seeds are imported from India, Argentina, and Bulgaria. The volatile oil (anethole constituent) in fennel seed is an adaptable flavoring agent used in the preparation of pickles, perfumes, soaps, liquors, cough drops, and chicory candy. Florence fennel (*Foeniculum officinale*), a leaf-stem type salad crop, is native to southern Europe and resembles wild fennel. The Carosella, extensively used in Naples and scarcely known in any other place, is referred to by authors as *Foeniculum piperitum* D.C. It is closely related to *Foeniculum officinale*. The plant is used while running to bloom. The fresh and tender stems are served raw and are still enclosed in the expanded leaf stalks. It is only available from the end of March until June. Italian fennel (*Foeniculum dulce*), also called finnochio, is a short-lived perennial that is cultivated as an annual. The leaf base becomes enlarged and bulb-like and, when blanched, has the texture of celery. It is used primarily for flavoring.

The globe artichoke (*Cynara scolymus* L., $2n = 2x = 34$), a member of *Asteraceae* (compositae) family and *Cynarae* tribe, differs from the Jerusalem artichoke (*Helianthus tuberosus* L., $2n = 102$), which is an important vegetable in Mediterranean countries, where 90% of the world's artichokes are produced. Italy, Spain, France, and Argentina are the main producers of the globe artichoke. The genus *Cyanara* is very small, with only three recognized species. They are:

- *Cyanara cardunculus* L. var. sylvestris Lam (the wild cardoon), widely spread in the western Mediterranean basin (Spain, Morocco, Algeria, Tunisia, and Sicily),
- *C. sibthorpiana* Boiss and Heldr, located in the central part (the Peloponnese, Aegean Islands, and Cyrenaica), and
- *C. syiaca* Boiss, found in the eastern part (Palestine).

Jerusalem artichokes belong to the same family, but they bear tubers and are native to North America. They are a herbaceous-perennial but, again, are usually grown as an annual.

Kohlrabi (*Brassica oleracca* var. gongylodes), a member of Brassicaceae (cruciferae) family, is a biennial herbaceous vegetable crop grown as an annual. The kohlrabi produces a swollen bulb-like stem. It was described by writers in ancient Rome and was developed in northern Europe during the fifteenth century. It is a minor crop grown in temperate countries and in some subtropical areas. The tubers (swollen stems), which develop above the ground, may be due to secondary growth. The tuber is harvested before it becomes tough or woody.

Oca (*Oxalis tuberosa* Molina) belongs to the family Oxaliolaceae. It is an ancient crop cultivated by pre-Columbian people in the Andean highlands. Commercial production occurs in Mexico, Central America, and the South Island of New Zealand.

Parsnip (*Pastinaca sativa* L., $2n = 2x = 22$), a biennial crop, is native to Europe and western Asia. It is cultivated for its large and fleshy taproot. It was introduced to the West Indies in 1564, but it only grows in the tropics at high altitudes. The Romans and Greeks used it for medicinal purposes and for food in ancient times. It belongs to the family Umbelliferae (*Apiaceae*).

Rhubarb (*Rheum rhaponticum*) is an early and high vegetable crop well suited for cultivation in cool regions. UK, the Netherlands, Germany, the Nordic-countries, Canada, and the US cultivate the most rhubarb. It is a minor commercial crop grown in small areas, but it is very common in kitchen gardens. It is a long-lived perennial plant with edible stalks, and is native to Siberia.

Morphology and Taxonomy of Edible Part

American winter green plants are prostrate, with their creeping stems giving rise to erect branches (15 cm high and leafy at the top). The lower leaves are alternate and serrated with short petioles. Their upper leaves are oval, 2.5–5 cm long, apiculate, glaucous, and shiny. The flowers are solitary, or in racemes or panicles, and are scarlet in color.

The edible portion of asparagus is the spear, which develops from the crown. Green asparagus, which is the greater portion of crop, is cut 2.5 or 5.0 cm below the soil surface. Its spears are harvested before the excessive elongation occurs. Internode lengthening and loss of tip compactness and tenderness reduce quality. Blanched spear harvesting is more difficult. Spears are harvested when the tip is about to emerge or just protrudes through the soil surface. Even a slight amount of tip greening diminishes its perceived market quality.

Baby corn is an herbaceous monocot and a warm season annual. Plants are monoecious with male flowers borne as the terminal inflorescence (tassels) on the main stem. Female flowers are borne separately as a lateral inflorescence (ear) developing at a leaf axil. Plants produce one to several ears. Baby corn is the young ear of a maize plant harvested before fertilization, when silks have just emerged. Husked, light-yellow colored, and tender ears of baby corn are nutritious. It is an ingredient used in soup, vegetable biryani, mixed vegetables, Chinese food, and an array of others dishes. Crispy vegetable salad and pickles made from baby corn are also common. It provides diversity because of its texture and flavor, in addition to its significant nutritional value. Tender ears canned in 2% citric acid are exported to the US and European countries. Its recognized cultivars are Prakash and Composite Kesari.

Broccoli (*Brassica oleracea* var. italic) forms a head consisting of green buds and thick fleshy flower stalks. The terminal head is rather loose and green in color, and the flower stalks are longer than those of cauliflower. The internodes are long and the plant produces axillary flowering shoots in addition to the terminal inflorescence. The color of the flower buds, forming the edible portion, varies from white to green—depending on the cultivar. The inflorescence is made of fully differentiated flower buds. It is considered a good quality curd if these reach the open stage. The sprouts in the leaf axils develop sturdily, especially after removal of the terminal head. Both the terminal head and the sprouts with bud clusters are consumed as food.

Celery, a member of Apiaceae (Umbelliferae) family, is characterized by enlarged, tender, edible petioles, or leaf stalks.

The petioles are broad, with sheathing bases. It is biennial, but a few strains and related wild species are annual. The plants will bolt when subjected to chilling temperatures, producing a seed stalk and making them unmarketable. The most common form bears 5–12 thick petioles in a tight bunch. A less popular form is turnip-rooted celery, known as celeriac (var. rapaceum). It is a biennial cool season crop, but it is sensitive to prolonged chilling temperatures. Growth through the first year normally produces a tight cluster of petioles and leaves attached to a very compressed stem. Its leaves are divided, pinnatified, and smooth with almost triangular, toothed leaflets that are a dark green color. The leaf stalk is broad, furrowed, and concave on the inside. The stem, which appears in second year, is furrowed and branching. Early vegetative growth spreads, but the leaves arising from the apex of the short stem produce compact and elongated heads. The root system of celery is spread out and fibrous with many feeder roots close to the soil surface. The plant produces compound clusters (umbels) of small, white, perfect flowers with five petals and five stamens. The seeds (fruits formed from two compressed carpels enclosing the actual seed) are very small.

Dandelions produce leaves, which are deeply toothed, in a basal tuft and a single, composite, yellow flower atop a hollow stalk. Its cultivated forms are larger and leafier than the weedy forms. Improved cultivars (mostly of French origin) are larger, tenderer, less bitter, and slightly greener than the wild types.

Florence fennel is an annual, very distinct, low growing, and thickset plant with a very stout stem that has joints close together toward the base. The leaves are very finely cut, and green. The leaf stalks are very broad and have a whitish green hue. They overlap one another at the base of the stem, the whole forming a head, or enlarged areas that vary in size (the inside is white and sweet). The height of the plant, even when grown for seed, does not exceed 60–75 cm. The flowers are greenish and are in a broad umbel of stout, stiff rays. The seed, twice as long as it is wide, is flat on one side and convex on the other. It is traversed by five thick, yellowish ribs, which almost occupy the entire surface of the skin.

In Globe artichokes, the edible organ is the young capitulum, which is harvested when it is still in rapid growth. The enlarged receptacle (bottom) and the tender thickened base of the bracts are eaten. If the capitulum is picked at an early stage, the heart (after removal of tough outer bracts), the receptacle (lower part of inner bracts), and the undeveloped choke (immature florets, bristles, and pappus) are eaten. The stem just below the young head is also edible. In Jerusalem artichokes, the underground tubers can be oblong or elongated and weigh 80–120 g.

Kohlrabi (*Brassica oleracea* var. gongylodes) is often called turnip-rooted cabbage and is closely related to cabbage. The stem, which is edible, is enlarged immediately above ground and is an excellent vegetable if used before it becomes woody, tough, and stringy. The most popular varieties of kohlrabi in India are white Vienna, green Vienna, purple Vienna, and earliest ear furt.

The compact and bushy growth of oca (perennial) is between 20 and 30 cm in height. Tubers can be eaten immediately after harvest, but the flavor is better after they have been exposed to the sun (reduced bitterness). Oca is consumed after boiling, baking, frying, pickling, or uncooked. Leaves and young shoots are eaten in salads or as cooked vegetable.

Chemical and Nutritional Composition

The artichoke has interesting nutritional characteristics related to its high content of phenolic compounds, that is, flavonoids, inulin, fiber and mineral salts, which are derivatives of caffeic acid. Extracts containing cynarin (1,5-dicatteoyl quinic acid) affect hepatobiliary disease, hyperlipidaemia, and cholesterol metabolism. The pharmaceutical industry mainly uses the leaves. Baby corn is a good source of proteins and lipids, and is a source of pro-vitamin A (beta-carotene).

Celery is an important source of minerals, vitamins, and amino acids. Celery leaves are also characterized by higher levels of vitamin C, carotene, and essential oils. Many traits, such as stalk and petiole shape and color, crispness, pithiness, stringiness, how ribby it is, petiole cracking, and flavor contribute to quality. Having a low content of fat, celery is popular in the Western world. Of 100 g of celery, around 71 g is edible, made up of moisture (88 g), protein (6.3 g), minerals (2.1 g), carbohydrates (1.6 g) and fiber (1.4 g). It also contains energy (37 kcal), calcium (230 mg), phosphorus (140 mg), sodium (126 mg), iron (6.3 mg), carotene (3990 μg), vitamin A (240 IU), thiamine (0.9 mg), vitamin C (0.62 mg), niacin (1.2 mg), and riboflavin (0.11 mg). The composition varies at different stages of maturity, and total sugars show a marked decline in the leaf blades from harvest time to the end of storage. This decrease is accompanied by increased concentrations in petioles. Soluble nitrogen increases in leaf blades and petioles towards the end of storage.

Hardly any information is available, with respect to nutritional composition, for Florence fennel and American winter green vegetables. However, it is reported that dandelion leaves are an excellent source of vitamin A (14 000 IU per 100 g), vitamin C (35 mg per 100 g) and calcium (187 mg per 100 g edible part). Oca nutrition qualities are comparable to the potato; on a dry weight basis, about 85% of the tuber is carbohydrates and the starch is of good quality.

Post-Harvest Handling and Storage

Harvest maturity of asparagus is usually reached when the spears are about 12.5–20 cm above the ground. They should be cut before they are too long and the tips begin to spread. The spears should be harvested when they are rounded, and before they become ribby. Spears with open tips decay more rapidly, toughen, and are unattractive. Selective harvesting of asparagus is advocated since new shoots appear daily over a period of 6–10 weeks. Straight spears, green-tinged with purple on the bracts and with tightly closed tips, are preferred. Asparagus with white butts are less perishable than all green asparagus. Asparagus loses freshness and quality rapidly after harvest, meaning it is desirable to market or process it as soon as possible. The instant cooling of spears helps to maintain quality and considerably improves marketability. Hydro cooling can be used to reduce spear temperature rapidly. Generally,

chlorine is added to the water for cooling to reduce bacterial populations. The spears should be stored at low temperatures. At high temperatures, rapid elongation and senescence will occur; ethylene exposure also causes senescence. The loss of total sugars is pronounced at higher temperatures. In addition to general deterioration growth, loss of tenderness, flavor, and vitamin C, and decay take place at moderately high temperatures. An increased rate of fiber development is directly correlated with spear length and age, and with high post-harvest temperatures. Asparagus is packed in plastic film bags or crates without bunching. Butts are cut off and the spears are put in boxes lined with oily paper with a layer of wet moss at the bottom. Packing only spears with tightly closed tips can extend the shelf life. Packing in film bags maintains market quality by reducing moisture loss, keeps the edible quality by preventing fiber formation, and sustains the nutritional value by reducing ascorbic acid losses. However, impermeable film bags can produce off-flavors due to anaerobic decomposition. Such packaging leads to uncontrolled accumulation of CO_2 and depletion of O_2 with possible injury to the produce. The film must be sufficiently permeable to permit exchange of CO_2 and O_2 to dissipate the respiratory heat. Asparagus, if placed horizontally, will exhibit negative geotropism with the tips turning upward. Specially shaped containers, which are wide at the base and narrow at top, are often used to accommodate long tapered spears. High humidity is essential to preventing desiccation, particularly at the ends. Humidity is obtained by placing the butts on wet pads. Pre-packaging spears in perforated films can also obtain a high relative humidity. Spears continue to elongate after harvest, and headspace is provided to avoid tip damage. Asparagus is highly perishable and deteriorates rapidly at temperatures above 5 °C. Storage conditions at 0 °C with 95% relative humidity are recommended to extend the marketable life of asparagus to about 3–4 weeks, but it is subjected to chilling injury when held for longer at this temperature. The recommended handling temperature is 2 °C with the relative humidity greater than 95%. Chilling damage occurs at temperatures lower than 2 °C for prolonged periods. Controlled atmosphere storage of asparagus is known to reduce post-harvest deterioration because it prevents the development of off-flavor, water and chlorophyll losses, and toughening. Exposure of spears to CO_2 $7 \pm 2\%$ and O_2 2% for 24 h retards bacterial rot. No chilling injury is observed at temperatures of 1.7 °C and 15% CO_2 level. Controlled atmosphere storage of asparagus has three major advantages:

(i) the reduction of decay,
(ii) the retardation or even reversal of toughening, and
(iii) a more desirable color.

It provides a useful technique not only to retain a high quality in fresh asparagus, but also to improve the quality of the processed product. Controlled atmosphere stored spears retain more sugar, organic acids, and soluble proteins than spears stored in air. Shelf life of several leafy vegetables including asparagus has been reported doubled by immersing the cut ends, or dipping the whole spear, in solutions of 2-chloroethyl trimethylammonium chloride (CCC or cycocel).

Broccoli is harvested shortly before the buds begin to open while their heads remain compact and cut to a length of about 20–25 cm. The axillary shoots, as they develop, are cut at the same stage as the central head. The broccoli heads are further trimmed to a length of about 15 cm, and bunches weighing about 700 g are tied together for packing. Bunches are packed in crates that can hold up to 28–30 bunches each. The broccoli buds continue to develop and the flowers begin to open or turn yellow. Bunches are hydro cooled to 4.4 °C, packed with ice, and stored in refrigerated conditions. The respiration rate of freshly harvested broccoli is high compared with that of asparagus or sweet corn. Therefore, broccoli must be cooled soon after harvest to reduce the respiration rate and it must be stored at low temperatures in an oxygen-free environment to prolonged shelf life. Broccoli should be hydro-cooled or packed in ice immediately after harvest and kept at 0 °C to maintain good marketable conditions. Film wraps can be beneficial in maintaining high relative humidity and extending storage life.

There is no definitive stage of maturity at which celery should be harvested for satisfactory quality. Celery plants are cut off below the soil surface. The plants should be moved from field quickly because they wilt easily. Stripping to remove suckers and diseased and damaged leaves, washing, grading, packing, and pre-cooling are done for marketing. It is advisable to store celery near 0 °C to avoid decay. To avoid wilting, packaging in ventilated wraps is advantageous. Box or crate liners should have about one hole per square foot. Celery can be stored at temperatures between 0 and 0.6 °C with relative humidity at 90–95% for about 8 weeks. In controlled atmosphere storage, the oxygen level of $<5\%$ retards yellowing of celery only slightly and $CO_2 > 5\%$ may be damaging. Therefore, all wraps should be perforated to avoid potentially dangerous accumulation of CO_2 or the reduction in CO_2 levels to $<1\%$. Celery in storage absorbs foreign flavor. Hence, it should be kept away from the odor of other produce.

Dandelion plants are trimmed, washed, and stored in a container at a low temperature (0 °C) and high humidity (90–95%) to preserve their quality. Similar conditions may also be used for other crops.

Florence fennel plants are harvested just above the taproot. Upper petiole and leaf blades are trimmed relatively close to the bulb. Fennel has good post-harvest storage quality if maintained at a temperature of 0 °C with high relative humidity.

Globe artichoke flower buds require careful handling to avoid bruising and desiccation. The harvested buds are put in suitable containers to be emptied into bulk bins for transport to the packing shed, where they are graded according to their size and quality. Following harvest, the artichoke buds must be pre-cooled as quickly as possible to retain their quality. Hydro cooling is effective for both cooling and cleaning, but hydro- and room-cooling to 4.4 °C (within 24 h) are used widely. When storage is required, conditions providing temperatures of 0–2 °C and a relative humidity of 95% can maintain good quality for as long as 10 days. Globe artichokes are packed in different layers in paper-lined boxes. For prolonged storage, temperatures close to 0 °C are recommended, although 1.7–2.8 °C is satisfactory for normal marketing periods. Decay can be prevented effectively by holding artichokes below a temperature of 4.4 °C. Gentle handling aids in maintaining high quality because physical injury can accelerate decay as much as a 10 °C rise in temperature. Injured and decayed buds at harvest deteriorate 1.5 times more rapidly than sound buds, especially when they are held at 4.4 °C or

above. Wilting can be prevented by hydro cooling or washing the bracts in cool water.

Tubers of kohlrabi can be kept in good condition for 2–3 months at 0 °C and 98–100% relative humidity. High humidity is advocated to prevent shriveling and toughening. Packaging in perforated film can be used to reduce moisture loss. Kohlrabi with attached leaves has a storage life of only 2 weeks at 0 °C temperature.

Ploughing or hand-digging are used to harvest parsnip. Foliage is removed before lifting the roots. Harvesting is often delayed until lower temperatures have occurred, because root quality is improved under such conditions. With advancing maturity, the starch in roots is converted to sugars, and this is accelerated by exposure to cold temperatures. Parsnip can be stored below 0 °C with greater than 90% relative humidity. Since the roots easily desiccate, high humidity is important for extended storage. As with carrots, parsnips exposed to ethylene during storage become bitter. Oca storage characteristics are relatively good if they are properly cured, and moisture loss is minimized.

Salmonella: Detection

Introduction

The genus *Salmonella* is a member of the Enterobacteriaceae family of enteric bacteria. They are a large group of closely related rod-shaped, Gram-negative, facultatively anaerobic bacteria, many of which are known to be potent human pathogens. The nomenclature of the *Salmonella* genus is complex and has undergone many revisions. In its current state, there are two species, namely, *Salmonella enterica* and *S. bongori*. Most pathogenic *Salmonella* belong to the species *S. enterica*, which is further divided into subspecies *enterica* (I), *salamae* (II), *arizonae* (IIIa), *diarizonae* (IIIb), *houtenae* (IV), and *indica* (VI). The subspecies themselves can be divided into serovars of which there are more than 2500. Typically, the names of *Salmonella* serotypes are abbreviated and so, for example, *S. enterica* subspecies *enterica* serovar typhimurium becomes *S.* typhimurium. *Salmonella* can grow in a temperature range of 6–46 °C with an optimum of 32–37 °C and in a pH range of 4–9.5 with an optimum of 6.5–7.5.

Salmonella is of significant worldwide concern as a human pathogen and results in numerous deaths and cases of severe disease annually. Illness in humans caused by pathogenic *Salmonella* is generally referred to as salmonellosis. Symptoms of the disease include watery diarrhea, nausea, abdominal pain, fever, and headaches. Complications can occur, and in some cases, *Salmonella* may invade the body and become systemic. The elderly, very young, and immunocompromised are at higher risk of complications and mortality from the disease. *Salmonella* generally infect individuals by the fecal–oral route with animals or animal products being the most common source of infection. *Salmonella* is routinely encountered in the gastrointestinal tracts of a wide range of animals and does not generally cause disease in them. Sporadic cases and outbreaks of salmonellosis are commonly associated with variety of foods including those of animal origin such as poultry, beef, eggs, pork, and milk. In addition, foods such as fresh produce, which are indirectly contaminated with *Salmonella*, also cause a substantial number of cases of disease.

The ability to detect the presence of *Salmonella* in food and in the food chain is important to verify process controls put in place by the industry. The presence or absence of *Salmonella* (as determined by growth and isolation on culture media) in a given amount of food (often 25 g) has traditionally been used as a criterion for this. The effectiveness of this approach is limited by a number of factors most notably (1) the great diversity of *Salmonella* described earlier, which makes it difficult to provide media suitable for recovery of them all; (2) the presence of sublethally injured *Salmonella* on foods, which require the inclusion of recovery steps; (3) the presence of *Salmonella* at levels too low for detection by these methods resulting in the requirement for selective enrichment steps; and (4) the presence of competing bacteria with similar characteristics, which makes it difficult to easily separate and visualize the *Salmonella*. Developments in detection technologies based on immunology, molecular biology, and other approaches have resulted in the introduction of techniques that overcome some of these problems. Implementation and uptake of these techniques is, however, relatively slow at both a regulatory level and an industry level. Factors that have slowed this uptake include the need to verify the efficacy of the new methods for regulatory approval, the cost of implementing the new technologies, and concern from industry over detection of significantly larger numbers of samples. The advantages of the new technologies are, however, becoming more apparent and their use is likely to become more widespread as time progresses. The range of different approaches used for the detection of *Salmonella* in foods, including their relative advantages and disadvantages, are described in the succeeding text.

Culture-Based Methods

Detection of *Salmonella* in food and food environments is still most widely achieved using culture-based methods. These methods may vary significantly with respect to the media and protocols used depending on the jurisdiction in which they take place. All methods require lengthy incubation times and the entire process generally takes from 5 to 7 days. The exact media and protocols employed in these methods vary, but the major steps in the detection process tend to be very similar in most cases (Figure 1).

Typically all culture-based methods initially entail taking a portion of food and subjecting it to a nonselective preenrichment step. This step allows any *Salmonella* present to recover from injury sustained during processing. The preenrichment step usually involves incubation of the food at suitable growth temperatures (usually ~37 °C) and time (usually 18–24 h) in a relatively rich medium (such as buffered peptone water). The number of *Salmonella* (and other bacteria) present in the medium increases during this process, making a higher number available for subsequent selective isolation. The importance of this step for culture-based and other detection methods that involve preenrichment is critical due to an increasing association of *Salmonella* outbreaks with foods of low water activity, such as spices and peanut butter. *Salmonella* survive well in these environments for a non-spore-forming Gram-negative bacterial genus but are likely to experience a higher degree of stress and sublethal injury than in some other foods. In addition and for the same reason, they may be present in lower numbers in these foods than in foods with a higher water activity. To mitigate these issues, methods used to detect *Salmonella* in low-water-activity foods may include a soaking step (to reduce the shock of sudden hydration), longer preenrichment times (to allow better recovery from stress), or the use of larger sample sizes (to increase overall numbers of *Salmonella*). The choice of method needs to be specific to the

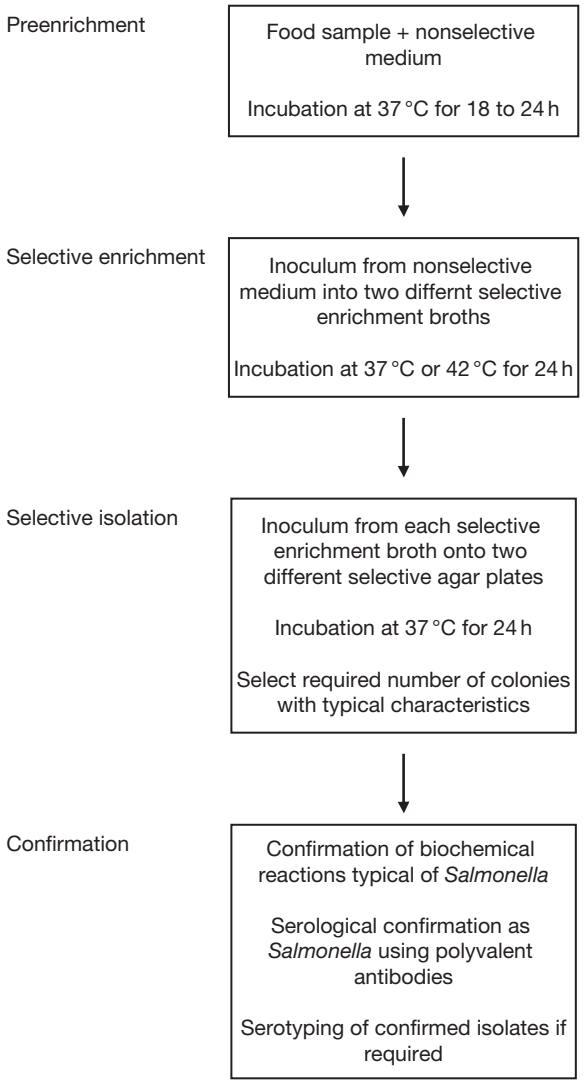

Figure 1 Generic scheme for detection of *Salmonella* in foods using culture-based methods.

product being examined as individual products have different properties and have been prepared using different stress-inducing methods. This is an active area of research, and better protocols for low-water-activity foods are likely to be developed in the near future.

Subsequent to the preenrichment step-selective primary enrichment for *Salmonella* is undertaken. This step is designed to specifically allow the growth of *Salmonella* while suppressing the growth of other bacteria that may otherwise be present in much higher numbers. Without selective enrichment, these other bacteria may either outcompete or simply mask the presence of *Salmonella* present in the sample. There are numerous enrichment broths available and these include Rappaport Vassiliadis soya broth and tetrathionate broth, to name but a few. Most protocols require the inoculation of more than one broth type from the preenrichment. This is done to assure that specific *Salmonella* strains that may be sensitive to the selective components in one type of broth have the opportunity to grow in the other. The enrichment broths are incubated (usually at 37 or 42 °C and for 18–24 h), and secondary enrichment and isolation of presumptive *Salmonella* on selective agar follow.

In the secondary enrichment step, the primary enrichment cultures are inoculated onto *Salmonella*-selective agars such as xyline lysine deoxycholate (XLD) agar, bismuth sulfite agar, or brilliant green agar, to name but a few. Incubation conditions for the secondary enrichments are generally similar to those of the primary enrichments. Most protocols require that more than one agar type is inoculated from each of the primary enrichment broths, once gain to ensure that all *Salmonella* strains present are able to grow and be differentiated from other bacteria. Based on the number of primary and secondary enrichment media available, a wide variety of combinations are possible. Some protocols are completely prescriptive but most specify media of one of each enrichment type and allow some choice with the second. Colonies displaying typical morphology and characteristics for *Salmonella* on the particular media (e.g., red yellow with black centers on XLD) are selected and isolated, generally on a nonselective medium. These colonies are subsequently taken through a battery test to confirm that they are in fact *Salmonella*. This step is necessary as other bacterial species may display the same characteristics as *Salmonella* on most media and if misidentified can result in false-positive tests being reported.

Confirmation is traditionally achieved by taking presumptive bacterial isolates from the secondary selective enrichment through a series of key biochemical and serological tests. The most common biochemical tests are for the production of H_2S (+) and indole (−), glucose and dulcitol fermentation (+), urease reaction (−), and the presence of lysine decarboxylase (+). The presumptive strains are also tested for agglutination with polyvalent H and O antisera. The correct biochemical and serological outcomes are sufficient to confirm the isolate as a *Salmonella*. Further characterization of the isolate to subspecies, strain, and serovar levels may be carried out if required and is generally done by specialist reference laboratories that have the necessary sera and equipment.

Ways to increase the speed and accuracy of the culture-based protocols described earlier have been developed. These are generally methods designed to amend or replace one of the steps described earlier. One of these is the use of immunomagnetic separation after the preenrichment stage. This technique uses magnetic beads coated in *Salmonella*-specific antibodies to trap, separate, and concentrate *Salmonella* in the medium. The beads can then be plated on the secondary enrichment-selective agars eliminating the need for the primary selective enrichment and reducing the time to complete the protocol. Other techniques that can be incorporated into the protocols include the use of miniaturized biochemical test kits to eliminate the preparation involved in the individual test required for confirmation. In addition, chromogenic agars based on unique characteristics of *Salmonella* can be used for more definitive and accurate isolation of these bacteria. While useful new methods add to the diversity of options available for the isolation and culture of *Salmonella*, establishing a clear and consistent approach to achieving this becomes more difficult.

The entire process described earlier is time-consuming and labor-intensive. For the food industry, this may increase costs and reduce productivity. In addition, food companies may face

requirements for different culture-based *Salmonella* testing protocols from different markets, particularly if they export. While many jurisdictions require (through standards) testing approaches to be followed in a very prescriptive way, others allow for leeway, which may speed up the process slightly. Attempts at harmonizing culture-based testing methods for *Salmonella* have been made, for example, through national and international standard setting bodies, and this has improved the situation for companies to some degree. There are a range of new and more rapid and accurate methods to detect *Salmonella* in food and food-related environments being developed, and the speedy dissemination of these into regulation should further reduce the burden on industry.

Nucleic Acid-Based Methods

Advances in the understanding and application of molecular techniques based on the specificity of nucleic acid (and most commonly DNA) sequences have resulted in the development of a variety of methods for the detection of *Salmonella* in food and food-related environments. These methods are generally much more rapid than the culture-based techniques described earlier as they are more sensitive and specific than them and therefore able to detect fewer cells of *Salmonella*. This reduces or eliminates the need for extensive enrichment procedures. These techniques were initially labor-intensive and very expensive, but numerous commercial platforms are now available, which means they are accessible for everyday use by the food industry. Despite their strong potential, nucleic acid-based techniques do suffer from a number of drawbacks depending on the method use. These include a higher rate of false-positive results, the inability of most techniques to differentiate between live and dead *Salmonella* in the sample being tested, and the inability of some methods to quantify *Salmonella* in the sample in cases where this is required. Solutions to these problems are being worked on, and future developments in this are likely to overcome these making the use nucleic acid-based techniques more powerful.

Most of the nucleic acid-based methods used are based on the polymerase chain reaction (PCR), which is a technique for amplifying nucleic acid. The exact protocols employed in these methods vary, but the major steps in the detection process tend to be very similar in most cases (Figure 2). Put simply, this method uses short pieces of added nucleic acid (primers) to identify and bind to a specific nucleic acid sequence in particular bacteria (e.g., *Salmonella*) present in the sample being analyzed. These primers, in the presence of an enzyme and under the influence of cycling temperatures, allow amplification of the target sequence to very high numbers. The amplified target is visualized; this is regarded as evidence of the presence of target sequence and by inference the bacteria of interest in the sample. The target sequence must be specific to the bacteria of interest and not appear in closely related bacteria. A good knowledge of the genetics of the bacteria of interest is therefore required. In the case of *Salmonella*, a number of genes have been used for this purpose, and these have, for example, included the gene encoding fimbrial subunits, a gene involved in host invasion, and a gene involved in virulence. It is a likely that other targets will be developed as our understanding of the molecular biology of *Salmonella* increases. In most cases, PCR-based techniques still require some enrichment (usually nonspecific) to boost numbers of *Salmonella* to levels at which detection of the target nucleic acid is easier. In addition, the target nucleic acid must be purified from the sample. This is generally easily achieved using commercial kits designed for this purpose. Depending on the food or other matrices that make up the sample to be examined, some of which may interfere with the PCR process, further purification steps may be required. Once enriched, however, PCR-based techniques allow confirmation of the presence of *Salmonella* in a sample in a matter of hours to a day, reducing the time required by 2–3 days as compared to conventional culture-based techniques. Using preenrichment, some PCR-based techniques are able to detect as few as 4 *Salmonella* cells in 25 g of sample, which is a very high level of sensitivity. At the end of this period, no bacterial isolate is available for further examination, however, and if this is required (e.g., if the serovar needs to be established), isolation from the sample by culture-based methods may still take place.

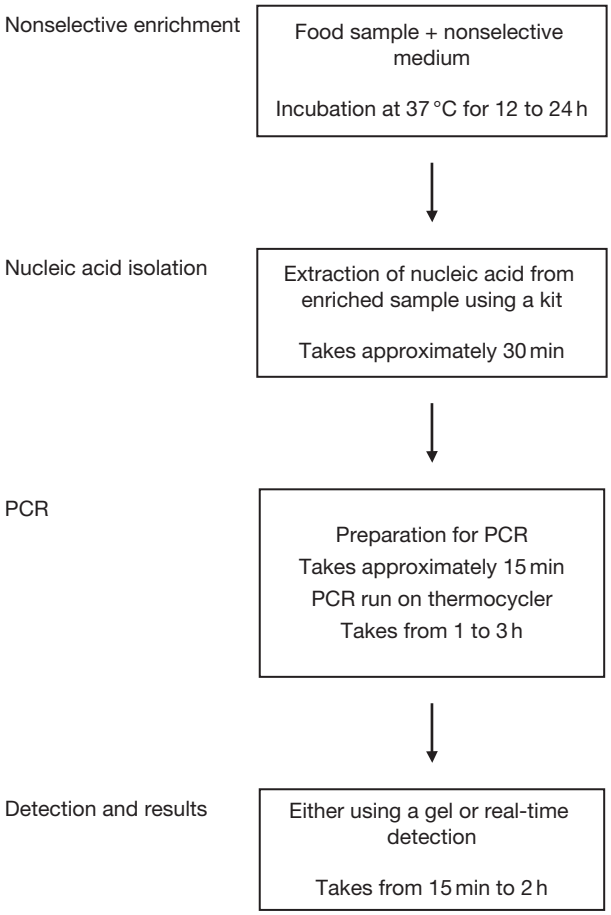

Figure 2 Generic scheme for detection of *Salmonella* in foods using nucleic acid-based (PCR) methods.

Traditionally, PCR products have been detected by separating them on polyacrylamide gels. This method is time-consuming and most commercial platforms for detection of *Salmonella* now use a modified PCR technique, called real-time

PCR, which eliminates the need for this step. This method entails the use of various fluorescent dyes that are incorporated in the PCR product as the PCR progresses. This incorporation is monitored in real time and allows the identification of positive samples in a shortened time and without the need for a second step. The inclusion of appropriate controls is very critical for this technique, but it has, together with the introduction of a kit format, made nucleic acid-based detection of *Salmonella* accessible and practical for most food testing laboratories, even those in small to medium enterprises. As indicated earlier, in some cases, for example, where the risks associated with particular foods are under investigation, quantification of *Salmonella* present in a food sample is required. A version of real-time PCR called quantitative PCR has been used to overcome this issue. For this technique, the real-time PCR platform is used on samples, generally without enrichment, but is also calibrated against series of controls with known quantities of bacterial template present in them. A standard curve established allows an accurate estimation of the numbers of *Salmonella* (or *Salmonella* templates) in a sample. This technique tends to be accurate only within a certain range of values and is less accurate when the number of *Salmonella* in the samples is lower.

One of the issues associated with many of the techniques using nucleic acid is the inability to differentiate whether the DNA present is from live bacteria or bacteria that may have died, for example, during processing, and no longer represent a risk to human health. This could result in the reporting of false-positive results, and possibly recalls, and imposes a cost burden on the industry. In order to overcome this issue, a specific PCR technique called reverse transcriptase PCR has potential. This technique entails converting messenger RNA (mRNA) into complimentary DNA (cDNA) and amplifying the resulting cDNA. The principle of this technique is based on the fact that mRNA only remains viable for a very short period of time and therefore will only be present in a sample if live cells are present. This technique has been applied to detect *Salmonella* in various matrices, but correlation between bacterial counts and this method remain poor. While not currently a commercial option, this method has substantial future potential.

Detection of the presence of *Salmonella* using specific DNA sequences is also possible without using PCR. Techniques of this type often entail the use of specific sequences of DNA labeled with fluorescent of other markers. The probes are allowed to bind to immobilized *Salmonella* cells or DNA (often after enrichment) and detected using colorimetric or other means. These techniques are not widely used in the industry and are more often used as research tools, although some commercial kits are available. Another area of interest is the use of the loop-mediated isothermal amplification (LAMP) technique. As the name suggests, like PCR, this method uses an enzyme to amplify nucleic acid, but unlike PCR, this technique does not require temperature cycling and can be measured by the simple production of turbidity. This has the advantage of allowing the development of methods that can be performed in the field and with minimal equipment. Currently, a number of techniques for the detection of *Salmonella* using LAMP are being evaluated, and despite some initial difficulties with sensitivity, this technique has substantial potential for the future.

Immunology-Based Methods

The specific interaction between antigens and antibodies is another approach used to detect *Salmonella* in food matrices and environments. Variations of this technique have already been mentioned as adjuncts to the culture-based techniques described earlier. Specifically, these interactions are the basis of immunomagnetic separation and the agglutination assays used for confirmation and serotyping. These techniques can, however, be used in their own right as integrated methods for the detection of *Salmonella*. Antibodies that target specific unique antigens and that are displayed on the cell surface can be used to 'capture' *Salmonella* cells. In the majority of methods using this technique, the specific antibodies are immobilized on a surface. The captured cells are detected by using additional antibodies (to the same or different antigens) conjugated to an enzyme. The enzyme is then used to convert its substrate to a color compound, the intensity of which is measured (by eye or a spectrophotometry) as a positive reaction. This technique is known as an enzyme-linked immunosorbent assay (ELISA). The exact protocols employed in these methods vary, but the major steps in the detection process tend to be very similar in most cases (Figure 3). A number of commercial systems using

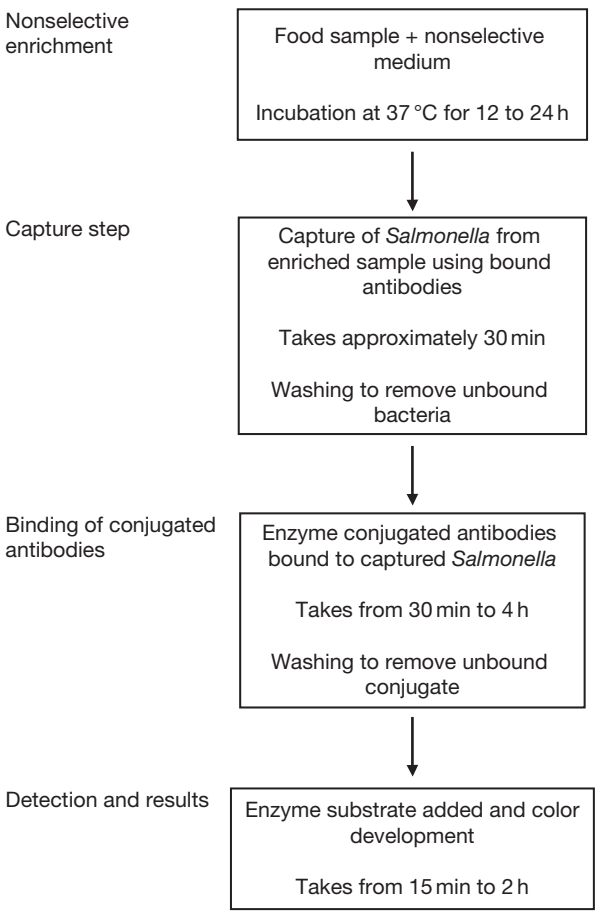

Figure 3 Generic scheme for detection of *Salmonella* in foods using immunology-based (ELISA) methods.

this method are available, and many of these have a relatively high degree of automation. The format of these tests may include microtiter plate-based assays, individual tube-based assays, or the use of once off membrane flow devices (similar to pregnancy testing kits) that produce a colored line if the sample is positive. Variations of the ELISA technique in which the antigens (*Salmonella* cells) are attached to a substrate and the antibodies added subsequently are available although less commonly used.

The steps in the ELISA technique are relatively rapid as compared to culture-based methods. The test itself can be performed in a matter of hours, but it has a relatively low sensitivity and still requires a nonselective enrichment step. As is the case for the nucleic acid-based techniques, the end result does not provide live cells for analysis, and if this is required by regulation, then isolation of *Salmonella* by culture-based methods will still need to be performed in the case of positive samples. The ELISA-based techniques can also suffer from other flaws such as cross-reaction with antigens on other bacteria resulting in false-positive signals and issue with detecting variable antigen production by some *Salmonella* strains resulting in false-negative results. Advances in technology and our understanding of *Salmonella* are reducing the occurrence of these issues, and a number of methods are accepted by regulatory authorities. Quantification of *Salmonella* using these techniques is currently not common although numerous hybrid methods to achieve this are under development.

Other Methods

Methods for the detection of *Salmonella* using techniques other than those fitting into the main groups described earlier are under development. The main one of these is bacteriophage-based detection. Bacteriophages are viruses that infect bacteria, many in a very specific way targeting individual genera, strains, or species. The specificity of these bacteriophage–bacteria interactions can be used in the same way as antibody–antigen interactions to detect bacteria of interest. These detection systems may operate in a variety of different ways. For example, they may use engineered bacteriophage designed to express luminescence when infecting their *Salmonella* host or bacteriophage proteins as a trap for *Salmonella* in a similar way to that used in antibody-based techniques. The potential of some of these methods lies in its ability to establish the viability of cells as bacteriophage signal will only be produced from live bacteria. While still in its infancy, this method has potential as it is more rapid than culture-based methods with the advantage described earlier.

Conclusion

The methods described earlier are diverse, and anyone wishing to detect the presence of *Salmonella* in food or food-related environments is faced with a dilemma of what to use. Often, the method to be used will be dictated by a regulatory authority, but even in this case, some choice in methodology is often allowed. The choice of method is necessarily a trade-off between a number of factors including speed, time, accuracy, cost, and relevance. Economies of scale are also important to consider and the approach used to examine only a few (or occasional) samples is likely to be different to that for routine processing of a large number of samples. The current trend is towards using the more rapid nucleic acid-based or immunology-based techniques to screen samples and then applying culture-based techniques only to samples found to be positive. Unless the rate of positive samples is expected to be high, this approach generally provides a happy medium between the factors listed earlier.

Advances in technology and our understanding of *Salmonella* biology continue to allow developments and improvements in the detection of this pathogen. Separation of *Salmonella* from other bacteria and from complex food matrices has improved but is an ongoing area of work. Increasing the rapidity and sensitivity of techniques and their ability to detect live cells is an area also receiving much attention. Improvements in, for example, sensitivity will necessarily result in an increased ability of regulatory authorities to impose stricter limits on the presence of this pathogen. The rapidly evolving technological and regulatory environment means that selection of techniques will become more specific to particular products and choosing the right method critical at all levels. Increasing globalization of the food supply will provide further challenges with respect to *Salmonella* detection and harmonization of the methods used, increasingly important.

Introduction

Salmonella enterica infections are a cause of extensive morbidity and mortality throughout the world. In the United States, the Centers for Disease Control and Prevention (CDC) estimates that there are approximately 1 million cases of nontyphoid *Salmonella* infections leading to over 19 000 hospitalizations and nearly 400 deaths each year. *Salmonella* is the leading cause of bacterial foodborne illness, with approximately 95% of nontyphoid salmonellosis cases due to the consumption of contaminated food products. Estimates for the cost of salmonellosis range from approximately 2–11 billion US dollars each year due to loss of work, medical care, altered quality of life, and loss of life. The potential sources of *Salmonella* infection are numerous, as the bacteria have been found to persist in a wide range of environments and hosts including food animals, fruits and vegetables, legumes, nuts, pets, and reptiles.

Salmonella Basics

When humans are infected, salmonellosis can occur in the form of gastroenteritis, bacteremia, typhoid fever, and organ system infections. Typhoid fever, which is typically not considered a foodborne illness, is associated with *S. enterica* serotype Typhi and related serotypes and will not be extensively discussed in this article. Most cases of nontyphoid salmonellosis are limited to gastroenteritis that develops between 6 and 72 h following exposure. Gastroenteritis symptoms, including abdominal cramps, diarrhea, vomiting, and fever, typically resolve within a week without antimicrobial therapy. In some instances, a more invasive disease can occur, with patients developing bloodstream infections and infection of organs and tissues. These more severe manifestations most often occur in young children, the elderly, or those with a weakened immune system and often require antimicrobial treatment to resolve the infection. The typical antimicrobials used include the fluoroquinolones (which are not approved for use in children) or third-generation cephalosporins.

Members of *S. enterica* are generally identified based on their serotypes. Serotyping relies on the differential recognition of antigens present on the surface of the bacterium using antisera to distinguish serotypes. The antigen–antibody agglutination patterns separate *Salmonella* into at least 2600 distinct serotypes based on the Kauffmann–White scheme. Many of the serotypes are capable of causing human illness. In the United States, the most common serotypes associated with salmonellosis are Enteritidis, Typhimurium, Newport, Javiana, and Heidelberg. In Europe, *S.* Enteritidis is the predominant serotype, and in many parts of Asia, *S.* Choleraesuis is among the top serotypes, which causes relatively few cases in the United States. Most cases of salmonellosis are due to the consumption of contaminated foods such as meat and poultry products, eggs, unpasteurized dairy products, seafood, legume and nut products, and fresh produce. In addition, direct contact with infected animals, including reptiles and amphibians, can also be a source of infection.

Many of the serotypes commonly associated with human infections are also among the most commonly associated with food animal species. For example, of the ten most implicated serotypes for human infections in the United States, eight are among the top ten most isolated from one or more of the major meat or poultry species. Indeed, foods of animal origin are among the most commonly identified sources of human *Salmonella* infections; thus, there is a need for improved methods to limit contamination along the farm-to-fork continuum. This is especially important in light of the statistics that consumers are eating greater amounts of meat and poultry products throughout the world. In the United States, for example, the US Department of Agriculture (USDA) reported that there have been a greater than sixfold increase in per capita consumption of poultry products and a 20% increase in beef and pork consumption between 1910 and 2005. To combat the potential for increased foodborne illnesses, public health agencies, producers and processors, and consumers are working to limit *Salmonella* contamination and rapidly respond when a potential disease outbreak occur to limit the impact of foodborne illnesses.

Since *Salmonella* is primarily a foodborne disease, prevention of infections involves prevention of contamination of food products, either before/after harvest or through proper handling/preparation for both the food industry and the consumer. The optimum growth temperature for *Salmonella* is between 35 and 37 °C, but can grow in the range of 15–45 °C. For many food products, pasteurization is an effective way to kill *Salmonella.* For the consumer, improperly prepared and cooked foods are common sources of infections. Therefore, it is recommended that all meat products should be cooked to an internal temperature between 71 and 82 °C (depending on the type of meat). Also, care should be taken to avoid cross contamination with raw fruits and vegetables (e.g., use separate cutting boards to prepare meats and vegetables).

Salmonella Pathogenesis

Early Infection

Salmonella infections are typically due to ingestion of fecal material that may be present on contaminated foods or other vehicles. The estimated infectious dose, or number of organisms that need to be ingested to cause illness, is variable,

ranging from as few as 30 to greater than a billion organisms. The wide range is likely due to several factors, including the immune status of the patient, the genetics of the bacteria, and the type of food contaminated and consumed. For example, high-fat foods and those that can limit the impact of stomach acidity appear to allow for a lower infectious dose. *Salmonella* also have physiological properties that allow them to tolerate the low pH and presence of organic acids in the stomach to reach their sites of colonization in the intestinal tract. The production of acid shock proteins allow for *Salmonella* to elicit an acid tolerance response (ATR) mediated by regulatory factors including RpoS σ-factor, PhoPQ, and Fur proteins. These regulatory proteins allow the organisms to respond to the different inorganic and organic acids that are present in the stomach, by altering the expression of multiple ATR proteins. The exact roles that each of the regulated proteins, which impact protein expression and folding, metabolic function, and cell surface structures, play in the *Salmonella* ATR are not fully understood; however, it is evident that multiple factors contribute to the overall process.

Salmonella that survive passage through the stomach compete with members of the resident intestinal microbial populations (microbiota) for colonization sites within the small intestine or colon. When *Salmonella* attach to the intestinal epithelium, the adhesion is initiated by fimbriae or pili, which are located on the surface of the bacterium. Different *Salmonella* serotypes and strains can produce different types of fimbriae, which may contribute to some of the differences in the abilities of serotypes to infect various host species. Some common types of fimbriae associated with colonization include type 1 fimbriae, long polar fimbriae, curli fimbriae, and plasmid-encoded fimbriae. The different fimbriae bind to specific receptors on the host cells, which leads to differences in the cell types that *Salmonella* expressing different fimbriae are able to attach to and ultimately infect.

Following epithelial attachment, *Salmonella* can express a multiprotein structure termed as type III secretion system (T3SS), which initiates the uptake and invasion of intestinal cells. The T3SS is regulated by the HilA protein, whose expression is modulated in response to environmental factors that are important to cell survival. The structure of the secretion system is formed by the interaction of more than 20 structural and regulatory proteins to form the functional T3SS. The genes for the T3SS associated with intestinal cell invasion are carried on *Salmonella* pathogenicity island 1 (SPI-1). Pathogenicity islands are genetic regions that contain multiple genes that encode factors, such as host cell adhesion, invasion, and toxin production, which are important for increased virulence within a bacterium. The SPI-1 T3SS functions as a sort of molecular syringe that allows for the transport of protein effector molecules from the bacterial cytoplasm into the host cell. In the functional T3SS, a needlelike structure extends from a base anchored in the *Salmonella* cell membrane and the cell wall. An inner channel allows for effector molecules to be transported through the base structure into the needle, which interacts with the host cell. During the transport of effector molecules, chaperone proteins in bacterial cytoplasm enable interaction between the effector and T3SS-associated ATPases that drives the translocation of the effector into the needlelike structure. The tip of the needle interacts with a bacteria-derived translocation complex, which is inserted into the host cell membrane to facilitate delivery of effector proteins into the host's cytosol.

The translocated effector proteins have several effects on the host cells; SipA, SipC, and SopB proteins interact with actin to induce membrane ruffling associated with the engulfment and internalization of the bacterium. In membrane ruffling, the actin cytoskeleton undergoes rearrangement, and the cell membrane shape is altered to surround the *Salmonella* organisms. The internalized *Salmonella* subsequently reside in a membrane-bound compartment termed the *Salmonella*-containing vacuole (SCV). During the infection, the SCV migrates from the intestinal lumen to the basal membrane of the epithelial cell, where the *Salmonella* can interact with macrophages and/or dendritic cells in the submucosal tissue. The process of transfer from the epithelial cells to phagocytes remains poorly understood.

The SopB protein also appears to play an important role in the development of *Salmonella*-associated diarrhea, which is a key feature of gastroenteritis. SopB is likely involved with the attraction of neutrophils at the site of infection leading to inflammation and an alteration of the ion balance within the cells due to the disruption of chloride channels in the host cells. The altered ion balance leads to fluid secretion and subsequent diarrhea. In addition to SopB, several other effector molecules, including SipA, SopA, SopD, and SopE2, have been identified as potentially contributing to gastroenteritis.

Intracellular Survival and Systemic Infection

In addition to their function in epithelial cells, SCV are important for the survival of *Salmonella* within phagocytic cells, such as macrophages and dendritic cells, during invasive infections. Within the phagocytes, the SCV formation likely occurs distinct from the normal phagolysosomal processing pathways that immune system cells use to clear many bacteria from the host. The survival and persistence of *Salmonella* within the SCV are associated with a second T3SS that is encoded on SPI-2. The SPI-2 T3SS is only expressed inside the SCV and allows for the assembly of the secretion system apparatus and expression of affiliated effector proteins, chaperones, and regulatory proteins needed to function. A number of conditions within the SCV have been associated with SPI-2 T3SS expression, including changes in osmolarity and nutrients and acidification of the SCV.

SPI-2 T3SS effectors, such as SifA, SseF, and SseG, interact with the microtubule bundles and motor proteins within the host leading to morphological changes and the formation of vacuolar appendages that extend from the SCV, termed *Salmonella*-induced filaments (SIF). SIF are likely important in *Salmonella* pathogenesis, and their formation often coincides with the intracellular replication of *Salmonella*. In addition, the effector protein SpiC likely aids in the ability of *Salmonella* to persist intracellularly by interfering with phagolysosomal processing to avoid killing by reactive oxygen and nitrogen compounds that kill many other bacterial species.

Intracellular survival of *Salmonella* within macrophages and dendritic cells is an important attribute in the development of severe systemic infections. *Salmonella* present in the immune cells can be transported from the intestinal submucosa to other sites within the body. In contrast to macrophages, *Salmonella*

likely do not replicate within dendritic cells, but remain viable with reduced metabolic activity. SPI-2 T3SS effectors likely limit antigen presentation by dendritic cells, thereby further suppressing the immune response to *Salmonella*. When the infected phagocytes enter organs or certain tissues, they can spread to uninfected host cells leading to increased pathology associated with severe infections.

Antimicrobial Resistance

Resistance Trends of Salmonella

Salmonella are a public health concern not only due to the number of cases per year and the pathogenesis of the bacterium but also due to the number of strains resistant to antimicrobial agents. In the United States, the Food and Drug Administration, the USDA, and the CDC collaborate with the National Antimicrobial Resistance Monitoring System (NARMS) that tracks resistance trends of *Salmonella* and other enteric bacteria. The antimicrobials tested by NARMS include amikacin, amoxicillin/clavulanic acid, ampicillin, cefoxitin, ceftiofur, ceftriaxone, chloramphenicol, ciprofloxacin, gentamicin, kanamycin, nalidixic acid, streptomycin, sulfisoxazole, tetracycline, and trimethoprim/sulfamethoxazole. At the time of this writing, the most recent NARMS Executive Report summarized data collected in 2010 and indicated that in 2010, 15.3% of non-Typhi *Salmonella* isolates from humans were resistant to at least one antimicrobial agent. The most common multidrug resistance phenotype reported was resistant to ampicillin, chloramphenicol, streptomycin, sulfonamides, and tetracyclines (ACSSuT), which was detected in 4.3% of isolates tested. The resistance trends for individual antibiotics are summarized in Figure 1. The antibiotics with the highest percentage of resistant isolates include ampicillin, streptomycin, sulfonamides, and tetracyclines; however, the percentage of isolates resistant to these drugs has either decreased or remained stable since 1999.

On the veterinary side, 51.9% of the *Salmonella* samples isolated from veterinary diagnostic sources were resistant to at least one antimicrobial agent with the ACSSuT phenotype also the most common resistance profile detected among veterinary isolates. Overall, when antimicrobial resistance data from both veterinary and human NARMS reports were compared, the trend appeared to indicate that the percentage of resistant isolates was greater in strains of veterinary origin. The trends for individual antibiotics are summarized in Figure 2. Veterinary-associated *Salmonella* isolates demonstrated the highest percentage of resistance to ampicillin, streptomycin, sulfonamides, and tetracyclines. Resistance to each of the drugs was on a general upward trend from 1999 to 2010, with the exception of sulfonamides. There have been sharp increases in resistance to amoxicillin/clavulanic acid, ceftriaxone, and ceftiofur among veterinary-associated *Salmonella* isolates. The increase in resistance among *Salmonella* to extended spectrum cephalosporins (ceftiofur and ceftriaxone) has become a significant public health concern due to the importance of ceftriaxone in the treatment of severe salmonellosis in children. Because ceftiofur-resistant organisms are cross resistant to ceftriaxone, the use of this antimicrobial agent in food animals has come under increasing scrutiny as a selective agent potentially responsible for the emergence and dissemination of ceftriaxone resistance in *Salmonella* and other enteric pathogens.

Mechanisms of Antimicrobial Resistance

The development of resistance in *Salmonella* to antimicrobial agents can be attributable to one of multiple mechanisms, which include production of enzymes that inactivate the drug, reduction of cell permeability, activation of efflux pumps, and modification of cellular targets. Resistance to penicillins and cephalosporins (i.e., ampicillin, cefoxitin, ceftiofur, and ceftriaxone) is commonly due to the production of β-lactamase enzymes that degrade the β-lactam ring of the antimicrobial agents. β-lactamases are a diverse group of enzymes, some with affinities for a limited number of antimicrobial agents, while others are able to degrade a wide array of antibiotics. Other enzymes inactivate the antimicrobial agents by modifying their structure, rather than degrading them. Resistance to aminoglycosides (i.e., amikacin, gentamicin, kanamycin, and streptomycin) in *Salmonella* is often the result of the production of modifying enzymes, which function by phosphorylating, acetylating, and adenylating certain aminoglycosides.

Other mechanisms of resistance involve the modification of the drug binding target of the cell. Resistance to quinolone and fluoroquinolone drugs (i.e., nalidixic acid and ciprofloxacin) is often associated with this mechanism. Mutations in the genes encoding the topoisomerase enzymes that are required for bacterial DNA replication alter the drugs binding site and prevent the antimicrobial activity of the drug. Resistance to tetracycline and chloramphenicol is often associated with the expression efflux pumps that reduce the level of antimicrobial drugs inside the bacterial cell. In addition to efflux-mediated resistance, some chloramphenicol resistance in *Salmonella* is associated with drug target modification by chloramphenicol acetyltransferases. The drugs trimethoprim and the sulfonamides function by competitively inhibiting different enzymes in the folic acid biosynthetic pathway in bacterial cells. Resistance to sulfonamides is often associated with genes that encode altered dihydropteroate synthetase enzymes that have a reduced affinity to the sulfonamides but function in folic acid biosynthesis. Likewise with trimethoprim resistance, resistance genes encode altered dihydrofolate reductases that have reduced affinity for the antimicrobial agent, allowing folic acid biosynthesis to occur in the presence of trimethoprim.

Mechanisms of Antimicrobial Resistance Dissemination

There are several mechanisms that are important for the dissemination of antimicrobial resistance; these include transformation, transduction, and conjugation. Natural transformation is characterized by the uptake, integration, and expression of free DNA from the environment. DNA is released into the environment from decomposing cells, damaged cells, or viruses and can be taken up by competent bacteria. Once DNA has entered the cell, it can be integrated into the chromosome or plasmids. If a resistance gene is incorporated into the recipient genome, the cell may develop resistance to the corresponding antimicrobial agent. In transduction, DNA is transferred from one bacterial cell to another by bacterial viruses (phages). Phages that have

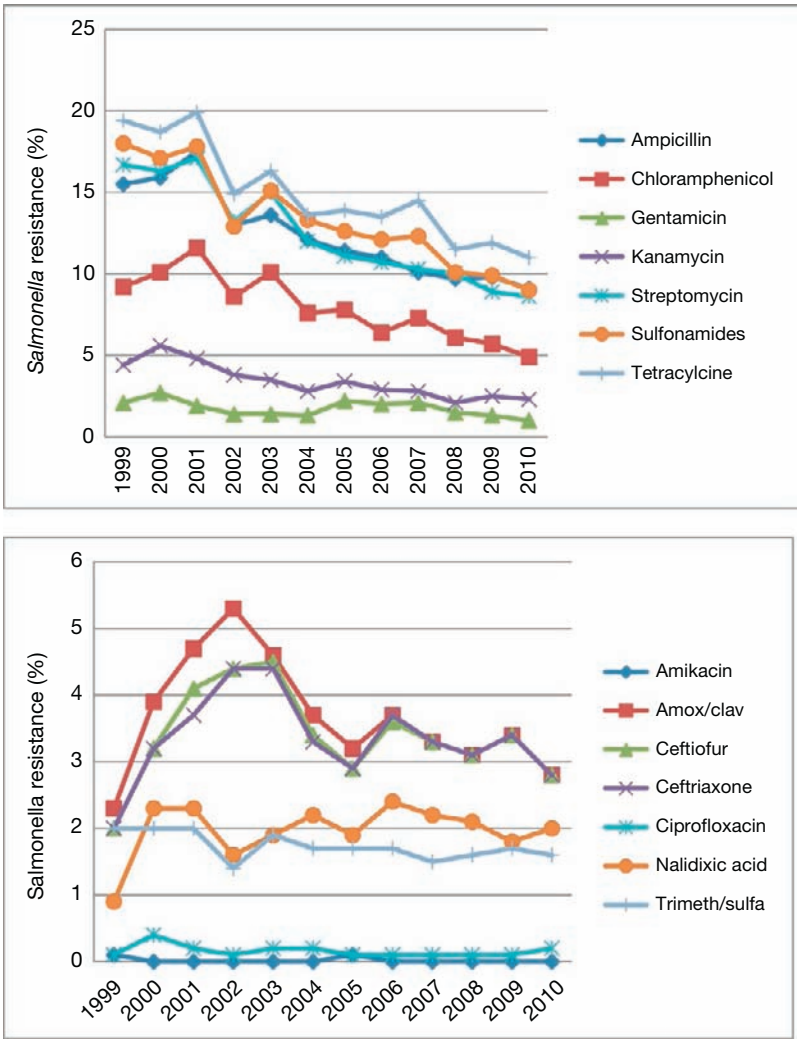

Figure 1 Trends in antimicrobial resistance in *Salmonella* from human sources from 1999 to 2010. Data are presented for Salmonella resistance to 15 different antimicrobial agents tested by the National Antimicrobial Resistance Monitoring System for Enteric Bacteria for all non-Typhi *Salmonella*. The abbreviations Trimeth/Sulfa and Amox/Clav are used in the symbol legend for the trimethoprim/sulfamethoxazole and amoxicillin/clavulanic acid drug combinations, respectively.

infected a bacterium can package small fragments of bacterial host DNA during viral replication. After the phage, with the host DNA fragment, is released into the environment, it can inject the new fragment of DNA into another bacterium it comes in contact with. As with transformation, the new piece of DNA can integrate into the host cell's chromosome and be expressed. With conjugation, transfer of plasmids is mediated by a cell-to-cell bridge (pilus), which is encoded by the plasmid. During conjugation, the donor cell produces a pilus that contacts a recipient cell and forms a mating pair. The plasmid begins replication and one strand of DNA is transferred to the recipient. Both strands finish replication in their respective cells resulting with the donor cell and a transconjugant (recipient cell with newly acquired plasmid).

Another important means of antimicrobial resistance dissemination is through integrons, which are mobile genetic elements that can be located on plasmids or the chromosome. Integrons contain the genes needed for insertion and excision of genetic material from plasmids or chromosomes and a complement of resistance genes. Class 1 integrons are the most common antimicrobial resistance integrons found in *Salmonella*. Class 1 integrons include a gene encoding an integrase (*intI*), a recombination site (*attI*), and a gene cassette. The gene cassette usually contains antimicrobial resistance genes and a short 59-base element (*attC*) that functions as a recognition sequence for the specific recombination site. The integrases can recombine the gene cassette into a specific recombination site. Immediately downstream of the gene cassette are the genes *qacE*Δ and *sul1*, which encode resistance to quaternary ammonium compounds and sulfonamides, respectively. Integron transfer of resistance genes has been shown to spread across serotype and even species barriers raising concern for potential resistance gene transfers from multiple sources to and among *Salmonella* strains.

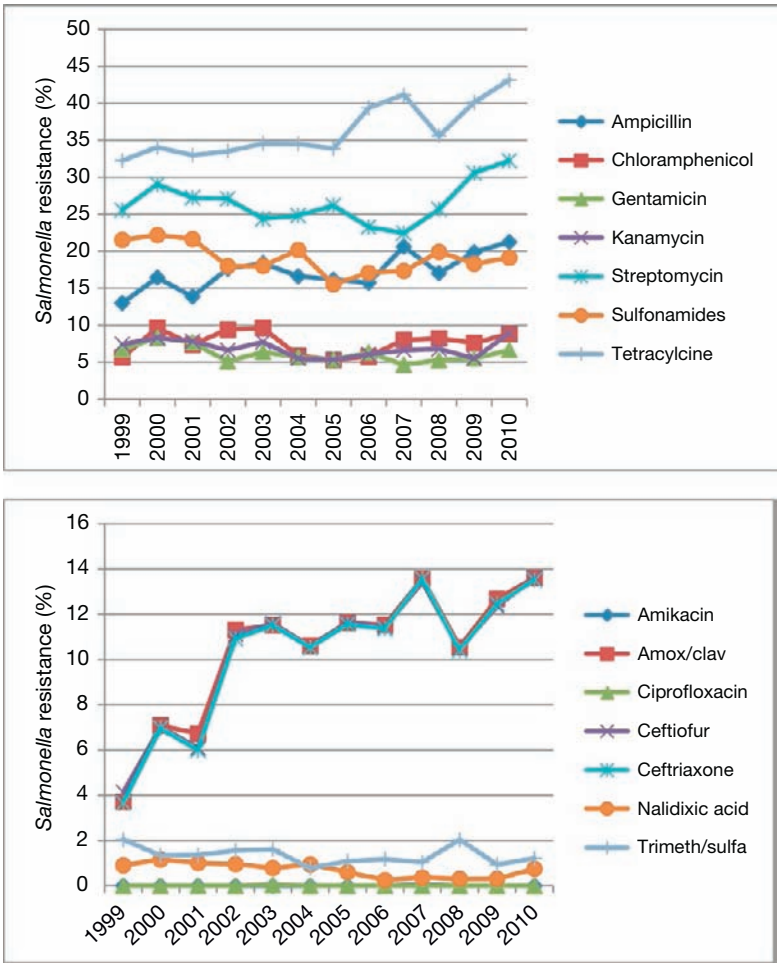

Figure 2 Trends in antimicrobial resistance in *Salmonella* from veterinary sources from 1999 to 2010. Data are presented *Salmonella* resistance to 15 different antimicrobial agents tested by the National Antimicrobial Resistance Monitoring System for Enteric Bacteria for all non-Typhi *Salmonella* tested. The abbreviations Trimeth/Sulfa and Amox/Clav are used in the symbol legend for the trimethoprim/sulfamethoxazole and amoxicillin/clavulanic acid drug combinations, respectively.

Conclusions

Salmonella are important human pathogens that cause millions of infections each year throughout the world. The pathogens have evolved to survive the hostile environment of the upper gastrointestinal tract and enter the intestines where they are often able to compete with intestinal microbiota and attach to the intestinal mucosa. This attachment facilitates the SPI-1 T3SS-mediated invasion of the intestinal epithelium. Effector proteins associated with the SPI-1 T3SS are likely responsible for the diarrhea that is typically associated with *Salmonella* gastroenteritis. Other effector proteins are involved in the engulfment and internalization of *Salmonella* that is the hallmark of infection. *Salmonella* can migrate through the intestinal epithelial cells and ultimately be taken up in macrophages or dendritic cells. *Salmonella* that are able to persist in these phagocytes can potentially spread to different parts of the body leading to increased pathology associated with the invasive infections.

Severe infections caused by *Salmonella* often require antimicrobial therapy. Resistance to antimicrobial agents is a public health concern in *Salmonella* especially with the increased resistance trends seen in veterinary isolates. Of great concern is the emergence of resistance to extended spectrum cephalosporins, such as ceftiofur and ceftriaxone, because ceftriaxone is the primary drug of choice for treating severe salmonellosis in children. *Salmonella* remains an important pathogen of both humans and animals, and research on understanding the mechanisms of pathogenicity and the development and dissemination of antimicrobial resistance is needed to help alleviate the burden of these pathogens.

Introduction

Salmonella remains one of the most important zoonotic pathogenic bacteria and is the causative agents of salmonellosis. The aim of this article is to give an overview of *Salmonella* and salmonellosis, starting by describing the characteristics of the microorganism *Salmonella*, including biochemical properties, physiology, classification, and nomenclature. Thereafter, the epidemiology of the organism is introduced, including the routes of transmission. Finally, the disease salmonellosis, the virulence mechanisms, and the prevalence in different types of food are described.

Characteristics of the Organism

Biochemical Properties

Salmonella are rod-shaped motile Gram-negative bacteria with flagella distributed uniformly over the cell surface (Figure 1). Nonflagellated variants and nonmotile strains containing dysfunctional flagella have been reported. *Salmonella*e are facultative anaerobic and nonspore-forming, able to utilize a wide variety of nutrients (chemoorganotrophic). They use both respiratory and fermentative metabolic pathways. Generally, *Salmonella*e are oxidase-negative and catalase-negative and grow on citrate as sole carbon source. Most strains produce hydrogen sulfide, decarboxylate lysine, and ornithine and do not utilize urea. Many of these traits are used when designing methods for identification, for example, selective xylose lysine deoxycholate agar plates used in the ISO 6579 standard method.

Classification and Nomenclature

The *Salmonella* genus is a member of the family Enterobacteriaceae and contains two species, *Salmonella enterica* and *Salmonella bongori*, each consisting of multiple serotypes. *S. enterica* is subdivided into six subspecies: *S. enterica* ssp. *enterica* (I), *S. enterica* ssp. *salamae* (II), *S. enterica* ssp. *arizonae* (IIIa), *S. enterica* ssp. *diarizonae* (IIIb), *S. enterica* ssp. *houtenae* (IV), and *S. enterica* ssp. *indica* (VI). *S. bongori* was formerly classified as subspecies V. *S. enterica* ssp. *enterica* is mainly associated with humans and warm-blooded animals, whereas the other subspecies are found in cold-blooded animals and the environment. This classification scheme has historically undergone a number of rearrangements over time, as a result of the methodological improvements to reveal the true relationship between bacteria in this group.

The subspecies of *Salmonella* are further separated into serovars according to the White–Kauffmann–Le Minor scheme. The separation of serovars is based on antigenic polymorphisms of lipopolysaccharide (O antigens), flagellar proteins (H antigens), and capsular polysaccharides (Vi antigens). Currently, about 2600 serovars of *Salmonella* have been identified, where most of the serotypes belong to *S. enterica* (Figure 2).

Physiology

Salmonella can be found in natural environments, such as water, soil, and plants, but it does not seem to grow significantly there. However, since *Salmonella* are known to be quite resistant toward different environmental factors, it can survive for weeks in water and several years in soil, as long as the conditions are favorable. It has also been reported to survive for extended time periods in foods stored frozen or at room temperatures. The optimal growth temperature for *Salmonella* is 37 °C, but the organism can grow in a quite broad range (7–45 °C). In extreme cases, *Salmonella* growth in food has been observed at 2–4 °C. *Salmonella* can grow at pH 4.5–9.5, with an optimum pH for growth at 6.5–7.5. The water activity (a_w) needs to be ≥ 0.93 to support the growth of *Salmonella* in food and it is generally inhibited by the presence of 3–4% NaCl.

Salmonella has a great ability to adapt to various more or less unfavorable environmental conditions, such as low pH, high temperature, and low a_w. This makes these bacteria able to outcompete other microorganisms in, for example, different food production chains possibly leading to problems with cross contamination and biofilm formation in food production environments.

Epidemiology

Salmonella is found worldwide and is an important zoonotic pathogen. It is estimated that *Salmonella* is responsible for 93.8 million cases of human gastroenteritis globally each year, and of these, 80.3 million cases are estimated to be foodborne. In the EU, 95 548 confirmed cases of human *Salmonella* infections were reported to the European Food Safety Authority in 2011. However, cases of salmonellosis are considered to be underreported as many of the sick individuals do not seek medical attention.

Approximately 50 serovars (all in subspecies *enterica*) account for 99% of all clinical isolates from humans and warm-blooded animals. The two serotypes, *Salmonella* ser. Enteritidis and *Salmonella* ser. Typhimurium, are the most frequently reported serovars, together accounting for almost 70% of all human *Salmonella* infections in Europe. Human *Salmonella* ser. Enteritidis cases are mostly associated with the consumption of contaminated eggs and poultry meat, whereas *Salmonella* ser. Typhimurium cases most commonly are linked with the consumption of contaminated pork, beef, and poultry meat.

The routes of *Salmonella* transmission to humans include the environment, contact with animals, and human-to-human contact (Figure 3). In industrialized countries, the main source of *Salmonella* infections is contaminated animal-derived food products, notably fresh meat and eggs as identified, for example, using source attribution models based on outbreak data. In developing countries, a large proportion of the human cases are from contaminated vegetables, water, and human-to-human

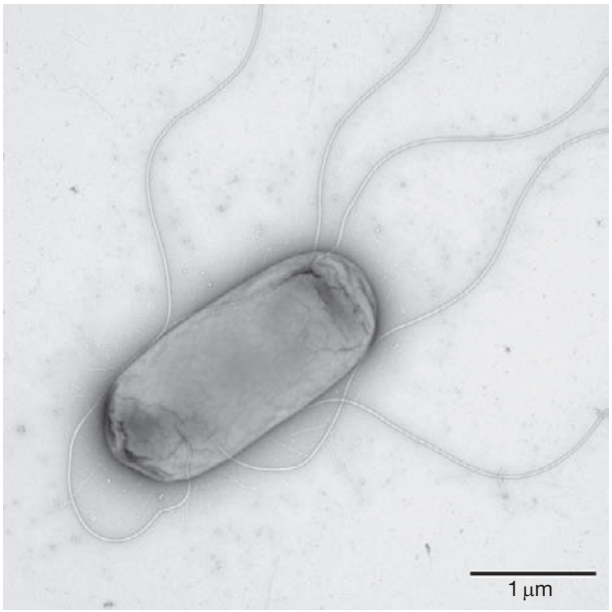

Figure 1 A light microscope picture of *Salmonella*. ©Dr. Jochen Reetz, Federal Institute for Risk Assessment (BfR), Berlin, Germany.

transmission. Recently, there has been an increase in the reported outbreaks of salmonellosis caused by contamination of fruits and vegetables possibly related to the greater worldwide trade with fresh produce.

Salmonellosis

Symptoms and Infectious Dose

S. enterica is a common agent of foodborne infections and the human infections can range from enteric fever (typhoid fever) to nontyphoidal *Salmonella*, which normally cause gastroenteritis. A few *Salmonella* can cause infection, especially for the more susceptible part of the population (e.g., young, elderly, and immunocompromised), but the infective dose is generally considered to be $>10^4$ CFU g^{-1}. Low infectious doses have been reported especially for food with a high fat content, including cocoa butter in chocolate and animal fat in meat or with food or ingredients with low a_w values.

Enteric fever is associated with serotypes Typhi and Paratyphi A, B, and C, and symptoms include diarrhea, prolonged and spiking fever, abdominal pain, headache, and prostration appearing after an incubation period of 7–28 days. After the initial acute phase of the disease, an asymptomatic chronic carrier state is common. Under certain conditions, it is possible for *Salmonella* to cause invasive (systemic) disease, entering the

Hinton (ed.), Geneva, p. 22. Available online: http://apps.who.int/iris/bitstream/10665/66402/1/VPH_83.42_%28p1-p66%29.pdf (Date: July 2014).

blood stream and spreading throughout the body. The nature and severity of *Salmonella* infections depend on several factors such as the infecting *Salmonella* serotype, virulence of the strain, infection dose, and the host. Treatments of enteric fever include the use of supportive therapy and/or antibiotics to avoid systemic infections. However, strains resistant toward several antibiotics have been increasingly found, limiting the usefulness of antibiotic treatment.

Salmonellosis with nontyphoidal *Salmonella* strains has a shorter incubation period of 8–72 h after ingestion of the pathogen. Gastrointestinal infections are primarily caused by serovars such as Enteritidis and Typhimurium. Usually, *Salmonella* colonize the intestine by attaching to the epithelial cells using the fimbria, followed by invasion of the intestinal mucosa and multiplication in the gut-associated lymphoid tissue. Symptoms include nonbloody diarrhea and abdominal pain and the illness is usually self-limiting. Usually, only supportive therapy is used to treat nontyphoidal salmonellosis since the use of antibiotics has been found to prolong the carrier state. Nontyphoidal salmonellosis can also sometimes result in systemic infections and chronic conditions such as aseptic reactive arthritis.

Pathogenicity and Virulence Factors

Salmonella enterica possesses a large set of virulence factors enabling it to withstand the host defense mechanisms, invade the gut epithelial layer, and persist in a localized area during gastrointestinal infections or even spread systemically in the case of typhoid fever. Because bacterial growth and the expression of those factors often lead to immune activation, it has to be well regulated depending on the invasion level by regulatory proteins or two-component-systems (TCSs).

One of the first lines of defense is the antimicrobial condition of the stomach. To survive especially at low pH, *Salmonella* uses a complex acid tolerance response (ATR) that consists of more than 50 acid shock proteins. The ATR is regulated depending on the growth phase by either *rpoS*-encoded σ^S (organic acids) or PhoPQ TCS (inorganic acids) during exponential growth and the OmpR/EnvZ TCS in the stationary phase, which is therefore also essential for persistence in the host cell phagosome.

Nevertheless, only 1% of the bacteria reach the gut and adhere to the epithelium by the fimbriae, nonfimbrial adhesins like SiiE or BapA, and autotransporter proteins like ShdA, MisL, or SadA. The repertoire of fimbriae is strain-specific and consists of more than 20 different loci, which might be important for tissue and cell tropism. Type 1 fimbriae (Fim) bind to enterocytes, long polar fimbriae (Lpf) bind to microfold (M) cells, whereas the plasmid-encoded fimbriae (Pef) and thin aggregative or curli fimbriae (Tafi) adhere to epithelial cells *in vitro*.

For the subsequent invasion of epithelial cells, macrophages, and dendritic cells, as well as for the intracellular persistence, *Salmonella* possesses two type III secretion systems (T3SSs). They are encoded on two *Salmonella* pathogenicity islands (SPI-1 and SPI-2), which are the most studied SPIs out of 21 known to date. Most of them are found in the majority of subspecies I *Salmonella* strains but a few are

serovar-specific, like SPI-14 for *Salmonella* ser. Typhimurium or SPI-7, SPI-15, SPI-17, and SPI-18 for *Salmonella* ser. Typhi. *Salmonella* uses its SPI-1 T3SS to secrete at least six effector proteins into the host cell cytosol that are important for the invasion process: *Salmonella* outer proteins SopB, SopE, and SopE2 induce by activating Rho GTPases Cdc42, Rac1, and RhoG an actin rearrangement, while *Salmonella* invasion proteins SipA and SipC stabilize the newly formed actin filaments. This leads to a membrane ruffling followed by an uptake of the bacteria into macropinosomes. Fission of the membranes is supported by SopD. Especially SopB, SopE, and SopE2 activity has, besides its role in the invasion process, other important consequences. SopE/E2 contribute to inflammation by inducing MAPK pathways leading to IL8 expression in epithelial cells and inducing IL1-β secretion and pyroptotic effects in macrophages by enhancing caspase-1 activation. SopB is directly involved in promoting diarrhea by elevating intracellular Ca^{2+} level and inducing a chloride and water efflux. Another SPI-1 effector, SipA, has also been shown to contribute to fluid efflux.

The SPI-2 T3SS and its effectors have been shown to promote intracellular survival although some effectors of both T3SSs are acting at the same time, which presumes a complex coordination of both SPI-1 and SPI-2 effector genes. HilA encoded by SPI-1 is known as master regulator of the SPI-1 effector expression, whereas three different TCSs SpiR/SsrB, EnvZ/OmpR, and PhoPQ are regulators of the SPI-2 virulence genes. The cross talk of the SPI-1/SPI-2 regulatory network is mediated by HilD, which controls both HilA expression and SsrAB expression. The main function of the 20 different SPI-2 effectors known to date is to facilitate intracellular replication by redirecting intracellular vesicular trafficking and maturation of the *Salmonella*-containing vacuole (SCV). The main effectors in that process are SifA, SseG, and SseF, which provoke the motion of the SCV in a juxtanuclear position, and SopD2, SifA, and PipB2, which are required for *Salmonella*-induced filament (Sif) formation by interacting with kinesin and the microtubule network. The function of Sifs for pathogenesis is still not completely understood but a Sif-forming ability has been shown to be necessary for full virulence in mice.

In addition to the SPIs, a lot of virulence factors are encoded on mobile elements like prophages and plasmids. Certain *Salmonella* serovars harbor a serovar-specific, 50–100 kb large, low-copy-number plasmid. Part of that plasmid is the 8 kb *Salmonella* plasmid virulence (*spv*) operon. Signals resulting in *spv* transcription are typically conditions of the SCV interior like iron or nutrient depletion, elevated temperatures, a low pH or the stationary growth phase. The operon is regulated by SpvR and the chromosomal *rpoS*-encoded σ^S. This plasmid seems to be an important component for intracellular persistence and growth, cytotoxicity, and the systemic spread although such a plasmid is missing in prominent serovars causing typhoid or paratyphoid like *Salmonella* Typhi and Paratyphi A. In addition to *spv*, some serovars harbor specific virulence genes on their plasmids like *rck* that influences the serum resistance of *Salmonella* ser. Typhimurium and Enteritidis. The fimbrial gene *pef* is encoded on *Salmonella* ser. Typhimurium, Enteritidis, and Choleraesuis but not on *Salmonella* ser. Dublin or Gallinarum plasmids.

Recently, a putative virulence plasmid called pR(ST98) has been described in *Salmonella* ser. Typhi, which supports drug resistance and cytotoxicity to macrophages. Even antimicrobial resistance is often transmitted by the so-called R plasmids. For example, the multidrug resistance (MDR) phenotype of *Salmonella* ser. Typhi is associated with an (Inc)HI1 plasmid. In addition to those factors, *Salmonella* ser. Typhi harbors some exclusive virulence factors, which might explain its strong virulence in humans. A so-called typhoid toxin (CdtB/PltA/PltB) similar to the pertussis toxin has been identified, which is expressed intracellularly and causes para- and autocrinely cytotoxic effects. Target specificity is accomplished by specific carbohydrate moieties on surface glycoproteins.

Another important factor is the expression of a virulence (Vi) capsular polysaccharide encoded by the *viaB* locus in a few *Salmonella* serovars. Depending on osmolarity, the expression of the Vi antigen is regulated by TviA and the EnvZ/OmpR TCS. Due to a regulatory network with RcsB, the induction of *tviA* and suppression of flagellin as well as T3SS genes are coregulated and support evasion from immune recognition.

Altogether, *Salmonella* evolved a complex network of virulence genes and regulators enabling it to successfully adapt to different environmental conditions and evade or rather manipulate the host immune defense mechanisms in a serovar-specific and host species-specific manner to form its own niche.

Occurrence in Food

Persistence in the Food Chain Environment

The adaptation and persistence of *Salmonella* in food production chains have been suggested to be partly a result of bacterial attachment and surface colonization. Colonization of *Salmonella* on surfaces in contact with food provides a reservoir of bacteria that can increase the risk of contamination in the production line. *Salmonella* present in biofilm are generally more resistant toward environmental stresses, for example, disinfections, desiccation, organics acids, and heat. Besides attaching to the materials used in the production line, *Salmonella* can also attach to surfaces of the food product or be localized inside the food item for products such as vegetables and fruits.

Salmonella in Meat and Eggs

Salmonella can enter at any stage of the food chain, from the livestock feed, at the slaughterhouse or packing plant; in manufacturing, processing, and retailing of food; and through catering and cooking at home. Colonized pigs constitute the main reservoir for carcass contamination in slaughterhouses and many of the carcasses harbor *Salmonella* on the skin or in the rectum. However, the slaughter line is an open process with many possibilities for cross contamination. Carcasses can throughout the slaughter line be contaminated from tools and equipment used for the slaughtering, and since the equipment can be very difficult to clean and sterilize, the *Salmonella* has the possibility to colonize and form biofilms. Eggs and egg products are another important source of *Salmonella* and salmonellosis. *Salmonella* are usually located on the shell surface but can also be found inside the egg making sanitation

difficult. Outbreaks associated with the consumption of eggs or egg products are common.

Recent data on monitoring of the *Salmonella* prevalence in the United States found the following percent positive rate of *Salmonella* per product class for the calendar year 2012: young chicken (4.3%), market hog (1.3%), cow/bull (0.0%), steer/heifer (1.1%), ground beef (1.9%), ground chicken (28%), ground turkey (11%), and turkey (2.2%). Data from the European Union report the following % positive rates: broiler meat and products thereof (5.9%), pig meat and products thereof (0.7%), and eggs and egg products (0.1%). Note that these data are difficult to compare as the sampling systems and analysis methods differ between different countries.

Salmonella in Fresh Produce

Recently, there have been an increasing number of reported cases and outbreaks due to *Salmonella* in fruits and vegetables, for example, herbs, melons, and tomatoes, and products derived from fruits and vegetables, for example, peanut butter. Moreover, *Salmonella* has the ability to attach and survive in or on fresh produce and might contaminate through cultivation practices, handling, or processing. A large number of outbreaks have been caused by the use of contaminated water sources used to irrigate and wash produce crops. Fresh produce is mostly consumed without a heating step that would kill *Salmonella*, and as *Salmonella* also can be found inside the crops, rinsing is sometimes ineffective.

Other Sources

Salmonella can also be found in a variety of other food items, such as milk, chocolate, and fish, and outbreaks due to these vehicles have been reported. Other routes of transmission include contact with animals and person-to-person transmission (**Figure 3**).

Conclusions

Salmonella and salmonellosis (both enteric fever and nontyphoidal salmonellosis) remain significant problems worldwide, leading to increased public health concerns and economic burden on society. *Salmonella* adapts easily to various environmental conditions, giving it a competitive advantage toward other microorganisms, and enables survival in many different food products and food production chains. The molecular mechanisms for salmonellosis are complex, combining several different systems. This also contributes to the success of *Salmonella* to survive and proliferate in its hosts. Important vehicles contributing to the spread of *Salmonella* are different types of food, in particular meat, eggs, and fresh produce.

Sanitization

J Rovira, University of Burgos, Burgos, Spain

© 2016 Elsevier Ltd. All rights reserved.

The General Framework of Sanitation

Sanitation is the combination of activities and procedures conducted in a food-processing plant with the aim of obtaining a manufacturing environment free from hazards that may contaminate the foodstuffs processed therein and that could therefore threaten food safety for the consumer and shorten the shelf life of the foodstuff manufactured.

It is a broad-ranging concept that covers the correct choice of location for the construction of the food-processing plant, its hygienic design, careful selection of equipment designed to facilitate hygienic cleaning thereof, a pest-control plan, a waste-treatment plan, and, obviously, an effective cleaning and disinfection plan.

The final aim is to minimize the presence of contaminants in the manufacturing environment as far as possible, thereby preventing them from entering the foods processed. Sanitation is a basic and essential requirement for fully effective application of the Hazard and Critical Control Points (HACCP) system and to guarantee the safety and quality of the products manufactured in the food-processing plant.

In addition to allowing food companies to meet regulatory standards, the advantage of correct sanitation includes guaranteed food safety by eliminating the vast majority of physical, chemical, and microbiological contaminants present on tools, equipment, and surfaces, thereby preventing them from affecting consumer health. Sanitation also guarantees food quality, preserving its sensory characteristics and increasing its shelf life, and aids correct maintenance of the machinery, equipment, and facilities used by preventing corrosion caused by microorganisms or chemical reactions. In addition, correct sanitation transmits an impression of hygiene and order to both clients and consumers and improves the working environment. In short, it increases the efficiency of food production without compromising the brand name during possible food crises.

The cost of incorrect sanitation is a poor-quality product, increased maintenance costs, delays in completing customer orders, interruptions to production, the need for product reprocessing, client/consumer complaints, the possibility of product recalls, with their associated costs, including civil liability, and damage to the company's image.

Among the various actions and plans that allow correct sanitation of the food-processing plant, the cleaning and disinfection plan is perhaps the most important. Clearly, this plan will be more effective if the other actions have been correctly implemented. In other words, the plant should have been located at a site far from sources of contamination, should have an appropriate hygienic layout, and should use equipment and machinery purchased with a hygienic design that facilitates the cleaning thereof, and the pest-control and waste-treatment programs should be correctly implemented, all of which will favor and greatly improve the effectiveness of the cleaning and disinfection plan.

Cleaning and Sanitization: Situation of the Concepts

As its name implies, the process of 'cleaning and sanitization' comprises two parts. In the first step, cleaning comprises the removal of all soil from the equipment and manufacturing environment, enabling subsequent application of a sanitizer to reduce the number of microorganisms that have not been removed in the previous stage more effectively. The sanitization process then eliminates microorganisms that may contaminate foodstuffs from contact surfaces or the manufacturing environment. Sanitization is therefore a specific part of the broader process of sanitation referred to in the preceding text.

Cleaning covers the set of practices and processes used to eliminate all soil from surfaces and the manufacturing environment. Its main objectives are (1) to remove large foodstuff remnants such as shells, leaves, and pieces of food; (2) to remove food component residues, such as fat, blood, proteins, and sugars, which may serve as nutrients for microorganisms; (3) to remove other types of soil inherent to the foodstuff manufacturing process, such as containers, labels, dirt from the operators, machinery and equipment, dust, soil, and chemicals (lubricants, additives, etc.); (4) to treat the surfaces to ensure effective disinfection (free from organic matter and/or mineral deposits); and (5) to remove some of the microbial contamination by sweeping.

Disinfection, in turn, concerns elimination of the majority of microorganisms from work surfaces and facilities (manufacturing environment). Its objectives therefore include the total destruction of all pathogenic microorganisms and a reduction in nonpathogenic microorganisms to a level at which they are no longer detrimental to the quality or shelf life of the products.

Cleaning must always be performed prior to sanitization. Sanitizers must never be used on dirty surfaces as organic matter inhibits their action. As such, it is important to remove all soil particles that form on surfaces, such as biofilms and fat or protein films, deposits of mineral origin (e.g., limescale), or milkstone. Incorrect removal of these dirt films and incrustations contributes to the proliferation of microbiological contamination and promotes biofilm formation. Such films can form by way of various mechanisms, such as soil redeposition phenomena, chemical adsorption as a result of chemical reactions between surface molecules and soil molecules, physical adsorption as a result of van der Waal's-type electrostatic interactions, and adsorption to the porous structure formed by the surface.

A biofilm consists of microorganisms adhered to a surface and an extracellular polymeric substance (EPS), mainly comprising polysaccharides and glycoproteins, secreted by them. Biofilms are used by microorganisms to defend themselves against their surroundings by providing protection against the action of biocides and helping them to proliferate. They

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00609-7

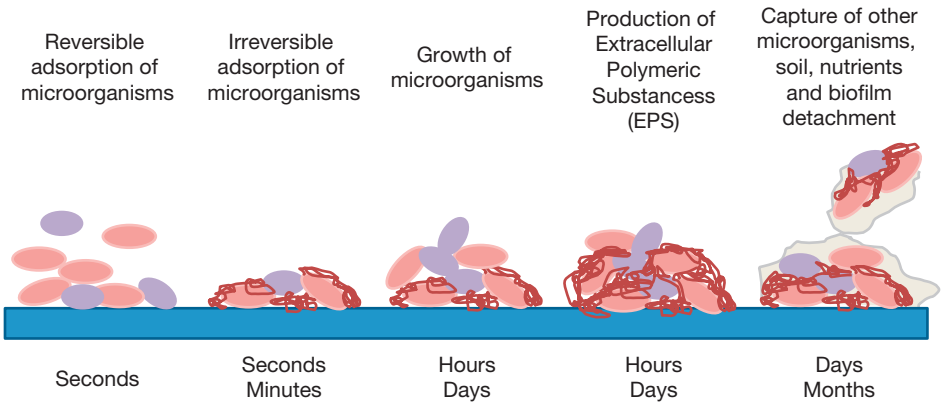

Figure 1 Biofilm formation.

usually contain various microbial species at the same time, including bacteria, molds, algae, and even protozoa. The presence of water or moisture on the surfaces is essential for biofilm formation. In the food industry, soil films and incrustations represent a highly suitable substrate for biofilm formation.

Biofilm formation is shown graphically in Figure 1. In the first stage, the microorganisms reversibly attach themselves to the surface. In some cases, if they encounter soil stuck to the surface or cracks in it, they may attach irreversibly. These microorganisms subsequently multiply and begin to excrete EPS, which envelops them in a matrix and protects them against external attacks. This matrix captures more soil and nutrients, thus allowing the biofilm to continue to grow. Once it reaches a certain size, pieces, which go on to colonize other surfaces or the foodstuffs themselves, thereby acting almost as microorganism reservoirs, begin to detach.

Biofilms provide four main benefits for the microorganisms, namely, (1) protection against the action of adverse agents, such as sanitizers, (2) the provision of nutrients for growth, (3) a reduced likelihood of dehydration (water represents ~95% of its composition), and (4) easier transfer of genetic material between microorganisms.

As these formations may contain pathogenic microorganisms and present greater resistance to disinfection, the probability of contaminating the foodstuff and provoking an outbreak of food poisoning is higher; therefore, the presence of biofilms on contact surfaces in the food industry is considered to be a clear health risk.

Cleaning: Dealing with Sinner's Cycle

As mentioned earlier, cleaning is the first step to follow for correct sanitization. However, as can be seen from Table 1, the main types of soil that can be found in a food-processing plant vary according to their source, composition, and removal characteristics.

In order to ensure correct cleaning, the five factors that constitute Sinner's cycle must be taken into account (Figure 2). These factors are water, temperature, chemical compounds, time, and mechanical action.

Table 1 Main types of soil found in the food industry

Criteria	*Type of soil*	*Examples*
Source	Animal	Blood, fats, proteins,
	Plant	Sugars, fats
	Mineral	Oxide, dust
Composition	Organic	Fats, proteins, sugars
	Inorganic	Mineral substances, carbonates
Removal methods	Soluble in water	Sugars, sodium chloride, calcium chloride, etc.
	Soluble in acid solutions	Iron oxides, Ca and Mg carbonates, milkstone
	Soluble in alkali solutions	Fats, proteins, blood
	Insoluble	Paints, inks, tars, wheel prints from pallet trucks, lubricants

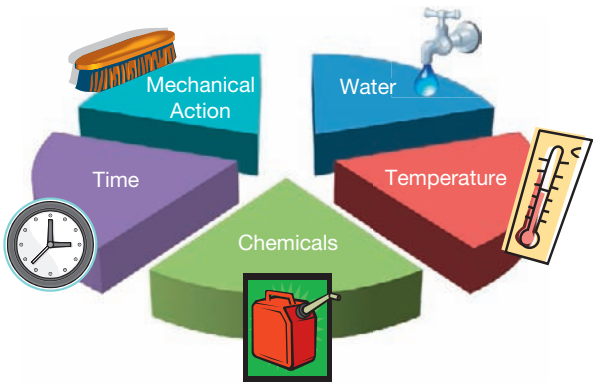

Figure 2 Sinner's cycle.

Water

Water is the most important and essential factor in the cleaning process as it acts as a vehicle via which cleaning is performed. It is the solvent for cleaning products and usually represents 95–99% of the cleaning solution. Moreover, it dissolves some of the components of soil. In addition, it often provides the mechanical energy (pressurized water or turbulence) or heat (temperature) for the process and is the vehicle via which remnants of soil dissolved, dispersed, or in suspension and remnants of cleaning products are removed.

In addition to its cleanliness, one of the most important characteristics of cleaning water to be taken into account is its hardness, in other words the concentration of Ca^{2+} and Mg^{2+} ions, which form insoluble salts that bind strongly to the substrate and result in the formation of limescale. As such, it is important to use soft water in the cleaning process and avoid the use of hard water ($CaCO_3$ concentrations higher than 250 ppm). Consequently, water hardness has an impact on the efficacy of cleaning and disinfection as well as on the performance of equipment at the plant. Some of the problems caused by hard water include a reduced efficacy of cleaning and disinfection products and a reduction in the efficacy of the equipment used to undertake thermal treatments (e.g., boilers or cookers) as a result of the deposition of limescale on the transfer surfaces and the contribution to biofilm formation on the equipment and surfaces.

Temperature

The use of heat is often necessary or advisable as it improves the efficacy of the mechanisms in the cleaning process. An increase in the temperature of the cleaning water increases the speed of the reaction between the detergent and the soil, reduces the viscosity of fats and oils and favors their dissolution, increases the solubility of the soluble components of soil, and decreases the surface tension of the water, thereby improving its wetting power. The recommended usage temperature for cleaning water is usually 15 °C above the melting point of fats, meaning that a water temperature of 55–72 °C should be used. However, it should be noted that higher temperatures may have the opposite effect as proteins are denatured at temperatures higher than 75–80 °C, thus allowing them to stick more strongly to the substrate to be cleaned and making their removal more difficult. In addition, very high temperatures may also degrade or deactivate some detergents and disinfectants, thereby reducing the efficacy of the cleaning and disinfection process.

Chemical Products

A cleaning product or detergent is a substance or mixture of substances that, when applied under specific conditions, is able to remove soil from the surface to be cleaned. The cleaning products used in practice are substances that adapt to the needs of each type of soil to be removed in the best manner possible. As such, the product to be used may vary markedly depending on the type of soil.

In order for a cleaning product to be as effective as possible, in addition to reacting chemically with the soil particles to be removed, it must also possess certain properties that enhance the cleaning action. For example, they must present a high wetting power, meaning that such products must contain surfactants that can reduce the surface tension of the cleaning solution in order to cover a greater cleaning surface and increase the penetrability of the product. They must also be able to dissolve, disperse, and/or emulsify the components of the soil and to reduce the hardness of water to prevent limescale formation (sequestering effect). In addition, they must be able to prevent redeposition of dispersed soil particles by adsorption and increase the rinsability in order to improve and promote fast drying of the surfaces to be cleaned. In general, no single substance possesses all these characteristics simultaneously. Therefore, cleaning solutions are usually a combination of different chemicals that present one or more of these actions to a greater or lesser degree. A list of these chemicals, with their most relevant actions, can be found in Table 2.

In light of the preceding text, an ideal detergent must be readily soluble in water at the temperature used, noncorrosive for equipment and facilities, nonirritant for the skin and eyes, nontoxic, free from added aromas, easy to rinse, biodegradable, stable when stored, inexpensive, and suitable for the type of soil and cleaning procedure. Detergents do not normally need to be bactericidal, although some compounds possess this property (Table 3).

Time

The cleaning process is a chemical reaction in which the cleaning products react with the soil to be eliminated. As with all chemical reactions, this is not instantaneous and a period of time is required for it to occur and to obtain an effective cleaning process.

The time that must be used for the cleaning process mainly depends on the temperature at which the cleaning process is performed and the capacity of the cleaning product. Thus, more powerful (or more concentrated) products require shorter contact times.

Time is normally a limiting factor related to the production capacity of the food-processing plant. However, it must be remembered that a lack of time must be compensated with more energy, higher temperatures, and/or higher concentration of cleaning agents (Sinner's cycle).

Mechanical Action

Mechanical energy is important during the cleaning process as it enhances separation of the soil from surfaces, including biofilms, divides and breaks up soil particles, and maintains them in suspension, thus preventing it from being redeposited. This mechanical action can be applied using various methods depending on the type of surface to be cleaned. For example, water at high pressure, manual scrubbing, circulation of the detergent solution through closed circuits, and automatic washing can be used.

Spraying water onto the surface to be cleaned under pressure means that soil is more readily swept away, separated, and broken down into small particles, thereby favoring its dispersion. Pressurized water can be sprayed manually when used to clean surfaces of the food-processing plant or equipment surfaces or automatically when washing machines are used to clean molds or boxes, for example. If a manual system is used, the plant must be equipped with a sufficient number of hookup stations with their corresponding hoses and spray guns, which themselves should be equipped with different types of nozzles in order to perform different functions during the cleaning protocol, such as washing, foam generation, or rinsing. These hookup stations are normally used to apply water and chemicals, either detergents or sanitizers. The working pressure used may be low (3–6 kg cm^{-2}) when water from

Table 2 Main cleaning substances used in the food industry

Cleaner/ detergent	*Action against soil*	*Most commonly used*	*Effects*
Alkali	Displacing, emulsifying, saponifying, and peptizing agents Prevents limescale	Sodium hydroxide and caustic soda (lye)	Corrosive to aluminum and galvanized steel (especially lye)
Phosphates	Emulsifying, peptizing agent, softening water, and preventing soil deposition and mineral precipitation		Harmful to the environment
Wetting/ surfactants	Promote wetting and rinsing Emulsify, disperse, and suspend soil such as oil as small droplets in water		Are noncorrosive, soluble in cold water, and not affected by hardness
Anionic	pH-neutral, compatible with acids or bases		
Nonionic	Better for oils Some will suppress foaming		
Cationic	Wetting agents	Typically quaternary ammonia compounds (QACs)	
Acids	Good for cleaning alkali soil and removing minerals, especially calcium and magnesium		
Inorganic		Phosphoric acid, hydrochloric acid, and sulfuric and nitric acids	Strong and corrosive, not recommended for food plant use
Organic		Strong and corrosive, not recommended for food plant use	More commonly used in food plants
Chlorinated cleaners	Increase peptization, minimize limescale Make alkaline cleaners more effective		
Chelating agents	Control mineral deposits through water softening Displace soil through peptization	Ethylenediaminetetraacetic acid (EDTA)	

Table 3 Main characteristics of an ideal cleaner or detergent used for food sanitation

Readily soluble in water at the use temperature
Noncorrosive for equipment and facilities
Nonirritant for the skin and eyes
Nontoxic
Free from added aromas
Easy to rinse
Biodegradable
Stable when stored
Inexpensive and easy to handle
Suitable for the type of soil and cleaning procedure
Sanitizing or disinfectant capability not necessary

the distribution network is used; medium (15–30 kg cm^{-2}), usually applied to generate foam; or high (>30 kg cm^{-2}) when high-pressure lances are used or in compact washing machines. High-pressure lances should not be used when food-processing plant surfaces are cleaned as they generate aerosols containing microorganisms in suspension, which may recontaminate zones that have already been cleaned.

During manual scrubbing, the mechanical action is generated by the operator performing the cleaning, using brushes, scourers, brooms, etc. Manual scrubbing is usually used for machinery in which water cannot be freely used, such as those that need to be dismantled in order for the internal parts to be correctly cleaned and also as support for other methods when the soil is deeply encrusted.

A cleaning in place system comprises circulating a cleaning solution through closed circuits that cannot be reached using standard methods, such as the cleaning of ducts, tubes, and pasteurizers. Circulation of a liquid (water or cleaning solution) through a tube at the appropriate flow rate generates turbulence by collision of its molecules against the walls of the tube. The solution is circulated in the opposite direction to that used normally in order to remove the soil from difficult regions such as bends and dead spaces. This type of cleaning is commonly used in liquid foodstuff processing plants, such as those used to manufacture fruit juices or dairy products.

Automatic washing is performed using rotating brushes that scrub the surface to be cleaned, thereby removing the dirt. This method is normally used to clean large surfaces, such as floors or conveyor belts. Floor cleaners are usually equipped with a brush to collect the water and dry the surface that has been cleaned. The use of squeegees and shovels is preferred for floor cleaning rather than brooms or brushes as squeegees are easier to clean than the latter, which can become encrusted with food material.

General Procedure

The cleaning process usually comprises three different phases: separation of the soil from the surface, dissolution of this soil in the cleaning solution, and prevention of soil redeposition. The factors described earlier play a role in these three phases to a greater or lesser extent. In the first phase, it is important to apply heat and mechanical energy together with the detergents in order to separate the soil stuck to the surface. Some of the compounds present in the formulation of the cleaning product play a role in the second phase by dissolving the soluble

components of the soil, emulsifying any fats and dispersing insoluble soil particles. Finally, the aim of the third phase is to retain the soil in the cleaning solution and prevent it from being redeposited on the surface to be cleaned. To this end, it is essential to maintain the cleaning solution in motion to prevent the precipitation of mineral substances and, finally, to remove the cleaning solution together with the soil from the surface to be cleaned. Once the surface has been cleaned, it is ready for the following disinfection phase.

To prevent cross contamination with the materials used during the cleaning phase, they must be regularly deep-cleaned and disinfected. Similarly, the cleaning solution must be changed regularly in order to maintain its active components in their optimal state.

Sanitizing and Disinfection

Once the cleaning step, including rinsing, has been correctly carried out, the process can proceed with the sanitizing step. It has been observed that some pathogens are able to survive for long periods of time on hard, nonporous surfaces. This is the case for hepatitis A virus and rotavirus, both of which can survive for up to 1 month on this type of surface. Moreover, noroviruses can survive for around 40 days on the same surfaces, and some foodborne pathogens, such as *Listeria monocytogenes*, can persist for periods ranging from several months to up to 10 years.

As was mentioned in the preceding text, the main aim of cleaning is not to kill or eliminate the microorganisms present in the food-processing plant. However, if cleaning is performed regularly and effectively, a significant reduction in the number of microorganisms of around 2–3 logs can be achieved. Moreover, additional agents, known as sanitizers and disinfectants, are required to sanitize or disinfect the surfaces of such plants. Sanitization follows cleaning and comprises the application of heat or chemicals to a correctly cleaned and thoroughly rinsed surface.

In a processing plant, it is necessary to distinguish between food-contact and non-food-contact surfaces (NFCS). Food-contact surfaces (FCS) are those belonging to any equipment or utensil that normally comes into direct contact with foodstuffs or surfaces normally in contact with them, such as food-processing equipment, conveyor belts, knives, cutting boards, and operators' hands. In contrast, non-NFCS are those that do not come into direct contact with food in the processing plant, such as equipment casings, floors, drains, walls, and walkways, among others.

Definitions

Although they are both used in the sanitization/disinfection step and normally with the same meaning, it is important to distinguish between sanitizers and disinfectants.

Sanitizers reduce, but do not necessarily eliminate, the number of microorganisms on surfaces that come into contact with food to levels considered safe according to public health codes or regulations. Sanitizers are not effective against viruses and fungi. They are ordinarily used in food-processing, food-handling, preparation, and service industries and include FCS and NFCS. Sanitizers tend to be used at lower concentrations for a shorter period of time and no perfumes are allowed in food-contact sanitizers.

Sanitizers with disinfectant properties used to sanitize food-contact surfaces must reduce the bacterial counts for specific bacteria by 5 logs or 99.999% in 30 s at 20 °C, whereas food-contact sanitizers with no disinfectant properties, or NFCS sanitizers, must only reduce bacteria by 3 logs or 99.9% within 5 min at the same temperature.

Disinfectants are used to destroy or irreversibly inactivate microorganisms, including bacteria, fungi, and viruses, but not necessarily spores. Disinfectants are used on all hard surfaces of a food-processing plant (NFCS), normally at much higher concentrations and with a longer contact time than sanitizers. In addition, perfumes can be added to their composition. The efficacy of disinfectants is based on the statistical significance of killing test bacteria on carriers, measuring the percentage of nonviable microorganisms in a set of test tubes under specific conditions.

Finally, sterilization is the process of destroying all living microorganisms, including bacterial spores. These compounds must demonstrate an absence of growth in test samples or a reduction of 6 logs or 99.9999% and include specialized chemicals such as glutaraldehyde and formaldehyde. Dry heat (use of dry-heat ovens) and moist heat (use of steam under pressure) are also used for sterilization.

These compounds show a different effect according to the different target microorganisms and resistant forms. Thus, their effect could be bacteriostatic (preventing the growth of a specific group of microorganisms but not necessarily killing them), bactericidal (killing a specific group of microorganisms), fungicidal (effective against molds), virucidal (effective for eliminating viruses), or sporicidal (destroying spores).

Methods

Sanitization may be achieved by physical or chemical methods, with heat and irradiation being the most widely used physical methods. Both dry heat and wet heat are used in the food industry, with the last being most commonly used to sanitize the pipelines of fillers or pasteurizers, for instance. Hot water at 80 °C or steam must be used, and it is important to ensure that all points of the pipeline reach this temperature for a minimum time. This method is normally combined with chemical sanitization. One disadvantage of the wet heat method is that it favors the formation of limescale when used with hard water.

UV irradiation is a disinfection method that uses short-wavelength ultraviolet radiation (UV-C) at 254 nm that is harmful to microorganisms, killing them by disrupting their DNA and leaving them unable to perform vital cellular functions. This method is used to disinfect water, air, and some food-processing surfaces, such as conveyor belts or some packaging materials.

However, chemical sanitization is more frequently used in food-production facilities than thermal or irradiation techniques. This method includes the use of active substances (chemicals) that are applied via aerosol or smoke to sanitize or disinfect ceilings and the air in the food-processing plant or in solution for other foods and NFCS.

Chemical Sanitizers Used in the Food Industry

A sanitizer/disinfectant contains one or more active compounds (chemicals with a bactericidal effect) together with other chemicals that add some interesting properties that facilitate their application and can also produce a synergistic effect. This is the case of certain compounds that increase wettability, thereby improving the penetrating power of the solution and favoring contact between the sanitizer and microorganism, substances with binding properties that decrease the negative effect of hard waters on sanitizer activity, pH correctors, and foam-forming compounds. The main characteristics for an optimal sanitizer/disinfectant are listed in Table 4.

Table 4 Main characteristics for a sanitizer/disinfectant used in the food industry

Easy application
Low toxicity
Noncorrosive
Good penetrating power
Fast acting
Not adversely affected by organic matter
Active before and after dilution with hard water
Compatibility with other chemicals and construction materials
Broad spectrum of activity toward Gram-positive and Gram-negative bacteria, fungi, and viruses
No harmful
No offensive odor
Stability (long shelf life)
Not persistent in the environment
Demonstrated residual activity
Cost-effective

Several chemical compounds can act as sanitizers or disinfectants depending on the concentration used. The most commonly used sanitizers in food-production environments are chlorine, quaternary ammonium compounds (QAC), and iodine. The dose, use conditions, and main advantages and disadvantages of these sanitizers are summarized in Table 5.

In order to eliminate the use of harsh chemicals at food-processing facilities, which often have negative environmental and safety impacts, various new methods have been proposed. These include the use of ozone (O_3), which has a demonstrated bactericidal effect against some foodborne pathogens and other microorganisms, the use of which was approved by the FDA in June 2001. Ozone has the advantage of not producing toxic residues on treated surfaces, although it can be corrosive at high concentrations on some types of surfaces and overexposure during its generation can result in bodily injury.

Electrolyzed water (EW) can be easily produced using common salt and an apparatus connected to a power source. The current, along with ion-selective membranes in electrolytic cells, produces two types of solution: sodium hydroxide, a high-pH, noncorrosive dirt and grease-cutting cleaner, and hypochlorous acid, a low-pH, high-dissolved-oxygen, chlorine-containing sanitizer and disinfectant. EW is effective against a wide range of microorganisms, including viruses, fungi, and spores, within 1–15 s of application and has been proved to be 80% more powerful at 50 ppm than chlorine bleach at 200 ppm. As the size of the machine is quite small, EW can be produced at the site where it is to be applied.

Peracetic acid (PAA), which is produced by the reaction of acetic acid with hydrogen peroxide, has been promoted as a potential chlorine replacement. The recommended usage dose concentration for food-contact surfaces is 150–200 ppm. At

Table 5 Main sanitizers used in the food industry

Sanitizing compound	*Conditions*	*Advantages*	*Disadvantages*
Chlorine			
Sodium hypochlorite, chloramines	50 ppm (maximum 200 ppm) in water 24–38 °C; 7 s >200 ppm rinsing is necessary	Effective against broad spectrum of vegetative bacteria and viruses (norovirus) Not affected by water hardness Effective in pH range of 6–8 Inexpensive (generally)	Corrosive, irritating to the skin Effectiveness decreases with increasing pH Activity decreases in the presence of organic matter
Iodine			
Iodine together with a stabilizing agent or carrier (iodophors)	12.5–25 ppm in water at least 24 °C, 30 s >25 ppm rinsing is necessary	Not affected by water hardness Active against a wide variety of non-spore-forming bacteria (vegetative bacteria and viruses) Relatively stable in the presence of organic matter Optimum pH range is 5.0 or less	Bactericidal effectiveness decreases greatly with an increase in pH (pH 7) Gram-negative bacteria may be able to survive Not very effective against spore-forming bacteria and bacteriophages Cannot be used at temperatures higher than 40 °C Discoloration of surfaces
Quaternary ammonium compounds			
Benzalkonium chloride	Maximum 200 ppm in water at least 24 °C; 30 s Rinsing is necessary	Nontoxic, odorless, colorless, noncorrosive, nonirritating Stable to heat and relatively stable in the presence of organic matter Active over a wide pH range Quite active against thermoduric organisms	Retarded effect on coliforms and psychrophilic bacteria Inactivated by proteins and soaps Not compatible with anionic detergents and hard water salts Not effective against bacteriophages

this concentration, it is capable of destroying microorganisms and removing milk stone deposits (dairy industries) and limescale, suppressing odors and removing biofilms from food-contact surfaces. However, this compound has no sporicidal effect and is more expensive than other sanitizers or disinfectants.

Factors Affecting the Effectiveness of Sanitization

When designed, a good sanitization procedure must take into account several factors in order to be more effective when applied at the food-processing plant. These factors include (1) previous cleaning status; (2) surfaces, facilities, and equipment to be sanitized; (3) type, counts, and possible niches of expected microorganisms; (4) concentration and stability of sanitizers used; and (5) physical parameters, such as temperature, pH, and water quality.

Previous cleaning status: It is important to properly clean and rinse the surface prior to sanitization in order to avoid the presence of organic and/or inorganic inactivators that may be present in dirt or detergent residues from an improperly cleaned surface. The presence of organic matter (food residues) on the surface can interfere with the antimicrobial activity of sanitizers and disinfectants by reducing the level of activity or by protecting the microorganisms from attack by acting as a physical barrier. Moreover, organic or inorganic debris can favor the appearance of biofilms on incorrectly cleaned surfaces. In this sense, the microbial load can affect sanitizer activity, with more time being needed when the number of microorganisms present is higher.

Surfaces: Before using a sanitizer or disinfectant, it is very important to determine its compatibility with the surfaces on which it will be used as these chemicals tend to react differently with plastic, glass, metal, and wood. Iodine, for instance, can be corrosive when applied to a metal surface and may stain porous surfaces and some plastics. Frequent or extended exposure to alcohols can also damage plastic materials. The surface area, topography, and geometry of the surface also have a major influence on the effectiveness of sanitizers and disinfectants. Thus, surfaces with cracks, pits, or crevices are more difficult to sanitize and disinfect than smooth surfaces because penetration to all areas may not occur. Food-contact equipment with multiple parts must be dismantled to ensure that all parts are correctly cleaned and sanitized.

Microorganisms: The different types of microorganism must be taken into account before applying a sanitizer or disinfectant. Gram-negative bacteria such as *E. coli*, *Campylobacter* spp., and *Salmonella* spp., for example, are more difficult to kill than Gram-positive bacteria due to the presence of the outer membrane, which act as a 'barrier' to sanitizers and disinfectants. These compounds also vary in their effectiveness against yeasts, molds, fungi, and viruses. Among the latter, nonenveloped viruses such as noroviruses or hepatitis A virus are less susceptible to disinfection than enveloped viruses because of their hydrophilic nature and lack of lipids. Finally, spores are more resistant to disinfection than vegetative cells due to the presence of the spore coat and cortex, which protects them.

Sanitizers and disinfectants (*chemicals*): When applying a sanitizer or disinfectant, it is very important to take into account the manufacturer's instructions for use, especially as regards concentration and contact time. Too low a concentration will result in an inadequate reduction of microorganisms and too high a concentration can be toxic, can be corrosive to equipment, and can lead to less effective cleaning over time. The more concentrated the chemical used, the greater its efficacy and the shorter the time required to kill the microorganism, with the exception of iodophors. As disinfectants are used at a higher concentration than sanitizers, they can achieve complete destruction of microorganisms, whereas sanitizers only achieve a 3–5-log reduction. To kill microorganisms, cleaned items must be in contact with the disinfectant for the time recommended by the manufacturer. Sanitizers and disinfectants have a minimum contact time for exerting their activity, with longer contact times generally being more effective than shorter ones.

Physical factors: The optimal temperature range over which chemicals are more effective is 20–50 °C. Nevertheless, the activity of most sanitizers and disinfectants increases with temperature, although there are some exceptions. For instance, chlorine-based solutions have higher killing rates at higher temperatures, although their corrosiveness also increases and the vaporization of chlorine is favored, thereby decreasing their effectiveness. As such, care must be taken not to exceed the optimal temperature range. In contrast, QACs are stable at high temperature. An increase in pH improves the antimicrobial activity of some sanitizers and disinfectants, such as glutaraldehyde and QACs, but decreases the activity of others, such as phenols, hypochlorites, and iodine. As mentioned previously, water hardness also affects the optimal performance of sanitizers and disinfectants, reducing the destructive activity of some of them.

Rinsing

It is important to determine whether rinsing is needed for each sanitizer and disinfectant after application and to follow the product label and manufacturer's instructions. This step is concentration-dependent, and rinsing is usually compulsory when a sanitizer is applied to FCS but not when applied to NFCS. In some food-processing plants, it may be of interest to allow the sanitizer to act overnight on FCS, for instance, to maintain a residual effect and avoid bacterial growth during night. However, it is always necessary to rinse the sanitizer off to avoid product contamination before starting production.

Resistance and Persistence

Phenotypic resistance to disinfectants at bactericidal concentrations occurs among all attached cells irrespective of whether they are involved in a biofilm or not. When an attached community of bacterial cells on surfaces from high-risk chilled food-processing plants is subjected to a deep cleaning and disinfection, only a few are able to resist. This fraction of surviving cells decreases as the disinfectant concentration increases but is greater for old established communities, which are referred to as 'persistent microorganisms.' These cells become persistent when their growth rate exceeds destruction by cleaning and disinfection, and the best way to avoid their presence is to prevent bacterial growth.

The most important recommendation is that premises and equipment must be hygienically designed so that bacteria cannot find harborage sites where they are protected from the action of chemicals. These sites are hard to eliminate and only a low initial bacterial load is required for subsequent persistence. In such cases, an early cleaning and disinfection intervention will be the only way to avoid persistence. According to this hypothesis, some authors believe that there are no bacterial strains with unique properties that lead to persistence, but simply harborage sites in food-processing plants and equipment where these bacteria can persist.

As most sanitizers and disinfectants are nonspecific, the development of resistance is mostly caused by innate factors, chromosomally controlled properties naturally associated with the organism, that include the existence of impermeable cell barriers that prevent the penetration of the sanitizer, cellular efflux mechanisms, lack of a biochemical target for antimicrobial attachment or microbial inactivation, and inactivation of antimicrobials by microbial enzymes. If resistance is discovered by specific testing, a disinfectant with a different active ingredient must be used. Higher concentrations of the same disinfectant are not recommended as this could promote the emergence of more resistant cells.

Finally, two key points must be taken into account when assessing the efficacy of a C&D procedure in order to avoid misinterpretation of the results. The first of these is that swabs used to sample surfaces do not detach all the microbial cells, and the second is that although some cells are not culturable, they may still be alive. As such, it is important to make use of a combination of not only culture-dependent but also culture-independent methods when sampling environmental food-processing facilities and equipment.

Conclusion

In all food manufacturing plants, cleaning and disinfection (sanitization) plays a key role in order to reduce or eliminate most of the microbiological hazards associated with food-production environment. This fact is extremely important to design a proper and effective HACCP system that guarantees the shelf life and safety of food products. Moreover, in order to obtain an optimum sanitization status of the food-processing plant, other prerequisite programs must be properly implemented such as proper layout of the food plant, waste treatment, pest control, and hygienic design of food-processing equipment and especially its implication to the food plant personnel.

This article is reproduced from the *Encyclopedia of Food Sciences and Nutrition*, vol. 8, pp. 5095–5097, © 2003, Elsevier Science Ltd., with an updated Bibliography section supplied by the editor.

Background

Saponins are a heterogeneous group of glycosides that are widely distributed in plants of agricultural importance, particularly legumes. Many of these legumes are staple items of the human diet. Foods particularly rich in saponins are soya beans (*Glycine max*), chickpeas (*Cicer arietinum*), and beans derived from *Phaseolus vulgaris*.

When saponins are agitated in water, they form a soapy lather. Other properties generally ascribed to this wide group of compounds are hemolytic effects on red blood cells, cholesterol-binding properties, and a bitter taste. These properties characterize particular types of saponins and are not necessarily shared by all members of the group. From a biological point of view, some of these properties are beneficial, whereas others are considered to be adverse.

Of particular interest is the observation that dietary saponins reduce plasma cholesterol levels in primates, thus having the potential to lower the risk of coronary heart disease in humans.

Chemical and Physical Properties of Saponins

Saponins consist of an aglycone unit linked to one or more carbohydrate chains (Figure 1). The aglycone or sapogenin unit consists of either a sterol or the more common triterpene unit. In both the steroid and triterpenoid saponins, the carbohydrate side chain is usually attached to the 3-carbon of the sapogenin.

Saponins possess surface-active or detergent properties because the carbohydrate portion of the molecule is water-soluble, whereas the sapogenin is fat-soluble. The stability and strength of forage saponin foams are affected by pH, and this may have an effect on the development of bloat in ruminants. Saponins are remarkably stable to heat processing, and their biological activity is not reduced by normal cooking.

Isolation of saponins from plant material involves extraction with a polar solvent after removal of lipids, with petroleum ether or chloroform, followed by various purification techniques. A number of chromatographic procedures have been used to separate individual saponins.

The analysis of saponins is complex and potentially subject to considerable errors during their isolation, separation, and quantification stages. Thus, many early reports of the saponin content of food plants and processed food should be treated with caution. The data presented in Table 1 were obtained using rigorous methodology and are the most reliable data available at present. More recent studies have shown that many legume seeds contain several saponins, for example, five different saponins have been separated from soya beans.

Biological Effects of Saponins

Ingested saponins can influence animal performance and metabolism in a number of ways.

Sensory Properties of Saponins

Recent studies have shown that a bitter or astringent taste is related to amounts of soya saponin I isolated from pea and soya flour. It is possible that saponins are a contributing factor to the undesirable organoleptic properties that humans associate with some legumes and legume products. The bitter taste of saponins may be responsible for the low palatability of lucerne to ruminants and may explain the reduced feed intake observed in many experiments when using this material as forage. Many stocks will discriminate against feeds containing high levels of lucerne meal.

Erythrocyte Hemolysis

Saponins have pronounced hemolytic properties when given intravenously, the degree of effect on the red blood cells varying among different mammalian species. The release of hemoglobin from red blood cells is the direct result of the interaction of saponins with membrane-bound sterols, which causes an increase in the permeability of the plasma membrane, bringing about the destruction of the cell.

The hemolytic activity of saponins has been widely used as a means of detecting and assaying saponins in plant materials. The potentially toxic effects of intravenous injection of saponin extracts have resulted in this class of compounds being regarded as antinutritive factors in foods. Their low oral toxicity and the potentially useful nutritive value in foods have only recently been appreciated.

Effects on Blood and Tissue Cholesterol Levels

Since many legume saponins form insoluble addition complexes with cholesterol, the effects of dietary saponin on cholesterol might be expected. Saponin in the diet of chicks has been reported to reduce plasma cholesterol in cholesterol-fed animals. Saponin extracted from *Quillaia saponaria* has been shown to reduce liver (but not plasma) cholesterol levels in chicks. An exhaustive series of experiments, with a variety of saponins, have consistently demonstrated cholesterol-lowering effects. These include the feeding of lucerne saponins to rats, rabbits, and monkeys. Some workers have suggested that dietary saponins do not have any effect on plasma cholesterol concentrations. This is perhaps to be expected in experiments with rats that received no dietary cholesterol.

Experiments on humans have produced variable results. Different saponin levels in a dietary supplement based on soy flour had no effect on plasma cholesterol levels in

hypercholesterolemic men. As the experiment was conducted on free-living subjects, it cannot be guaranteed that the subjects actually consumed the experimental diets.

In a more closely supervised trial, with subjects having normal blood cholesterol levels, it was found that a dietary supplement containing saponins did not have a significant effect on plasma cholesterol level. Increased fecal excretion of bile acids and neutral sterols was observed. Foods containing saponins, or diets supplemented with saponins, have been shown to reduce blood cholesterol levels in humans under conditions that would be expected to induce high levels of blood cholesterol.

Mode of Action

Saponins remain within the gastrointestinal tract. Some interact directly with dietary cholesterol, producing an insoluble complex that prevents the cholesterol being absorbed. Others appear to affect cholesterol metabolism indirectly by interacting with bile acids. An increased fecal excretion of bile acids is observed in response to feeding additional saponins in the diet. Bile acids thus diverted from the enterohepatic cycle would be replaced by hepatic synthesis from cholesterol.

In the digestive tract, saponins form mixed micelles with cholesterol and bile salts; their hydrophobic triterpene or steroid groups stack together like small piles of coins. These micelles are then too large to pass through the intestinal wall.

Bile salts normally pass through the wall of the small intestine by both passive diffusion and active transport. Passive diffusion takes place along the entire length of the ileum and jejunum; active transport is confined to the terminal ileum. Saponins can interact with cell membranes, as shown by their hemolytic activity. It is possible that they may also have an effect on the cell membranes of the intestinal mucosa. However, the effects of saponins on both passive absorption and active transport can be explained simply as being due to the reduction in the concentration of free bile acid, because bile acids assist lipid absorption. Low concentrations of free bile acids would also impair the efficiency of lipid absorption and presumably affect the absorption of fat-soluble vitamins. Thus, there may also be a significant metabolic effect within the animal as well as in the digestive tract.

Effects on Growth

When lucerne saponin was added at high levels to the diets of monogastric animals, reduced feed efficiency and growth rates were observed. It is clear that species differ considerably in their responses to dietary saponin, for example, poultry are more sensitive than rats. In contrast, soya bean saponins had little effect on the growth rate of experimental animals. Some saponins increase the permeability of the small intestinal mucosal cells, thereby inhibiting the active transport of some nutrients, but at the same time, they facilitate the uptake of materials to which the gut would normally be impermeable.

The biochemical mechanism that accounts for the growth-depressing effects has not been fully identified. In at least one experiment, the addition of 1% cholesterol to the diets of chicks completely overcame growth depression produced by 0.3% saponin.

It is possible that, in addition to their effects on lipid absorption, saponins also affect chymotrypsin and trypsin activity, which would affect the absorption of protein.

In addition to observing reduced intestinal uptake of cholesterol in rat intestinal perfusates on the addition of soy saponin extracts, some workers have also observed a significant reduction in cholate and glucose uptakes. It was observed that the saponins could be washed out of the intestinal lumen, suggesting that inhibition, at least in the short term, was not caused by modification of, or damage to, the intestinal mucosa.

Metabolism of Saponins

Toxicity studies indicate that only very low levels of saponin absorption occur. Saponins are between 10 and 1000 times more toxic when administered intravenously than when given orally. Destruction of saponins in the digestive tract of both ruminants and monogastric animals has been observed.

Saponins are degraded by rumen bacteria and by microflora found in the cecum of rats, mice, and chicks. Since saponin in the cecum is past the major sites of absorption, the release of sapogenins and sugars is considered to be insignificant.

Conclusion

The substantial evidence that saponins from a number of plant species can reduce plasma cholesterol levels in man is likely to encourage further interest in these plant foods. It is generally recognized that the overall nutritional value of many Western-type diets would be considered improved if more legumes or legume-based products were consumed regularly. The acceptance of more legumes in Western-type diets is limited by undesirable taste characteristics, some of which may be due to the higher levels of saponin found in many legume seeds.

There is little doubt that saponins can be incorporated into human diets at levels that can give a beneficial effect and would not entail a risk of acute toxicity. The fact that saponins can increase the permeability of intestinal mucosa raises the possibility of interesting nutritional and pharmacological uses.

Satiety

MM Hetherington, University of Leeds, Leeds, UK

Defining Satiety

Satiety can only be understood with respect to the entire appetite control system. Thus, the state of satiety is reached by consuming an adequate amount of food in a specific period of time. Food intake is driven by a powerful biological need to obtain sufficient energy to sustain life. However, meals are initiated before significant food deprivation is experienced and intake terminated before nutrients are delivered to the system. Recent theories of what controls food intake have shifted from purely homeostatic to the proposal that there are both direct and indirect controls of food intake. An idea that was first suggested by Smith in his seminal article from 1996. In order to provide a context for research on satiety, a short historical background will be provided and then evidence from alternative theories discussed; then, sensory-specific satiety (SSS) is illustrated as one example of satiety linked to specific foods eaten. The implications for this research for the consumer will be discussed in relation to both weight management and other benefits of enhanced satiety.

Homeostasis

The early theories of food intake were predicated on the control of eating as a primary biological drive, a problem of nutritional homeostasis. Theories of the 'wisdom of the body' promoted by Walter Cannon and developed from Claude Bernard's concept of the 'milieu intérieur' in which internal systems function in harmony to achieve a stable, optimal state suggest that food intake is 'regulated.' Thus, the motivation to eat was initially conceptualized as an emergent property of a system with falling energy or nutrient stores. Put simply, food is sought when the animal is in a state of hunger caused by periods of deprivation. This conceptualization of the body defending against external threats such as famine, nutrient depletion, and seeking to maintain a stable energy supply to prevent deterioration provides the essence of a homeostatic system.

However, these early theories were then superseded by a greater focus on behavioral neuroscience in which the neural circuits and gut pathways to the brain were thought of as responding to the presence of nutrients both in the environment (behavioral responsiveness and indirect controls) and in the gut (direct controls). In this theoretical formulation, both direct and indirect controls of meal size are considered alongside the neural mechanisms underpinning a complex appetite control system.

It is clear that while body fat stores appear to be well defended and maintained over time, food intake is variable and can occur in response to environmental (indirect) cues. Thus, in laboratory settings, animals will eat in anticipation of deficit and in response to a conditioned stimulus even when tested in a satiated state. The idea then that food intake occurs *only* in response to low energy supplies, in order to maintain homeostasis, has been replaced with a more complex model of food intake acknowledging the primary importance of maintaining energy stores and at the same time the strong influence of environmental cues to initiate eating when food is available or when cues are associated with feeding.

Satiety Cascade

A central component of this more complex model is embodied within the notion of 'negative feedback,' a concept borrowed from engineering. Any behavior that is goal-directed and purposeful such as eating requires negative feedback in order to modulate the drive. Thus, in the example of a thermostat, energy is released in the form of heat to achieve the set temperature, and once, this is achieved, the heating is turned off. Similarly, satiation and satiety form part of the negative feedback loop from the gut to the brain to slow and then to stop eating. The problem for this analogy is that unlike the thermostat, there is an interval between seeking food, securing the food, eating the food, and then digesting the components of the meal to achieve the goal of satisfying the need for nutrients. Therefore, in the case of food intake, satiation and satiety are initiated in advance of metabolizable energy being made available, an observation elegantly explained by Blundell in his text on Physiological Psychology in 1975. The negative feedback loop relies upon sensory (smell and taste), mechanical (distension), and chemical (peptide) signals from the gut to the brain to prompt both satiation and satiety. In humans, satiety is also influenced by cognitive processes broadly incorporated into learning (expectancy) and memory (monitoring current and previous meal intake). It is this cognitive component of the satiety cascade that allows humans to control appetite, to resist the temptation to eat when food is so freely available in the environment, and to use what is known about satiety to select foods with a higher satiating capacity to enhance satiety for weight management (Figure 1).

The Negative Feedback Loop

If it is accepted that satiation and satiety provide negative feedback to slow and to stop eating behavior, how then are these processes defined and how are they distinguished?

Satiation is the process by which the drive to eat begins to wane. It is characterized by eating rate slowing down and by sensory, gastric, and physiological signals combining to inhibit further eating. Satiation determines how much is eaten within the bout or episode (meal size). Satiation is influenced by the characteristics of the food eaten, for example, it is thought that

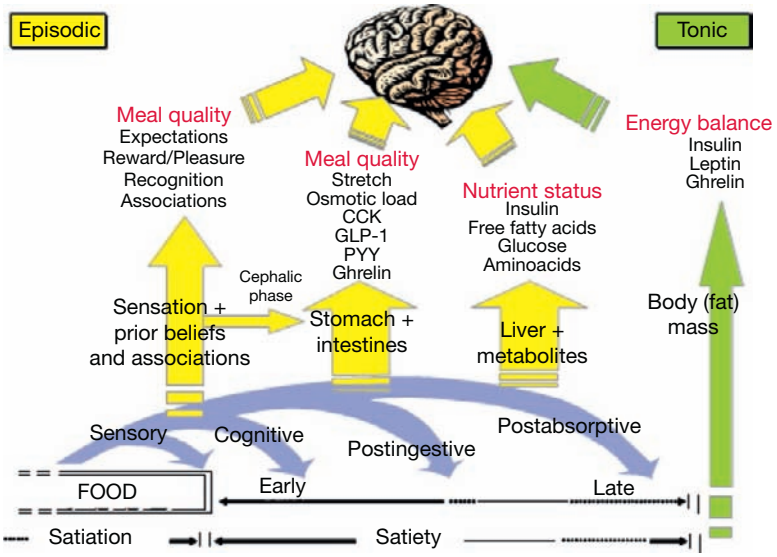

Figure 1 Satiety cascade as adapted by Blundell and Mela.

masticatory effort will enhance satiation. Liquids are less satiating than semisolids, which are less satiating than solid foods. Using this example, when foods are given to participants with the same underlying constituents – such as apple, given as juice, puree, or whole – the resulting effect on subsequent intake is that whole apple reduces energy intake due in part to the oral metering involved in chewing the solid form compared with the puree or liquid. Thus, a consistent finding across studies that systematically manipulate food form is that greater chewing or oral processing enhances satiation and satiety. This is confirmed by the elegant studies performed by Cees de Graaf and his colleagues at Wageningen University.

Satiety is the later state of inhibited eating that follows satiation and determines the interval until the next meal episode and how much is eaten at the next eating occasion. During this process, signals arising from the presence of nutrients in the gut feedback to the brain to inhibit further intake. Like the related process of satiation, satiety is influenced by the characteristics of the food eaten. For example, protein is considered the most satiating macronutrient and high protein foods are known to reduce subsequent food intake compared with high fat foods. Similarly, foods high in fiber are known to promote satiety, in part due to an increase in the release of satiety peptides – an observation made by Johannson and colleagues in 2013.

As the stomach is distended and the meal progresses, gut hormones are released, which then form part of the satiety circuit. One of the most well characterized of these signals is cholecystokinin (CCK). This is a peptide hormone secreted by I-cells of the epithelium of the small intestine. When the stomach is distended, CCK is released and the presence of nutrients delivered directly into the duodenum also stimulates the release of CCK. The pioneering work of James Gibbs and Gerard Smith in the Bourne Laboratory at Cornell University Graduate School of Medical Sciences from the early 1970s demonstrated the impact of CCK injected intraperitoneally into fasted rats, namely, that despite the fasted state known to drive intake, CCK inhibited food intake by up to 50% in the first 30 min of free access to food. This team showed that CCK induces the same behavioral satiety sequence as a meal, it slows gastric emptying, and it reduces food intake. There is now a substantial body of evidence linking CCK to satiety across many different species. Thus, acute administration of CCK to humans and other animals inhibits food intake. However, in the longer term, chronic administration fails to sustain this effect on satiety, and in experimental models, animals become resistant to the satiety-inducing effects of CCK. Thus, it has been suggested by Scott and his colleagues that there is little therapeutic benefit of CCK for the treatment of obesity. Nevertheless, CCK is a potent, short-term satiety signal and is a key component of the negative feedback loop determining how much is eaten within a meal.

A more promising therapeutic target is glucagon-like peptide-1 (GLP-1) – another satiety hormone, but one that is released in the ileum and colon and whose receptors are highly evident in the hypothalamus. The functional properties of GLP-1 as a satiety signal have been found reliably in humans. Thus, a meta-analysis conducted by Verdich and colleagues in 2001 examining seven studies of GLP-1 administration in lean and overweight participants demonstrated a dose-dependent effect of GLP-1 on satiety in part due to delayed gastric emptying. There appears to be less resistance to the effects of GLP-1 in the longer term. For example, diabetic patients given GLP-1 by subcutaneous infusion over 6 weeks reported reduced hunger and appetite, increased fullness, and weight loss relative to a saline control group. This outcome gives credence to the proposal that GLP-1 can be exploited as a drug target in the treatment of both diabetes and obesity.

It is also thought that high-fiber foods enhance satiety through the release of gut peptides. For instance, in the case of indigestible carbohydrates such as whole kernels of barley, the satiety effect (increased fullness, reduced hunger, and reduced intake) is linked to an increase in GLP-1 secretion and to a reduction in free fatty acids due to gut microbial fermentation of the indigestible carbohydrates, an observation made by Johansson and colleagues in 2013. This has direct

implications for clinical and consumer benefit. High-fiber foods offer enhanced satiety and the potential net outcome of reducing overall energy intake to assist in weight loss or weight management.

Other gut hormones such as oxyntomodulin have been found to enhance satiety. Oxyntomodulin is secreted by L-cells of the small intestine in response to food intake. It is known to suppress food intake by around 19% when administered intravenously. In a longer-term study, where participants were trained to deliver subcutaneous oxyntomodulin three times per day before meals, energy intake was reduced in the initial stages by 25%, and by the fourth week, intake had declined by 35%. This resulted in a significant weight loss compared to a saline control group as reported by Wynne et al. in 2005. Clearly, there is substantial potential for developing drug targets exploiting the action of satiety peptides in promoting weight loss through reduced food intake and in the case of oxyntomodulin by increasing energy expenditure.

Given the efficacy of gut hormones and their ligands to reduce food intake in experimental settings and clinical trials, other less invasive methods have been considered for weight management. For example, the use of ingredients to promote satiety in food products is an issue explored by Hetherington and colleagues.

Sensory-Specific Satiety

Returning to the satiety cascade, it is clear that the sensory characteristics of foods play an important role in influencing satiation and satiety. At the beginning of the meal, foods are experienced as pleasant and desirable, but as the food is eaten, the appeal of this food declines. Thus, the hedonic appeal of a food just eaten decreases with time and is less relative to other foods that have been tasted but not eaten. Changes in liking or pleasantness may signal the onset of satiation. This phenomenon has been described in detail by Barbara Rolls in her review paper published in 1986. It is known as 'sensory-specific satiety,' and it has been observed in a number of different species and across the life span in humans. It is considered important in determining how much of a food is eaten within a meal and it may influence food choice beyond the meal. Thus, typically within human eating patterns, foods eaten at one meal are avoided at the next. It is thought that this desire for variety is important to the omnivore ensuring that a diverse diet is consumed rather than just the most favored or available food.

Long-term studies of repeat consumption of food items demonstrate that variety is considered important. A study of Ethiopian refugees who had been maintained on a diet of three staple foods indicated that those who had just arrived at the camp rated the foods as acceptable relative to three other foods but those who had been in the camp for 6 months rated the staple foods as significantly less pleasant than the comparison foods. Similarly, in the twenty years of studying army personnel and their response to army rations, Meiselman and his colleagues found that army rations were discarded or traded to avoid monotony. Greater variety in the contents of the military ration was a consistent request from personnel. Variety is sought out to maintain health and well being, while SSS may be important in achieving the goal of a varied, nutritious diet.

Satiety can be specific to the particular foods eaten repeatedly or to a defined set of sensory features (appearance, smell, texture, and taste) associated with the eaten food(s). The classic, early studies by Barbara and Edmund Rolls reliably demonstrated that subjective pleasantness decreased for the food just eaten (and foods sharing similar sensory properties) but remained high for other foods in humans, that these same foods were rejected in favor of uneaten foods in both humans and monkeys, and that recording in single cells of the lateral hypothalamus reflected a reduction in firing rate in response to the eaten food relative to uneaten foods. Specific satiation to olfactory stimuli in humans was demonstrated by Blundell and Freeman in 1981. They used stimulus-induced salivation in response to food-related odors (honey, lemon, and meat) following ingestion of a glucose load (50 g in 200 ml water). Salivation in response to the sweet odor (honey) declined significantly after the sweet (glucose) load but not for the other odors. If salivation is a good indicator of willingness to eat a food, then this experiment revealed selective satiation related to the sensory component of the load (sweet taste). Thus, satiety can be specific to the sensory properties of the food eaten.

There are two central and reliable features of SSS: The first is that there is a significant response decrement (whether firing rate of single neurons, subjective pleasantness ratings, or stimulus-induced salivation) to the eaten food and the second that there is a consequence for consumption (rejection of the same or similar foods and acceptance and intake of different foods). The implications for dietary choice are obvious – if satiety is specific to a set of eaten foods, then the more variety offered, the greater the food intake, and in the longer term, variety might promote overeating and even weight gain. This is certainly true of the so-called cafeteria diet, first described by Anthony Sclafani at Brooklyn College in 1976. In this paradigm, the varied selection of high energy density, highly palatable foods produced hyperphagia and obesity over time. In earlier studies by Jacques Le Magnen in the 1950s, it was demonstrated that chow paired with specific odors had the 'specific capacity to satiate.' However, when rats were offered four different odors in succession, intake increased by 70% within the bout. This effect of variety illustrates the power of environmental cues to stimulate excessive food intake and the ways in which satiety signals arising from the gut may be overridden by the presence of food cues.

SSS is generally measured using subjective ratings of pleasantness or liking under laboratory conditions, but advances in technology in neuroimaging demonstrate that specific reward pathways can be investigated in relation to the affective valence of gustatory stimuli. SSS can be conceptualized as a process in which experienced pleasure changes during eating, thereby reducing the motivation to continue eating this food during the current eating episode and to influence when this food will be selected again. There have been attempts to harness these observations for weight management; thus, the 'Flavor Point Diet' seeks to reduce variety as a means to limit food intake for weight loss. While this is an attractive idea in theory, the potential effects of monotony as described by Meiselman and colleagues in addition to the lack of convincing data on long-term weight loss maintenance temper the practical application in practice.

Potential Benefits of Satiety

Rather than seeking to limit variety as a means to enhance satiety, there are other ways to promote satisfaction with different foods included in the diet, as a means to assist consumers in limiting intake for appetite control. For example, diets that contain whole grains, fruits, and vegetables and that are relatively high in fiber and low in energy density tend to promote satiation and satiety. The potential benefits associated with enhanced satiety include enhanced resistance to overeating tempting foods, strengthening weak internal satiety cues in consumers who have experienced binge eating, enjoyment of lower-energy foods without feeling 'deprived,' reduced hunger dysphoria, improved hunger management, and improved compliance with goal-directed behaviors such as eating a healthy, balanced diet. It can also serve as a potential adjunct to achieving weight loss or avoiding weight gain (see Figure 2).

Studies of consumer understanding of satiety reveal that most consumers do not use the term 'satiety.' Instead, feelings of fullness or satisfaction are considered as the postmeal subjective sensations, which are more commonly used. Using focus groups involving American students and staff, Murray and Vickers in their 2009 paper revealed that fullness is described as having both physical and psychological components, which are experienced as either typical or extreme. Thus, consumers describe fullness as 'a feeling of food in the stomach,' 'stomach stretch,' 'satisfaction,' or 'lack of desire to eat.' Not only are these descriptions mainly focussed on gastric signals at the end of a meal, but also they reflect the experienced absence of the desire to consume foods that extends for some duration following meals.

More recently, consumers across four different European countries were asked to interpret example satiety claims that could be found on product labels. The results indicated that consumers had a reasonable knowledge of what is meant by a satiety claim with most accepting that such products can only play a part in weight management and do not provide a simple, single solution to weight control. Most respondents understood that personal efforts are required to translate product attributes into potential weight control benefits. However, dieters were more likely than nondieters to misinterpret a satiety claim, which is of interest since this is precisely the consumer often targeted for satiety claims by food manufacturers.

As one example of satiety enhancement, adding fiber and protein to foods can promote satiety. Thus, a novel, low-fat yogurt enriched with protein and fiber was consumed by produced a significant reduction in appetite and reduced energy intake compared to a standard product. This is an observation reported by Lluch and her colleagues in 2010. However, whether enriched foods can be used in the longer term to control appetite, to resist overeating, to manage hunger dysphoria, or to assist in weight management is subject to some controversy.

It is possible that satiety claims may be misunderstood by some consumers. They might believe that 'enhanced satiety' claims equate to a slimming claim. Thus, Blundell has cautioned against claims that cannot deliver on weight loss even if food ingredients or products have been shown in the laboratory to enhance satiety in the short term. This is simply due to the components of energy balance. If satiety is enhanced within a meal under laboratory conditions, any short-term benefits observed do not guarantee that this will be sustained in a free-living environment or that consumers will lose weight overall since weight is regulated over the long term.

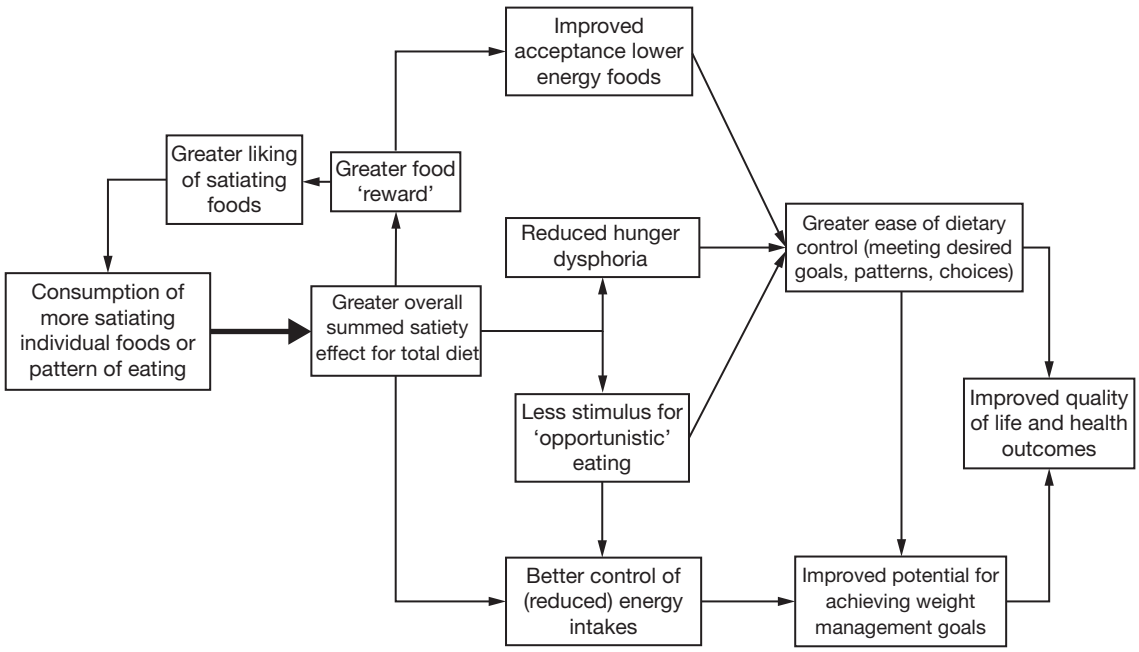

Figure 2 Benefits of enhanced satiety for consumers. Reproduced from Hetherington, M. M., Cunningham, K., Dye, L., et al. (2013). Potential benefits of satiety to the consumer: scientific considerations. *Nutrition Research Reviews* **26**: 22–38.

Conclusions

Overall, satiety is understood as part of the appetite control system. The related processes of satiation and satiety operate in tandem to reduce food intake within an eating episode. These processes determine how much is eaten within a meal and can influence the timing and content of the next meal. Over the past 40 years, research on the gut hormones that signal satiety has been targeted as potential therapeutic agents for obesity, and more recently, food manufacturers have sought to make claims about satiety enhancement to benefit consumers. It is likely that characterizing the mechanisms underpinning all aspects of the satiety cascade will provide potential targets for obesity treatment. It is also clear that consumers are aware of satiety claims and that there are potential benefits of satiety enhancement beyond the direct effects on food intake. Improved satisfaction with specific products and across the whole diet may indirectly benefit dietary control, weight management, or achieving a healthy, balanced diet through enhanced satiety.

Sausages and Comminuted Products: Cooked Sausages

M Flores, Institute of Agrochemistry and Food Technology (IATA-CSIC), Paterna, Valencia, Spain

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Sausage making has a rich history in most cultures. Sausage was a way to store meat for extended periods when mechanical refrigeration was unavailable. Today, the combination of meat and seasonings produces a broad type of sausages and generates different categories from fresh, smoked, cured, and cooked sausages. In addition, cooked sausages can generally be divided into two groups: those consisting of a homogeneous meat batter and another group consisting of a mixture of visible particles, principally comprised of meat and fat. The wide variety of sausages is due to differences in composition, shape, size, and cultural preferences and traditions.

Sausage Production

The manufacturing process of sausages has not changed over the years. But from the formulation point of view, manufacturers are always trying to improve the nutritional profile of these meat products.

Raw Materials

The selection of raw materials, lean meat and fat materials, for the manufacture of sausages is based on economic reasons. The main ingredient is meat, although other materials are used such as edible carcass by-products, liver, tongue, pork skin emulsion, and blood. Different types of carcass trimmings are employed in the manufacture, thereby creating a variety of sausages. The ingredients used in sausage formulations are different from substantial water content (in the form of ice) to a wide range of ingredients: meat from different species (beef, pork, poultry), salt, caseinates, vegetables, cereals, starch, and spices. The differences in ingredient composition frequently are dependent on cultural traditions and preferences.

Lean meat is the most expensive component in a cooked sausage, and its quality contributes positively to a good texture and development of red curing color. The first point in the selection of raw materials for sausage manufacture is the hygienic status of all the ingredients used and which should be as high as possible to avoid high microbial counts in the final sausage product. This factor will affect shelf life, and color stability, as well as flavor in the final sausage product. The handling of all raw ingredients will affect cooked sausage quality. The temperature of chilled meat and fat materials should be between 0 and 4 °C to delay bacterial growth and optimize the solubility of myofibrillar proteins from lean meat. In some cases, the raw materials, lean meat and fat, are stored frozen, but never for prolonged periods of time due to the fact that although freezing prevents microbial growth, it does not inhibit chemically based deteriorative processes like rancidity. The use of pale, exudative, and soft meat should be avoided as it not only affects the water-holding capacity of myofibrillar proteins, but also affects color. The use of meat from different species (pork, beef, mutton, etc.) may contribute differently to sensory characteristics. Sausage variety ranges from high-quality all-meat sausages to those economy-style forms that are manufactured using lower meat quality cuts augmented with higher fat levels, hydrocolloids, and other functional ingredients. The use of mechanical deboned meat (MDM) is widely used for cooked sausages, although its texture has to be built up with gelling materials (soy proteins, starch, etc.) to give firmness to the cooked sausages.

The fat used in cooked sausages stabilizes the solubilized protein network because it acts as a filler, thereby preventing protein shrinkage during the cooking process. Pork fat is widely used in cooked sausages from loin, belly, and neck due to its low unsaturated fatty acid content, although it is generally sourced from all parts of the carcass. The fat content of cooked sausages varies from 5% to 30%, with a popularly consumed sausage product like frankfurters having an average fat content of 28%. The type of fat used in cooked sausages depends on the type of sausage manufactured. In finely ground sausages the type of fat tissue is of less importance, whereas the requirements of fat with higher melting points is necessary when manufacturing cooked sausages with coarse cutting or with fat inclusions like mortadella.

Salt levels in sausages ranges from 1.5% to 2.5%; however, higher or lower percentages can be found in cooked sausages. Salt and phosphates play a role in the solubilization of myofibrillar proteins, which retain much of the water added during sausage formulation. During cooking, the solubilized proteins coagulate and aggregate producing the matrix, which is a three-dimensional gel network. The amount of salt in cooked sausages varies considerably, and current nutritional trends now target reductions in salt content to produce sausage products with low sodium content.

The use of phosphates in cooked sausages is common as, after common salt, it is the most efficient additive in solubilizing myofibrillar proteins. Phosphates are used during chopping or mixing at the beginning of the process to open up myofibrillar protein structure, thereby allowing salt to work more efficiently at solubilizing myofibrillar proteins.

Water (in the form of ice) is not an additive, but it is required to solubilize myofibrillar proteins. The use of ice counteracts heat generation during processing in the bowl cutter.

Nitrite is added to cooked sausages at levels of 120–150 mg kg^{-1} to develop curing color rapidly. The use of ascorbates is recommended together with nitrite, as it accelerates the curing process and reduces the risk of nitrosamine formation. Generally, ascorbic acid also reduces the levels of residual nitrites in cooked sausages. Originally nitrate was used in meat products; however, only nitrite is allowed for use in cooked sausages, and its usage is responsible for the curing

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00613-9

properties and distinctive flavor and color associated with the final products. Nitrite plays an essential role in meat quality and safety. Nitrite has been shown to be effective against spore-forming, anaerobically respiring bacteria like *Clostridium botulinum*. The antibotulinal properties of nitrite in meat products are further strengthened through interaction with other factors, such as; salt, pH, heat treatment, initial spore level, and original and residual nitrite level in the meat. Nitrite fixes color by the reaction of the nitric oxide generated by nitrite reduction with myoglobin and generating the cured color nitrosomyoglobin. It contributes to the cured meat flavor and effectively controls rancidity by inhibiting lipid oxidation. It has been indicated that the cured flavor differences among products with and without nitrite are due to the nitrite suppression of oxidation products, thereby controlling the generation of flavor compounds during processing. In addition, the antioxidant effect of nitrite is produced by its reduction to nitric oxide, which reacts with heme proteins, chelates trace metals and free radicals, and generates antioxidant nitrosyl compounds.

Since the twentieth century the use of nitrite has been progressively reduced due to controversies about its safety. One of the options proposed in the United States was the use of natural curing, which has grown in popularity in recent years. These natural-cured meat products are characterized by the use of vegetable sources of nitrate and nitrite such as celery instead of adding the synthetic chemical compounds. The vegetable addition is done together with a nitrate-reducing bacteria that produces the generation of nitrite from nitrate during processing.

Several color enhancers are used to intensify color such as ascorbic acid and glucono delta lactone. The use of acid additives is recommended toward the end of the cutting process because the pH of the mixture should be kept at optimum levels for protein solubilization. However, as acid additives lower the pH, they would consequently have a negative effect during processing.

Due to economic reasons, other proteins are added to cooked sausage formulations such as soy proteins. Soy protein is frequently used in cooked sausage formulations, and the levels used can range from 1% to 14% to compensate for the use of less expensive or fattier ingredients. However, the use of soy protein will affect texture, firmness, and flavor.

Other ingredients added to increase water retention in cooked sausages are carrageenan and various hydrocolloids due to their high water-binding capacity and their ability to reduce purge in the finished product. In addition, other thickeners such as starch and cereal flours are also used for enhancement of water-holding capacity in final sausage products.

Finally, the desired cooked sausage flavor is produced by the addition of spices and herbs. The combination of spices is very important, and in several cases, flavoring ingredients like liquid smoke or smoke flavor is added. A smoking process is typically applied to cooked sausages and relies on the penetration of smoke volatiles into meat products during the thermal combustion of wood. The wood used in the smoking process consists of a mixture of cellulose, hemicellulose, and lignin, the latter component of wood being responsible for the production of phenolic compounds, which are responsible for the characteristic organoleptic properties associated with smoked meat products.

Processing

During manufacture of cooked sausages (Figure 1), the objective is to solubilize as much myofibrillar protein as possible because this solubilized protein immobilizes the added water and emulsifies fat. The solubilized protein forms a thin layer around particles of fat preventing their separation during cooking. The thermal treatment causes the denaturalization of the protein thin layer, and the fat is maintained inside the layer forming a network. This network prevents the fat particles from joining with other fat particles. Emulsifying capacity is due to the solubilization of the myofibrillar proteins, principally actin and myosin.

As indicated earlier, protein solubilization depends on the amount of protein present and the level and type of additives used. Salt and phosphates increase the ionic strength producing an increase in myofibrillar protein solubilization.

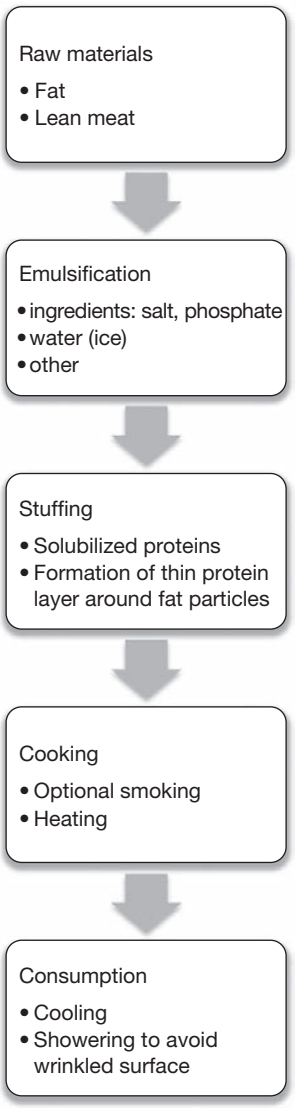

Figure 1 Process flow for the manufacture of cooked sausages.

The processing conditions used in the bowl cutter fractionate myofibrils and affect the partial solubilization of myofibrillar proteins. During chopping, the sausage mix should be cut for long enough that no particles are seen and, at the same time, ensure that as much protein as possible has been solubilized. During this process a stabilized emulsion should be obtained and the layer of proteins around fat particles fulfilled so that the risk of fat separation during the cooking process is reduced. Different interactions occur between protein–water, protein–fat, and protein–protein fractions that ensure the stability of the meat emulsion.

After the emulsion is formed, it should be filled firmly into casings and heated as soon as possible thereafter. The filling speed can be affected by sausage diameter, using lower speeds for high-diameter sausages. The filling process can affect the firmness of the product, and filling should avoid leaving air or free water in or around the final product, which would affect the final cooked sausage.

The cooking process used for cooked sausages varies according to the variety of sausages made. Large quantities of sausages are smoked, as this process produces high impacts on sensory characteristics (color, taste, flavor, and texture). The length of the smoking process depends on the desired color and smoked flavor required. This smoking process is usually carried out in smoking chambers or through the use of liquid smoke.

Afterward, the cooking of sausages can be done by steaming or water immersion. However, the products that are smoked are generally steamed, as they remain hung during all processing steps. During cooking, the solubilized proteins are denatured, thereby forming the three-dimensional matrix and stabilizing the fat particles. Generally, cooking is carried out between 74 and 80 °C, with a core temperature of 70–72 °C being targeted. The temperature range between 65 and 68 °C is not sufficient to stabilize the curing color, and undercooked products will fade over time. In general, the cooking temperature used is typically 6–10 °C higher than the core temperature being targeted.

Finally, the cooling process is applied by showering the product, especially products filled in natural casings and which can become wrinkled. Showering will depend on the casing-type used. All sausages should be cooled rapidly to an internal temperature of 10 °C to prevent bacterial growth. Finally, the completed products will be packed and storage for consumption.

To extend the sausage shelf life the final product is packaged and stored, and this packaging also delays lipid oxidation and microbial contamination. The preservation of sausages is based on hurdle technology as the preservation is achieved by the combination of preservation technologies such as low temperatures, high pressure, irradiation, and modified atmosphere packaging. A variety of packaging systems are available for cooked sausages, for long-term storage vacuum packaging, modified atmosphere packaging, or controlled packaging. Vacuum packaging is extensively used, as the preservative effect is achieved by the development of an anaerobic environment within the pack, and due to the barrier film used, the entrance of oxygen from the outside is restricted. The use of modified atmosphere packaging, where the air is replaced by a gas mixture, is to promote the overall quality of the packaged product, especially color stability.

Patterns of Consumption

The level of meat consumption within the diet is generally estimated for meat and meat products, and reports have described variable consumer consumption values ranging from 85 to 184 g per day, respectively. In general, the caloric contribution of meat and meat products is about 10–20% of the total calories in industrialized countries. Cooked sausages are not only consumed in Europe, but their consumption is increasing in the United States and not only for pork-based products, but also for beef sausages (http://www.hot-dog.org/ht/d/sp/i/38583/pid/38583). There are more than 800 types of sausages, and their consumption occurs globally. The U.S. patterns of meat intake and overall consumption differs among the population and is dependent on factors such as cultural, social, regional, and financial status. Overall, meat consumption has increased in the United States with red meat being the largest proportion of meat consumed. However, there are also differences in meat consumption patterns across Europe. Central and northern European countries have rather similar meat consumption patterns, whereas lowest meat intakes have been reported for Britain and France. In addition, processed meat consumption is higher than that for fresh meat among European consumers. In Europe, the sausage consumption rate is highest for German consumers, followed by Norwegian, Swedish, Danish, and Dutch consumers.

Impact on Nutrient and Bioactive Compounds Availability of Key Food Constituents

Fat Content

The fat content of lean meat is low (typically around 2.0–2.5%), whereas the fat content in cooked sausages is variable (Table 1); however, it is essentially high, and many efforts have been made to reduce it. From the nutritional point of view, fat is an energy source and provides essential fatty acids and liposoluble vitamins. However, the high content of saturated fatty acids in meat, together with a low polyunsaturated fatty acid content, has singled out meat as a food product for criticism.

In addition, cholesterol is an essential constituent of animal cells and therefore is present in meat products. Studies that linked dietary fat and cholesterol intake with chronic diseases have assisted in promoting a negative image for meat products due to their high fat and cholesterol content. The cholesterol content in meat products (Table 1) varies considerably due to numerous differences in their production, such as the use of different meat species, muscles, feeding regimens, levels of fat content, and formulations. In general, the higher the fat content in a processed meat, the higher the cholesterol contribution of the product to the diet. In addition, the use of carcass by-products such as liver in cooked sausages like 'pate' increases the cholesterol content. It has been shown that meat and meat products contribute from one-third to one-half of the daily recommended cholesterol intake (300 mg per day).

The profile of saturated, mono- and polyunsaturated fatty acids determines the nutritional quality of a cooked sausage. Although the content of monounsaturated fatty acids plays a

Source: Chizzolini, R., Zanardi, E., Dorigoni V. and Ghidini S. (1999) Calorific value and cholesterol content of normal and low-fat meat and meat products. *Trends in Food Science & Technology* **10**, 119–128; Honikel, K. O. (2010) Curing. In: Toldrá, F. (ed.) *Functional Meat Products. Handbook of meat processing*. Ames, IA: Blackwell Publishing.

neutral to favorable role in cardiovascular diseases, this is in contrast to saturated fatty acid content. In addition, the increase of polyunsaturated fatty acids at the expense of a reduction in the saturated fatty acid content in pork fat satisfies ideal dietary guidelines. Although the pork industry has developed leaner genotype pigs, meat processors (sausage industry) have improved the nutritional profile of meat products by reducing the fat content and also the level of salt.

However, one of the problems that can be caused through the reduction of fat content in meat products is an impact on flavor. The reason is that fat acts as a precursor of flavor compounds, and it can modify the flavor perception due to the changes in the interaction and release of volatile compounds, and finally, it produces changes in certain ingredients such as salt, spices, flavorings, and so on, due to the changes observed in the matrix.

The fat reduction in cooked sausages can be an effective way to reduce dietary fat intake. Fat reduction can be done by two ways: using raw materials with higher lean content, which makes the end product more expensive, or by adding other ingredients that act as fat substitutes. These ingredients should not adversely affect the sensory characteristics of the product as nonmeat proteins (blood plasma, egg protein, caseinate, soybean derivatives, etc.) and carbohydrates (fiber, maltodextrin, starches, gums, etc.). Many studies pertaining to fat reduction in meat products have been performed in cooked products, where the main effects observed were aroma/flavor losses and problems relating to texture, although acceptable sensory quality products have also been obtained. In some cases vegetable oil has been used as a substitute to solid fat; however, this approach produces lighter-colored cooked sausages.

Muscle Proteins and Peptides

Because connective tissue proteins have a lower content of essential amino acids than those of contractile proteins (myofibrillar proteins), products with a high percentage of collagen will also have a relatively lower nutritive value. However, connective tissue may not be nutritionally disadvantageous until the ratio of connective tissue nitrogen to muscular tissue nitrogen is >1. This can happen in cooked sausage where connective tissue is used to replace meat.

The high quality of meat proteins and their source of essential amino acids can be of interest in illnesses relating to protein turnover like sarcopenia. Sarcopenia produces a reduction in muscle mass and strength producing a physical disability and poor quality of life. Dietary interventions may have the potential to counteract sarcopenia, and meat may play an essential role.

Meat proteins are hydrolyzed extensively during gastrointestinal transit and are converted to amino acids and small peptides, which are transported through the gastrointestinal tract to be delivered to the systemic circulation. The functionality of these peptides generated during the gastrointestinal digestion has been studied recently with a focus on observing different biological functions. One of these biological functions is attributed to the presence of peptides with antihypertensive effect due to their inhibitory ACE activity (ACE, Angiotensin I-Converting Enzyme) originated from the hydrolysis of myofibrillar and sarcoplasmic proteins. In addition, the production of these ACE inhibitory peptides has been reported in other sources such as chicken collagen hydrolysates, but not as yet from other species. Apart from this inhibitory ACE activity, several antioxidative peptides have been obtained from myofibrillar hydrolyzates reporting different effects, like antifatigue activity in mice. These hydrolyzed peptides with biological activities can originate during the gastrointestinal transit of the ingested meat product or also during the processing of the cooked sausages. Further research is required in this field to show the presence of biological activities in cooked sausages.

Due to the contribution of meat ingredients to human health, the values for a recommended daily intake of protein has been indicated to be from 1.1 to 1.5 g per day to contribute to better muscle and bone maintenance and to improve quality of life. In this context, cooked sausages contribute to the daily protein intake.

Meat products, like cooked sausages, are also characterized by the content of endogenous antioxidants: glutation, uric acid, carnosine, and anserine. Carnosine and anserine are the most abundant dipeptides in meat and are not found in vegetal foods. The bioavailability of these compounds has been measured in human plasma after the ingestion of beef meat, and the highest dipeptide concentration was reached after 2.5 hr postingestion.

Health Effects

In terms of nutrition, meat provides the best quality of protein, and it is an excellent source of essential amino acids in adequate proportion. However, the preparation (high temperatures) and processing of meat products through the addition of certain ingredients, including salt, nitrites/nitrates, phosphates, and saturated fats, has contributed to indicate a reduction in meat product consumption due to health concerns in developed countries. An overview of the sausage composition and effect of ingredients on health is shown.

Minerals

The content of mineral components in meat products is in low proportion, although the most important is potassium followed by phosphorous and sodium. In addition the high content of iron is important in cooked beef sausages, but is less so for other sausage species. In addition, the presence of organs such as liver in the formulation of cooked sausages increases the content of several minerals such as iron, copper, and zinc. It is estimated that heme iron contributes to 10–15% total iron intake because of its higher bioavailability in relation to nonheme iron from plants. It is believed that diets containing red meat increase overall iron absorption. In addition, after meat-based diets, it has also been observed that a significantly higher calcium absorption occurs, which could have implications for bone health; however, this latest fact has not been clinically tested yet.

The use of MDM in sausages can modify their nutritional value. The reason for this is the variable levels of connective tissue and calcium present in MDM, and this results in an increase in the content of calcium, general ash components, iron, and bone-derived collagen.

Vitamins

Vitamins are also present in meat, but cooked sausages are not an important source of such, although the specific content of several vitamins like Vitamin B_1 in pork is higher than in other meat species. Even in cooked sausages, the percentages of vitamin B_1 recovered after processing are high.

Fatty Acids

Meat is also a source of essential fatty acids like linoleic (C18:2), linolenic (C18:3), and arachidonic (C20:4) acids. In cooked sausages, the content of this essential amino acid is affected by many factors like species used during manufacture, feeding regimens, muscle location, and so on. Therefore, the content of these essential fatty acids in cooked sausages will depend on manufacturing conditions. In addition, in meat derived from ruminants, a group of isomers from octadecadienoic acid (CLA) was identified as an anticarcinogenic compound in extracts of grilled beef and also was attributed with anti-atherosclerotic, antioxidative, and inmunomodulatory properties. However, the CLA content in beef meat varies according to breed, feed, and stage of lactation. This fact also means that its content in a cooked sausage will be affected.

Salt

The use of NaCl is very important for meat product flavor for a number of reasons. First, it is responsible for the salty taste that consumers perceive as sodium salt binds to protein receptors. Second, sodium has a synergetic effect with food matrix, and it enhances the sensory characteristics of meat as the typical desirable meat flavor. Third, salt produces the release of volatile aroma compounds from the food matrix (salting-out effect) because salt changes the ionic strength. In addition, chloride ions interact with meat proteins and favor the retention of water by the increase in the water-holding capacity and, finally, produce an impact on cooking yields. As indicated earlier, sodium chloride is a key ingredient in cooked sausages as it contributes to water-holding capacity, color, texture, and flavor. The main concern about its reduction is the loss of protein functionality and flavor. The increase in salt consumption in modern countries and its relationship with cardiovascular diseases has become the target of government authorities that have settled on different strategies to reduce salt content in processed foods. The reduction can be done over a period of years to produce an adaptation of the population to lower salty taste. These strategies have been adopted within and outside of Europe (http://ec.europa.eu/health/nutrition_physical_activity/docs/salt_report1_en.pdf) and also in the United States (http://www.nyc.gov/html/doh/html/diseases/salt.shtml).

Phosphates

The use of phosphates in cooked sausages is widespread as it contributes to protein functionally. Its use is associated with higher water retention and higher processing yields. More attention has been paid to salt reduction in cooked sausages, but the recent appearance of a scientific article suggesting an association between high intake of phosphates as food additives and increased cardiovascular risk in the general population has led to more attention being paid to phosphates. Therefore, a recent report from the European Food Safety Agency (EFSA) indicated that in the absence of actual information, it is not possible to make causal inferences for serum phosphate levels and adverse effects. The EFSA indicated the necessity to reevaluate phosphate usage as food additives.

Nitrites

Nitrite usage has been reduced in cooked sausages to reduce the risk of nitrosamine formation. The function of using nitrite in meat products has been indicated earlier, and it is considered an essential ingredient in cooked sausages. The concern over nitrite in cured meats came about when nitrosopyrrolidine was found in bacon. Later it was also found in other cured meats, but usually at lower levels than in bacon. Generally the residual nitrite levels in cooked meat products are 10 ppm or less at which nitrosamines are not likely to form.

In recent years concern about nitrite, nitrate, and nitrosamine exposure has led to several epidemiological investigations. The published results have been used in deliberations by governmental bodies. Several reports indicated that red meat and/or processed meat consumption was associated with higher rates of certain types of cancer. Therefore, several recommendations about limiting red meat and processed meat consumption were given. However, food researchers have challenged these conclusions and recommendations based on epidemiological associations of weak magnitude. Nevertheless, the meat industry has changed meat curing practices to minimize potential nitrosamine formation, such as adoption of additional regulatory limits and elimination of nitrate usage in cooked meat products. Disagreement and debate over the real health impacts of dietary nitrite and nitrate in cured meats still exist.

Polycyclic Aromatic Hydrocarbons

The impact of cooked sausages in health has been evaluated together with other meat products. But in numerous cases the results obtained may be confused by other dietary factors and cooking methods. Regarding cooking methods, the grilling of meat products can induce the development of polycyclic aromatic hydrocarbons (PAH) in the product, as it is affected by the cooking procedure employed. The contamination of PAH in grilled foods is mainly due to the pyrolysis of melted fat, and it can be reduced by avoiding excessive heating or keeping the melted fat away from the heat source. PAH has been demonstrated to be carcinogenic in experimental animal trials, and therefore, it is essential to minimize the contents of PAH in cooked sausages. However, high variation of PAH contents in smoked meat products has been detected. The relationship between PAH content and smoking conditions has been studied, and it has been reported that the PAH contents increases with smoke density and ventilator velocity. It has been recommended to achieve low smoke generation temperatures (below 600 °C) to lower PAH contents in hot smoked sausages; however, this approach requires longer smoking times with higher weight losses to obtain a comparable color. Benzo(a)pirene is one of the most important carcinogenic PAH compounds, and it has been used as marker, although a maximum level of 5 μg kg^{-1} has been established for smoked meat products. The intake of PAHs has been estimated for some European countries, and it has been shown that the major food contributors are cereals, oils, and vegetables. Grilled and barbecued meat products produce a significant proportion of the daily PAH intake (21%) in the United States. In this context, well-done red meat, and the intake of bacon and sausages has been associated with increased cancer risk and colorectal adenoma in the United States. However, the total intake of processed meats has not been associated with this risk. Once again, the high temperature used during cooking and the intake of benzo(a)pirenes were associated with this risk. The recommendation to reduce the exposure to these compounds are to use slow cooking for longer periods of time, turn meats more frequently to reduce surface temperatures, and add complementary consumption of foods rich in fiber and flavonoids.

Sausages and Comminuted Products: Dry Fermented Products

I Astiasarán and D Ansorena, University of Navarra, Pamplona, Navarra, Spain

© 2016 Elsevier Ltd. All rights reserved.

Dry Fermented Sausages: Introduction

The FAO defines 'dry fermented sausages' as uncooked meat products that consist of more or less coarse mixtures of lean meats and fatty tissues combined with salts, nitrite (curing agent), sugars and spices, and other nonmeat ingredients filled into casings. Their typical properties (flavor, firm texture, and red curing color) are obtained through fermentation processes. Shorter or longer ripening phases combined with moisture reduction ('drying') are necessary to safely build up the typical flavor and texture of the final product. These products do not receive any heat treatment during processing and they are mostly consumed raw.

As with other groups of foods, there is a great variety of dry fermented sausages and their variety is dependent upon the ingredients used in their formulation and also on the technological conditions applied during their processing. In most cases, these differences are related to the regions or countries from where the products are typically derived. Different meat species (pork, beef, deer, lamb, calf, and even goose), lean/fat ratios, curing salts, carbohydrates, spices, scents, starter cultures, and processing conditions (meat particle size, diameter and type of casings, and use of molds) give rise to a broad variety of sensory properties, which in turn creates a variety of very different products. Additionally, fermentation and drying conditions (temperature, humidity, time of drying, and smoking) can define the final characteristics of the products. For instance, high fermentation temperatures (around 26 °C), typical of that employed in Northern European countries, give rise to faster lactic acid production and lower ultimate pH products (pH from 4.8 to 5.2) as compared to using lower processing temperatures (<12 °C), as used in Mediterranean countries, that produce less acidic products (pH from 5.3 to 5.8). In the United States, very fast fermentation processes caused by high temperatures (35 °C) are typical. Additionally, in the United States, it is common for rapidly fermented dried sausages to be fully cooked in order to meet government regulations, thereby generating slightly different product forms to those found anywhere else in the world.

Types of Fermented Sausages: General Composition

Meat and meat products are recognized in the Western diet as the main source of essential amino acids, high-biological-value proteins, bioavailable iron and other minerals, and B vitamins. Dry fermented sausages are a group of processed meat products that supply these nutrients, providing these with the accompaniment of some rather unique sensorial properties derived from the lactic fermentation and the drying that takes place during their processing.

Table 1 reports the composition of some of the most common types of dry fermented sausages from different countries in the world. Differences in composition are derived from the raw materials used, the processing procedures (including the lactic acid bacteria strains responsible for the fermentation process), and the degree of drying.

As the main ingredients of dry fermented sausages are meat and back fat, protein and fat are the main macronutrients responsible for the high energetic value associated with these products.

Proteins are an essential component of the diet, meat being widely used as a nutritional source of this macronutrient. The amount and type of meat used in the sausage formulation give rise to different percentages of protein. In general, protein content is around 20% in the majority of product forms, with the highest percentages accounted to chorizo (a Mediterranean high-quality product from Spain that showed 27%) and the lowest to cervelat (from Norway, with 10.7%) and salami (from Denmark, with 13.9%). Moreover, the quality of these proteins is variable depending on the amount of connective tissue present in the meat. Protein from skeletal muscle has a high biological value, supplying significant amounts of essential amino acids. However, connective tissue has a much lower biological value, being rich in collagen, protein with hydroxyproline as characteristic amino acid contributors. It is generally stated that the higher the hydroxyproline amount in the protein fraction of the product, the lower the biological value of the protein. Additionally, the amino acid composition of meat can vary according to several factors related to anatomical location, breeds, sex, species, or feeding regime of the animals.

The importance of dietary protein cannot be underestimated in the diets of older adults; inadequate protein intake contributes to a decrease in reserve capacity, increased skin fragility, decreased immune function, poorer healing, and longer recuperation from illness. Additionally, it has been postulated that increased dietary protein has been shown to promote healthy body weight and composition, in part by increasing satiety and by improving vitality and stamina. The supply of protein from dry fermented sausages to the total diet could be considered significant.

Furthermore, it is important to take into account that dry fermented sausages could have a significant fraction of nitrogen compounds that are released from the protein fraction during the fermentation process. Among these compounds, bioactive peptides possessing interesting antioxidant, antimicrobial, and antihypertensive properties can be found.

Fat is the most significant fraction in every product, with percentages ranging from 17% to 49%. This high fat content is the main factor responsible for the negative health aspects relating to the high intake of these products and, in consequence, to the current recommendation that suggests an occasional intake of this type of product. In fact, fat is responsible for the greatest fraction of their energetic value. Furthermore, the amount and type of fat have a significant influence on the sensorial properties of food, being positively related to the

sensory features of the final product. Products such as fuet, Cantonese, pepperoni, and some of the salamis and chorizo consist of more than 40% fat.

The fatty acid profile of fat depends on the animal species and the diet received by the specific animal species prior to slaughter. In most cases, the major part of all fat in fermented sausages corresponds to pork back fat, whose polyunsaturated fatty acid (PUFA) level can be modified by means of animal nutrition practices. As it can be observed in Table 1, the monounsaturated fatty acid (MUFA) fraction is, in general, the highest fat fraction in dry fermented sausages, accounting for values around 44–50% of the total fat content. This is in agreement with the fatty acid profile of pork back fat, which is rich in this lipid fraction due to the presence of oleic acid. The saturated fatty acid (SFA) fraction is also quite high, reaching values of 35–40% in most of the product forms. In contrast, PUFAs account for the lowest lipid proportion, ranging from 8% to 15% in most of the products. Regarding cholesterol contribution, amounts derived from dry fermented sausages can be considered similar to other products from animal origin and are far lower in content than foods such as shellfish and eggs.

Carbohydrate content is generally low in dry fermented sausages, and they are derived from the starches or other poly- and oligosaccharides added as ingredients to enhance the fermentation process. In some products, the amounts are more significant reaching 9.5% for sucuk or 7.7% for Cantonese sausage.

The mineral fraction of dry fermented sausages, and of processed meat in general, is very rich in some nutrients, such as iron, zinc, calcium, potassium, and especially sodium. The high amount of sodium is due to the use of common salt as ingredient, which plays an important role as preservative and also contributes to sensorial aspects. In recent years, a great effort to reduce the amount of salt used in dry fermented sausages has been undertaken. As it can be observed in Table 1, there are still some products on the market possessing sodium concentrations of around 1650 mg/100 g.

Iron is one of the micronutrients that still show significant deficiencies in some population groupings, even in developed countries. Meat and processed meats, including dry fermented sausages, constitute an interesting group of food supplying this nutrient. Sometimes, an intake of iron supplements is required to minimize the risk of deficiencies, but in some cases, as in the case of pregnant women, these intakes have been correlated with hyperglycemia.

Diets of high iron bioavailability contain generous amounts of meat and foods that enhance iron absorption (e.g., containing ascorbic acid (AA)), and it has been suggested that only meat intake has consistently (positively) been associated with higher iron stores (in the form of serum ferritin). There are two major forms of nutritional iron, heme and nonheme. Iron acquired from meat is 40% heme iron and 60% nonheme iron. Heme iron has a good bioavailability being very efficient in decreasing anemia, although in the last few years, some studies have indicated a relationship between this nutrient and some forms of diabetes and cancer. The amount of iron in dry fermented sausages is around 1.8 mg/100 g. The dietary reference intake for iron is 8 mg day^{-1} for men and 18 mg day^{-1} for menstruating women.

Zinc is another micronutrient that is present in significant amounts in dry fermented sausages. The DRI for zinc is 11 mg day^{-1} for males and 8 mg day^{-1} for females. The mean value for the sausages presented in Table 1 was 2.5 mg/100 g, a value that can be considered as significant when compared with levels found in other food groups, especially when compared with sources derived from vegetal origin rich in inhibitor factors that decrease its absorption, as well as that of iron and calcium. Other trace elements, such as selenium, could be supplied in some significant amounts by fermented sausages. The contribution of meat and meat products to daily selenium intake is around 21%.

In relation to calcium, the DRI is 1000 mg day^{-1}, so the intake of this nutrient from meat products (including dry fermented sausages) is in general low. However, the amount of vitamin B_{12} in dry fermented products (0.9–3.7 μg day^{-1}) significantly satisfies the DRI (2.4 μg day^{-1}). It is noteworthy that this vitamin is present only in foods from animal origin, meat and meat products being the main source in the diet.

In a recent paper, McNeill published a review about the beneficial aspects of red meat intake (which partially could be extrapolated to processed meats including fermented sausages) and its supply of proteins and micronutrients.

Controversial Aspects

Although the amounts and quality of different nutrients present in dry fermented sausages are of major interest, several factors operate against these products being among the most recommended foodstuffs.

Diseases as type 2 diabetes, high blood pressure, and coronary heart disease are correlated with overweight and in consequence with the intake of an excess of calories. So the high energetic value showed by most of the dry fermented products is a key factor limiting their intake.

Some studies have associated red and processed meat consumption with the development of two of the major chronic diseases in the Western world: CVD and colon cancer. The World Cancer Research Fund and the American Institute for Cancer Research have stated that there is epidemiological evidence of the relationship between red meat and processed meat consumption and colorectal cancer. In this sense, there are papers in which a deep research about the mechanisms explaining these effects is demanded.

Additionally, as previously stated, conventional formulations of this type of products include high amounts of fat. According to WHO, dietary fat intake should range between 15% and 35% of total energy value, with saturated fat making up to a 10% of this total and the polyunsaturated fraction making up between 6% and 11%. Regarding SFA, it has been long known that they primarily raise LDL-cholesterol in comparison to MUFA and PUFA, and suggestion to replace SFA by these other types of fat has been proposed. However, incipient epidemiological data challenge the concept that SFA increases the risk of CVD, suggesting the revision of current dietary recommendations for these fatty acids. In any case, the high fat content of traditional dry fermented sausages currently hinders their regular intake.

Another health concern related to the composition of dry fermented sausages deals with the use of nitrite (KNO_2/E249 and $NaNO_2$/E250) and, indirectly, nitrate ($NaNO_3$/E251 and

KNO_3/E252) in their formulations, not only basically to avoid the growth of *Clostridium botulinum* and other pathogens but also for technological reasons (nitrite contributing to adequate color and cured meat flavor). Despite these positive actions, the traditional use of nitrate/nitrite in the meat industry is being questioned due to their involvement in nitrosamine formation and inducement of methemoglobinemia with excessive intakes of nitrite. However, it has been also postulated that dietary amounts of nitrate may have robust NO-like effects in humans, including blood pressure reduction, inhibition of platelet aggregation, and vasoprotective activity, which could have beneficial health effects, including protection against cardiovascular disease and type 2 diabetes.

Healthier Fermented Sausages: Reformulation Strategies

As a consequence of these previously mentioned nutritional drawbacks, and in light of the strategies that propose food reformulation as one of the ways to improve the nutritional quality of the diet, extensive research has been conducted in order to achieve this objective. Consequently, it has been postulated that meat products could be excellent matrices for functional foods: They appeal to a wide range of consumers; they are versatile (e.g., minimally processed to comminuted products), and as has already been mentioned, they intrinsically contain high-quality nutrients (proteins, vitamins, and minerals).

Thus, dry fermented meat products are currently available in which addition, reduction, replacement, or increment of compounds with physiological or biological activity has been carried out to enhance final formulation. Additionally, other approaches dealing with animal nutrition practices for improving the nutritional quality of the resulting meat and meat products have also been carried out.

Lipid Fraction

Reducing the total fat content or substituting fat by nonlipid ingredients or healthier lipid sources is among the most usually studied strategies to improve the nutritional value of dry fermented sausages.

Replacement of pork back fat by healthier fat sources began with the use of olive oil (to increase the monounsaturated fat content), firstly as a direct ingredient in formulations and later by means of their incorporation into soy protein emulsions or soaking them in bread crumb, which resulted in better products. Products such as Greek slow-fermented sausages, chorizo, Italian salami, and sucuk have been elaborated with significant amounts of olive oil by different authors.

Regarding the incorporation of PUFAs, most of the scientific publications deal with the use of different oil sources rich in omega-3 fatty acids. Linseed oil was used to substitute 25% of pork back fat by an O/W emulsion in Spanish dry fermented sausages, achieving a relevant supply of a-linolenic acid (2.53 g/100 g product). Additionally, the use of different very long-chain omega-3 fatty acid sources has allowed the development of acceptable products if the amounts added were carefully adjusted. Thus, oil from microalgae *Schizochytrium* sp. was used to substitute 15% of pork back fat by a soy emulsion, thereby attaining a final formulation level of 1.30 g/100 g product of DHA, with an interesting $n-6/n-3$ ratio and good product stability with acceptable sensory properties storage under vacuum.

In sucuk sausage, hazelnut oil was directly incorporated to substitute an 11.11% of beef fat, contributing to a final PUFA concentration of about 7 g/100 g product, increasing both linoleic and linolenic acids as compared to the control product and reporting good sensory results. Additionally, sunflower oil and lard-based diacylglycerols have been tested as pork fat substitutes, at levels of 5%, giving rise to good sensory ratings, especially in the case of sausage formulations containing sunflower oil.

Not only have single oils been investigated, but also mixtures of oils have also been employed as a means of attempting to obtain a balanced lipid profile, closer to current lipid recommendations, without compromising the stability and sensory properties of products. A combination of 0.44 olive oil, 0.38 linseed oil, and 0.18 fish oil fractions was emulsified into konjac gel to be incorporated into low-fat fermented sausages. A significant fat reduction (up to 68%) and increments of linoleic, eicosapentaenoic, and docosahexaenoic acids as compared to the control product were reported. However, and due basically to the fat reduction, the sensory analysis of these products resulted in some sensory limitations (lower firmness and lower acceptability), so further modifications would need to be considered in order to improve the formulation.

Different fibers have also been used as fat replacers in different types of dry fermented products. Vegetable sources, such as inulin, cereal fibers, sugar beet, and fibers of red wine by-products, have been used with successful results at the doses tested. When amounts added were high, some textural defects were noticed. Moreover, a nitrite-reducing effect has been appreciated and enhancement of microbial quality was observed using orange fiber from different products.

Salt Reduction and Mineral Modification

The important role played by salt in dry fermented sausages challenges its reduction or replacement. In fact, there is no single ingredient that can fully substitute the effect of sodium chloride in foods, and several strategies have been generally tried to do so in processed foods.

The use of chloride and nonchloride salts has been the most common practice employed to date in an attempt to reduce salt, either by being used separately, or in combination, or with the incorporation of enhancers in the mixtures. KCl (alone or combined with potassium lactate) can substitute up to a 50% (molar basis) of NaCl in different small caliber products, with higher percentages causing bitterness and metallic aftertaste. KCl, in combination with $CaCl_2$ and Mg Cl_2, was also used in chorizo, reporting good technological properties, but lower saltiness perception. Consequently, in order to counteract the lower aroma perception of reduced salt products caused by lower sulfur compounds and higher aldehydes, inoculation with *Debaryomyces hansenii* has been explored in reduced fat and salt fermented sausages. These authors found better results when fat or salt was reduced than when the modification was carried out simultaneously.

Another yeast, *Saccharomyces cerevisiae*, was used in combination with KCl to replace up to 50% NaCl, achieving good sensory results due to relevant production of volatile compounds from amino acids and carbohydrate metabolism. A similar salt reduction was also reached by using lysine, disodium guanylate, and disodium inosinate as successful flavor enhancers in combination with KCl.

Interesting approaches that combined salt reduction with enrichment with calcium and other deficient minerals have also been tested. Thus, calcium ascorbate partially replaced NaCl in a 7:3 w/w mixture or in different mixtures up to 8:2 in chorizo. In this last example, which also modified the lipid fraction by increasing omega-3 fatty acids, sodium reduction reached 50% and calcium supply reached 5.2 g kg^{-1}, thereby resulting in a healthier product from a broader nutritional perspective.

Other works in which a combined modification of the lipid fraction and salt content have been performed simultaneously reduced fat (reduction to 10% of the initial fat content) used 3% sunflower oil instead of pork back fat and reduced salt (form 205% to 1.5%) in fuet (a small caliber non-acid fermented sausage).

Besides salt replacement, enrichment in other minerals has been successfully carried out by addition of salts (calcium lactate, citrate, and gluconate for calcium enrichment) or by addition of selenium yeast (for Se enrichment).

Nitrite Reduction

Alternatives to the use of additives have been explored to decrease direct nitrite addition without compromising the quality and safety of dry fermented products. Among them, the use of plant extracts and modification of the processing conditions have been examined.

Celery concentrate was used in combination with tocopherol (200 mg kg^{-1}) in an attempt to produce low-nitrite dry-cured sausages (salchichón), without creating oxidation or sensory-related problems. Another approach was attempting to use the nitrite-reducing effects of glucono-delta-lactone (GDL) and AA to lower residual nitrite levels in sucuk. Data from this study showed that nitrite reduction was achieved with AA but yield and sensory scores for sucuk sausages were compromised.

Curing with reduced amounts of nitrites/nitrates has been evaluated in formulations of salchichón (a typical Spanish sausage product), where the reduction accounted for 25% or 50% of the maximum amount allowable under European regulations (150 ppm each). Inoculation with *Listeria innocua* or *Salmonella* Typhimurium allowed these authors to conclude that the absence of nitrate/nitrite favored pathogens growth, with 2–2.5 log cfu g^{-1} higher counts at the end of ripening, compared to control sausages using normal commercial levels of nitrate/nitrite. Additives such as these represent essential tools in the growth control of pathogens, even when pH and water activity are below the values considered as minimum for their growth. Additionally, omission of curing agents without sufficient technological knowledge and modification of processes results in a product of poor quality and of questionable safety status.

Antioxidants

Some of the strategies that modify the lipid fraction lead to products with a higher unsaturated fatty acids content, which in turn may leave products open and susceptible to oxidation compared to traditional formulations, resulting in lower-quality products, with deleterious modifications in sensory and nutritional properties. The use of synthetic antioxidants, such as BHT and BHA, has been shown to control oxidation during the storage of these products. However, the demand for natural antioxidants in the meat industry has increased primarily because of concerns relating to potential adverse health effects associated with synthetic antioxidants.

In this sense, both vegetable by-products and edible medicinal plants have been explored as sources of antioxidant compounds. The use of green tea extract, *Urtica dioica* and *Hibiscus sabdariffa*, was investigated to control lipid oxidation and amine formation in sucuk. Water extracts from *Borago officinalis* leafs (340 mg kg^{-1}) controlled lipid oxidation in linseed oil-enriched chorizo, whereas *Melissa officinalis* (686 mg kg^{-1}) was effective in a similar product elaborated with an emulsion containing a mixture of linseed and algal oil as partial replacers of pork back fat. Both extracts showed high concentrations of rosmarinic acid, a substance known for its antioxidant capacity. In chorizo, the use of phytochemicals obtained from by-products of grape seed and chestnut processing has been reported. Studies concluded that, at the doses used (1 g kg^{-1}), extracts were more effective than synthetic antioxidants, with grape seed extract better accepted from the sensory point of view. Additionally, cocoa extracts (0.5% w/w) were found to be suitable for enrichment of dry fermented sausages (fuet and salchichón) with health-beneficial polyphenols (mainly flavan-3-ols), without modification of the sensory properties of the products.

Sausages as Probiotics

The commercialization, in 1998, of a German salami product containing three intestinal lactic acid bacteria strains (*Lactobacillus acidophilus*, *Lactobacillus casei*, and *Bifidobacterium* spp.) and a Japanese equivalent containing *Lactobacillus rhamnosus* FERM P-15120 has been reported, claiming to have beneficial health effects. However, the commercial application of probiotic meat products is yet a challenge. Nevertheless, some papers discuss the possibility of using different strains of *Bifidobacterium*, *Lactobacillus*, or *Pediococcus* in several types of fermented meat products: dry sausages, salami, and sucuk.

One of the challenges when dealing with probiotic foods is to demonstrate their ability to survive passage through the alimentary tract and remain in the gut. A number of studies in this area using fermented meat products are noteworthy. A human intervention study demonstrated that the strain *Lactobacillus rhamnosus* CTC1679 was a suitable starter culture for producing safe potentially probiotic reduced fat and *sodium low-acid fermented sausages* (fuets), and it also showed its capacity to survive through the gastrointestinal tract. These products achieved a satisfactory overall sensory quality rating, without negative flavors and with the sensory properties typical of low-acid fermented sausages.

Additionally, *Bifidobacterium animalis* 241a, and especially *Lactobacillus acidophilus* CCDM 476, allowed for the successful manufacture of fermented mutton sausages with good sensory properties and produced viable microorganisms after a 14-day consumption period in healthy volunteers.

However, a debate continues about the actual amount of fermented meat products needed to be ingested to realize the

potential beneficial effects associated with probiotic consumption in this manner.

Conclusions

Dry fermented sausages are meat products produced globally with different procedures giving rise to a broad variety of products. They contribute significant amounts of nitrogenous compounds, minerals, and vitamin B_{12}. At the same, time they have a relatively high energetic value and supply high amounts of fat, a high SFA content, and sodium.

Reformulation of conventional dry fermented sausages allows counteracting some of their nutritional drawbacks, thereby becoming healthier products, without producing negative impacts on their sensory and technological performance. Products with low fat, enriched in MUFA and PUFA, and low sodium have been successfully developed to date, but there remains much scope for further compositional and nutritional improvement of dry fermented meat products.

Selenium: Properties and Determination

M Roman, Ca' Foscari University, Venice, Italy; CNR, Institute for the Dynamics of Environmental Processes, Venice, Italy

Chemical Properties and Biogeochemistry of Selenium

Selenium (Se) is an element of the group 16 and period 4 of the periodic table. It has four natural oxidation states: −II (selenide, SeH^-), 0 (elemental Se, Se^0), +IV (selenite, SeO_3^{2-}), and +VI (selenate, SeO_4^{2-}). The chemical and physical properties of Se are close to those of sulfur (S) as they belong to the same group in the periodic table. These two elements have similar outer valence-shell electronic configuration, atomic size, bond energies, ionization potential, and electron affinity. As Se shares numerous chemical behaviors with S, it is easily incorporated in biomolecules instead of the latter. Nevertheless, the two elements are not fully interchangeable because some key properties are significantly different. In biological systems, Se can replace S in the amino acid cysteine by means of a selenolic (−SeH) group, forming selenocysteine (SeCys). Selenols have stronger acidity compared to thiols (−SH) by up to three orders of magnitude and hence are negatively charged at physiological pH, while thiols are mainly neutral. Moreover, the bond stability of organic Se compounds is lower than in the S analogs, resulting in decreased stability. It follows that Se compounds are more reactive, easily oxidized, and liable to decomposition following exposure to air and light. SeCys is also much more susceptible to degradation under acid hydrolysis conditions than its sulfur analog.

Se is a low-abundance ($0.05\ mg\ kg^{-1}$) constituent of crustal rocks, mainly occurring as metallic selenides and as a minor component of metal-S minerals. The main sink and source of Se is rock material, from which the biogeochemical cycle starts with erosion and follows a number of pathways, as represented in Figure 1. Plants and microorganisms take up Se from soil, incorporating it into tissues, and release it into the atmosphere in the form of volatile methylated metabolites. Animals (and humans) who consume plants and cattle assume Se mainly through their diet. Se is relatively rapidly eliminated when consumed by higher organisms, and biomagnification in the higher levels of the food chain is therefore limited. Se compounds present in soil or released from the decomposition of biological tissues may be partly immobilized under reducing conditions in water or sediments, which makes them no longer bioavailable for plants. Like S, Se vaporizes at high temperatures and thus is also released in the atmosphere by volcanic activity as SeO_2. Upon cooling, volatile Se compounds condense onto PM's surface and undergo wet deposition, closing the cycle. Many anthropogenic sources were introduced into the biogeochemical cycle of Se over the last centuries, including fossil fuel combustion, soil fertilization, and many industrial processes. The addition of selenate to commercial fertilizers, aimed to improve the dietary intake in regions where soil Se is scarce, has an important impact on the whole food chain up to humans.

Se in Soil and Water

The level of Se in soil depends strictly on the parent rock material. The concentration varies geographically over a wide range, from a minimum of $0.01\ mg\ kg^{-1}$ to a maximum of $1250\ mg\ kg^{-1}$, but most soils contain between 0.01 and $2\ mg\ kg^{-1}$ of Se. A level below $0.1\ mg\ kg^{-1}$ identifies Se-poor regions, mainly located in northern Europe (Finland), Siberia, subequatorial Africa, Australia, and scattered areas of Nepal, China, and North Korea. Regions with Se-rich soils, up to the order of $g\ kg^{-1}$, are located in the North American Great Plains, Venezuela, Ireland, India, Nepal, China, and Australia.

Se in soil can exist in all oxidation states, mainly depending on the pH and redox state. Acidic conditions favor the formation of selenite, which has very low solubility and adsorbs to clays and Fe/Al/Mn hydroxides, remaining unavailable for plants. Elemental Se is assumed to form under further reducing poorly aerated conditions, whereas in well-drained and alkaline environment, the equilibrium shifts toward the soluble and bioavailable selenate. In most soils, selenate is the prevalent form and is easily taken up by plants. Organic compounds of Se, mainly amino acids, exist in soil as part of residues of vegetal tissues, but are less important than the inorganic forms.

Se concentrations in natural and domestic waters are generally very low, usually below $1\ \mu g\ l^{-1}$. The WHO has set the maximum limit of Se in drinking water to $0.01\ mg\ l^{-1}$, a standard later adopted also by the EU. With the exception of seleniferous or contaminated areas, such limit is very far from the average concentration of Se in drinking and even natural waters. Thus, water quality criteria for Se are primarily set on the basis of ecotoxicological criteria for organisms at the top of the aquatic food chain, rather than for human consumption. In oxic surface waters, Se speciation is dominated by the oxyanions selenite and selenate, still depending on the redox potential; chlorination in drinking water further favors the predominance of the selenate species. Speciation in freshwater impacts the acute toxicity of Se, a factor taken into account by the US EPA guidelines, but the total level of Se is so generally low that speciation is not determined under normal monitoring.

Se in Food

The main route for Se intake in humans is the diet, while the contribution from the water and air is negligible. The total amount of Se in the diet varies widely depending on the food type and composition, as shown in Figure 2. Bread and cereals, meat, fish, eggs, and milk/dairy products are the primary food sources of Se. The level of Se in crops correlates to that in the soil, whose conditions (pH, redox state, salinity, and organic matter) regulate its bioavailability. The crops, being consumed on a global scale, are an important source of Se. Nevertheless, Se in crops is generally in low abundance because such plants

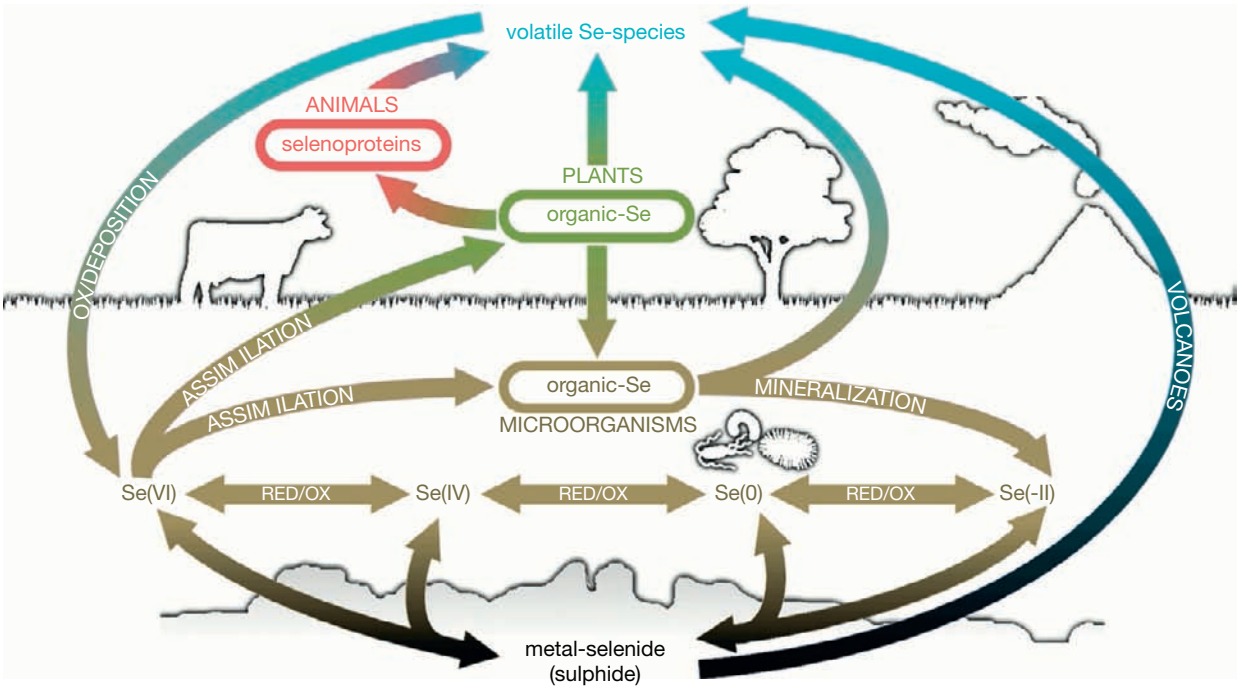

Figure 1 Main pathways of Se biogeochemical cycle.

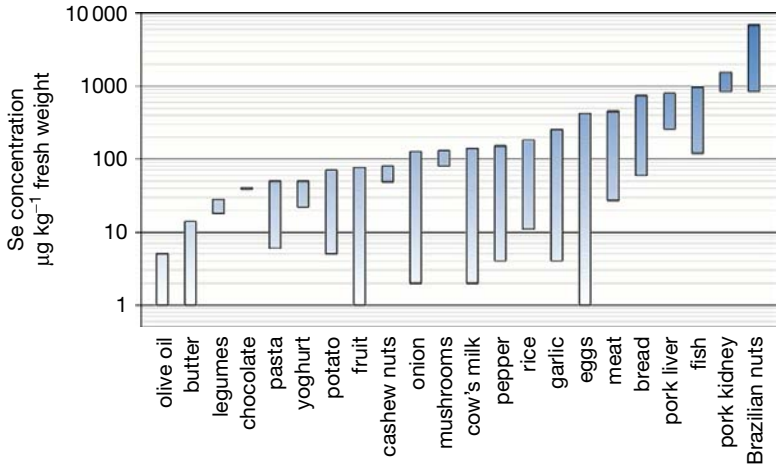

Figure 2 Range (min–max) of Se concentration observed in a variety of food types (the *y*-axis is in log scale).

do not require the element for growth and normally do not accumulate it. A level ranging between 10 and 550 μg kg^{-1} of Se was reported in cereals, whereas Se in bread is generally found at a level of ~60–160 μg kg^{-1}. Unlike crops, some vegetables such as those of the *Allium* family, including garlic and onion, can accumulate significant amounts of Se, reaching concentrations up to 68 and 96 μg g^{-1}. High amounts of Se can be accumulated also by mushrooms and broccoli. The richest natural source of Se is the Brazilian nut, in which this element can reach a concentration of 83 μg g^{-1}. In animal products, the level of Se reflects the one present in the cattle feed used. In meat, eggs, and particularly fish, which are rich in proteins, the Se content is relatively high, in the range of ~50–750 μg kg^{-1}. Additionally, specific organs, such as the liver and kidney, may contain a particularly high level of Se, up to 1500 μg kg^{-1}.

A crucial aspect is that different food types provide Se in distinct combinations of chemical forms (species), each one associated to a specific bioavailability of the element. The main Se species in vegetables are selenomethionine (SeMet) and selenate/selenite; minor species are SeCys, Se-methylselenocysteine (SeMCys), and γ-glutamyl-Se-methylselenocysteine (GGSeMCys). Selenate/selenite, SeMet, and SeCys are the prevalent species in animal products, with widely variable proportions depending on the animals' diet. Each species is characterized by specific absorption/assimilation routes and efficiency. Speciation analysis of Se in food is therefore a key requisite to estimate the actual bioavailability of the uptake.

Se in the Human Body

The concentration of Se in human tissues is below 1 $\mu g\,g^{-1}$, even in organs that play a key role in Se physiology. The adult whole-body amount of Se estimated for different countries reflects its uneven geographic distribution in soils and ranges between 2 and 20 mg. In good health conditions and sufficient dietary intake, the highest Se concentration was observed in the kidney, followed by the liver, spleen, pancreas, heart, brain, lung, bone, and skeletal muscle. Figure 3 summarizes the estimated level of Se in various parts of the human body. Notably, the distribution of the element may vary widely among distinct tissues in the same organ. For instance, the average level of Se in the brain can be estimated around 0.1 $\mu g\,g^{-1}$, but such a value is better representative of the cortex and white matter, whereas the cerebellum and pituitary gland exhibit much higher local levels of the element (0.28 and 0.55 $\mu g\,g^{-1}$, respectively). Relative to the body mass, 25–50% of Se was found in skeletal muscle, 16% in bone, 7–10% in blood, and 4% in kidney. Under conditions of Se deficiency, the distribution of the element within the body may change significantly, favoring those organs that play a key role in its utilization.

Se-Specific Detectors

A variety of detectors are available for the element-specific determination of Se. The most commonly used include inductively coupled plasma-mass spectrometry (ICP-MS) and atomic absorption spectrometry or atomic fluorescence spectrometry (AAS or AFS). Other analytic techniques that are occasionally used, but are not widespread in their application, include instrumental neutron activation analysis (INAA), inductively coupled plasma-atomic emission spectrometry (ICP-AES), and to an even less extent electrochemical and spectrofluorimetric methods. Most instrumental setups are conceived to provide a quantitative measure of the concentration of Se in a liquid medium. Hence, liquid extraction or wet acid mineralization is required for solid samples, whereas filtration, acidification, and dilution may be sufficient for liquids. Attention must be paid throughout the sample preparation, particularly mineralization, in order to prevent the generation and subsequent loss of volatile Se species; long times/low temperatures or closed environments are preferable for such operations. Solid samples can be directly analyzed in particular cases, for instance, when using graphite furnace (GF)-AAS, INAA, and ICP-MS with laser ablation (LA) interface.

ICP-MS is the most powerful technique for Se determination, as it provides high resolution and sensitivity and instrumental limits of detection (LODs) below 0.1 $\mu g\,l^{-1}$ and also enables multielemental analysis. The US EPA published standard methods for the analysis of trace elements, including Se, by ICP-MS in a variety of matrices. The most widespread mass analyzer for ICP-MS is the low-resolution quadrupole, although high-resolution systems such as the double-focussing magnetic sector field are also employed. Compared to other elements, the sensitivity provided by ICP sources for Se is

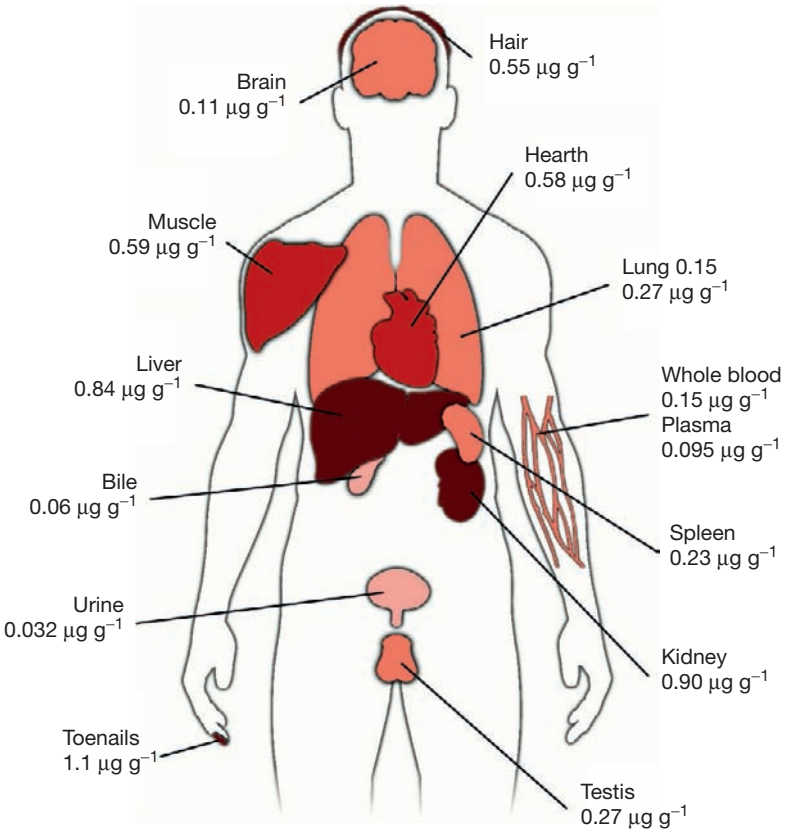

Figure 3 Average Se concentration estimated in various human organs.

relatively lower, due to the high ionization potential of this element. Se has six stable isotopes, all suffering from spectral interferences that must be carefully evaluated before analysis. High-resolution MS allows one to monitor the isotopes ^{77}Se and ^{82}Se free of their main interferences from $^{40}Ar^{37}Cl$ and $^{81}Br^{1}H$, whereas quadrupole MS does not. However, the major isotopes ^{78}Se and ^{80}Se can be resolved from their interferences ($^{38}Ar^{40}Ar$ and $^{40}Ar^{40}Ar$, respectively) only using quadrupoles equipped with dynamic reaction cell (using CH_4 or CO as reaction gas) or collision/reaction cell (using H_2) technologies. Matrix effects must also be taken into account when analyzing complex matrices such as soil or biological materials. For instance, the sensitivity to Se is strongly influenced by the level of organic carbon in the media; hence, the complete mineralization of organic material must be ensured when analyzing solid samples and can be useful also for liquid samples with elevated carbon content (e.g., plasma). The use of elemental internal standards (such as tellurium, Te), isotope dilution, matrix matching, or standard addition strategies for calibration are recommended to overcome possible matrix effects. ICP-MS enables the direct analysis of solid samples by coupling to LA but yields only qualitative or at best semiquantitative data.

AAS is a traditional reference method for the determination of Se, at a relatively low cost compared to ICP-MS. Boosted hollow cathode lamps and electrodeless discharge lamps are available to provide a specific and intense radiation for Se. GF and electrothermal ionization are often used in AAS, as they are more efficient than flame for the atomization of Se. Even if GF requires sample-specific operational procedures, it has the advantage of being applicable to the direct analysis of solid samples. Detection limits down to the range of 0.1–1 $\mu g\,l^{-1}$ can be achieved by GF-AAS or by combining AAS with hydride vapor generation (HG) interface, the latter being the most used setup for the determination of Se by AAS. In HG, all Se species are firstly converted into Se(IV) and then reduced to volatile H_2Se by reacting with $K_2S_2O_8$–NaOH, $KBrO_3$–HBr, or KBr–HCl. The resulting hydrogen stream can be used to create an H_2 microflame, where atomization takes place. In recent years, AFS has also become popular for Se determination. Theoretically, this technique yields even lower LODs compared to AAS, because it measures a small fluorescence signal relative to no background rather than a difference between two signals, and requires simpler and cheaper instrumentation. AFS for determination of Se is typically used only in combination with HG.

ICP-AES can also be used to measure Se, but its application remains limited because of the higher LODs (between 10 and 100 $\mu g\,l^{-1}$) compared to other techniques, caused by the relatively low emission intensity of the element. Such LODs complicate the measurement of Se in digested samples and make the analysis of waters almost impossible. The detection wavelengths for Se are in the deep UV region of the spectrum, potentially hampering the quantification, and the primary detection wavelength (196 nm) suffers from a minor interference from Fe.

INAA is an excellent method for the determination of total Se, as untreated and small weight samples are directly analyzable. INAA allows one to perform multielemental analyses with an LOD of ~0.05 ng but provides only a measurement of the absolute amount of the analyte rather than a concentration, which limits the comparability between samples. This technique requires the use of research reactors, because the samples must be irradiated for the subsequent detection of the 162 keV γ-rays from ^{77m}Se. Its application is therefore limited to very specific studies.

Determination of Se in Soil and Water

The techniques most commonly used for Se determination use liquid samples, and their application to soils therefore requires the previous extraction or mineralization of the sample. Unlike in rocks, Se in soil is generally not incorporated into the mineral lattice, but adsorbed on the surface. The absorption is also weak because selenate is typically the dominant form, having no high affinity for silicates, so HF is generally not necessary to digest soil for Se analysis. The main tasks for digestion are to reach a quantitative dissolution of the organic materials and to oxidize all forms of Se to Se(VI). The method with better efficiency, safety, and compatibility with detectors uses HNO_3/H_2O_2 mixtures for microwave digestion at high temperature and pressure in closed vessels. Dilution of the digests with water is generally sufficient to decrease the acidity, which is preferable in ICP-MS, and to not interfere with the subsequent chemical reduction when HG is used in combination to AAS or AAS. Calibration strategies based on matrix matching and/or internal standardization are recommended to overcome the variability of matrix effect associated to the heterogeneous composition of the samples. Contamination due to sampling/storage/preparation equipment and manipulation during sample preparation is usually not a problem for Se determination in soil. The only concern is the possible loss of volatile species, which is why drying/lyophilization and dry ashing should be avoided. Sample freezing is preferable, and digestion should be carried out on the wet sample, with the water content determined apart. Although 0.1 g of material may be sufficient for the determination of Se in soil, with LODs in the range of 0.01 mg kg^{-1} when using either ICP-MS or HG-AFS/AAS, it is preferable to use 0.5 g or more to guarantee the representativity of the sample.

From an analytic point of view, assigning exact chemical structures to the binding forms of Se in soils may be very difficult. However, their individual determination can be achieved on the basis of operational criteria by means of the so-called fractionation. A soil fractionation analysis typically consists in sequential extractions with media of increasing aggressiveness. The weekly adsorbed Se species can be firstly extracted in water media (phosphate or $MgCl_2$ solutions). Treatment with alkaline solutions allows one to decompose selectively the organic matter without oxidizing the reduced forms of Se (0 and –II). Fe–Mg minerals can be dissolved reductively to release the strongly bound Se species, whereas Se^0 can be extracted with CS_2 without attacking the sulfide mineral fraction. Finally, the sulfide mineral fraction can be dissolved by acid oxidation. For a fractionation study, preserving the redox conditions of the sample until analysis is crucial. Freezing, working in a glove box, and reducing as much as possible the time for storage and manipulation are valuable strategies.

Analyzing water for Se content is much easier. Since Se is not highly particle-reactive under typical oxic conditions, the

dissolved fraction approximates closely the total level. Acidification of freshwaters with 1–0.1% HNO_3 is a sufficient treatment for the determination of Se, aimed to prevent coprecipitation with major elements during storage. Even if contamination from sampling and storage containers and equipment does not remain a major concern, the level of Se in water may be very low, so that decontamination of plastics and working in clean environment may help to guarantee a good signal-to-background ratio.

Determination of Total Se in Biological Samples

The preparation of solid biological samples for the determination of total Se is analogous to that mentioned for soils, as it typically comprises microwave digestion with mixtures of HNO_3/H_2O_2. Liquid samples containing clots, cells, or proteins (e.g., whole blood and plasma) are also analyzed more reliably *previa* digestion; systems to perform on-line microwave digestion can be coupled to elemental detectors. The concentration of Se in many biological materials, particularly human tissues, is often very low (below 1 $\mu g\,g^{-1}$ level) and may be further reduced by dilution after digestion. Decontamination of laboratory equipment and working in a clean environment is therefore recommended. Loss of Se is also a major risk due to the presence of volatile metabolites (in urine, plant, and microbial materials) or to their generation by enzymatic reactions after sampling. Immediate freezing for storage is advisable, whereas drying should be avoided, and the percent moisture should be determined separately. If homogenization is necessary, grinding in liquid N_2 is a good option. Detection limits of the order of 0.1–1.0 $ng\,g^{-1}$ can be routinely achieved by AFS/AAS and even lower ones by ICP-MS using the reaction cell modes. The US National Institute of Standards and Technology (NIST), the National Research Council of Canada (NRC/CNRC), and the EU Community Bureau of Reference (BCR) provide a variety of biological matrices certified for Se concentration, which are very useful for validation and quality control.

Speciation of Se in Biological Samples

Unlike soils, biological matrices offer the opportunity to assign exact chemical structures to individual species of Se-binding compounds, each of which plays a specific role within the physiological processes, and corresponding analytic tools for their specific determination, the so-called speciation analysis. The Se species in biological matrices include assimilated inorganic and organic compounds, intermediate and final Se metabolites, and selenoproteins. The latter are the mediators of the biological action of Se as an essential nutrient for animals.

Sample Preparation

The sample preparation procedure for speciation of Se must be milder than the acid digestion employed for the total determination, in order to prevent species degradation and interconversion. Figure 4 summarizes the main sample preparation

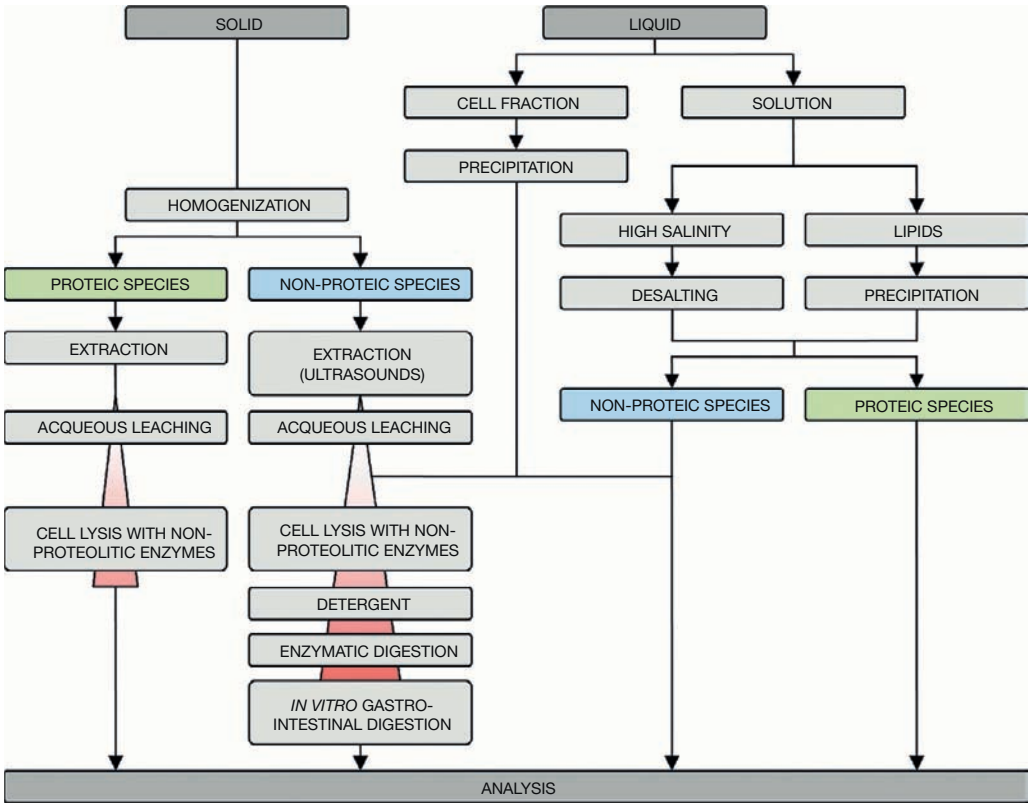

Figure 4 Flowchart of the sample preparation strategies for the speciation analysis of Se in biological matrices.

strategies used to perform speciation analysis of Se in biological matrices. Blood and its fractions (plasma, serum, and erythrocytes), breast milk, and urine are the bodily fluids most commonly analyzed for Se speciation. Plasma and urine have the advantage of containing soluble compounds, while erythrocytes must be lysed to release the Se species. Desalting or water dilution can be necessary for the analysis of urine, because the high salt concentration can be incompatible with chromatography. The normal constituents of urine are water-soluble and this enables direct chromatographic separation. Plasma/serum samples usually do not require a special treatment, a part of filtration to remove cell residues and cloths. For erythrocytes lysis, the most common method involves freeze–thaw cycles, followed by centrifugation and filtering. The analysis of milk requires the elimination of lipids by centrifugation and precipitation of casein with acetate.

The preparation of solid biological samples is more complex because the analytes must be extracted into a liquid phase. Some free Se amino acids or Se peptides are water-soluble and can be extracted with deionized water or various buffer solutions (Tris–HCl, phosphate, and HEPES). This procedure has been applied with variable recoveries to selenized yeast (10–15%), animal tissues (10–76%), plants and seeds (2–73%), and mushrooms (36%). Acid or alkaline hydrolysis can been applied to Se extraction with much higher recoveries, but degradation or transformation of the species can easily occur. Enzymatic hydrolysis using proteolytic enzymes or cocktails is the most frequently applied method for the pooled extraction of proteic and free Se amino acids, allowing one to operate at room temperature and neutral pH and thereby preventing species degradation. Conversely, when proteins must be preserved in their intact form, spiking the extraction buffer with inhibitors of proteases is important. EDTA inhibits metalloproteases by chelating Mg and other metal ions that are part of their active site, without affecting Se speciation because the element is covalently bound to its ligands. Detergents such as SDS, Triton-X, and Igepal break down the cell membrane and form ion pairs with proteins. This process not only increases the extraction of selenoproteins but also can denaturate them. Protein precipitation by organic solvent and size-exclusion chromatography can also be used as additional steps for size-based fractionation and concentration. A particular application of sequential extraction is the establishment of Se bioaccessibility by using an *in vitro* gastrointestinal digestion method, which consists in a first treatment with synthetic gastric juice containing pepsin, followed by a second treatment with synthetic intestinal juice containing pancreatin, amylase, and bile salts. Se amino acids, including SeCys and SeMet, and selenoproteins are susceptible to oxidative degradation with consequent loss of Se from the residues. To prevent the oxidation of amino acids, a feasible approach is the addition of iodoacetic acid or reducing agents such as dithiothreitol and β-mercaptoethanol, whereas selenoproteins are better protected by working under N_2 atmosphere.

Separation of Se Species and Coupled Techniques

The major techniques employed for Se-species separation in liquid samples or extracts are high-performance liquid chromatography (HPLC), gas chromatography (GC), and electrophoretic techniques, particularly capillary zone electrophoresis (CZE). These techniques are applicable to different classes of expected species and differ in the separation power (i.e., the number of compounds that can be separated in one single run). Theoretically, all these techniques can be coupled on-line to elemental detectors including ICP-MS, HG-AFS/AAS, and ICP-AES, leading to the so-called hyphenated techniques. The on-line coupling allows one to perform the separation and individual quantification of the various Se species in one single analytic run, saving time and minimizing manipulations. If the coupling is unavailable, Se speciation analysis can be performed using the same separation techniques, followed by fraction collection and subsequent off-line elemental analysis.

Generally, HPLC is more effective to separate relatively simple mixtures of small molecules such as inorganic species, small metabolites, and Se amino acids, providing a versatility derived from a wide variety of separation mechanisms. For studies in which only a few known Se species are monitored and eventually quantified, multidimensional HPLC methods offer higher specificity and technical flexibility that makes them adapted to a wide variety of compounds. Size-exclusion chromatography does not guarantee sufficient resolution for quantitative purposes, but is often applied to achieve a preliminary fractionation of Se biomolecules with Mw in the range 10–1000 kDa or to screen complex samples with unknown composition. Reverse phase is the most widespread mode used in HPLC and is particularly effective to separate Se amino acids and metabolites. Its coupling to ICP may be problematic because it requires eluents with high percentage of organic solvents. The diffusion of micro- and nanoflow HPLC systems and nebulizers allowed researchers to overcome this problem by maintaining the absolute amount of organic solvent carried to the ICP source at a low level. Another strategy consists in adding ion-pairing agents (TFA, HBFA, or room-temperature ionic liquids) to the mobile phases to increase the retention of the analytes with lower organic media. Ion exchange is another mechanism widely used in HPLC to separate inorganic species of Se and other easily ionizable Se compounds. In recent years, affinity and multiaffinity chromatography emerged as new powerful separation mechanisms, designed to retain individual selenoproteins with high specificity. Methods for the speciation of plasma/serum selenoproteins based on affinity HPLC-ICP-MS have been recently developed. GC coupled to elemental detectors can be used to separate and determine the volatile or readily derivatizable Se compounds. Solid-phase microextraction can be used to extract/preconcentrate Se metabolites from urine or particular volatile metabolites from plant extracts and can be directly combined to GC-ICP-MS for their determination.

Complex mixtures of Se compounds and intact selenoproteins are more efficiently separated by electrophoretic techniques. CZE is a separation technique based on differences in the electrophoretic mobility of target analytes and on electroosmotic properties. Its coupling to ICP-MS offers attractive features for Se speciation, including high resolution, a sample amount below 1 ng, absolute detection limits at pg levels, and the possibility of analyzing relatively labile species. So far, a few applications of hyphenated techniques based on CZE have been proposed for Se peptides (from enzymatically digested

selenoproteins), amino acids, and metabolites, but this technique is one of the most promising trends in the field.

Identification Techniques and Integrated Approaches

It is worth noting that Se speciation using elemental detectors is the best method for quantification but does not provide direct identification of the species because molecular information cannot be achieved. Identification can be only relative to the analysis of individual standards, but this approach may be unfeasible when appropriate standards are unavailable, particularly selenoproteins or unknown molecules. Molecular MS techniques such as electrospray ionization (ESI)-MS and ESI-MS/MS and matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF)-MS are useful tools by which structural information can be achieved to reach the univocal identification of Se species. Theoretically, ESI-MS/MS can allow the direct detection of Se heteroatom based on its characteristic isotopic pattern, whereas this is practically impossible in MALDI-TOF-MS due to inadequate resolution. For low Mw Se-species identification, ESI-MS and ESI-MS/MS are more frequently used, since they allow high specificity and relative sensitivity for the unambiguous identification of the compounds by their exact mass and fragmentation pattern, as well as easy on-line coupling with HPLC and CZE. This technique can also be an alternative to ICP-MS for quantification purposes down to the ng g^{-1} order of concentration. Selenoproteins can be studied *previa* enzymatic digestion carried out either before or after separation, followed by the analysis of the resulting peptides. Carboxymethylation is essential in this case to protect the selenolic groups in SeCys, even if the derivatization agent may react with SeMet producing artifact peaks. The efficiency of species separation is also crucial, because a minor Se peptide must arrive virtually pure at the ESI source in order to be detected. Through fragmentations patterns, *de novo* sequencing of proteins can be achieved by ESI-MS/MS. MALDI-TOF-MS is a competitive method for the identification of selenoproteins: it not only provides the exact mass of their digests, which can be used to trace the peptide mass fingerprint, but also allows one to characterize the mass of their intact forms.

Approaches based on tandem total and speciation ICP-MS analyses and molecular MS for the study of complex matrices are extremely powerful strategies to provide information about the number of compounds that should be identified, their concentration, the efficiency of sample preparation, and analytic recovery. Such integrated ICP-MS-assisted approaches, also defined as 'synergic' or 'multimode' and schematically resumed in Figure 5, are the most actual trend in Se proteomics and metallomics.

Evaluation of the Se Nutritional Status

The action of Se as essential trace element is mediated by selenoproteins. Although their biochemistry is still partially unknown, it has become evident in recent years that each of them participates in distinct biological processes, according to a precise ranking in the incorporation of the element. According to the current interpretation, good health should not be defined as the absence of pathologies, but rather as optimum biological functionality. In this context, the diversity and specificity of selenoprotein action complicate the assessment of the status of Se due to the difficulty to establish (i) the actual correlation between intake (and speciation in food) of Se and the overall biological functionality; (ii) which biological function is the limiting process for the definition of the optimum health state; and (iii) which marker(s) better represents such biological functionality. Despite its widespread use until recent years, the total concentration of Se in body fluids cannot be considered a representative marker of Se status. Nowadays, the most frequently adopted parameter is the activity of the individual plasma selenoproteins glutathione peroxidase type 3 (GPx3) and selenoprotein P (SelP) compared to their

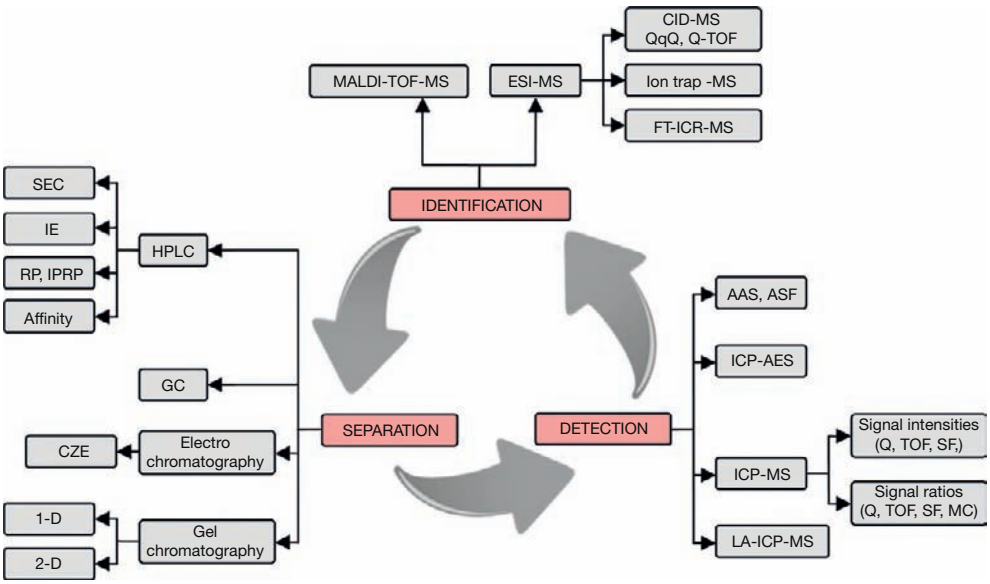

Figure 5 Flowchart of the integrated methodologies for the speciation analysis of Se in biological samples.

maximum (~100 and 124 ng ml^{-1} of Se, respectively), which is representative of the systemic distribution and correlates to the short-term intake (a few hours). However, plasma selenoproteins lose their validity as markers when Se overcomes their basal requirement, because they do not respond to additional increases of the element. New multiparametric markers, such as the expression of Se-protein mRNA in circulating leukocytes, integrated with the comprehensive analysis of health parameters, endocrine and immunological status, selenoprotein polymorphism, and other variables, are under evaluation, but introduction in a regulatory context is still to come.

Recommended Se Intake, Current Values, and Supplementation

Several institutions worldwide proposed reference values for the daily estimated average requirement (EAR, the intake level meeting the needs of 50% of the population) and recommended dietary allowance (RDA, the intake level meeting the needs of 97.5% of the population) for Se, taking into account the most reliable epidemiological studies. Figure 6 represents the range of theoretical dose–response curves used by various institutions to calculate such reference intakes, their hypothetical correspondence to plasma Se level, and possible endpoints for the evaluation of Se status. The basal requirement of Se is defined as the intake allowing the prevention of pathologically and clinically relevant signs of dietary inadequacy. An intake of ~20 μg day^{-1} for adults is generally accepted as the minimum needed to prevent Keshan disease onset and corresponds to the lower limit of the proposed EARs. Based on GPx3 activity maximization, the RDA adopted by various institutions ranges between 25 and 75 μg day^{-1} (most commonly between 50 and 60 μg day^{-1}), with small differences between genders and for particular categories (i.e., pregnant women) or age groups. The activity of other important selenoproteins such as SelP and iodothyronine deiodinases (DIOs) can provide an additional indication on the functionality of the Se system. Providing upper limits (ULs) for tolerable Se intake is more difficult due to limited data on Se toxicity for humans. So far, acute toxic symptoms were associated with extremely high Se intakes ranging between 3200 and 6700 μg day^{-1}. However, symptoms such as fingernail changes have also been reported for lower Se intakes, so that a threshold of 1260 μg day^{-1} is considered as the reference at which clinical selenosis appears, whereas the ULs

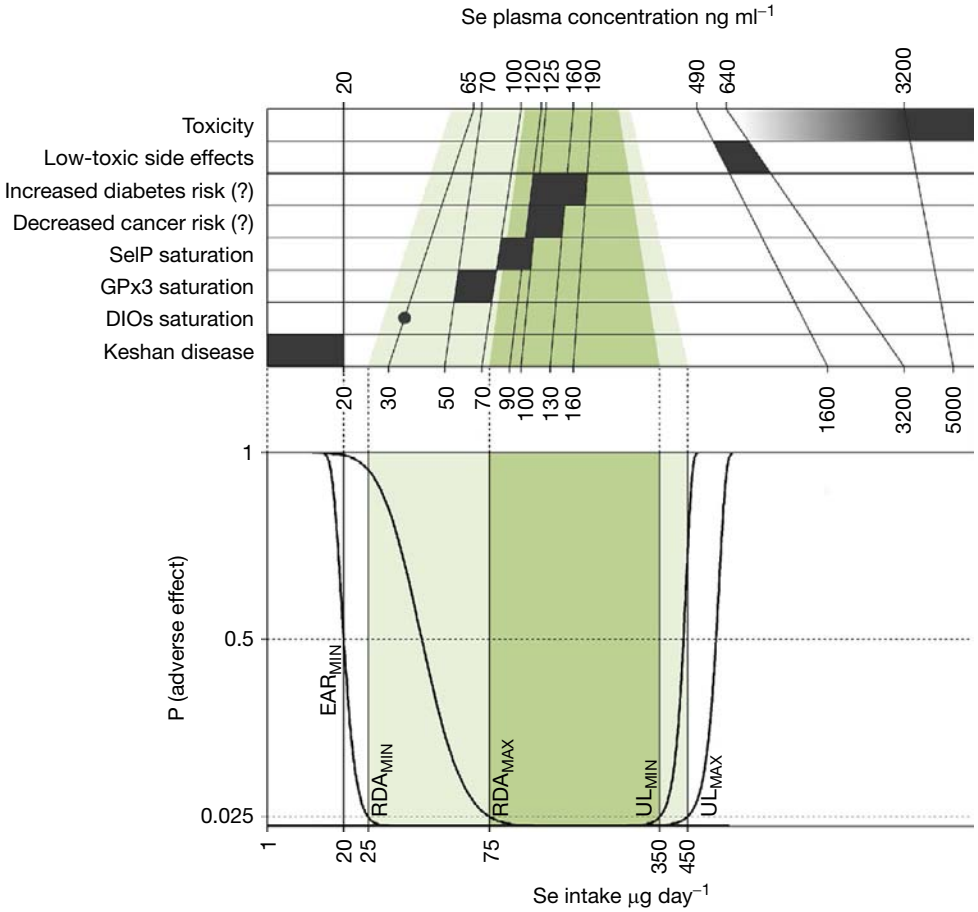

Figure 6 Indicative association among Se daily intake, plasma Se concentration, and possible endpoints for the evaluation of Se status. Two theoretical dose–response curves are represented to extrapolate the reference intake values (EAR, RDA, and UL), respectively, corresponding to the minimum and maximum of the range of values provided by the main institutions worldwide. The range of the endpoints is defined by the minimum and maximum values reported in the literature. The *x*-axis is in log scale.

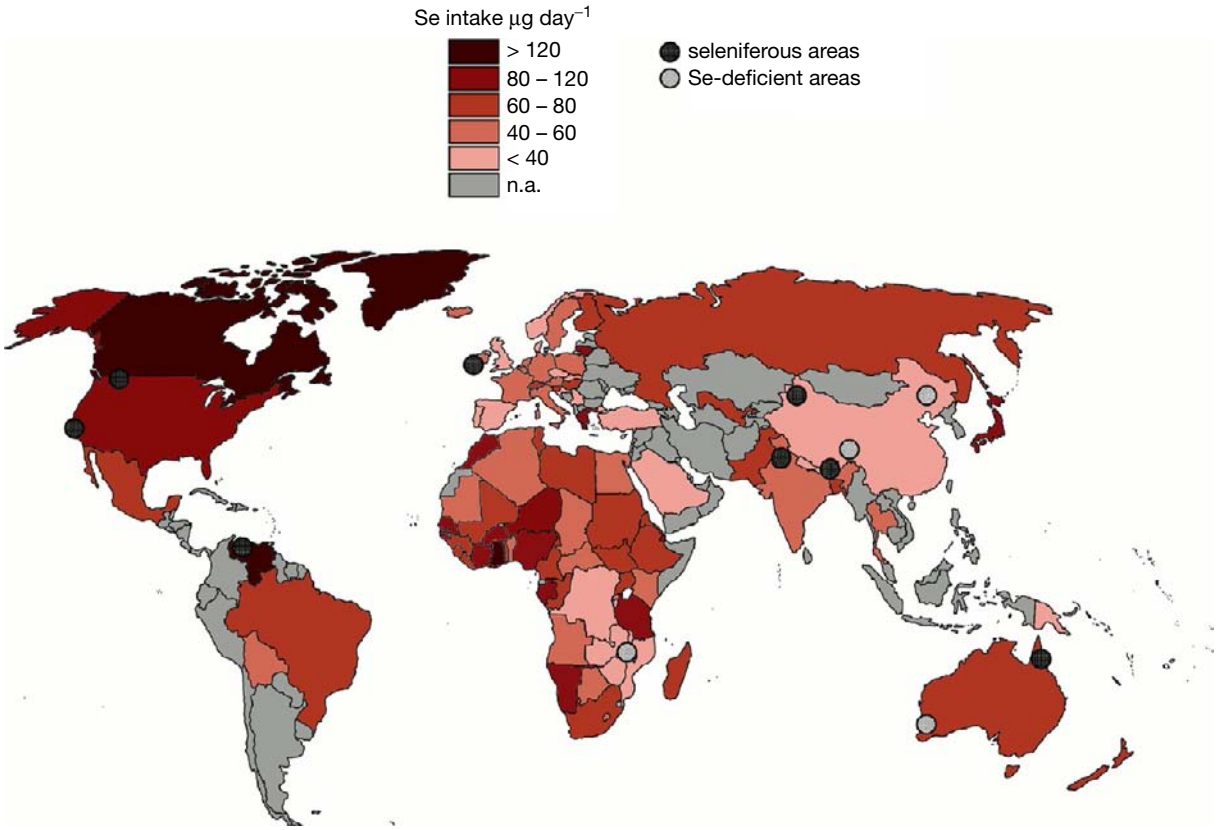

Figure 7 Estimated daily intake of Se for adults in various countries worldwide.

(corresponding to no adverse effect) usually range between 350 and 450 µg day^{-1}.

A number of approaches can be used to estimate the actual dietary intake of total Se, ranging from direct analysis of composite food types to indirect calculation using dietary or market basket surveys and food composition tables. Each approach has specific limitations, and in most large-scale evaluations, speciation, although important, is still overlooked. Since the total concentration of Se in food reflects primarily the soil conditions and secondly the nutritional habits, the dietary intake varies widely with the geographic localization, as shown in Figure 7. The individual dietary intake of Se was estimated between 3 and 7000 mg day^{-1} worldwide, with the highest levels in localized seleniferous regions of China, India, Venezuela, the United States, Australia, and Ireland. The average intake in Europe is ~50 mg day^{-1}, close to the typical RDAs. Some regions of northern Europe, the United States, and other countries exhibit relatively low levels of soil Se, but only a few extremely deficient regions were documented, mainly located in China, Australia, and Malawi. Because of the low abundance of soil Se in some areas around the globe, a wide variety of Se-enriched materials have been produced in order to supply populations with RDA adequate levels of Se. Among them, the use of fertilizers enriched in sodium selenite is a very effective, readily controlled, and widely used strategy to obtain vegetables with high Se concentrations. The total Se intake in Japan, Australia, Finland, and the United States, as well as in the Keshan areas in China, was significantly increased in the last decades thanks to this strategy.

Introduction

Sensations and hedonic experiences cannot be shared directly with other people, and therefore, it was thought that these experiences were inaccessible to direct measurements. However, after some years of studies, psychologists and researchers in the food area have accepted the use of methods with scales to measure sensory and hedonic responses. Since there are theoretical and practical differences among the various scales, many studies, discussions, and controversies existed and still exist.

The focus of most methods using scales consisted of measuring the intensity of sensations. The development of hedonic scales fell behind since the assessment of product acceptance was considered minor by psychophysicists. However, in recent years, the interest in measuring hedonic responses has grown dramatically, resulting in the development of several new methods.

Rating and scoring methods are the basis for the quantification of sensory information. Although these terms are often used as synonyms, actually, they have different meanings. Rating refers to the quantification of information through the use of ordinal categories, while scoring is a more definite way of rating, using a numerical interval or a ratio scale, whose properties are known. Thus, with rating information about the order of acceptance of the samples is obtained, while with scoring, it is possible to determine differences in acceptance among the products or consumers and the size of this difference, depending on the scale used.

Since the methods with scale to measure the intensity of sensations were always discussed, this article will focus on methods with scales that have been developed to measure hedonic responses. We intend to compare the different methods with scales for product acceptance assessment, showing their advantages and disadvantages, in order to help in the selection of the best method for each research.

Types of Scales

Four types of scale can be used to obtain sensory data of product acceptance: nominal, ordinal, interval, and ratio. Table 1 presents information about the different scales.

Nominal Scale

Nominal scale is that in which the collected data are categorized by name or number. The categories have no logical order, so the arrangement order in the evaluation sheet does not change the logic of the question or data processing. In addition, there is no quantitative relationship among them.

Nominal scales are hardly used in sensory analysis. An example of its use would be a test where assessors should indicate the number 1 for the products they consider good and 2 for those they consider bad. They can also be used to classify demographic data of the participants such as gender, age, education, and frequency of consumption of the product in question. The data analysis and interpretation are made through histograms, indicating the frequency of occurrence of responses in each category. Then, it is determined if there are more observations in one category than another through the chi-square test.

Ordinal Scale

Ordinal scale allows one to determine the order in which the products are accepted by consumers (e.g., product A, the most accepted; product B, the second most accepted; and product C, the least accepted). This type of scale cannot quantify the degree of difference among products. Ranking is considered an ordinal scale.

Interval Scale

Interval scale is used to measure magnitudes (different degrees of acceptance) assuming equal distances among the points of the scale and the existence of an arbitrary zero. Nine-point hedonic scale is often considered an interval scale, although this classification is debatable since the intervals are numerically but not psychologically equal.

Ratio Scale

Ratio scale is also used to measure magnitudes, and it is a special case of interval scale, wherein the acceptance of a

Table 1 Types of scales

Scale	*Basic operation*	*Number usage*	*Permissible statistics*	*Example hedonic scales*
Nominal	Categorization	Used as labels	Nonparametric	1: Good 2: Bad
Ordinal	Greater or less	Rank order	Nonparametric	Ranking
Interval	Differences	Degrees of difference	Parametric	Category scale
Ratio	Ratios	Relative proportions	Parametric	LAM, LHS

The numerical values for the semantic labels can be found in the original papers for each scaling method (Lim et al., 2009 [LHS], Schultz and Cardello, 2001 [LAM], Guest et al. (2007) [OPUS], and Green et al. (1993) [gLMS]).

Source: Adapted from Lim, J. (2011). Hedonic scaling: a review of methods and theory. *Food Quality and Preference* **22**, 733–747.

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00617-6

product can be expressed as a percentage or ratio of acceptance of the other products. Ratio scale has an absolute zero. For example, a product obtaining score 8 is twice more accepted than that obtaining score 4. Labeled affective magnitude (LAM) and labeled hedonic scale (LHS) are examples of ratio scales.

Rating Methods

The rating methods involve quantifying the acceptance of products using ordinal scales. In this type of method, it is not possible to quantify the degree and ratio of the difference in acceptance, that is, you cannot know how much a sample is more accepted than the other is.

Ranking

This method is used when the objective is to compare several samples according to the preference, although it may be used when assessing any attribute, such as sweetness and crispness. It is a simple way to compare the samples, but the data are ordinal and no measure of the degree of difference is obtained from the participants. Products are presented all at once in balanced order, which can limit the number of samples due to sensory fatigue. The assessor is required to rank according to the attribute of interest or, for example, the preference.

The ordering of up to five or six products is possible; however, it depends greatly upon the nature of the sample. Data are analyzed using nonparametric statistics (e.g., the Friedman test) in order to determine whether there is difference in acceptance and among which samples. Ordering test does not provide data on the absolute values of acceptance or rejection. In addition, the products are ranked according to the degree of acceptance, but it is not possible to say whether all samples were accepted or rejected.

The judges can taste the products as often as necessary and review or change their scores, preventing inappropriate ratings caused by forgetting of previous samples. This is because, when the assessment is performed monadically, the scores given to each product, as well as the exact sensation it promotes, may be forgotten. With permission to try the products as often as they wish, the judges may change the order of products in the scale, until they are convinced that the degrees of acceptance of samples are properly represented.

When this protocol is compared to the monadic assessment, where tasting products more than once and monitoring assigned scores are not allowed, it presents fewer errors due to memory losses. In addition, it has the advantage that many judges find it easy to do the ordering of products as they are used to order 'things' in everyday life. Finally, human behavior as a data source would be more convenient than numerical estimates obtained with verbal scales.

However, this protocol may not be suitable in certain situations, such as when products subject to sensory adaptation are evaluated, precisely because there are multiple tastings of the same sample. In addition, it is considered a time-consuming method, and elderly or those with difficulty in reading or performing mathematical tasks would have difficulty using it.

Best–Worst Scale

A best–worst scale is an alternative preference elicitation method and is more readily understood through an example. Consider four products (A, B, C, and D) that will be evaluated for acceptance by consumers. An experimental design is used to generate sets of three samples from the four products (A, B, C, and D), which will be evaluated in four sessions with three products per session (Figure 1).

The participants of the test are required to indicate the most accepted (the most liked) and the least accepted (the least liked) product out of the three products available. Responses are converted into individual scales for each sample: (1) The number of times a certain sample has been indicated as the most accepted and the number of times it was considered as the least accepted is counted; (2) these numbers are subtracted. For example, a final value of 1 means that the sample was indicated twice as the most liked and once as the least liked ($2-1=1$), for example. A value of 0 means that the sample was indicated the same number of times as the most liked and the least liked. It is possible to assess the final results among participants or, overall, for the samples, indicating the most and the least accepted ones (Table 2).

The data from the first six assessors are shown in Table 2. For subject 1, the most accepted sample was sample A (value 3) and the least accepted sample was sample C (value -3). Overall (aggregated value), the preferred sample was C and the least preferred sample was A. The results of this scale can be transformed into a scale of probability when analyzed by multinomial logit.

Least liked sample	Set 1	Most liked sample
□	Sample B	□
■	Sample C	□
□	Sample A	■

Least liked sample	Set 2	Most liked sample
□	Sample D	□
□	Sample A	■
■	Sample B	□

Least liked sample	Set 3	Most liked sample
□	Sample A	■
□	Sample D	□
■	Sample C	□

Least liked sample	Set 4	Most liked sample
■	Sample C	□
□	Sample B	□
□	Sample D	■

Figure 1 Example of best–worst scale using four products. Reproduced from Jaeger, S. R., Jorgensen, A. S., Aaslyng, M. D. and Bredie, W. L. P. (2008). Best–worst scale: an introduction and initial comparison with monadic rating for preference elicitation with food products. *Food Quality and Preference* **19**, 579–588.

Scoring Methods

Scoring methods are those in which one can observe the acceptance differences and in some cases the size of such differences. Furthermore, in many cases, it is possible to evaluate differences in acceptance among groups of consumers.

Category Scales

Category scale is a measurement method in which the assessor is asked to 'measure' the intensity of a stimulus assigning a value (category) on a limited scale, which is usually numerical. Category scales are widely used in sensory analysis for affective responses (related to the preference or acceptance of products). These are scales where the degree of acceptance is evaluated through verbal (nine-point hedonic scale) or numerical labels (numerical nine-point hedonic scale).

Nine-point hedonic scale

Nine-point hedonic scale is widely used for acceptance testing when the goal is to determine how much a specific product is liked by the consumer. It consists of a balanced bipolar scale around the neutral category (5 = neither liked nor disliked), with four positive categories (6, 7, 8, and 9 = liked slightly, liked moderately, liked very much, and liked extremely, respectively) and four negative categories (1, 2, 3, and 4 = disliked extremely, disliked very much, disliked moderately, and disliked slightly, respectively) (Figure 2).

The categories are composed of sentences representing several degrees of affection and are arranged successively, suggesting continuity of liking and disliking of products. The sentences help consumers to respond adequately and researchers to interpret the responses regarding the acceptance of products.

Table 2 Example of data of six judges evaluating four samples using best–worst scale

Participant	*B–W (sample A)*	*B–W (sample B)*	*B–W (sample C)*	*B–W (sample D)*
1	3	−1	−3	1
2	0	0	3	−3
3	−3	−1	2	2
4	−1	−3	3	1
5	−3	3	1	−1
6	−3	2	−1	2
Aggregate	−7	0	5	2

Source: Jaeger, S. R., Jorgensen, A. S., Aaslyng, M. D. and Bredie, W. L. P. (2008). Best–worst scale: an introduction and initial comparison with monadic rating for preference elicitation with food products. *Food Quality and Preference* **19**, 579–588.

This scale can also be displayed vertically and be adapted to a seven-point scale or present 'faces' representing the degree of like/dislike, to facilitate its use with children or people who cannot read. This type of scale is often used for comparison among samples in *Food Science*, considering that if consumers 'liked extremely' sample 'A' and they 'liked slightly' sample 'B,' then sample 'A' is more accepted and preferred than sample 'B.' Thus, this scale infers the preference.

When using this scale, products must be presented in a monadic way, that is, one at a time, with no new assessment of the same sample or reference to the scores given to previous samples. The idea is that in purchasing situations, consumers do not test several products and then select the preferred one; they evaluate the products, one at a time, and select one based on their comparative memory of previous evaluations of products, that is, comparing the products to their internal and individual reference. The aim when evaluating samples monadically is to promote absolute evaluations that are not affected by comparisons with other products, thus removing contextual effects. Ideally, the samples should be evaluated on different days or weeks, but for practical conditions, products are evaluated one after the other and the evaluation sheet with the scores and samples are removed after each assessment. The order of samples presentation must be balanced to avoid positioning errors or carryover effects, and for this, designs are already available to facilitate the implementation of tests.

The main reason the nine-point hedonic scale is the most used in acceptance testing is that, compared to other scales (e.g., magnitude estimation), it has a limited number of categories, making it easy to use by different segments of the population and requiring no prior training. For researchers, the evaluation of the generated data is easier when compared to other techniques, which require measurement of lines or estimation of ratios that may include fractions. In addition, it was demonstrated that scales with simple categories are as sensitive as the other scales (magnitude estimation) in relation to the power of sample discrimination. So, if the main goal of a study is to measure differences in acceptance among samples or predict the acceptability, the nine-point hedonic scale has proved to be simple and effective. Many companies have stored data based on this kind of scale, which facilitates the comparison of products under development to those already available on the market.

However, although it is widely used in *Sensory Science*, several limitations are attributed to the nine-point hedonic scale. First, by having unequally spaced categories, the result indicates which samples are more accepted but does not quantify how much a sample is more accepted than another sample (because if a product obtained score 8, it does not mean that it is twice more accepted than a product obtaining score 4), nor compares the acceptance among individuals or groups.

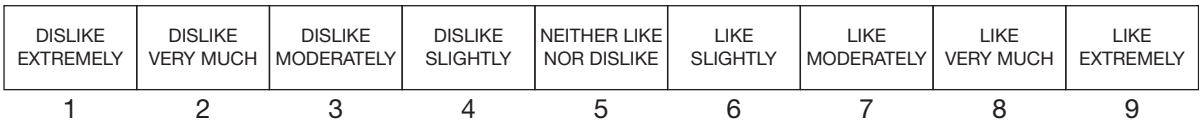

Figure 2 Nine-point hedonic scale with the numbers used in the statistical assessments. Reproduced from Wichchukit, S. and O'Mahony, M. (2014). The 9-point hedonic scale ranking in food science: some reappraisals and alternatives. *Journal of the Science of Food and Agriculture*. http://dx.doi.org/10.1002/jsfa.6993.

Figure 3 Numerical nine-point hedonic scale.

Secondly, due to the limited number of categories, it offers the assessors little freedom to express in full their hedonic experience when tasting the product. In addition, there is a general tendency among assessors of not using the extremes of the scale, reducing it from 9 to 7 points and limiting the ability to discriminate samples that consumers liked or disliked a lot (located at the scale extremes). This is because the assessors think that, once they assign a sample the maximum/minimum score, the following products that may be perceived as more or less accepted may not be adequately evaluated.

Frequently, there are errors by adaptation, that is, there is a tendency for the judges to repeat the same evaluation in conditions in which a series of products are displayed. The presence of a neutral category ('neither liked nor disliked') reduces the scale efficiency, since it encourages a certain degree of complacency by individuals, that is, they consider this category as being safe, which they can use without effect on the assessment.

Finally, considering the viewpoint of statistics, as the generated data are categorical and discrete, without a zero point, the type of statistics is restricted to nonparametric statistics. However, it is a common practice among researchers to use parametric statistics such as analysis of variance to analyze the collected data, although it is mathematically inappropriate because the homogeneity of variances and normality of experimental errors must be assumed.

Large numbers of consumers are required to evaluate the acceptability of a product with sufficient degree of reliability, since there is large subjectivity in the assessment.

When the nine-point hedonic scale shows only numbers, it is called numerical scale (Figure 3), and labels may be added at the extremes and in the middle of the scale. The judges are asked to taste the samples one by one and indicate the degree of acceptance, using the numerical values.

The numerical hedonic scale is useful when comparing a product under development to the market leader, as well as to products with intermediate and worst sales. If the new product reaches a score similar to that of the leader, it means that it is as accepted as the leader, no matter if the score obtained was 9, 8, or 7.

When using the traditional nine-point hedonic scale, the accepted products are positioned at the top of the scale (liked slightly to liked extremely). In the case of numerical hedonic scale (without using labels), products are expected to be positioned along the scale, which does not imply that a product at positions 1–4 is rejected. This is because the judge may have liked all products, positioning them on the scale in order of preference. When the labels are added, the numerical scale behaves similarly to the traditional scale, although the numbers do not represent the same hedonic sensations.

Continuous line scales

Unstructured or linear hedonic scales are represented by a line, anchored at their extremes with the minimum and maximum degrees of acceptance (disliked extremely and liked extremely) (Figure 4).

Figure 4 Unstructured or linear hedonic scale.

The line size is generally 100 mm; however, it may vary according to the test requirements. Very short lines can reduce the power of discrimination of products by judges, while very long lines prevent the judges from being accurate in their assessments.

The collected data are measured within an interval; however, they must be considered as ordinal, as explained for the nine-point hedonic scale.

The use of unstructured or linear hedonic scale has the advantage of giving judges more freedom to express their sensory perceptions; reduce contextual effects; accurately assess the acceptance, because it is possible to mark any point on the scale; and present data with smaller deviations from normality than the nine-point hedonic scale. However, its use is limited because it is more difficult to understand, thus slowing sensory evaluation.

Magnitude Estimation

In this method, the judges are required to provide numbers for the samples, without restriction, so the magnitude of values can reflect the magnitude of acceptance of the products. As with other hedonic scales, the scale used is bipolar, with positive numbers representing the acceptance of products, negative numbers representing rejection, and an intermediate value of 0 (neutral point). The magnitude of acceptance of a sample can be easily estimated and interpreted by comparison. For example, if a sample is positioned at +50 and another sample is positioned at +25, it means that the first one is twice more accepted than the second one.

Such method has some advantages when compared to the category or linear scales. First, as the judges can use any number to express the hedonic response, scale size is not restricted and therefore there is no problem of not using the extremes. Secondly, inferences can be made about the magnitude of the differences among samples. Therefore, in the case of product reformulation, it is possible to quantify how much an ingredient of higher cost would increase the acceptance of a product and thus assess whether its replacement would be convenient. In other methods (such as nine-point hedonic scale), this quantification of the difference in acceptance is not possible. Furthermore, the magnitude estimation method has higher power to reveal differences among samples when the number of products to be evaluated is large or the number of samples is few but very acceptable ones.

Obviously, the method has important limitations: (1) As all assessments are made comparing the products with each other and each judge can choose his/her own values on the scale, there is no general rule in the assessment, so there is no certainty that a magnitude of 9 means the same thing to all

judges, and therefore, comparisons among the values assigned by individuals have no meaning; (2) the absence of a label (e.g., 'disliked very much') makes difficult the translation of numbers into perceptions of acceptance; (3) it does not provide ordinal data on the acceptance or rejection of products; (4) the numerical nature of the method, using numbers to estimate the magnitude of the differences in acceptance, can be a difficult task for the general population, so the quality of the data obtained often depends on the judges' experience or training level; (5) there is a tendency among judges to use rounded values, such as 5, 10, 20, and 100, casting doubt on the validity of the method; and (6) data analysis is complex, requiring normalization and standardization even before the statistical analysis begins. Therefore, the magnitude estimation scale requires very detailed instructions and practice with the method, which cannot be achieved in experiments involving consumers. For this reason, it is not widely adopted in applied sensory research.

Hybrid Hedonic Scale

It is a linear scale (0–10) resulting from the combination of structured and unstructured scales (Figure 5). The hybrid hedonic scale is anchored with verbal labels on middle regions (5 = neither liked nor disliked) and extremes of scale (0 = disliked extremely and 10 = liked extremely), which makes it easier to be used by the consumer than the unstructured scale. The other portions are marked with equidistant points in order to better define the degree and direction of hedonic continuity.

Advantages attributed to this scale are the following: (1) Since it is not restricted to a limited number of categories, it provides better discrimination power; (2) it reduces errors by adaptation (repeating the answers when there are a number of products), encouraging the judge to conduct the evaluation in a more conscious and discerning manner; (3) it reduces or eliminates the numerical and contextual effects, allowing its use in cross-cultural studies; and (4) it generates continuous data, allowing a safer use of parametric or nonparametric analyses.

Category-Ratio Scales

Discussions focusing on the validity and superiority of category or magnitude scales fostered the proposition of a new type of scale containing the strengths of both. The category-ratio scale is linear and has verbal descriptors positioned according to the semantic magnitude, with the positions determined empirically by magnitude estimation.

The first category-ratio scale was developed for the evaluation of the intensity of oral sensations, which was called oral labeled magnitude scale (LMS). This scale had the term 'without sensation' at the lower end and 'strongest imaginable oral sensation of any kind' at the upper end, with five additional descriptors spaced in a quasi-logarithmic manner. After a few years, there were discussions about the top of the scale, as it was considered that oral sensations were different among individuals due to differences in the tongue anatomy and that the correct action should be anchoring the top end more generally. Thus, the upper anchor was replaced by 'strongest imaginable sensation of any kind,' and this scale was called general version (gLMS) (Figure 6).

One of the first scales developed for purposes of product acceptance was LAM, in which the labels were derived from the nine-point hedonic scale, with two additional anchors:

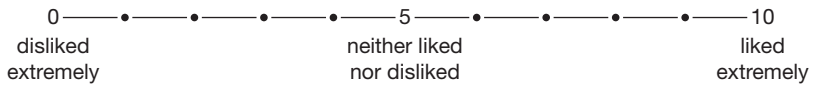

Figure 5 Hybrid hedonic scale. Reproduced from Villanueva, N. D. M., Petenate, A. J. and Silva, M. A. A. P. (2005). Performance of the hybrid hedonic scale as compared to the traditional hedonic, self-adjusting and ranking scales. *Food Quality and Preference* **16**, 691–703.

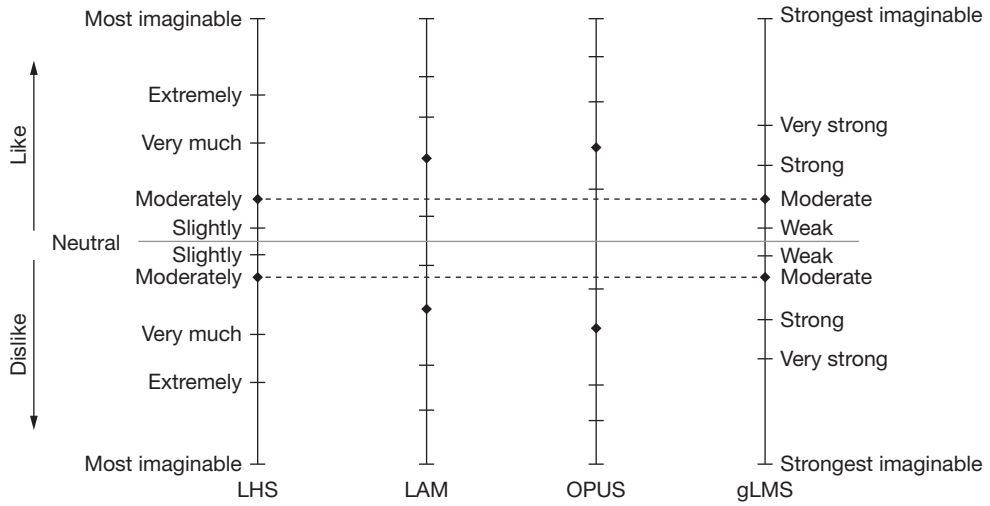

Figure 6 Category-ratio scales. Reproduced from Lim, J., Wood, A. and Green, B.G. (2009). Derivation and Evaluation of a Labeled Hedonic Scale. *Chemical Sciences* 34: 739–751.

'greatest imaginable like' and 'greatest imaginable dislike.' The development of the scale followed the procedures used in the creation of LMS.

After that, other scales have been developed ((hedonic) gLMS, OPUS, etc.), with advantages and disadvantages, such as incorrect quantification of the magnitude of acceptance, inappropriate descriptors, and inappropriate spacing among descriptors.

A few years ago, a group of researchers developed the LHS, using a procedure similar to that used in the development of LMS and comparing the magnitude estimation and nine-point hedonic scales. The LHS generated data identical to those obtained by the magnitude estimation, validating the positioning of descriptors and assuming that the magnitude of acceptance can be quantified. In addition, it had the power of sample discrimination slightly higher than that of hedonic scale and greater resistance to the effects of nonuse of the scale extremes, resulting in data with a more normal distribution.

The advantages of category-ratio scales, especially LHS, are as follows: (1) They generate magnitude data, making them possible, for example, to evaluate the relationship between the acceptance and the amount of a given ingredient and how much a sample is more accepted than another one (product A is three times more accepted than product B); (2) it is possible to translate the numerical data into perceptions of acceptance, because the positions of the category labels were determined; (3) since they are continuous scales, the judges are not confined to a limited number of categories; (4) by presenting more spaced anchors (most liked/disliked sensations imaginable), scale sensitivity is increased when discriminating samples, especially those that are very or little accepted; (5) data on the acceptance are normally distributed, so parametric analyses can be applied requiring no preliminary processing of data; and (6) the scales as well as the nine-point hedonic scale are easy to use, although they require instructions and practice so that the data obtained are reliable.

The disadvantages of this type of scale would be as follows: (1) As the anchors are far away from the other categories, there could be a compression of ratings in the center of the scale, reducing its power of discrimination, and (2) it can be misused by some groups of judges such as those with lower education or who are already used to other scales. For example, it was observed that many judges performed evaluations of samples only at the positions where the labels were located, making it a category scale. Therefore, instructions on the use of the scale are of vital importance for obtaining reliable data.

Conclusions

In this article, the four basic types of scales used in sensory evaluation of food were presented: nominal, ordinal, interval, and ratio. The main properties of the methods with scale were listed, emphasizing the use in acceptance testing. By describing the properties, advantages, and limitations of the methods with scales used in acceptance testing, we do not intend to show the superiority of a single method compared to others, but direct the researcher's choice of the appropriate and valid method, according to the study objective.

From demands of users of sensory analysis, it is expected that researches are conducted for the development of new methodologies with scales to evaluate the acceptance of products by consumers, in order to quantify the magnitude of differences among samples and segment consumers according to the preference. One has to keep in mind, however, that not always what is new is the best. On the other hand, it is not because a methodology has been used for years that it has no disadvantages.

Sheep: Meat

EN Ponnampalam, Agriculture Research, DEDJTR, Attwood, VIC, Australia

Introduction

Since antiquity, sheep (*Ovis aries*) have been domesticated for the production of meat, albeit often as a secondary product from wool production. This has resulted in a range of sheep breeds that vary in terms of production and climatic adaptation specializations. Therefore, there are inherent differences between sheep breeds regarding meat productivity and quality. For example, a purebred Australian Merino is a specialized wool breed that will produce lighter carcass weight with lean meat over a longer growth period when compared with a meat specialist breed such as Suffolk or Texel. Using this information, producers have tailored their production systems to optimize breed effects, in terms of feed usage and production localities, to achieve optimum meat yields and quality. Furthermore, tactical management of feeding systems prior to slaughter that offers optimum dietary nutrients as protein, energy, and micronutrients can provide more shifts in yield and quality and allow producers greater responsiveness to changes in market requirements or specification.

Sheep meat production is highly versatile and immediately employs many livelihoods around the globe, in both small holdings and large-scale extensive or intensive production systems. This is facilitated by its inclusion within various culinary diets, based upon sheep meat having a highly nutritious composition and distinctive flavor – although ideal flavor is debatable, depending on cultural backgrounds. Consequently, sheep meat is a key tradable commodity and the focus of much effort to enhance its nutritional and eating qualities and ensure these are preserved from production to consumption through processing and retail. To assist in the clarification of sheep meat, animals are generally divided into age-dependent categories: lamb, being meat from animal slaughter prior to 12 months of age; hogget or yearling, defining the age bracket between lamb and mutton; and mutton, being meat from animals once the age of 24 months old is surpassed. These definitions highlight the importance of animal age to carcass value, meat composition, and eating quality characteristics. Herein, the word sheep meat covers aspects of meat from both lambs (younger age animals – lamb) and sheep (older age animal – mutton).

This article aims to detail sheep meat, with reference to production and processing aspects, in terms of production types, nutritional composition and health implications, sensory and eating quality traits, and spoilage pathways that require preservative attention.

Production

In 2010, sheep meat production represented only 3% of the total global meat production, and this market share emphasizes the huge potential for growth available. This scope for advancement in sheep meat production is encouraging to traditional sheep meat-producing nations, such as New Zealand and Australia, which have a strong export focus and access to developing markets in the European Union, the Middle East, North America, and Asia. However, the global sheep meat industry faces limitations, which may undermine future growth, including animal and human welfare considerations, increased competition for land and feed resources, climatic impacts from intensified production, and economic restrictions on international trade. Overcoming these hurdles is the responsibility of all sheep meat stakeholders. Regardless, domestic consumption of sheep meats is increasing over recent years, and this has resulted in better prices being offered for sheep meat productions, especially lamb, in comparison with other meats.

Stakeholders across the supply chain from producer, processor, to retail are vital to the industry, but producers are particularly important. The production of sheep meat, broadly speaking, can be categorized into two groups: (1) small holdings, which are more common in developing countries or hobby farms and generally maintain a small flock (often <20 animals), or (2) large holdings, which can have flock numbers into the thousands and routinely manage animals on an entire flock basis. Animals are reared under two main feeding systems: (1) extensive grazing on traditional pasture feeding and (2) intensive production systems maintained on concentrate–grain-based diets. However, feeding systems can be combined depending on availability of resources, quality of feeds, and the purpose of production. Sheep maintained under extensive grazing receive diets with high protein (e.g., green pasture) and grow slower, while animals maintained under intensive systems receive high energy and grow faster. These in turn can impact on the muscle composition and eating quality traits of meat.

Historically, operations with a wool-only production focus would consider sheep meat as a by-product, but this is no longer universally true. The advent of synthetic fibers and narrow potential for expansion in traditional or new market share have both contributed to low wool prices. As a result, many traditional wool producers have adopted dual-purpose production focus. This entails flocks dominated by dual-purpose sheep breeds, such as Corriedale and Finnsheep, that equally specialize in both wool and meat production. Another approach to dual-purpose production uses a base wool specialist flock joined with a meat specialist breed to achieve progeny with hybrid vigor and both wool and meat quality characteristics. Under traditional Australian commercial practices, lambs under grazing conditions are slaughtered between 4 and 10 months of age, where they reach a live weight to produce carcasses of 18 kg or more. Sheep production in Australia uses different genotypes under various production systems.

The genotypes investigated were Australian Merino (M), Border Leicester (BL), and Poll Dorset (PD).

Adapted from: Ponnampalam, E. N., Butller, K. L., Hopkins, D. L., Kerr, M. G., Dunshea, F. R. and Warner, R. D. (2008). Genotype and age effects on sheep production. 5. Lean meat and fat content in the carcasses of Australian sheep genotypes at 20-, 30- and 40-kg carcass weights. *Australian Journal of Experimental Agriculture* **48**, 893–897.

The major types of animals produced for sheep meat are about 40% from second cross (Poll Dorset × (Border Leicester × Merino)), 25% from first cross (Poll Dorset × Merino and/or Border Leicester × Merino), and 20% from pure Merino genotypes. This latter approach is popular among traditional wool producers as it allows their original wool flock genetics to be preserved, it avoids a full production system overhaul, and it allows better flexibility to match market flux (Table 1).

Sheep meat-only production focus routinely uses meat specialist breeds. This may include wooled breeds such as Dorset or Cheviot that produce coarse wool that can be harvested as a by-product of production. Otherwise, haired breeds that shed their coats may be used, for example, Dorpers and Barbados – these are gaining popularity as labor prices increase and wool prices remain low. As a sidenote, dairy sheep (e.g., East Friesian) are another source of sheep meat as they are typically slaughtered at the end of their primary usefulness and may be considered a by-product of the production focus just as described with a wool-only production focus. Selection of a production focus ultimately is regulated by market demands and preferences.

Composition

Sheep meat has a complex structure and consists of water (73%) and protein (21%) fractions, with lipid (5%), carbohydrate, and many vitamins and minerals also present but in smaller amounts. The major water, protein, and fat of meat (or muscle) composition can be affected by sheep genetics, feeding background, and age of sheep. The fat content of meat ranges from 2% to 10% and can substantially influence the meat quality aspects such as flavor/aroma, juiciness, and texture. It was observed that when sheep are reared under the same paddocks, within a given age and genotype category, sheep with smaller carcasses deliver less fat and more lean than sheep with larger carcass counterparts. This implies that within a genotype at a particular age, there is variation in fat and muscle deposition, with faster growing animals diverting more energy into fat deposition than muscle growth compared with smaller growing animals.

The protein-rich muscle fibers (myofibrils) of sheep meat mostly contribute to its distinctive texture (tenderness of meat). Myofibrils are arranged into bundles or sheets and are individually surrounded by an endomysium and sarcolemma (a plasma membrane); in turn, these are encapsulated in groups by a perimysium and as a whole muscle by an epimysium. A collective term for endomysium, perimysium, and epimysium is connective tissues. There are three myofibril types, and the prevalence of these has been found to vary depending on muscle function and location; these are (1) type 1/slow twitch, using aerobic metabolism and found in postural muscles; (2) type 2A/fast twitch, which are similar to type 1 but found mostly in limb muscles; and (3) type 2B/fast twitch, using anaerobic metabolism and found in locomotive muscles. The density of myofibril types can affect the sensory characteristics and nutritional quality of meat. This protein fraction is highly digestible, more so than plant protein, and provides consumers with the essential amino acids, lysine, threonine, methionine, phenylalanine, tryptophan, leucine, isoleucine, and valine.

As a red meat, sheep meat is a rich source of dietary iron (Fe) within a heme (Fe) complex – containing comparatively higher levels of Fe than beef. Heme (Fe) is readily absorbed when compared with nonheme (Fe), partly due to sheep meat being rich in glutathione in which its activity promotes iron absorption. Humans require iron to avoid anemia and the inhibition of several cellular processes – including oxygen transportation throughout the cardiovascular system. The consumption of heme (Fe) has, however, been associated with an increased incidence of colorectal cancer and congenital heart diseases. But evidence suggests that provided sheep meat such as trim lamb cuts or lean meat is consumed as part of a well-balanced diet, the risk from these diseases can be ameliorated. Sheep meat is also a valuable source of selenium and can provide approximately 20% of the daily recommended intake for an adult per 100 g serving. It also provides zinc that can be more readily absorbed than plant-sourced zinc because of the absence of many phytates and fiber that hinder its uptake. Sheep meat is also an important source of calcium, magnesium, copper, phosphorus, and potassium, all being essential to human health. Interestingly, the presence of these minerals does not only solely contribute to nutritional health benefits but also play a role in many sensory characteristics and keeping quality of meat.

Sheep meat, as with other red meats, has an unmerited notoriety for its high content of 'unhealthy' saturated fatty acids (SFA); these are unfavorable because of their association with cardiovascular disease and antagonism of several cancers. However, recent efforts are making progress to reverse this negative reputation by developing sheep meats with an improved 'healthy' fat content through genetics and nutritional improvement. It is also worthy to state that lean meat cuts from sheep are

low in fat and can contribute to the intake of key nutrients in a diet. Omega-3 polyunsaturated fatty acids ($n-3$) are one such 'healthy' fat, as these have been linked with improved resilience against coronary disease and diabetes, better mental status and infant development, and the maintenance of neural and optical tissues. Many types of $n-3$ exist, but those associated with these benefits are long-chain (>C13) $n-3$, which include eicosapentaenoic acid (EPA: 20:5$n-3$) and docosahexaenoic acid (DHA: 22:6$n-3$). In general, people fail to consume the recommended EPA + DHA levels by the World Health Organization (0.5–2% of total caloric intake), the United States (0.25–2%), or the United Kingdom and Australia (12%). Lamb has been identified as a 'good source' of these $n-3$'s – where a 'good source' refers to $n-3$ content above 60 mg/100g of food according to Food Standards Australia New Zealand. Furthermore, $n-3$ content can be improved by supplementing lambs with feeds rich in $n-3$ (e.g., some algae and flax) as part of a flock dietary management strategy. It should be noted that meat cut selection will influence the available $n-3$ as EPA and DHA are primarily located in membrane phospholipids and therefore are found in greater quantity in muscles rich in slow-twitching fibers (type 1 myofibrils). Another 'healthy' fat found in sheep meat is conjugated linoleic acid (CLA), which has been found to reduce the risk of some cancers, diabetes, and arthritis. The amount of CLA in sheep meat is highly correlated with fat content and is influenced by animal diet, but generally, 0.2–2% of total tissue fat is CLA. Animal genetics and rumen flora also play major roles in determining the fat content and composition of sheep meat (Table 2).

Table 2 This information was sourced from Food Standards Australia New Zealand (2010) and describes the nutrient content of raw meat (per 100 g fresh weight) sampled from 11 different cuts that were from various regions of the sheep carcass (lamb and mutton)

Sheep meat is a valuable source of several key vitamins. A 100 g serving can provide nearly two-thirds of an adult's daily recommended intake of vitamin B12 and one-quarter of their daily vitamin B2, B3, B5, and B6 requirements. Sheep meat is also a useful source of many lipid-soluble vitamins, including vitamin A, but efforts to produce leaner sheep meat have had a negative influence on its content. Leaner sheep meat also has implications on some sensory characteristics and is described in the following section.

Quality

The quality of sheep meat is fundamentally determined by its appeal to consumers and their tangible experience following mastication. To better understand the appeal of sheep meat, consumer responses are routinely defined as major sensory characteristics: (1) tenderness, also known as mouthfeel or texture; (2) flavor, which is the intrinsic combination of both smell and taste senses; (3) appearance or color when sheep meat is retailed or on display; and (4) juiciness or moistness. These four sensory characteristics provide insight into the overall consumer acceptability of sheep meat.

Tenderness refers to the ease by which sheep meat can be severed and chewed during mastication. This is widely considered to have the most authority over perceived quality when compared with other sensory characteristics and hence acts as a key discriminating factor for consumers selecting sheep meat. In Australia, for example, lamb maintains a significantly larger portion of the sheep meat market than mutton, largely related to improved tenderness. This highlights the influence animal age has on tenderness, but other factors such as breed, genetics, muscle type, and even location within a muscle can affect tenderness. The pathway by which these shape meat tenderness revolves around their influence on myofibril type, distribution, and amount and intramuscular fat (IMF) content. Evidence suggests that tender sheep meat results from a greater density of thinner myofibrils with improved collagen solubility and when IMF levels exceed 3% – which is the threshold for consumer acceptability. Therefore, much investigation toward understanding genes controlling tenderness and their inheritability has been undertaken for inclusion into breeding programs. However, genetic contribution to tenderness must be balanced with management practices to achieve optimum tenderness.

The management of animal stress prior and during slaughter, particularly during lairage and on the kill floor, is important to improve meat tenderness. It is also common following slaughter and during the processing stage to apply other methods to further enhance tenderness. These methods include (1) mechanical stretching, wherein a carcass is positioned (e.g., pelvis hanging, or tenderstretch) or physically manipulated (e.g., carcass pull); (2) temperature manipulation, which avoids toughening in response to cold shortening or heat shortening in combination with various hygienic and spoilage considerations; (3) pH modification, to prompt a better and hygienic pH and temperature decline rate and prevent cold shortening; and (4) aging; increasing the period between slaughter and consumption of meat kept refrigerated allows myofibrils and muscle structures to tenderize due to changes

in enzymatic activity and provide less resistance to mastication – although this approach may allow contamination and faster spoilage. With the exception of aging, these methods aim to prevent myofibril shortening during which their density and therefore toughness increase. Research has found that a combination of these approaches results in most significant increases in meat tenderness, especially when electrical stimulation of a carcass is used to manage the pH of carcass post-slaughter. This proves an effective and cheap way to rapidly change pH via the stimulation of glycogen metabolism.

Flavor refers to the combination of consumer smell/aroma and taste sensations immediately prior to and during consumption. Smell is stimulated by the numerous volatile compounds released from sheep meat, mostly released following cooking, perceived by the olfactory receptors within consumer nasal cavities. These volatile compounds often result from protein and lipid lyses during cooking, but not much information exists linking specific compounds with sheep meat aroma – with exception to 2-ethyl-3,6-dimethylpyrazine and 2-pentylpyridine (heterocyclic compounds) and 3-methylindole acid and 4-methylnonanoic acid (MNA) and 4-methylphenol (skatole compounds), which have been associated with a mutton aroma. Nevertheless, it can be construed that their prevalence relies upon the base compounds of sheep meat, which may be influenced by animal diet. Taste refers to the stimulation of taste bud receptors within the mouth and throat to sheep meat compounds, especially branched-chain FA, which are identified as a precursor to the unique 'sheep' taste. Therefore, taste relies on many of the same compounds as smell and is also manageable with dietary controls. Hence, smell and taste are often referred to as flavor and are influenced by animal diet. For example, 4-methylphenol, methyloctanoic acid, and MNA content are intensified when animals are fed with pasture-based diets and result in a 'pastoral' sheep flavor. Also, it is general perception that when sheep are fed with canola and other oil-rich feeds, their meat can develop a foreign or atypical lamb/mutton flavor.

Nonvolatile compounds from sheep meat can also influence flavor, including antioxidants, carotenoids, and lipids. The contribution from these compounds can result from their opposing influence on lipid peroxidation from which many 'off-odor' and sour or off-tasting compounds are a by-product. As a rule, however, it is difficult defining an ideal sheep meat flavor because consumer culinary preferences, cooking methods, and cultural heritage can all influence its acceptability. This can affect the objective measurement of flavor, and therefore, it is typically measured using a trained sensory panel and reported within the context of the sample represented. This is necessary as, for example, British and Australian sheep meat consumers prefer stronger sheep flavors than Asian consumers, and if both these sampled the same sheep meat, they could provide different results on consumer perception and acceptability.

Many consumers' first encounter with sheep meat is in a retail environment, wherein an impression of freshness, quality, and value is often formulated based on appearance and color. Research has demonstrated that sheep meat must have a bright cherry red color and bright white fat content to match consumer ideal or preference. Achieving this appearance is essentially a function of myoglobin (Mb) oxidation – with Mb being a complex protein with a central iron atom and a role in oxygen transportation that is plentiful in sheep meat. This Mb will adopt a deoxymyoglobin (DMb) structure when sheep meat is stored in an anaerobic environment but will change to oxymyoglobin (OMb) when exposed to oxygen in a reversible reaction. This causes a color shift from purplish to cherry red. Prolonged exposure to oxygen, however, will result in OMb assuming a metmyoglobin (MMb) structure and will consequently instill a brownish color to sheep meat. The concentration of MMb is directly associated with this discoloration; hence, work has been undertaken to find a threshold value indicative of perceived quality and methods to prevent this threshold from being breached. For example, improving sheep meat antioxidant (e.g., vitamin E) and other micronutrient (e.g., beta-carotenoids) contents with dietary management (Figure 1) and using innovative meat packaging technologies have provided means to manage its appearance. This proves true for both meat and fat appearances.

When juiciness is used within the context of a sensory quality, it describes the amount of fluid released from sheep meat upon maceration in combination with that contributed from the consumer via salivation. Salivation is prompted by the IMF content, and a threshold level of 3% of IMF has been identified as necessary for juicy meat. The fluid discharged from sheep meat when it is chewed is a function of its water-holding capacity (WHC), which is the potential of meat to withhold liquid during (1) storage periods, otherwise lost as 'drip' and purge; (2) heating, referred to as 'cooking' loss although the cooking method can have significant implications on this factor; and (3) chewing and mastication, with fluid released promoting perceived juiciness. Ideally, sheep meat should be juicy and this requires a high WHC. The WHC can be influenced by animal carcass energy reserves, which are measureable as pH with high pH equating to high energy reserves and therefore heightened WHC. This may be improved using electrical stimulation technology. However, the WHC does contribute to carcass yield, and when the WHC is low, meat yield as well as subsequent profits are less. Not only the amount of water but also the distribution of water in muscle tissue has an effect on meat color, firmness, and drip loss. Under postmortem conditions with the onset of rigor, water moves from the myofibrillar compartment into the intermyofibrillar space and then in turn into the extracellular space. The degree of myofibril shrinkage will impact on the reflection of light from the muscle surface, and the ultimate pH will impact on this by affecting the amount of water loss.

Ultimately, an accurate indication of overall liking or achievement of a consumer-acceptable product can be provided by combining these four major sensory characteristics. However, this relies upon accurate assessment, which is often difficult due to the sometimes subjective nature of sensory panel protocols, experience of panel members conducting the evaluation, and expense needed to facilitate a statistically sound insight. As a result, efforts have been distinctly focused toward developing and validating objective measures as a proxy for consumer responses.

Spoilage and Preservation

All meat is susceptible to spoilage, and this can have detrimental implications upon perceived value, consumer safety, and wastage. Spoilage refers to the degradation or downgrade of

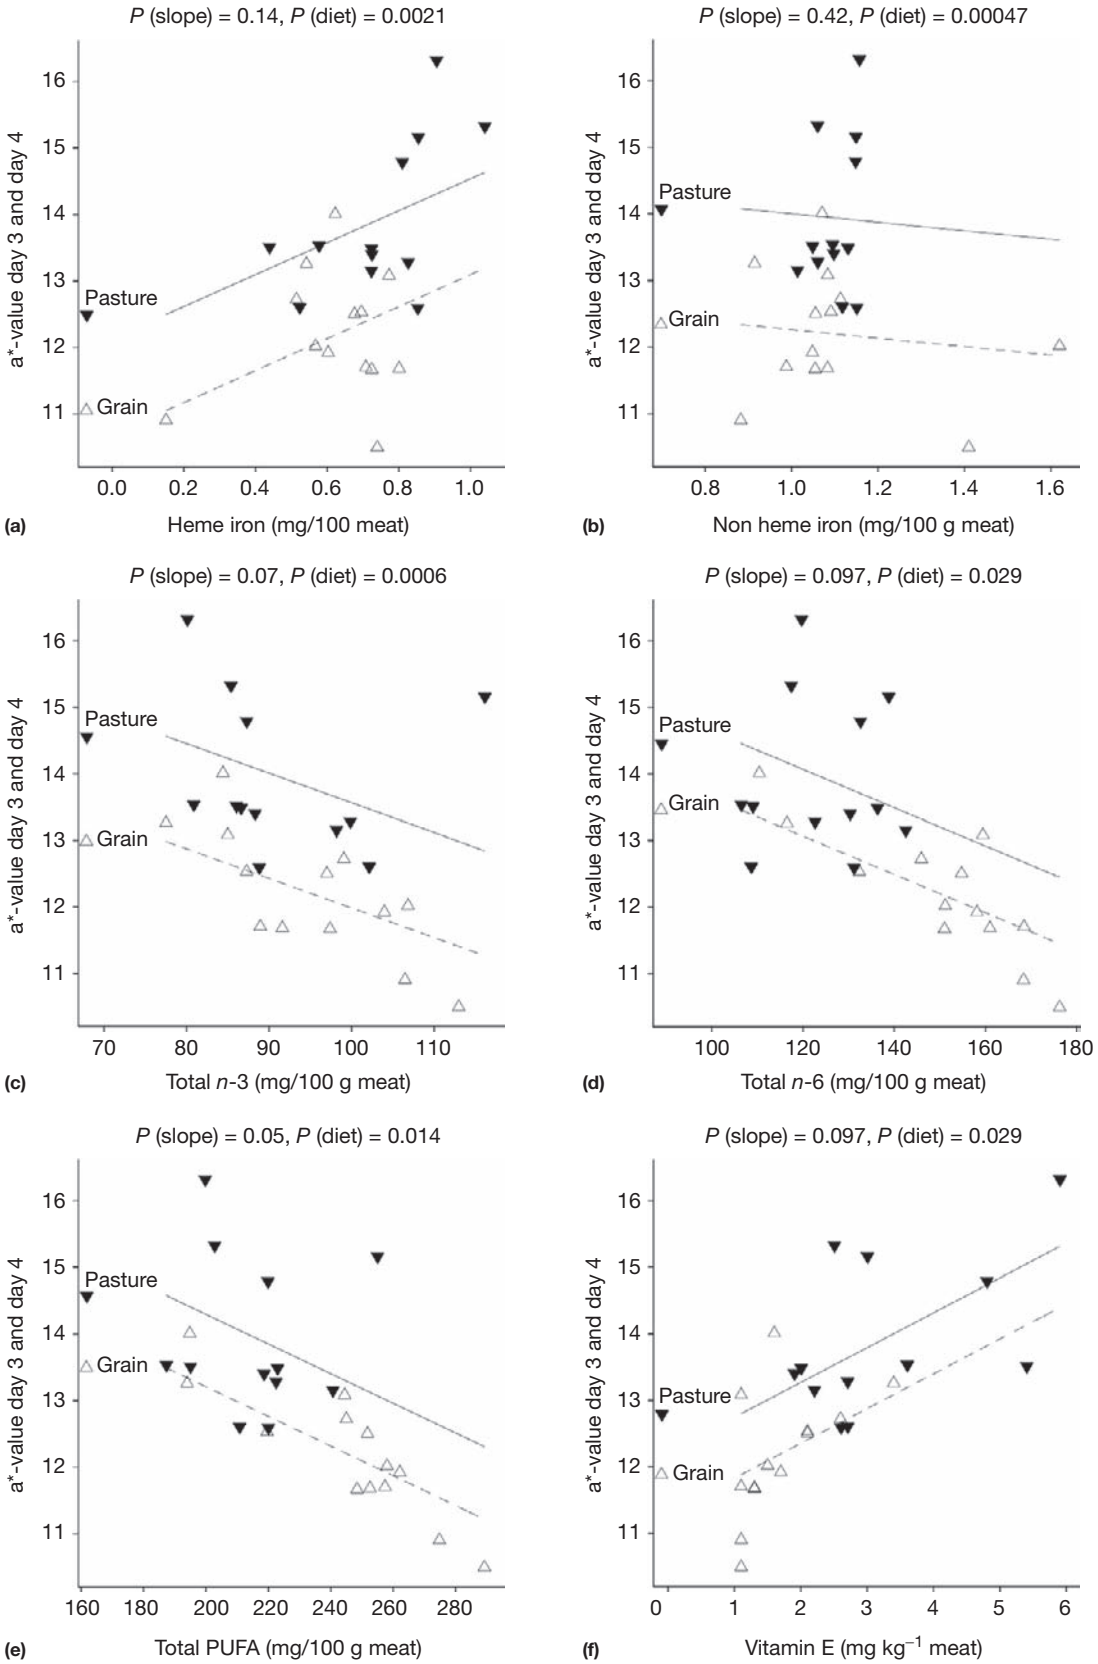

Figure 1 Scatter plots of redness (a*) of sheep meat after 3 and 4 days of retail display with (a) heme iron, (b) nonheme iron, (c) total omega-3 (*n*−3), (d) total omega-6 (*n*−6), (e) total polyunsaturated fatty acid (PUFA), and (f) vitamin E, measured in the *M. longissimus lumborum*. Parallel regression lines are fitted for lambs grazing pasture only (dashed) or offered with hay supplemented with grain (solid). Adapted from Ponnampalam, E. N., Butler, K. L., McDonagh, M. B., Jacobs, J. L. and Hopkins, D. L. (2012). Relationship between muscle antioxidant status, forms of iron, polyunsaturated fatty acids and functionality (retail color) of meat in lambs. *Meat Science* **90**, 297–303.

sheep meat quality, both sensory and nutritional, to an extent after which a meat product fails to meet safety and quality standards dictating consumption. The spoilage of sheep meat can be assessed as discoloration, a loss of integrity and texture, the development of sour and off-flavors and odors, loss of moisture, and/or visible bacterial and fungal infection. Bacterial and fungal infection could indicate the contamination of meat with pathogenic bacteria or toxic by-products from fungal and bacterial growth. As a general observation, meat spoilage results in a compromise of core compound structures, such as the lipid and protein fractions, from oxidation and/or microbial infection.

Sheep meat is a rich source of SFA and UFA, the latter being especially prone to lipid peroxidation. Lipid peroxidation is the oxidation of a fatty acid molecule and occurs as three sequential phases: (1) initiation, when a UFA reacts with a free radical species and donates a hydrogen ion to become a fatty acid radical; (2) propagation, which occurs during a fatty acid radical reaction and acceptance of an oxygen atom (or oxidizes) to become a peroxyl-fatty acid radical – this can then be used in the former phase and create a cyclic reaction; and (3) termination, when a fatty acid radical reacts with a nonradical (e.g., antioxidant), which interrupts the initiation and propagation reciprocal interactions. In instances where the termination phase fails to occur, the previous phases will continue until the original UFA is completely degraded into its many potential secondary oxidative products, which include reactive aldehydes, ketones, alcohols, hydrocarbons, epoxy compounds, and volatile organic acids. Lipid peroxidation of meat does compromise not only nutritional and health-promoting advantages from UFA but also meat structural integrity during prolonged storage and cooking and can affect perceived juiciness and tenderness qualities. Furthermore, the secondary products from lipid peroxidation can have a negative influence over sheep meat flavor and cause atypical and undesirable tastes and aromas. These can also be employed to initiate protein oxidation, and in this respect, lipid peroxidation acts as a precursor reaction.

Protein oxidation, or proteolysis, is catalyzed when protein peptides are exposed to oxygen and reactive radical species. Hence, this commonly follows lipid peroxidation because of the high reactivity of peroxyl-fatty acid radicals and other secondary oxidative products with protein peptides. This reaction causes the protein structure to change as peptide bonds are cleaved and amino acid side chains are modified – this latter change being the most common and can result in the synthesis of protein carbonyl groups. As an upshot from protein oxidation, many covalent intermolecular cross-linked protein secondary species are created. These include disulfide, dityrosine, and protein hydroperoxide species groups. An outcome from protein oxidation is a change in protein structure and a resultant inactivation of several enzymatic functions, although often the proteins become more prone to the effects of proteolytic enzymes – potentially sourced from microbial infections. It is interesting to note that some amino acids are more susceptible to oxidation than others, for example, cysteine, tyrosine, arginine, lysine, and methionine, and therefore, proteins rich in these amino acids will be preferentially oxidized. The presence of transition metals can also influence protein oxidation, and this has implications on heme proteins such as Mb. Mb is oxidized when, as OMb, it autoxidizes before MMb enzymatic reduction, when it is catalyzed by the degradation of lipid peroxyl-fatty acid radicals, or when Mb acts as a pseudoperoxidase. However, it is the central Fe molecule within Mb structures that significantly contributes to Mb oxidation, as this is readily oxidized from MbFe(II) to MBFe(III) as OMb becomes MMb. Nonheme Fe and other transition metal ions can contribute to protein oxidation, provided hydrogen peroxide is present – resulting in a 'Fenton' reaction.

The end result from protein oxidation on sheep meat quality is most apparent on its sensory qualities. For instance, when meat is aged, its structural proteins within myofibrils and connective tissues will degrade resulting in increased tenderness. It should be noted that this response is mediated by the calpain system wherein calpain enzymes, specifically μ-calpain and m-calpain, and several cathepsins sever myofibrils. Protein oxidation can interfere with the calpain system, with research showing that oxidation can inhibit μ-calpain activity and therefore causes the tenderness response to aging to be lessened. Protein oxidation also affects juiciness by prompting changes to myofibril diameters and protein cross-linkage connections, which can alter sheep meat WHC. Consequently, drip loss is found to increase during protein oxidation, and less fluid is retained within sheep meat, which can be released upon chewing; hence, consumer-perceived juiciness is reduced. The effect of protein oxidation on appearance is centered upon its effects on Mb as discussed.

Practicality dictates that sheep meat cannot be processed without experiencing some degree of bacterial or fungal (microbial) contamination. However, not all microbial contaminations contribute to spoilage, and therefore, efforts have been made to identify causal agents. Examples of spoilage bacteria that have been identified as hazardous to sheep meat preservation against spoilage include lactic acid bacteria (LAB), Enterobacteriaceae, *Brochothrix thermosphacta* sp., and *Clostridium* spp., as these often continue to proliferate during cold storage. As a rule, these contribute to spoilage as a result of their metabolism and subsequent breakdown of sheep meat protein and lipid fractions and glycogen reserves, which can influence integrity and texture. Furthermore, a by-product of metabolism by some microbes is the synthesis and deposition of often rancid-smelling or rancid-tasting compounds, which makes sheep meat unacceptable – these are commonly sulfur-rich metabolism products. In other instances, the by-products or the microbes themselves may be toxic to consumers and pose health risks. For instance, *E. coli*, *Salmonella*, and *Campylobacter jejuni* are three examples of pathogenic bacteria that if found above threshold levels on sheep meat will cause it to be inedible. Fortunately, microbial contamination can be controlled by direct application of health organization-approved antimicrobial agents to a sheep meat carcass or, more commonly, the manipulation of storage conditions to match those that inhibit microbial proliferation. This latter control focuses on temperature and oxygen availability factors primarily during the storage stage in the journey of sheep meat from processor to consumer through retailing sector.

With these effects of oxidation and microbial infection on sheep meat understood, it becomes apparent that spoilage is unavoidable. Instead, delaying spoilage onset and restricting its extent provide the best measure of combating spoilage until

consumption. This is routinely achieved by using specialized storage containments with inherent preservation and quality enhancement properties. For example, keeping sheep meat in chilled or frozen storage is a time-tested approach to restrict spoilage, as these low temperatures limit oxidation and microbial growth and therefore slow their contribution to spoilage. Recent efforts have used vacuum packaging or modified atmospheric packaging to shift the atmospheric gas surrounds of sheep meat to lower its exposure to oxygen – a necessity for propagation and growth of many spoilage bacteria and oxidation. Increasingly, intelligent sheep meat packaging is emerging as a means to restrict spoilage by better informing stakeholders along the supply chain to the extent of spoilage using embedded sensory equipment. These packages may also have antioxidants or antimicrobial agents incorporated into packaging films to directly reduce spoilage. However, preserving against spoilage is not solely a role for processors as producers make significant contributions using feeding management. Research has demonstrated that sheep fed with diets rich in antioxidants and vitamin E (α-tocopherol) will have increased antioxidant levels in their meat and hence better resistance to oxidation when compared with control animals (Figures 2 and 3). This has shown that when vitamin E levels exceed 2.95 mg kg^{-1} of muscle, sheep meat will be better preserved against lipid peroxidation. All these preservative methods share the common priority to interrupt or delay oxidation and microbial growth, and, in doing so, prolong sheep meat longevity.

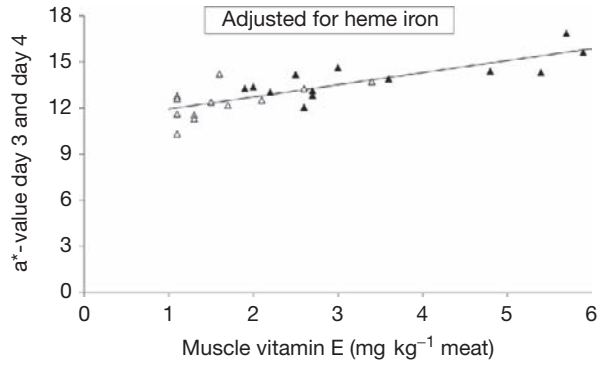

Figure 2 Relationship ($P = 8.9 \times 10^{-7}$) between redness (a*) of sheep meat after days 3 and 4 of retail display and *M. longissimus lumborum* vitamin E, after a* was adjusted for muscle heme iron for lambs offered with pasture only (▲) or offered with hay supplemented with grain (Δ). Relationship between muscle antioxidant status, forms of iron, polyunsaturated fatty acids and functionality (retail color) of meat in lambs. *Meat Science* **90**, 297–303.

Conclusion

The production and consumption of sheep meat support many persons around the globe. This support may be economic, with a section of most communities basing their livelihoods on sheep meat retailing, processing, and/or producing, or support may be nutritional, as sheep meat proves to be a highly nutritious source of many vitamins, minerals, protein, and 'healthy' fats such as omega-3s. Consequently, it is meritorious for all stakeholders to explore production strategies, animal management, welfare of animals from farm to slaughter, and technological methods at processing and retail to improve sheep meat quality and achieve a shared priority to deliver a product that a consumer finds attractive and acceptable. This has resulted in much research into what describes consumer preferences for sheep meat and the underlying principles of preservation, spoilage, or the degradation of these quality traits. Understanding spoilage has allowed steps toward preserving or maintaining sheep meat quality until consumption to be successfully achieved, as fundamentally, it is consumer preference and satisfaction with a sheep meat product upon which the entire industry is based.

Introduction

The sheep (*Ovis aries*) milk, which is the secretion of the mammary glands, is the only food of the lambs during the initial period of their life. The milk constituents provide both energy and the building materials necessary for its growth. Milk also contains antibodies that protect the lambs against infection. The milking of sheep dates back to the domestication of animals. In many countries, the cow has replaced the sheep as the major milk producer, but the sheep and goats remain important sources of milk in countries where land is too poor to support cows. With the search for alternative farm incomes, there has been a rekindling of interest in sheep dairying in northern Europe, Australia, India, New Zealand, and the United States. Attractions are low capital investment, limited land requirement, high profit margins per liter, and lack of quota limits on production. Milk plays a tremendous role in building a healthy society and can be used as vehicle for rural development, employment, and slowing down the migration of the rural population. Much less information is available on sheep milk composition than on cow, buffalo, and goat milk. Although some reviews cover both goat and sheep milk, most discuss goat milk in depth and sheep milk only superficially. Most studies are related to effects of animal feeding on fatty acid (FA) composition.

Production of Sheep Milk

Although China was the top producer of sheep milk in 2010 (17%), about 61% of the world's sheep milk is produced in the Mediterranean region and Middle East and mainly used as a raw material for producing cheese and other dairy products. In 1989, 8 778 000 tons of sheep milk was produced worldwide. Asia and Europe are the continents with the highest levels of production, the main producers being concentrated in the North Mediterranean Basin, the Black Sea area, Iran, and Central Asia. In many of these countries, the normal practice is to milk the ewes after the lambs have been weaned, the milk being an essential food in the diet of the local population. However, sheep can only be considered as dairy animals when they are milked for the greater part of their lactation, the lamb only suckling for 1–2 months. The concentration of sheep dairy production is at present mainly restricted to Europe and Israel. The trends in sheep population and milk production are shown in Table 1.

Breeds of Dairy Sheep

All breeds of sheep can be used for milk production, and in many localities, strains of sheep have been selected for their ability to produce significant quantities of milk. In the Mediterranean, at least 48 breeds can be classified primarily as milk producers; worldwide, the number would be much higher. The breeds most used for milk production in large commercial flocks are the Friesland and the Texel, although the Lacaune is favored in the Roquefort region of France and the Awassi in Israel. Many flockmasters cross a milk breed with a local breed to introduce hardiness or use breeds such as the Finn Dorset cross to encourage prolificacy.

Yields of Milk

Sheep milk yield varies depending on factors such as length of lactation, time and year of lambing, level of nutrition, and housing. However, yields of 120–1000 l per lactation are quoted, the normal yield being 200–300 l per lactation. To maintain a constant supply of milk, out-of-season lambing can be practiced. In this type of lambing management, each ewe produces three lamb crops in 2 years; thus, it will increase profitability. An alternative method is to keep two flocks, one lambing at the traditional season and the other out of season. Both methods require a high level of husbandry practices.

Milking

Milking is carried out mechanically in commercial flocks. Milking machines are similar to those used for dairy cows except that the vacuum level is set at 10 lb (4.5–5 kg) and the clusters are specialized units each with two lightweight teat cups. Milking is normally carried out in a parlor, which may be of static or rotary design. The milk is then transferred either to milk churns or to a bulk milk tank depending on the size of the enterprise. The milk must be cooled to below 5 °C as soon as possible after milking. In the case of churns, this can be achieved by passing the milk over a surface cooler before it enters the churn or by using an in-churn cooler. Churns should then be stored in a refrigerator. With a bulk tank, cooling is automatically carried out.

Composition of Sheep Milk

As with other milk, variations in composition with breed, stage of lactation, diet, season, milking times, and procedure have been recorded. The fat and total solids content tends to increase with the length of lactation leading to about 10% (w/v) fat content at the end of lactation. The average contents of protein (5.6%) and fat (6.4%) in sheep milk are high; only buffalo milk contains more fat on an average when milk from major dairy species is considered (Table 2). Sheep milk also contains more lactose than human, cow, buffalo, and goat

milk. The higher lactose content is compensated for by lower sodium and potassium levels, although most of the other minerals are present in higher amounts in sheep milk, in line with the higher ash content. The average fat globule size is reported to be even smaller in sheep milk than in goat milk, which makes the milk naturally homogenized. Milk composition is affected by various factors including stage of lactation, breed differences, number of calvings, seasonal variations, age and health of animal, and feed and management effects, which makes it difficult to compare compositional data between various studies. In order to permit such meta-analyses, published studies should include information on the factors mentioned earlier and analytic methods used and, where possible, include a control group for comparison. A detailed account of composition of sheep milk is summarized below.

Lipids in Sheep Milk

Lipids are one of the most important components of milk in terms of physical and sensory characteristics and in the nutritional properties that they confer to dairy products. Lipids are present in the form of globules, which in ovine milk are characteristically abundant in sizes of less than 3.5 μm. The average fat globule size in sheep milk is the smallest among all the ruminant milk. This is advantageous for digestibility and more efficient lipid metabolism compared with cow milk. The structure and composition of the globule membrane are similar to cow and goat milk fat, and it represents approximately 1% of total milk fat volume. Fat globules contain one hydrophobic lipid core, consisting mainly of triglycerides (TAGs), surrounded by a membrane made mainly of phospholipids and glycoproteins.

The FA profile of sheep milk is fairly similar to that of goat milk: five FAs make up more than 75% of the fat (C10:0, C14:0, C16:0, C18:0, and C18:1). SFA content (65–75 g/100 g total FA) is comparable to that in cow, buffalo, and goat milk. Sheep milk contains more retinol than cow and goat milk. As in goat milk, the nonprotein amino acid taurine is reported to be present in sheep milk. Sheep milk products can provide a profitable alternative to cow milk products owing to its specific taste, texture, typicity, and natural and healthy image. Nevertheless, consumers are requesting more and more information concerning the hygienic quality and nutritional composition of these products. All these characteristics can be influenced by several factors, such as breed, genetic, physiology, feed, environment, and technology.

Different fatty acids composed of fat globule core and membrane address a potentially healthy profile and have been detected in sheep milk. The C14:0 and C16:0 are present in greater amounts in the core, while polyunsaturated fatty acid (PUFA) omega-3, conjugated linoleic acid (CLA), and the precursors of the latter are more represented within the globule membrane. The unsaturated/saturated fatty acid ratio is lower in the fat globule core than in the membrane.

TAGs in Sheep Milk

The TAGs are the biggest group of lipids including a large number of esterified fatty acids. TAGs in sheep milk present a wide range of molecular weights when distributed according to the number of carbon atoms from C26 to C54. The TAG profile of sheep milk shows similarities to that for cow milk. However, sheep have a higher percentage of medium-chain TAG (C26–C36) than cow milk and a lower proportion of long-chain TAG (C46–C54). The unique characteristic of sheep milk fat is its content of about 25% medium-chain TAG.

Saturated Fatty Acids

The five most important fatty acids in quantitative terms (C18:1, C16:0, C10:0, C14:0, and C18:0) account for >70% of total fatty acids in sheep milk. It does not substantially differ in butyric acid (C4:0) content, but it contains more caproic (C6:0), caprylic (C8:0), and capric (C10:0) acids than cow milk. These fatty acids are associated with the characteristic flavor of cheeses and possess different biological properties.

Low concentrations of butyric acid can inhibit growth in a wide range of human cancer cell lines, including prostate.

Unsaturated Fatty Acids

Oleic acid (*cis*-9 C18:1), the second predominant fatty acid in sheep milk fat, is regarded as an antiatherogenic agent. Human diets high in oleic acid are mostly reported to decrease the level of low-density lipoprotein (LDL) cholesterol, whereas high-density lipoprotein (HDL) cholesterol levels are not affected notably. The PUFAs in sheep milk fat mainly comprise linoleic (*cis*-9 *cis*-12 C18:2) and α-linolenic (*cis*-9 *cis*-12, *cis*-15 C18:3) and smaller amounts of their positional and geometric isomers. Both are the essential fatty acids and they have many diverse functions in human metabolism and they promote an antiatherogenic effect. Sheep milk is not a rich source of linoleic and α-linolenic acids. However, other omega-3 PUFAs are hardly found in sheep milk fat, except when animal diets are supplemented with marine oil source.

Trans-Fatty Acids

Trans-fatty acid (TFA) content in sheep milk fat ranges from 2.5% to 5% of total fatty acids, mainly depending on diet and season. Monoene TFAs are the most abundant in all species. In ruminants, sheep milk presents the highest quantities, after cow and, finally, goat milk fat. The main source of TFA consumed daily by humans is partially hydrogenated vegetable fats and oils, although these compounds also occur naturally in ruminant milk as a result of partial biohydrogenation of PUFA caused by rumen microorganisms.

Conjugated Linoleic Acid

The generic name CLA is a collective term embracing all positional and geometric isomers of linoleic acid, which contain a conjugated double-bond system. Among ruminants, sheep milk fat could contain not only one of the highest levels of CLA but also the major content of vaccenic acid, its physiological precursor. The biological activity of other CLA minority isomers detected in sheep milk fat is marginal. Conversion of sheep milk to cheese has no effect on the final concentration of CLA. The isomeric profile and its content are primarily dependent on the CLA level of the unprocessed milk.

Other Minor Lipid Compounds

Along with TAG, sheep milk presents complex lipids (phospholipids) and different liposoluble compounds (sterols, β-carotene, and vitamins) with biological activity. The proportions of corresponding phospholipid classes in sheep milk are remarkably similar to other ruminants. Sterols are a minor fraction of sheep milk total lipids, the main sterol being cholesterol (about 300 mg/100 g fat, equivalent to approximately 10 mg/100 ml milk). The sterol fraction of milk is of nutritional interest because high levels of cholesterol in plasma are associated with an increasing risk of cardiovascular disease. Values for cholesterol content of sheep milk vary considerably and are associated with breed and the use of different analytic techniques. Small amounts of other sterols implicated in cholesterol biosynthesis have also been found in ovine milk.

Proteins in Sheep Milk

The sheep milk is a rich source of biologically active proteins. The amount of protein content in sheep milk is significantly higher (4.52–5.50%) than buffalo, cow, and goat milk. The protein components of milk have multiple functions. They provide amino acids, which are necessary for growth and development. The essential amino acids are present at concentrations similar to those in cows' milk, although isoleucine, leucine, serine, glutamic acid, and tyrosine may be slightly lower. In addition, milk proteins and peptides have more specific physiological functions. The biological properties of milk proteins include antibacterial activity, immunoglobulins, lactoferrin, lactoperoxidase, lysozyme, hormones, and growth factors. Most studies are performed with proteins of bovine and human origin, but these activities can be extrapolated to milk from other origins. Immunoglobulins are among the first host protein defense systems. The iron-binding protein, lactoferrin, is widely considered to be one of the most important defense proteins present in milk. Lactoferrin exhibits activity as an antimicrobial agent for host defense and as a physiological regulator with respect to both inflammatory and immune responses. Lysozyme and lactoperoxidase are also important antimicrobial proteins found in milk and colostrum. Lysozyme is mainly active against Gram-positive microorganisms, whereas Gram-negative microorganisms containing catalase, such as pseudomonads, coliforms, salmonellae, and shigellae, are killed by activated lactoperoxidase, provided that the hydrogen peroxide substrate is present in excess. Hormones, growth factors, and analogs are also present in milk, and they could act as development and metabolic regulators.

Carbohydrates in Sheep Milk

Lactose is quantitatively the main milk sugar in sheep milk. Its concentration is similar in horse, donkey, and human milk but lower in bovine or other ruminant milk. Lactose content in milk of buffalo, cow, goat, and sheep varies from each other. It is reported that the lactose content of buffalo milk ranges from 4.53% to 6.23%, cow milk 3.91–4.92%, goat milk 3.77–4.90%, and sheep milk 4.39–5.20%. Other milk carbohydrates, which are free or bound to lipids, proteins, or phosphate, include a small fraction of oligosaccharides. They are composed of galactose, fructose, *N*-acetylglucosamine, and/or *N*-acetylneuraminic acid (sialic acid) and contain mostly a lactose unit at their reducing end. They have the potential to modulate the growth of intestinal flora, to influence different gastrointestinal and inflammatory processes, and to provide protection against bacterial and viral infections. Their structural complexity however renders a functional comparison between species difficult.

Minerals in Sheep Milk

Interest in the nutritional significance of milk minerals and trace elements has markedly increased in recent years. There are about 20 minerals that are considered nutritionally essential

for humans (Na, K, Cl, Ca, Mg, P, Fe, Cu, Zn, Mn, Se, I, Cr, Co, Mb, F, As, Ni, Si, and B). Milk and dairy products can make an important contribution to the daily intake of some of them, especially Ca and P. The minerals in sheep milk have not been as extensively studied as in bovine milk, even though they may be of nutritional and health interest. Sheep milk has around 0.9% total minerals or ash, compared to 0.7% in cow milk. Sheep milk, goat milk, buffalo milk, and deer milk contain on average more Ca and P than bovine milk (Table 3). The most abundant elements in sheep milk are Ca, P, K, Na, and Mg; Zn, Fe, Cu, and Mn are the trace elements. In general, mineral contents of sheep milk seem to vary much more than those of cow milk. The mineral content of sheep milk is not constant but is influenced by a number of factors such as stage of lactation, nutritional status of the animal, and environmental and genetic factors due to feeding differences and seasonal variations. The salt balance in sheep milk is interesting as a contribution to the knowledge of nutritional characteristics of these types of milk and to the retention of these elements in the curd during cheese making. Because sheep milk is mainly used in cheese making and most of the soluble elements are lost in the whey during manufacture, the knowledge of element distribution would allow the evaluation of the influence of milk composition on the mineral content in cheese.

Vitamins in Sheep Milk

The total vitamin content of milk is highly variable and depends on the vitamin status and the feeding regime of the mother (with the level of water-soluble vitamins being more influenced by the feed than the level of the fat-soluble vitamins). The vitamin content of horse and donkey milk is on average lower than that of ruminant milk. The data on the vitamin content of sheep milk show that most of the known vitamins are contained in ovine milk, and for some of them, this foodstuff is a rich source. A comparative account of vitamin B content of sheep milk and cow milk is presented in Table 4. Daily riboflavin (B2) requirements, for instance, are completely covered by drinking just two cups of sheep milk without eating anything else. As consumption of sheep milk is not widespread, it is likely that two cups of sheep milk yogurt would meet those daily requirements or the milk equivalent in 90 g of sheep cheese. From the data available in published literature, it is evident that the sheep milk is richer than cow milk in most of the vitamins.

Table 3 Minerals in ewe milk and cow milk

Minerals	*Ewe milk*	*Cow milk*
Sodium (g l^{-1})	1.41–1.32	0.3–0.9
Potassium (g l^{-1})	1.01–1.52	1.1–1.7
Calcium (g l^{-1})	1.62–2.59	1.1–1.3
Magnesium (g l^{-1})	0.14–0.19	0.09–1.1.0
Phosphorus (g l^{-1})	0.82–1.83	0.9–1.0
Iron (mg l^{-1})	0.29–1.39	0.3–0.6
Copper (mg l^{-1})	0.19–1.30	0.1–0.3
Zinc (mg l^{-1})	4.66–11.8	2.0–6.0
Manganese (mg l^{-1})	0.032–0.13	NA

Physicochemical Properties of Sheep Milk

A comparative appraisal of various physicochemical properties of livestock animals are depicted in Table 5.

Hygiene in Milk Production

High levels of hygiene must be maintained at every stage of production and handling of the milk, paying particular attention to the following:

1. Sheep should be kept as clean as is practicable and the hair and wool clipped away from the area around the udder.
2. Udders should be cleaned prior to milking; particularly, the attention should be given to teats and teat orifices.
3. Cleaning and sterilization of the milking equipment must be carried out thoroughly after each milking.
4. Milk must be cooled promptly and kept at less than 5 °C until used.

Nutritional Significance

From the compositional data, it can be seen that sheep's milk has a higher nutritive and energy value than cow and goat milk. Advantages to the processors are that yogurt can be made without increasing the levels of solids not fat, and cheese yields are high. The small size of the fat globules may enhance digestibility of the milk and products. Allergy sufferers who are intolerant to cow milk readily tolerate sheep milk.

Table 4 Vitamin B content of ewe milk and cow milk

Vitamins	*Ewe milk*	*Cow milk*
Riboflavin (mg l^{-1})	4.3–5.0	1.5–2.3
Thiamin (mg l^{-1})	0.6–1.2	0.3–0.6
Nicotinic acid (mg l^{-1})	3.9–5.4	0.6–1.3
Pantothenic acid (mg l^{-1})	3.5–5.3	3.5
Vitamin B6 (mg l^{-1})	0.7	0.4
Folic acid (μg l^{-1})	54.0	50.0
Vitamin B12 (μg l^{-1})	1.4–9.8	3.0
Biotin (μg l^{-1})	50.0–90.0	20.0

Table 5 Physicochemical properties of milk of livestock animals

Type of milk	*pH*	*Specific gravity*	*Titratable acidity*
Sheep milk	6.63	1.034	0.23
Goat milk	6.55	1.030	0.16
Cow milk	6.64	1.029	0.17
Buffalo milk	6.75	1.033	0.21

Production of Processed Foods

Cheese and yogurt are the main products of sheep milk worldwide. Smaller markets exist for liquid milk and other products. Liquid milk may be pasteurized, frozen, or spray-dried. The main difference between the milk of sheep, cow, and goat is that the former contains almost double the solids because sheep milk is rich in fat, protein, minerals, and vitamins. However, the methods of production and processing and the potential microbiological problems are similar. The high level of the total solids contents in sheep milk makes it particularly suitable for manufacture of yogurt, cheese, butter, and ice cream.

Yogurt

The uniform small fat globules in sheep milk ensure that there is no separation of cream in the yogurt; consequently, there is no need of homogenization. The method of manufacture is the same as for cow milk; the set type is normally manufactured, although a small amount of the strained variety is made, particularly in Greece.

Cheese

Sheep milk can be successfully used to make cheese by any of the recipes used for cow milk, although the resultant cheese is unlikely to resemble the corresponding cow milk cheese. A wide range of cheeses (fresh, soft, brined, hard, and blue-veined varieties) have been made traditionally, many of which are produced in one locality. Roquefort, feta, pecorino, and ricotta are probably the best known. Until the introduction of modern technology, feta cheese, which should be white, could only be made successfully from sheep milk as there is too much natural color in cow milk. Pecorino is the hardest of the sheep milk cheeses and is associated with the production of ricotta. Ricotta, which is not technically a cheese as it contains no casein, is produced by heating the whey of any cheese that has not been salted to at least 85 °C. The resultant white foam is skimmed off and allowed to drain overnight in a 'ricotta' basket or strainer. In recent years, a wide range of 'new' cheeses have been developed from the sheep milk to suit modern tastes.

Butter

The production of butter from sheep milk is not yet commercially explored. But in some localities, sheep milk is utilized for butter making for domestic use, while in a few sheep belts in India, it is used to produce ghee.

Ice Cream

Sheep milk ice cream is not available commercially. However, some manufacturers make small quantities of ice cream from sheep milk, which they sell from their own premises as a cottage-level income-augmenting activity.

Public Health Significance of Sheep Milk

Relatively little information exists on the microbiology of sheep milk and its public health significance. However, such milk and its products are subject to similar public health and quality problems as is milk from other animals. Milk drawn aseptically from sheep udder is practically sterile, provided that the animal is free from any disease. However, after leaving the udder, it can be easily contaminated during unhygienic handling. The studies on freshly produced bulk milk showed poor picture of its microbiological quality with average viable counts of 10^5–10^6 CFU ml^{-1}. This is partly due to the preponderance of production in developing countries and rural areas where conditions are primitive and understanding of hygiene lacking. Milk produced under hygienic conditions can be of excellent microbiological quality. However, contamination from milking equipment can be a problem as the high fat content of the milk makes surfaces difficult to clean. The common cause of clinical mastitis and therefore the most likely contaminant of milk from this source is *Staphylococcus aureus*. However, *Pasteurella haemolytica* may be as or more important in some flocks. Mastitic streptococci and a variety of other bacteria may also be present in the milk owing to clinical or subclinical udder infections. The only report of disease of animal origin transmitted via sheep's milk or products in the United Kingdom has been of staphylococcal intoxication from raw milk cheese. Many strains of mastitic *S. aureus* have been shown to be enterotoxigenic, so this seems to be a public health risk. *Listeria monocytogenes* causes circling disease in sheep and can be excreted in the milk. This poses a potential health risk since infection is not usually associated with severe mastitis or organoleptic changes in the milk. Sheep can also become infected with salmonellas and campylobacters, and a carriage pattern of campylobacter in healthy sheep similar to that in cows has been found in the United Kingdom, creating a potential risk. Other pathogens involved in zoonosis through sheep milk and products are *Mycobacterium tuberculosis* (rare in sheep), *Brucella melitensis/abortus*, *Coxiella burnetii*, and *Toxoplasma gondii*.

Postpasteurization contamination of milk is thought to have been the cause of an outbreak of *Salmonella enteritidis* from cheese in Spain. Contamination of human origin has caused outbreaks of *S. aureus* intoxication and shigella infection.

Introduction

Shellfish are recognized as all exoskeleton-bearing aquatic invertebrate organisms harvested for human consumption, including crustaceans, bivalve mollusks, and gastropod mollusks. These organisms have high economic and nutritional relevance, being considered as delicacies and healthy food items, since they are important sources of proteins and have low fat levels with important levels of $n-3$ fatty acids. This article intends to provide an overview of the morphological, ecological, and nutritional characteristics of the most relevant shellfish consumed worldwide, namely, crustaceans and bivalves.

Crustaceans

Crustaceans (phylum Arthropoda, order Decapoda) can be mainly divided into four categories: crabs, clawed lobsters, spiny lobsters, and shrimps/prawns (see differences in Figure 1). All crustaceans are covered with a hard and rigid outer shell composed of calcium and chitin. The shell is periodically replaced by a large one enabling animal growth (molting). Generally, eggs are incubated in females' pleopods, and newly hatched planktonic larvae are released into the water.

Crabs

Worldwide, the most relevant crab species harvested are the horse crab (*Portunus trituberculatus*) (one-quarter of the total), followed by flower crab (*Portunus pelagicus*), snow crab (*Chionoecetes* spp.), blue crab (*Callinectes sapidus*), brown crab (*Cancer pagurus*), Dungeness crab (*Metacarcinus magister*), and mud crabs (*Scylla serrata*), each with more than 20 000 tons annually. The most relevant crabs consumed in Europe are the brown crab (*Cancer pagurus*), velvet crab (*Necora puber*), spider crab (*Maja* squinado or *Maja brachydactyla*), and green crab (*Carcinus maenas*). The main ecological (geographic distribution, habitat, and behavior) and morphological (biology) characteristics are shown in Table 1. They show marked sexual dimorphism, where the females' abdomen is broad with four pairs of hairy appendages on which the eggs are attached during spawning, whereas the males' abdomen is narrow with abdominal appendages modified in copulatory organs and larger claws (in adults).

Clawed and Spiny Lobsters

Several species are harvested globally, despite only four species account more than 20 000 tons annually, such as the American lobster (*Homarus americanus*), Norway lobster (*Nephrops norvegicus*), Caribbean spiny lobster (*Panulirus argus*), and tropical spiny lobsters (*Panulirus* spp.). The most relevant clawed lobsters consumed in Europe are the European lobster (*H. gammarus*), American lobster (*H. americanus*; imported from the United States and Canada), Norway lobster (*Nephrops norvegicus*), and spiny lobsters (represented by several *Palinurus* species; mostly imported). The main ecological (geographic distribution, habitat, and behavior) and morphological (biology) characteristics are shown in Table 1. Lobsters have long bodies with muscular tails and move by slowly walking on the seafloor or swim backward by quickly curling and uncurling their abdomen.

Shrimps and Prawns

Globally, the most relevant shrimps and prawns harvested or produced are the whiteleg shrimp (*Litopenaeus vannamei*), giant tiger prawn (*Penaeus monodon*), akiami paste shrimp (*Acetes japonicus*), northern prawn (*Pandalus borealis*), southern rough shrimp (*Trachysalambria curvirostris*), fleshy prawn (*Fenneropenaeus chinensis*), and banana prawn (*Fenneropenaeus merguiensis*). The most relevant shrimps and prawns consumed in Europe are the tiger prawn (*Penaeus monodon*; imported) and freshwater shrimp (*L. vannamei*; imported from Asian countries), among others. The main ecological (geographic distribution, habitat, and behavior) and morphological (biology) characteristics are shown in Table 1. Shrimps and prawns possess stalked eyes with long narrow abdomens, long antennae, and fragile legs adapted to swimming.

Bivalves

Bivalves (phylum Mollusca, class Bivalvia) include marine and freshwater organisms with laterally compressed bodies enclosed by a hard and rigid outer shell that grows with the animal, composed of calcium carbonate (secreted by the mantle tissue epidermis) and divided into two parts (valves) joined in one edge by a flexible ligament in conjunction with teeth.

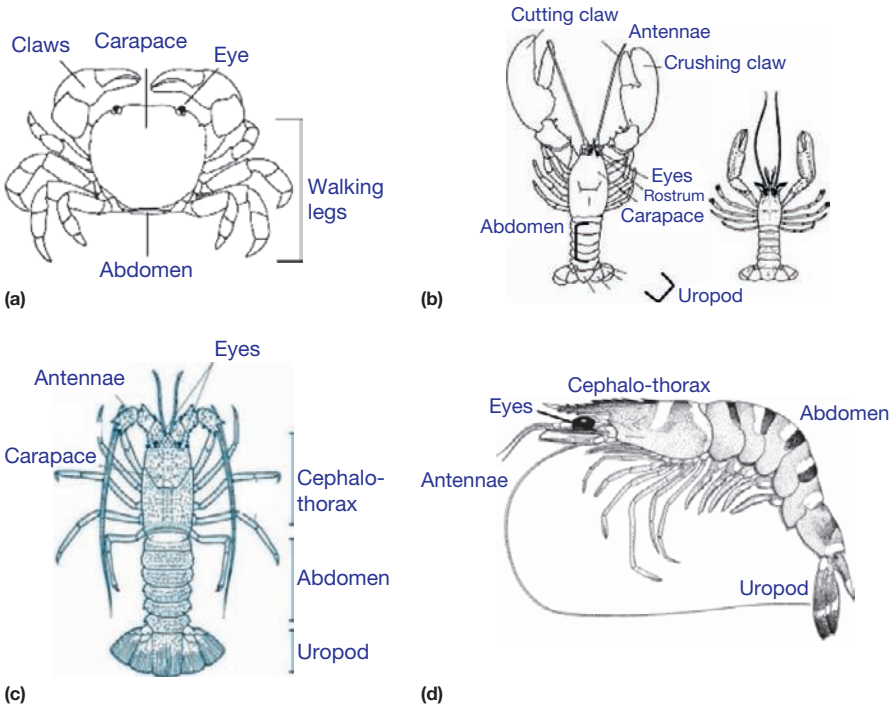

Figure 1 Schematic representation of different categories of crustaceans: (a) crabs, (b) clawed lobsters, (c) spiny lobsters, and (d) shrimps/prawns. Adapted from the Illustration of Jo Taylor; source: Museum Victoria, Australia.

Most species do not have heads, and the edible tissue is mainly composed of the mantle and viscera. Bivalves mostly consumed in Europe can be mainly divided into four categories: clams, mussels, oysters, and scallops (see differences in Figure 2). The bivalve categories have a notable variation in shape, size, thickness, and color.

Clams

Worldwide, the major species of clams for production are the Manila clam (*Ruditapes philippinarum*), razor clam (*Ensis*, *Siliqua*, and *Solen* genera), blood cockle (*Anadara granosa*), and northern quahog (*Mercenaria mercenaria*). The most important clam species consumed in Europe are the Manila clam (*R. philippinarum*), grooved carpet shell (*R. decussatus*), cockle (*Cerastoderma edule*), and Vietnamese clam (*Meretrix lyrata*; imported). The main ecological (geographic distribution, habitat, and behavior) and morphological (biology) characteristics are shown in Table 2.

Mussels

The New Zealand green-lipped mussel (*Perna canaliculus*), Chilean mussel (*Mytilus chilensis*), blue mussel (*M. edulis*), and the Mediterranean mussel (*M. galloprovincialis*) are the most relevant mussels produced worldwide. The most consumed mussels in Europe are the blue mussel (*M. edulis*) and the Mediterranean mussel (*M. galloprovincialis*). The main ecological (geographic distribution, habitat, and behavior) and morphological (biology) characteristics are shown in Table 2.

Oysters

Worldwide, the most important edible oysters are representatives of the genus *Crassostrea*, notably *C. gigas* in the western Pacific, *C. virginica* in North America, and *C. angulata* in Portugal. The two most important oyster species consumed in Europe are the Pacific cupped oyster (*C. gigas*) and the Portuguese oyster (*C. angulata*). The main ecological (geographic distribution, habitat, and behavior) and morphological (biology) characteristics are shown in Table 2.

Scallops

The Atlantic sea scallop (*Placopecten magellanicus*), Yesso scallop (*Patinopecten yessoensis*), Atlantic bay scallop (*Argopecten irradians*), Chinese scallop (*Chlamys* spp.), and Peruvian calico scallop (*Argopecten purpuratus*) are the most relevant scallops produced in the world. The king scallop (*Pecten maximus*) is the most important scallop species consumed in Europe. The main ecological (geographic distribution, habitat, and behavior) and morphological (biology) characteristics are shown in Table 2.

Nutritional Characteristics

The nutritional characteristics of shellfish vary among species. Also, the specimens' age, sex, maturation stage, origin, season, seawater physical–chemical properties, and feed availability may influence the levels of nutrients (example in Figure 3). Shellfish edible tissues are mainly composed of proteins (10–21%), lipids (0.3–20%), and carbohydrates (0.4–7%) (Tables 3 and 4). The energetic value in crustaceans' muscle

Table 1 Characteristics of the most consumed crustacean species in Europe in terms of distribution, habitat, behavior, and biology

Crustaceans	*Common name*	*Distribution*	*Habitat and behavior*	*Biology*
Crabs				
Cancer pagurus	Brown crab	European west coast (Portugal to Norway) and North Africa	Bottoms of sand, gravel, and rock up to 200 m depth, shallow in warm season and deeper waters in cold season, predators (bivalve mollusks, polychaetes, and crustaceans)	Heavy, oval-shaped body, with a 'piecrust' edge and massive black-tipped pincers, red-brown color, sexual dimorphism, grows up to 30 cm; females store sperm until eggs are developed
Carcinus maenas	Green crab	European west coast (Portugal to Norway) and North Africa	Marine and estuarine habitats in mud, sand, or rock substrates up to 60 m depth, predators (bivalve mollusks, polychaetes, and crustaceans)	Carapace with five short teeth along the rim behind each eye, sexual dimorphism, grows up to 10 cm; color varies from green to brown to gray or red; females store sperm until eggs are developed
Maja spp.	Spider crab	Mediterranean/European west coast (Portugal to Scotland) and North Africa	Rocky or coarse sandy areas up to 50 m depth, predators (bivalve mollusks, polychaetes, and crustaceans)	Red, brown-red, or yellow color, grows up to 20 cm, circular to oval carapace, broad at the back and narrow at the front, legs covered by hairs, shell covered with algae, sexual dimorphism; females store sperm until eggs are developed
Necora puber	Velvet crab	Mediterranean/European west coast (Portugal to Scotland) and North Africa	Stony and rocky substrata in shallow and sheltered water, predators (bivalve mollusks, polychaetes, and crustaceans)	Fast-moving swimming crab, blue-brown color, dorsal surface with velvety texture, red eyes, sexual dimorphism, grows up to 8 cm; females store sperm until eggs are developed
Lobsters				
Homarus gammarus	European lobster	European west coast (Portugal to Norway) and North Africa	Rocky substrata, living in holes and excavating tunnels up to 60 m depth, territorial and noctivagous, omnivores and eat fish, mollusks, crustaceans, worms, and algae	Blue-colored above with spots and yellowish below, body without strong spines or ridges, eggs fertilized during mating, grows up to 1 m; first pair of walking legs are massive but slightly unequal claws
Homarus americanus	American lobster	Atlantic coast of North America (North Carolina to Labrador)	Cold, shallow waters in rocky substrata; omnivores and eat fish, mollusks, crustaceans, worms, and algae; depths from 2 to 480 m	Dark bluish-green to greenish-brown color, red on the body and claws, and green on the legs, rostrum with spines, eggs fertilized during mating, grows up to 61 cm
Nephrops norvegicus	Norway lobster	Mediterranean/European west coast (Portugal to Norway) and North Africa	Muddy bottoms; digging hole to burrow; nocturnal; omnivores and eat fish, mollusks, crustaceans, worms, and algae; depths from 15 to 800 m	Color pale orange, grows up to 25 cm, head and thorax with a nonsegmented carapace, abdomen segmented, fanlike tail, first three pairs of legs with claws, two pairs of antennae (one longer and thinner), large black eyes, eggs fertilized during mating
Palinurus sp./ *Jasus* sp./ *Panulirus* sp.	Spiny lobster	South European, American, African, and Australasian coasts	Warm seas; live in crevices of rocks and coral reefs; only occasionally leaving at night to eat; omnivores and eat fish, mollusks, crustaceans, worms, and algae; depths from 5 to 200 m	Several colors, long, thick, and spiny antennae, lack of claws in the first four pairs of legs, slightly compressed carapace, lacking lateral ridges, eggs fertilized during mating, grows up to 60 cm
Shrimps				
Penaeus monodon	Prawn	Coasts of Australia, Southeast Asia, South Asia, and East Africa	Tropical marine coastal estuaries, lagoons, or mangrove areas, nocturnal activity, burrowing during the day, eggs fertilized during mating, muddy or sandy bottoms up to 20–50 m depth	Green, brown, red, gray, blue, and transverse blue or black and yellow band colors on abdomen and carapace, rostrum well developed and toothed dorsally and ventrally, grows up to 33 cm
Penaeus vannamei	Shrimp	Native to the eastern Pacific coast and farmed in America and Asia	Tropical marine habitats ($>$20 °C), ocean, coastal estuaries, lagoons, or mangrove, eggs fertilized during mating, muddy or sandy bottoms up to 72 m	Translucent, blue or olive with dusky bands, reddish-brown on the antennules, and white legs, grows up to 23 cm

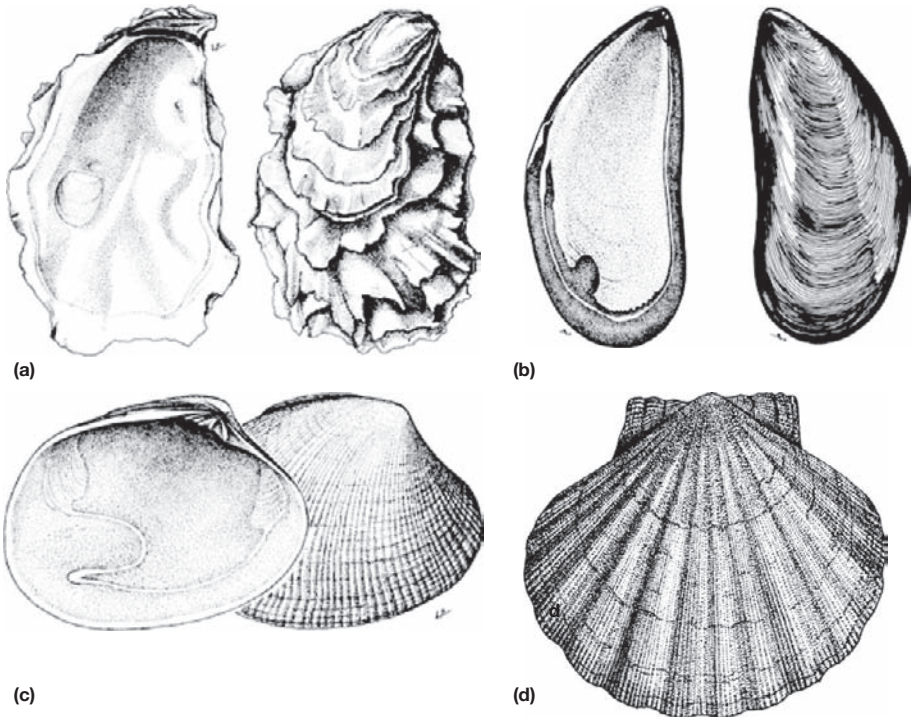

Figure 2 Schematic representation of different categories of bivalves: (a) oysters, (b) mussels, (c) clams, and (d) scallops. Adapted from FAO source.

Table 2 Characteristics of the most consumed bivalve species in Europe in terms of distribution, habitat, behavior, and biology

Bivalves	*Common name*	*Distribution*	*Habitat and behavior*	*Biology*
Cerastoderma edule	Cockle	European west coast (Portugal to Scotland) and North Africa	Able to burrow up to 5 cm depth in clean sand, muddy sand, mud, or muddy gravel, separate sexes, intertidal areas, filter feeder (phytoplankton)	Shell with radiating ribs, crossed by concentric ridges, outer surface white, yellowish, or brownish, two siphons and two adductor muscles, large muscular foot, external fertilization, grows up to 5 cm; shell is solid, thick, equivalve, globular, and broadly oval shape; gonads occupy a major portion of the visceral mass
Crassostrea spp.	Oyster	Mediterranean/European west coast (Portugal to Scotland), North Africa, Asia, America, and Australia	Intertidal and subtidal firm (attach to rocks, debris, or other oyster shells), mud or mud–sand bottoms, between 5 and 40 m depth, protandrous hermaphrodites (start as males), filter feeder (phytoplankton)	Shell solid, inequivalve, extremely rough, extensively fluted, laminated, white color with purple streaks and spots, white shell interior, irregular shell shapes, with a single adductor muscle, external fertilization, grows up to 30 cm
Mytilus spp.	Mussel	Mediterranean/European west coast (Portugal to Norway) and North Africa	Hard exposed intertidal substrates, attached by byssus threads to rocks and piers in sheltered harbors, estuaries, and coastal rocky shores, sometimes living in dense masses, separate sexes, up to 40 m depth, filter feeder (phytoplankton)	Extremely variable in shape and color, shell solid, equivalve, inequilateral, beaks at the anterior end, triangular shape, shells blue, purple, or dark brown, external fertilization, grows up to 15 cm
Ruditapes spp.	Clam	Mediterranean/European west coast (Portugal to Scotland), North Africa, America, and Asia	Buried in sand, muddy gravel, or stiff clay, below mid-tide level and littoral lagoons, separate sexes, up to 4 m depth, filter feeder (phytoplankton)	Shell solid, equivalve, inequilateral, beaks in the anterior half, broadly oval to quadratic shape, extremely variable in color and pattern, shell white, yellow, or light brown, sometimes with rays, steaks, blotches, or zigzags, two siphons, two adductor muscles, large muscular foot, external fertilization, grows up to 8 cm; gonads occupy a major portion of the visceral mass

Table 2 (Continued)

Bivalves	*Common name*	*Distribution*	*Habitat and behavior*	*Biology*
Pecten maximus	King scallop	European west coast (Portugal to Norway)	Clean firm sand, fine, sandy gravel, and occasionally muddy sand, active swimmer, functional hermaphrodite, between 4 and 100 m depth, filter feeder (phytoplankton)	Shell valves fan-shaped with an ear on either side of the apex of the valve, right valve strongly convex, with a white, yellow, or light brown color and often with bands or spots of darker pigment, left valve flat and light pink to red-brown, with radiating ribs, no siphons, one large and well-developed adductor muscle, conspicuous and well-defined gonads, external fertilization, grows up to 15 cm
Meretrix lyrata	Vietnamese clam	Indo-West Pacific coasts	Brackish tropical waters, buried in mud flats with sandy or muddy bottoms, separate sexes, up to 20 m depth, filter feeder (phytoplankton)	Trigonal ovate shape, equivalve, exterior color light tan to light brown, posterior dorsal margin dark brown, interior white with a purple or dark brown ray of pigment along the posterior dorsal margin, two siphons, two adductor muscles, large muscular foot, external fertilization, grows up to 5 cm; gonads occupy a major portion of the visceral mass

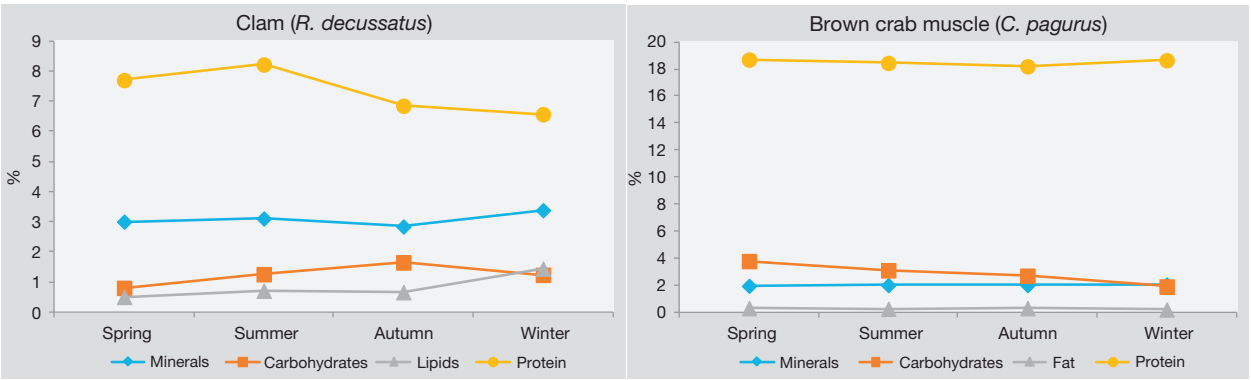

Figure 3 Seasonal variation of protein, lipid, carbohydrate, and mineral contents in a bivalve and a crustacean species.

and bivalves is generally reduced, containing less than 100 kcal (418 kJ) per 100 g portion but can be high in brown meat (243 kcal per 100 g portion). The lipid fraction does not exceed 5%, except crustaceans' brown meat (i.e., mixture of hepatopancreas and gonads). Despite considerable variations between species, shellfish fatty acid profile is particularly interesting, as the long-chain polyunsaturated fatty acids (PUFA) are predominant, such as eicosapentaenoic acid (EPA; 20:5$n-3$) and docosahexaenoic acid (DHA; 22:6$n-3$). Palmitic acid (16:0) is the prevailing saturated fatty acid (SFA) in shellfish species, whereas oleic acid (18:1$n-9$) is the main monounsaturated fatty acid (MUFA). Despite shellfish has long been assumed to possess high cholesterol levels, recent findings reported that only 25–40% of the total sterols in shellfish correspond to cholesterol. In fact, shellfish contains less cholesterol than meat or poultry, and the highest values are observed in crustaceans' brown meat. Protein contents in shellfish are, in general, more stable than lipids, revealing high levels of digestible proteins with essential amino acids similar to those of reference protein. Shellfish also have higher contents of carbohydrates compared with finfish, mainly stored as glycogen, exhibiting a clear seasonal variability related to reproduction. Other components responsible for the sapidity of shellfish are also found in shellfish, such as nonprotein nitrogen compounds (e.g., free amino acids, nucleotides, and volatile compounds). Shellfish contains most of the naturally occurring

minerals (e.g., C, H, S, K, P, and Ca) and Se and Cu in high concentrations. Toxic elements (e.g., Hg, Cd, Pb, and As) are also detected in edible tissues, though the concentrations are usually low, with the exception of Cd in crustaceans' brown meat. Vitamins vary according to species, origin, and season, but vitamins A, B12, B3 (niacin), B2, and E are, generally, referred as the most abundant in shellfish.

Crustaceans

Most studies assessing the biochemical composition of crustaceans only consider the muscle (WM found in claws and legs) as edible tissue. However, crustaceans' BM (viscera) is also consumed. Major differences are encountered between both tissues (see Table 3), particularly in the lipid and mineral fraction. Fat and cholesterol contents can be extremely high in crustaceans' BM, whereas WM is a lean (fat $<0.2\%$) and low-cholesterol product. BM has also higher shares of carbohydrates, SFA (e.g., 14:0 and 16:0), MUFA (e.g., 16:1$n-7$, 18:1$n-9$, and 20:1$n-9$), and minerals (1.4–7%). In opposition, lower contributions of EPA and DHA are detected in BM, as well as lower protein (10–14%) and EAA levels. The most relevant minerals in BM are K, P (data not shown), Na, Ca, Zn, and Mg. High concentrations of Cu can also be found in crustaceans' BM. Regarding toxic elements, the levels of Hg, Pb, and As are usually similar in WM and BM, while Cd concentrations are much higher in BM. Despite Cd is only regulated in crustaceans' WM, Cd concentrations in BM can be 100 times above the maximum permissible concentration set by the EU. The information concerning vitamins is scarce for crustaceans' BM, whereas in WM, relevant contents of vitamins A, E, and B12, folates, and niacin have been found in brown crabs and European, Norwegian, and spiny lobsters. In this context, the assessment of crustaceans' nutritional value should also take into account the BM.

Bivalves

Bivalves are lean products due to the low lipid content in most species' edible tissue ($<3\%$; Table 4). Overall, high shares of PUFA are detected, namely, from the $n-3$ group. Other fatty acids are also typically found at high concentrations in bivalves, such as 16:0, 18:1$n-9$, and 20:4$n-6$. Low cholesterol content is usually detected in most bivalve species; however, higher values can be found in scallops (28–85 mg 100 g^{-1}). The protein content is stable (13–18%), though higher in scallops. The presence of some free amino acids, such as threonine, glycine, and alanine, confers the characteristically sweet taste of bivalves, whereas glutamic and aspartic acids are responsible for the acidic taste, and aspartate and glutamate are associated with the *umami* taste, also described as meat flavor. Carbohydrate content in bivalves also varies considerably mostly due to seasonal variations related to these species' reproductive cycle, reaching its lower peak immediately after spawning. The mineral content varies mostly according to species (0.8–3%) and origin, and the most abundant elements are K, P (data not shown), Na, Ca, and Mg. Within toxic elements, As is the most important, although the levels in bivalves are, generally, lower than those observed in crustaceans. Despite some variations within species, relevant contents of vitamins A (high in mussels: 360 μg 100 g^{-1}), B12 (high in oysters), B6, and B1 and niacin can be found in bivalves.

Introduction

Seafood is one of the most important food commodities consumed worldwide. The health benefits of a diet rich in seafood have been extensively recognized. Namely, $n-3$ polyunsaturated fatty acids (PUFAs) are associated with decreased morbidity and mortality from various illnesses like reduced risk of coronary heart disease, hypertension, and stroke. The World Health Organization and Food and Agriculture Organization recommend a regular fish consumption of 1–2 servings per week in order to provide an equivalent of 200–500 mg of eicosapentaenoic acids (20:5$n-3$) (EPA) and docosahexaenoic acids (22:6$n-3$) (DHA). Within seafood, shellfish (including crustaceans and bivalves) are, together with fish and cephalopods, the most relevant items consumed worldwide. This article aims to describe the role of crustaceans and bivalves in the European diet, including the description of sources and production, consumption preferences, and hazards and benefits to consumers.

Sources and Production

Mollusks and crustaceans have gained increasing importance to European consumers, raising the annual *per capita* consumption from 300 to 400 g in 1961 to almost 2 kg in 2009 (Figure 1(a)).

In the last decade, mussels were the most relevant bivalve group produced in Europe (though showing wide variability; reaching 78% of the whole bivalves production in 2012; main producers: Spain, Italy, and France), followed by clams (12%; main producers: Italy, Spain, and Portugal), scallops (7%; main producers: the United Kingdom, France, and Ireland), and oysters (3%; main producers: Ireland, the Netherlands, and Spain) (Figure 1(b)). The overall production of bivalves in Europe accounted 423 000 tons in 2012. Mussels were also the most relevant bivalve species exported from the EU in 2012 (67%; main destination: Switzerland), followed by scallops (14%; main destination: Vietnam), clams (10%; main destinations: China and Switzerland), and oysters (9%; main destinations: China, Russian Federation, and Switzerland), with an overall exportation volume accounting 219 000 tons (Figure 1(c)). Similarly, mussels were the most relevant bivalve group imported by the EU in 2012 (60%; main suppliers: New Zealand and Chile), followed by scallops (19%; main suppliers: the United States, Peru, and Argentina), clams (15%; main suppliers: Vietnam, Chile, and Republic of Korea), and oysters (6%; main supplier: Republic of Korea), representing a global importation volume of 271 000 tons (Figure 1(d)). Therefore, the trade balance of bivalves in Europe is slightly negative due to mussels, scallops, and clams (−52 000 tons).

Concerning crustaceans, the most relevant group produced in the last decade in Europe was shrimps and prawns (60% of the whole crustacean production in 2012; main producers: Italy, the Netherlands, and Germany), followed by lobsters (22%; main producers: the United Kingdom, Ireland, and France) and crabs (18%; main producers: the United Kingdom, Ireland, and France) (Figure 1(e)). The European crustacean production accounted 121 000 tons in 2012. Shrimps and prawns were also the most relevant crustaceans exported by the EU in 2012 (91%; main destinations: Morocco, China, and Russian Federation), followed by lobsters (6%; main destinations: China, Vietnam, and Japan) and crabs (3%; main destinations: China, the United States, and Indonesia), with an overall exportation volume reaching 81 000 tons (Figure 1(f)). Similarly, shrimps and prawns were the most relevant crustaceans imported by the EU in 2012 (93%; main suppliers: Ecuador, India, and Argentina), followed by lobsters (5%; main suppliers: the United States, Canada, and Cuba) and crabs (2%; main suppliers: Greenland, Madagascar, and Norway), representing a total importation volume of 471 000 tons (Figure 1(g)). The crustaceans trade balance in Europe is very negative due to shrimps and prawns (−390 000 tons).

Consumer Preferences of Bivalve Mollusks and Crustaceans: Portugal as Case Study

European seafood annual *per capita* consumption has increased consistently over the past four decades, from 14 kg in 1961 to 22 kg in 2009. European seafood consumption varies considerably according to country and region, being generally higher and more traditional in southern countries than in northern and western Europe. Portugal is the eighth biggest seafood consumer worldwide and has the highest annual seafood *per*

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00625-5

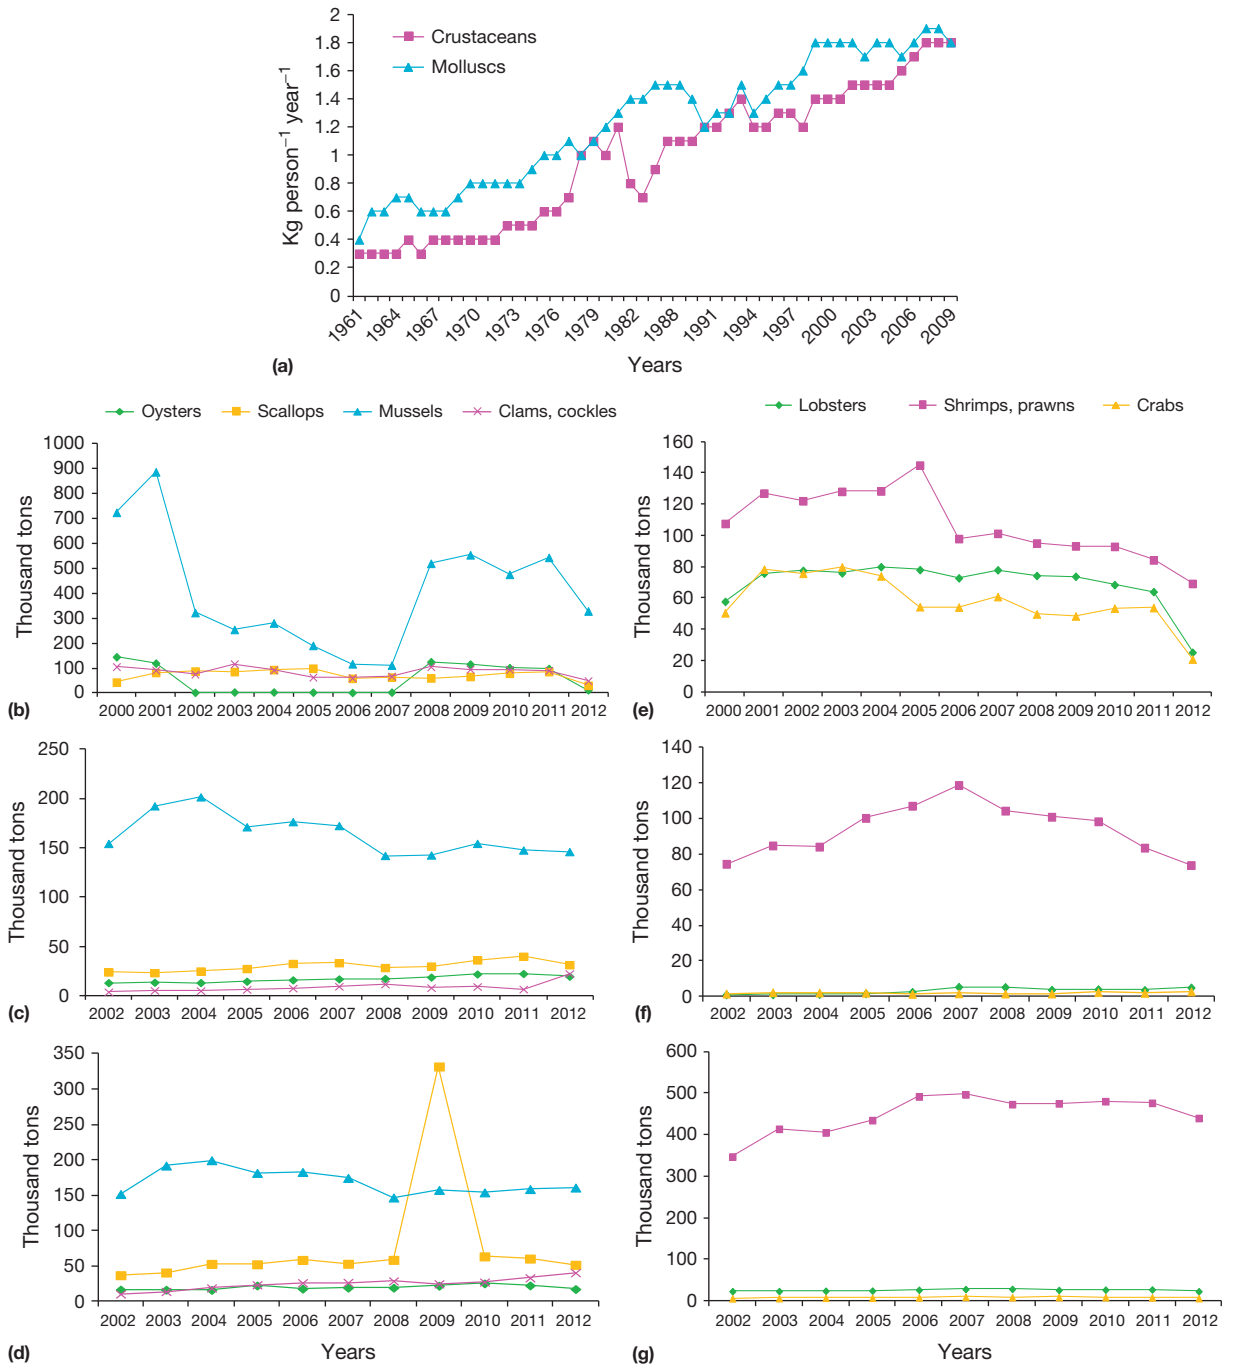

Figure 1 Trade balance, production, and consumption of crustaceans and bivalves in Europe: per capita consumption (a); bivalves production (b), exportation (c), and importation (d); and crustaceans production (e), exportation (f), and importation (g). Source: Eurostat.

capita consumption in the EU, with an annual average of 61 kg, well above the average world *per capita* consumption (18.4 kg, 2009). Among seafood, crustaceans and bivalve mollusks are greatly appreciated by European consumers from a social and gastronomic point of view, particularly in Southern Europe. Both items are usually maintained alive until the culinary preparation as a guarantee of freshness, but bivalves are preferably consumed either live/raw (e.g., oysters) or lightly cooked (e.g., clams and mussels).

Several studies have focussed the seafood consumer preferences in several European countries, such as seafood and bivalves in Portugal, shellfish in Greece, and oysters, mussels, and seafood in France. Most studies showed that consumers' behavior and attitudes vary considerably according to their demographic and socioeconomic characteristics. Portugal is an excellent case study to assess consumer preferences concerning seafood, since it is the largest *per capita* seafood consumption country in Europe. Therefore, information regarding

bivalve and crustacean consumers' preferences was collected through online surveys in Portugal (see Figures 2 and 3). In general, the Portuguese population widely consumes crustaceans (94%) and bivalves (80%) (Figures 2(a) and 3(a)). The most consumed crustacean groups are shrimps, prawns, and brown crab, representing more than 50% of the overall crustacean consumption in Portugal (Figure 2(b)). Concerning bivalves, the most important species consumed in Portugal are the pullet carpet shell clam (*Venerupis pullastra*), grooved carpet shell clam (*Ruditapes decussatus*), and Japanese carpet shell clam (*Ruditapes philippinarum*), representing 66% of the overall bivalve consumption (Figure 3(b)).

The less important species are lobsters, spider crabs, Norway lobster, velvet crabs, European lobsters, and green crabs, contributing with 36% of crustaceans' consumption, and mussels, oysters, hard clams, scallops, surf clams, and peppery furrow shell clams, accounting 32% of bivalves' consumption. The unpleasant flavor and high price are the main reasons for not consuming crustaceans (55%; Figure 2(c)) and bivalves (39%; Figure 3(c)). Additionally, Portuguese consumers also highlighted that crustacean consumption is a concern due to allergies (13%), whereas food poisoning can hamper bivalve consumption (18%). A high proportion of the population reported low consumption frequencies particularly of bivalves; that is, 39% of the population consumed bivalves one to five times per year (bimonthly to annually; Figure 3(d)), while crustaceans are mainly consumed (51%) 6–11 times per year (monthly to bimonthly; Figure 2(d)). Overall, the consumption of shellfish varies seasonally, increasing in summer particularly for bivalves (45%, Figure 3(e)), whereas crustaceans are also highly consumed in New Year festivities. The local markets seem to be the most convenient place to purchase crustaceans in Portugal (50%; Figure 2(e)), while bivalves are mostly purchased at supermarkets (51%; Figure 3(f)). In contrast, most European countries reveal other preferences to buy bivalves, principally mussels from traditional fish shops (viz., Greece, Switzerland, Poland, Norway, and France). Most consumers buy live (51%) or frozen (42%) bivalves, and the majority of consumers slightly cook them (52%) or use long cooking practices (47%) (Figure 3(g) and 3(h)). In contrast, concerning crustaceans, consumers buy mostly frozen shrimps and prawns (31%) and cooked-chilled products (28%) (Figure 2(f)), and most consumers prefer to boil (56%), grill (25%), and fry (19%) crustaceans (Figure 2(g)).

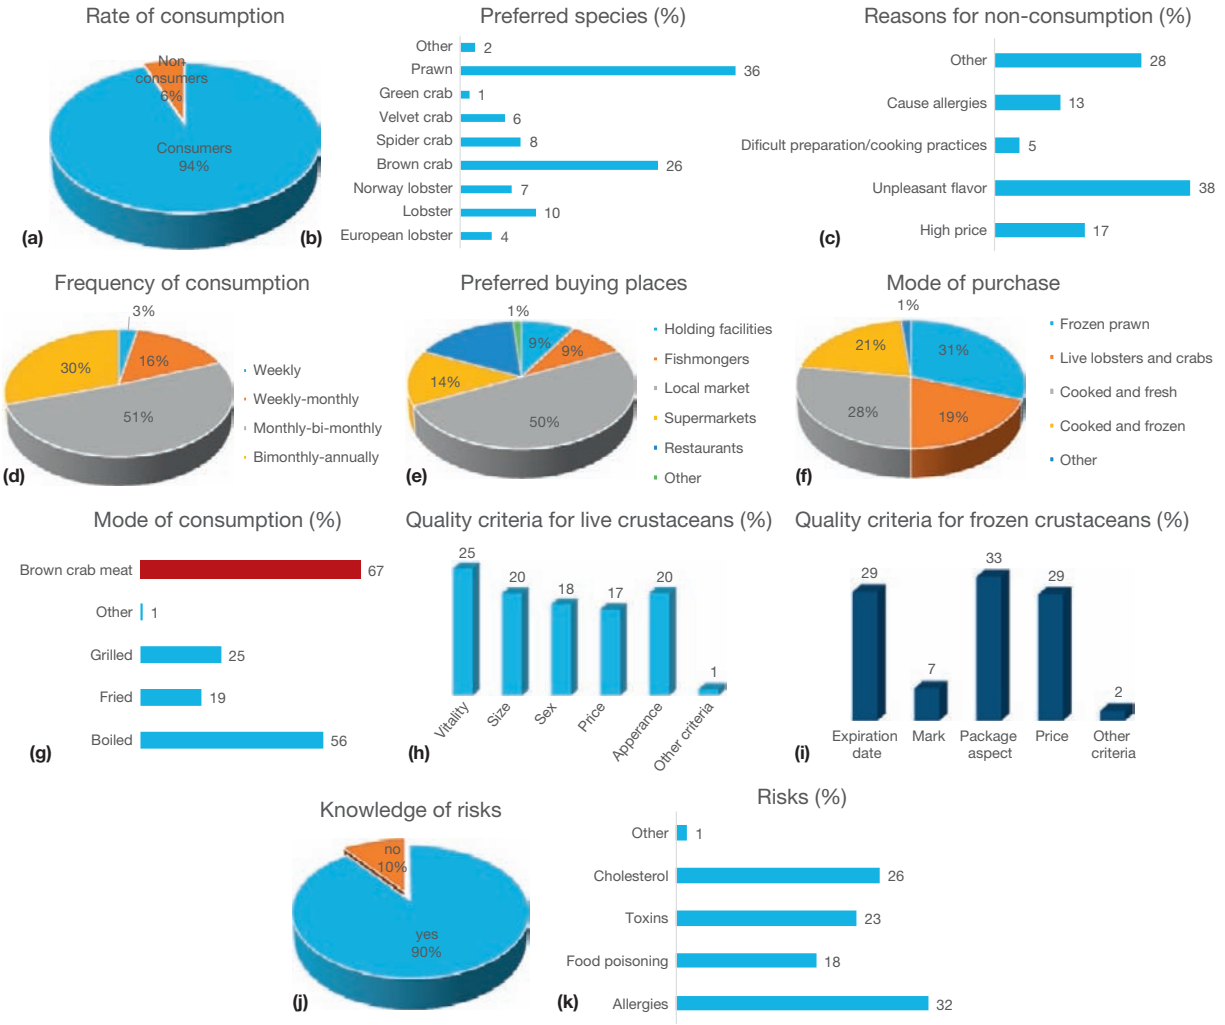

Figure 2 Consumers' patterns of crustaceans: Portugal as case study. Results from an online survey in 2009.

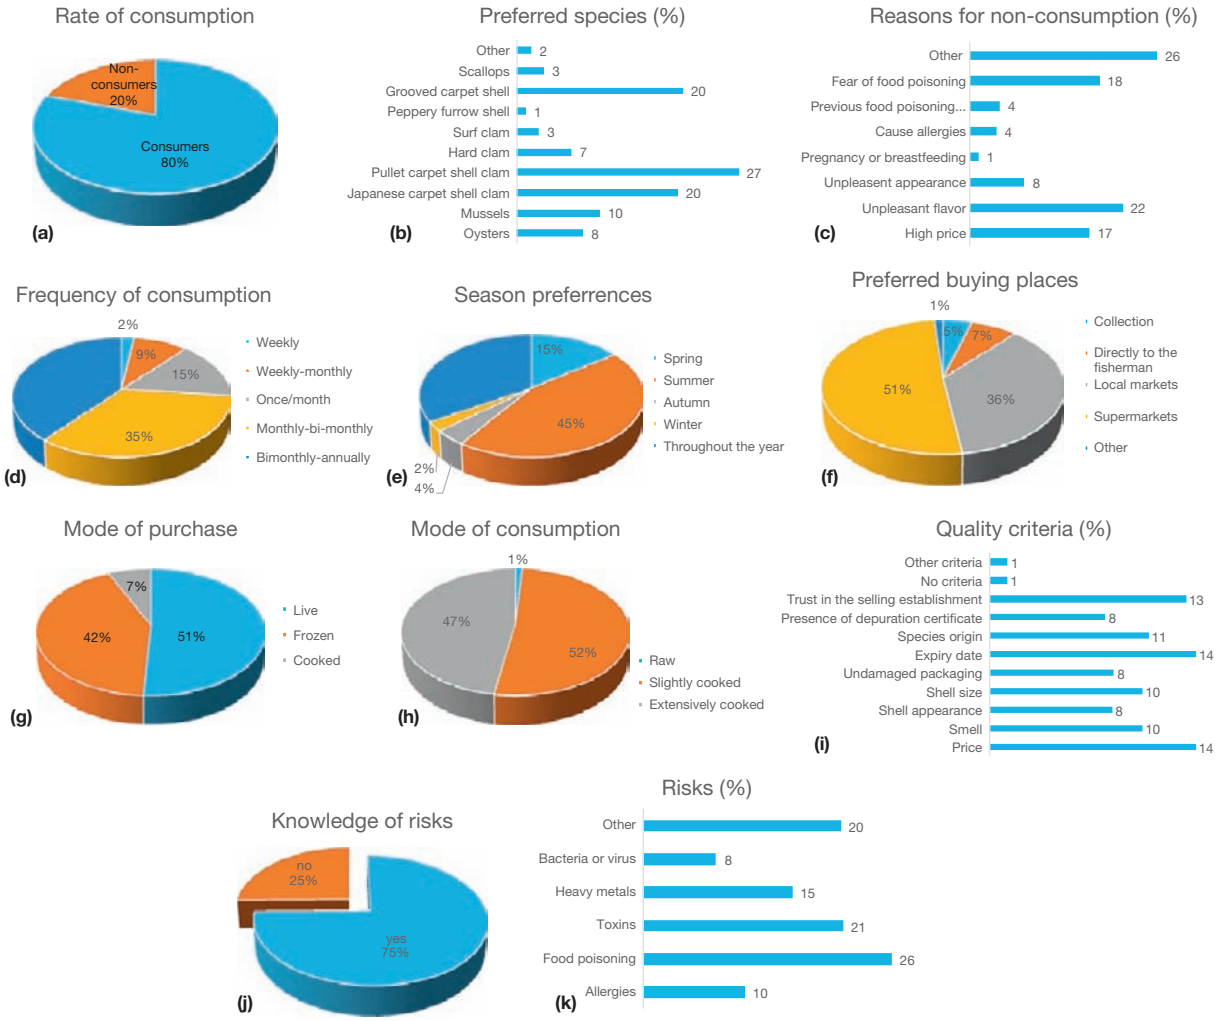

Figure 3 Consumers' patterns of bivalve mollusks: Portugal as case study. Results from an online survey in 2012.

Portuguese consumers are more exigent regarding the quality of shellfish. In this sense, the most important quality criteria for choosing live crustaceans are vitality, appearance, and size, accounting 64% of preferences, whereas frozen crustaceans are mainly chosen by consumers through package aspect, expiration date, and price, contributing with 91% of the preferences (Figure 2(h) and 2(i)). Concerning bivalves, price, expiry date, trust in the selling establishment, origin, size, and smell were the most crucial quality parameters for consumers, representing 73% of all items (Figure 3(i)).

In general, most consumers are aware of the hazards associated with the consumption of crustaceans (90%; Figure 2(j)) and bivalves (75%; Figure 3(j)), pointing out allergies and cholesterol as the highest hazards for crustaceans consumption (58%; Figure 2(k)) and food poisoning and toxins for bivalves (46%; Figure 3(k)). Even though consumers reveal, overall, a high level of hazards' awareness, inadequate practices often occur, such as harvesting/consuming shellfish from polluted areas, purchasing products directly to fisherman, performing short cooking procedures that do not effectively inactivate most pathogenic agents, and consuming bivalves with broken or closed shells. These practices may constitute a higher risk to human health than those highlighted by consumers, since there is a potential source of serious infections and diseases. Within crustaceans, crab species are particularly appreciated by Portuguese consumers, and their brown meat (BM) (i.e., hepatopancreas and gonads) is considered by most as a delicacy (67%). However, BM can pose serious risks to human health due to the high cadmium content.

Assessing consumer preferences is an excellent tool for stakeholders involved in the shellfish trade chain to adapt their products, processes, and practices according to consumers' requirements and preferences. Such understanding is also highly relevant to enable the evaluation of shellfish benefits and hazards for human health by health authorities and policy makers.

Hazards, Benefits, and Health Effects

Worldwide, consumers have been encouraged to increase seafood consumption due to several human health benefits of

eating these products. Bivalves and crustaceans have a strong presence in the European gastronomy due to their sensory attributes greatly appreciated by consumers. Yet, safety and quality concerns regarding these products are often raised by consumers, partially due to the presence of contaminants and presumably high cholesterol levels. As filter-feeding species, bivalves can accumulate biological contaminants such as bacteria, viruses, and toxic microalgae, thus potentially representing a risk to consumers. Regular monitoring programs have been established in EU countries, banning the harvesting of bivalves whenever toxic microalgae blooms occur and, therefore, safeguarding consumer's safety. Sanitary control programs are also carried out regularly to monitor and classify bivalves' harvesting areas according to the levels of bacterial contamination, that is, category A (may be consumed immediately after harvesting), category B (may be consumed after depuration), category C (may be consumed after processing), and interdicted harvest. However, regardless of the area category, the consumption of raw bivalves is discouraged, and the duration of cooking procedures should be extended to ensure an effective inactivation of pathogenic agents, therefore avoiding health hazards to consumers. As discussed elsewhere in this Encyclopedia, bivalves' and crustaceans' white meat (WM) is considered lean products (<3%), and the consumption of 100 g of these products, generally, does not exceed 50% of the cholesterol recommended daily intake (see Figure 4).

On the other hand, these values can be much higher in crustaceans' BM. High shares of long-chain $n-3$ PUFAs, such as EPA and DHA, are one of the nutritional attributes of seafood, in general, as these fatty acids have proved to play a major role in the prevention and recovery from cardiovascular diseases, asthma, diabetes, arthritis, cancer, and fetal malformations. However, the consumption of 100 g of shellfish usually does not meet the recommended intake of 500 mg per day, except in mussels and some crustaceans' BM, which contain higher lipid contents. Considering the beneficial aspects of unsaturated lipids (monounsaturated fatty acids and PUFAs) in the prevention of cardiovascular diseases, opposed to the adverse effects of saturated ones (SFA), different quality indexes are used, such as $n-3$PUFA/$n-6$PUFA ratio, PUFA/SFA ratio, atherogenic index (AI), and thrombogenic index (TI). Despite the lower values in BM, shellfish products evidence balanced ratios of PUFA/SFA and $n-3$PUFA/$n-6$PUFA, as the minimum recommend values are exceeded for most species. Recommendations regarding AI and TI have not yet been proposed, though the values obtained with shellfish are similar to those found in other seafood products.

Bivalves and crustaceans contain adequate levels of high-quality protein, as 100 g meal composed of these species satisfies the adult daily requirements for most essential amino acids, with the exception of methionine and cysteine that are, usually, limiting amino acids in these species (Figure 5). Moreover, it should be highlighted that the high digestibility of shellfish proteins facilitates the absorption of essential amino acids during the human digestion process.

Shellfish are also important sources of macro and trace minerals, as they contain almost all essential minerals in their edible parts (Figure 6). Selenium, Cu, and Ca (in crustaceans' BM) are the most relevant minerals, since their concentrations often exceed the recommended daily allowances set for adults. Some shellfish species, such as oysters, crabs, and clawed and spiny lobsters, can also provide good intakes of Zn and Fe (Figure 6). As mentioned elsewhere in this Encyclopedia, Se levels are much higher in shellfish than in terrestrial animals, which is particularly beneficial for consumers since this essential mineral participates in the regulation of hormones, vitamin C, and other molecules and also acts as an antioxidant, protecting cells against oxidative stress. Despite that most minerals found in shellfish are required in several human metabolic processes, they must be uptake from the diet in

Figure 6 Essential and toxic elements composition (%) of bivalves and crustaceans taking into account a meal of 100 g.

balanced doses, as high intakes can become toxic. For example, Cu upper intake level (the highest level of daily intake that is likely to pose no risk of adverse health effects to almost all individuals in a population) is exceeded when considering the consumption of 100 g of clawed lobsters' BM. Some adverse effects of high Cu intakes are gastrointestinal distress and liver damage. Toxic metals can also be found in shellfish as discussed previously. In order to regulate consumers' exposure to toxic elements, the European Food Safety Authority has established a tolerable weekly intake (TWI) of 2.5 μg kg^{-1} body weight (BW) for Cd and 1.3 μg kg^{-1} BW for the most toxic form of Hg (methyl Hg). According to the low Hg levels in shellfish, even if considered that 100% of the total Hg content in these species is in the methyl Hg form, the consumption of a shellfish meal (100 g) would place adult consumers (with 71 kg of average BW) well below the methyl Hg TWI. In contrast, the extremely high levels of Cd found in crabs and clawed lobsters' BM can represent a significant risk for consumers, since more than 100% of TWI for this contaminant is reached in a single meal (100 g). Nephrotoxicity, osteoporosis, carcinogenicity and genotoxicity, teratogenicity, and endocrine and reproductive disruptions are some of the adverse effects associated with high Cd intakes.

Overall, the potential hazards related to the consumption of shellfish are, largely, outweighed by the benefits, namely, considering the importance that these products have in the gastronomic traditions and consumers' social habits, holy days, and festivities. Nonetheless, bivalves' and crustaceans' WM should be preferred by consumers, whereas the consumption of BM should be moderated to avoid excessive intakes of cholesterol, Cu, and Cd.

Sherry Wines: Manufacture, Composition and Analysis

MÁ Pozo-Bayón and MV Moreno-Arribas, Instituto de Investigación en Ciencias de la Alimentación (CIAL) (CSIC-UAM), Madrid, Spain

© 2016 Elsevier Ltd. All rights reserved.

Background

Sherry wines are among the most distinctive Spanish wines, mainly produced in southern Spain (particularly in Jerez and Montilla-Moriles regions). France (Jura), Italy (Sardinia and Sicily), the United States (California), and various South African and Australian regions are some of the other foremost producers of sherry-like wines in the world, and the quality of these wines is highly regarded. By international legal agreement, the name 'sherry' and some of the technical/style names associated are only accepted for producers operating within DO (Origin Denomination) Jerez.

Palomino Fino and Pedro Ximenez grape varieties are used to obtain high-quality base wines for sherry wine production. The main types of sherry wines are the Fino, Oloroso, and Amontillado, which are obtained from the same base wine but subjected to different aging procedures. Fino wines are obtained by biological aging under the action of *flor* yeast growing on the wine surface, while Oloroso wines are exclusively obtained by oxidative aging after fortification with ethanol to avoid the growth of *flor* yeast. Amontillado wines are produced by two consecutive biological and oxidative aging steps; therefore, they have chemical and sensory characteristics between Fino and Oloroso sherries. Other types of sherry wines are the darkest and sweetest Pedro Ximenez styles, where ripe grapes are further concentrated by raising on mats prior to fortification and barrel maturation.

The biological aging of sherry wines (Jerez-Xérèz-Sherry, Spain) is a unique and well established winemaking practice to obtain high-quality wines. It is mainly based on a microbiological process that occurs under a biofilm of a *Saccharomyces* yeast strain called the *flor* velum yeast. According to the industrial process, after the must fermentation, the young wine is fortified with wine alcohol to 15% (v/v) and is then clarified and transferred into oak casks for storage. Wine aging occurs in the *solera* and *criaderas* system under the *flor* film of yeast. During this period, a thick layer of *flor* yeast (1–3 cm) develops naturally on the surface of the wine in contact with air. The velum, which isolates and protects the wine from excess oxidation, is the origin of complex biochemical reactions that result from the oxidative metabolism of the *flor* yeasts and the reducing environment created in the wine.

Manufacturing Process for Sherry Wines

Fino wines are among the most characteristic sherry types. They are biologically aged following a unique process consisting of two consecutive steps. The first consists of grape must fermentation, which produces a 'young' wine using fermentative yeasts. Once a high-quality wine is obtained, a postfermentative treatment, in which this young wine is fortified with wine alcohol to approximately 15.0–15.5% (v/v ethanol), is carried out. This operation is known as *encabezado*. In Montilla-Moriles, no fortification is required due to the natural sugar content of musts, making it possible to reach naturally an adequate alcohol content (15% v/v).

Flor yeasts that grow in wine with a high ethanol content adapt to these conditions by forming a *flor* film (velum) on their surface, and their metabolism becomes oxidative. In the production of sherry wines, a few months after alcoholic fermentation has finished, the wine is transferred and yeast lees are removed. In the area of Jerez (Southern Spain), the wine is stored before starting the biological aging process. During the intervening time, it undergoes malolactic fermentation and spontaneously develops a yeast film. Wine stored in this way is referred to as *sobretablas* wine.

Biological aging takes place in American oak casks of variable capacity, depending on their position in the aging system, by a dynamic process called *criaderas and solera* (Figure 1). This involves stacking the casks in rows called *criaderas* (scales) in such a way that all casks in a row contain wine of the same type and are aged for an identical length of time. The casks are filled to four-fifths of their capacity in order to allow a biofilm of *flor* yeasts to develop on the wine surface. A series of casks hold wine in the process of maturing; the casks are arranged to facilitate a progressive, fractional blending. The row standing on the floor, which is called the *solera*, contains the oldest wine in the system. It is from this row that the commercial wine is withdrawn for bottling extraction, and never exceeds 40% of the cask contents per year. This process is carried out three or four times each year. The amount of wine extracted from the *solera* is replaced with an identical volume of wine from the upper row, which is called the first *criadera*. Likewise, the amount extracted from the first *criadera* is replaced with wine from the next row (the second *criadera*), and so on (Figure 1). Finally, the topmost *criadera*, which contains the youngest wine, is replaced with *sobretablas* wine. The number of scales typically ranges from 4 to 6; usually, the greater the number, the higher the quality of the final wine.

The *rocío* operation consists in the transference of wine from one scale to the next. The wine extracted from the casks in a scale is homogenized in a tank and then transferred to the casks in the next (older) row. This operation must be carefully performed in order to not disrupt the *flor* film on the wine surface. In addition, the *rocío* favors the adequate supplementation of nutrients from the young to the old wine, which in turn is required to form and maintain the yeast film. In addition, this process provides aeration, which is highly beneficial for the wine and *flor* yeasts. This dynamic process allows wine of similar sensory characteristics to be obtained year after year, irrespective of the particular vintage.

The Microbiological Process in the Biological Aging of Sherry Wines

The restrictive conditions of the biological aging process (low pH, presence of sulfite, high ethanol and acetaldehyde

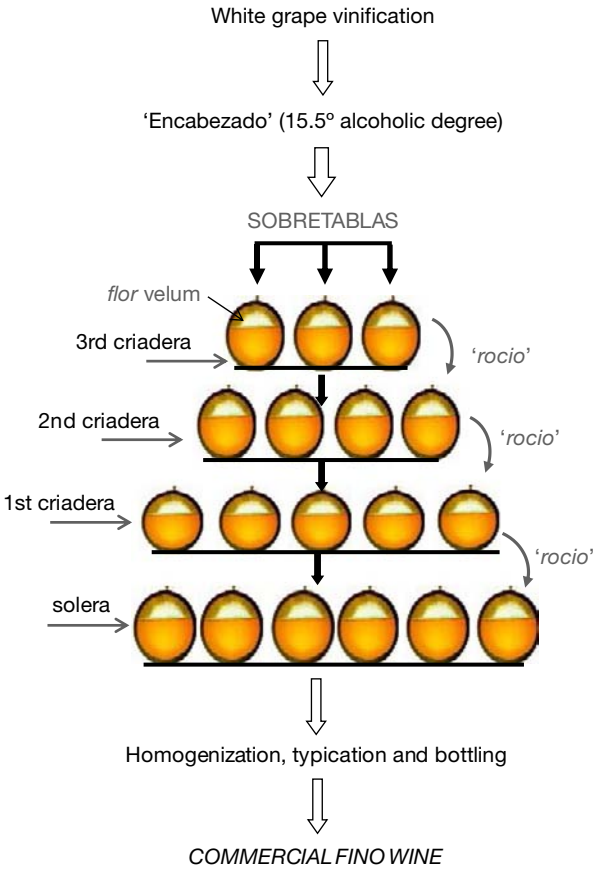

Figure 1 Main steps in the biological aging of sherry wines.

concentrations, lack of sugars, and low oxygen concentration) are compatible with only a few *Saccharomyces cerevisiae* races; therefore, more than 95% of the film microbiota usually consists of film-forming *S. cerevisiae*. Physiological and molecular characterization of the yeasts present in the velum of sherry wines has shown that most of them belong to different races of *S. cerevisiae*, mainly *beticus*, *cheresiensis*, *montuliensis*, and *rouxii*. These *flor* yeasts differ physiologically from the typical fermentative yeasts (which are unable to grow aerobically in wine), and they have different metabolic and genetic characteristic.

By using restriction mitochondrial DNA (mtDNA) analysis, it has been possible to study the dynamics of these yeast strains during specific steps or during the whole process of sherry winemaking. In these studies, it has been shown that other microbial populations, such as lactic acid bacteria (e.g., *Lactobacillus plantarum*, *L. casei*, *L. brevis*, and *L. Zeae*) and other *non-Saccharomyces* yeasts (e.g., *Debaryomyces*, *Zygosaccharomyces*, *Pichia*, *Hansenula*, and *Candida*), can coexist with the velum yeast. Moreover, species of the genera *Dekkera* and *Brettanomyces* have been related with an abnormally higher acidity in the casks containing biologically aged wines.

In recent years, genetic improvement in *flor* yeasts, such as studies on the genes responsible for flocculation, such as *FLO11*, have lead to advances in cell-immobilization technology. In 2006, a *S. cerevisiae* strain var. *capensis* was successfully coimmobilized with *Penicillium chrysogenum* in order to obtain biocapsules for potential use in a number of fermentation processes. On the other hand, the relatively large aging time necessary to obtain high-quality wines (4–5 years for Fino and more than ten for Amontillado wines) has promoted new research. Consequently, it has been shown that the expression of genes such as *SOD1* (superoxide dismutase 1) may facilitate the establishment of a more stable velum and a reduction in aging times. Likewise, the characterization of cell wall proteins and the encoding genes of *S. cerevisiae* and its relevance to *flor* formation have also been recently explored.

Analysis and Chemical Composition of Sherry Wines: Evolution During Biological and Oxidative Aging and Consequences for Wine Quality

The different production conditions involved in the manufacturing of the main types of sherry wines (Fino, Oloroso, and Amontillado) determine their differences in chemical composition and, therefore, in sensory characteristics. Some of the most important changes in chemical composition during the biological and/or the oxidative aging of sherry wines are revised as follows.

Polyphenols

Color is one of the most important characteristics of sherry wines, and the content and type of phenolic compounds are close behind. The type and amount of these compounds largely depend on the grape variety and winemaking technology employed in their production. For instance, the characteristic and appropriate pale yellow color of Fino wines is determined by the exclusively biological aging process. It has been suggested that *flor* yeast growing on the surface of the wines protects wines against oxidation because it minimizes oxygen diffusion into the wine, preventing the formation of browning pigments. In addition, *flor* yeasts have the ability to retain brown pigments produced during oxidation. After bottling, Fino wine tends to get browner, lowering its quality. This is one of the main sources of economical loss for producers of pale sherry wines. This is a natural process that inevitably occurs to some extent during bottled storage. In order to extend the commercial life of these wines and keep their pale color, different strategies have been evaluated. Some viticultural practices such as harvesting grapes during the night, or hyperoxidating musts in order to reduce the initial concentration of phenolic compounds, have been suggested. To avoid or minimize changes in color after bottling, the use of PVPP or activated charcoal is often employed in sherry production. In addition, the use of yeasts to retain previously formed browning compounds or specific yeast strains to decrease browning rate by inhibiting certain enzymatic reactions involved in the formation of colored compounds have been suggested. Another essayed strategy is the use of immobilized yeast in k-carragenate. It has been shown to be an effective alternative to the use of synthetic products to reduce oxidation in sherry wines, and is adequate for the production of organic wines.

In the absence of biological aging, Oloroso-type sherries are exclusively subjected to oxidative aging. Their high content in ethanol (between 18 and 20 °C) does not allow yeasts to grow.

They are submitted to extended dynamic oxidation, which gives these wines very particular organoleptic characteristics. Wood allows the slow diffusion of atmospheric oxygen into casks, which in the absence of *flor* yeast causes a slow oxidation of wine phenolic compounds. As a consequence, a progressive darker color develops, with mahogany cues. Particularly, the flavan-3-ol monomers and oligomers have been described as good substrates for browning by different chemical pathways. Basically, the oxidation of phenolic compounds produces quinones, which by polymerization lead to compounds showing a reddish-brown color. The rate of this process in the cellar depends on various factors, including the acidity of the wine, its SO_2 content, the presence of metals (Fe), the amount of available O_2, and the temperature. As aging progresses, the polyphenol oxidation reactions progress, thus increasing the dark color of the wine. On the other hand, during oxidative aging, phenols undergo oxidation and polymerization reactions, thereby decreasing the content of those compounds of low molecular weight. Brown color can also increase by condensation reactions of some polyphenols, such as flavan-3-ol monomers and oligomers with acetaldehyde. Moreover, flavanols are implied in the progression of browning via a condensation–oxidation process involving glyoxylic acid, which is formed by oxidation of tartaric acid in the presence of some metals. In addition, the concentration of some other phenolic compounds increases during prolonged aging because of the extraction of some compounds from the wood. Their nature depends on the type of wood, aging temperature, and so on. The length of time that wines spend in wood has been recently shown to be directly related to the antioxidant activity of these wines. However, it has also been suggested that the browning of the wines is more strongly dependent on the aging temperature than on the phenolic compounds supplied by the cask wood. The hydrolysis of oligomers, in particular the flavan-3-ol derivatives fraction, and the loss of water and ethanol through the wood and/or by evaporation might also explain the increase in the concentration of phenolic compounds during oxidative aging.

Because the Amontillado sherry type is produced by a two-stage aging process, combining a biological and an oxidative process, these wines exhibit a phenolic composition between Fino and Oloroso sherry wines.

Common to any wine, the analysis of sherry wine polyphenols requires a previous extraction step, usually performed by using C18 resins, and a further analysis with high-performance liquid chromatography. Normally, detection is performed using diode-array detectors (DADs), although currently mass spectrometers (MS) are widely employed. By using these techniques, it has been shown that the different sherry winemaking conditions generate a very different phenolic profile. For instance, in Fino sherry wines, the phenolic aldehydes typically associated with wines aged in wood are very low or almost absent. In addition, they do not experience great changes during the aging process. The only phenolic compounds that increase in these wines during aging are the benzoic acids, due to the contribution made by lignin and by the deamination of nitrogen compounds produced during the autolysis of the *flor* yeast. Benzoic and cinnamic acids are present throughout oxidative aging in Oloroso sherries. However, some other phenolic acids, such as gallic, syringic, and caffeic, experience greater changes during aging. In addition, the content of esterified derivatives is lower than in Fino sherries. Oloroso wines are also characterized by a high content of 5-(hydroxymethyl)-2-furaldehyde (HMF), mainly occurring at the end of the aging process. Amontillado sherries are characterized by a phenolic composition between Fino and Oloroso wines. Wines from the youngest scale of the *criadera* system (scale $n°7$) present a very similar profile to the samples of Fino wine taken from its final scale. However, in subsequent scales, their behavior becomes more similar to that of Oloroso wines than to Fino wines. In these wines, some aldehydes such as vanillin and p-hydroxybenzaldehyde show considerable increases during aging, whereas syringaldehyde remains constant. In addition, HMF shows a considerably increase during aging.

Volatile Compounds

Volatile compounds are responsible for the aroma of wines, and are therefore directly linked to wine quality and consumer preference. Similar to polyphenols, the different sherry wine production technologies produce wines with very different volatile compositions and sensory characteristics. In general, because of their low concentration, different types of extraction and concentration techniques are required prior to their analysis. Most of these techniques involve the use of organic solvents and/or the use of absorbent polymers, and further steps of concentration. The use of headspace solid-phase microextraction has been shown to provide good selectivity, and sensitivity avoiding the concentration steps. In any case, gas chromatography (GC) is the technique used for the analysis of volatile compounds. The use of GC coupled to flame ionization detectors or MS has provided a valuable tool for the characterization of the volatility profile of sherry.

Ethanol is the main volatile compound produced during yeast fermentation from grape sugars. After water, ethanol is the major component of wines. Its content is highly variable across wines, depending on the sugar content of the must and the winemaking technology involved in production. In the case of sherry wines and other fortified wines, its content ranges between 15% (in Fino wines) and 18–21% (in the case of Oloroso wines). Ethanol might have an impact on the sensory characteristics of wines because it occurs in sherry wines above its perception threshold. During the biological aging of sherry wines, the concentration of ethanol decreases because of its consumption by *flor* yeast. It is used as the main source of carbon and energy, and other secondary metabolites such as acetaldehyde (the main subproduct), acetic acid, butanediol, diacetyl, and acetoin. Ethanol can be also metabolized via the tricarboxylic acid pathway, and can be lost by evaporation through the oak cask.

Acetaldehyde constitutes one of the most important compounds produced during biological aging. Besides its contribution to the ethereal and overripe apple notes, it is responsible for the pungent aroma of Fino sherry wines. The acetaldehyde content allows the differentiation of Fino wines from other types of sherry wines. Its concentration can reach values between 350 and 450 mg l^{-1} and occasionally of 1000 mg l^{-1}. This compound is produced by *flor* yeast, mainly

from the oxidation of ethanol by alcohol deshydrogenase II (ADH II), which produces NADH. This enzyme is repressed by glucose. The acetaldehyde content increases with aging, although the most important changes occur in the scales containing the youngest wine, due to the intense metabolism of *flor* yeast. It also takes part in different reactions during biological aging, such as its combination with ethanol to produce 1,1-diethoxyethane. It can occur in wines at concentrations above 100 mg l^{-1}. This acetal has been shown to contribute to wine aroma, giving fresh, fruity, and green aromatic notes. Acetaldehyde is also involved in the formation of other aroma compounds, such as acetoin, 2,3-butanodiol.

It has been shown that *flor* yeasts increase the content of other aroma compounds, such as higher alcohols, ethyl esters, lactones, and terpenes. For instance, higher alcohols are very important contributors to the aroma of Fino wines, although the concentration of most of them (e.g., isobutanol, 2-phenylethanol, isoamylic alcohols) is quite stable through aging. One exception is propanol, which can dramatically increase during aging. The biosynthesis of higher alcohols is mainly produced in the fourth, third, and second *criaderas* from their corresponding amino acids. This is coincident with the maximum yeast activity. In addition, it has been suggested that their production can increase due to yeast autolysis.

Regarding esters, their concentration depends on the synthesis and hydrolysis reactions accounted for during aging, but also on the enzymatic activity of yeasts. These depend on the type of yeast, physiological state, and other factors. Many of these compounds contribute to fruity aroma notes. In general, the concentration of higher alcohol acetates decreases through hydrolysis over the first few months of aging, while ethyl esters of organic acids (lactic, succinic) increase.

Sotolon is an important lactone produced during the biological aging of Fino wines, but also is important in wines produced under oxidative aging conditions. This compound is produced from the aldolization reaction between α-ketobutyric acid (from the deamination of L-threonine by *flor* yeast) and acetaldehyde. Because of its low perception threshold (10 μg l^{-1}), this compound has been described as an important odor impact compound, with nut, curry, and candy cotton notes, in both biologically aged sherry wines and those produced under oxidative aging conditions. Its concentration in sherry wines depends on the duration of aging, but it normally occurs at concentrations above 200 μg l^{-1}. Recently, by using GC-MS and GC-olfactometry (GC-O), an ethyl analog of sotolon, identified as abhexonm (5-ethyl-3-hydroxy-4-methyl-5(*H*)-furan-2-one), has been associated with curry/spicy/honey nuances. It is also associated with two theaspirane oxidation products: dihydrodehydro-β-ionone with dried/fruit/Sauternes-like odors, and 4-hydroxy-7,8-dihydro-β-ionone. The latter exhibits a strong grenadine-like odor. They have also been identified in Jura Flor sherry wines ('yellow wines').

Other lactones detected in these wines include α-butyrolactone and pantonolactona (2,4-hydroxy-3,3-dimethyl-butyrolactone). They are typical of sherry wines. Besides the duration of aging, their concentration is closely linked with the yeast strain. Solerone (4-acetyl-γ-butyrolactone) was once believed to be an important contributor to biological aged sherry wines; however, its impact on wine aroma has been shown to be very low. Biologically aged wines are aged in oak casks that are rarely emptied or cleansed; therefore, the wines extract a few lactones from wood. It is only possible to find them in the scales containing the oldest wine.

Compounds released by the casks used during sherry wine aging can also be important contributors to the aroma of biological-aged sherry. They are absolutely essential when explaining the aroma of oxidative sherry wines (Oloroso). For example, some lactones such as *Z*-whisky lactone, also known as wood lactone, contributes to vanilla notes. Other compounds, such as the phenols eugenol and 4-ethylguaiacol, contribute to the spice aroma of clove. They are derived from precursors extracted by ethanol from the casks, and their concentrations increase with increasing wine wood contact time. The type of wood, the ethanol content of the wine, and the temperature of the cellar are the main factors that influence the efficiency of extraction in all type of wines.

The odor activity value (OAV) can be used to determine the odor impact of a volatile compound. It is calculated as the ratio of odorant concentration to odor threshold. From a sensorial point of view, by using the OAVs and odor descriptors, the sensory profile between the three main types of sherry wines was assessed (Table 1). Fino wines have a markedly floral and fruity character (because of the presence of compounds such as farnesol, β-citronellol, and β-ionone), as well as cheesy, rancid (butanoic acid), and pungent (acetaldehyde) aromatic notes. Oloroso wines exhibit smoky and ethereal notes associated to compounds such as ethylguayacol and ethyl acetate, respectively, whereas Amontillado wines are characterized by the presence of flavor notes from both aging processes, having the most complex aroma of the three.

Other Compounds

Organic Acids

In general, the content of organic acids decreases during biological aging. Prior to the incorporation into the biological aging system, wine is stored after its fortification with ethanol, and it is during this period that it undergoes malolactic fermentation. Therefore, most of the malic acid is converted into lactic acid. In addition, lactic and acetic acids can be metabolized by *flor* yeasts and converted into acetaldehyde and other by-products. In general, the climatic conditions in the southern regions of Spain where these wines are produced (Jerez and Montilla-Moriles) result in musts with low acidity (4–4.5 g l^{-1}); therefore, addition of tartaric acid is common during winemaking. Afterward, the concentration of tartaric acid decreases during biological and chemical aging due to its precipitation as potassium bitartrate.

Other acids, such as gluconic acid in sherries, can be used as a measure of the degree of grape rot; a concentration below 1 g l^{-1} shows wines suitable for biological aging. *Flor* yeast can use gluconic acid without provoking changes in the sensory quality of the wines. Acetic acid might be produced by yeast during fermentation, although its concentration is usually below 0.7 g l^{-1}. In addition, this acid is metabolized by *flor* yeast during biological aging, by incorporation via Acetyl-CoA into the Krebs cycle, or used in the synthesis of fatty acids.

The OAV data are the average of nine values.

***, >99%; SL, significance level versus Amontillado wine; ns, <99%; nd, not detected.

Data are from Zea, L., Moyano, L. and Medina, M. (2008). Odorant active compounds in Amontillado wines obtained by combination of two consecutive ageing processes. *European Food Research and Technology* **227**, 1687–1692.

Glycerol

Glycerol is also one of the most abundant components of sherry wines. It can contribute directly to flavor perception because of its sweet taste. It also imparts viscosity to the wine. Therefore, it is involved in mass transfer phenomena and aroma release. It is mainly produced during a glycerol-pyruvic fermentation at the beginning of the alcoholic fermentation. *Flor* yeast can use it as a carbon source; therefore, its concentration decreases during wine aging. This could be useful as an indicator of wine age.

Nitrogen-containing Compounds

Nitrogen-containing compounds are important not only to yeast growth and metabolism, but are also known to be involved in the production of sluggish or stuck fermentations. *S. cerevisiae* can grow in a wide variety of nitrogen-containing substrates. The rate of consumption and the metabolism of these compounds largely depend on the yeast strain, its physiological state, and the physicochemical properties of the wine. *S. cerevisiae* can use amino acids, either in the biosynthesis of proteins, or as a nitrogen source. Amino acids are degraded by the cells, and the nitrogen that they contain is released (generally as ammonia). It is used it for the synthesis of other nitrogenous constituents. The carbon of the amino acids might also be used by the yeast for synthetic purposes. In this case, the compound acts as a carbon source that can be excreted into the medium. The biological aging of sherry wines reduces the content of amino acids and other nitrogenous wine components (ammonium and urea). The main source of nitrogen for yeasts during biological aging is L-proline, although yeasts differ in the amount of assimilable nitrogen they can use and have preferences for amino acid consumption. It has been shown that short aeration, used in accelerated aging conditions, did not increase the overall consumption of assimilable nitrogen. However, it accelerated the consumption of particular nitrogen compounds, such as L-proline, L-tryptophan, L-glutamic acid, ammonium ion, L-lysine, and L-arginine. Besides the use of amino acids as a nitrogen source, *flor* yeasts may use these compounds to balance the oxidation–reduction potential under conditions of restricted oxygen. This involves releasing some amino acids into the medium to restore the intracellular redox balance, by means of oxidizing the excess NADH.

Shigella

C Jenkins, Public Health England, London, UK

© 2016 Elsevier Ltd. All rights reserved.

Historical Background

The first full description of shigellae is attributed to Kiyoshi Shiga (1898) following a large dysentery epidemic in Japan in 1897 that affected over 91 000 people, caused by *Bacillus dysenteriae* (now called *Shigella dysenteriae* serotype 1). Following work carried out over the next two decades, Murray (1918) proposed a classification for *Bacillus dysenteriae* that included four groups: Shiga, Kruse, Schmitz, and Flexner that later became *S. dysenteriae* serotype 1, *S. dysenteriae* other than serotype 1, *S. sonnei*, and *S. flexneri*, respectively, in the modern classification system. *S. boydii* was first described in 1938. *S. dysenteriae*, *S. sonnei*, and *S. boydii* had simple antigenic structures and were easily differentiated from each other, whereas the Flexner group had complex antigenic structures and differentiation was difficult.

The 1914–18 war was a key driver of research into bacillary dysentery and gastrointestinal symptoms caused by *Shigella* species, which continued to be a major concern for military personnel operating in high-risk regions, such as Africa, the Middle East, and the Indian subcontinent. Away from the military setting, shigellosis was endemic in both developed and developing countries throughout the twentieth century. During this time, *S. sonnei* and *S. flexneri* were responsible for most cases of endemic shigellosis in northwest Europe and North America, with outbreaks of *S. sonnei* traditionally associated with nursery schools and day-care centers. More recently, the majority of *Shigella* infections (and almost all *S. dysenteriae* and *S. boydii* infections) in developed countries are associated with cases reporting recent travel abroad. Nevertheless, outbreaks still occur in community settings mainly linked to person-to-person spread and foodborne transmission. Diarrhea caused by *Shigella* continues to be a major cause of morbidity and mortality in developing countries, particularly in children under 5 years old.

The Pathogen

Bacteria belonging to the genus *Shigella* in the Enterobacteriaceae family are small, unencapsulated, nonmotile, nonsporulating, facultative anaerobic Gram-negative bacilli and are part of the genomic species *Escherichia coli* (with the exception of *S. boydii* serotype 13).

In the contemporary classification scheme (Enterobacteriaceae Subcommittee Reports, 1954), the genus *Shigella* is divided into four subgroups based on the following biochemical and serological criteria:

- Group A, *S. dysenteriae*: all types that do not ferment lactose or mannitol (at least 15 serotypes)
- Group B, *S. flexneri*: all types that ferment mannitol but not lactose and possess type-specific antigens and group antigens (at least 15 serotypes)
- Group C, *S. boydii*: all types that ferment mannitol but not lactose and possess type-specific antigens but none of the antigens of *S. flexneri* (at least 18 serotypes)
- Group D, *S. sonnei*: all types that ferment mannitol and lactose (one serotype)

Incidence

A large proportion of all diarrheal episodes, an estimated 167 million worldwide including over a million deaths annually, are attributed to *Shigella*, with the greatest burden occurring in resource-poor countries in children under 5 years old. The Global Enteric Multicenter Study (GEMS) to identify the etiology and population-based burden of pediatric diarrheal disease in sub-Saharan Africa and South Asia found *Shigella* to be one of the four most common causes of moderate-to-severe diarrhea in this setting.

In the United States, between 14 000 and 22 000 laboratory-confirmed cases of shigellosis are reported each year with a population-based incidence of 3.99 per 100 000, although the true burden is likely to be nine times that number. Similarly, in the United Kingdom, the annual incidence of *Shigella* infection is estimated to be around 30 per 100 000, although recent studies show that only 2.8 per 100 000 are reported based on cultures submitted to Public Health England (PHE). Recent studies in Africa and Asia estimate 30.4 million diarrheal episodes (5308 deaths) in Africa and 58.1 million diarrheal episodes (10 158 deaths) in Southeast Asia due to shigellae in 2010. In Argentina, the incidence is 187 cases/year/100 000 children under 15 years old, and in Israel, the average annual incidence of culture-proved shigellosis is 97/100 000.

Globally, *S. dysenteriae* and *S. boydii* are less common than *S. sonnei* and *S. flexneri* in industrialized countries and are isolated mainly from travelers returning from abroad. *S. sonnei* is the dominant species of *Shigella* in industrialized countries. In England, *S. sonnei* is the most commonly isolated *Shigella* species (50%) with *S. flexneri*, *S. boydii*, and *S. dysenteriae* representing 38%, 7.5%, and 4.5% of the total number of strains, respectively. There is similar dominance of *S. sonnei* in the United States where *S. sonnei* accounts for 71% of all reports of laboratory-confirmed *Shigella* species (*S. sonnei*, 71.7%; *S. flexneri*, 18.4%; *S. boydii*, 1.6%; *S. dysenteriae*, 0.7%; and no serogroup reported, 7.6%).

Historically, *S. sonnei* has been predominantly responsible for dysentery in developed countries but is now emerging as a problem in the developing world, replacing *S. flexneri*, particularly in areas undergoing economic development. Data from the International Centre for Diarrhoeal Disease Research, Bangladesh (ICDDR,B) in Dhaka showed that 63% of children with shigellosis were infected with *S. flexneri*, 20% with *S. dysenteriae* type 1, 10% with *S. boydii*, 4% with *S. sonnei*, and 3% with *S. dysenteriae* types 2–10. In China, the prevalence

of *S. flexneri* (76.2%) is decreasing, whereas *S. sonnei* (21.3%) is increasing in line with the rapid economic growth seen in recent years.

Clinical Symptoms

Infection with *Shigella* species affects the distal small intestine and results in loose stools of small volume accompanied by fever, nausea, vomiting, and abdominal cramps. Stools typically contain blood and mucus (dysentery) resulting from mucosal ulceration and colonic crypt microabscesses. Dysentery caused by *S. sonnei* usually causes a milder illness than the other three *Shigella* species. Previous studies have shown that *S. boydii*, *S. flexneri*, and *S. dysenteriae* cause more severe gastrointestinal symptoms. *S. dysenteriae* serotype 1 is associated with hemolytic uremic syndrome (HUS) and toxic megacolon. Post-infectious complications may include reactive arthritis and irritable bowel syndrome.

Transmission

The human gastrointestinal tract is the only significant reservoir of *Shigella* infection. Infection may follow ingestion of as few as ten cells. The incubation period is between 12 h and 4 days (usually 1–3 days, median 2 days) but may be up to 1 week for *S. dysenteriae* serotype 1. Cases of *Shigella* are potentially infectious for as long as the organism is excreted in the stool. Shigellae may survive for up to 20 days in favorable environmental conditions resulting in transmission through contact with contaminated fomites.

Transmission is predominantly via the fecal–oral route from cases with diarrhea in households or institutions, especially those with young children, and person-to-person spread is the most likely route of transmission. Outbreaks have been reported in specific settings, such as day-care centers and religious communities. The reported attack rate in school and day-care centers can be associated with a high risk of transmission. Outbreaks have also been associated with recreational water facilities.

Since the 1970s, shigellosis has also been reported as a sexually transmitted infection among men who have sex with men (MSM), and an increasing number of outbreaks of MSM-associated shigellosis have been reported in Northern America, Asia, and Europe. Oroanal contact and coinfection with HIV are key risk factors for shigellosis, with a significant number of MSM shigellosis cases being HIV-positive.

Foodborne Outbreaks

Gastrointestinal infection caused by *Shigella* species can be spread through the ingestion of contaminated food and water. Foodborne outbreaks caused by *Shigella* documented in the literature since 2002 have been mostly associated with *S. sonnei* (Table 1). Research from the United States also indicates that 72–79% of *Shigella* outbreaks relate to *S. sonnei*. Implicated food included imported lettuce, fresh basil, sugar snap peas, and baby corn, with contamination most likely occurring in the country of origin (Table 1).

Table 1 Documented foodborne outbreaks caused by Shigella since 2002

Year	*Implicated food product*	*Species*	*Country*
2001–09	Leafy greens, herbs, seed sprouts	*Shigella* sp.	Canada
1973–2008	Guacamole and salsa	*Shigella* sp.	The United States
2011	Imported basil	*S. sonnei*	Norway
2009	Sugar peas	*S. sonnei*	Norway, Denmark
2009	Baby corn	*S. sonnei*	Denmark, Australia
2004	Unpasteurized milk curds	*S. sonnei*	Lithuania
2006	Tomatoes	*S. flexneri 2a*	The United States
2004	Raw carrots	*S. sonnei*	International
2004	Oyster	*S. sonnei*	Japan
2003	Parsley	*S. sonnei*	The United States

Foodborne outbreaks of *Shigella* species commonly relate to an infected food handler and salad items are often implicated. Between 2007 and 2010, Greig and colleagues published a series of informative articles reviewing the role of food workers in foodborne outbreaks. They found that the most frequently reported factors associated with the involvement of the infected worker were bare hand contact with the food, failure to properly wash hands, inadequate cleaning of processing or preparation equipment or utensils, cross contamination of ready-to-eat foods by contaminated raw ingredients, and temperature abuse. Many of the workers were asymptomatic shedders or had infected family members and/or used improper hygienic practices. Multi-ingredient foods were most frequently implicated, most likely because of more frequent hand contact during preparation and serving, and usually were served in restaurants or hotels, at schools, and at catered events.

Shigella species are among the pathogens most likely to be transmitted by food workers as the infectious dose is low (<10 cells). Shedding of the pathogen during the prodromal phase of illness, lengthy postsymptomatic shedding periods, and excretion by asymptomatic individuals should be considered during the implementation of hygiene protocols and the overall management of food workers.

Management

Strategies for *Shigella* control in the public health setting include the sanitary disposal of feces, hand washing, hygiene measures, and the isolation/exclusion of infected cases. Where information indicates a point source, efforts aim to minimize ongoing exposure. Guidelines for the management of *Shigella* infections in the United Kingdom (2004) recommend the exclusion of cases of *S. sonnei* from school or work until 48 h after the first normal stool and clinical surveillance for both

cases and contacts. However, cases and contacts in risk groups (Group A: Any person of doubtful personal hygiene or with unsatisfactory toilet, hand washing, or hand drying facilities at home, work, or school. Group B: Children who attend preschool groups or nursery. Group C: People whose work involves preparing or serving unwrapped foods not subjected to further heating. Group D: Clinical and social care staff who have direct contact with highly susceptible patients or persons in whom a gastrointestinal infection would have particularly serious consequences.) of *S. dysenteriae*, *S. flexneri*, and *S. boydii* should be screened microbiologically for clearance, which is defined as having two negative stool samples not less than 48 h apart. Guidelines from other countries expected to have similar nonendemic rates of *S. dysenteriae*, *S. flexneri*, and *S. boydii* (e.g., the United States and Australia) vary in the degree to which cases and contacts are screened microbiologically.

In food service operations, direct contact with food by hands should be prevented and gloves can substantially reduce opportunities for food contamination. Other control measures include protecting the food and food preparation areas from insects and other pests, food shields to prevent aerosol contamination, work clothing designated strictly for work, and the use of utensils to prevent direct contact between hands and the food being prepared or served. Disinfectants should be used to remove microorganisms (including pathogens) from objects or materials used during food production and preparation.

The most convenient and efficient way of removing pathogens from hands is through hand washing. Hand washing should occur regularly and after any activity that soils hands and always before preparing, serving, or eating food. Antimicrobial soaps are marginally more effective than plain soaps, as constant use results in a build-up of the antimicrobial compound on the skin. The time taken to wash hands and the degree of friction generated during lathering are more important than water temperature or antimicrobial soaps for removing soil and microorganisms. Disposable paper or high-speed air blades should be used to dry hands, rather than cloth towels (risk of contamination is associated with the fact that towels are not changed after use) or conventional warm air dryers (conventional dryers take too long for efficient use). Be aware that excessive washing and scrubbing can cause skin damage leading to infections and an increased risk to contamination of the food.

Survival of *Shigella* in the Environment

Previous studies indicate that *Shigella* species are heat-sensitive, acid-resistant, and salt-tolerant and may survive in foods such as fruits, vegetables, cured ham, and certain cheeses. More recently, studies measuring the effects and interactions of temperature (4–37 °C), pH (2–6), and NaCl (0.5–9%) on survival kinetics of *S. flexneri* demonstrated that foods with low levels of organic acids stored at low temperatures support the survival of the bacterium for extended periods of time. Other recent studies have confirmed that the temperature range permitting growth for *Shigella* was 6.1–47.1 °C but that the pathogen could survive for extended periods of time when held at −20 to 4 °C. Traditional pasteurization and cooking temperatures are sufficient for inactivation.

Studies investigating the survival of shigellae in apple juice and tomato juice, strawberries, and a fresh fruit salad demonstrated that the ability of *S. flexneri* to survive and grow at a given pH is influenced by previous exposure to acidic environments and by incubation temperature. Acid foods, especially if kept at refrigeration temperatures, support the survival of *Shigella* spp. and may cause *Shigella* food poisoning. Early studies showed that a variety of fruit and vegetables can support the growth or survival of *Shigella*, including papaya, watermelon, raw cabbage, onions, peppers, and coleslaw. High survival rates have also been observed in *Shigella* in water, supporting the historical association of shigellosis outbreaks and water sources.

Experimental results have shown that the combination of antimicrobial bacteriophage cocktails with a commercial levulinic acid produce wash is a very effective method for treating produce contaminated with enteric pathogens, including *Shigella* spp., even in the presence of high loads of organic matter. Lactoperoxidase–thiocyanate was shown to be an effective bactericidal candidate at low pH for decontaminating fruit. Other studies concluded that detergent (0.1% Tween 80 and 0.1% sodium lauryl sulfate) was no more effective in removing organisms from produce than water.

Detection

Shigella grows as non-lactose-fermenting colonies on MacConkey agar, although a more selective agar is used for the isolation of *Shigella* from feces, such as deoxycholate citrate agar and xylose lysine deoxycholate agar. Biochemically, *Shigella* spp. are unable to ferment lactose or utilize citrate and urea or to produce lysine decarboxylase. They are nonmotile and produce acid from glucose but no gas. Biochemical identification is confirmed by serological reactions to specific *Shigella* antisera. Isolation of *Shigella* from food is difficult, as colonies can be obscured by more robust commensal microbiota, such as *Escherichia*, *Enterobacter*, and *Proteus* species, and the level of contamination can be low.

More recently, a polymerase chain reaction (PCR) targeting the invasion plasmid antigen H (*ipaH*) gene has been used to detect the pathogen directly in fecal and food samples. This PCR approach is much more sensitive than conventional culturing. The *ipaH* gene is the target of choice, as it is encoded multiple times on both the chromosome and the large virulence plasmid. Thus, the test has increased sensitivity over PCRs targeting single copy genes, and detection of the pathogen is possible in the event the large virulence plasmid is lost.

There are a variety of *Shigella* PCR assays described in the literature. Most incorporate primers targeting the *ipaH* genes located on both the virulence plasmid and chromosome and an internal amplification control and have been well validated and tested on several high-risk foods. The specificity and sensitivity of the assays are approximately 1–3 colony-forming units and 5–50 fg of target (total) DNA. Different post-enrichment extraction protocols have been compared, and the InstaGene matrix was found to be the most consistent and sensitive.

Multiplex real-time PCR assays for the simultaneous detection of *Campylobacter jejuni*, *Salmonella* spp., *Shigella* spp./

enteroinvasive *Escherichia coli (EIEC)*, and *Yersinia enterocolitica* in fecal samples have been described in the literature. The sensitivity of the PCR is approximately 61 colony-forming units per ml for *Shigella* spp. The use of PCR in clinical settings increases the overall clinical sensitivity from 78% to 100% when compared with conventional culturing. The specificity was 99.4% for the PCR, compared with 99.9% for conventional culturing. The real-time method for the amplification of the *ipaH* gene in food as recommended by the European Union Reference Laboratory can be accessed by following http://www.iss.it/binary/vtec/cont/EU_RL_VTEC_Method_07_Rev_0.pdf.

Typing

Strains are serotyped (*S. dysenteriae*, *S. boydii*, and *S. flexneri*) or phage-typed (*S. sonnei*) to facilitate outbreak investigations. The *S. sonnei* phage-typing scheme is a rapid and cost-effective approach to typing during outbreak investigations. However, it is a labor-intensive, low-level discriminatory method requiring a specific skill set, and few laboratories now report phage-typing data.

The *S. flexneri* serotyping scheme differentiates isolates serologically, based on the expression of the major type-specific somatic antigen (I–VI) and common group factor antigens (3,4 and 7,8). Currently, there are 15 established serotypes. Recently, a multiplex PCR approach for molecular serotyping of *S. flexneri* has been published. This method differentiates the 15 accepted serotypes based on known differences in their *gtr* genes (encoding the type-specific antigens, group factor antigen 7,8, and 1c), the *oac* gene that mediates O-acetylation modification, and the wzx_6 for detection of serotype 6.

The most common *S. flexneri* serotypes in England are 2a, 3a, and 6. The ICDDR,B reports that serotypes 2a and 2b are most common in their region. In China, *S. flexneri* serotypes 2a and 4c account for 21.5% and 12.9% of *S. flexneri* infections, respectively, in the past decade. In Israel, *S. flexneri* 2a and *S. flexneri* 6 are the most common serotypes accounting for 71% of the isolates. *S. flexneri* 2a (10.9%) and *S. flexneri* 3a (6.3%) are the most common types in Thailand.

S. boydii and *S. dysenteriae* are composed of 20 and 15 recognized serotypes, respectively. Globally, detailed serotyping data for these two species are scarce. In England, strains of *S. boydii* and *S. dysenteriae* are mostly isolated from travelers, and the most common serotypes are 4, 2, and 1, whereas serotype 2 and provisional serotype E112707 were the most frequently submitted *S. dysenteriae* serotypes. In Egypt, serotypes 7 (30%), 2 (28%), and 3 (23%) accounted for most of the *S. dysenteriae* isolates; 50% of *S. boydii* isolates were serotype 2. Many strains previously identified as *Shigella boydii* serotype 13 that were found not to harbor the *ipaH* gene and to be more active biochemically than *Shigella* species have been reclassified as *Escherichia albertii*.

If a higher level of discrimination is required, there are a variety of molecular typing methods available, including pulsed-field gel electrophoresis (PFGE), multilocus variable-number tandem repeat analysis (MLVA), and, more recently, whole genome sequencing (WGS).

WGS has been used to investigate outbreaks at the local level and to inform evolution and global transmission. Phylogenetic analysis shows that the current *S. sonnei* population descended from a common ancestor that existed less than 500 years ago and diversified into several distinct lineages. This diversification occurred in Europe and was followed by more recent establishment of local pathogen populations on other continents, predominantly due to the pandemic spread of a single, rapidly evolving, multidrug-resistant lineage.

Pathogenicity

Shigellae are facultative intracellular pathogens derived from *E. coli* by a combination of gene loss and acquisition. Deletions are associated with the loss of metabolic pathways (e.g., *cadA*) that are no longer required for an intracellular lifestyle, and antivirulence factors (e.g., *nadA* and *nadB*) that suppress pathogenicity. Acquisition genes are associated with bacterial invasion and intracellular survival (e.g., *virB* and *mxiE*), iron acquisition (e.g., *iuc* and *fuc*), and toxin production (e.g., *set1A* and *set1B*) encoded on the invasion plasmid pINV and the chromosomally located *Shigella* pathogenicity islands (SHIs) SHI-1 and SHI-2, SHI-O, and SRL.

Pathogenesis of *Shigella* involves four steps:

(i) Bacteria invade the epithelial cell in the large intestine via M cells.
(ii) On reaching the submucosa, they are engulfed by macrophages where they survive and multiply.
(iii) In the macrophage, they induce apoptosis and the release of cytokines that destroy the integrity of the epithelial layer.
(iv) On escaping from the macrophage, they invade the epithelial cells from the basolateral side, and traverse the intracellular cytoplasm of the invaded cell and neighboring cells, by formation of an actin tail on the bacterial surface that provides the propulsive force required for directed motility.

Diarrhea results from the breakdown of the integrity of the colonic epithelium and the subsequent reduction in its capacity to reabsorb fluid and the action of enterotoxins (ShET1 and ShET2) in the jejunum.

Three serine protease autotransporters of Enterobacteriaceae (SPATEs) potentially contribute to enterotoxic activity of *Shigella*:

- SigA is chromosomally encoded and exerts a cytopathic effect on HEp-2 cells.
- SepA may be associated with causing inflammation and tissue damage.
- Pic is implicated in mucinase activity, serum resistance, hemagglutination, enterotoxicity, and immune modulation.

Treatment

Oral rehydration is an essential therapeutic response to *Shigella* infection and with appropriate rehydration shigellosis is generally a self-limiting disease. Antibiotics are recommended in some cases when symptoms are severe or to reduce the likelihood of transmission. Antibiotics have been shown to reduce

the duration of symptoms from 5–7 to 3 days. It has been suggested that antibiotics may also reduce the period of asymptomatic carriage.

Resistance to ampicillin, tetracycline, and the sulfonamides is widespread. Despite some reservations concerning its use in children, ciprofloxacin has been the recommended drug of choice for many years although there is evidence of increasing resistance in strains isolated from cases returning from the Indian subcontinent. Ceftriaxone and azithromycin are alternatives, but strains resistant to both these antibiotics have been described.

Vaccines

A safe effective vaccine for *Shigella* is greatly sought after as oral rehydration therapy is less effective against this pathogen than against other toxin-producing gastrointestinal pathogens such as *Vibrio cholerae* and enterotoxigenic *E. coli*. More importantly, there are limited therapeutic options due to increasing resistance to antimicrobials. The genus *Shigella* comprises a wide range of serotypes, but studies have shown that a vaccine covering *S. sonnei* and *S. flexneri* serotypes 2a, 3a, and 6 would provide protection against more than 65% of *Shigella* infections. Vaccines targeting the variable lipopolysaccharide (O) antigens include polysaccharide conjugates and synthetic conjugates. An alternative strategy is to target the conserved antigens, such as the major outer membrane proteins and the invasion plasmid antigens.

Two factors are impeding progress:

(i) The lack of a small animal model – non-human primate (NHP) models mimic human disease but cost and availability prohibit the use of NHP in most studies.
(ii) The complexity of the immune response observed following *Shigella* infection that involves both humoral and cell-mediated antibodies and systemic and mucosal arms of the response.

Conclusion

Every year, *Shigella* species cause an estimated 167 million episodes of diarrhea worldwide and over a million deaths. *S. sonnei* is predominantly responsible for dysentery in developed countries but is now emerging as a problem in the developing world, replacing *S. flexneri*. MSM-related shigellosis is responsible for a significant proportion of domestically acquired cases in developed countries and is changing the epidemiology of *Shigella* in 'low-risk' regions. Foodborne outbreaks of *Shigella* species are often linked to salad items contaminated at the country of origin or by the food handler. Use of PCR targeting the invasion plasmid antigen H (ipaH) gene has improved the detection of *Shigella* in fecal and food samples. Highly discriminating and robust molecular typing methods are available including PFGE, MLVA, and, more recently, WGS. Increasing antibiotic resistance is driving the search for a safe, effective vaccine.

Introduction

The term *single-cell protein* (SCP) refers to a dead, dry cell mass of microorganisms such as yeast, bacteria, fungi, and algae, which grow on different carbon sources. The term *SCP* was first coined by Carrol Wilson in 1966. These are the potentially important foodstuff-containing proteins, lipids, carbohydrates, and a variety of nucleic acids and other nonprotein nitrogenous compounds, vitamins, and inorganic substances. Microorganisms have been employed for many years in the production of high-quality proteinaceous food products like cheeses, fermented milk products, mushrooms, and soybean products. Proteins are the main nutritional components in all these types of foodstuffs. Owing to a large proportion of cell dry weight is accounted for protein, the nutritional value of SCPs is determined by the levels of protein produced. Use of microbes as a food source may appear to be unacceptable to some people but the idea of consumption of microbes as food for humans and animals is certainly innovative to solve the global food problem. Due to their ability to upgrade low-protein organic material to high-protein food, microorganisms are exploited for production of SCPs on an industrial scale. This phenomenon was employed in Germany during the First World War when the growth of *Saccharomyces cerevisiae* was exploited for human consumption. Moreover, *Candida arborea* and *C. utilis* were used during the Second World War, and about 60% of the country's prewar food input was replaced. The rapidly increasing world population generates the challenge of providing additional food sources. In particular, protein supply poses a problem because essential amino acids cannot be replaced. One possible solution to this problem is SCP production. Bacteria and yeast are candidates for the purpose. Protein contains the element N in addition to C, H, and O. The N comes from soil, but in limited quantum; however, the other elements are in the products of photosynthesis, which relies on CO_2 and water, which are reasonably easily available to plants. Production of protein from animal sources (meat/milk) depends on protein from plants: grass for grazing or animal feeds, which requires large areas of land. To grow the feed and fodders requires nitrogenous fertilizers, which can cause a variety of problems if not used in the prescribed doses. Similarly, stored and prepared animal feeds also pose economic and environmental problems. SCPs are gaining steady popularity as they require limited land area for growth. Similarly, the growth of microorganisms is faster than that of animals. A range of materials can be considered as suitable substrates depending on the microorganism chosen, and the microorganisms have the ability to upgrade low-protein organic material to high-protein food. Research on SCPs has been stimulated by a concern over the eventual food crisis or food shortage that will occur if the world's population is not controlled. Many fungal species are used as SCPs. They provide the B-complex group of vitamins and also show a low level of nucleic acid content.

SCP to Fulfill Protein Requirements of a Growing Population

Earth has always been subject to rapid and drastic changes under the name of development. Based on current trends, population experts predict that the world's population will increase by 38% from 6.9 billion in 2010 to 9.6 billion in 2050. The world population will continue to grow exponentially over the next 50 years. India is the second-most-populous country after China. During the last four decades Indian population has been doubled. At least 1.3 billion people will be added to the world population over the next 25 years (Figure 1). A jet of the population is considered both developing and developed countries, but with a difference in the rate of explosion. Countries in the developing world have about 98% of the total increase in the population, whereas developed countries add the remaining 2% difference. The World Health Organization estimates that 12 million people die due to hunger and hunger-related diseases each year, 50% of which are of 5 year age. The population explosion has adverse effects on the economy of the country and the social and political aspects. Population growth, rapid urbanization, and the rapid reduction of the area under agricultural production all pose problems to meet all our needs and rations, but the changes are so rapid that the resources provided are falling short due to population dynamics. The rapidly increasing world population generated the challenge of providing necessary food sources to fulfill the dietary needs of growing population, which suggested the need to explore the possibility of developing SCPs. In particular, protein supply poses a problem because essential amino acids cannot be replaced.

Substrates for SCP Production

Many industrial and agriculture waste substrates have been tried for production of SCPs. Though these wastes appear to be cheap, various factors like cost of transportation, pretreatment, seasonality of production, scattered production, and fluctuation in rates may act as limiting factors. Following are some of the substrates generally utilized for production of SCPs:

- Whey: Whey is a by-product of the cheese and paneer industry, which contains proteins and lactose. As per the stringent Laws under Environment Protection Acts, disposal of the whey is a big challenge for the dairy industry. The

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00628-0

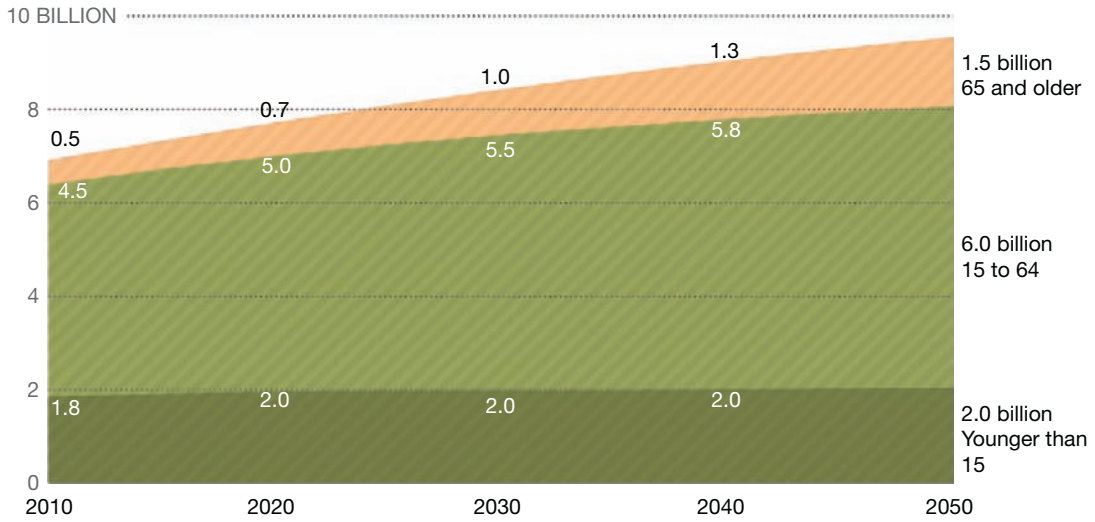

Figure 1 Estimated global population by age (2010–50). Source: UN, Department of Economics & Social Affairs, World Population Prospectus (June 2013).

dairy industry waste is liquid in nature and its transportation results into high costs. However, utilizing the whey for production of SCPs has proved to be a boon.

- Molasses: Generally molasses is available from four sources viz. cane, beet, corn, and citrus. The sugar industry utilizing cane produces large quantities of molasses, which are utilized for production of SCPs using *C. utilis* or *S. cerevisiae* as the starter cultures. Molasses is an excellent substrate for SCPs. Molasses may require pretreatment to reduce mineral content and remove suspended solids before use. Cellular yields from molasses are about 25%.
- Carbohydrates: Pure carbohydrates are not utilized for production of SCPs due to their high value. Cassava and other starchy products can be hydrolyzed to give a glucose syrup, which is used for production of SCPs. Similarly, in countries like India, clarified cane juice provides a cheap and readily available substrate for fermentation to produce SCP. In addition it provides a strategic source of proteins to replace imported products such as soya bean meal.
- Ethanol: It has many advantages over other substrates used for production of SCPs, but it is more expensive. It is probably the worthwhile substrate only where local overproduction of ethanol demands its disposal.
- Methanol: It presents the dual advantages of a clean and reliable substrate giving a high yield of SCPs together with availability and a reasonable source. The use of methanol as a substrate has been developed for full-scale commercial production of SCPs. This technology has a great potential for areas of the world with methane supplies and a need for an indigenous source of high-quality protein.
- Sulfite waste liquor: This is the waste product of wood-pulping industry. The effluent as the liquor can be fermented by *C. utilis* to produce SCPs.
- Methane: The natural gas methane at first sight appears to be an attractive substrate for SCPs because it is easily available and relatively inexpensive, it is pure, and it requires less quantities as compared to other substrates. But some of the bottlenecks of methane in SCP production includes that it is not readily water soluble, and its mass transfer is slow and energy intensive. Pure cultures of methane-fermenting organisms are difficult to cultivate, and there is no consistency in production. Similarly, the explosive nature of air–methane mixtures presents serious difficulty in design and operation of a large-scale plant, leading to excessive capital-related costs of production.
- Renewable plant sources: Glucose, cellulose, and starch are used as substrates/carbon sources for SCP production. They play an important role in the production of SCPs by microorganisms. The use of glucose as a carbon source is very attractive, considering its lower costs. Studies were conducted by using different concentrations of glucose as a source of carbon and revealed that the highest levels of SCP were produced by using 8% (w/v) glucose. It was observed that the protein content in the microbial cells was increased when the concentration of glucose was increased from 1% to 8% (w/v). By using glucose as a substrate, SCPs can be produced from *Fusarium graminearum*. The strategy is to use the fiber content of the mycelium to produce a range of products with value addition including analogues of meat for human consumption.

Cellulose has also great potential as a source of carbon for microorganisms. A mixed culture of Cellulomonas and Alcaligenes can be used for production of SCPs. Starches from potato wastes, tapioca, and cassava can be fermented symbiotically in a single-step continuation process by *Endomycopsis filburger*. It hydrolyzes starch and converts it into simple sugars, which are then used for the production of biomass *C. utilis*. Starch can be fermented directly by some amylolytic fungi and subsequently used for production of SCPs.

Criteria in Selection of Microbial Strains for Production of SCPs

Following are the parameters that are invariably considered while selecting the microbial strains for production of SCPs:

- Low generation time
- Ability to grow on different substrates without requirement of growth factors
- High nutritional content
- Low content of nucleic acid
- Nonpathogenic and nontoxin producing
- Suitability in downstream processing
- High digestibility
- Tolerance to high cell density
- Ease in handling
- pH tolerance
- Stability in growth rate during continuous cultivation
- Good organoleptic properties
- Ability to utilize complex substrate
- High fidelity with carbon source

Microbes Used for Production of SCPs

The following microbial genera are widely used for production of SCPs.

(a) Bacteria: Different types of bacteria are used for production of SCPs. Many strains, such as *Bacillus*, *Hydrogenomonas*, *Methanomonas*, *Methylomonas*, and *Pseudomonas* are commonly used for commercial scale production of SCPs. Bacteria have a slight advantage over other microbes in respect of requirement of energy source. This is due to their growth rate, relatively high protein content, and sulfur amino acids. About 80% of crude protein is present in total dry weight. Content of nucleic acids, particularly RNA, is based on the dry weight and is reported as 15–16%. In bacteria, more methionine is present than other groups, which is around 2.2–3.0%, which is relatively higher than in algae (1.4–2.6%) and fungi (1.8–2.5%).

(b) Yeasts: *Saccharomyces*, *Candida*, and *Rhodotorula* are commonly used for production of SCPs. Yeasts are widely used in production of biomass, which is used in both food and feed industries. For millions of years, we have used yeast as a food source in brewing, wine making, baking, and so on. An added benefit of yeast is that it will grow in acidic condition (pH 4.5–5.5), which is severe and inhibits growth of bacterial contaminants. This has an added benefit of no need to maintain strict aseptic conditions. Yeasts have many practical features such as the ability to use a wide variety of substrates, susceptibility for induced genetic variation, the ability to aggregate, and high nutritional value. One drawback of yeast is that the SCPs obtained are insufficient in sulfur-containing amino acids.

(c) Filamentous fungi: *Fusarium*, *Aspergillus*, and *Penicillium* are commonly used for SCP production. Filamentous fungi grow slowly and are highly prone to contamination by the yeast, so it should be grown under sterile conditions. They have some advantages like readily filtered from the liquid culture thereby reducing the cost of harvesting. As agricultural waste contains more carbohydrate, it is preferred for production of fungal SCPs.

(d) Algae: *Spirulina*, *Chiarella*, and *Scenedesmus* are generally used for production of SCPs. Algae (Cyanobacteria and unicellular eukaryotes) is autotrophic and synthesizes food by taking the energy of sunlight or artificial light and CO_2 as the source of carbon. In some countries, the culture is performed in large sections in the oxidation of sewage basins using sunlight or artificial light for use in life supportive systems for extended space exploration. The massive culturing of algae began in many countries, such as India, Japan, West Germany, Czechoslovakia, and Mexico. It can be harvested by simple and less-expensive methods. Algae is highly digestive (85–95%) due to thin wall and low nucleic acid contents. It contains a high percentage of digestible proteins (60–75%), vitamins, amino acids, and other nutrients.

Nutritive Value of SCPs

Changes in cultural conditions and medium play a crucial role in microbial composition like limitation of nitrogen content in medium, microbes accumulate more lipid content. Synthesis of fats and proteins in cells is totally dependent on C:N ratio in the culture medium. As the growth rate of microbes increases, RNA content also increases. In optimum conditions, the average contents of crude protein, nitrogen, fat, nucleic acid, and ash in microbes, plants, and animals are given in Table 1.

Proteins in SCP

Proteins are made up of different amino acids, and thus the nutritional quality of the protein is totally dependent on amino acids and their contents. In terms of amino acids, the bacterial protein is similar to the fish protein. In addition to this, yeast protein is almost identical to the soybean protein, and the fungal protein is smaller than a yeast protein. The essential amino acid composition of microbial sources is depicted in Table 2. A comparison with standard egg amino acid composition shows that these microbes are largely an amino acid motif, and it is well balanced but low-sulfur-containing amino acids.

Source: http://www.fao.org/docrep/field/003/AB468E/AB468E05.htm.

Generally, in bacteria, there is higher methionine content than yeast, whereas in case of lysine it is the opposite. Lysine and threonine are present in higher concentration in microbes than in wheat or cereals adding value of SCPs as a supplement to cereal diet.

Microbial species possess high protein content, which is the main reason to consider them as an unconventional source of protein. The percentage of crude proteins is higher in bacteria than other microbial groups. It is 72–78% in bacteria and lowest in fungi (31–50%). However, this estimate is not entirely true because 20% of the total nitrogen is nonprotein in origin. This includes purine bases 8–13%, pyrimidine bases 4%, 0.5% choline, 0.5% glucosamine, and a few percent of other nitrogenous compounds.

Vitamins in SCP

Microorganisms mainly contain vitamin B. It plays key role in animal feed supplements (0.5–1.5%). Yeast is one of the rich sources of vitamin B. The vitamin B is generally lower in mycelial fungi than yeast. Algae are also good sources of vitamin B. They also contain tocopherol and β-carotene. Bacterial cell contains high amounts of vitamin B_{12}, whereas algae are generally rich in vitamin A. The most common vitamins in the SCP are riboflavin, niacin, thiamine, pyridoxine, choline, pantothenic acid, folic acid, inositol, biotin, p-aminobenzoic acid, and vitamin B_{12}.

Fatty Acids in SCPs

Fatty acids are primary metabolites of the acetyl CoA pathway. The fat content is higher in algae than other microbial group members. It is 7–20% in algae and lowest (1.5–3%) in bacteria. One difference between higher plants and algae is that many algae are capable of producing long-chain polyunsaturated fatty acids, which are beneficial for human health and nutrition. Algal fats and oils have very wide and potential applications. The algal oils resemble fish and vegetable oils. Some microbial species are rich in essential fatty acids such as C20 derivatives, eicosapentaenoic acid (20:5ω3), and arachidonic acid (20:4ω6) and C18 linoleic (18:2ω6) and γ-linoleic (18:3ω3). These fatty acids are important components in human diets and animal feeds. In aquaculture also, these fatty acids contribute an important role in fish growth.

Nucleic Acids in SCP

High nucleic acid content is a property of rapidly growing cells. Compared with traditional foods, microbes contain a high quantity of nucleic acids, which is between 8 and 25 g nucleic acid per 100 g proteins. Animal cells like intestinal mucosa, pancreas, liver, and kidney have 4 g nucleic acid per 100 g protein, whereas fishes like sardines and roe have 2.2 and 5.7 g nucleic acid per 100 g protein, respectively. As compared to animal sources, plant sources like wheat and rye flour have less nucleic acid (1.1 and 4.0 g per 100 g, respectively).

Introduction

The muscular system is responsible for the movement of the human body. Attached to the bones of the skeletal system are about 700 named muscles that make up roughly half of a person's body weight. Each of these muscles is a discrete organ constructed of skeletal muscle (SM) tissue, blood vessels, tendons, and nerves. Muscle tissue is also found inside the heart, digestive organs, and blood vessels. In these organs, muscles serve to move substances throughout the body. There are three main types of muscles: (1) SM, which is also called voluntary muscle because it can be consciously controlled; (2) smooth muscle, which is also termed as involuntary muscle as it is not under voluntary control; and (3) cardiac muscle, which is a specialized muscle. SMs differ in size and shape according to the jobs they have to perform. They are attached either directly or indirectly to bones. SM is the only voluntary muscle tissue in the human body (controlled consciously). It derives its name from the fact that these muscles always attach to the skeleton in at least one place. Every physical action that a person consciously performs (e.g., speaking, walking, writing) requires SM. The function of SM is to contract to move parts of the body closer to the bone that the muscle is attached to.

Most SMs are attached to two bones across a joint, so the muscle serves to move parts of those bones closer to each other. They work in opposite pairs, that is, one muscle in the pair contracts, whereas the other relaxes to produce body movements as diverse as walking, threading a needle, and an array of facial expressions. SM cells form when many smaller progenitor cells aggregate to form long, straight, multinucleated fibers. Striated just like cardiac muscle, these SM fibers are very strong.

Smooth muscles occur in the walls of internal body organs and perform actions such as forcing food through the intestines, contracting the uterus in childbirth, and pumping blood through the blood vessels. For voluntary muscles, all contraction (excluding reflexes) occurs as a result of conscious effort originating in the brain. The brain sends signals, in the form of action potentials, through the nervous system to the motor neuron that innervates several muscle fibers. In the case of some reflexes, the signal to contract can originate in the spinal cord through a feedback loop with the gray matter.

Anatomy of SM

Most SMs are attached to two bones through tendons (Figure 1). Tendons are tough bands of dense regular connective tissue whose strong collagen fiber strongly attaches muscles to bones. Tendons are under extreme stress when muscles pull on them, so they are very sturdy and are woven into the coverings of both muscles and bones. Muscles move by shortening their length, pulling on tendons, and moving bones closer to each other. One of the bones is pulled toward the other bone, which remains stationary. The place on the stationary bone that is connected via tendons to the muscle is called the origin. The place on the moving bone that is connected to the muscle via tendons is called the insertion. The belly of the muscle is the fleshy part of the muscle in between the tendons that does the actual contraction (Figure 2).

Types of SM Fibers

Three principal types of muscle fibers are found in varying proportions in human SM. These fiber types may be distinguished from one another on a histochemical, metabolic, morphological, and mechanical basis. Most muscles contain a mixture of fiber types, although one usually predominates.

Type 1 or Slow Oxidative Fibers

These fibers have a slow contraction speed and a low myosin ATPase activity. These cells are specialized for steady, continuous activity and are highly resistant to fatigue. Their motor neurons are often active, with a low firing frequency. These cells are thin (high surface to volume ratio) with a good capillary supply for efficient gas exchange. They are rich in mitochondria and myoglobin. Myoglobin is responsible for the red color of fibers. They are built for aerobic metabolism and prefer to use fat as a source of energy. These are the fibers of importance to the marathon runner.

Type 2A or Fast Oxidative-Glycolytic Fibers

These fibers have a fast contraction speed and a high myosin ATPase activity. They are progressively recruited when additional effort is required, but are still very resistant to fatigue. Their motor neurons show bursts of intermittent activity. These cells are thin (high surface to volume ratio) with a good capillary supply for efficient gas exchange. They are rich in mitochondria and myoglobin, which gives them a red color. They are built for aerobic metabolism and can use either glucose or fats as a source of energy. These are general-purpose muscle fibers, and they provide the edge in athletic performance. However, these fibers are metabolically more expensive to operate than type 1.

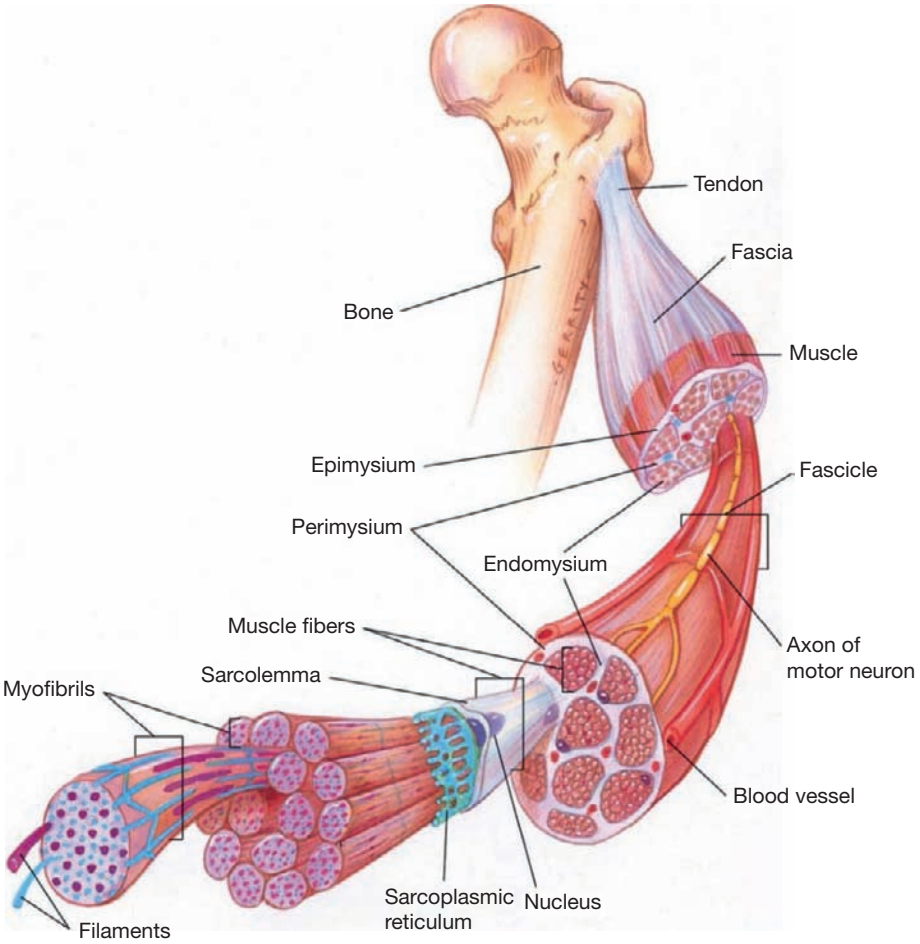

Figure 1 Connective tissue surrounding skeletal muscle.

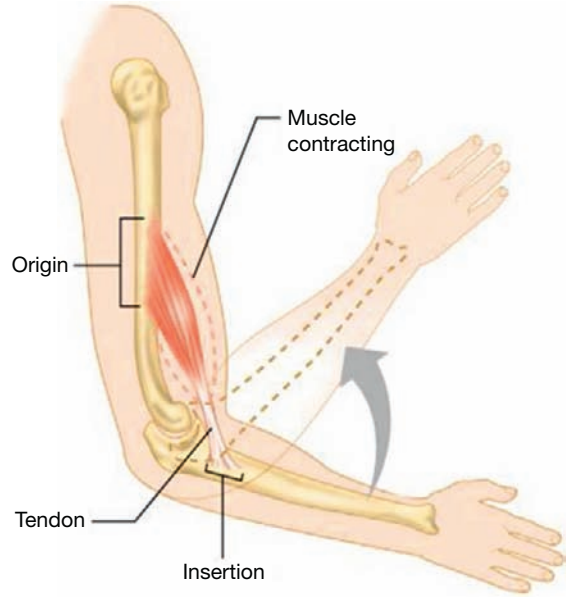

Figure 2 Isotonic muscle action.

Type 2B or Fast Glycolytic Fibers

These fibers have a fast contraction speed and a high myosin ATPase activity. They are only recruited for brief maximal efforts and are easily fatigued. Their motor neurons transmit occasional bursts of very high frequency impulses. These are large cells with a low surface/volume ratio, and their limited capillary supply slows the delivery of oxygen and removal of waste products. They have few mitochondria and little myoglobin, resulting in a white color. They generate adenosine triphosphate (ATP) by the anaerobic fermentation of glucose to lactic acid.

Nomenclature of SMs

The nomenclature of the SMs is based on various factors including the location, number of origins, shape, size, direction, and function.

Based on Region

Many muscles are named from their anatomical region. The rectus abdominis and transverse abdominis, for example, are

found in the abdominal region. Some muscles, like the tibialis anterior, are named after the part of the bone (the anterior portion of the tibia) that they are attached to. Other muscles use a hybrid of these two, like the brachioradialis, which is named after a region (brachial) and a bone (radius).

Number of Origins

Some muscles connect to more than one bone or to more than one place on a bone and therefore have more than one origin. A muscle with two origins is called a biceps. A muscle with three origins is a triceps muscle. Finally, a muscle with four origins is a quadriceps muscle (Figure 3).

Shape, Size, and Orientation of Fibers

Muscles are also classified by their shapes, for example, the deltoids have a delta or triangular shape. The serratus muscles feature a serrated or saw-like shape. The rhomboid major is a rhombus or diamond shape. The size of the muscle can be used to distinguish between two muscles found in the same region. The gluteal region contains three muscles differentiated by size – the gluteus maximus (large), gluteus medius (medium), and gluteus minimus (small). Finally, the direction in which the muscle fibers run can be used to identify a muscle. In the abdominal region, there are several sets of wide, flat muscles. The muscles whose fibers run straight up and down are the rectus abdominis, the ones running transversely (left to right) are the transverse abdominis, and the ones running at an angle are the obliques.

Origin and Insertion

Some muscles are named based on their connection to a stationary bone (origin) and a moving bone (insertion). These muscles become very easy to identify once you know the names of the bones that they are attached to. Examples of this type of muscle include the sternocleidomastoid (connecting the sternum and clavicle to the mastoid process of the skull) and the occipitofrontalis (connecting the occipital bone to the frontal bone).

Function

Muscles are sometimes classified by the function that they perform. Most of the muscles of the forearms are named based on their function because they are located in the same region and have similar shapes and sizes. For example, the flexor group of the forearm flexes the wrist and the fingers. The supinator is a muscle that supinates the wrist by rolling it over to face palm up. In the leg, there are muscles called adductors whose role is to adduct (pull together) the legs.

Architecture of the Muscle

The description of SM architecture includes the arrangement of the fibers in relation to the axis of force (amount of pennation), muscle fiber length, muscle length, muscle mass, and the physiologic cross-sectional area. These structural variations affect not only the overall shape and size of the muscles but also the function of the SM. Arrangement of fascicles (muscle fiber groups) varies among muscles. The fasciculi may be parallel to the long axis of the muscle, may spiral around the long axis, or may be at an angle to the long axis. Muscles that have a parallel fiber arrangement (parallel to the long axis and to each other) are designated as strap or fusiform muscles. Muscles that have a fiber arrangement oblique to its long axis are called pinnate muscles. In unipennate muscles, the obliquely set fascicles fan out on only one side of a central muscle tendon. In a bipennate muscle, the fascicles are obliquely set on both sides of a central tendon. In a multipennate muscle, the oblique fascicles converge on several tendons.

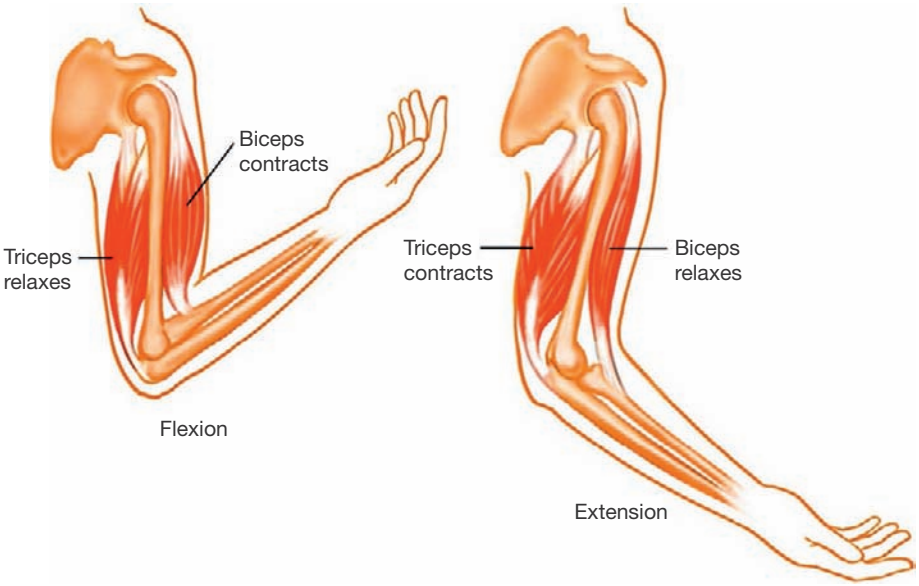

Figure 3 Biceps and triceps muscles.

Group Action in SM

SMs rarely work individually to achieve movements in the body. They work in groups to produce precise movements. The muscle that produces any particular movement of the body is known as an agonist or prime mover. It always pairs with an antagonist muscle that produces the opposite effect on the same bones. For example, the biceps brachii muscle flexes the arm at the elbow. As the antagonist for this motion, the triceps brachii muscle extends the arm at the elbow. When the triceps is extending the arm, the biceps would be considered the antagonist. In addition to the agonist/antagonist pairing, other muscles work to support the movements of the agonist (Figure 3). Synergists are muscles that help to stabilize a movement and reduce extraneous movements. They are usually found in regions near the agonist and often connect to the same bones. Because SMs move the insertion closer to the immobile origin, fixator muscles assist in movement by holding the origin stable.

Histology of the SM

SM fibers differ from other tissues of the body due to their highly specialized functions. Many of the organelles that make up muscle fibers are unique to this type of cell. A single muscle contains many fascicles, a group of muscle fibers (cells) surrounded by connective tissue. SM tissue is made up of individual muscle cells called myocytes. Myocytes are cylindrical and multinucleated cells that run parallel to each other within a muscle. An SM cell is surrounded by a plasma membrane called the sarcolemma with a cytoplasm called the sarcoplasm. It acts as a conductor for electrochemical signals that stimulate muscle cells. The transverse tubules (T tubules) are connected to the sarcolemma. They carry electrochemical signals into the middle of the muscle fiber. The sarcoplasmic reticulum acts as a storage facility for calcium ions (Ca^{++}), which are essential for muscle contraction (Figure 4).

Mitochondria are abundant in muscle cells to break down sugars and provide energy to activate muscles. Structure of muscle fiber is made up of myofibrils. These are the contractile structures of the cell made up of many proteins fibers arranged into repeating subunits called sarcomeres. It is the functional unit of muscle fibers made of two types of protein fibers: thick filaments and thin filaments. Thick filaments are made of many bonded units of the protein myosin. Myosin is the protein that causes muscles to contract.

Thin filaments are made of three proteins, namely, actin, tropomyosin, and troponin. Actin forms a helical structure that makes up the bulk of the thin filament mass. It contains myosin-binding sites that allow myosin to connect to and move actin during muscle contraction. The myosin filaments are slightly thicker and make up the dark band (or A-band). The actin filaments make up the light bands (I-bands), which are situated on either side of the dark band. The actin filaments are attached to the Z-line. This alternate arrangement of dark and light bands gives a striated appearance to muscle, which is why SM is also known as 'striated muscle.'

Tropomyosin is a long protein fiber that wraps around actin and covers the myosin-binding sites on actin. Troponin is bound very tightly to tropomyosin and moves tropomyosin away from myosin-binding sites during muscle contraction.

Working of Muscles: Sliding Filament Theory

A concentric contraction is a type of muscle contraction in which the muscles shorten while generating force. The muscle

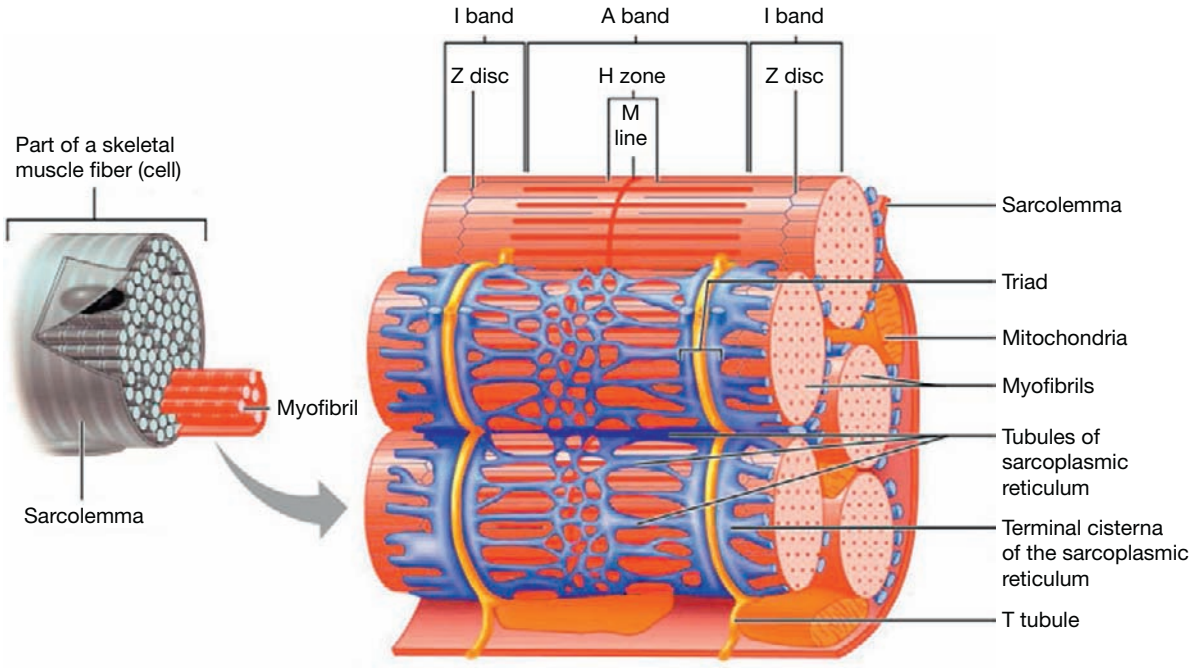

Figure 4 Sacroplasmic reticulum.

fiber will shorten (contract) if a sufficient number of sarcomeres actively shorten and if either one or both ends of the muscle fiber are free. In contrast to a shortening contraction, in which thin filaments are being pulled toward the thick filaments, the muscle may undergo an eccentric contraction, or lengthening contraction. In a lengthening contraction, the thin filaments are pulled away from the thick filaments, and cross-bridges are broken and reformed as the muscle lengthens. Tension is generated by the muscle as cross-bridges are reformed.

For the muscle as a whole to contract, the actin and myosin filaments must overlap, causing the sarcomere to shorten. This process is triggered by the release of calcium ions in the presence of troponin and tropomyosin. The release of calcium, which is provided by ATP, facilitates the interaction of myosin and actin at the molecular level. At high levels of magnification, it is detected that small bridges, known as myosin cross-bridges, on the thick filaments extend over to the thin filaments. These cross-bridges continually attach, rotate, detach, and reattach, which results in the sliding of the filaments, shortening of the sarcomere, and finally what we see to be muscle contraction (Figure 5).

Energy Required for Muscle Contraction

The energy for the muscular contraction is provided by the conversion of ATP into adenosine diphosphate (ADP) and inorganic phosphate, releasing energy. Enzyme myosins ATPase catalyze the reaction in the presence of Ca^{2+} and Mg^{2+} ions:

$$\text{ATP} \xrightarrow[\text{Myosin ATPase}]{Ca^{2+},\ Mg^{2+}} \text{ADP} + \text{Pi} + \text{energy}$$

The used-up ATP is restored for additional contractions, so phosphocreatine now comes into the picture. It donates its high energy–phosphate bond to ADP, producing ATP. This reaction is catalyzed by an enzyme creatine kinase

$$\underset{\text{(Phospho creatine)}}{\text{Creatine phosphate}} + \text{ADP} \xrightarrow[\text{Creatine Kinase}]{} \text{ATP} + \text{Creatine}$$

When creatine phosphate is used up, new ATP is generated by aerobic respiration in the muscle cells. If the ATP is used up faster than the muscle fibers can produce aerobically, then the muscle fibers start anaerobic respiration to provide ATP. This produces lactic acid. This lactic acid is diffused into the blood, leaving a small part to accumulate in the muscle fiber. The major part of lactic acid is passed into the liver, where it is oxidized to CO_2 and H_2O. The energy released from this oxidation is used for changing the remaining lactic acid to glycogen.

$$\text{Lactic acid} + \text{oxygen} \rightarrow CO_2 + H_2O + \text{ATP}$$

$$\text{Remaining lactic acid} + \text{water} \rightarrow \text{glygogen in liver cells}$$

Biochemical Changes During Contraction of Muscles

During muscle contraction a number of biochemical changes occurs. In a resting muscle fiber, sarcolemma is electropositive outside and electronegative inside. This potential difference

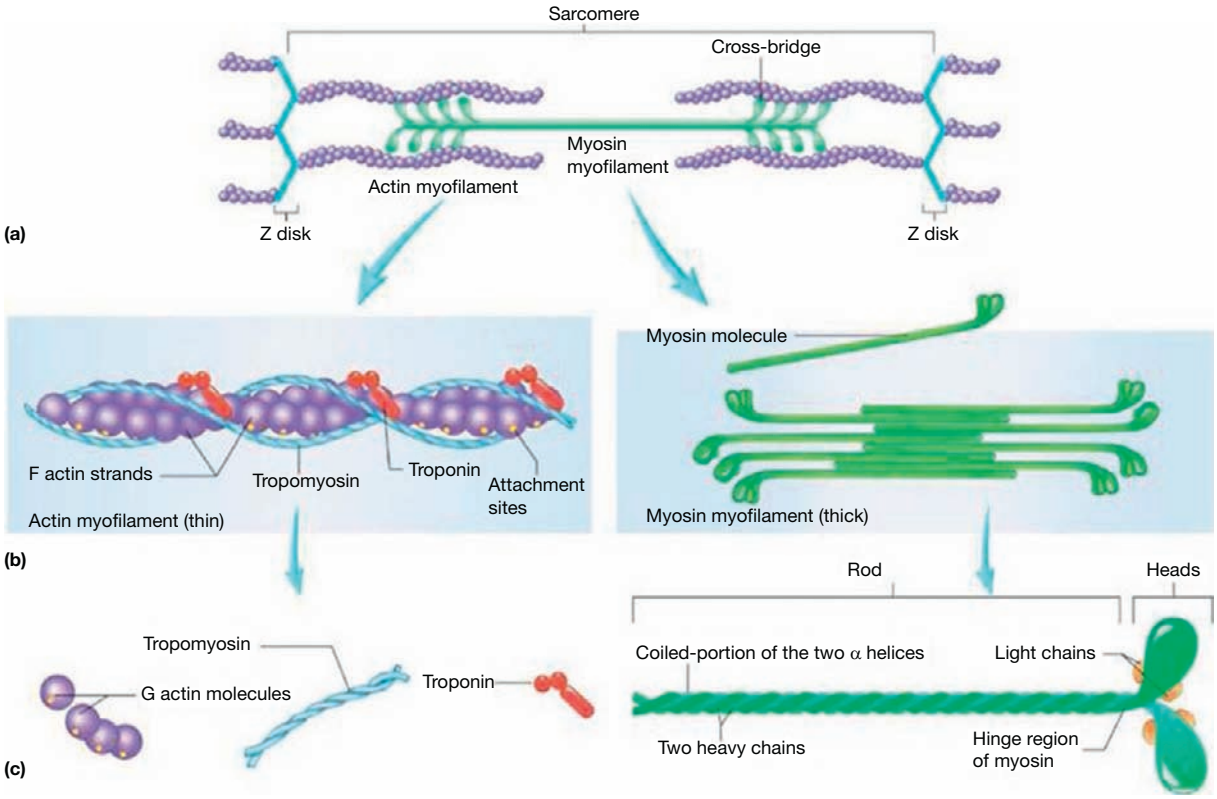

Figure 5 Sliding filament theory.

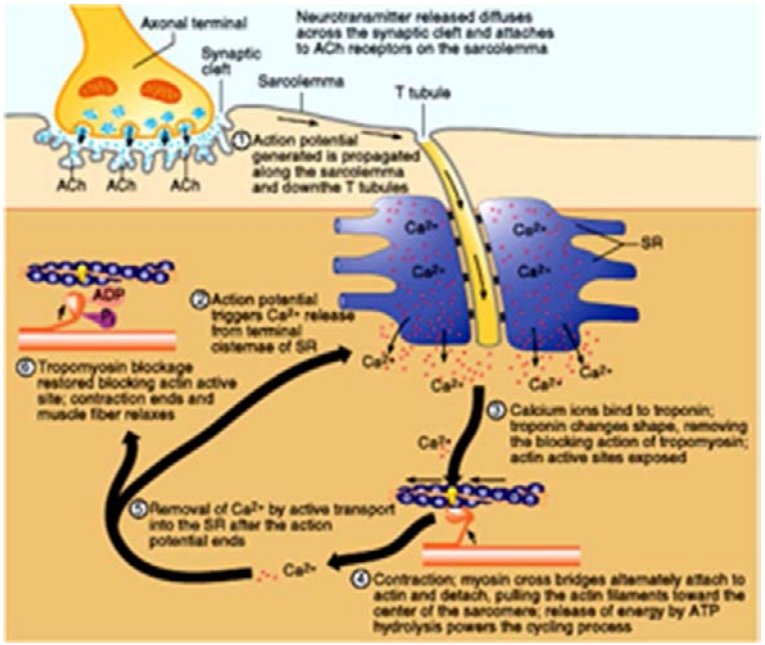

Figure 6 Schematic representation of contraction of muscle.

across a membrane is called resting potential. A membrane with such a resting potential is said to be polarized. Na^+ ions predominate the outside of the sarcolemma, and potassium ions predominate the inside. Due to the difference in concentration on the two sides of the sarcolemma, potassium ions leave and sodium ions enter the muscle fiber. Sarcolemma is more permeable to K^+ ions than to sodium ions. Hence the potassium ions leave the muscle fiber faster than sodium ions enter, and this builds a positive charge outside.

When the motor nerve impulse reaches the neuromuscular junction, the vesicles present in the motor end plate secrete a neurotransmitter chemical called acetylcholine (Ach). It binds to the receptors on the sarcolemma and makes it more permeable to Na^+ than K^+ so that sodium rapidly diffuses along the concentration gradient and the electrical gradient. Now sarcolemma becomes electropositive inside and electronegative outside. This new potential difference is called action potential. Such sarcolemma is called depolarized. Action potential stimulates the sarcoplasmic reticulum to release calcium ions, which then initiate the biochemical changes in muscle contraction. Calcium and magnesium ions act as cofactors for myosin ATPase enzyme, which hydrolyzes ATP into ADP and inorganic phosphate releasing energy (Figure 6).

Control of Muscle Contraction

The SMs are organized into hundreds of motor units, each of which is a motor neuron and a group of muscle fibers. A graded response to a circumstance will involve controlling the number of motor units. Whereas individual muscle units contract as a unit, the entire muscle can contract on a graded basis due to their organization into motor units. Neuromuscular junction is the point where a motor neuron attaches to a muscle. Ach is released from the axon end of the nerve cell when a nerve impulse reaches the junction. A wave of electrical charges is produced in the muscle cell when the Ach binds to receptors on its surface. Calcium is released from its storage area in reticulum. An impulse from a nerve cell causes calcium release and brings about a single, short muscle contraction called a twitch (Figure 7).

Disorders Affecting SMs

Some of the most common diseases affecting the SMs include myasthenia gravis, muscular dystrophy and fibromyalgia. Other primary muscle disorders include inflammatory myopathies, including polymyositis, which is characterized by inflammation and progressive weakening of the SMs. The most common symptom a muscle disorder is weakness. In addition the symptoms include abnormal fatigue with activity, as well as muscle spasms and pain. Electromyography is often used to diagnose muscular disorders. It helps to characterize the causes of nerve and muscle disorders by stimulating nerves and recording responses.

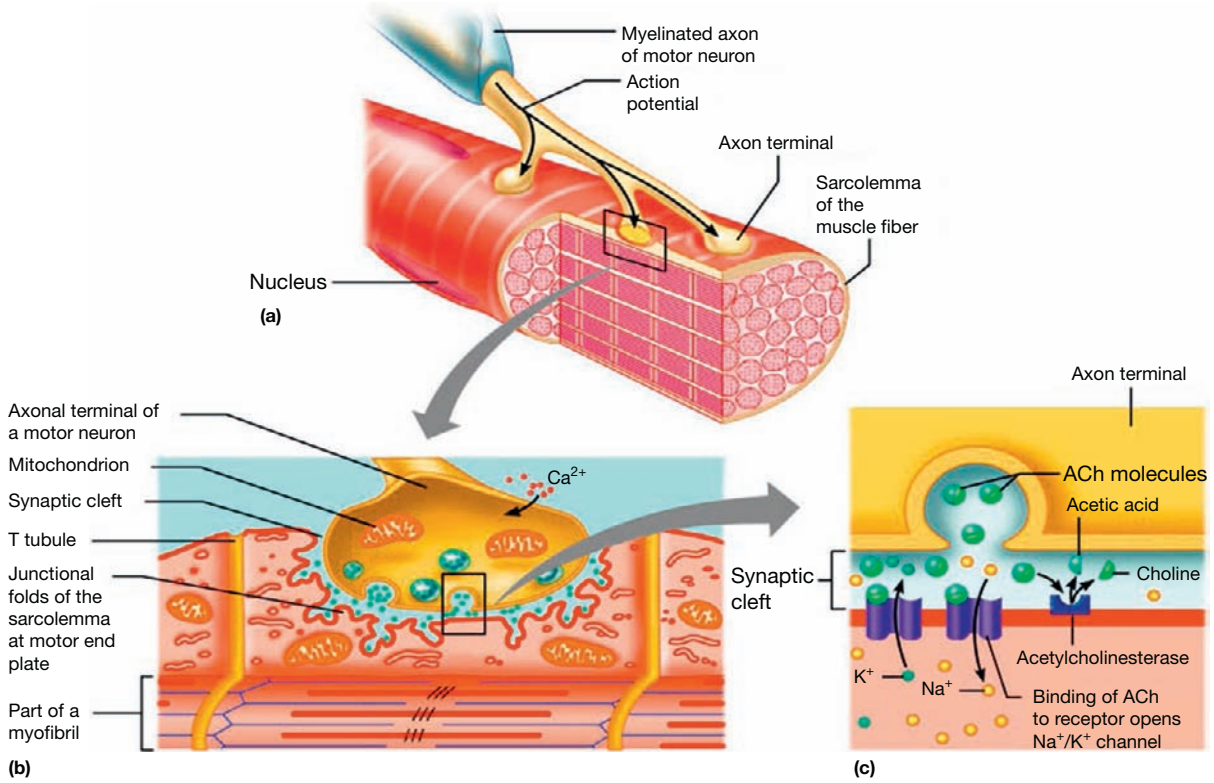

Figure 7 Schematic representation of mechanism of control of muscle contraction.

EDITORS-IN-CHIEF

Benjamin Caballero is professor of International Health and of Maternal and Child Health (Bloomberg School of Public Health), and professor of pediatrics (School of Medicine) at Johns Hopkins University.

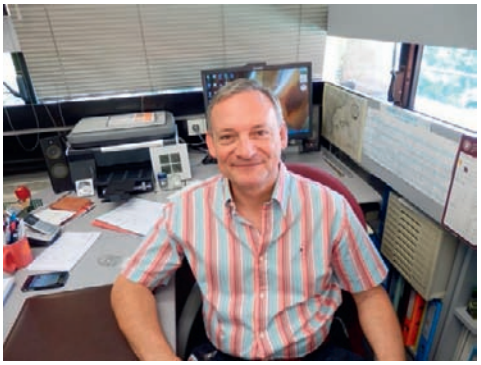
He obtained his MD from the University of Buenos Aires, his MSc in biochemistry from the University of San Carlos, and his PhD in neuroendocrine regulation from MIT, in Cambridge, MA. He started his academic career as assistant professor of pediatrics at Harvard Medical School and director of the Nutrition Unit of Boston Children's Hospital, and subsequently became the founding director of the Center for Human Nutrition at Johns Hopkins University, in Baltimore.

Prof. Caballero has focused his research on child nutrition and health in developing countries. In particular, he has explored the combination of undernutrition and overweight that has become increasingly prevalent in low- and middle-income countries. He was a member of the Food and Nutrition Board of the Institute of Medicine, National Academy of Sciences, USA, and of a number of expert panels created by the Institute, including the Dietary Reference Intakes (DRI) Committee, the Expert Panel on Macronutrient Requirements, and the Childhood Obesity Task Force. He was also a member of the Dietary Guidelines for Americans Advisory Committee, of the Scientific Advisory Board of the Food and Drug Administration (FDA), and of a number of advisory committees of the National Institutes of Health (USA).

He is the editor-in-chief of the *Encyclopedia of Food Sciences and Nutrition*, a 10-volume work on food production, consumption and biological effects. He is also editor-in-chief of the *Encyclopedia of Human Nutrition*, which received the Book of the Year Award from the British Medical Association. His *Guide to Dietary Supplements* summarizes the current scientific basis for the use of mineral and vitamin supplements. His book *The Nutrition Transition: Diet and Disease in the Developing World* explored the impact of demographic and economic development on diet- and lifestyle-related diseases in developing countries. His book *Obesity in China* summarizes research conducted in rural and urban China to track the impact of socioeconomic development on health outcomes. He is also coeditor of a widely used textbook on human nutrition, *Modern Nutrition in Health and Disease*.

He is a member of the Spanish Academy of Nutritional Sciences, and a Fellow of the American Society for Nutrition and of the Royal Society of Medicine (UK). Recent awards include the Donald Medearis Lectureship from the Massachusetts General Hospital/Harvard Medical School, the Mataix Prize for lifetime achievements in nutrition science from the Spanish Academy of Nutritional Sciences, the Ancel Keys Prize for achievements in international public health, and the Thompson–Beaudette Lectureship from Rutgers University.

Paul Finglas joined the Institute of Food Research in 1981 and is currently head of the Food Databanks National Platform and Research Leader in Food and Health at the Institute (http://www.ifr.ac.uk/science/platform/FD/default.html). He has, for most of his science career, been involved in a wide range of research in food composition and analysis, and the nutritional effects of micronutrients in food and health research. Paul has considerable experience of co-coordinating both national and international projects (e.g., EuroFIR, TDS-EXPOSURE, Bacchus and QualiFY (all EU FP7), and is currently of the spin-out EuroFIR AISBL, a non-profit international association based in Belgium, from one of these projects. Paul has a broad range of experience in science publishing and is currently editor of the journals *Food Chemistry* and *Trends in Food Science and Technology*, and was one of the coeditors for the *Encyclopedia of Food Science and Nutrition* (2nd Ed.). Paul has a degree in chemistry from Aston University in Birmingham and has published over 150 publications on a wide range of topics in food science and nutrition.



Fidel Toldrá holds a BSc in chemistry (1980), high degree on food technology (1981) and PhD in chemistry from the University of Valencia (1984). Professor Toldrá was a Fulbright postdoctoral scholar at Purdue University in West Lafayette (US, 1985–86) and visiting scientist at the University of Wisconsin-Madison (1991 and 1995), and the Institute of Food Research-Bristol (UK, 1987). Currently, he is research professor at the Instituto de Agroquímica y Tecnología de Alimentos (CSIC), in Paterna, Valencia (Spain). He is also associate professor of food technology at the Polytechnical University of Valencia.

Prof. Toldrá has focused his research on food biochemistry and its relationship with nutrition, quality and safety. He has filed 12 patents, directed 22 PhD thesis and published over 245 manuscripts in recognized scientific journals and more than 115 chapters of books. His h-index is 41. Prof. Toldrá has authored two books and edited/co-edited more than 30 books for major publishers like CRC Press, Wiley-Blackwell, Elsevier and Springer.

Prof. Toldrá is the European editor of *Trends in Food Science and Technology* (2005–) and associate editor of *Meat Science* (2014–); he was the editor-in-chief of *Current Nutrition & Food Science* (2005–2012), section editor of the *Journal of Muscle Foods* (2009–2010) and guest editor of 12 special journals issues. He is a member of the editorial boards of *Food Chemistry*, *Food Analytical Methods*, *Journal of Food Engineering*, *Journal of Food and Nutrition Research*, *The Open Nutrition Journal*, *The Open Enzyme Inhibition Journal*, *Recent Patents in Agriculture*, *Food and Nutrition*, *Food Science & Nutrition* and *Current Opinion in Food Science*.

He has been a member of the Scientific Panel on food additives, flavorings, processing aids and materials in contact with foods (periods 2003–2008) and the Scientific Panel on flavorings, enzymes, processing aids and materials in contact with foods (2008–2015) of the European Food Safety Authority (EFSA) acting as Chairman of the Working groups on Irradiation (2009–2010), Processing Aids (2011–2014) and Enzymes (2010–2015). He was a member of FAO/WHO group of experts to evaluate chlorine-based disinfectants in the processing of foods (2008–2009). He was a member of the Executive Committee of the European Federation of Food Science and Technology (EFFOST, 2002–2009). He is a Fellow of the International Academy of Food Science and Technology (IAFOST, 2008) and of the Institute of Food Technologists (IFT, 2009–). He received the Iber Award on Food and Cardiovascular Diseases (1992), the Institute Danone award in Food, Nutrition and Health (2001), the International Prize for Meat Science and Technology from the International Meat Secretariat (2002), GEA award on R+D activity from the Valencian Community (2002), and the Distinguished Research Award (2010) and Meat Processing Award (2014), both from the American Meat Science Association.

EDITORIAL ADVISORY BOARD

Siân Astley has worked extensively with individuals and organizations throughout Europe from a variety of disciplines including research, food and biotech industries, and the media. She is the author of more than 300 popular science articles for magazines and trade publications as well as 25 peer-reviewed papers, and she was awarded her Diploma in Science Communication in 2009 (Birkbeck University of London). After 14 years as a bench-scientist, Siân became communications manager for NuGO, one of the first FP6 networks of excellence, and was the European communications manager for the Institute of Food Research in Norwich (UK) until April 2012. Currently, she is the training and communications manager for the European Food Information Resource (EuroFIR AISBL) supporting training within EU-funded research projects and networks, and communication of research activities.

David J. Baer is a supervisory research physiologist with the US Department of Agriculture's Beltsville Human Nutrition Research Center located in Beltsville, Maryland. He serves as the research leader for the Center's Food Components and Health Laboratory and also serves as the director of the Center's Human Studies Facility.

Dr. Baer conducts controlled dietary intervention studies to investigate the relationship between diet and the risk for chronic degenerative diseases, especially cardiovascular disease, cancer, and diabetes in people. His research also includes studies on the health impacts of weight gain and determining the calorie content of foods. Some of the dietary interventions he has investigated include the effects of different types of protein, fats and fatty acids, fiber, margarine, butter, plant sterols, salad dressings, nuts, whole grains, berries, alcohol, and tea on overall nutrition and health. In addition to dietary intervention studies, Dr. Baer is involved in research studies to validate food survey methodologies and in developing new methods for dietary assessment.

Dr. Baer earned his bachelor's degree from the University of Illinois and his master's and doctorate in nutrition from Michigan State University.

Marina Carcea was awarded a master degree in agricultural sciences at the University of Pisa, Italy "cum laude" in 1980, and a PhD in food science also "cum laude."

She is currently a senior researcher in the Research Center on Food and Nutrition of the Council for research in agriculture and analysis of agricultural economy (CRA-NUT formerly INRAN National Research Institute on Food and Nutrition) and she was the director of the Cereals Research Programme in INRAN. CRA-NUT is a primary research institute in Italy under the egis of the Ministry of Agriculture. Dr. Carcea joined INRAN in 1989 after having worked in Italian and English universities (Queen Elizabeth College, King's College, and University of London) and after a two-year contract with the Food and Agriculture Organization (FAO) of the United Nations (UN), Rome.

She has a vast experience in the field of research on foods, cereals in particular. In recent years, her main research interests have been: chemical characterization and study of the functional properties of cereal components; study of the interactions between components and of the interrelationships between the biochemical properties of components and the technological properties of the raw material and derived products; development of new, cereal-based products; development of methods to assess technological parameters of the raw material; nutritional value of cereals; and developments of protocols for quality assurance of cereals, food authenticity.

She has taken part and/or co-ordinated several research projects within national or international programs (European Commission, FAO) involving several institutions. She is the author of more than 160 scientific publications, mostly in international journals, eight book chapters, and two scientific books. She delivered lectures on her research activity at about 150 national and international congresses and she seats in several national and international committees (Italian Ministry of Agriculture, Codex Alimentarius, and European Commission) regarding food and nutrition topics. She is also a member of the editorial board of scientific journals.

From 1994 to 2006, she has also been a lecturer of food science and technology at the University of Tor Vergata, Rome, Italy.

She is a founding member of AISTEC, the Italian Association of Cereal Science and Technology. Since 1996, she is an elected member in the Executive Committee of the same association and since 2009, president of the association.

Since 2000, she is the Italian National Delegate of the International Association for Cereal Science and Technology (ICC) and she was also the president of the same association for 2011–2012.

In 2004, she was the first woman to be awarded the International Harald Perten Prize for her excellent research achievements in the field of cereal science and technology.

She is also a member of the Georgofili Academy in Florence, Italy.

Lawrence J. Cheskin graduated from Dartmouth Medical School and completed a fellowship in gastroenterology at Yale–New Haven Hospital. He is an associate professor of health, behavior, and society at the Johns Hopkins Bloomberg School of Public Health, with a joint appointment in International Health–Human Nutrition, and in medicine (GI) at the Johns Hopkins University School of Medicine. Dr. Cheskin is also a founder and director of the Johns Hopkins Weight Management Center, a comprehensive treatment program for obesity.

In his research, Dr. Cheskin has studied the effects of medications on body weight, the gastrointestinal effects of olestra, how cigarette smoking relates to dieting and body weight, and the effectiveness of lifestyle and dietary changes in weight loss and weight maintenance.

He is also the author of four books: *Losing Weight for Good*, *New Hope for People with Weight Problems*, *Better Homes and Gardens' 3 Steps to Weight Loss*, and *Healing Heartburn*. Dr. Cheskin has appeared on television news programs and lectured to both professional and lay audiences on the topics of obesity and weight control.

Nigel Cook is a graduate of the University of Dundee. After postdoctoral research in the Universities of Aberdeen and Leicester, he moved to the Central Science Laboratory (now the Food and Environment Research Agency (FERA)) at the Food Science Laboratory, Torry, Aberdeen in September 1994, before relocating to new facilities in York. At FERA, he studies the transmission of pathogens, particularly enteric viruses, through foods and the environment. He has a visiting professorship at the Katholieke Universiteit Leuven in Belgium. He is a councilor of the International Association for Food and Environmental Virology. He is a project leader within the standardization working group ISO TC34 SC9 WG6, currently developing a standard for detection of *Cryptosporidium* and *Giardia* on berry fruits and leafy green vegetables. He was a coordinator of the European Framework 7 project "Integrated monitoring and control of foodborne viruses in European food supply chains (VITAL)," and a chair of COST Action 929 "A European Network for Environmental and Food Virology" from 2006 to 2010. Between 2009 and 2014, he was a member of various European Food Safety Authority's Working Groups preparing opinions on the risk of foodborne viruses, and represented the European Communities on the Codex Committee on Food Hygiene Working Group developing *Guidelines on the Application of General Principles of Food Hygiene to the Control of Viruses in Food*. He was a member of the UK Advisory Committee on the Microbiological Safety of Food's Viral Infections Subgroup. He was the founding editor of the journal *Food and Environmental Virology*, published by Springer.

Luca Simone Cocolin graduated in 1994 in food science with a grade of 110/110 and remark followed by food biotechnology PhD studies from 1995 to 1998. In February 1999, he defended his thesis acquiring the title of PhD in food biotechnology. From 1998 to 2001, he received a scholarship from the Friuli Venezia Giulia region (Italy). From November 1, 2001, he was an assistant professor at the University of Udine, Faculty of Agriculture, Food Science Department, Italy, and in October 1, 2006, he became an associate professor at the University of Torino, Italy. In January 2014, he had the habilitation for full professor and from June 2015, he is the full professor in food microbiology at the University of Torino.

From September 2008, he is an executive board member of the International Committee on Food Microbiology and Hygiene (ICFM) part of the International Union of Microbiological Societies (IUMS) (http://www.icfmh.org/). From January 2008, he is the editor-in-chief of the *International Journal of Food Microbiology* and he is a member of the editorial board of *Applied and Environmental Microbiology*, *Food Analytical Methods*, *Frontiers in Food Microbiology*, and *Frontiers in Nutrition and Food Science Technology*. He regularly reviews paper for *Food Microbiology*, *Meat Science*, *Journal of Applied Microbiology*, and *Letters in Applied Microbiology*. He is a co-author of more than 180 papers on national and international journals and he attended national and international congresses with oral and poster presentations. On Scopus (www.scopus.com, consulted on March 2015) he has 172 documents reviewed, which were cited 3520 times, resulting in an h index of 33.

His scientific interests comprise:

development, optimization, and application of molecular methods for the detection, quantification, and characterization of foodborne pathogens;
study of the microbial ecology of fermented foods (mainly sausage, cheese, and wine) by using culture independent and dependent methods;
bioprotection: molecular characterization of bacteriocin production and its study *in vitro* and *in situ*;
selection of new putative probiotics from artisanal fermented foods; and
study of the human microbiome and its influence on human health.
