Dietary fiber comprises carbohydrate and noncarbohydrate polymers; most of these are structural components. The carbohydrate polymers are often described as nonstarch polysaccharides (NSPs) to differentiate them from the (relatively) easily digested starch components of food. Figure 1 shows the proportion of the monomeric constituents of fiber polysaccharides from three food categories (11 cereals, 13 fruits, and 11 vegetables) and from canned mushrooms, peanuts, and baked white beans. As can be seen, arabinose is a major NSP component of cereals, peanuts, and beans. Xylose is present in large amounts only in cereals. Pectic substances (uronic acids) represent a substantial part of fruit, vegetable, peanut, and bean NSPs. Mushroom NSP is formed mostly of glucose residues. These results were based on the analysis of composites made of up to 20 individual foods purchased over a 30-month period using the Englyst gas–liquid chromatography method. A more recent version of this method would have given a higher proportion of xylose relative to glucose.

The different monomeric residues of Figure 1 are the basic units that form the major NSP macromolecular constituents shown in the upper part of Table 1. Cellulose and β-glucans are generally unbranched polymers containing mostly glucose residues. The β-glucans have mixed β-1,3 and β-1,4 interresidue linkages and are a constituent of dietary fiber from barley and oats. The glucose residues of cellulose are joined by β-1,4 linkages. In addition to their resistance to the enzymes of the human digestive tract, these linkages allow greater inter- and intrapolymer hydrogen bonding than the α-1,4 linkages of starch do. This allows the formation of tightly condensed crystalline regions within the cellulose microfibrils. Cellulose includes structurally amorphous regions where the presence of other sugars can be found. The final cellulose structure is a function of the glucose and nonglucose contents: the degree of cellulose crystallization is inversely proportional to the nonglucose residue content. Cellulose is a minor fraction of the total cereal dietary fiber but is a major fraction of dietary fiber in other foods. The proportion of cellulose in the dietary fiber of a food is not reflected by the glucose content of the NSP fraction, since glucose is also a major component of other fractions such as β-glucans and hemicelluloses.

Xylose is a part of the primary chain of hemicelluloses and gums and the secondary chain of gums and pectin. Arabinose is in the primary chain of gums and the secondary chain of hemicelluloses and pectin. Hemicelluloses constitute a major fraction of dietary fiber; this fraction is largely made of arabinose and xylose in cereals and of xylose and glucose in fruits and vegetables (Table 1). Pectic substances are prevalent in citrus fruits. They are also present in vegetables, legumes, and cereals in small amounts (Table 1). Other polysaccharide constituents are mainly represented by galactose or mannose in bananas. Nonstructural NSPs represent a small portion of dietary fiber. The monomeric NSP composition is of limited usefulness in predicting the properties and functions of dietary fiber. This is because the structural architecture of dietary fiber plays a large role in many of its physiological properties, and this structure cannot be predicted by its composition. Indeed, two dietary fibers with a similar component profile (e.g., wheat bran and corn bran) can have clearly different structures, even under optic microscopy, and can show different behaviors in the gastrointestinal tract.

Nonsaccharide Fiber Components

The minor components of dietary fiber that are not polysaccharides and, hence, not NSPs also play an important

structural role. Table 1 shows the distribution of the nonsaccharidic polymers that are intimately associated with dietary fiber structure. These polymers include glycoproteins (fruits, vegetables, and legumes), proteins (cereals), phenolic esters (cereals), and lignins (lignified tissues of fruits, vegetables, and cereals). Lignin is of special interest because of its role in slowing down the fermentation of dietary fiber. It is a complex group of phenyl propane polymers formed by the condensation of aromatic alcohols and is especially important in conferring structural stability. As such, highly lignified tissues are found in the stems of plants such as trees and bushes and in the stalks of cereals. Lignification occurs at the expense of water and pectin as cells differentiate and mature. This increases cell wall rigidity in critical areas. Since edible plant tissues are consumed when relatively immature, their cells are largely undifferentiated and, largely, unlignified. Wheat bran and the small seeds covering strawberries are examples of lignified tissues. In most fruits and vegetables, lignin represents only a small part of dietary fiber, although it can be as high as 4% of dry matter in mature pears.

Cutin, waxes, or suberin may also be present in some tissues. These compounds are mixtures of lipids, proteins, and carbohydrates that form the waterproof covering and cuticle on the outer cell wall of plants. They are especially resistant to digestion and fermentation. As such, they impair the digestibility of other cell wall components and are usually found in the feces.

Structure

Models of primary cell walls of plants were often obtained from nonfood materials such as wood and tobacco. Because the cell wall material forms a large part of these plants, the models provide a wealth of information on the interactions between cell wall components such as carbohydrates and lignin and protein and carbohydrates. More recent reports have provided some structural information on the cell walls of plant foods. These reports have shown that, in carrots, protein–protein or protein–polysaccharide linkages may contribute to the formation of a rigid, inextensible cell wall. Other data have shown that protein may form up to 10% of cell walls in immature plants and appears to be important for structural cohesion. The major part of the flesh of fruits and vegetables contains undifferentiated types of cell wall that have significant amounts of highly branched hemicellulosic types of polysaccharides. The cellulose content is usually low, and cellulose is laid down in a more oriented arrangement in the matrix. This may reflect stresses on the plant. The cell walls are often rich in pectic substances and contain ~10% protein, as described earlier. These cell walls are thin and elastic with the cell form maintained by osmotic pressure.

In contrast, the outer layers of many seeds and nuts contain thick lignified cell walls that are difficult to break. These serve as mechanical protection to the seed within and as a vapor barrier to prevent desiccation.

Physical Properties

Soluble and Insoluble Dietary Fibers

It is possible to separate the total dietary fiber (TDF) into soluble and insoluble components based on solubility in water, but quantifying the amount of soluble fiber remains problematic. This is because the conditions utilized to measure the proportion of soluble fiber differ among laboratories (e.g., time, temperature, pH, and type of buffer; see the section '**Definition (Based on Function and Structure)**'). It should be noted that the distinction between soluble and insoluble fibers is somewhat artificial, since it is difficult to predict the actual fiber solubility in the gastrointestinal tract.

For many years, it was thought that soluble fiber was not commonly found in foods. Reports on pectin, guar, legume fiber, and oat bran appeared in the early 1960s, and currently, it is estimated that about a third of the daily TDF intake is soluble fiber. Pectic polyuronides are the major soluble dietary fiber components of vegetables and fruits, but the exact composition varies from plant to plant. When measuring dietary

fiber, one must also take into account the method of food preparation because the soluble fiber content of a fiber source is influenced by the method of food preparation. For example, some polyuronides are susceptible to depolymerization at the high temperatures used to cook the foods. Similarly, some insoluble fiber is susceptible to depolymerization at higher temperatures and may be found in the soluble fiber fraction.

In addition to the distinction between soluble and insoluble fibers, viscosity may also be an important fiber characteristic. This is because viscous fibers modestly lower blood cholesterol and triacylglycerol concentrations and attenuate the postprandial glucose response. It is thought that the increased viscosity of the intestinal lumen reduces the rate of diffusion of glucose, cholesterol, and triacylglycerols to their respective receptors along the intestinal wall, reducing absorption. The results of a recent meta-analysis using several different clinical studies showed a statistically significant lowering of plasma triacylglycerols and cholesterol in subjects fed for at least 14 days with a diet supplemented with oats, psyllium, pectin, or guar gum, but the effect was modest: a decrease of $\sim 1\ \mathrm{mg\ dl^{-1}\ g^{-1}}$ of soluble fiber was observed. If we consider that an individual with moderately higher blood cholesterol has a total serum cholesterol value of $\sim 300\ \mathrm{mg\ dl^{-1}}$, the change brought about from the consumption of viscous, soluble fibers is on the order of 0.3%. Considering that oat bran contains about 20% fiber by weight and only half of this is soluble, one can calculate that 10 g of oat bran per day is needed for each 0.3% change in total cholesterol.

Insoluble dietary fiber is, by definition, the fraction of the TDF that is not soluble in hot buffer solution. However, the measured proportion of insoluble fiber can vary depending on the dietary fiber methodology. Insoluble dietary fiber consists primarily of hemicellulose, cellulose, and lignin. It is often incorrectly believed that insoluble fiber is not fermented to any great extent by the bacteria present in the large bowel. However, actual measurements of fiber fermentability have shown that a significant proportion of insoluble dietary fiber is fermented. This is true even for wheat bran, which has a relatively lower insoluble fiber fermentability of between 30% and 40% (~90% of the wheat bran TDF is insoluble dietary fiber). The fermentability of oat bran is even greater – up to 80% of the insoluble fiber (approximately half of the TDF) is fermented in the human large intestine. The degree of fermentability is a property unique to each dietary fiber and depends largely on the nature and the structural arrangement of the fiber components and also on other physical characteristics such as particle size. For example, the structure of coarse wheat bran favors a high water-holding capacity (see later) and a slow rate of fermentation. This permits the microtrapping of slowly released fermentation gases, increasing fecal bulk and stimulating defecation.

Water-Holding Capacity

Dietary fiber holds water by adsorption and absorption. Some water is also retained outside the fiber matrix (free water). The particle size, chemical composition, and structure of dietary fiber influence the water-holding capacity. The *in vitro* water-holding capacity cannot be used to predict the impact of highly fermentable fiber on colonic function.

[c]MPS, geometric mean particle size.
[d]WHC, water-holding capacity, grams of water per gram of insoluble fiber, using the centrifugation method; mean ± SEM of three measurements.
[e]Grams of glycocholate bound per 0.2 g of insoluble fiber; mean ± SEM of four measurements.

Although lettuce fiber isolates retain much water, the water-holding capacity expressed in grams of water held by fiber per gram of edible portion of food has been found to be higher for wheat bran fiber (4.5 g) and carrot fiber (2.1 g) than for that of lettuce and various other foods (0.3–1.3 g). The water-holding capacity of fiber from the bran of ready-to-eat breakfast cereals is positively correlated ($r \geq 0.85$ and $P < 0.05$) with its mean particle size (MPS): the water-holding capacity of 160 μm MPS wheat bran fiber is 59% of that of 800 μm MPS wheat bran fiber (Table 2). A large portion of the water held by wheat bran fiber appears to be free water.

The water-holding capacity has a significant effect on fecal output and stool hardness, as discussed earlier. These factors are important physiological effects of wheat bran and contribute significantly to its laxative effects.

Bile Salt Binding and Serum Cholesterol Reduction

There is considerable interest in the cholesterol-reducing properties of dietary fiber. This is because the influence of serum cholesterol (low-density lipoprotein (LDL) and high-density lipoprotein (HDL) cholesterol, in particular) on cardiovascular disease is considerable. Three different mechanisms have been proposed to account for the serum cholesterol-reducing properties of dietary fiber. As discussed earlier, a certain soluble viscous fiber may modestly lower cholesterol by increasing luminal viscosity and preventing cholesterol (re)absorption. Acetic and propionic acids, produced by the fermentation of dietary fibers in the gut, are thought to inhibit liver cholesterol synthesis at the metabolic level. Dietary fibers also have the ability to bind cholesterol directly: deconjugated bile salts are bound to pectic substances by hydrogen bonding, and lignin appears to bind bile salts through hydrophobic interactions. The actual *in vivo* mechanism is unknown, and it is likely that different fibers operate through different combinations of all three mechanisms to influence blood cholesterol levels.

In vitro evidence suggests that the physical form of the fiber may also play an important role in binding bile salts. In commonly ingested ready-to-eat cereals, glycocholate binding ($r = 0.90$, $P < 0.001$) and taurocholate binding ($r = 0.86$, $P < 0.05$) have been positively correlated with the MPS of the

neutral detergent fiber (NDF). Reducing the particle size of wheat bran NDF from 800 to 160 μm reduces its glycocholate binding by 19% (Table 2). The bile salt-binding capacity of fiber isolates, although method-dependent, may reflect events in the terminal small intestine. Purified fiber fractions may be poor (cellulose) or strong (lignin) binders. Some rice bran appear to have a high capacity to bind bile salts.

Human cholesterol-lowering studies have linked the consumption of dietary fiber with lower total plasma cholesterol and increased LDL/HDL ratios in addition to reductions in serum triglycerides. Studies such as these have suggested that cardiovascular risk may be reduced by consuming particular types of foods high in dietary fiber, most notably whole cereal grains. However, it should be noted that coronary heart disease (CHD) is a complex disease and is affected by many factors. For example, the reduction in CHD observed in a recent study was larger than would be expected from the beneficial effects of soluble dietary fiber on serum cholesterol levels only. Thus, reductions in CHD are likely to be the result of many factors, one of which is TDF intake.

Cation Exchange Capacity

Cation exchange is partly dependent on the presence of uronic acid in the nonesterified form. The preparation of the fiber material may decrease the number of nonesterified carboxyl groups and the apparent cation exchange capacity. Wheat bran contains little uronic acid, and its cation exchange capacity is mainly due to diffusion within the dietary fiber network. The cation exchange capacity of fiber from different sources is difficult to compare, unless it is expressed per edible portion. According to the affinity of minerals for carboxylic acid groups, cabbage and coarse wheat bran show a high cation exchange capacity compared with pectin.

There has been some concern that the ability of dietary fiber to bind minerals (as measured *in vitro*) may lead to mineral deficiencies in individuals consuming high-fiber diets. In North American diets, calculations show that mineral intakes far exceed the potential binding capacity of dietary fiber so that no need for concern arises. In addition, minerals that are bound to fibers or that are trapped in the (as yet undigested) cell wall matrix may not be absorbed in the small intestine but could be partially released and absorbed in the colon when the fiber is degraded by bacteria. Absorption of minerals in the colon has been suggested as a mechanism for accounting for increased mineral absorption in rats fed with fructooligosaccharides. This may explain why cation adsorption has not been consistently related to mineral bioavailability. However, wheat bran fibers can permanently bind heavy metal ions to decrease their toxicity.

Viscosity and Gelling Properties

As mentioned earlier, certain soluble fibers, such as oat β-D-glucans, are viscous when dissolved in water, while others, such as pectins, show gelling properties. These fibers influence gastric emptying and absorption rates in the small intestine. Direct measurement of the viscosity produced by concentrations of fiber likely to be used in diets has shown little effect of low-methoxy pectin, a slight increase with wheat bran, and a significant increase with high-methoxy pectin. Some of the nonstructural dietary fiber components can also increase viscosity.

Microbial Degradation (Fermentability)

Most dietary fiber remains undegraded until it reaches the large intestine, where the extent of fermentation depends on the source and several other factors, including the physical structure of the fiber, presence of specific components in the fiber matrix, nitrogen source, bacterial adaptation, and transit time. It is generally accepted that soluble fiber is almost completely fermented in the large intestine, but unfortunately, it is also generally believed that insoluble fiber is not fermented. Actually, both insoluble and soluble fibers are extensively fermented. On average, 70–80% of the TDF from mixed diets (e.g., fruits, vegetables, legumes, and most cereals) is degraded by colonic bacteria. Since insoluble dietary fiber is the major dietary fiber fraction, representing approximately two-thirds of the TDF in Western diets, this means that insoluble fiber is highly fermented. Indeed, as indicated in the preceding text, 70–80% of the insoluble fiber from oat bran and up to 40% of the insoluble dietary fiber from wheat bran are fermented.

There is some indication that fermentability depends on particle size, with small particle sizes being more readily fermented, but this has not been consistently reported, and the effect appears modest. In rats fed with purified diets containing 15% hard red wheat bran, NDF fermentability was largely unchanged (34–36%) when the MPS varied from 1275 to 394 μm. Similar trends were observed when American Association of Cereal Chemists soft and hard wheat bran were fed at various MPSs. In these experiments, 37.3–37.6% and 30.0–32.8% of the NDF were fermented, respectively.

Interaction between Structure and Physiology

Food Processing

The physicochemical properties of dietary fiber per se are dependent on the chemical composition and the structural characteristics of the fiber. However, as noted earlier, knowing the former does not allow one to predict the latter. When considering the potential *in vivo* effect of dietary fiber, one must also take food processing practices into consideration. Many different types of food processing practices are currently employed. Foods can be boiled, canned, frozen, blanched, parboiled, extruded, adiabatically extruded, and milled. All processes can have an effect on dietary fiber content, as measured by current methodologies. For example, heat treatment can break glycosidic linkages in dietary fiber polysaccharides. This can solubilize some of the insoluble fiber and reduce the TDF content if the polymers are broken down into small molecular mass fragments. Heat treatment can also reduce the overall length of the polysaccharide chains to lower viscosity and the water-holding capacity of the fiber. The pentosans in dietary fiber can react with amino acids such as lysine (Maillard reaction) and form new polymers that do not behave physiologically like dietary fiber. The boiling of vegetables increases the apparent TDF content, but this seems to be due to the loss of nonfiber components to the water.

It is often difficult to predict beforehand the effect of a food processing method on the TDF and the distribution between insoluble and soluble fractions. For example, extrusion cooking of some cereal bran apparently increases its water-holding capacity *in vitro*, although this does not translate into a change in fecal water-holding capacity *in vivo*. Extrusion cooking of wheat bran not only causes small decreases in the TDF and insoluble dietary fiber but also gives rise to small increases in soluble dietary fiber. Processing of rice (abrasion or parboiling) removes the seed coat and the majority of the dietary fiber. Some collapsing of the fiber structure also occurs during food preparation and/or mastication due to the reduction of particle size, and the fiber structure of sources such as spinach may be modified by cooking.

Milling is known to significantly affect TDF fermentation in the human colon. Cereal grains have a tough outer seed coat that would be completely resistant to digestion if the cereals were not milled prior to consumption. After milling, the thin-walled dietary fiber structures from the endosperm are partly disrupted and, thus, easily broken during fermentation. Milling, therefore, not only makes the endosperm accessible to the digestive enzymes in the upper digestive tract but also makes the dietary fiber more accessible to colonic bacteria. However, milling can also negatively affect the physiological properties of the dietary fiber in grains. While coarse grinding and adequate mastication appear to be sufficient for the digestion of cereals, fine grinding disrupts much of the cell wall architecture, and further milling can even interfere with its determination by gravimetric methods. Table 3 shows the effect of milling on the dry bulk volume of wheat bran, as measured in a volumetric cylinder. The volume of the coarse bran was reduced from 5 ml g^{-1} to <2 ml after grinding in an M5 Wiley mill using a 0.5 mm screen. Fiber from different sources ground under the same conditions may behave differently during milling, so that their resulting particle sizes may be different.

As discussed earlier, the particle size of unfermented wheat bran fiber may be related to colonic function and fecal characteristics in humans and laboratory animals. Finely ground cellulose or even wheat bran, for example, may have a constipating effect, whereas coarsely ground wheat bran prevents constipation. The influence of particle size on fecal bulking has been measured directly in rats. When rats were fed with diets containing 12% hard wheat bran, the fecal wet density was 0.796 ± 0.010 (mean $\pm$ SEM, $n = 12$) in the coarse bran group (geometric MPS: 850 μm) but increased to 0.888 ± 0.013 in the fine bran group (geometric MPS: 308 μm). This increased density was not due to a change in fecal weight but was due to a decrease in fecal volume, paralleling the effect demonstrated for bran in Table 3. In ready-to-eat breakfast cereals, the fiber MPS has been found to vary between 350 and 2000 μm. Increased particle size normalizes gastrointestinal transit time, delays gastric emptying, and may also affect the extent of insoluble fiber fermentation. Although dietary fiber has many positive effects on the digestive tract, excessive milling of dietary fiber to produce small particles in the range of 7–70 μm may have negative effects. Smaller particles do not exhibit the transit time normalization associated with larger bran particles, and the persorption of a small amount of very fine fiber particles may occur in some regions of the intestinal wall. Contrary to persorbed starch granules, persorbed fiber particles are not degraded in the blood and may impose an increased workload on the kidneys. Data on persorption are scarce, and much work is needed on this subject.

Table 3 Effect of grinding on dry bulk of wheat bran (ml g^{-1}): duplicate measurements

Sieve aperture[a]	*Bran A*[b]	*Bran B*	*Bran C*	*Bran D*

2.0 mm (10 mesh)	2.7	2.4	2.8	2.1
1.0 mm (18 mesh)	2.2	2.1	2.4	2.0
0.5 mm (35 mesh)	1.8	1.8	1.9	1.7

[a]Using an M5 Wiley mill. Mesh sieve equivalence is indicated in parentheses.
[b]Bran A was American Association of Cereal Chemists-certified soft white wheat bran; bran B–D were soft or hard wheat bran from other sources.

Studies with apples, apple puree, and apple juice have highlighted the link between the physical integrity of the cell wall and the beneficial effects of unprocessed dietary fiber, in this case, a lowering of the glycemic index of a food (the rise in blood glucose that accompanies the ingestion and digestion of a carbohydrate-containing food). Only the unprocessed apple had a reduced glycemic index; the apple puree, containing the physically degraded dietary fiber, was similar to apple juice in response. This demonstrates the importance of the physical encapsulation of available macronutrients within the fiber matrix. This effect has also been observed with rolled oats where higher glycemic indexes were observed with more finely cut oats. Studies such as these show that the integrity of the cell wall is important in bringing about beneficial physiological effects, even in the presence of viscous, soluble fiber types (β-glucans in the cell wall; see the section '**Bile Salt Binding and Serum Cholesterol Reduction**').

In Vitro Measurements

In vitro properties of fiber isolates have been used to estimate their potential *in vivo* effect. However, *in vitro* data should be used with caution. The measurements are influenced by the methods used to follow digestion *in vitro* and by the methods used to prepare the fiber. Other confounding influences are also present: the fiber residue obtained *in vitro* may have been altered by heat or chemicals or may still contain residual digestible materials. For these reasons, *in vivo* conditions generally result in a more extensive digestion than that measured *in vitro*.

Digestive Events

An important consideration when examining the physiological effect of dietary fiber is the fact that dietary fiber is concentrated and denuded only in the terminal small intestine. This means that the dietary fiber that is partially associated with digestible materials in the jejunum and duodenum may have different physical properties from those of an entirely denuded fiber matrix at the terminal ileum. In the large intestine, most of the soluble fiber and a large but variable portion of insoluble dietary fiber are degraded by the colonic microflora. As already

discussed, fermentation plays an important role in mediating many of the physiological effects associated with dietary fiber.

Definition (Based on Function and Structure)

In the early 1970s, it became evident that cellulose represents only a small part of the TDF content of foods. Prior to this, there was a tendency to equate dietary fiber with cellulose because that is what was measured using the old crude fiber method. While this helped reinforce the use of the term 'dietary fiber' (cellulose has a fibrillar structure), cellulose represents only a small part of the TDF content of foods. Thus, at that time, new methodologies were emerging, and it was clear that there was a need for a dietary fiber definition that was linked to the actual physicochemical composition of dietary fiber.

It is in this context that the dietary fiber hypothesis appeared, a few years after Cleave's hypothesis in 1956, which related refined foods and Western diseases. The dietary fiber hypothesis thus appeared as a refocusing of Cleave's original ideas, reversing the original emphasis to become a diet high in unrefined edible plant material that is protective against Western diseases of the bowel. The dietary fiber hypothesis is important in understanding the 'dietary fiber concept,' since it links botanical structure to digestive processes and health outcomes – mainly noninfective colonic diseases such as constipation, diverticular disease, irritable colon, ulcerative colitis, appendicitis, hemorrhoids, polyps, and cancer of the large bowel. It is this link to these and other health outcomes that has characterized much of the work in the dietary fiber field over the last 30 years. The first dietary fiber definition in 1972 sought to describe the plant structures and components that were responsible for mediating these health benefits: "that portion of food which is derived from cellular walls of plants which is digested very poorly by human beings... Fibre is composed largely of cellulose,... hemicelluloses, pentosans, pectin and lignin."

There are many different definitions of dietary fiber. However, they all include certain specific and critical aspects. First and foremost, a definition must include the fact that dietary fiber corresponds mostly to the structural material in the edible part of plant foods in the usual human diet. This has been consistently reflected throughout the decades by the inclusion of the term 'plant cell wall' when referring to dietary fiber (Table 4). The term 'dietary fiber' itself is something of a misnomer, since dietary fiber is not fibrillar (except for cellulose). To reflect this fact, many other terms have been proposed over the years, including unavailable carbohydrate and plantix. None of these terms have succeeded in replacing 'dietary fiber.'

Another important aspect of any dietary fiber definition is that it is resistant to human digestive secretions (including enzymes) and not absorbed in the small intestine. The observation that dietary fiber increased fecal weight initially gave the impression that dietary fiber was resistant to both human digestive secretions and bacterial digestion in the lower gut (fermentation). While it is true that dietary fiber is not digested and absorbed in the small intestine, a large proportion of dietary fiber is fermented in the colon. The extent of this fermentation is a function of several different factors (see the section 'Microbial Degradation (Fermentability)'), meaning that the extent of fermentation cannot be used as a criterion to define dietary fiber.

Using 'resistance to endogenous digestive secretions' alone as a criterion may be confusing. For example, some dietary fiber may be partly degraded by acids in the stomach, while

some small intestine-digestible material can reach the colon where bacterial fermentation occurs. In addition, a definition based on the resistance to digestibility by endogenous digestive secretions could be problematic if the material is not specified as coming from the edible part of plant foods. Indeed, such a definition could be erroneously interpreted as meaning that dietary fiber is any material resistant to *in vivo* digestion or even as any material measured as dietary fiber by a specific dietary fiber method. Among the materials to be excluded from the dietary fiber definition are 'ruminant fiber' and the products formed during processing and/or cooking. There have been requests to include some other plant components and manufactured polymers, and this is a subject of much debate. Among the criteria that could be used to accept or reject a material as dietary fiber, only 'edible plant cell wall' is specific enough to allow an absolute definition. In addition, it links current dietary fiber definitions to the original 'dietary fiber concept,' which recognized that a diet high in minimally processed edible plant foods provided many health benefits. Confusion often arises because of the overlapping characteristics and physiological effects of the different 'candidate' materials with those of a dietary fiber 'reference.' Examples of 'candidates' are polydextrose (a randomly bonded synthetic glucose polymer), inulin and fructooligosaccharides (naturally occurring glucose–fructose oligomers and polymers), and resistant starch (formed by food processing methods and largely undigested in the small intestine). This overlapping means that it becomes virtually impossible to distinguish between fiber and nonfiber material based on resistance to digestion alone. Debates such as this started shortly after dietary fiber became popular in the 1970s. They are still ongoing, as demonstrated by the publication of a recent international survey of 147 professionals. While a complete discussion of the merits of either side is beyond the scope of this article, it is important to remember the origins of the dietary fiber definition and the dietary fiber hypothesis that firmly linked fiber to physiological outcome.

The definition of dietary fiber was first centered on the 'original dietary fiber concept' that linked the consumption of 'plant cell walls' in unrefined, traditional foods to positive physiological outcomes. Table 5 shows two definitions that were proposed after the turn of the millennium. These two definitions have taken the original ideas of the dietary fiber hypothesis into account and included a reference to some specific physiological effects in humans.

While the newer definitions of dietary fiber specifically mention the fact that dietary fiber has physiological benefits, the list is rather specific and deals primarily with effects observed with viscous fibers (lowering postprandial serum glucose and lowering serum cholesterol) or effects brought about from partial fermentation and water-holding capacity (laxation). These effects are well supported by clinical experiments with laboratory animals and with humans. However, the original dietary fiber concept related dietary fiber intake to the diseases of Western man, including heart disease, cancer, and obesity. As mentioned earlier, the link between viscous dietary fiber and heart disease is supported in the literature through its effect on serum cholesterol and triglycerides, but the link with other Western diseases has been much harder to demonstrate. It has been well established that eating patterns that favor foods high in dietary fiber and low in red meat significantly reduce the risk of cancer, heart disease, and obesity. However, it has been relatively difficult to isolate this effect to dietary fiber consumption per se. Part of the problem comes from the almost exclusive reliance on epidemiological studies to demonstrate any association. There are several reasons why epidemiological studies are generally favored. First, these studies provide data on free-living humans, rather than inbred laboratory animals. Second, these studies follow the long-term effect of dietary fiber consumption on health outcomes. Third, the sample size can vary from a few hundred (case control studies) to many thousands of individuals (prospective cohort studies). This gives the studies good statistical power and lends weight to the conclusions. However, epidemiological studies also suffer from a number of shortcomings including problems with assessing food intake for the past 2–3 years (case control studies) or with monitoring food intake 2–3 times over a period of 5 years and using this to predict disease outcome 15 years later (prospective cohort studies), problems that arise from the use of incomplete dietary tables to calculate dietary fiber intake, and problems arising from the use of inappropriate methods for correcting energy intake.

The most striking conclusion from epidemiological studies is a failure to provide support for an inverse correlation between dietary fiber intake and colon cancer. This concept has long been entrenched in the literature largely because of studies with laboratory animals that have provided much data in favor of a protective effect of dietary fiber. The animal studies are supported by plausible physiological and biochemical mechanisms that can account for the observed results. However, the epidemiological data are inconsistent in its support for an inverse relationship between colon cancer and dietary fiber intake, and clinical trials that examined the effect

of diet on the reappearance of colon polyps (colon cell growths that have a 1/20 chance of forming a cancerous tumor) found no protective effect of dietary fiber. Even though the link between adenomatous polyps and cancer is not straightforward, these studies show that more research is needed to elucidate the relationship between the known physiological benefits of dietary fiber and cancer.

Sources of Dietary Fiber

The TDF content of a food depends on many factors, including (1) the plant variety, (2) the stage of maturity when harvested, (3) the plant-growing conditions, and (4) the method of food preparation. Although not all the methodological issues have been completely resolved with respect to measuring dietary fiber, there is now general consensus on the TDF content for a majority of foods.

The names of 49 common dietary fiber sources are provided in Table 6. The foods are classified according to their TDF content expressed on an 'as is' basis. Since some methodological variability is inevitable, the letters 'E,' 'M,' and 'P' in the right-hand column designate which methods would give TDF values in the range shown. Other methods not included in the comparison are likely to agree with these values. The letter 'E' refers to NSPs as measured by the Englyst GLC procedure and includes a lignin value measured separately with potassium permanganate. The letter 'M' refers to the Mongeau rapid method, and the letter 'P' refers to the Prosky method. The last two methods are gravimetric and include lignin in the final determination. Table 6 shows a considerable agreement between methodologies: 33 of 49 foods are designated 'EMP,' meaning that all three methods give similar values. In addition, three foods are designated 'MP' and 13 foods 'M' only because sample size limitations precluded measurement with other methods. The TDF values are based on winter and summer collections of up to 20 individual foods over 30 months in different locations.

Table 6 Sources of dietary fiber

TDF[a]	*Foods*	*Methods*[b]
0.1–0.5	White rice, cooked	M
	Orange juice from concentrate	M
0.6–0.9	Lettuce	M
	Cucumbers	EMP
	Pineapple, melons (cantaloupe)	EMP
1.0–2.2	White bead	EMP
	Corn kernel (canned), potatoes (boiled), green beans (boiled), cabbage (raw), celery (raw), onion (cooked), green peppers (raw)	EMP
	Cauliflower (cooked), tomatoes	M
	Apple, bananas, orange, pears, strawberries, cherries, grapefruit, plums	EMP
	Apple pie, blueberry pie, pasta (cooked)	M
2.3–3.0	Rye bread	M
	Mushroom ($E = 2.0$)	MP
	Beets (canned), rutabaga (raw), carrots (raw), broccoli (raw)	EMP
	Blueberries ($E = 1.9$)	MP
3.1–4.3	Brown rice	EMP
	Raisins (seedless)	M
4.4–6.4	Bran muffins, wheat cereal, wholemeal bread	EMP
	White beans (baked)	EMP
	Kidney beans (baked), peanut butter	M
6.5–7.3	Peanuts	EMP
	Green peas (boiled)	M
8.0–9.3	Oatmeal cereal	EMP
9.4–10.3	Shredded wheat	EMP
12.3–13.1	Bran flakes	EMP
15.5–15.8	Oat bran	EMP
40.6–40.9	AACC hard wheat bran ($E = 36.4$)	MP

[a]TDF, total dietary fiber range in grams per 100 g on an 'as is' basis.
[b]Methods: E, Englyst GLC method plus potassium permanganate lignin; M, Mongeau rapid gravimetric method; and P, Prosky gravimetric method.
Source: Mongeau, R. and Brassard, R. (1989). A comparison of three methods for analyzing dietary fiber in 38 foods. *Journal of Food Composition and Analysis* **2**, 189–199; Mongeau, R., Brassard, R. and Verdier, P. (1989). Measurement of dietary fiber in a total diet study. *Journal of Food Composition and Analysis* **2**, 317–326.

Most fruits and vegetables contain low amounts of dietary fiber (1.0–2.2% TDF) on an 'as is' basis. Legumes contain intermediate amounts of dietary fiber (around 4% TDF), and cereals contain between 1–2.2% TDF (corn kernels) and 15.5–15.8% TDF (oat bran). The dietary fiber content of foods is greatly influenced by the moisture content. Thus, cereal TDF values are high because these foods contain little moisture (up to 10% at most), whereas fruits and vegetables contain 80–90% moisture on an 'as is' basis. The values of Table 6 are reported as a percentage of weight, but when calculating dietary fiber intake, it is important to factor in the serving size (30 g for breakfast cereals, 50 g for lettuce and raisins, and 125 g for vegetables and fruits). For example, 1 serving of bran flakes will provide ~4 g of dietary fiber, 1 serving of lettuce will provide 0.35 g of TDF, 1 serving of raisins will provide about 1.8 g of TDF, and 1 serving of corn will provide about 2 g of TDF.

How to Build the 'Perfect Diet'?: A Methodological Approach

From the era of the 'fathers' of medicine, like Aesculapius, a large attention has been given to a correct diet as the best way to maintain health. During the last century, we have sampled many data on diets or specific diet components that could have positive or deleterious effects on health. Nevertheless, what kinds of data are available?

Preclinical Data

Preclinical data are those derived from test performed in cellular models or in animals. They are usually carried out on single components of the diet or of a nutrient and furnish information on the pharmacological activities of foods or food components. Even if the obtained results are usually of scientific interest, the proposed models do not adequately represent the complexity of human diets and human metabolism, so they can only constitute a basis for further research on humans.

Epidemiological Data

Epidemiological data relate the assumption of specific dietary components or specific dietary patterns with the risk of developing a disease. They are actually the milestones on which we built dietary guidelines and furnish dietary advices. They are particularly relevant when obtained from large population samples followed up for years with a standardized methodology. The main limitations of epidemiological data are the following:

- They are population-specific: It is not immediately true that a protective habit for a population is also protective for a different one because other factors could be involved, such as other dietary components, physical activity, environment, and genetics/genomics. Moreover, the dietary questionnaires used in various studies are frequently different, and they are not always validated in different populations.
- They are usually 'old': During the time in which the study is carried out (from years to decades) and the data are analyzed, the dietary and behavioral habits of the population could have changed. A typical example is the one of the Mediterranean diet, codified on the basis of the southern Italian habits in the 1950s, which are totally different from the current ones.
- They are usually related to a lifelong exposition to a specific diet or diet components. Nonetheless, observing that the lifetime exposition to a diet component seems to be protective against the development of a given disease does not immediately mean that it will be protective when introduced/increased in the diet starting from the middle or old age.

Clinical Data

Data derived from clinical trials represent the best source of evidence. They clearly show how changing a diet pattern or increasing/reducing a specific diet component is associated with a modification of biological parameters (usually a laboratory or instrumental biomarker) in humans. The main limitations of clinical trials are the large number of concomitant parameters to be controlled (both in the diet and outside the diet) and the lack of long-term large trials with hard outcomes (morbidity or mortality).

Systematic Reviews/Meta-analyses/Metaregressions

Finally, we could 'cumulate' the evidence derived from epidemiological studies or clinical trials in order to obtain a general conclusion on a specific dietary exposition or intervention on specific parameters of human health. These analyses, when available, usually constitute the basis for new guidelines, even if their value could not be absolute for the single subject or a specific subpopulation. Then, their conclusion does not always reflect a final answer to a scientific question, especially when the available trials are strongly heterogeneous as it regards design, number, and kind of subjects enrolled and other study characteristics. Thus, from all these data, we still have no definitive idea about the 'perfect diet' to be adopted by the general population in order to conduct a healthy and prolonged life, but we can highlight some milestones.

General Rules for the General Population

Large-scale unfocused interventions on lifestyle habits have been proved to be needed but hardly cost-effective. The best way to plan dietary suggestions in order to improve the global health of a whole population, apart from the individual needs, is to attentively detect, between the most recent scientific literature, the most evidence-based milestones of a healthy diet and healthy lifestyle, avoiding in particular to focus on intermediate outcomes, but rather concentrating on morbidity and mortality. Moreover, the suggestions have to be as short, clear, and simple as possible, feasible by the subjects, and possibly transversally useful to prevent the most common chronic diseases in a population. To do this, a possible way consists on focusing our attention on the results of the largest available systematic reviews and meta-analyses.

Overall, the main recent meta-analysis of clinical data suggests the following:

- Water is a milestone of a healthy diet.
- Any excessive energy intake has to be avoided: Since preclinical data show that a mildly reduced energy intake is per se associated with an increased life span, an adequate

energy intake is probably overall more relevant than any other dietary indications.

- Increased sodium intake was associated with an increased risk of stroke (~25%), stroke mortality (~60%), and coronary heart disease mortality (~30%).
- A diet with a low glycemic index (GI) and glycemic load (GL) is associated with a reduced risk of developing type 2 diabetes (T2D) and coronary heart disease (CHD). In particular, the risk of developing T2D is 33% higher in subjects in the highest quintile of energy-adjusted GI than those in the lowest one. Participants who consume a combination diet high in GI or GL and low in cereal fiber have an ~50% higher risk of T2D. GL appears to be more relevant than GI in increasing the risk of CHD (~50%) and stroke (~20%) in a dose-dependent manner.
- Overall, nonrigid vegetarian diets (neither vegan nor fruitarian) are associated with a lower risk of developing cardiovascular diseases, cancers, and autoimmune diseases.
- A diet rich in cereal and vegetable fiber is associated with a dose-dependent reduction of developing cardiovascular disease (~9% per 7 g per day) and various gastrointestinal (~10–40% per 10 g per day) and some nongastrointestinal cancers. The total intake of fruit and vegetables had a negative association with risk of asthma in adults and children (~45%).
- Red meat is per se not significantly associated with total or cause-specific mortality; conversely, the intake of processed meat was associated with a 30% higher rate of cardiovascular disease (per 50 g per day) and higher cancer mortality. Preservatives are the notable difference; the calculated blood-pressure effects of sodium differences (~400% higher in processed meats) explain most of the observed higher risk. ~3% of deaths could be prevented if all participants had a processed meat consumption of less than 20 g per day. Moreover, increasing the intake of red meat of more than 0.50 servings per day is associated with an increased risk of developing T2D of ~55% while reducing the intake of the same amount leads to a decreased risk of ~15%.
- The highest category of fish consumption (i.e., $\geq$4 times per week) is associated with the greatest risk reduction in CHD (~20%). In dose-response analysis, each additional 100 g serving of fish per week was associated with an ~5% reduced risk.
- There is a linear association of consumption of total dairy products, low-fat dairy products, cheese, and yogurt and the risk of T2D. The relative risk reduction is ~5% and ~10% for 200 g per day total and low-fat dairy consumption, respectively. The relative risk reduction is ~20% and ~10% for 30 gper day cheese and 50 g per day yogurt consumption, respectively.
- Dietary consumption of saturated fatty acids and cholesterol is not significantly associated with an increase in cardiovascular disease risk, if not because usually assumed with high-energy diet.
- Extreme quintiles of total trans fatty acid intake (3–10 g per day) are associated with an increased risk of ~20% of CHD and ~25% of fatal CHD.
- The consumption of nuts is inversely associated with fatal CHD (~25% less risk), nonfatal CHD (~20% less risk), and T2D (~10% less risk).
- Coffee intake is associated with a lower risk of mortality for every cause (high vs low category of coffee consumption: RR = 0.86). In particular, this seems to be related to a reduction in the risk of developing cardiovascular disease, T2D, and some cancers too. Moreover, coffee consumption seems associated with a lower risk of developing seropositive rheumatoid arthritis, urolithiasis, and Parkinson's disease.
- High-quality chocolate intake is associated with a reduced risk of developing stroke of ~20%.
- Low alcohol intake (from every source, not necessarily from red wine) is associated with a reduced risk of CHD (~20%), total stroke (~15%), ischemic stroke (~20%), and stroke mortality (~30%), but heavy alcohol intake is associated with an increased risk of total stroke (~20%). Moreover, compared with lifetime abstainers, the RR for T2D among men is most protective when consuming 22 g per day alcohol and becomes deleterious at just over 60 g per day alcohol. Among women, consumption of 24 g per day alcohol is most protective and becomes deleterious at about 50 g per day alcohol. Furthermore, low alcohol intake also seems to be associated with a lower risk of developing rheumatoid arthritis, urolithiasis, and Parkinson's disease. However, even a low alcohol intake is a risk factor for (among others) gout, atrial fibrillation, colorectal adenoma development, and upper aerodigestive tract cancer mortality.
- Potassium intake is associated with a reduced risk of developing stroke (~20%).
- Dietary magnesium (per 200 mg per day increment) is associated with a 22% lower risk of CHD. The association of dietary magnesium with fatal CHD is nonlinear, with an inverse association observed up to a threshold of ~250 mg per day, compared with lower intakes.
- For total calcium intake, each 300 mg per day increase is associated with an approximately 8% reduced risk of colon cancer. For supplementary calcium, each 300 mg per day increase is associated with a 9% reduced risk of colon cancer.

Overall, the available evidence suggests that a complete balanced 'Mediterranean-like' antioxidant and anti-inflammatory diet, mainly based on fresh vegetables and whole-grain carbohydrates (nearly vegetarian, not necessarily vegan), should be advised to most of the people in order to preserve and promote their health (Box 1). Most of the successful diets (Mediterranean, Asian, Atkins, and zone/dissociated) are low-

Box 1 Milestones of a Healthy Diet

- Total energy intake proportional to physical activity
- Low salt intake
- Carbohydrates with low glycemic index as the main source of energy
- Very low intake of simple sugars
- Large intake of water, fresh vegetables, legumes, and berries
- Fish and nuts and moderate amount of nonprocessed meat
- Moderate doses of dairy products (preferably fermented, rich in probiotics, and low-fat)
- Coffee, high-quality dark chocolate, and low quantity of alcohol (from either wine or beer) not forbidden

energy diets fundamentally based on these principles. Low-carb/high-protein diet could be considered for a short period in selected overall healthy subjects to reduce body weight and related cardiovascular risk factors, but then, a standard balanced diet has to be recovered as soon as possible. Extreme diets (high protein, vegan, etc.) have to be avoided, especially on the long term for the risk of developing deficit of intakes (for instance, of essential amino acids and some vitamins) or excessive intakes (for instance, of nonessential amino acids) of specific micro- and macronutrients.

Finally, all the potential suggestions previously reported increase their potential effect on global health if associated with a strong message on dramatic reduction of active and passive exposition to cigarette smoking and on an improvement of everyday physical activity amount.

The main advantage of this approach is that the same lifestyle suggestions seem to be useful to reduce the risk of cardiovascular disease, obesity, type 2 diabetes, nonalcoholic liver fatty acids, age-related degenerative maculopathy, the most frequent cancers, some degenerative neurological diseases, and rheumatologic diseases.

A factor that has to be considered is that a healthy diet is often slightly but significantly more expensive than an unhealthy diet, so, when formulating suggestions, the availability of the foods and their cost always have to be kept in mind. For instance, even if Asian goji berries have a very high antioxidant power, it is nonsense to recommend their consumption in Europe, where various much less expensive berries with high antioxidant power are available.

It is also relevant to remember that some of the previously reported suggestions do not count for every subject. For instance, obese, diabetics, hypertriglyceridemics, and patients affected by hyperuricemia have to consume fruits in moderation since they are a relevant source of energy and induce the synthesis of uric acid.

Another factor to be considered is the modality of cooking. Some foods (in particular, vegetables) have not to be cooked in order not to lose vitamins and minerals. The best ways to cook are with steam or on hot stones, less salting, boiling, or baking. Pasta and rice have to be boiled just the time to make them chewable (slightly underdone), but not overcooked, in order not to increase their glycemic index. Salt has to be limited at minimum and possibly substituted with spices (e.g., pepper, chili, and aromatic herbs), lemon juice, or vinegar. Vegetable oils (preferably extra virgin olive oil, less sunflower oil, corn oil, or rice oil), rich in n-6 fatty acids, which can be useful in the prevention of cardiovascular disease, have to be used without reaching their smoking point, that is, before they are peroxidized. Anyway, even though they are 'healthy,' vegetable oils constitute a relevant source of energy and thus have to be consumed in moderation. Animal fats have to be avoided; however, they are always preferable than modified trans-hydrogenated fats.

The Individual Approach

Mind over Food and Eating Disorders

If we only had our core systems such as the brain stem and hypothalamus, we would not probably have many of the problems linked to food, such as obesity and related diseases or eating disorders. The communication between the internal system of fuel availability and the hypothalamus, where hunger and the satiety centers are located, is regulated by a homeostatic control system through hormones capable of crossing the blood–brain barrier. In this way hunger, satiety, metabolic functions, and fat reserves are adjusted in the short and long terms.

The main molecules involved in homeostatic control are *leptin* and *adiponectin* (produced by the adipose tissue), *ghrelin* (produced by the stomach), *peptide YY* (produced by the intestinal cells), and *neuropeptide Y* and *agouti-related protein* (produced by the hypothalamus), where ghrelin and neuropeptide Y stimulate the appetite, while leptin and peptide YY inhibit the appetite.

With respect to cardiovascular disease risk, adiponectin is a 'good' adipokine due to its anti-inflammatory, antiatherogenic, antidiabetic, and cardioprotective effects and the promotion of good endothelial function. Leptin, on the contrary, could be considered a 'bad' adipokine given that it promotes insulin resistance, high blood pressure, atherosclerosis, MI risk, vascular inflammation, VSMC hypertrophy and proliferation, oxidative stress, and endothelial dysfunction.

Our modern lifestyle puts pressure on the homeostatic system. Many factors such as stress, anxiety, depression, and nervousness could influence our body weight. Palatable food high in fat, sugar, and salt can increase dopamine in the subcortical mesolimbic system (the ventral tegmental area, nucleus accumbens, amygdala, and hippocampus). This generates an intense pleasure and can corrupt neural functions of the brain system involved in hedonic, motivational, and cognitive processing. For this reason, it has been suggested that there is a possibility for the development of a food addiction. Further studies are needed to better describe these mechanisms and to understand how to utilize the modern neuromarketing to promote the consumption of healthy food.

An abnormal relationship with food can result in an *eating disorder* (ED). The main consequences of EDs are malnutrition, obesity, a worse quality of life due to the obsessive thoughts related to food, and increased mortality. They are commonly rare in the general population; the prevalence of all EDs is about 5%. Patients who suffer from an ED tend to deny the disease and avoid treatment. The derivation of EDs is psychological. The causes could be genetic or they could derive from other pathologies such as anxiety, depression, and alcoholism. The Diagnostic and Statistical Manual of Mental Disorders (5th edition) distinguishes EDs as anorexia nervosa and bulimia nervosa, which are common in adolescent women; binge eating disorders typical in men and adults; and not otherwise specified EDs. The therapy for EDs consists in a team treatment carried out by different professionals: psychiatrists, psychologists, nutritionists, nurses, and other medical professionals. The nutritional rehabilitation of an ED should provide a gradual modification of eating habits. The expectation is often not a complete cure, rather the improvement of the nutritional status and the quality of life of the individual.

Clinical Nutrition and Morbidities

Many diseases require a personalized nutrition for their care. The diet thus becomes an integral part of the therapy. If you

think you are suffering from one of these conditions, you should contact medical professionals and a nutritionist.

Overweight and obesity

The key *strong recommendations* for overweight and obesity recently published in the *Journal of the American College of Cardiology* are as follows:

- Advising overweight and obese individuals who would benefit from weight loss to participate for ≥ 6 months in a comprehensive lifestyle program that assists participants in adhering to a lower calorie diet and increasing physical activity through the use of behavioral strategies
- Prescribing on-site, high-intensity (i.e., ≥ 14 sessions in 6 months) comprehensive weight loss intervention
- Using a very-low-calorie diet (≤ 800 kcal day^{-1}) only in limited circumstances where a medical supervisor is required
- Advising overweight and obese individuals who have lost weight to participate in a long-term (≥ 1 year) comprehensive weight loss maintenance program

Cardiovascular disease and dyslipidemia

In order to lower the levels of total cholesterol and LDL cholesterol in heart diseases, the *American College of Cardiology* and the *American Heart Association* recommend normalizing body weight and reducing the consumption of saturated fats, cholesterol, and trans fats. Saturated fats are found primarily in dairy products, meats, and certain oils (coconut and palm oils). Trans fats are found in many snacks and fried foods and are listed on labels as 'partially hydrogenated oils.' The intake of soy protein and functional foods rich in phytosterols could play a positive role in reducing heart diseases. In order to lower triglycerides, it is useful to reduce the consumption of alcohol, simple sugars, and carbohydrates. Finally, a rise in unsaturated fats and constant physical activity could help increase our HDL cholesterol levels. However, in our attempts to cut 'bad fats,' we should be careful not to increase the intake of other potentially dangerous nutrients, such as sugars. Heart health is also linked to the adequate introduction of protective foods, such as fruits and vegetables, recommended by the World Health Organization in an amount of 400 g per person per day. Cholesterolemia being strongly genetically determined, recent guidelines also suggest to include in the everyday diet some specific nutraceuticals and functional foods in order to further reduce the LDL cholesterol plasma levels.

Diabetes

The *American Diabetes Association* recognizes the integral role of nutrition therapy in overall diabetes management. For individuals with type 1 diabetes, participation in an intensive flexible insulin therapy education program, using the carbohydrate counting meal planning approach, can result in improved glycemic control. A simple diabetes meal planning approach, such as portion control or healthy food choices, may be better suited for individuals with type 2 diabetes. In summary, people with diabetes should

- limit or avoid the intake of sugar-sweetened beverages;
- reduce sodium to less than 2300 mg per day, with additional reductions individualized for those who have a high blood pressure;
- eat fatty fish at least 2 times (two servings) per week (they do not benefit from the use of omega-3 (EPA/DHA) supplements for the prevention or treatment of cardiovascular diseases);
- not use vitamin or mineral supplements without proved deficiencies (additionally, there is no evidence supporting the use of cinnamon or other supplements).

Food allergies and food intolerances

Whereas a food allergy causes an immune system reaction, a food intolerance does not. In some cases, an allergic reaction to food can be serious, even deadly. Food intolerance symptoms generally appear gradually and are limited to gastrointestinal effects, whereas food allergy symptoms are more severe. If you have a food allergy, you will need to avoid the allergenic food completely. If you have a food intolerance, you may generally be able to eat a small amount of the food in question. *Lactose intolerance* is a common example of an enzymatic intolerance, which is due to a lack of lactase needed to digest lactose. *Celiac disease* is a permanent intolerance to gluten, a protein found in oats, wheat, spelled, Kamut®, barley, and rye. Indeed, the consumption of gluten, also in small quantities, can cause several more or less serious consequences. The *nonceliac gluten sensitivity* is today a still poorly defined condition. The aim of the scientific community is to test and find a definition of the specific markers and precise diagnostic criteria.

Inflammatory bowel diseases

Patients with inflammatory bowel diseases (IBDs) should generally avoid foods that worsen symptoms, eat smaller meals in frequent intervals, drink adequate fluids, and avoid caffeine and alcohol. IBD patients should eliminate dairy if they are lactose-intolerant, limit excess fat, reduce simple carbohydrates, and reduce high-fiber foods during the inflammatory phase.

Chronic kidney disease

People with a chronic kidney disease (CKD) need to make changes to their diet such as limiting fluids; eating a low-protein diet; limiting sodium, potassium, phosphorous, and other electrolytes; and paying attention to malnutrition. The diet can be changed if the kidney disease worsens and during dialysis.

Neurodegenerative diseases

Neurodegenerative diseases (NDs) are hereditary and sporadic conditions, characterized by a progressive nervous system dysfunction. They include Alzheimer's disease and other dementias, such as Parkinson's disease. The following guidelines suggest how to prevent and delay the symptoms:

- The intake of saturated fats and trans fats should be reduced to the lowest amount possible.
- Vegetables, legumes, fruits, and whole grains should replace meats and dairy products.
- Vitamin E should come from foods, rather than from supplements.
- A reliable source of vitamin B_{12} should be part of one's daily diet.

- If using multiple vitamins, choose those without iron and copper and consume iron supplements only when directed by your physician.
- Those who desire to minimize exposure to aluminum should avoid the use of cookware, baking powder, or other products that contain aluminum.
- Aerobic exercise should be included in an individual's routine.

Conclusion

A global healthy diet associated with a healthy lifestyle is advisable for the general population and has to be founded on some basic suggestions. The assumption of fresh foods, without the addition of salt, in amounts proportional to the energy expenditure, would be sufficient to prevent the largest part of chronic diseases in Western countries. Only subjects with specific diseases or characteristics should have a structured individual diet support.

Introduction

Dietary reference intakes (DRIs) are a set of nutrient-based reference values that provide quantitative recommendations by gender, age, life stage, or physiological condition (such as pregnancy or lactation) for nutrient intakes of individuals living in the United States and Canada. The reference values include the estimated average intake (EAR), the recommended dietary allowance (RDA), the adequate intake (AI), the tolerable upper intake level (UL), and, for energy providing nutrients, the acceptable macronutrient distribution range (AMDR). DRIs provide nutrient standards that are used to shape various public policies, such as nutrient standards for school lunch programs, congregate and delivered elderly meal programs, and guidelines for the women, infants, and children supplemental feeding program. The DRIs are the basis for developing dietary advice for patients requiring medical nutrition therapy and to establish the daily values displayed on the nutrition fact panels of packaged food and supplements. They are the foundation for formulating the Dietary Guidelines for Americans.

History

The DRIs replaced the RDA, a nutrient standard used in the United States from 1941 to 1989 and a similar Canadian standard. These newer values were developed because of changes in science, limitations of the existing RDA, and the need to consider the role of nutrients in preventing dietary deficiency diseases as well as their associations with diet-related chronic degenerative diseases and toxicities. Starting in 1994, expert committees examined the scientific data on requirements of nutrients for these functions. The Standing Committee on the Scientific Evaluation of DRIs coordinated the effort under the direction of the Food and Nutrition Board, Institute of Medicine (IOM) of the National Academy of Sciences, and Health Canada.

Indicators Used to Establish DRIs

Many possible functional indicators and health outcomes exist and are examined by the DRI committees, including chronic disease indicators. The DRIs are based on the relationship between a nutrient and a single functional indicator of the health outcome of interest. These functional indicators may involve intake of a nutrient such as vitamin D and a status biomarker such as 25-OH-D of known sufficiency for bone health outcomes. Alternatively, for other nutrients such as ascorbic acid, the functional biomarker is a plasma ascorbic acid level above the threshold, 0.2 mg dl^{-1}, which is adequate to prevent scurvy. For example, night blindness is associated with vitamin A deficiency and its prevention is a desirable health outcome. The ability of the retina to adapt to dim light depends on AIs of vitamin A (retinal). It plays an important role in rod function during dim light. Without an adequate retinal supply, the functions of the rods become compromised in dim light settings, and if chronic vitamin A deficiency occurs, it can result in night blindness.

Definitions of DRIs

Table 1 summarizes definitions of the DRIs. After the choice of a criterion for nutrient adequacy is established, the existing experimental data are analyzed and summarized. The estimated average requirement (EAR) is the amount of a nutrient that meets the requirement of a specific criterion of adequacy (as determined by the functional indicator) for half of the healthy individuals within a defined age, gender, and life stage. There must be enough scientific evidence available to set an EAR for a nutrient and to calculate an RDA. The RDA is the average daily dietary intake that meets the nutrient requirements of nearly all healthy individuals of a specific age, gender, life stage, or physiological condition for the outcome of interest. If the statistical distribution of the amounts of nutrient intake needed to achieve the EAR, for example, the desired level of the functional indicator for the specific population, is determined to be normal (Gaussian) (Figures 1 and 2), and the standard deviation (SD) can be determined, then the following calculation is used:

$$\mathrm{RDA} = \mathrm{EAR} + 2 \times \mathrm{SD}$$

When there are insufficient data or variability in order to calculate an SD for the nutrient, a symmetrical distribution is assumed and then a coefficient of variation (CV) of 10% EAR is usually used. The calculation then becomes

$$\mathrm{RDA} = \mathrm{EAR} + 2 \times \mathrm{CV} \text{ or } \mathrm{EAR} + 2(0.1 \times \mathrm{EAR})$$

Note: the CV is usually set at 10% unless variability is known to be greater.

When nutrient requirements are not normally distributed, as, for example, is the case for iron, then statistical transformation of the data is required before the EAR and RDA are set.

When insufficient evidence is available to determine an EAR and RDA, then an AI is derived to provide an intake recommendation. The AI is a recommended daily intake of a nutrient that is based on observational and experimental data or observations of average intakes of a group or groups of presumably healthy people. The AI represents an informed decision about what seems to be an appropriate intake for an individual based primarily on epidemiological rather than an experimentally determined value and it should be used more cautiously than the RDA.

Table 1 Terms used in US reference standards

Term	*Definition*
Estimated average requirement (EAR)	The amount of an individual nutrient that meets the requirement for a specific criterion of adequacy for half of the healthy individuals within a defined age, gender, or life stage
Recommended dietary allowance (RDA)	The average daily dietary intake level that meets the nutrient requirement of nearly all healthy individuals of a specific age, gender, life stage, or physiological condition
Adequate intake (AI)	The nutrient intake amount that is set when decisive data on the requirement are lacking in order to set an EAR and RDA
Tolerable upper intake level (UL)	The highest level of daily nutrient intake that is likely to pose no risk of adverse health effect to almost all individuals
Acceptable macronutrient distribution range (AMDR)	A range of intakes for macronutrients expressed as the proportion of total energy intake that is associated with chronic disease reduction and provides adequate amounts of the nutrient while maintaining energy balance
Estimated energy requirement (EER)	The requirement for energy of healthy adults with a body mass index (BMI) in the normal range of 18.5 and 25
Total energy expenditure (TEE)	Set of equations that estimate the energy expenditure needed to maintain current body weight and activity levels

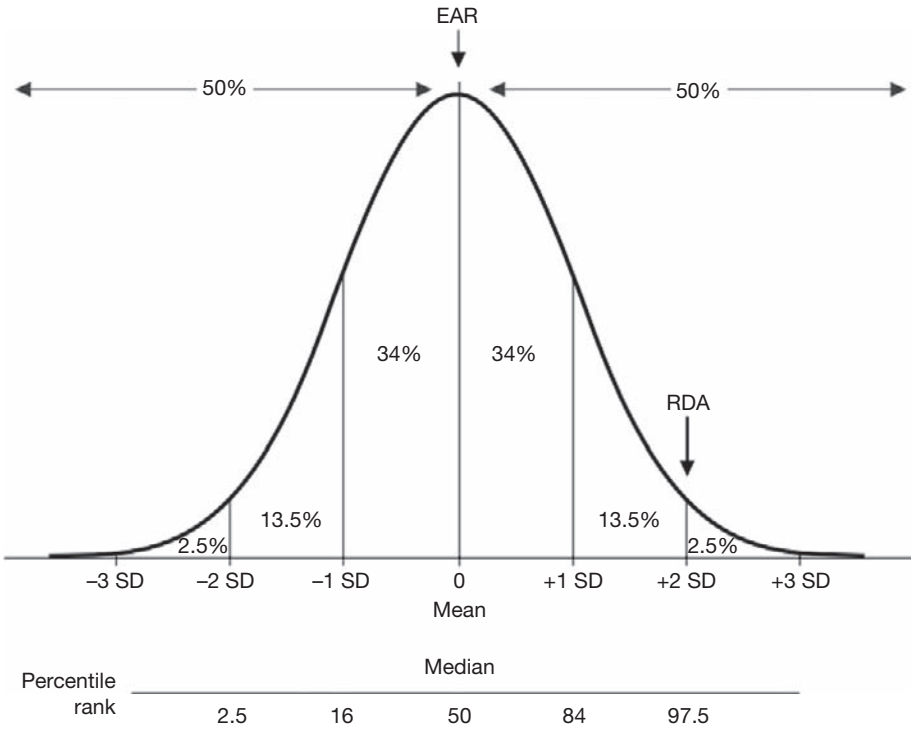

Figure 1 The normal distribution of a nutrient requirement and placement of the EAR and RDA. Reprinted with permission from *Dietary reference intakes: the essential guide to nutrient requirements*, 2006 by the National Academy of Sciences, courtesy of the National Academies Press, Washington, DC.

Table 2 presents the RDA and AI for vitamins, and Table 3 presents the same values for mineral elements. Table 4 presents the RDA and AI for total water and macronutrients.

Little experimental data are available on nutrient requirements for children, and thus, the EAR, RDA, and UL are based on extrapolations from adult values. For setting an EAR, the extrapolations for infants include scaling down the requirements by a specified power to adjust for metabolic differences or adjustments based upon reference body weights. The AIs are estimated by observing the amounts of nutrients eaten by healthy infants or children.

The AMDR provides acceptable high and low limits of protein, carbohydrate, and fat ($n-6$ and $n-3$ polyunsaturated fatty acids) expressed as percent of energy needs. It is based on some intervention trials but primarily on epidemiological studies indicating that an imbalance in macronutrients can increase risk of several diet-related chronic degenerative diseases including coronary heart disease, obesity, type 2 diabetes, and some cancers. Table 5 presents the AMDRs. One of the key features of the AMDR is that it gives an upper- and lower-level boundary for the range since there is an increased risk resulting from chronic intakes both above and below it. Note that the

Note: This table (taken from the DRI reports; see www.nap.edu) presents recommended dietary allowances (RDAs) in **bold type** and adequate intakes (AIs) in ordinary type followed by an asterisk (*). An RDA is the average daily dietary intake level, sufficient to meet the nutrient requirements of nearly all (97–98%) healthy individuals in a group. It is calculated from an estimated average requirement (EAR). If sufficient scientific evidence is not available to establish an EAR, and thus calculate an RDA, an AI is usually developed. For healthy breastfed infants, an AI is the mean intake. The AI for other life stages and gender groups is believed to cover the needs of all healthy individuals in the groups, but the lack of data or uncertainty in the data prevents one from specifying with confidence the percentage of individuals covered by this intake.

[a]As retinol activity equivalents (RAEs). 1 RAE = 1 μg retinol, 12 μg β-carotene, 24 μg α-carotene, or 24 μg β-cryptoxanthin. The RAE for dietary provitamin A carotenoids is twofold greater than retinol equivalent (RE), whereas the RAE for preformed vitamin A is the same as the RE.

[b]As cholecalciferol. 1 μg cholecalciferol = 40 IU vitamin D.

[c]Under the assumption of minimal sunlight.

[d]As α-tocopherol. α-tocopherol includes *RRR*-α-tocopherol, the only form of α-tocopherol that occurs naturally in foods, and the *2R*-stereoisomeric forms (*RRR*-, *RSR*-, *RRS*-, and *RSS*-α-tocopherol) that occur in fortified foods and supplements. It does not include the *2S*-stereoisomeric forms (*SRR*-, *SSR*-, *SRS*-, and *SSS*-α-tocopherol), also found in fortified foods and supplements.

[e]As niacin equivalents (NE). 1 mg of niacin = 60 mg of tryptophan; 0–6 months = preformed niacin (not NE).

[f]As dietary folate equivalents (DFE). 1 DFE = 1 μg food folate = 0.6 μg of folic acid from fortified food or as a supplement consumed with food = 0.5 μg of a supplement taken on an empty stomach.

[g]Although AIs have been set for choline, there are few data to assess whether a dietary supply of choline is needed at all stages of the life cycle, and it may be that the choline requirement can be met by endogenous synthesis at some of these stages.

[h]Because 10–30% of older people may malabsorb food-bound B_{12}, it is advisable for those older than 50 years to meet their RDA mainly by consuming foods fortified with B_{12} or a supplement containing B_{12}.

[i]In view of evidence linking folate intake with neural tube defects in the fetus, it is recommended that all women capable of becoming pregnant consume 400 μg from supplements or fortified foods in addition to intake of food folate from a varied diet.

[j]It is assumed that women will continue consuming 400 μg from supplements or fortified food until their pregnancy is confirmed and they enter prenatal care, which ordinarily occurs after the end of the periconceptional period – the critical time for formation of the neural tube.

Note: This table (taken from the DRI reports; see www.nap.edu) presents recommended dietary allowances (RDAs) in **bold type** and adequate intakes (AIs) in ordinary type followed by an asterisk (*). An RDA is the average daily dietary intake level, sufficient to meet the nutrient requirements of nearly all (97–98%) healthy individuals in a group. It is calculated from an estimated average requirement (EAR). If sufficient scientific evidence is not available to establish an EAR, and thus calculate an RDA, an AI is usually developed. For healthy breastfed infants, an AI is the mean intake. The AI for other life stages and gender groups is believed to cover the needs of all healthy individuals in the groups, but the lack of data or uncertainty in the data prevents one from specifying with confidence the percentage of individuals covered by this intake.

Table 5 Dietary reference intakes (DRIs): acceptable macronutrient distribution ranges (Food and Nutrition Board, Institute of Medicine, National Academies)

	Range (percent of energy)		
Macronutrient	*Children, 1–3 years*	*Children, 4–18 years*	*Adults*
Fat	30–40	25–35	20–35
n−6 polyunsaturated fatty acids[a] (linoleic acid)	5–10	5–10	5–10
n−3 polyunsaturated fatty acids[a] (α-linolenic acid)	0.6–1.2	0.6–1.2	0.6–1.2
Carbohydrate	45–65	45–65	45–65
Protein	5–20	10–30	10–35

Macronutrient	*Recommendation*
Dietary cholesterol	As low as possible while consuming a nutritionally adequate diet
Trans-fatty acids	As low as possible while consuming a nutritionally adequate diet
Saturated fatty acids	As low as possible while consuming a nutritionally adequate diet
Added sugars[b]	Limit to no more than 25% of total energy

[a]Approximately 10% of the total can come from longer-chain *n*−3 or *n*−6 fatty acids.

[b]Not a recommended intake. A daily intake of added sugars that individuals should aim for to achieve a healthful diet was not set.

AMDR for an individual can only be calculated once the total energy expenditure (TEE) is estimated and that it is not based on experimental data.

The UL is the highest level of daily nutrient intake that is likely to pose no risk of adverse health effect to almost all individuals. These are limits set for safety reasons and are not derived from a continuous distribution like the EAR that permits statistical manipulation of the probabilities of exceeding the value. UL is determined using a risk assessment model adapted for nutrients that is set based on expert judgment for the adverse effect of interest for the nutrient. Table 6 presents the UL for vitamins, and Table 7 presents the UL for mineral elements (Figure 2).

The other DRIs describe energy intakes. They include the resting energy requirement, or REE, and the TEE, an estimate of the energy expenditure needed to maintain current body weight and activity levels. There is no RDA for energy since an excess above one's energy requirement would result in weight gain. An individual's resting energy expenditure only describes needs at rest. The estimated energy requirement (EER) is the estimated average dietary intake associated with an individual of a specific sex, age, height, weight, and activity level. The EER values are determined from equations that reflect the energy expenditure of individuals of normal body composition using data from doubly labeled water experiments. The EER and TEE are the same under conditions other than growth, pregnancy, or lactation; the EER prediction equations also account for the deposition of new tissue during pregnancy or growth and production of milk in the case of lactation. Many different equations are used to estimate the TEE or REE, depending on the individual's height, weight, age, and current activity level. Some use a multiplier reflecting physical activity level, ranging from 1 for sedentary, to 1.48 for moderately active, to higher for the very active. For hospitalized patients, different multipliers are sometimes used to account for metabolic stresses due to illness. All of these equations are approximations but useful to obtain a rough rule of thumb on energy needs.

The DRIs are based on a 'reference person' of a given weight and body composition. Those references are based on typical characteristics of American and Canadian citizens in these regards. They present reference values for each nutrient by age, sex, and physiological condition (pregnancy or lactation) for healthy people.

Applications

The DRIs are used to assess nutritional adequacy and make recommendations for dietary planning of individuals and groups. They are also used as standards for establishing nutrient recommendation for those who are ill. The DRIs for individuals suffering from disease only change when a specific nutrient requirement is affected by a disease or condition.

Assessment

The DRIs are used to assess the adequacy of nutrient intakes of individuals and populations from recalls or records of usual intake for micronutrients, protein, essential fatty acids, and carbohydrates. They are also used as a rule of thumb for assessing the intakes of individuals, but caution is needed. Usual intake and not a single day's intake must be considered. Moreover, since an individual's requirement is never known, only qualitative statements about adequacy are possible. The EAR is the average requirement for a group, but by definition, it does not meet the requirements of half of the population. In contrast, the RDA meets the requirements of virtually all individuals. Usual intakes at or above the RDA mean a low probability of inadequacy since the RDA is calculated to meet 97–98% of the needs of the population. Note that intakes below the RDA may be sufficient for some individuals whose requirements are low. However, we never know if a given individual's requirement is high or low. The likelihood of nutrient inadequacy increases as usual intakes fall further and further below the RDA, but intakes below the RDA cannot be assumed to be inadequate.

Although definitive statements cannot be made, mean intakes of an individual below the EAR very likely need to be improved because the probability of inadequacy is by definition at least 50%. An individual's observed mean intake between the EAR and the RDA probably needs to be improved, because the probability of inadequacy is more than 50 but less than 97%. Only if an individual's intake has been reported for a large number of days can one have a considerable degree of confidence that the diet is inadequate. For nutrients without an EAR or RDA, those who have intakes above the AI can be considered to have reasonably good intakes. The AI is an intake at or above which there is low probability of inadequacy. Therefore, many intakes are already likely to be in excess of requirements; an intake that is low by the AI standard may still be perfectly adequate.

The UL is the usual intake above which there is an increased risk of adverse effects for almost all individuals in the general population. When assessing nutrient intake, the UL can only show the likelihood of adverse effects from usual (chronic) intakes above the UL, not intake on a single day. It is important to note that with most nutrients, the UL applies to all sources of dietary intake, but for one nutrient, magnesium, only pharmacological sources are included.

Dietary assessment of an individual is only one component of a complete nutritional status evaluation. It should be combined with clinical, biochemical, and anthropometric data to provide a valid picture of nutritional status, especially in those who are significantly different than the 'reference person.'

The goal of assessing nutrient intakes of a population using the DRI is to determine the prevalence of inadequate or excessive nutrient intakes within it. There are several methods available to estimate usual intake distributions from dietary intake data on two or more days' worth of intakes. More information and a link to software are available through Iowa State University at http://www.cssm.iastate.edu/software/side/. The statistical techniques are well worked out, and today, monitoring of dietary adequacy and excess is done on an ongoing basis in the US National Health and Nutrition Examination Survey.

Planning

The primary goal of planning an individual's diet is to devise an intake pattern that ensures nutrient adequacy while also minimizing risk of excess and maximizing individual

Note: A tolerable upper intake level (UL) is the highest level of daily nutrient intake that is likely to pose no risk of adverse health effects to almost all individuals in the general population. Unless otherwise specified, the UL represents total intake from food, water, and supplements. Due to a lack of suitable data, ULs could not be established for vitamin K, thiamin, riboflavin, vitamin B_{12}, pantothenic acid, biotin, and carotenoids. In the absence of a UL, extra caution may be warranted in consuming levels above recommended intakes. Members of the general population should be advised not to routinely exceed the UL. The UL is not meant to apply to individuals who are treated with the nutrient under medical supervision or to individuals with predisposing conditions that modify their sensitivity to the nutrient.

[a]As preformed vitamin A only.

[b]As α-tocopherol; applies to any form of supplemental α-tocopherol.

[c]The ULs for vitamin E, niacin, and folate apply to synthetic forms obtained from supplements, fortified foods, or a combination of the two.

[d]β-Carotene supplements are advised only to serve as a provitamin A source for individuals at risk of vitamin A deficiency.

[e]ND = not determinable due to the lack of data of adverse effects in this age group and concern with regard to the lack of ability to handle excess amounts. Source of intake should be from food only to prevent high levels of intake.

Note: A tolerable upper intake level (UL) is the highest level of daily nutrient intake that is likely to pose no risk of adverse health effects to almost all individuals in the general population. Unless otherwise specified, the UL represents total intake from food, water, and supplements. Due to a lack of suitable data, ULs could not be established for vitamin K, thiamin, riboflavin, vitamin B_{12}, pantothenic acid, biotin, and carotenoids. In the absence of a UL, extra caution may be warranted in consuming levels above recommended intakes. Members of the general population should be advised not to routinely exceed the UL. The UL is not meant to apply to individuals who are treated with the nutrient under medical supervision or to individuals with predisposing conditions that modify their sensitivity to the nutrient.

[a]Although the UL was not determined for arsenic, there is no justification for adding arsenic to food or supplements.

[b]The ULs for magnesium represent intake from a pharmacological agent only and do not include intake from food and water.

[c]Although silicon has not been shown to cause adverse effects in humans, there is no justification for adding silicon to supplements.

[d]Although vanadium in food has not been shown to cause adverse effects in humans, there is no justification for adding vanadium to food and vanadium supplements should be used with caution. The UL is based on adverse effects in laboratory animals and these data could be used to set a UL for adults but not children and adolescents.

[e]ND = not determinable due to the lack of data of adverse effects in this age group and concern with regard to the lack of ability to handle excess amounts. Source of intake should be from food only to prevent high levels of intake.

preferences, including meal patterns, culture, religious beliefs, and taste. Perfectly adequate diets from the nutrient standpoint that are not eaten are nutritionally useless. When planning for individuals, the nutrient goal should be at least the RDA or AI to minimize risk of inadequacies. There is no increased risk of adverse effects when an individual's intake is greater than the RDA as long as it remains below the UL. Similarly, when planning for populations or particular groups, it is important to ensure that virtually all individuals exceed the EAR without exceeding the UL.

Many tools are available for diet planning. The USDA provides daily food plan guides (http://www.choosemyplate.gov/myplate/index.aspx) by food groups for those with varied daily calorie needs. Additionally, the USDA periodically issues the Thrifty Food Plan (http://www.cnpp.usda.gov/USDAFoodPlansCostofFood.htm), which is a guide to selecting foods and menus for individuals using Supplemental Nutrition Assistance Program benefits to maximize the amount and nutritional value of food while receiving benefits.

Challenges, Additional Research, and Future Steps

The development of the DRIs has been important in improving national assessment and monitoring of dietary intakes and planning of federal and other programs, but research challenges remain.

Tolerable Upper Intake Level

The UL is the level of nutrient intake below which adverse health effects are unlikely. Adverse events have not been collected routinely on a systematic basis in studies of high levels of nutrient intakes requirements, and therefore, there are often very little data upon which to base the UL. Moreover, dose–response studies are rarely done at high levels, and in some cases, they would be unethical, yet in order to accurately determine a health risk associated with an intake above the UL, it is necessary to know the dose–response relationship between chronic intake of the nutrient and the observed adverse effect chosen. More data are needed in order to estimate dose–response curves for most nutrients. A second problem with the UL is that the level of severity of the adverse effects upon which the UL is based varies greatly from one nutrient to another. For example, exceeding the UL on a chronic basis for pyridoxine is a major concern since it may produce irreversible nerve damage. In contrast, exceeding the UL for choline is likely of lesser concern since the UL is based on a fishy body odor. A final problem with the UL is its characteristics; it is based on a toxicological model with many safety factors that are based on expert judgments but not necessarily on empirically determined data. The UL is a defined as a sharp cutoff and is difficult to manipulate from the statistical standpoint.

Protein Requirement

The current DRI for protein is based on the analysis of nitrogen balance studies, which have many limitations. Nitrogen balance may give falsely high estimates because it is easy to overestimate nitrogen intake and underestimate excretion due to incomplete collections and difficult to measure dermal and miscellaneous nitrogen losses that vary greatly under some environmental conditions. Protein requirements can also be determined using other techniques, such as stable isotopes, carbon balance, and amino acid flux. However, before new methods are adopted, there is a need to conduct comparative studies using the proposed techniques to harmonize them with the nitrogen balance studies of requirements.

One alternative technique that has been proposed to estimate requirements of essential amino acids is the indicator amino acid oxidation method to determine indispensable amino acid (IDAA) requirements in humans. It is based on the idea that when one IDAA is deficient for protein synthesis, then the excess of all other IDAAs will be oxidized, including the amino acid marked with a stable isotope. Proponents claim that this method is robust, minimally invasive, more rapid, and sensitive to changes in amino acid intake than nitrogen-based studies. Studies using it have identified amino acid requirements that are much higher than those based on nitrogen balance.

Better Experimental Data on Subgroups

Many of the DRIs for specific life stage groups have been extrapolated from adults, due to the lack of data on the specific nutrient and life stage group. More studies of these groups are needed in order to set more accurate DRIs.

DRIs for Nonnutrient Bioactives?

Nonnutrient bioactive constituents may have significant health benefits. They include food components such as fiber, carotenoids, glucosinolates, and flavonoids, among others. With the exception of fiber, DRIs are not established for these components.

There are many challenges in determining recommendations for consumption of bioactives including their variable bioavailability and bioactivity, errors in intake measurement, and health benefits based on surrogate biomarkers of effect rather than health outcomes. Historically, much of the discussion around setting recommendations for bioactives was about the paucity and quality of scientific data available. Phenols, polyphenols, and flavonoids were excluded from consideration by the DRI panel at the time the DRIs were last revised because of the lack of sufficient data. Since then, there has been a substantial increase in research and available data, although randomized clinical trials of intakes of these constituents with health outcomes are still few in number. Some other types of guidance may be more appropriate than to establish DRI for them.

Chronic Disease Endpoints

More attention needs to be paid to methods for linking nutrient intakes to chronic disease endpoints/outcomes and setting recommendations based on these.

Updates and Harmonization

It may be time for reevaluation of the DRI development process. Perhaps, it should establish criteria for which nutrients are most in need of revision and then concentrate on revising one nutrient at a time rather than many nutrients. At present, the Food and Nutrition Board and Health Canada have received nominations for many nutrients thought to be in need of revision, of which four were selected for further consideration (vitamin E, sodium, magnesium, and omega 3 fatty acids). It remains to be seen what nutrients will be chosen. Finally, there is a need to harmonize efforts on setting requirements with other authoritative bodies in Europe, Australia, New Zealand, and elsewhere, to avoid needless overduplication of work.

Dietary Surveys: National Food Intake

MC Ocké, CTM van Rossum, and EJ de Boer, National Institute for Public Health and the Environment, Bilthoven, The Netherlands

© 2016 Elsevier Ltd. All rights reserved.

Introduction

National food intake surveys are surveys that monitor the food consumption of groups of individuals that are representative for a national population or important population groups within a country. National food intake surveys provide insight into the consumption of foods, the intake of energy and nutrients, and the exposure to potentially harmful chemical substances. Regular repetitions of national food intake surveys show dietary trends in a population.

Apart from national food intake surveys, other sources of national food data are available in countries. These data from food balance sheets and household budget and expenditure surveys are sometimes used as a surrogate for food intake data. However, each of them provides information about a different level in the flow of food production to consumption and on different aggregation levels. Food balance sheets give information on the national per capita food supply, and household budget surveys focus on food acquisition at the level of households, sometimes supplemented with foods acquired out of home. The data of food balance sheets and household budget surveys are thus not directly comparable with data from food consumption surveys (see Figure 1). Only national food intake surveys allow to estimate the population distributions of consumption of foods, intake of energy and nutrients, and exposure to chemicals and to do this for subgroups within a population such as by gender and age groups.

Many countries conduct national food intake surveys. For the European Union, food intake data of 22 member states are available in the comprehensive food consumption database of the European Food Safety Authority (EFSA). The number of countries that carry out food intake surveys on a regular basis rather than incidentally is however limited. The most well-know long-standing national food intake surveys are probably those in the United States, starting from the National Food Consumption Survey in 1935 to the ongoing dietary surveys as part of the National Health and Nutrition Examination Survey (NHANES).

This article highlights major uses of national food intake data, important aspects about the design and methodology of food intake surveys and their European harmonization, limitations associated with food intake surveys, and future directions.

Major Uses and Stakeholders of National Food Intake Data

Data from national food intake surveys together with data on the composition of foods and information on nutritional status are needed to develop and evaluate health, nutrition, and food policy. Examples are the evaluation of diet from a health perspective, simulating the impact of dietary policy measures, describing trends in food and nutrient intakes, and deriving optimal levels of food fortification. Moreover, the food intake data are essential to develop food frequency questionnaires, dietary indexes, and food-based dietary guidelines.

Similarly, data from national food intake surveys in combination with data on contaminants, additives, or chemical constituents in foods are essential for the assessment of exposure to hazardous substances, as part of the risk assessment process. This information is also useful for the evaluation of new food legislation. Examples are dietary exposure assessment, derivation of safe maximum fortification levels, communication of risks associated with the food chain, estimations of the effects of particular diseases caused by infectious agents that can be transmitted between animals and humans, and identification of core foods for total diet studies.

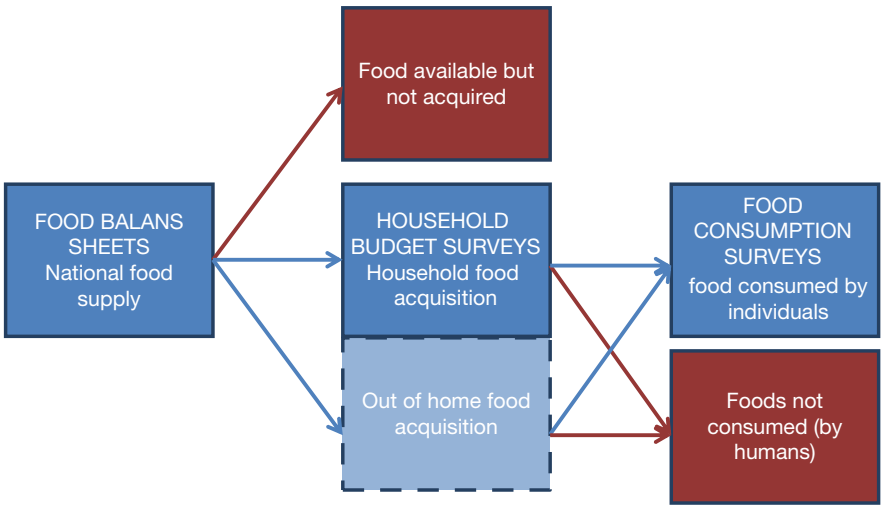

Figure 1 Relationships between food supply data, food acquisition data, and food consumption data.

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00237-3

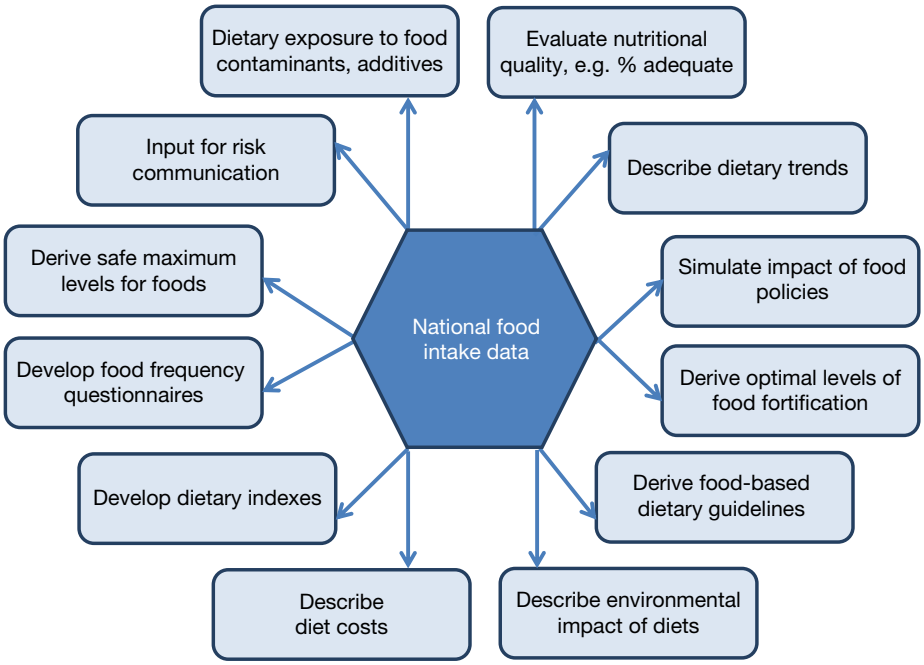

Figure 2 Examples of uses of food intake surveys.

Additionally, food intake data can be used for the assessment of the environmental impact of diet or to describe dietary costs (see Figure 2).

Stakeholders of national food intake data are ministries of health, ministries of agriculture, food industry, dieticians, patient organizations, branch organizations, journalists, universities, and national and international health and food safety organizations like the World Health Organization (WHO), Food and Agriculture Organization (FAO), and EFSA. Scientists in public health or nutrition institutes, food safety agencies, universities, and research departments of the larger food industries often have an interest to conduct specific statistical analyses in national food intake databases themselves.

Study Design, Data Collection, and Handling

Two features are critical for the success of national food intake surveys. The first critical aspect is to obtain a study population that is representative of the target population. The second challenge is to collect food intake data that are valid and precise and contain sufficient detail for their purposes.

Study Population

When planning a national food intake survey, the first step to be taken is defining the target population. The target population is the entire set of individuals to which findings of the survey are to be extrapolated. Typically, a broad age group within a national population is defined as the target population for a food intake survey. The target population may not be the same as the study population, that is, the population that can be defined accurately and reached in a study. In order to precisely define the study population, it is necessary to agree on exclusion criteria. Institutionalized subjects are often not included in food intake surveys as their inclusion makes the sampling procedures and/or the field surveys too complicated. Also, language barriers are commonly used as exclusion criteria. In order to obtain a representative study population for the target population, excluding subjects due to language barriers or other practical reasons should be kept to a minimum.

The sampling frame is the list of units from which the sample is drawn. The availability of sampling frames varies from country to country. For national food intake surveys, the most complete lists can be chosen among population registers, electoral lists, and census lists. Alternative sampling frames are telephone lists, lists of schools or day care centers, market research panels, and lists of medical centers or general practitioners. Great care must be taken when making decisions on the sampling frame, particularly with regard to bias due to undercoverage. Overcoverage of the sampling frame normally can be detected and dealt with during the fieldwork. Specific subgroups within a population might need a different sampling frame, since electoral list is only suitable for adults and list of day care centers or schools is especially suitable for young or older children, respectively.

Sampling from the sampling frame can be done in various ways. It is considered a good survey practice to use a sampling design that yields a probability sample. Under such a design, each sample unit of the sampling frame has a nonzero probability of being selected. It does not necessarily require that every person has the same probability of being selected. Stratified sampling, for example, sampling by subgroups of age and gender, is often conducted in food intake surveys to ensure that there are a sufficient number of people in each subgroup to allow meaningful analysis. For practical reasons, cluster sampling or multistage sampling can be applied. In cluster

sampling, first, a random sample of naturally occurring units or groupings within the population is taken (e.g., areas, cities, or schools). Then, either all members of the chosen clusters or a random selection from among them is included in the sample. Multistage sampling is an extension of cluster sampling where a hierarchy of clusters are chosen going from larger to smaller.

The required size of a food intake survey population depends on the variability in intake, the statistics of interest (i.e., mean, percentiles, or variance), and the level of precision needed. Information on intake variability (from previous studies) is therefore needed in order to determine the number of subjects to include in a survey. In the European Food Consumption and Validation (EFCOVAL) project, the sample size per country was estimated to be, on average, equal to 2000 subjects for a desired precision of 5% in nutrient and food group intake. In simple random samples, high percentiles can be assessed with sufficient accuracy if the minimum sample sizes for the 95th, 97.5th, and 99th percentiles can be estimated to be equal to 160, 320, and 800, respectively. When results are presented for different subgroups within a study population, the minimum sample size has to be available for each subgroup.

The expected response rate should be taken into account in determining the sample size for achieving a certain number of actual participants. In the case of recruitment in waves through a year, adjustments in the number of invited participant can be made according to the actual response rates for specific strata in previous waves. Moreover, it is important to collect information on nonrespondents in order to eventually correct for lack of representativeness of the study population for the target population. For active nonparticipants, it is possible to administer a concise nonrespondent questionnaire (among those willing); for passive nonparticipant with which no contact was established, only information from the sampling frame can be used (see **Figure 3**).

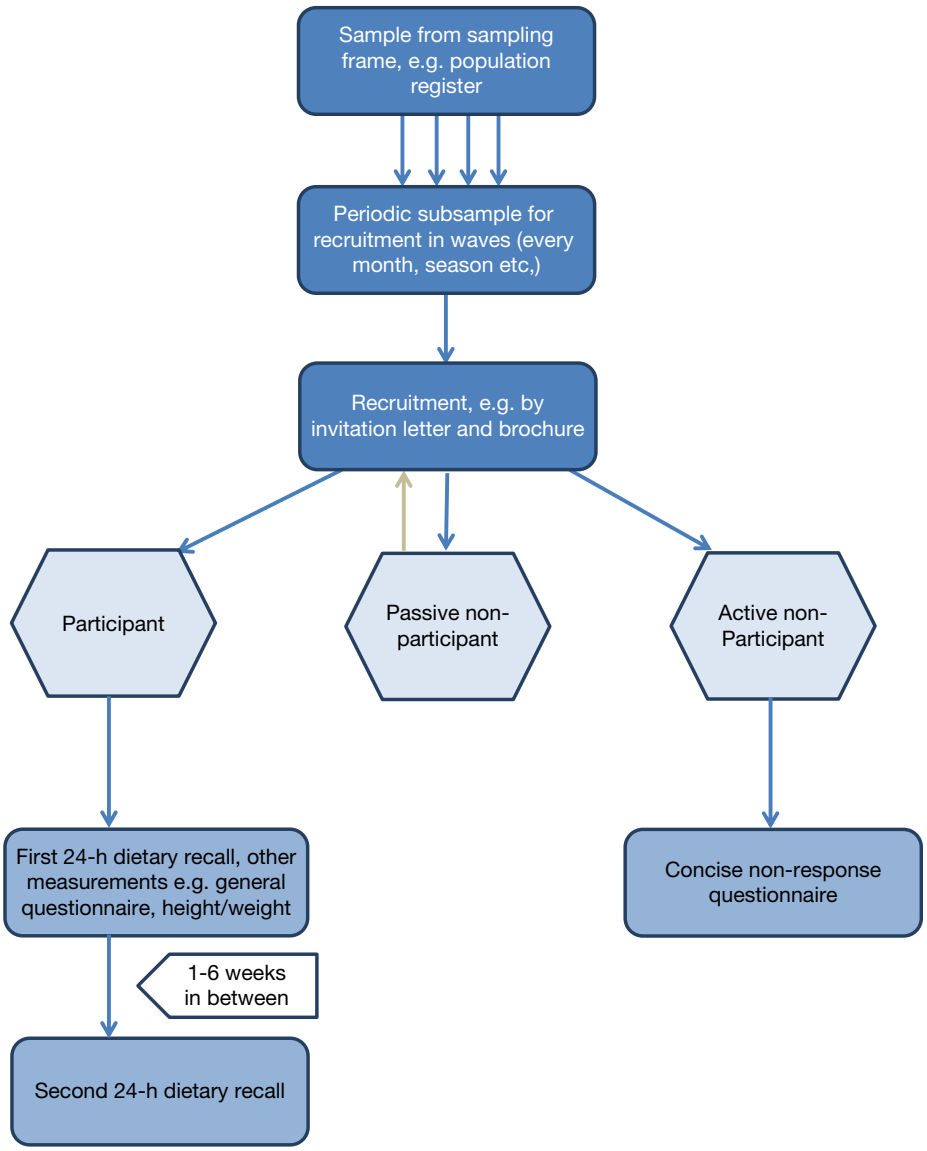

Figure 3 Example of the logistic flow of a food intake survey.

Dietary Assessment

Traditionally, four main methods of dietary assessment are distinguished. These are food records, dietary recalls, food frequency questionnaires, and dietary history questionnaires. Food frequency questionnaires capture usual intake, but they are not quantitatively precise and thus cannot estimate the percentage of the population with inadequate intakes or too high intakes. This was clearly demonstrated in a biomarker-based validation study in the United States, the Observing Protein and Energy Nutrition (OPEN) Study. The traditional dietary history also captures usual intake but is extremely labor-intensive and involves a high subject burden with an interview of several hours, whereas the modern version of a dietary history method has similar problems to food frequency questionnaire with estimating intake quantitatively. Therefore, food frequency methods and dietary history methods are not suitable for national food intake surveys.

Well-conducted food records and dietary recalls are better able to quantify food intake for the specific days they cover. Since usual intake is of interest for food intake surveys, at least two repeated nonconsecutive food records or dietary recalls are required together with statistical modeling of usual intake. With the statistical modeling, the within-person day-to-day variation in the intake data can be accounted for. For foods that are important contributors of nutrients and that are consumed by less than 50% of the population, additional information on the frequency of consumption has added value. Examples of these products are types of dietary supplements and liver.

Whether a food record or dietary recall is the preferred dietary assessment method for food intake surveys depends on the survey population. In populations with notably low response rates, the preferred method is the method with less respondent burden; this is the dietary recall. The dietary recall method is also preferred in populations with high illiteracy levels. In other populations, food records might be preferred. The food record is a prospective method and therefore does not have the disadvantage that it relies on memory such as the retrospective 24 h dietary recall method. However, it is well-known that people change their diets because of keeping a record of everything that is consumed. For harmonized pan-European food intake surveys, EFSA advises to apply dietary recalls as dietary assessment method, particularly because of the lower burden to the participants.

In order to obtain intake data that are usable for many purposes, it is important to collect information on all foods, beverages, and dietary supplements consumed. The information should contain a sufficient level of detail for the different purposes, for example, information on fat content, sweetening (sugar and/or artificially sweetened), fortification, preparation method, conservation method, and package material. Brand name information can help to ascertain aspects like sweetening and fortification that are often not known by consumers. It is also necessary to estimate the consumed amount for each eaten food. There are different options, which can be used in combination: estimation in household units like glasses or spoons, estimation in natural units, for example, for eggs or apples, estimation in commercial units for products like chocolate bars and sweets, estimation using food models or food photographs, and estimation in gram or milliliter.

To conduct a high-quality standardized 24 h dietary recall, it is advised to use a computer-administered software for 24 h recalls. With the software, the interviewer is guided by automatic response routing to ask tailored questions and prompts for specific foods. Using multiple steps, the system helps to ensure completeness and consistency across interviewers. There are automated links to food lookup tables and data quality checks. It is of major importance to test any software before applying it in a survey; preferably, a validation study should be conducted. Examples of carefully developed and extensively tested and validated software are the five-step multiple-pass method used in the NHANES in the United States and GloboDiet, previously known as EPIC-Soft, used in food intake surveys of Austria, Belgium, France, Germany, Malta, the Netherlands, and Switzerland.

Specific subgroups within a population might need a different dietary assessment method. For example, a 24 h dietary recall is less suitable for young children in case the child is often not together with the parent or caretaker that is interviewed. Also for older adults with a higher likelihood of impaired short-term memory, a 24 h dietary recall is less suitable. In both age groups, a dietary record or a food diary and 24 h dietary recall could be an option. For less developed countries, more emphasis is needed for feasible and robust methods.

Supplemental Information to be Collected from Participants

Depending on the specific aims of a food intake survey, other information is collected besides the dietary data. All food intake surveys collect information on background characteristics of the participants, usually including sociodemographic information and information on dietary practices. This enables to stratify the results by sociodemographic subgroups and to judge the representativeness of the study population.

Because of the high prevalence of overweight, additional information on physical activity and anthropometric information like height, weight, and waist circumference is also collected in many food intake surveys. Information on body weight is also of prime importance if chemical exposure from the diet is to be compared with health limits. These health limits are usually expressed per kilogram body weight. Moreover, some surveys collect information on health and others on food choice determinants, biological marker for nutritional status, or aspects important for microbiological risk associated with food consumption. It is outside the scope of this article to detail methods for collecting these data.

Administration Protocol

The study design must consider that in order to capture the interseasonal variability in consumption patterns, subjects must be uniformly distributed over the four different seasons and each seasonal sample must represent each survey stratum (e.g., on age and sex). This can be done by recruitment of participant in waves throughout the year (see Figure 2). It is of prime importance to monitor response and the completed number of participants and to adjust procedures if response or the completed number of participants falls behind.

The survey calendar must be organized in such a way that all days of the week are represented proportionally in the food consumption data. Specific emphasis on an adequate proportion of weekdays and weekend days at population group level is needed, since this is the main source of variation in intake over the days. For food intake surveys with nonconsecutive dietary records or recall, it is advised to have an interval of 1–6 weeks in between both administrations. More than 6 weeks in between, which might be an option theoretically, might result in losing study participants and is therefore not advised.

The administration of the interviews is usually done face to face, although in some surveys, telephone interviews are conducted. Face-to-face interviews can be conducted at a study center or at the home of the participant. The latter has the advantage that consumed foods and used household measures are available to show to the interviewer. Interviewers should preferably be trained dietitians or nutritionist; although, with more extensive training on consumed foods and recipes, also interviewers with other backgrounds are used in practice. During the survey period, refresher trainings are recommended. Moreover, it is of prime importance to monitor the quality of the interviewers and provide them feedback to improve their work.

Data Cleaning and Analyses

After data collection, data cleaning is an important phase. It is recommended to start data cleaning immediately after the first data are received from the interviewers, rather than waiting until the survey period is finalized. Data cleaning should include checking for missing, inconsistent, and extreme values and considering data-related remarks made by interviewers. When the food intake data are checked, further handling can include linkage to nutrient databases for foods and dietary supplements, databases with concentrations of chemicals in foods, or other food-related databases. More information on nutrient databases can be found in this encyclopedia.

Subsequently, statistical analyses can be performed. In these analyses, survey weights can be used to make the data representative for the target population. A commonly applied correction technique for lack of representativeness is weighting adjustment. It assigns an adjustment weight to each survey respondent. Persons with characteristics that are underrepresented get a weight larger than one, and those in overrepresented groups get a weight smaller than one. In the computation of survey results, not just the values of the variables are used, but the weighted values.

When usual intake is of interest, intake or exposure per person per day should be calculated and then usual intake modeling should be applied. In these models, the within-person variation in intake is removed from the data. Various tools to model usual intake exist. In the Statistical Program to Assess Dietary Exposure (SPADE), usual intake can be modeled for the combination of intake from foods and drinks as well as dietary supplements measured on two specific days. In the Monte Carlo Risk Assessment (MCRA) tool, usual exposure to chemical substances can be modeled, dealing, for example, with occurrence data below the detection limit and having the option to check the input data quality.

An important step in data analyses is evaluation of dietary intake against dietary reference values for nutrients and against health limits for food chemicals. Procedures for proper evaluation are described elsewhere in this encyclopedia.

Limitations

Two major challenges of food intake surveys are the internal validity and the external validity.

Internal validity of national food intake surveys is never perfect, since diet cannot be measured without error; both random error (including day-to-day variation) and systematic bias (social desirability) are present in the data. Important aspects within dietary recalls are the correctness of the reported foods (both omissions and intrusions occur), the completeness of food description, and the correctness of portion size estimation. In practice, dietary assessment based on self-reporting usually leads to underestimation of energy intake. Moreover, dietary assessment in combination with using food composition databases has additional limitations for specific components in the diet. This is, for example, the case for dietary exposure assessment of mycotoxins. Since the concentration of mycotoxins in foods is very variable due to, for instance, weather and storage conditions, duplicate diet studies or total diet studies are better equipped to estimate mycotoxin exposure. Another example is estimation of sodium intake. This is difficult because of the large variation in sodium concentrations in processed foods and recipes, as well as the difficulty of estimating discretionary salt intake. Dietary assessment of sodium (rather than urinary excretion) does however enable identification of important dietary sources of sodium, which can inform public health interventions to lower sodium intake.

What is important is whether the dietary assessment method is suitable for providing useful analytic measurement for a given purpose and context. For many purposes and in many contexts, 24 h dietary recall data from national food intake surveys proved to be useful in helping to address important research and policy questions, despite their known errors. Strategies to optimize the impact of food surveys are to have more transparency of raw research data, consistent data-staging techniques, improved data analysis, and reporting indicators for dietary intake quality such as indicators for underreporting.

External validity is impacted by low response rates that often occur. In practice, response rates between 26 and 97 are observed in national food intake surveys, with the majority between 42% and 71%. Low participation rates and selective nonparticipation may cause bias to the survey results based on participants alone. It is known that respondents and nonrespondents might differ in their socioeconomic and demographic status as well as in their health and lifestyle behaviors. Therefore, for achieving a representative study population, it is of utmost importance to use all means to obtain the highest response rate possible. Strategies to optimize response rates are choosing data collection methods with a lower burden for the respondents, providing a suitable incentive, flexibility in recruiting and participation (times available for the interview, second call if a no-show, etc.), personal contact in recruitment, and awareness of the study by media coverage.

Harmonization of National Food Intake Data Across Countries in the European Union

National food intake surveys in Europe are heterogeneous with respect to dietary assessment methodology and number of days for which dietary data are collected. This hampers the comparison of results across countries, for example, in dietary exposure assessment using the data of the comprehensive food consumption database such as conducted by EFSA. Therefore, EFSA stimulates European Union member states to collect national food intake data in a harmonized way and prepared guidance for this in 2009 with an update in 2014. Moreover, EFSA provides seed money to countries that conduct food intake surveys in accordance with EFSA guidance. This is called the EU Menu process. The guidance of EFSA was partly based on the results of previous European research projects, such as summarized in the succeeding text.

In the European Food Consumption Survey Method (EFCOSUM) project, recommendations for reliable and comparable pan-European collection of food intake data were formulated. As the most suitable method to collect internationally comparable data on population means and distributions of actual intake, the 24 h recall was recommended, to be conducted at least twice. This would also allow for the estimation of usual intake by a modeling technique that separates intra- and interindividual intake. GloboDiet, at that time called EPIC-SOFT, was considered the most suitable software for a standardized data collection in a pan-European survey. For a number of micronutrients, that is, vitamin D, folate, sodium, iron, and iodine, the use of biomarkers was recommended.

Subsequently, the EFCOVAL project further developed and validated the pan-European food consumption method recommended by the EFCOSUM project. The validation study confirmed that the repeated 24 h dietary recall using GloboDiet in combination with a food propensity questionnaire and modeling of usual intake is a suitable method for a pan-European food intake survey. This conclusion applied to healthy adults and possibly to children aged 7 years and older. As next step, it was recommended to provide and standardize an implementation plan to facilitate this methodology in European countries. The plan should account for maintenance and updates, sampling designs, national surveillance programs, tailored capacity building and training, and linkage to food composition and occurrence databases.

The objective of the PILOT-PANEU project was to develop, test, and evaluate the applicability of tools and procedures for conducting a pan-European food intake survey including adolescents, adults, and elderly people. The dietary assessment methodology consisted of two nonconsecutive 24 h recalls performed with GloboDiet methodology. The consortium made a number of recommendations for the improvement and further development of the tools and procedures. Assuming that the recommended modifications are made, the tools and procedures developed and tested were considered suitable for the EFSA EU Menu process in adolescents, adults, and the elderly.

Similarly, in the 'Pilot study for the Assessment of Nutrient intake and food Consumption Among Kids in Europe' (PANCAKE), the feasibility of tools and procedures for a pan-European food intake survey among children 0–10 years was tested. This included two alternative dietary assessment methods. One method consisted of a 3-day food diary, which was checked with a parent, and data were entered afterward using GloboDiet. The alternative method consisted of two nonconsecutive 1-day food diaries followed by GloboDiet completion interviews. Both dietary assessment methods with related tools and administration protocols were evaluated as feasible. The administration protocol with two 1-day food diaries with completion interviews was judged to offer more advantages for the EFSA EU Menu survey in children 0–10 years. It offered more complete description of the consumed foods, was more suitable to estimate usual intake, and resembled more the method in adults.

Future Directions

In the future, it is important to improve data collection methods and to collect food intake data in connection to other information.

First, improving data collection methods should focus on methods that have a small participant burden or that are attractive to participants, so that response rates increase. The use of modern technologies might help for this purpose, although for some population groups, it might not be appropriate. Additionally, future data collection methods should be less labor-intensive than current data collection methods, since the costs of the current methods are high and increase because of the dynamic and increasingly complex food market. Examples of promising data collection methods are online 24 h dietary recalls, devices that automatically take pictures of all food consumed, and apps for food records using bar codes and food pictures for portion sizes, or automatic recognition of photographed consumed food and volumes. These promising technologies need to be extensively tested in the general population and important subgroups of the population and validated positively before they can be incorporated in food intake surveys. At the moment, various interesting developments and validation studies with modern technologies are ongoing.

Second, it has added value to conduct national food intake surveys in connection to biomarker and other data collection. Combining with nutritional status monitoring and collecting information of biomarker of food intake allow for better interpretation of food intake results and provide insight in the validity of the results. Combining with data collection on other lifestyle information has the advantage that risk groups with multiple unhealthy lifestyles can be identified. Moreover, in order to get insight in ways to improve dietary intake, it is an asset to collect food intake data in combination with information on determinants of food choice, the food environment, and economical aspects of diet and health. Such integrated food intake surveys ask for ingenious study designs so that the participant burden can be kept acceptable, and not all information has to be collected from each participant.

Conclusions

Conducting regular national food intake surveys is important for the development and evaluation of nutritional and food safety policies. The current best practice in food intake surveys

is to obtain a representative sample from a national population register. For each participant, at least two nonconsecutive food records or 24 h dietary recalls combined with a short food frequency questionnaire need to be collected supplemented with at least sociodemographic background information. Statistical modeling should be used to estimate usual intake. For pan-European harmonization of food intake surveys, dietary recalls rather than food records are advised. Standardized collection of 24 h dietary recalls with much detail can best be done using validated software such as GloboDiet.

Overall, study preparation and data collection and data handling of food intake surveys with much detail in the food description are labor-intensive and therefore costly. Using the collected dietary data to their full potential will however lead to a return on investment. Potential uses are manifold. Moreover, investments can become smaller if the same methods are used repeatedly and shared with other groups. Output and lessons can increase if the collected data are easily discovered, user-friendly to access and understand, and freely available. The trend toward open data helps here.

This article described that two features are critical for the success of national food intake surveys. The first is the internal validity or validity of the collected food intake data. The second is the external validity or the representativeness of the survey population for the target population. In the practice of food intake surveys, we have to deal with suboptimal situation that diet cannot be measured without error and decreasing response rates. Future directions should address both these challenges and time and cost-efficiency.

Drying: Effect on Nutrients, Composition and Health

SV Crowley and JA O'Mahony, University College Cork, Cork, Ireland

Introduction

In their natural state, most foods contain a significant quantity of water. In foods with a high water activity (a_w), spoilage and/or pathogenic microorganisms can grow; in addition, degradative physicochemical changes occur more rapidly in high a_w foods. One of the most effective methods of increasing both the shelf life and safety of foods is through dehydration. Traditional drying methods, such as sun-drying, are slow and manual in nature, and can incur losses in yield due to difficult-to-predict factors relating to the local climate and indigenous wildlife. These traditional methods of dehydration are still successfully used in developing countries and also in the production of artisan or minimally processed food. However, the modern food supply chain is a global one, and the increased affluence of consumers has resulted in a strong demand for the year-round availability of a diverse range of foods. In industrial countries, this demand has contributed to the general adoption of mechanized drying technologies (e.g., spray- and freeze-drying) and a proliferation of food powders.

Food powders are nutrient-dense, low-volume products that can be easily transported nationally and internationally. The drying process itself can also be harnessed to encapsulate nutrients deemed to have specific health benefits, such as probiotics, fatty acids, and phytochemicals. These encapsulated nutrients can be stored for use as versatile ingredients in the fortification of a wide range of foods, which could allow their targeted delivery to a larger proportion of the world population. In this article, the influence of the drying process and powder storage on the stability of key nutrients in different food systems is discussed. Certain dried foods, such as herbs and spices, are omitted, as the low levels at which they are consumed were considered to render their nutritional contribution to the average diet negligible. A comprehensive overview of the effects of drying on a range of foods and nutrients is provided, including fruits, fruit juice, vegetables, egg, milk, wine, algae, infant formulas, enteral formulas, bacteria, and plant-derived oils. This overview is based on recent research, which has primarily focused on the effect of drying conditions (e.g., temperature and flow rate) and postdrying storage conditions (e.g., relative humidity and light exposure) on the stability of key nutrients. The effect of bulk density on nutrient dosage in nutritional powders and the role of accelerated stability tests and fortification overages in formulation design, two increasingly important topics in modern manufacturing practices for dried foods, are also highlighted before a general closing discussion on the link between dried foods and health.

Effect of Drying on Nutrients

Changes in Macronutrients During Drying and Powder Storage

Much of the focus of this article is on the changes that occur in the micronutrients present in foods during drying and subsequent storage. Although reactions occurring between macronutrients, such as those involving proteins and carbohydrates during nonenzymatic browning, are of nutritional consequence, individual macronutrients in food are generally not impacted to a significant degree by the drying process alone. In this section, the changes that occur in the macronutrient fraction are discussed briefly. The factors influencing the degradation of macronutrients during the drying of foods are also summarized in Table 1.

Protein

Protein is naturally present in many common dried products, including milk and egg powders, and can play a significant role in the encapsulation of lipids and probiotics. In addition, advances in processing technology have resulted in an increased availability of dairy-derived (whey protein and casein) and plant-derived (soy and rice) protein powders, bars, and beverages, which are popular product categories among young adults engaged in athletic activities; on the other hand, an aging or 'graying' global population is likely to result in increased instances of diseases such as pathological sarcopenia, which is accompanied by muscle wastage. In both cases, consumption of adequate quantities of protein is essential to aid in the process of muscle synthesis. Modification of the structure of proteins (i.e., denaturation and aggregation) has been associated with altered biofunctional properties such as allergenicity and digestibility, but these effects are generally not attributed to the drying process itself. Additionally, these structural modifications can occur in predrying processing, such as the pasteurization and evaporation treatments applied to some dairy systems. In the presence of carbohydrates, however, proteins may undergo structural modifications due to the Maillard reaction, a nonenzymatic browning process. This aspect is covered in '**Carbohydrate**.'

Carbohydrate

Carbohydrates are important structural components in dried food matrices. In powders, they are frequently the primary encapsulating material for other nutrients (e.g., fatty acids and probiotics). Degradative changes associated with carbohydrates of nutritional consequence are mostly limited to the generation of Maillard reaction products (MRPs) through nonenzymatic browning reactions between reducing sugars and amino acids. The generation of MRPs has been linked with increases in cytotoxicity, mutagenicity, and carcinogenicity; however, MRPs have also been associated with positive effects such as increased antioxidant activity. In addition to health effects, MRPs are associated with color and flavor development in foods. However, while the sensory attributes that Maillard browning imbues on certain foods, such as bakery and confectionary products, are often desirable, browning in food powders is typically considered a defect. Investigations of MRP generation in infant formula powders have been frequent, as

Table 1 General properties of the main macronutrients in foods related to the influence of drying on their nutritional quality

Macronutrient name(s)	*Main degradative reaction*	*Drying-induced changes*	*Storage-induced changes*	*Key influencing factors*	*Some potential adverse nutritional consequences*
Proteins	Denaturation	Negligible	Negligible	Predrying thermal processes (e.g., pasteurization and evaporation)	Protein digestibility⇓ Protein allergenicity⇑
Carbohydrates/ proteins[a]	Browning	Minor	Significant	Drying technology, drying temperature (spray-drying), feed composition (type of sugar), storage conditions (relative humidity, temperature, light exposure), crystallization of sugars	Cytotoxicity⇑ Mutagenicity⇑ Carcinogenicity⇑ Lysine levels in food⇓
Lipids	Oxidation	Significant	Significant	Emulsion state (e.g., fat globule size distribution, emulsifier type), encapsulation efficiency, protein/fat ratio, crystallization of sugars	Cytotoxicity⇑ Genotoxicity⇑ PUFA[b] biofunctionality⇓

[a]Nonenzymatic browning requires amino acids in addition to carbohydrates.
[b]PUFA, polyunsaturated fatty acid.

they are nutritional products high in both lactose and protein. MRPs can be generated during spray-drying, with reports highlighting the impact that spray-drying has had on infant formulas, resulting in greater loss of lysine than observed under processes of sterilization; however, it is also worth pointing out that higher concentrations of MRPs have also been measured in sterilized infant formulas compared with spray-dried formulas. Different drying techniques and feed compositions can influence the physical properties (e.g., porosity and morphology) and chemical behavior (e.g., crystallization and water sorption) of the dried material during storage, which in turn can influence the generation of MRPs. MRP generation also occurs in powders during storage. Environmental conditions during the storage of infant formula powders (e.g., relative humidity, temperature, and light and oxygen exposure) have a strong impact on the rate of generation of MRPs.

Lipids

Lipids are a primary contributor to the energy density and texture of foods. Lipid-containing foods are typically emulsions, consisting of lipids dispersed in a continuous water phase (O/W emulsion). Emulsified systems are intrinsically unstable, and to improve their stability, multiple strategies are employed, including the reduction in fat globule size through physical disruption (e.g., indent homogenization and microfluidization), increasing the viscosity of the continuous phase (e.g., addition of hydrocolloids), and the addition of amphiphilic molecules that adsorb at the oil–water interface and reduce interfacial tension (e.g., lecithin). When emulsions are dried, the continuous phase is removed and a solid carbohydrate/protein matrix forms around the fat. Effective encapsulation reduces the levels of free fat at particle surfaces and is dependent on the properties of the emulsion to be dried, the nature and level of the encapsulant, and the drying conditions. Oxidation of specific components in the lipid fraction, namely, fatty acids and cholesterol, is associated with losses in nutritional quality and is discussed in more detail in '**Fatty acids**' and '**Cholesterol**,' respectively.

Changes in Micronutrients During Drying and Powder Storage

Fatty acids

Consumption of foods that are rich in polyunsaturated fatty acids (PUFAs) has been associated with numerous health benefits. Soybeans are an example of a food that is naturally rich in PUFAs. Microwave-assisted drying has been reported to result in less PUFA degradation in soybeans compared to forced-convection drying, and PUFA degradation was independent of drying temperature if soybeans were dried to the same final moisture content. It has been demonstrated that sun-drying or freeze-drying resulted in higher retention of seaweed PUFAs compared to oven-drying. Although drying can result in PUFA degradation, it may be preferable to canning as a method of preserving seaweed, with one study reporting higher levels of total PUFAs in five dried seaweeds compared to two canned varieties.

Infant milk formulas are frequently fortified with PUFAs, as long-chain PUFAs are abundant in human milk and are believed to contribute to the development of cognition and visual perception. Infant formulas contain metals that are known to be pro-oxidizers, such as iron. Iron-binding proteins, such as lactoferrin, have been shown to protect against oxidation when added to infant formulas. Methods for the encapsulation of PUFA-rich oils (e.g., fish oil) have been developed, but the protective effect of the encapsulant can diminish during processing, and oxidation of PUFAs remains a challenge.

It has been reported that fortification of infant formula with microencapsulated fish oil resulted in higher peroxide values after 18 months. Reduced oxidation has been shown in infant formulas where casein was the dominant protein, compared to whey protein-dominant formulas, while higher levels of carrageenan or lecithin have also been demonstrated to reduce oxidation in infant formulas. Higher levels of PUFAs, elevated storage temperatures, and long storage duration generally result in increased oxidation.

There is ongoing research into the potential for the encapsulation of plant-derived oils that are high in PUFAs, such as walnut and chia oils, using spray-drying, with some recent

research showing that homogenization of a chia oil emulsion had a greater impact on the effectiveness of sodium caseinate–lactose encapsulation than the temperature at which the emulsion was spray-dried. Encapsulation of oils by spray-drying in the presence of hydroxypropyl methylcellulose, with or without rosemary oil (antioxidant), improved the oxidative stability of walnut oil but resulted in greater oxidation in chia oil; it was suggested that the poor stability of encapsulated chia oil was linked to chemical damage caused during spray-drying.

Cholesterol

The oxidation of cholesterol with a concomitant increase in the levels of cholesterol oxidation products (COPs) can occur during the manufacture of egg powders, which is a concern as COPs have been linked with disease in humans. In other dried products, such as spray-dried milk, cream, and infant formula powders, the levels of COPs are less of a concern. High outlet air temperatures and the generation of nitrogen oxides in a gas-fired air heater during spray-drying resulted in increased generation of COPs. In addition, COPS can form during storage of egg powders, but this can be controlled by the presence of antioxidants in the powder, such as ascorbyl palmitate and tocopherols. Spray-dried egg powders contained more COPs than freeze-dried varieties, with the generation of COPS being higher in those powders produced from liquid whole egg than liquid egg yolk alone.

Phytochemicals

Phytochemicals are plant-derived substances, such as polyphenols and flavonols, which are purported to have various bioactive properties. Studies have found that the levels of phenolic compounds in dried kale were highest when freeze-drying was used compared to air-drying, while blanching before drying led to reduced levels in kale dried by either method. Recent research has shown that Irish brown seaweed dried in a hot air oven at different temperatures (25, 35, or 40 °C) increased the levels of phytochemicals as drying temperature increased and that increasing temperature of rehydration of dried Irish brown seaweed in water results in faster rehydration times but lower levels of phenols.

It has been shown that drying conditions have no impact on the phytochemical contents of apricots, currants, or prunes, but do have an effect on grapes, while sun-drying has little effect on the levels of phenolic compounds in Italian bell peppers. A comparison of air- and freeze-drying for their ability to retain phytochemicals in physiologically dropped, unmatured citrus fruits reported that while air-drying was better at retaining flavonols, freeze-drying exhibited superior retention of phenols.

A phenol-rich ingredient, named piraltin, has been manufactured by freeze-drying red wine; piraltin contained ~70% of the polyphenols in the wine and was alcohol-free. Phenol levels in spray-dried bayberry juice, with maltodextrin as encapsulant, were nearly 100% of those in the original juice; when stored at 4 °C, the levels of polyphenols in the bayberry juice powder only decreased by <10% at the highest a_w studied (0.44); in addition, air-drying of apple pomace was more effective than vacuum-drying at preserving the phytochemical content. The use of maltodextrins with low dextrose equivalents and spray-drying at low inlet temperatures resulted in lower phenol losses during drying of extracts of phenols from black currant pomace. Encapsulation of a phenol extract derived from olive pomace by spray-drying at different inlet temperatures (130 or 160 °C), feed flow rates (5 or 10 ml min^{-1}), and maltodextrin levels (100 or 500 g l^{-1}) has also been studied, with the highest polyphenol levels at an inlet temperature of 130 °C, a feed flow rate of 10 ml min^{-1}, and a maltodextrin level of 100 g l^{-1}; it was also found that the powder underwent the least degradation of phenols when stored in dark conditions at low temperatures.

Probiotics

Probiotics are live bacteria or yeasts that are believed to have a beneficial role in the maintenance of gut health and the prevention of gastrointestinal diseases. In addition, a growing body of evidence supports a role for probiotics in the promotion of neurological function. Common probiotic strains, which are frequently added to foods in dried form, include *Bifidobacterium* (*B.*) and *Lactobacillus* (*L.*).

Adapting *L. paracasei* by growing it in a stressful environment (high heat or salt) resulted in a 16–18-fold increase in stability when the bacteria were inoculated into milk and dried. Similar findings have been reported for *L. casei* Nad and *L. plantarum* 8329 spray-dried with skim milk. When *L. salivarius* subsp. *Salivarius* was freeze-dried in distilled water, only 1% of viable bacteria remained; however, when the same probiotic was dried in a medium consisting of skim milk, glucose, and trehalose, >83% of viable bacteria remained; the survival of the freeze-dried probiotic during storage was best at the intermediate levels of moisture, which were studied (2.8–5.6%). Researchers have spray-dried *L. paracasei* inoculated in a skim milk/yeast medium using an inlet temperature of 175 °C and an outlet temperature of 68 °C and reported that ~15% of the probiotic was lost during drying; when cheddar cheese was fortified with the powder, the researchers found that the probiotic population grew during ripening.

The survival of *Saccharomyces boulardii*, a probiotic yeast, was greatest at acid pH and high inlet temperature, deemed by the authors to be due to optimal protein crust formation around the yeast in these conditions. Encapsulation of *B. animalis* subsp. *lactis* BB-12 in sweet whey resulted in reduced viability at acid pH and no difference in salt tolerance (bile or NaCl); when the probiotic was added to a refrigerated dairy dessert, it showed a consistently higher viability during 6 weeks of storage. Freeze-drying of *B. longum* 1941 in different protein–sugar encapsulants revealed that milk proteins (skim milk, sodium caseinate, and whey protein concentrate) outperformed soy proteins and that sugar alcohols (glycerol and mannitol) outperformed maltodextrins, in terms of postdrying viability and acid and bile tolerance. Experiments where single droplets containing *L. plantarum* A17 in addition to skim milk, whey protein isolate, lactose, or trehalose were dried revealed that the dairy ingredients were capable of protecting the bacteria to a greater degree than the sugars during drying, due to the formation of a crust that limited the thermal load applied to the encapsulated bacteria.

An interesting approach to the drying of probiotics is their codrying in the presence of prebiotics. Prebiotics are carbohydrates that cannot be digested by humans, but that can be used as a nutrient source by probiotics, thereby stimulating the

growth of the latter. For this reason, they are sometimes collectively referred to as 'synbiotics.' Recent studies have shown that *Bifidobacterium* species can be effectively encapsulated using inulin, oligofructose, oligofructose-enriched inulin, or polydextrose, while *Lactobacillus* species have been encapsulated using fructooligosaccharide. Other combinatory approaches at improving the manufacture of probiotics include the use of spray–freeze-drying, which combines spray-drying and freeze-drying technologies and has primarily been used in the production of biopharmaceuticals. Spray–freeze-drying was successfully used to dry *L. casei*, with 98% of the probiotic surviving the drying process.

Nucleotides

Nucleotides in the diet are thought to contribute positively to immune function, gastrointestinal health, and absorption of other micronutrients. Nutritional sources of nucleotides mainly include mammalian milks. It has long been known that human milk has innately high levels of nucleotides, and this has resulted in efforts to humanize infant formulas through fortification with nucleotides. Significantly lower levels of adenosine 5′-monophosphate and cytidine 5′-monophosphate have been measured in reconstituted skim milk powder compared to raw milk, indicating that the spray-drying process may cause degradation of nucleotides. It was also reported by the same group that pasteurized milk had lower levels of these nucleotides, and as the skim milk powders were pasteurized and evaporated before drying, it is difficult to ascertain the influence of the drying step in isolation; it is also worth noting that in-container sterilized and powdered milks were the only samples to contain significantly lower levels of orotate. A recent study found that pasteurization of human milk actually increased the levels of free nucleotide monophosphates; on the other hand, high-pressure processing caused a decrease.

Casein-dominant infant formulas have been shown to have naturally higher concentrations of nucleotides compared with whey protein-dominant formulas, whether the latter had been fortified or not. Additionally, the same author indicated that minimal degradation of nucleotides occurred in the powders studied during 1 year of storage. Recently, nucleotides in 11 infant formulas were analyzed and it was found that the majority had levels that were in general agreement with their label claim; however, one formula was reported to have nucleotide levels that were 90% less than what the label claims, indicating major losses during processing. More research is required to identify the potential role of spray-drying and other processing steps on the degradation of nucleotides in infant formulas.

Vitamins

Foods such as fruits and vegetables are widely known to be important natural sources of vitamins, while formulated products such as infant formulas are increasingly fortified with vitamins. Vitamin D_3, which is now routinely added to milk and infant milk products, was shown to undergo negligible degradation in the production of spray-dried milk. Vitamin C was shown to degrade during the air-drying of tomatoes, with higher drying temperatures resulting in greater losses; immersion in salt or sugar solutions prior to drying was found to inhibit this degradation. An inverse relationship between air-drying temperature and vitamin C levels in both tomatoes and papaya has also been reported.

Decreases in vitamins A, E, and C were measured during storage of infant formula powders for up to 18 months; the greatest losses were reported for vitamin C, and levels of all vitamins decreased more rapidly when powders were stored at elevated temperatures (40 °C vs. 25 °C). Tracking the degradation of vitamins A and E in infant formula powders after the packaging had been opened revealed that, while the levels of these vitamins did decrease over 70 d storage, the levels remained within regulatory limits. Enteral formula powders underwent reductions in vitamins A, B_1, and E during storage for up to 6 months at 30 °C that were sufficient to compromise the ability of those formulas to satisfy their label claims for RDAs, particularly in adverse conditions (high a_w and lengthy storage). Efforts to increase the retention of vitamins in powders by advanced drying techniques (nanospraying or electrospraying with encapsulants) have recently been investigated.

Minerals

The greatest potential for loss of minerals in products intended for drying is when the feed is in its liquid state. Mineral fallout in neutral-pH liquid products (e.g., cow milk, soy milk, and infant formula) can be caused by the use of insoluble calcium salts such as calcium carbonate, phosphate, and citrate, but this is less of a concern in acid products such as fruit juices. The stability of insoluble salts in liquids can be improved through the use of thickeners to increase the viscosity of the solvent or micronized forms of calcium that sediment less rapidly. Mineral loss from food during drying or during postdrying storage has not been demonstrated to be an issue affecting the nutritional quality of foods.

Other Considerations When Drying Nutritional Formulations

Influence of Bulk Density on Nutrient Dosage in Nutritional Powders

Powdered protein supplements are currently very popular among the physically active. In addition, powders are available that, once reconstituted, are intended to function as complete meal replacers, where they are the sole source of sustenance for the consumer. Critically, these products require the consumer to add a defined quantity of powder to a defined quantity of water to create a beverage with defined levels of key nutrients. In products such as these, infant formula powders being another example, the manufacturer must ensure that the powder has a consistent bulk density so that the consumer can scoop the correct quantity of powder into the liquid. In spray-drying, bulk density is influenced primarily by the viscosity of the feed, degree of aeration of the feed, type of atomizer, and agglomeration and/or instantization. If pneumatic conveying is used to transport powders within a manufacturing facility, additional care must be taken to prevent agglomerate breakage, which can result in deviation of bulk density from specified values. The manner in which bulk density can affect nutrient dosage in these products is illustrated in Figure 1.

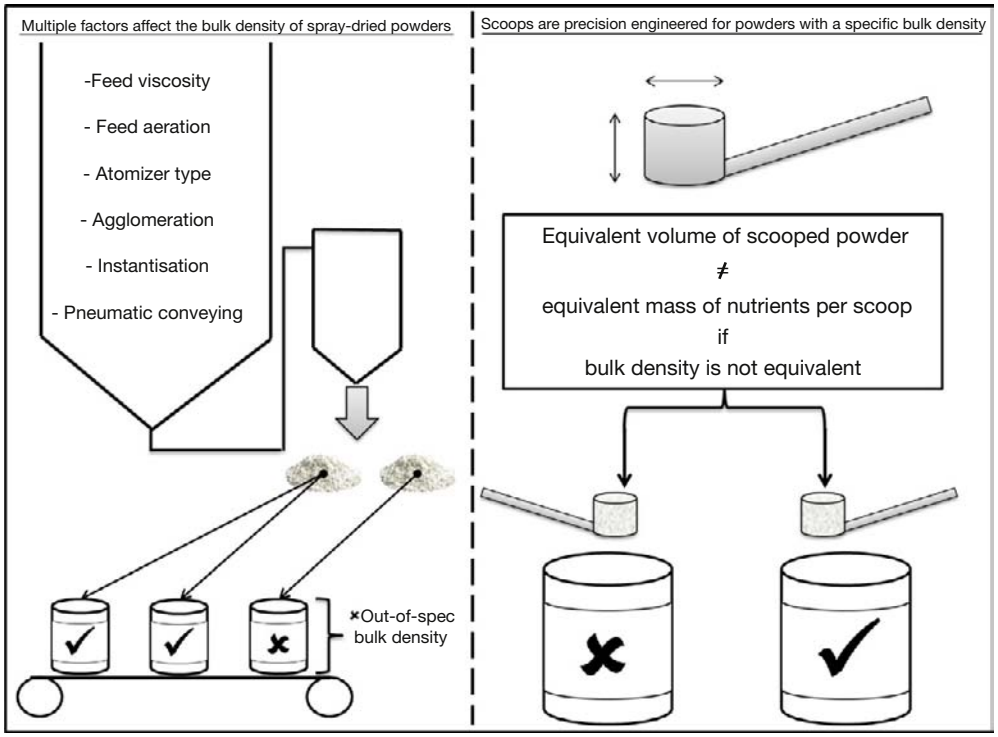

Figure 1 Influence of bulk density on nutrient dosage in spray-dried nutritional formulations, such as infant formula and meal replacers.

Role of Accelerated Stability Tests and Fortification Overages

In the development of new nutritional products, the final formulation and shelf life are determined by the integration of nutrient and physical stability testing data. For extended shelf life powders, the long shelf life necessitates the implementation of accelerated stability testing programs that complement traditional ambient stability tests. The principal environmental factors that are modulated during accelerated stability tests are temperature, light exposure/intensity, and relative humidity. Typical ambient and accelerated stability testing storage conditions for powders are 25 °C/60% relative humidity and 40 °C/75% relative humidity, respectively. For sensitive nutrients (e.g., B vitamins and PUFAs), the formulation overages required are normally determined based on measured losses during processing and stability testing. The principal factors affecting the overages required for individual nutrients vary but are generally determined by inherent stability of the nutrient, regulatory/quality limits, choice of drying technology and operating parameters, packaging material, transport and storage conditions, and the required shelf life. Some general considerations for nutrient stability testing are that ambient and accelerated programs should run in parallel and stability data should be generated using the actual commercial packaging material in all types and sizes that are manufactured. These concepts are illustrated in Figure 2.

Drying and Health: Overview and Future Perspectives

Most foods, in their natural, high-moisture state, are prone to rapid deterioration due to microbial spoilage and/or chemical degradation. Spoiled food is unpalatable and potentially toxic and generally has poor nutritional value. Dried foods and food powders have shelf lives that far exceed those of undehydrated varieties, and it may take many years before any spoilage eventually occurs. It would be a mistake to simply compare the nutritional value of a freshly harvested food with the same food recently dried, because the relative dynamics of degradation of each over time are also an important factor determining their potential health-giving properties.

For certain nutrient-dense foods, it may not be possible to produce them in certain regions of the world, or where they can be produced, the supply may be contaminated or otherwise untrustworthy; in cases such as this, dried foods are a low-volume product that can be transported from a reliable source at low cost and low environmental impact. Some of the research that has been highlighted in this article has demonstrated that the nutritional value of foods can indeed depreciate when being transformed into a dried product; however, many of these studies have also shown that this effect can be minimized or even eliminated if the drying process is carefully controlled.

The consumption of bioactive substances (e.g., phytochemicals, probiotics, and PUFAs) in sufficient quantities to extract their purported benefits is difficult to achieve in many regions, particularly for the socioeconomically disadvantaged. Encapsulation by drying affords the possibility of a range of bioactive-fortified foods becoming commercially available. The availability of such products may alleviate the burden on individuals to consistently source and acquire the requisite foods, which may be prohibitively expensive or otherwise inaccessible. Moreover, it is thought that targeted food fortification strategies may be needed to alleviate region-specific

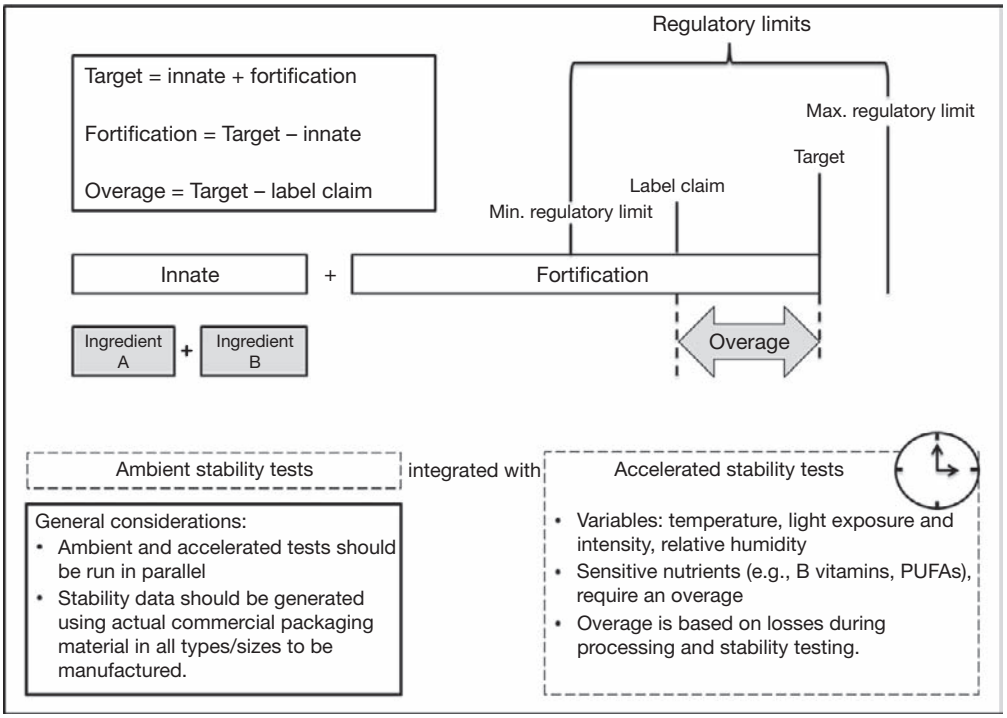

Figure 2 Principles of stability testing and fortification overages for sensitive nutrients during formulation of nutritional product.

deficiencies in certain vitamins, for example, vitamin D, the status of which is thought to be lower in northern latitudes due to a lack of sunshine; the effective incorporation of such fat-soluble vitamins into stable food systems is likely to require effective encapsulation technology.

Dried food is a valuable alternative to fresh food, where the latter is unsafe or unavailable. The nature of a given food needs to be considered during the design of appropriate processes for its dehydration. In general, dried foods should be stored in cool (<25 °C), dark environments and preferably in sealed containers, to prevent degradation of nutrients. Encapsulation processes for the manufacture of different bioactive substances have been reported as being successful by many researchers. The challenge now is to incorporate these ingredients into real food matrices, ensure their stability, and verify that they can have a positive influence on the health of the modern consumer.

Introduction: Useful Concepts in Food Drying

Food is an important part of our life, and all types of food need to be preserved one way or another for a number of reasons, drying being the most important and effective way of preservation. Fresh fruits and vegetables contain high amounts of water, which results in microbial damage. This reduces the shelf life of foods substantially, unless it is processed efficiently. A considerable volume of fruit and vegetables is lost every year because of microbial spoilage. The moisture in a food product can be reduced to an acceptable level using several thermal dehydration techniques to minimize the possibility of microbial damage. In addition to this, the cost for packaging, transportation, and storage for dried product is substantially less compared to canned or frozen food products. Nevertheless, drying is a highly energy-intensive unit operation because of the high latent heat of evaporation of water (2260 kJ kg^{-1} in free state); hence, the cost of reducing moisture to a very low level is expensive. There have been several developments in recent years in the field of thermal dehydration to enhance drying rates, reduce energy usage, and minimize environmental impact. However, in the case of food products, the quality of the dried product is more important, although other issues such as energy usage and environmental effects of a selected dryer/drying system cannot be neglected.

The moisture present in solids can be classified as bound or unbound moisture. The bound moisture exerts vapor pressure less than that of the pure liquid and the moisture in excess of bound moisture is the unbound moisture. When wet solids are subjected to thermal dehydration, two processes occur simultaneously: removal of surface moisture by evaporation and transfer of internal moisture to surfaces through diffusion and its subsequent evaporation. The removal of surface moisture depends on external conditions such as temperature, relative humidity of drying air, surface area of the wet material available for drying, airflow, and pressure. On the other hand, the removal of internal moisture depends on the physical nature of the solids present, temperature, and amount of moisture present. This largely decides physical and structural changes during the drying of any material. The variation in the airside variables such as airflow, temperature, and relative humidity becomes less important, except when increasing the heat transfer rates to the material. In case of food products, drying generally occurs in falling rate period as most of the moisture present is bound moisture; hence, physical and structural changes in products are quite common. This happens as a result of an excessive moisture gradient from the product interior to the surface, especially during the final stages of drying. This causes overdrying and shrinkage, which, again, result in structural damage.

Drying is a very complex heat- and mass-transferring process with several rate processes, including physical and chemical transformations. Other factors, which are responsible for these complexities, are different types of feedstocks, throughput, quality requirements of a particular product, and, very importantly, the existence of hundreds of dryer types. Therefore, selection of dryer or drying system is a crucial consideration in order to satisfy the demands for a particular application. Interested readers may refer to either the *Handbook of Industrial Drying* or *Mujumdar's Practical Guide to Industrial Drying* for a detailed discussion on classification and selection of dryers. This article will discuss, in short, some conventional and advanced drying techniques and their importance with respect to physical and structural changes in food products.

Importance of Drying in Foods: Benefits and Quality Importance

Fruits and vegetables – in particular – have many positive health effects. This food grouping has a high fiber content and other useful components that help control blood glucose levels, reduce cholesterol, and probably reduce the risk of cancers (colon especially). They also contain antioxidants, vitamins, and minerals, which also have positive health effects. It is important to preserve all nutritional qualities of such food products in their dried state as closely as they are in their native state.

Other important quality attributes are physical and structural changes, which include shrinkage, puffing, glass transition, rehydration capacity, density, and mechanical properties. These properties depend on several factors, such as pretreatment process prior to drying, dryer conditions (such as temperature, pressure, and, to some extent, relative humidity of drying medium), type of drying medium, type and extent of heat input, and physical state of the product to be dried. The selection of drying conditions and dryer type will depend on the desired and expected properties of the product. The following section presents some of the important physical and structural properties of dried products:

Shrinkage is a change in volume as a result of loss in moisture during drying. Shrinkage is an important consequence of drying, which determines the rate of drying and quality of the dried material to great extent. Shrinkage influences product structure and the rehydration ability of a dried food product. Shrinkage occurs as a result of capillary collapse due to the evaporation of water occupying the capillaries. Shrinkage can be either isotropic or anisotropic. Isotropic shrinkage is defined as uniform shrinkage of all geometric dimensions of a material. In anisotropic shrinkage, the extent of shrinkage of all geometric dimensions of a material is uneven or nonuniform in nature. As discussed earlier, the outer layer of the material loses moisture much faster than the interior; hence,

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00241-5

the surface layer shrinks. If the surface moisture is removed very fast, but the diffusivity or the migration of internal moisture to the surface is too slow, then an exterior layer, which is essentially impermeable to moisture diffusion, is formed. This phenomenon is known as *case hardening*. In food drying, case hardening is quite common and selection of proper drying conditions is very important; however, it may be desirable in some instances for some products.

Cracking is another phenomenon that occurs during the drying of foods. In this situation, the product surface shrinks during drying, causing tensile stress at the surface and compressive stress inside the material. When the tensile stress exceeds the material strength, cracking occurs. The cracking of material during drying needs to be avoided as it results in loss of material and consumer unacceptability. In the case of grains, cracking usually leads to material loss during milling and may also result in bacterial attack during storage. The internal *microstructure* of food products is also very important as it can have a profound influence on its nutritional value, rheology, and textural attributes. As the drying can substantially affect the internal structure of foods, it is necessary to understand the effect of various parameters on product microstructure. The *rehydration ratio* is defined and based on the mass of material after drying and its corresponding mass after soaking in water.

Drying rates can have dramatic effects on structure of the dried products as drying can cause case hardening. This consequently causes the surface to crack, which in turn allows the vapor generated within the body to flash out and cause poor appearance and nonuniform drying. This is undesirable. This phenomenon is product-dependent, and hence, laboratory testing is necessary. Discoloration of the product surface can also occur. Furthermore, gradients in porosity can lead to a nonhomogeneous product. The use of radiative heat input can also result in crust formation if the flux is too high. Drying at elevated temperatures, if it is elevated enough under the operating pressure used, can cause internal boiling of the liquid. The internal boiling leads to hollow particles in spray-dried powders. This again enhances the porosity, thereby resulting in better rehydration ability. The following sections present the effects that operating parameters and dryer types have on the physical and structural properties of dried foods.

Influence of Various Drying Parameters on Physical and Structural Food Modifications

Pretreatment

A pretreatment of wet product prior to drying is very important for foods. This is used to achieve physical or chemical changes in order to enhance the drying rates and product quality. Blanching and osmotic treatment are used for several food products, especially for fruits and vegetables. During osmotic dehydration, a product to be dried is treated with an osmotic solution; water from the food material migrates outward and is replaced by the solute from the osmotic solution. The presence of this solute also serves as a preservative. Although osmotic dehydration is mainly useful to improve product quality, including color, microstructure, and enhanced drying rate, however, it may sometimes have adverse effects on physical characteristics. Table 1 shows the impact that pretreatment has on the physical properties of fruit products.

Table 1 Use of pretreatment on physical properties of dried fruit

Product	*Type of pretreatment*	*Findings*
Kiwifruit slices of different initial textures (firm, medium and soft)	Sucrose syrup (70% w/w) for 2 h at 25 °C	Improved texture
Apple, banana	Sucrose solution (50% w/w) followed by air-drying at 70 °C	Porosity of the osmotically treated product decreased as a result of solid gain; however, it prevented color deterioration; increases the maximum stress and maximum deformation of the dehydrated product
Papaya	Osmotic dehydration followed by hot-air (HA) drying of papaya with a sucrose solution (65°Brix) with syrup to fruit mass ratio of 4:1	Better maintenance of cell structure of papaya when OD with additives was used followed by HA drying
Salak fruit	Thermal pretreatment (blanching)	Increase in the cross-sectional area of cells, which affects the water sorption characteristics

Recently, various approaches have been employed to enhance the process of osmotic dehydration. The use of microwave (MW), pulsed electric fields, ultrasound, and high hydrostatic pressure has resulted in enhanced osmotic dehydration rates. It has been shown that the ultrasound pretreatment improves the chewability of products such as dried sea cucumber (low hardness and high springiness) and results in a higher rehydration ratio as a result of microchannels formed during ultrasound pretreatment. The use of pulsed vacuum and ultrasound has also been shown to improve water removal rate, favorable glass transition temperature, and color. Some physical pretreatments include freezing, thawing, bruising, pinning, drilling holes on surface (to ease moisture diffusion), and extrusion (to increase the surface area). Each one of these techniques has been used selectively to either enhance drying rates or improve final product quality.

Temperature and Humidity

As explained earlier, the external drying conditions determine removal of surface moisture; however, the diffusion of internal moisture determines the drying rate when internal moisture needs to be removed. It was also highlighted that the drying of most food products shows a falling rate period; hence, the increase in temperature can elevate internal moisture diffusion.

However, the use of very high temperatures may harm the quality of a dried product. Several studies have been carried out in an attempt to understand the effect of temperature and initial moisture on the physical properties of material. In general, low-temperature drying results in lower shrinkage and higher rehydration compared with drying at a higher temperature, as it results in crispy crust formation. Some studies also observed increases in porosity with increase in temperature, which resulted in better preservation of the structure at intermediate temperatures. This is due to the fact that both the longer drying time at lower temperatures and the use of very high temperatures can result in development of wrinkled structure. Figure 1 shows scanning electron microscopy (SEM) photographs of carrot dried using hot-air drying; higher temperature affects the pore diameter. In the case of some products, such as gelatin films, crystallinity and glass transition temperature are important. The lower drying temperature can result in higher crystallinity and higher glass transition temperature of the dried product, which is important for better water absorption and lower levels of hysteresis.

The relative humidity of a drying medium also has an effect on physical properties of the dried material. In addition to temperature, the humidity also decides the rate of drying. If the drying medium is highly saturated with moisture, then the drying rates are slower; hence, either temperature rise or reduction of relative humidity is necessary. Besides this, relative humidity can also affect product structural properties if the glass transition temperature is affected by higher relative humidity, especially products containing sugars.

Pressure

The pressure used during drying can have considerable influence on the physical structure of the dried material. A dryer can be operated either at atmospheric, at subatmospheric, or with variable pressure cycles. Most commonly used dryers operate at atmospheric pressure. However, if there is a restriction on the drying temperature used, because of heat sensitivity of a particular product, then drying needs to be carried out at subatmospheric pressures. The moisture can be removed at lower temperatures when vacuum is used, although operating a dryer at subatmospheric pressure increases processing cost considerably. Drying under vacuum can open up voids within a material with a nonrigid structure. This increases the porosity and enhances rehydration ability. This has been observed by a number of researchers using a variety of drying methods, such as freeze-drying (FD), MW vacuum drying, and superheated steam drying. Some researchers have used variable pressures to achieve porous structures, such as successive pressure drop (déshydratation par détentes successives, DDS) and controlled instantaneous pressure drop (détente instantanée contrôlée, DIC). All these ideas and related findings will be discussed in more detail in the section on advanced drying techniques in this article.

Drying Medium

The choice of drying medium for food products is very important as it can have considerable effects on product quality. The most commonly used drying medium is air as it is the least

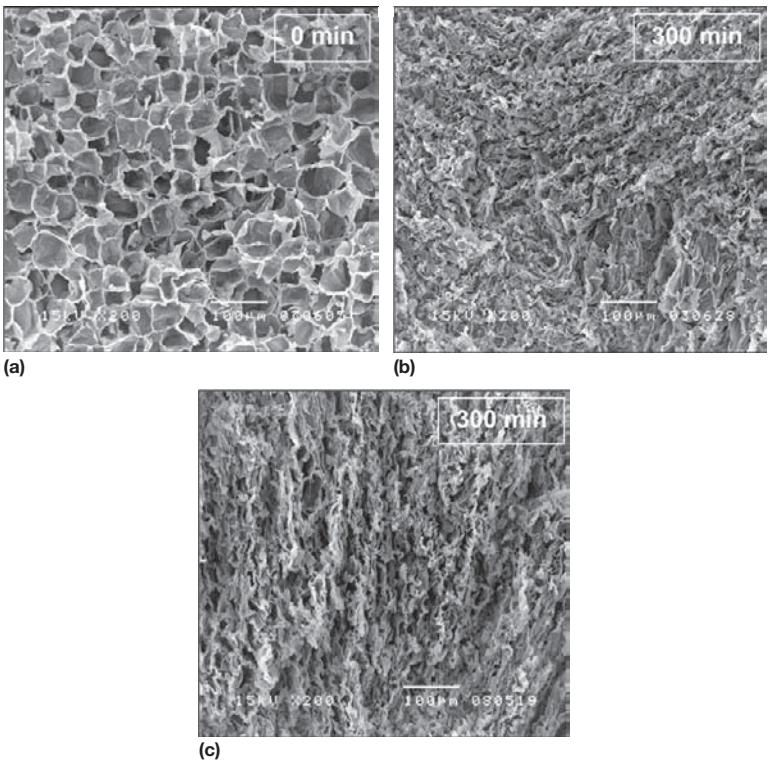

Figure 1 SEM photographs showing cross section of carrot cube undergoing hot-air drying (a) fresh sample; (b) hot-air drying at 60 °C; (c) hot-air drying at 80 °C.

expensive to use. However, the use of air can damage product quality in terms of browning (as a result of unwanted enzymatic or nonenzymatic reactions when in the presence of oxygen), shrinkage, porosity, and texture. Modified atmospheric drying can be carried out by replacing air with an inert medium such as carbon dioxide, nitrogen, or steam. This is very useful for many products, especially food products. The use of superheated steam was proposed in 1990s and has been developed over the years as an important drying technique for foods. There are several published reports on use of inert atmosphere during drying, although the system needs to be a closed cycle in order to minimize the volume of the drying medium used, thereby reducing processing cost. An extensive review on drying of foods using heat pump dryers has been published, which addresses the use of inert atmosphere for drying. This article elaborates on the improvement of quality attributes of dried products, such as reduction in browning, increased porosity, and production of less firm products compared with products obtained using heat pump drying (HPD) employing air. The improved structure of the products dried using an inert atmosphere also resulted in faster rehydration. It is certainly useful to use an inert atmosphere for foods, but one needs to consider several aspects such as added cost, improvement in quality, and possible returns.

Mode of Heat Input

The classification of dryers based on the mode of heat input is most common. Dryers are classified as direct and indirect. Direct dryers, also known as convective dryers, are by far the most commonly used in industry, although efficiencies are low. In direct dryers, the drying medium contacts the material to be dried directly and supplies the heat required for drying by convection. Drying gas temperatures may range from 40 °C to very high temperatures, the temperature selected being dependent upon the food material to be dried. As described earlier, the selection of dryer temperature is very important in order to minimize structural food damage. As described previously in this article, the drying of foods falls in the falling rate period. Hence, one can use intermittent heat supply at the end of the drying when the moisture transport from inside to the surface is very slow.

On the other hand, indirect dryers involve the supply of heat to the wet solids without direct contact with the heat transfer medium. The heat is transferred from the heat transfer medium to the wet solid by conduction, and the use of vacuum or gentle gas flow is necessary in order to remove the evaporated moisture. Heat transfer surfaces may range in temperature from 40 °C (as in FD) to very high temperatures; the selection of which is dependent upon the specific application. The application of indirect dryers in foods generally uses vacuum as most of the foods processed are heat-sensitive.

Heat can also be supplied by radiation (using electric or natural gas-fired radiators) or volumetrically by placing the wet solid in dielectric fields in microwave or radio-frequency (RF) ranges. These options, especially MW dryers, are worth considering as devices to speed up food drying in the tail end of the falling rate period in order to reduce changes to physical structure as a result of prolonged drying times. Some of these dryers and related applications are discussed in the following sections.

Effect of Drying Methods

It is extremely important to select an appropriate dryer or drying system for each food product as most are highly heat-sensitive. An incorrect choice of drying system and/or drying conditions adversely affects the physical and nutritional properties of the dried food. This section discusses conventional and recently developed drying techniques, as well as their effects on the physical structure of foods.

Conventional Drying Techniques

There are several techniques traditionally used for food drying, such as open sun drying, solar cabinet drying, and hot-air drying; however, these techniques result in unacceptable physical and nutritional properties of foods. The products from these dryers can be used to partly satisfy domestic demands, although one cannot sustain the ever-growing international markets. Table 2 lists several conventional dryers used for food drying. This list is based on type of feedstock used, although the dryers can be classified based on several other parameters.

For particulate materials, a variant of fluid bed is the most popular choice because of the requirement of very high heat and mass transfer rates as a result of vigorous mixing between particles and drying medium. A major limitation of fluidized bed dryers can be particle size and the feedstock particle size distribution. In the case of some food products, attrition results in unacceptable size distribution. In fluidized beds, the nonuniform distribution of drying gas also results in nonuniform quality of drying products in terms of shrinkage, moisture content, and rehydration ratio. Traditionally, tray drying is popular, but throughput and energy efficiency are major issues. Drying time can be very long, in the case of tray dryers, and hence, it can have adverse effects on product quality, especially with respect to physical structure. Though continuous tray dryers were also used, these dryer types are not popular anymore.

Spray drying is one of the techniques used extensively in food-related industries for liquid feedstocks. As heat contact time is very short and the rate of evaporation is high, spray drying produces a high-quality product, although cost may also be high due to energy consumption. The liquid droplets

Table 2 Classification of conventional dryers based on the type of feedstock employed

Type of feedstock	*Dryer types*
Particulates	Tray, fluidized bed dryers, belt conveyor, vibrated bed, rotary, screw conveyor, vacuum, freeze
Sheets, extruded material	Impingement, infrared, microwave, conduction
Liquids	Spray, variant of fluidized bed dryer with a bed of inert particles, drum
Paste	Paddle, fluidized bed, drum, rotary

containing solids are dried in seconds as a result of the highly efficient heat and mass transfers. The final product from a spray dryer is in the form of powder. However, granules or agglomerates are conveniently produced by combining a fluidized bed dryer or by recycling the fine particulates. There are several factors that decide the physical form of the spray-dried product, mainly atomization, chamber design, the type of contact between drying gas and droplets, and drying air conditions. SEM images of dried product are generally used to examine particle morphology. The use of very high temperatures can result in crust formation. There are several reports on SEM analysis of spray-dried food products, such as skimmed milk, fruit juices, and other extracts showing the effect of operating parameters, atomization, and chamber design on morphology of dried powder. Figure 2 shows SEM images of spray-dried powder of fermented mixed juice of carrot and watermelon at different operating conditions.

Spray drying is also commonly used in the food industry for microencapsulation. Microencapsulation is defined as a process by which one material, or a mixture of materials, is coated or entrapped within another material or system. The coated material is called the active or core material, and the coating material is called the shell, wall material, carrier, or encapsulate. It is necessary to obtain a rigid structure to protect the active ingredients trapped within the carrier. The selection of drying conditions and the type of carrier and its composition are extremely important in order to achieve efficient microencapsulated material.

Other techniques for drying of liquid materials are drum drying and drying on a bed of inert particles, which has grown in popularity in recent times. For sheets and extruded food products, mainly belt conveyors or batch tray dryers are used in combination with infrared (IR), microwave, or conductive heating. In the case of pasty materials, paddle dryers or fluidized bed of inert particles are more commonly used.

Recently Developed Drying Techniques

Each traditional drying technology described earlier can have numerous variants, which possess some unique characteristics. It is highly unusual to have a variant that only presents advantages without limitations. So, final selection is always a compromise based on the product specification. Selection of dryers is a very complex process. There are several reasons why few truly innovative technologies find commercial adoption, the most important being quality in terms of physical structure of the dried material. The following are some of the more recently developed drying techniques and their influence on the structural properties of the final dried products.

Heat pump drying

Although HPD is not a very new technology, there has been continuous improvement in the design and application of HPD technologies for food drying. HPD consists of a refrigeration cycle to recover heat from dryer exhaust air and reheat it to the required temperature before it enters back into the dryer. Detailed discussion on HPD and its operation can be found elsewhere. The HPD system was traditionally used for the recovery of heat; however, HPD is used in food drying to improve product quality by utilizing some of the other advantages it offers. The primary advantages of employing the HPD system include providing a wide range of operating conditions (humidity and temperature), possibility of using inert gas as drying medium, and combining with other heat modes. For heat-sensitive food products with long drying times, HPD is very useful as drying can be carried out using relatively lower temperatures in combination with dehumidified air. As presented in several published studies, the use of inert gas has resulted in better physical properties of the dried material. A closed-loop HPD system can substantially reduce the operating cost, as the same inert gas can be recycled, with some top-up as necessary. Some of the applications of inert gas food drying include drying of apple, ginger, guava, papaya, lecithin, etc.

The most common HDP system used is mechanical compression with low coefficient of performance. Some research has focused on improving process efficiency, including multistage heat pumps, chemical heat pumps, or use of heated pipes. The chemical heat pump has good commercial potential but needs thorough research. Another way of improving the performance of heat pump systems is using external heating modes such as microwave, RF, IR, or solar energies. This is useful during the final stages of drying in order to minimize possible damage to the physical structure of the foods. Solar-assisted HPD is extremely useful for agricultural products. Another approach of reducing product damage, as well as reducing the overall cost of drying, is by varying the operating cycle of HPD, such as through intermittent or time-dependent approaches. For more detailed discussion of recent technological advances and possible R&D opportunities in HPD, readers may refer to related book chapter and review articles listed in reference.

Refractance window drying

The refractance window drying is a relatively new method used to convert pulverized fruits and vegetables, pastes, and also thin slice of fresh fruits. In this technology, the IR energy coming from hot water (90–97 °C) is used to dry the thermally sensitive food materials. An IR-transparent plastic film is essentially allowed to float on top of thin layer of heated water body. The IR energy refracted through the plastic film due to the presence of 'window' of moisture in the product across the film is responsible for drying. The conduction of heat through the thin plastic film also assists with drying. This is a relatively energy-efficient system as the IR only gets refracted when the wet product is present across the film. The refractance gradually declines as the product dries. The loss of heat in this system (in the absence of product) is due to conduction. It is reported that this drying method preserves the color, texture, and antioxidant contents compared with other drying methods of similar heat intensity. This method is attracting increased research attention.

Filtermat spray drying

This is a relatively newly developed drying method (GEA Technologies, Denmark) in which spray drying is combined with Filtermat drying. This technology is especially designed to dry difficult-to-dry sugar-rich products. The Filtermat component involves a porous conveyor with controlled linear speed. The drying section is usually divided into different sections. The partially dried particles are deposited on this Filtermat, and

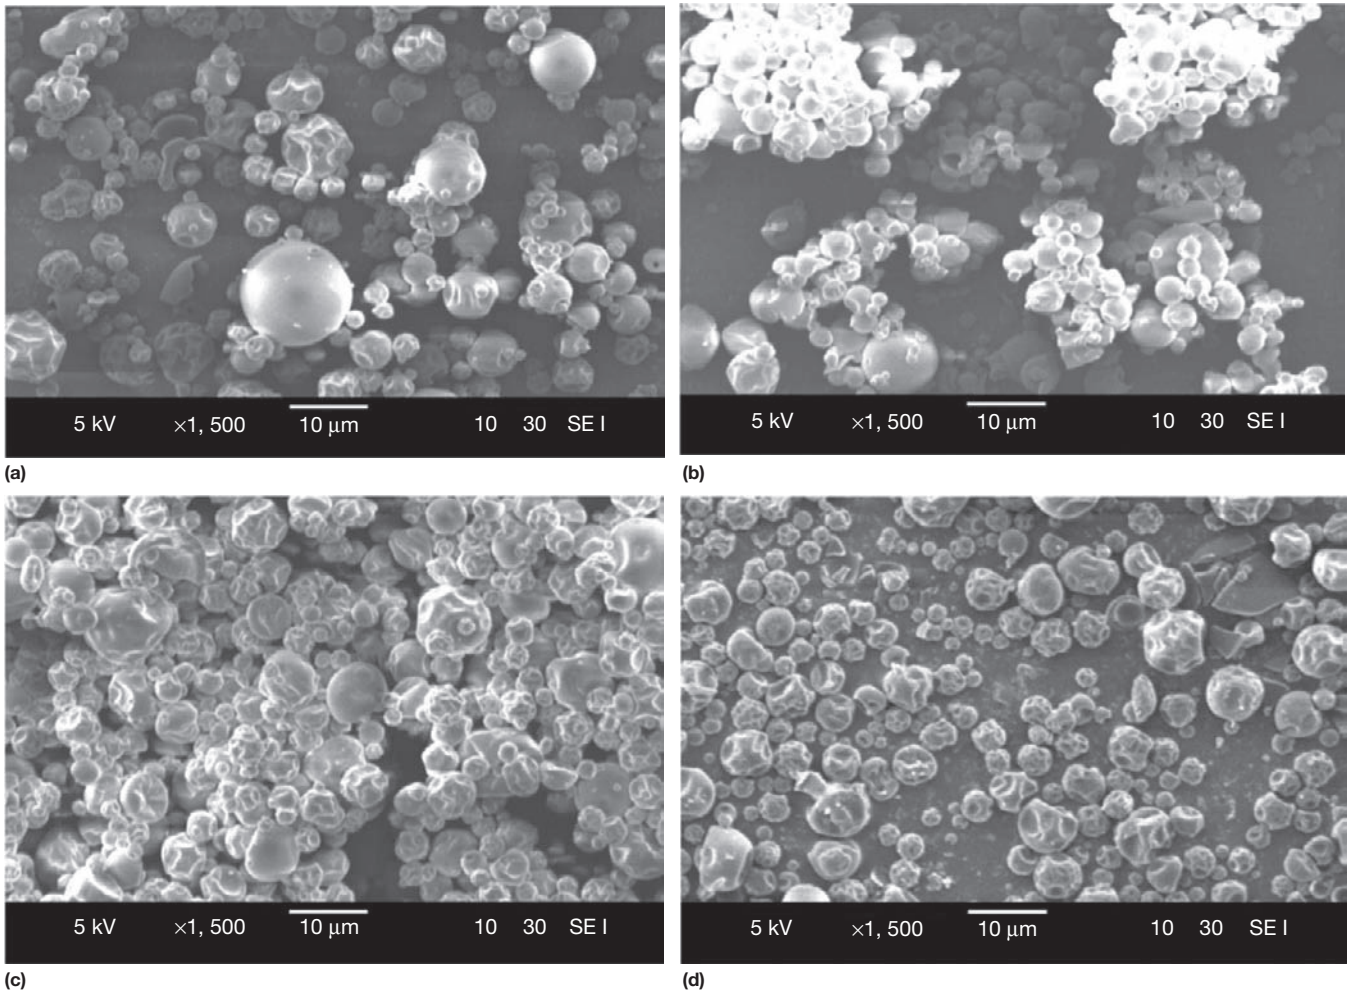

Figure 2 Scanning electron micrographs of spray-dried powder illustrating the variation in particle size and surface roughness when produced at different operating conditions (T, temperature; F, flow rate; P, pressure): (a) $T = 140\ ^{\circ}C$, $F = 3.5$ ml min^{-1}, $P = 2$ bar, maltodextrin = 17.5%; (b) $T = 160\ ^{\circ}C$, $F = 5$ ml min^{-1}, $P = 3$ bar, maltodextrin = 10%; (c) $T = 140\ ^{\circ}C$, $F = 3.5$ ml min^{-1}, $P = 2$ bar, maltodextrin = 12.5%; and (d) $T = 120\ ^{\circ}C$, $F = 5$ ml min^{-1}, $P = 1$ bar, maltodextrin = 15%. Reproduced from Mestry, A. P., Mujumdar, A. S. and Thorat, B. N. (2011). Optimization of spray drying of an innovative functional food: fermented mixed juice of carrot and watermelon. *Drying Technology* **29**(10), 1121–1131.

the hot air is allowed to pass through the pores of the conveyor and through the interstices of the deposited mass of particles. In the second stage, dehumidified cold air is used to further dry and cool the product. The final product requires certain degree of grinding. The difference in this method over fluidized bed drying is that the particles are not fluidized. The deposited agglomerates are allowed to dry as thin layer of porous cake. This type of dryer can be suitable for producing baby formula powders.

Intermittent drying

Intermittent drying is an attractive concept due to its potential to enhance energy efficiency and achieve better product quality as a result of uniform drying. In intermittent drying, drying airflow, temperature, or humidity is varied, or other alternative parameters such as system pressure and type of external heat source (microwave, IR, or RF) are varied with time in order to suit the requirements. Sometimes, cycles of different heating modes can be used. The main objective of intermittent drying is to allow internal moisture to migrate to the surface of the material during nonactive period – known as the tempering period. During the active period, the heat is supplied, while during tempering period, the supply of drying medium is completely stopped. As the moisture content at the surface is increased during tempering period, the rate of drying increases substantially during the following active period. However, as the drying rate is very small during the tempering period, the overall drying time may increase slightly, although this is compensated by the overall energy consumption.

Another intermittent drying approach is through the application of a stepwise change in operating conditions. This is especially important in the case of food products, as drying rates are very slow during final processing stages. This is due to the fact that drying is diffusion-controlled in the final stages; hence, the effect of external conditions is negligible. The use of this stepwise strategy of changes in the operating conditions is very useful as a lot of energy can be saved. At the same time, the product being dried is exposed to severe drying temperatures for a shorter time, and this results in less product shrinkage and less physical product damage. The concept of intermittent drying can be applied to various food products, using different drying methods, including the use of a tray dryer, conveyor dryer, vibrating bed dryer, and fluidized bed dryer.

Variable pressure methods

Drying can be carried out using either a controlled instantaneous pressure drop method or a cyclic pressure drop method. In a standard controlled instantaneous pressure drop (DIC) treatment, the product is subjected to high pressure, generally using gas or steam, while temperature is maintained by one of the various means available. This is followed by an instantaneous drop in pressure, usually assisted by vacuum technologies, which leads to autovaporization of water and sometimes volatiles. This process can be easily controlled and results in very good product quality, especially with respect to product expansion ratio and porosity and also in the enhancement of product texture. Swell drying is a combination of hot-air drying and the DIC texturizing process. The reduction in drying time, using swell drying, results in the significant enhancement of product quality. In a dehydration process, followed by successive decompression (DDS), the thermosensitive product undergoes a series of cycles, during which it is placed at a particular pressure for a defined time, followed by an instantaneous drop in processing pressure. The product is maintained at lower pressures for some time, before the following cycle begins, and each decompression step results in partial removal of water by autovaporization. The amount of water removed depends on various factors, such as operating conditions and the type of water present in the material dried.

The major advantage of these techniques is the considerable reduction in drying time that results compared to normal vacuum drying or hot-air drying techniques used for food products. The reduction in drying time always helps control the physical properties of dried products. The techniques of instantaneous and cyclic pressure drop have been successfully applied to various food products, including grains, fruits, vegetables, and fish. The DIC method is specifically used to tackle the problem of product shrinkage.

Superheated steam drying

Superheated steam is an attractive drying medium for some food products since the net energy consumption can be minimized if the exhaust (also superheated steam) can be utilized elsewhere in the plant. The quality of superheated steam-dried products tends to be better than that from conventional hot-air dryers. Superheated steam also allows pasteurization, sterilization, and deodorization of food products. This is particularly important for food and pharmaceutical products that require a high standard of hygienic processing. In addition, drying rates are higher in the case of superheated steam drying, in both constant and falling rate periods and under certain conditions, which are important to control in order to create the structural changes required in foods. Mujumdar had discussed the principles, advantages, and limitations as well as diverse applications of superheated steam drying technologies in a number of publications, including the *Handbook of Industrial Drying*.

Some products are not stable at 100 °C, then one option is to lower the operating pressure. The application of low-pressure superheated steam drying is used for products, such as potato chips, carrot, and longan. SEM images shows considerable improvement in structure (porosity), less shrinkage, and high rehydration ratio compared to hot-air drying. As an example, SEM images of fresh and dried carrot using hot air and the application of low-pressure superheated steam drying (LPSSD) are shown in **Figure 3**. Although one can obtain good dried product quality at low pressures, the process is still not popular due to the requirement for large equipment owing to low drying rates, but perhaps it may be necessary to use supplementary heat sources in order to improve the process. Much research and development is needed in this area in order to progress the drying technologies discussed.

Advances in FD

FD is undoubtedly the most acceptable drying technique for foods because it probably generates the best product quality, as

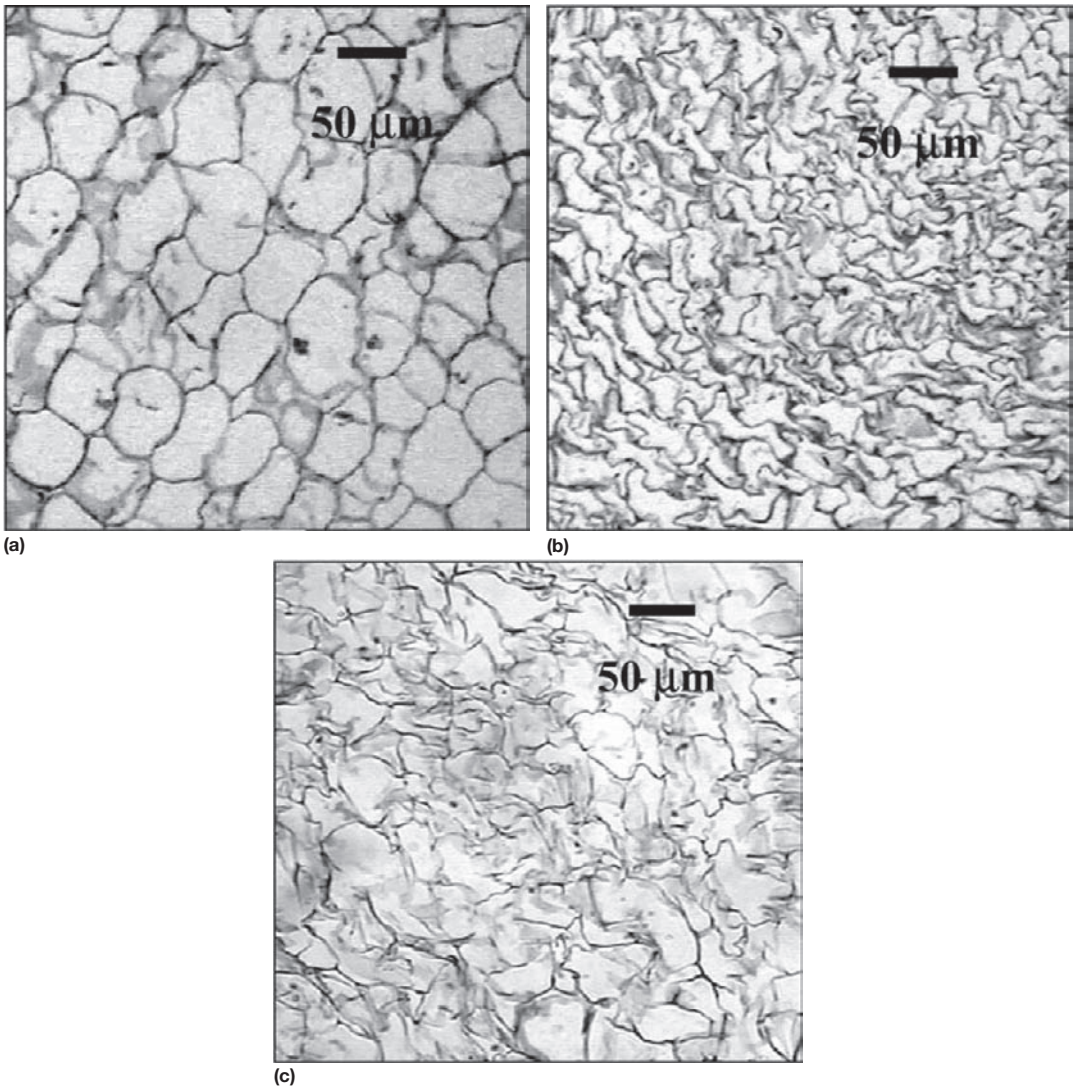

Figure 3 Microstructure of (a) fresh carrot, (b) carrot dried until reaching equilibrium moisture content using hot-air drying, (c) carrot dried using low-pressure superheated steam drying. the frozen product is not allowed to melt during drying. It prevents undesirable shrinkage and produces materials with high porosity, ultimately resulting in better product rehydration properties. There are several reports in the literature showing SEM images of freeze-dried products, clearly indicating that FD enhances powder microstructure compared with that produced using conventional hot-air drying. However, the industrial application of FD for food drying is limited because of the high associated processing cost. There has been significant effort to develop new techniques in order to achieve similar product quality obtained from FD, although it is difficult to achieve some characteristics, which only FD can achieve such as rehydration, color, and texture. The cost of FD can be reduced by improving the drying rates using external heating, but without allowing the product to melt. This can be achieved by either using magnetic and electric fields, using atmospheric FD, or using microwave in combination with FD (MFD). Application of ultrasound during the freezing stage also greatly improves the drying rate and product quality of freeze-dried products. A review on the use of electric and magnetic fields during freezing and their application to FD suggests better control on the ice crystals and, ultimately, on product quality. The use of microwave FD for products such as fruit, vegetable, and some marine-derived products has resulted in better drying rates and product quality, particularly in relation to product microstructure, shrinkage, and rehydration ratio. Figure 4 shows comparison of SEM images of banana chips dried using FD and microwave FD. A detailed discussion on FD and technological advances in the area can be found elsewhere in this book.

Hybrid drying

In the case of some food products, many conventional drying techniques may not provide the expected final moisture contents at sufficiently acceptable drying rates. In such cases, a

combination of dryers or drying technologies can be used. In recent years, hybrid drying is popular as it can reduce drying time substantially and provide more flexibility. Hybrid drying systems may adopt more than one drying technique or more than one heating mode in the same dryer. Microwave drying offers advantages in enhancing drying kinetics, precise control, fast start-up and shutdown times, quality of dried product, smaller footprint of equipment, etc. IR drying is also useful in removing final traces of product moisture at a faster rate. These techniques are typically combined with other drying methods to overcome the limitations of uneven heating, resulting in unacceptable physical structure, for example, overdrying at the corners and edges of products.

Spray FD is another hybrid drying technique used to prepare highly porous particles. This technique involves the spraying of a liquid feed in a cryogenic atmosphere, followed by FD of these frozen droplets. The technique of spray FD has been used for selected food application; however, necessary research and development work is needed to minimize associated costs.

Concluding Remarks

Drying of foods is an extremely important commercial and preservation process, and the approach used to dry foods will impact differently upon the physical and structural properties of the products in question. Drying rate and operating conditions can have considerable effect on structure of the dried product. To a certain extent, the structure can be controlled by selection of an appropriate drying technique and manipulation of operating conditions, although it is necessary to take into consideration cost-effectiveness and suitability of each method employed. Appropriate changes in existing drying systems and the use of some innovative dryers can give improved quality of dried foods such as porosity, rehydration ratio, texture, and microstructure.

New drying technologies such as microwave or RF-assisted drying, pulse combustion drying, intermittent batch drying, and superheated steam drying at subatmospheric pressure may be applied in specific cases to obtain desired product characteristics under optimal drying conditions. Experimental validation at laboratory or pilot scale is necessary as it is not possible to predict the effect of drying conditions on product characteristics with high reliability.

Drying: Principles and Types

JM Barat and R Grau, Universitat Politècnica de València, Valencia, Spain

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Drying is one of the oldest methods used for food preservation. In fact, it is quite evident that initially, drying occurred by chance and under natural conditions. Most of the raw material used as food comes from biologically active sources. Consequently, very few foodstuffs are inorganic in nature, such as table salt. Since water is needed for life, it implies that most raw materials destined for food consumption have a high water content and, ultimately, high water activity (a_w) values. Water activity is a thermodynamic term that is related with the degree of freedom of water.

Although the first objective for using drying was food preservation, nowadays, drying is also used to reduce food volume and/or weight in order to optimize its storage and transportation (e.g., milk powder) and to avoid the need for refrigeration or freezing conditions for preservation (e.g., dry-cured ham) and is used for food product development (e.g., snacks).

Food drying occurs when the water activity of the air surrounding food is lower than its a_w. One characteristic of the drying process is that the liquid water of food is transferred to the gaseous state in drying air at temperatures below the boiling point through an evaporation process.

The water activity of the air surrounding food is equal to its relative humidity (RH) divided by 100 and is usually lower than the original a_w value of the animals and plants used as food sources. Thus, when an animal or plant dies, a natural drying process occurs, during which the water activity value of food naturally decreases, thereby making it more stable.

Some characteristic water activity values of raw and dried food products are presented in Table 1.

Sometimes, drying is used in combination with other preserving techniques. The most common technique is addition of solutes, which contribute to further a_w reduction due to their interaction with the water present in food. The most widely used solutes are NaCl and sucrose. NaCl is normally used with meat and fish products (e.g., dry-cured ham and dry-salted cod), while sucrose is habitually employed with processed fruit products, like jams and marmalades.

Water Activity and Stability

The water activity of food is related with its stability. The original water activity of plants and animals is high enough to allow reactions that permit life (such as solute movement and biochemical reactions). This fact implies that when an animal or plant dies, the spoilage process begins quickly since high a_w values would promote microbial growth and allow chemical and biochemical reactions to proceed because of solute movement and the activity of natural reagents and enzymes.

Reduced a_w of food implies lower kinetics of spoilage reactions, and a time comes when the spoilage reaction stops altogether when a low enough a_w point has been reached within the food.

The only exception to this behavior is during fat oxidation. The kinetics of fat oxidation is initially diminished with a reduction in a_w of food, until a value (usually in the 0.2–0.3 range) is reached when oxidation kinetics begins to increase due to the direct exposure of fats to oxygen as a consequence of the removal of most of the water molecules that create a protective layer on the fat surface.

Thus, as a general pattern, the preservation behavior of food increases with the reduction of water activity, up to 0.2–0.3.

Water Activity and Equilibrium

As mentioned in 'Introduction,' water activity is a thermodynamic concept. This means that, in the absence of other forces, movement of water will occur from points with a higher a_w to points with a lower a_w. It is important to bear this in mind, since a very common mistake is to consider that food systems remain at equilibrium when the moisture at all points is the same, instead of the true condition, which is when the a_w of all its points is the same.

So, food also tends to its internal equilibrium and with the water activity of its surrounding air, which is the basis of the drying processes.

At equilibrium, the water activity at each point within the food is the same and equals that of the surrounding air. Within the range of high water activity values, predictive equations can be used to estimate the water activity of foods depending on their composition: water and solute concentrations. Within this range, food behaves similarly to the liquid phase contained within its structure, and models developed for nonionic or ionic solutes can be used, for example, Norrish for nonionic solutes, Pitzer and Bromley for ionic solutes, or Ross for a combination of solutes. If water activity values are low, predictive equations for solutions are not useful because the interaction of water with nonsoluble food compounds plays a major role. This is why sorption isotherms must be used, which represent the water activity of food versus the water content of food on a dry basis. The main disadvantage of using sorption isotherms is that they must be experimentally determined for each food type, owing to the variance in food composition and structure. Figure 1 shows a typical sorption isotherm, which relates the moisture of a certain food with a particular water activity.

The sorption isotherm can also be used to determine the equilibrium moisture of a certain food with the air used for drying, which is achieved at the end of a certain drying process if the air RH remains constant.

In commercial situations, the drying process usually finishes far from equilibrium conditions with the drying air because the drying rate is very low close to equilibrium.

Table 1 Characteristic water activity values of raw and dried food products

a_w *raw food*	a_w *dried food*
Raw fruit and vegetables	*Dried fruits and vegetables*
Apples: 0.99	a_w within the 0.6–0.7 range
Bananas: 0.98	
Figs: 0.97	
Grapes: 0.98	
Oranges: 0.99	
Carrots: 0.99	
Tomatoes: 099	
Fresh meat: 0.99	Dry-cured ham[a]: 0.87–0.92
	Salami[a]: 0.82
	Beef jerky[a]: 0.80
Fresh fish: 0.99	Dry-salted cod[a]: 0.65–0.75
Milk: 0.99	Milk powder: 0.20
	Aged cheese[a]: 0.87–0.89
Coffee: 0.99	Instant coffee: 0.20

[a]The final a_w of these products is due not only to drying but also to the combined effect with salt.

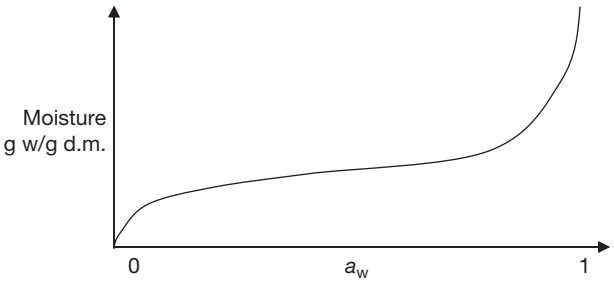

Figure 1 Typical sorption isotherm (w, water; d.m., dry matter).

When drying moist products begins, the decreased water activity in food is due mainly to the concentration of the solutes present in the food liquid phase. A time arrives when the liquid phase disappears and the interaction of water molecules with the solid compounds (insoluble or precipitated) of food occurs, and this plays a key role in the water activity of food.

Water Activity of Air

The water activity of air is equal to its RH divided by 100. On most occasions, the water activity of air is lower than the water activity of raw material used as food, which means that a natural drying process occurs, usually when food is stored without protection. Nevertheless, the reduction of air RH is usually desirable to increase the difference of a_w of food and air to enhance the drying process.

A number of actions can be performed to modify relative air humidity, of which the most common is to increase air temperature. This is why most drying techniques imply heating air by different means. Air RH is the water vapor pressure of air at a certain pressure divided by the saturated vapor pressure of air at the same pressure, at the system's temperature multiplied by 100. There is a direct relationship between saturated vapor pressure of air and its temperature (eqn [1]), and its value increases when temperature rises, so the water activity of air reduces:

$$p_{ws} = e^{(77.345+0.0057\ T-7235/T)}/T^{8.2} \quad [1]$$

where p_{ws} = water vapor saturation pressure (Pa), e = the constant 2718, and T = dry bulb temperature of moist air (K).

Nonetheless, heating air contributes not only to reduce its water activity but also, consequently, to increase the gradient between food and air. Air heating implies an increase in the kg of water that each kg of dry air can take from food. Finally, an increase in transport coefficients occurs because they are temperature-dependent, usually following the Arrhenius equation pattern.

Apart from using air heating to reduce water activity, the direct removal of water from air can be used if food products are sensitive to high temperatures. In this case, water removal can be done by passing air through hygroscopic media or by water condensation at temperatures below the dew point of air, followed by heating.

Understanding air thermodynamics is the most important in drying processes.

Water Transport Through Drying Processes

As previously highlighted, drying occurs if the water activity of food is higher than that of air and, more specifically, if the water activity on the food surface is higher than the surrounding air. Thus, a typical drying process implies transporting the water inside food towards its surface, evaporating air on the food surface, and transporting water vapor from the food surface to the bulk of the drying air:

- Transporting water inside food: transport of water inside food can occur in the liquid state (by diffusion, capillary forces, etc.) or as vapor.
  - The movement of water in the liquid state usually occurs in products with a free liquid phase. This is a fast process that implies food shrinkage equal to the volume of water lost from the food product.
  - The movement of water in the vapor state during drying usually occurs when food shrinkage is lower than the volume of water lost during drying. This implies that voids with a gas phase inside food appear. Thus, water needs to be in the gas state to leave food. A consequence of this type of movement is that the drying rate is very low.
- Transporting water inside drying air: transporting water inside air usually occurs by convection, since drying air is normally at a rate in the dryer that ensures convection. On rare occasions, water vapor moves by diffusion and is usually associated with storage conditions more than drying conditions.

In a real process, the transported water inside food is equal to the transported water inside drying air. In most drying processes, the limiting factor defining the drying rate is the transport inside the food itself, because the food structure is more limiting to water transport than air. This implies that the drying rate decreases with time, since reduced moisture inside food

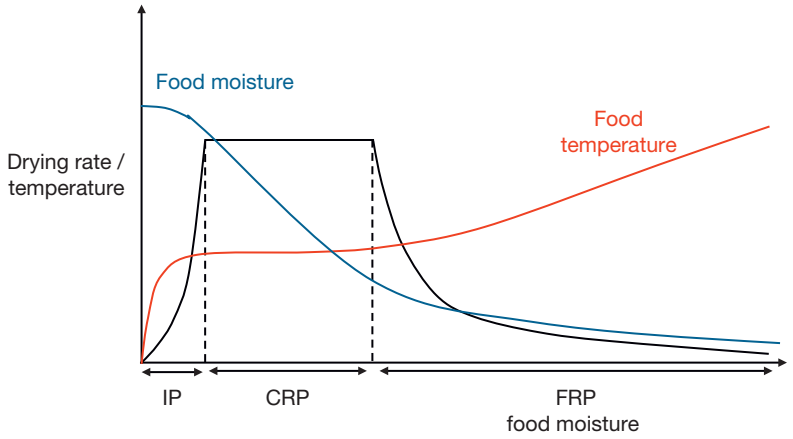

Figure 2 Typical drying curve (IP, initial period; CRP, constant rate period; FRP, falling rate period).

implies a lower transport coefficient (higher viscosity, higher shrinkage, smaller quantity of liquid phase, lower water activity, etc.). This period is called the falling rate period (FRP). The typical shape of this period is shown in Figure 2.

In products with a large amount of water, which can be easily evaporated, a constant rate period (CRP) can be observed at the beginning of drying. This is typical in the drying processes of liquid food, such as coffee or milk.

Finally, a very short drying period can be observed at the very beginning of the drying process, with an increasing drying rate (initial period) due to both the initial increase in temperature on the food surface and the mobilization of the water in the food product.

Figure 2 shows what can be considered a whole drying rate curve with the three typical periods.

Product and Process Variables Affecting Drying

In accordance with previous explanations, the mass transfer rate in drying processes is dependent on water activity gradients, which is the driving force of the process, and the mass transfer coefficients, which are dependent on the properties of the air or product involved in the drying process (eqn [2]):

$$V_i = K_i \cdot A \cdot (a_{w1} - a_{w2})/\Delta x \qquad [2]$$

where V_i = mass transfer rate in the i phase (food, interphase, or air), K_i = mass transfer coefficient in the i phase, A = mass transfer area, a_{w1} = water activity of point 1, a_{w2} = water activity of point 2, and Δx = distance.

The mass transfer rate equation can be applied to the transport of the water inside food (V_f), in the interphase of food with air (V_{int}), and in bulk air (V_a).

In a drying process, it can be considered that the following equality $V_f = V_{int} = V_a$ is fulfilled. The only exception to be considered is when case hardening occurs on the food surface because transporting the water in the food interior can be faster than on the food surface, with consequent moisture accumulation below the crust.

Thus, product and process variables are those that influence the value of the mass transfer coefficients (K), mass transfer area (A), distance (Δx), and water activity gradients ($a_{w1} - a_{w2}$):

- Product variables:
  - Type of surface: Most food that is dried is non-homogeneous (exceptions occur in slurries, liquid, or minced food). It is usual to find a surface that is resistant to water transfer, such as skin in tomatoes and grapes or skin and fat layers with hams. Sometimes, surface treatments are performed on food to enhance water transfer through the food surface, for example, treatment with acids, skin and fat perforation, or skin removal.
  - Internal food structure: The internal structure of foods has a direct influence on the transport coefficient of the water inside food. For instance, the presence of an intact cellular structure or internal fat layers represents barriers to water transport. Sometimes, treatment of food is possible to reduce the presence of internal barriers, such as freezing and thawing of cellular structures or milling, thereby leading to a product with a higher mass transfer coefficient.
  - Food shape and size: The mass transfer process inside food is limited by the maximum distance that water must cross to leave food (Δx_{max}) – the radius in a sphere or cylinder and half-thickness in a layer dried through both sides. If possible, the shape and size of food should be modified to reduce the aforementioned maximum distance. The variable-specific surface (surface/volume) is related with the total time needed to dry a product since the water contained in a certain volume leaves through the product surface; thus, the drying process is faster when the specific surface is higher. The higher the A value for the same sample volume, the higher the V value.
  - Temperature: Usually, the transfer coefficient of a product is exponentially temperature-dependent. This means that an increase in the temperature of the food product results in an increased mass transfer coefficient. There are some exceptions, mainly due to discontinuities in product structure as a result of temperature. This happens in meat products containing fat pieces. If temperature rises, fat can melt and an additional barrier inside food appears, which results in a slower drying process.
- Air variables:
  - Temperature: As mentioned earlier, the mass transfer coefficient (K) is dependent on temperature, which is

higher for rising temperatures. Thus, an increase in air temperature implies a higher mass transfer rate in air.
  - Air velocity: The mass transfer coefficient depends on air velocity since a rise in this value implies increased turbulence. Nevertheless, a time arrives when the water transfer rate does not increase at faster air velocities, because the limiting transfer rate of the process becomes the water transfer through the food interior.
  - RH: As previously explained, the water activity of air equals its RH divided by 100. For the same a_w of food, lowered RH implies that the a_w gradient increases, with the consequent rise in the water transfer rate. Nevertheless, case hardening can occur at a low RH in air due to excess food surface drying, which can slow the drying process.
- Type of drying: Apart from the product and air variables, there are other processing conditions that strongly influence the result of the drying process, such as type of contact of air and food, heating procedures, pressure, and movement. These processing conditions are closely related with drier design and are also related with the physicochemical properties, size, and shape of the food and/or with other food characteristics. This point will be explained in more detail in section '**Drying Equipment and Techniques (Types of Drying)**.'

Temperature and Drying

In most drying processes, air is heated by solar energy or by any other source of energy, such as electric resistance, or mainly through the combustion of gas, oil, or food industry by-products. As mentioned earlier, the rise in temperature results in lower RH of air (reduced a_w), an increase in the maximum capacity of air to take water vapor per kg of dry air, and higher mass transfer coefficients.

Nevertheless, temperature has a direct influence on the quality of dried food and is, therefore, a very important variable.

- Food temperature during drying: When food comes into contact with hot air, there is a tendency to equalize its temperature. Nevertheless, if food is very moist and the water inside food is transferred very quickly, food remains in the CRP, and the food temperature tends to equal the adiabatic saturation temperature, which, usually, is significantly lower than air temperature. This is because the energy transported from air to the food surface, due to temperature gradients, is used completely for changing its state from liquid to gas, and it returns to air as latent heat in water vapor.

When the food surface becomes dry and food is unable to transport as much water as drying air demands, it is known as the FRP, and the temperature on the food surface begins to rise to air temperature.

Temperature affects food properties in some ways:

- Vitamins and other nutritious compounds can be affected by high temperatures.
- Food can be cooked at a high temperature (this can happen with fruit and vegetables and meat and fish products).
- Microorganisms can grow if food is maintained at high a_w values for long periods of time at temperatures within the 3–40 °C range (e.g., in dry-cured ham production).
- Temperature can affect the Maillard reaction, sugar caramelization, etc.

These are some examples of changes that can occur in food because of air temperature, and a detailed analysis of the effect of drying temperature on the type of food and the processing conditions utilized is recommended.

Drying Equipment and Techniques (Types of Drying)

There are many types of driers, which are usually optimized for each product type. The following is a list of the characteristics of dryers to be considered for design purposes:

- Air contact with food: Air can flow in parallel or perpendicular to food through the bed of the product to be dried.
- Stirring food: Food can be static or stirred throughout drying. Stirring the product implies a faster, more homogeneous drying process. Stirring the product can be done mechanically or by means of the drying air.
- Air rate: The air rate is an influencing parameter in the drying process. Nevertheless, using a very high air rate can lead to stirring of products (fluid bed dryers) or even to product transport while drying (pneumatic drying).
- Heating system: The most common procedure is heating air before it enters the drying chamber by means of a heat exchanger. There are other alternatives, such as intermittent heating inside the drying chamber by means of a heat exchanger, radiation heat, and use of microwaves to heat the food product.
- Use of solar energy to heat air in drying processes: solar dryers can range from very simple (solar drying through direct exposure to the sun) to very sophisticated systems, where the only difference with other dryers is that solar energy is used, which can accumulate in thermal fluids and be used in a heat exchanger with or without being combined with other sources of energy.
- Pressure: Although the drying processes imply working at atmospheric pressure, the use of a vacuum pressure to improve the drying kinetics, by reducing heat damage, is an alternative in dryer designs.
- Air recirculation: Partial air recirculation is a usual practice to increase the dryer's energy yield due to the increased amount of water removed per kg of dry recirculated air.
- RH control: In most dryers, no control of RH exists. Nevertheless, controlling RH is an option, which is used mainly when drying at low temperatures.

There are many possible combinations of all the aforementioned parameters, and consequently, many different types of dryers exist. Nevertheless, the list in the succeeding text describes the most widely used dryers in the food industry:

- Spray dyer: It is a dryer for liquids. Liquid is sprayed at the top of a cylinder, and droplets are dried on their way to the bottom of the dryer, which is conical in shape.
- Drum dryer: It consists of one or two cylinders that are heated in their interior. The food to be dried (mainly viscous

products, such as potato puree or hydrolyzed baby food) is dosed onto the drum surface and dried by contact with the hot drum surface. The sheets of drum-dried product are removed from the cylinder surface and milled.
- Drying chambers: It is for small production batches or very long drying processes. Discontinuous drying is possible using drying chambers. Food products can be arranged on trays (e.g., apricot halves) or individually hung (e.g., dry-cured ham).
- Belt dryer: The products to be dried are continuously transported inside the drying chamber placed on a conveying belt. This can be used with many types of products, such as breakfast cereals covered later with honey and washed fruits and vegetables.
- Rotary drier: Food comes into contact with heated air on its way through a cylinder that rotates to facilitate the movement of food and to facilitate it coming into contact with the air circulating inside the cylinder. It can be used with products that are hard enough to resist impacts inside the cylinder or when there is no need to maintain the food shape and/or structure, such as seeds before solvent oil extraction.
- Fluid bed dryer: Food floats in the air that circulates upward. When food is dry enough, due to its lowered density, it is transported by air to the collecting unit.
- Pneumatic dryer: Food is transported and dried simultaneously by a fast air current. It can be employed for foods such as sugar and flour.
- Column dryer: These are vertical dryers used with free-flowing products, such as cereals. The products to be dried are placed into the column at the bottom and descend by gravity, while they are well mixed with hot air by various procedures, such as perforated cylinders.
- Superheated steam dryers: These dryers use superheated steam instead of air. This offers the potential for heat recovery and also enables operations with alternative heat sources while providing enhanced safety and improved environmental benefits.
- Paddle dryer: It is a dryer where heat is transferred by contact with heated paddles that are also used to stir food. It can be used with powdered, granulated, or pasty products (e.g., milk powder).
- Other types of drying: flash drying, freeze drying, and vacuum drying.

When talking about drying food, we commonly refer to the operation that implies loss of water due to gradients of a_w. This implies water passing from liquid to vapor by evaporation at temperatures below the boiling point. Nevertheless, some drying processes are based on the change of state of water due to boiling. The most well-known drying techniques based on this are the following:

- Flash drying: Food is heated at temperatures above the boiling point at atmospheric pressure. Water is maintained in the liquid state because high pressure is used. When the system is decompressed, water from food immediately evaporates, which leads to a porous, dry product, such as inflated rice for breakfast cereals.
- Vacuum drying: This process is based on lowering the water boiling temperature through use of low pressure. This results in the temperature of food being lowered in the process, thereby resulting in less thermal damage. One example is dried sausages. In this process, air scarcely moves due to its removal as a vacuum is used.
- Freeze drying: This is a particular vacuum drying situation based on water sublimation from frozen food by applying vacuum conditions. The drying temperature is very low, and some original food properties are well maintained, such as freeze-dried coffee extracts.

Changes in Product Properties Due to Drying

Drying implies not only reducing the a_w of food but also altering the characteristics of food products. As regards texture, hardness usually increases because the dry matter concentration increases. If moisture is low enough, the product can pass from a glassy to a vitreous state at room temperature, which implies a dramatic change in textural properties. If very fast drying is employed, case hardening can occur due to the very strong dehydration of the food surface, which leads to a hard and very dry surface and is an important barrier for water transport.

Drying also affects food structure due to shrinkage, as well as other properties such as color and flavor. Sometimes, these changes are positive, but may be negative in others, which depends on the product and the objective of the drying process.

Eating Disorders Are Motivated Behavioral Disorders

Eating disorders are motivated behavioral disorders and are characterized by (i) increasingly driven and ritualized behaviors that include dieting, purging, excessive exercise, and intermittent binge eating, (ii) narrowing of the behavioral repertoire with increased time spent on disordered eating behaviors, (iii) excessive preoccupation with food, (iv) progressive functional impairment, and (v) ambivalence toward, or frank avoidance of, treatment. Individuals diagnosed with eating disorders typically exhibit body dissatisfaction and a tendency to base self-evaluation on weight and shape.

As behaviors such as dieting or binge eating are repeated, learning and the conditioning of environmental cues and feeling states associated with disordered eating result in increasingly automatic and inflexible behavioral response patterns. Over time, repetition of these abnormal behavioral patterns deregulates homeostatic hunger and satiety signaling between the gut and the brain altering levels of neuropeptides and hormones such as cholecystokinin, pancreatic polypeptide, leptin, ghrelin, glucagon-like polypeptide-1, and opioid peptides. Some of these secondary changes are increasingly believed to further contribute to the maintenance and driven quality of disordered eating. In Anorexia Nervosa (AN), for example, starvation results in both physiological and psychological consequences that perpetuate the anorectic state. The landmark 1940s Ancel Keys' Minnesota Starvation Experiment focussed on the effects of starvation in 36 male conscientious objectors. These men developed many of the symptoms and behaviors typical of AN including depressed mood, apathy, preoccupation with food, eating rituals, increased obsessionality, and an overvalued concern with ascetic goals. Some exhibited increased drive to exercise and many developed binge eating behavior during the refeeding phase of the experiment.

Although unable to mimic all aspects of eating disorders, experimental animal models including the activity-based model of AN and rodent models of Bulimia Nervosa (BN) that alternate intermittent food restriction with access to palatable food have confirmed that physiological consequences of sustained or intermittent food deprivation can alter hunger and satiety signaling, influencing food reward and eating behavior.

Diagnostic Criteria of Eating Disorders

The Diagnostic and Statistical Manual of Mental Disorders, 5th Edition (DSM-V), provides the specific criteria to identify symptoms and diagnose individuals with an eating disorder.

Anorexia Nervosa

The primary features of AN include a significantly low body weight driven by caloric restriction and/or purging behaviors coupled with an intense fear of fatness or weight gain and the presence of body image disturbance such that the individual either places undue emphasis on the importance of their weight or shape or minimizes that his or her weight is dangerously low. A 'significantly low body weight' is defined as less than what would be expected given the individual's age, sex, health status, and developmental level. Both the World Health Organization (WHO) and the Center for Disease Control (CDC) define the lower level of 'normal' weight in adults as a body mass index (BMI) of 18.5 $kg\,m^{-2}$, and suggested BMI ranges for assigning a level of severity to AN in the DSM-V are as follows: mild (BMI $>$ 17 $kg\,m^{-2}$), moderate (16–16.99 $kg\,m^{-2}$), severe (15–15.99 $kg\,m^{-2}$), and extreme (BMI $<$ 15 $kg\,m^{-2}$). Fear of fatness need not be verbally acknowledged if the patient is of significantly low weight and consistently engages in behavior that prevents weight gain. Patients may recognize that they are too thin but remain overly concerned with the size of specific body parts, such as the stomach, hips, or thighs. Frequent or obsessional body checking and weighing are often used to evaluate weight and shape.

Individuals with AN are divided into two subtypes based on an assessment of disordered eating behaviors in the past 3 months. Patients who engage solely in restricting behaviors and excessive exercise, without regular (weekly) binge eating or purging behaviors, are diagnosed with AN, restricting subtype, whereas those whose restricting behaviors are accompanied by at least weekly binge eating and/or purging behaviors are diagnosed with the binge eating/purging subtype of AN. The 12-month prevalence rate among females is low (0.4%) and approximately 10% of cases are male. Of note,

AN has the highest standardized mortality rate of any psychiatric condition with fivefold risk of any cause of death and 18-fold risk of death by suicide compared to an age-matched female population.

Bulimia Nervosa

BN is characterized by recurrent episodes of binge eating and inappropriate compensatory behaviors. A binge is defined as eating a larger amount of food than typically normal in a discrete period of time, associated with a sense of loss of control over eating. Lack of control is defined as the inability to refrain from eating or to stop eating once an individual has begun. Compensatory behaviors are employed to prevent weight gain and include self-induced vomiting; misuse of laxatives, diet pills, or diuretics, restricting, and excessive exercise. Both the binge eating episodes and compensatory behaviors must occur on average at least once a week for 3 months. As in AN, excessive emphasis on body shape and weight as a measure of self-evaluation and self-esteem is a core criterion of BN. Individuals with BN are typically of normal weight or overweight; if significantly underweight, the diagnosis of AN-purging subtype trumps the diagnosis of BN. Within BN, the level of severity depends on the frequency with which individuals engage in compensatory behaviors and ranges between mild (1–3 episodes per week), moderate (4–7 episodes per week), severe (8–13 episodes per week), and extreme (14 or more episodes per week). BN is slightly more common than AN, with 12-month prevalence rates of 1–5% in females. Similar to AN, male patients represent approximately 10% of cases.

Binge Eating Disorder

Binge Eating Disorder (BED), defined as recurrent consumption of large amounts of food in a fairly short period of time accompanied by feelings of loss of control (without the compensatory behaviors seen in BN), has recently been changed from a provisional diagnosis in need of further research in the *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition (DSM-IV), to a unique psychiatric condition in the DSM-V. Binge episodes are associated with eating until uncomfortably full, eating rapidly, eating alone, eating in the absence of hunger, and/or feeling disgusted with oneself after binge eating. The DSM-V requires that at least three of these five features accompany binge episodes on average once a week or more for 3 months to make a diagnosis. Binge episodes differ from overeating in that they are often secretive, associated with shame, and occur in the context of negative affect and cognitions.

BED is associated with decreased quality of life and increased lifetime co-occurrence of medical (e.g., irritable bowel syndrome, fibromyalgia, type 2 diabetes, and obesity) and psychiatric disorders, including major depressive disorder, bipolar disorder, anxiety disorders, substance use disorders, and body dysmorphic disorder. Although not all individuals with BED are overweight or obese, approximately 30% of those seeking weight loss treatment meet criteria for BED in comparison to 2–5% prevalence rates in community samples. BED is particularly prevalent among those pursuing bariatric surgery, ranging from 10% to 50%, and preoperative BED may indirectly predict postsurgical weight loss mediated by postoperative eating behavior.

Other Eating Disorders

Avoidant/Restrictive Food Intake Disorder (ARFID) is an eating or feeding disturbance in which individuals avoid or restrict their oral intake of food in the absence of an underlying medical condition. This disturbance results in one or more of the following: significant weight loss, or in children, a failure to meet expected weight gain, nutritional deficiency, dependence on oral nutritional supplements or enteral feeding, or a significant impairment in psychosocial functioning. The avoidance or restriction of food in ARFID is not in response to scarcity of food or cultural and developmental norms such as picky eating in preschool-aged children. Typically, the avoidance/restriction results from a lack of interest in eating or food, or an avoidance of eating due to sensory characteristics of food, such as texture or smell. Unlike other eating disorders, individuals with ARFID do not experience a disturbance in the perception of body shape or weight.

In addition to these disorders, DSM-V distinguishes a fifth broadly defined category of Other Specified Feeding or Eating Disorders. The clinical presentations of these syndromes may be behaviorally similar to AN, BN, or BED and cause significant impairment and distress in the individual's life. However, the symptoms do not meet full diagnostic criteria for one of the earlier mentioned conditions, or there is insufficient information to make a diagnosis. Examples of these disorders include atypical AN, subclinical BN or BED, purging disorder, and night eating syndrome. In atypical AN, all the criteria for AN are met; however, despite significant weight loss, the individual's weight is within or above the normal range. Subclinical BN or BED may be diagnosed when the individual engages in binge eating or inappropriate compensatory behaviors less than once a week and/or for less than 3 months. Purging disorder is characterized by recurrent purging behaviors with the goal of preventing weight gain in the absence of binge eating. Night eating syndrome is defined as recurrent episodes of nocturnal eating in which an individual consumes an excessive amount of food after an evening meal or will eat after awakening from sleep. These episodes of eating are not in response to external influences or related to a medical or psychiatric disorder. Finally, unspecified Feeding or Eating Disorder may be diagnosed if a patient presents with symptoms of disordered eating that cause significant distress or impairment in functioning and is most commonly used when there is insufficient information to determine a diagnosis.

Disordered Eating Behaviors

Certain disordered eating behaviors are observed cross diagnostically. Further, these behaviors may occur in nonclinical samples and potentially signify the need for early intervention. Though restricting behaviors are thought to be primarily associated with AN, they are seen in other eating disorders as well, especially BN. Individuals who engage in restricting behaviors attempt to limit their dietary intake with the goal of weight loss or to prevent weight gain. Common restricting behaviors

include reducing the amount and frequency of meals and food portions, avoiding calorie-dense foods, and narrowing one's food repertoire such that consumption is limited to specific low-calorie 'safe' food items. In addition, individuals will often engage in prolonged periods of fasting. For example, after a binge episode, individuals may forgo food for an extended period of time to prevent weight gain.

Binge eating and purging behaviors also occur trans-diagnostically. Binge eating episodes are defined as consuming an unusually large amount of food (about two meals worth) in a discrete period of time coupled with a sense of loss of control over eating. When a sense of loss of control is associated with eating small amounts of food, this is termed a subjective binge episode. Subjective binge episodes are more frequently reported by patients with binge eating/purging type of AN than by those with BN. Common purging behaviors include self-induced vomiting and laxative, enema, or diuretic abuse. Uncommon but important additional purging behaviors employed in the service of weight loss by individuals with eating disorders can include insulin omission in type I diabetics and wasting expressed breast milk in postpartum mothers. The frequency of purging behavior use varies, with some individuals purging exclusively after binge eating episodes, whereas others may purge after consuming small amounts of food or after every meal.

Additional behaviors are observed across all eating disorder diagnoses. These include chewing and spitting and grazing. Chewing and spitting out food before swallowing is common, often associated with a sense of lack of control over eating, and can involve large amounts of food and feelings of shame/guilt afterward. This behavior may be utilized as a way to taste 'forbidden foods' without ingesting calories. In other cases, chewing and spitting is best conceptualized as an alternative to bingeing and purging and is perceived as less medically risky, with lower likelihood of electrolyte abnormalities or other medical complications than vomiting. Grazing is the unplanned, repetitive ingestion of small amounts of food that may occur in a compulsive manner, such as repeatedly eating from a container of food when walking past it. Although grazing is frequently observed in nonclinical and eating disorder samples, when accompanied by a sense of loss of control over eating, it is associated with increased psychopathology. Grazing behavior has received significant attention in the bariatric surgery literature, particularly since grazing postsurgically is associated with suboptimal weight loss and/or weight regain, and efforts are currently under way to determine the best way to define grazing both clinically and for research purposes.

Excessive exercise is a frequently observed behavior employed in the service of weight loss among individuals diagnosed with AN or BN and is commonly defined by dysfunction in the quality and quantity of exercise. Unlike normal exercise, excessive exercise manifests as a strict and compulsive adherence to exercise regimes, preoccupation with exercise, feelings of guilt if exercise is not completed, and exercising despite illness, injury, or physical complications. These behaviors are utilized to prevent weight gain, influence one's shape and/or weight, or reduce feelings of distress related to food consumption. In addition, individuals may engage in increased frequency, duration, and intensity of exercise. Excessive exercise is associated with increased psychological distress, psychopathology, and risk of relapse.

Laboratory Studies of Food Consumption/ Macronutrient Selection

Laboratory studies of eating behavior have consistently shown that individuals with eating disorders will engage in disordered eating under controlled laboratory conditions. Compared to healthy controls, patients with AN select fewer food items, eat fewer calorie-dense foods, and have a lower total caloric intake in laboratory test meals in which they are presented with a large variety of foods of different calorie densities. Macronutrient selection primarily consists of carbohydrates ($\approx$55%) and protein ($\approx$30%), with limited caloric intake from fat ($<$20%). Following treatment, weight-restored patients with AN show increased caloric intake in test meals but continue to eat fewer calorie-dense foods and have a more limited repertoire of food items compared to healthy controls. Further, studies of implicit and explicit liking (pleasure associated with food) and wanting (desire for food) show that current AN and recently weight-restored patients with AN report decreased explicit and implicit wanting of higher-calorie food items compared to healthy controls. Of concern, avoidance of calorie-dense foods and limited food choices are associated with increased risk of relapse in this population.

Laboratory studies of binge eating typically offer participants either single-item or multi-item food arrays and instruct participants to 'eat a normal meal' (meal paradigm) or 'eat as much as you would like' (binge paradigm). Individuals with BN and obese individuals with BED consume significantly more calories and significantly more calories from fat than healthy controls using normal meal and binge eating test paradigms. Patients with BN also eat more rapidly than controls during laboratory binge eating episodes and report higher caloric intake for binge eating episodes than individuals with BED. Binge size is positively correlated with BMI in patients with BED, but this has not been observed in BN samples.

Nutritional and Medical Complications of Eating Disorders

Complications of eating disorders are best thought of as consequences of starvation, purging behaviors, or both. Those individuals most at risk are therefore those with the binge/purge subtype of AN, who are both underweight and engage in purging behaviors. Medical complications can affect all body systems and several are severe and potentially life-threatening.

Cardiovascular complications of starvation include severe bradycardia and orthostatic hypotension, which can result from fluid restriction, vagal instability, or decreased venous return attributable to atrophy of peripheral muscles. A frequent cause of orthostatic hypotension in individuals who purge is dehydration resulting from vomiting or laxative or diuretic abuse. In very low weight patients, starvation-induced atrophic cardiomyopathy can lead to mitral valve prolapse as the mitral valve becomes too big for the heart. Cardiac arrhythmias are often the result of electrolyte imbalances but can also be due to abuse of caffeine or ephedra in the service of weight loss.

Of all metabolic complications, the most common and the ones of highest concern are hypokalemia, because of its

association with lethal heart rhythms, and severe hypoglycemia. Acid–base imbalances include metabolic alkalosis in individuals who vomit and metabolic acidosis in laxative abusers. Less frequently, starved patients may develop hypomagnesemia, hypocalcaemia, or hyponatremia. The latter can be due to sodium depletion in starvation, diuretic abuse, or water intoxication. Excessive water ingestion is motivated by a desire to increase satiety, make weight, or 'eliminate toxins.' Severe hyponatremia or hypoglycemia can result in seizures as the presenting symptom. Oral repletion of electrolytes is the safest initial route to stabilize patients, although adjunctive judicious intravenous repletion may be indicated in severe electrolyte deficiency.

Gastrointestinal complications are very common in eating disorders. One study found that 98% of eating disorder inpatients met criteria for a coexistent functional gastrointestinal disorder (FGID), one-half of whom reported three or more FGIDs. The most commonly reported of these were irritable bowel syndrome, functional abdominal bloating, functional constipation, functional heart burn, functional dysphagia, and functional anorectal pain. Even in a nonclinical college student population, severity of dieting has been associated with increased abdominal symptoms.

State-dependent consequences of starvation, including delayed gastric emptying and delayed gastrointestinal transit times, are associated with early satiety and abdominal discomfort, which impede patients' efforts to increase their food intake. Gastrointestinal symptoms in AN dramatically improve with refeeding alone. Delayed gastric emptying is also well documented in BN, and a recent study found that gastric emptying normalized faster in restricting subtype of AN than in those individuals with AN who also engaged in binge/purge behaviors. The use of proton pump inhibitors or metoclopramide may be of some help in select cases; however, improvement is limited without concomitant increase in nutritional intake and weight gain. Gastrointestinal complications arising from laxative abuse can include colonic dysmotility, development of hemorrhoids, and rectal prolapse.

In individuals who purge by vomiting, enamel erosion of the lingual surface of the teeth, parotid gland enlargement, and reflux esophagitis are common, and there is risk for a Mallory–Weiss tear presenting with hematemesis. Acute gastric dilatation is a potentially life-threatening complication of refeeding in which marked dilation of the stomach can result in infarction by compression of the mesenteric artery or rupture of the stomach. It is best treated conservatively with nasogastric decompression. Both pancreatitis and transaminitis can be seen as consequences of starvation and both may transiently worsen with refeeding before improving. High cholesterol is common in AN and has been attributed to depressed cholesterol-binding proteins or to low triiodothyronine levels that inhibit cholesterol breakdown.

Starvation is associated with multiple reversible endocrine abnormalities. These include hypercortisolemia, growth hormone resistance, low insulin-like growth factor 1 (IGF-1), hypothalamic amenorrhea, and sick euthyroid syndrome. All are reversible with refeeding and hormone replacement therapy is not indicated. As the typical age of onset of AN is peripubertal, there are developmentally relevant medical complications besides amenorrhea. Both stature and breast development can be stunted, and catch-up growth is limited following recovery from prolonged adolescent AN. This information may be helpful in motivating a reluctant teen to gain weight.

Osteopenia and osteoporosis occur rapidly in AN with up to 50% of patients demonstrating abnormal DEXA scans within 6 months of diagnosis. Osteoporosis is one of the most common, serious, and irreversible complications of AN and is thought to result from the combination of low estrogen, high cortisol, and low IGF-1. Unlike in menopause, estrogen is not protective of bone loss in AN, whereas refeeding clearly improves bone density in adolescent AN and prevents continued bone loss. Most experts agree that hormone replacement should not be routinely prescribed in AN as it results in monthly withdrawal bleeding, which exacerbates any underlying nutritional anemia and can contribute to the mistaken belief by patients that their reproductive function is normal. Prescription of calcium and vitamin D is recommended as well as weight-bearing exercise following weight restoration. Data on bisphosphonates are still lacking, and caution is warranted in using these compounds in women of reproductive age since they leach from bone during pregnancy and there is concern about their teratogenic potential.

Besides nutritional anemia, at low weights, hematologic complications of severe AN include hypocellular bone marrow on biopsy and pancytopenia. Leukopenia in severely cachectic patients is associated with immunocompromised status and increased risk of opportunistic infections, and thrombocytopenia can cause easy bruising or bleeding.

Renal complications are not common, but can include impaired creatinine clearance in AN binge/purge subtype relative to AN restricting type. This usually reverses with refeeding although occasional cases with renal failure attributed to laxative abuse are well described. Renal failure is presumed to be the result of chronic hypokalemia and chronic intravascular volume depletion.

Brain changes in AN are most notable for the development of atrophy, visible on MRI, which reverses at least partially with refeeding. Patients with AN have also been found to have state-dependent neuropsychological deficits in a number of domains including set shifting, delayed discounting, gambling, and attention.

In general, information on medical complications may serve as a therapeutic tool to increase patient engagement in treatment. Reviewing lab results and providing patients copies of any abnormal tests or scans while supportively but clearly stating that these are medical consequences of their behavior may help increase motivation to change and engage patients in behavioral treatment. Somatically preoccupied patients may be in denial about their eating disorder and be overly concerned about functional gastrointestinal symptoms. These patients often avoid eating disorders specialty treatment, presenting instead to medical providers with somatic complaints that are consequences of their eating behavior. In such cases, the clinician can maintain an agnostic stance about diagnosis while formulating behavioral treatment as physiological retraining aimed at reinstating normal homeostatic mechanisms of hunger and satiety. This explanation may be more acceptable to these patients than an eating disorder diagnosis. Educating family members on how they can work with health-care providers to help contain the patient's behavior and how this will ultimately return control to the patient is also helpful.

Treatment of Eating Disorders

Levels of Care

Treatment options for patients diagnosed with eating disorders include outpatient individual, family, or group psychotherapy, partial hospitalization, and residential or inpatient treatment. Inpatient hospitalization and partial hospitalization are reserved for the most severe cases, and a high proportion of these patients have very low BMI and are diagnosed with AN. These patients may require hospitalization for medical stabilization, refeeding, and monitoring cardiac irregularities and dehydration or for co-occurring psychiatric conditions such as depression with suicidal ideation. Patients with purging behaviors may be admitted due to electrolyte imbalances associated with frequent vomiting or laxative abuse especially hypokalemia.

Generally, the first step for patients diagnosed with an eating disorder is outpatient evaluation and treatment. While a wide variety of therapies have been used with this population, the most efficacious outpatient therapy modalities include family-based therapy (FBT) for adolescent patients with AN and cognitive behavioral therapy (CBT) for patients diagnosed with BN and BED. When indicated, admission should ideally be to a behavioral specialty program for the treatment of eating disorders as these programs are capable of helping patients interrupt unhealthy behavioral patterns and normalize eating with the help of an expert multidisciplinary team using a structured behavioral protocol and group therapy approaches. Inpatient treatment goals include medical stabilization, normalization of eating behaviors, weight restoration in low weight patients, and relapse prevention. Length of stay varies by patient and is influenced by a number of factors including co-morbidity, BMI at admission, insurance coverage, patient dropout, and rate of weight gain. For underweight patients with AN, a goal weight is determined by the treatment team (generally a BMI of 20 or above for adults). Most expert programs are able to achieve rates of weight gain of 1–2 kg per week.

Pressure from insurance companies to decrease inpatient hospital-based costs has resulted in expansion of residential and partial or day hospitalization programs. Partial hospital programs may be stand-alone treatment centers or hospital-based step-down programs integrated with an inpatient unit. Patients in partial hospital programs typically engage in treatment activities such as supervised meals and individual and group psychotherapy and may also participate in meal-based occupational therapy sessions such as restaurant outings, meal preparations, and grocery shopping in order to practice newly acquired social eating skills in real-world settings.

Nutritional Rehabilitation

Nutritional rehabilitation includes weight restoration as well as normalization of eating behaviors. Clinically, this requires patients to consume appropriate quantities of foods of a variety of calorie densities without engaging in binge eating or compensatory behaviors, such as purging or excessive exercise. Though not the sole focus of treatment, weight restoration is the primary goal of treatment for AN as it is associated with superior outcomes including long-term weight maintenance, correction of medical complications, and improvement in both eating disorder psychopathology and comorbid psychiatric symptomatology. Weight restoration is also associated with decreased frequency of disordered eating behaviors, reduced likelihood of readmission, and increased rate of recovery at both short and long-term follow-up and is often used as a marker of readiness to progress to a lower level of treatment.

Refeeding Syndrome and Medical Monitoring

Refeeding syndrome comprises a constellation of potentially life-threatening metabolic and clinical changes that result from rapid oral, enteral, or parenteral feeding. These are most likely to occur with parenteral refeeding and least likely with oral nutritional rehabilitation. In the absence of access to an expert behavioral program capable of restoring weight in patients through oral refeeding alone, the use of enteral feeds may be indicated to initiate weight restoration. Enteral feeding should not be the initial choice however as it does not address the fear of consuming calorie-dense foods central to the phenomenology of AN. Furthermore, although some specialty programs advocate use of supplementary nasogastric night feeds, the outcomes of these programs are not superior to those of expert behavioral programs that rely on oral nutrition alone. Finally, parenteral feeding should be resorted to rarely if at all given the high risk of line sepsis and refeeding complications especially in those with AN who are severely malnourished and immunocompromised.

The hallmark of refeeding syndrome is hypophosphatemia, which occurs within 1–3 days of an increase in food intake. Hypophosphatemia results from the intracellular movement of phosphate for the formation of ATP and other anabolic demands and places patients at risk for potentially lethal cardiac arrhythmias. Postprandial hypoglycemia is also common during refeeding as is the development of peripheral edema, which can lead in the extreme to congestive heart failure, ileus, or anasarca.

Edema is most common in individuals who abuse laxatives or diuretics and who self-induce vomiting once they stop purging. Most edema can be managed conservatively; however, chronic volume depletion from severe purging can result in pseudo-Bartter's syndrome marked by secondary hyperaldosteronism, salt retention, hypokalemia, and marked edema. Judicious use of spironolactone can alleviate severe edema. In low weight patients who do not purge, dependent edema during refeeding can result from low albumin, fragile capillaries, and third spacing of fluid into the interstitial compartment. Care should be taken not to rapidly replete intravascular fluid as this can worsen edema in these cases. For patients who abuse laxatives, these can be stopped abruptly and need not be tapered, although compliance with laxative discontinuation is difficult outside a structured inpatient setting. When compliant, however, most patients do well with a bowel regimen of a stool softener and bulk laxative, with the possible addition of an osmotic laxative agent as well as education and reassurance that their bowels will normalize over a period of a few weeks.

Other potential risks of refeeding include two very serious neurological complications associated with severe AN, Wernicke's encephalopathy due to thiamine deficiency and central pontine myelinolysis, which most commonly results from overly aggressive correction of hyponatremia. Wernicke's encephalopathy is especially a risk in patients with comorbid alcohol abuse. Thiamine should be repleted IV or IM in patients who are severely malnourished (BMIs of <14) before initiating refeeding or administering IV dextrose.

Since relief from medical symptoms is a common goal for both patient and provider, formulating behavior change as the path to symptom relief can make weight gain and treatment more acceptable to patients and help engage them in therapy. It is important to appreciate that medical complications can play a sustaining role in the maintenance of eating disorders.

Psychological and Behavioral Treatment

Family-based therapy

FBT based on the 'Maudsley model' is generally considered to be the most efficacious treatment for AN in adolescent patients with less than 3 years of illness. The Maudsley model of family therapy consists of training parents to take control of their sick child's eating schedule. Utilizing an agnostic stance toward the origin of AN, parents are informed of the grave nature of their child's illness and are encouraged to exclusively focus on refeeding their child, usually via the provision of high-calorie meals and supplements, meal and bathroom supervision, and the development of a system of rewards and consequences to increase compliance with eating. Regular family therapy sessions are used to support parental refeeding efforts and improve communication skills among family members. As symptoms begin to remit, patients gradually regain privileges based on their ability to make appropriate food choices and maintain their goal weight. When compared to ego-oriented individual therapy (focussed on building autonomy and improving self-mastery), FBT has been associated with better rates of weight gain and an increased likelihood of resuming menstrual functioning, which may lower the risk of osteoporosis. Following achievement of recovery, FBT has low relapse rates of 10% compared to 25–30% often reported following inpatient hospitalization, though the latter group may include more severe cases. Attrition is also much lower with only 10–15% of patients dropping out of treatment compared to drop-out rates of 50% or more from other treatment modalities.

Exposure and response prevention

A potentially promising yet understudied intervention in AN is exposure with response prevention (EX/RP). EX/RP in AN targets eating related anxiety by exposing patients to *in vivo* eating challenges while preventing them from engaging in ritualized compulsive behavior. Patients are encouraged to practice these skills between sessions and monitor their anxiety and compulsive rituals, including excessive exercise. Weight-restored inpatients with AN who received 12 sessions or EX/RP demonstrated increased caloric intake in a laboratory test meal compared with inpatients who received a cognitive-based intervention following weight restoration. In particular, EX/RP may be beneficial in relapse prevention as it focuses on achieving normative eating practices in real-world settings.

Psychological treatment for BN and BED

Fortunately for patients diagnosed with BN, outpatient treatment recommendations are quite clear: CBT for BN, a form of psychotherapy, was given the top grade from the National Institute for Health and Clinical Excellence in 2004. The goal of CBT for BN (CBT-BN) is to disrupt the diet–binge eating cycle by regulating the eating pattern, introducing avoided foods into the diet, and eliminating restrictive behaviors. It further addresses cognitive aspects of BN, including excessive concern about weight and shape, perfectionism, rigid thinking, and low self-esteem. It can be delivered in a variety of formats, including individual and group therapy, as well as in a guided self-help version. A recent treatment review reported that one-third to one-half of all patients treated with CBT-BN endorsed abstinence of behavioral symptoms (e.g., binge eating and purging behaviors) at the end of treatment and that these gains were generally maintained 1 year post treatment. CBT-BN was shown to be more effective than fluoxetine alone, and patients reported increased satisfaction with CBT-BN compared to medication. In a meta-analysis of treatment for BN, CBT-BN demonstrated superiority to nutritional counseling, supportive therapy, and interpersonal psychotherapy (IPT), a form of treatment that helps individuals resolve interpersonal problems and overcome their eating disorder indirectly by better managing negative feelings associated with interpersonal conflict. Although research on an eating disorder-specific model of IPT is in a much earlier stage than research on CBT, IPT has yielded comparable recovery rates to CBT in the long term for BN.

Although many individuals with BED are overweight or obese and seek weight loss treatment, CBT for BED (CBT-BED) is the most studied and established treatment for BED. Like CBT-BN, CBT-BED focuses on disrupting the binge eating cycle by promoting normative and structured eating patterns, developing skills for managing urges/triggers to binge, and encouraging the use of cognitive strategies to tackle problematic ways of thinking that maintain binge eating. A meta-analysis examining psychological and pharmacological treatments for BED found that psychotherapy and structured self-help based on CBT were superior to pharmacotherapy and weight loss treatment. Pharmacotherapy and weight loss treatment produced medium and moderate effects on binge eating, respectively. Individual versus group formats of CBT-BED do not significantly differ when examining their effect on reductions in binge eating frequency and recovery and relapse at follow-up. When examining predictors of outcome in CBT-BED, rapid response during early treatment (the first four therapy sessions) is predictive of more favorable long-term treatment outcomes. Furthermore, those who cease binge eating during treatment tend to lose the most weight in the long but not in the short term; therefore, it is generally agreed that treating binge eating should be the first phase of treatment in BED before treating weight.

Conclusion

Eating disorders are motivated behavioral disorders marked by serious morbidity and mortality. A range of restricting, binge

eating, and purging behaviors occur across diagnoses and are accompanied by body image disturbance in AN and BN and often in BED, although body image disturbance is notably absent in ARFID. Medical and nutritional complications may be severe and life-threatening and include cardiac arrhythmias, electrolyte imbalances, pancreatitis, transaminitis, anemia, and osteoporosis. FGIDs are also common in this population, with the majority of patients presenting with one or more FGID. Discussion of medical complications with patients may serve to increase motivation to engage in treatment. Behaviorally oriented treatments that emphasize weight restoration or maintenance, as well as normalization of eating behaviors, are associated with the best outcomes. In particular, FBT for adolescents with AN and CBT for individuals with BN and BED are the best evidenced current treatments. Weight restoration in AN and the resumption of normative eating practices across diagnoses are associated with decreased rates of relapse.

Eggs: Composition and Health Effects

ML Fernandez, University of Connecticut, Storrs, CT, USA
CJ Andersen, Fairfield University, Fairfield, CT, USA

© 2016 Elsevier Ltd. All rights reserved.

Egg Composition

The basic components of eggs are the white and the yolk, which differ greatly in their ratio of fluid, physical characteristics, and nutrient content. A current existing misconception is that the egg white is more healthful than the yolk due to its high protein content. However, the egg yolk is a much more important source of nutrients, some of which exert protective effects that go beyond nutrition. While eggs from a range of different birds are produced for human consumption, this article will present data relevant to chicken eggs – the most common and significant type of egg consumed in the human diet. The egg white is composed of 88% water, 11% protein, 0.2% fat, and 0.8% ash, while the egg yolk is made of 48% water, 17.5% protein, 32.5% lipids, and 2% ash. Regarding micronutrient composition, one large egg contains 186 mg cholesterol, 126 mg choline, 0.2 mg riboflavin, 0.5 μg vitamin B12, 24 μg folate, 0.1 mg vitamin B6, 41 IU vitamin D, 270 IU vitamin A, 0.5 mg vitamin E, 99 mg phosphorus, and 0.9 mg iron. These nutrients are distributed between the egg white and the yolk. The percent distribution of the different nutrients is presented in Table 1.

Eggs have been reported to be a nutrient-dense food with high-quality protein, which is present in both the egg white and the yolk. Kwashiorkor and other types of malnutrition have been correlated with lower egg consumption in underdeveloped countries. Eggs can also be part of weight loss diets due to their effect in suppressing appetite and decreasing caloric intake during the next 24 h.

In addition to its cholesterol content, a highly controversial topic regarding heart disease risk, the egg yolk also contains the carotenoids lutein and zeaxanthin, which are key antioxidants in protecting against oxidative damage, low-density lipoprotein (LDL) oxidation, and age-related macular degeneration (AMD). Further, the egg yolk has other micronutrients absent from the egg white including iron, vitamin E, and vitamin A. Egg yolk is also a good source of choline, a nutrient that plays a major role in normal fetal development and cognitive function and may possibly protect against Alzheimer's disease. Therefore, eggs contain major nutrients that are important throughout the life cycle, in addition to other components that have been shown to protect against chronic diseases such as AMD, sarcopenia, and Alzheimer's disease. However, the perceived concern of eggs being a source of dietary cholesterol is highly associated with decreased consumption and dietary recommendations in the United States limit and target eggs as a source of dietary cholesterol.

Egg Sources and Production

Eggs are produced in many countries throughout the world. As of 2006, China was the largest producer of eggs, followed by the United States, India, and Japan. The number of cases of eggs produced in United States in 2012 was 223.7, 58% of which were allocated to retail, 31.9% for food preparation, 9% for institutions, and 3.8% for export. There are a number of factors that determine egg production, including time of the year, color of the eggshells, and health-related concerns due to eggs' cholesterol content. However, health concerns are decreasing as the public becomes more aware of the healthful benefits of eggs and the lack of correlation between egg intake and heart disease. A closely controlled breeding program results in maximum egg production. Other factors that need to be considered are (1) laying more eggs early although in the long run, this can result in smaller eggs; (2) resistance to disease, and (3) favorable genetic factors. Today, the Single White Leghorn hen dominates the egg industry although in certain regions such as New England, consumers prefer the brown-shelled eggs; thus, the Rhode Island Red, New Hampshire, and Plymouth Rock hen breeds predominate in this region.

The production of eggs can be classified into four main categories: (1) conventional cage eggs, (2) cage-free eggs, (3) free-range eggs, and (4) organic eggs. In the first category, hens live in communal cage systems, which vary depending on the size of the bird and the facility. These eggs are normally collected by an automatic collection system. For the second category, hens live on indoor floor operations and are housed in a barn or poultry house, and they may be allowed to roam outdoors. Depending on the farmer, egg collection may or may not be automated. In the third category of free-range hens, animals are raised outdoors or have access to the outdoors; shelter is provided during inclement weather. All of these housing systems participate in handling and care practices. Organic eggs are produced according to specific standards that exist in many countries. For example, in the United States, the United States Department of Agriculture (USDA) dictates the organic standards in relationship to methods, practices, and substances used in the production of crops. In addition, antibiotics and growth hormones are prohibited. All organic systems are cage-free. It is important to note that the nutrient content of eggs is not affected by the way the hens are raised. Other important facts regarding production are that only 5% of eggs come from cage-free systems and they are generally more expensive. In addition, eggs from conventional systems have been found to have lower bacterial levels than that those from cage-free or free-range hens. Eggs need to be produced under the best sanitary conditions since the moment an egg is laid; physical and chemical changes begin to occur that can reduce freshness.

Patterns of Consumption

Eggs are consumed throughout the world in various forms. Item penetration for eggs in the United States is 93%, which

means that eggs can be found in almost every household. According to a consumer research conducted by Miller-Zell, 85% of consumers view eggs as very or somewhat healthy. This research also concluded that individuals are more likely to consume eggs if they are told how to prepare nutritious dishes with eggs rather than providing information on the nutritional benefits of eggs.

According to the USDA's Economic Research Service 2000 data, it was estimated that more than 70 billion eggs were eaten in the United States, corresponding to an annual 250 eggs per person. These data include not only eggs that were eaten individually as main dishes but also eggs that were incorporated into other foods as ingredients or beverages. According to USDA Continuing Survey of Food Intakes by Individuals data, eggs are used in more than 900 different foods in the United States. These data are supported by the fact that the primary dietary sources of eggs are processed foods or mixed dishes that use eggs or egg components as ingredients. This is true regardless of whether individuals are eating at home or away. Findings from USDA surveys also revealed that per capita consumption of eggs increases from low- ($<$185% of poverty line) to high-income ($\geq$300% of poverty line) groups and that men consume more eggs than women on average. Further, per capita egg consumption increases with overweight status and obese weight status in adults.

Nutrients in Eggs

Cholesterol

Cholesterol, a sterol and a lipid-soluble compound, has essential functions in the body, among which are to provide permeability and fluidity to cell membranes and to be the precursor of bile acids, steroid hormones, and vitamin D. Despite these key functions, an excess of cholesterol in the body leads to a number of metabolic dysregulations that can result in an accumulation of cholesterol in vital organs including the liver, adipose tissues, and heart arteries leading to fatty liver, inflammation, and atherosclerosis. However, it is important to make a clear distinction between dietary cholesterol and cholesterol in our bodies. Since our body produces about 78% of the cholesterol handled on a daily basis, dietary cholesterol only comprises 22% of the total. Therefore, it is important to make a clear distinction between dietary cholesterol and circulating cholesterol or cholesterol accumulated in diverse organs.

A large egg contains between 186 and 230 mg of cholesterol, which has resulted in the perception that eggs, being a high source of this dietary component, may lead to heart disease risk and other problems. In the next paragraphs, some strong evidence that the cholesterol in eggs should not be a concern for healthy populations is presented.

Health effects

Epidemiological studies

Epidemiological studies do not support an association between egg consumption and coronary heart disease (CHD) risk. This could partly be explained by the presence of other nutrients in eggs that are known to be protective against oxidative stress and dyslipidemias. In addition, the response to dietary cholesterol is highly variable. Some individuals respond by having no changes in plasma cholesterol following a dietary challenge as high as three eggs per day for 12 weeks, while others could have a higher response than 0.05 mmol l^{-1} for each additional 100 mg of dietary cholesterol, which is considered the average response. However, all those individuals who are responders to a dietary cholesterol challenge have increases in both LDL cholesterol (LDL-C) and high-density lipoprotein cholesterol (HDL-C), resulting in a maintenance of the LDL-C/HDL-C ratio, a central marker of CHD risk.

The main epidemiological studies addressing the effects of specific foods and nutrients on the development of chronic disease – including Framingham Heart Study, the Nurses' Health Study, National Health and Nutrition Examination Survey (NHANES), and the Lipid Research Clinics Prevalence Follow-up Study – do not support a relationship between dietary cholesterol/egg intake and increased risk for CHD. Further studies conducted in Japan in which more than 9000 individuals were evaluated reported an inverse association between egg consumption and heart disease risk. There are, however, some epidemiological data reporting that egg intake can adversely affect heart disease risk, but these are mostly in people with documented heart disease or diabetes. In summary, the preponderance of the epidemiological evidence from the past 14 years does not support a relationship between egg intake and risk for CHD.

Clinical studies

A number of clinical studies conducted in recent years have demonstrated that eating two or three eggs per day for 4–12 weeks does not increase the risk for heart disease. Individuals from these studies did not have changes in their LDL/HDL ratio or even had improvements in this ratio; this is possibly due to the consistent finding that egg intake increases HDL. Further, studies have been conducted with individuals having metabolic syndrome, a population with an increased risk for both diabetes and heart disease. These individuals were

prescribed a carbohydrate-restricted diet (25% of total energy) and were randomly allocated to consume either three eggs per day for 12 weeks or the equivalent amount of egg substitute. After the intervention, individuals consuming the eggs did not have increases in LDL, but they presented a consistent increase in HDL; therefore, there was an improvement in the LDL/HDL ratio. Another finding in all these clinical interventions is that egg intake favors the formation of the large LDL, which is less atherogenic, and the large HDL involved in reverse cholesterol transport.

Cholesterol and dietary recommendations

A very interesting observation is that a number of countries including the European Union, Japan, Korea, India, Canada, and New Zealand, among others, do not have an upper limit for dietary cholesterol in their guidelines; thus, their dietary guidelines do not restrict egg consumption. In the United States, both the USDA and the American Heart Association consider that consuming one egg per day is appropriate for healthy populations, which still results in a cautionary and confusing message for most individuals. It is very clear that most of the recently published data support the lack of effect of whole egg consumption on heart disease. Dietary recommendations should not target the elimination of a food that not only has a substantial amount of nutrients but also provides additional health benefits. In fact, a recent report on the management to reduce cardiovascular disease states that "There is insufficient evidence to determine whether lowering dietary cholesterol reduces LDL-C," a statement that clearly supports both recent epidemiological data and clinical studies.

Protein

Eggs are known to be one of the best sources of high-quality protein. The 2010 USDA National Nutrient Database for Standard Reference reported that one large egg contains 6.3 g of protein on average. Egg protein is distributed between the egg yolk and egg white portions, with egg white containing more protein than egg yolk. On average, a large egg containing 6.3 g of protein in total will provide 3.6 g of protein in the egg white, in addition to 2.7 g of protein in the egg yolk. In total, one egg provides approximately 13% of one's recommended daily intake for protein.

Egg protein composition

Eggs are a rich source of essential amino acids and are particularly abundant in glutamine, leucine, and asparagine/aspartic acid. The majority of egg protein can be found in the white (57% of total protein) rather than in the egg yolk (43% of total protein).

Egg whites contain a number of different proteins that exert a range of biological and antimicrobial activities. The predominant protein in egg whites is ovalbumin, comprising approximately 54% of total egg white protein. Conalbumin, the second most predominant egg white protein, binds metal ions, whereas flavoprotein and avidin are known to bind riboflavin and biotin, respectively. A number of egg white proteins have proteinase inhibitor activity, including ovomucoid, ovomacroglobulin, and ovoinhibitor. Ovomucin possesses antiviral properties, whereas lysozyme exerts antimicrobial *N*-acetylmuramidase enzyme activity to disrupt Gram-positive bacteria cell walls. Together, these proteins protect eggs against microbial contamination and spoilage.

Egg yolk additionally contains a variety of proteins that have biological functions. The predominant proteins in egg yolk fractions include lipovitellins, livetins, and phosvitin. Lipovitellins represent HDL in egg yolk, whereas livetins correspond to proteins found circulating in chicken blood, such as serum albumin, α_2-glycoprotein, and γ-globulin. Phosvitin contains a relatively high amount of phosphorous and strongly binds multivalent cations such as iron and calcium. The ability of phosvitin to bind heavy metal ions supports antioxidant activity and protects against lipid oxidation. Egg yolks additionally contain antibodies referred to as immunoglobulin Y, which have promising therapeutic potential in human and veterinary medicine.

Health effects

Eggs confer a number of health effects due to their protein content. High-quality protein from eggs supports skeletal muscle synthesis and maintenance, which is particularly important in athletes and aging populations to protect against sarcopenia. Individuals who consume eggs for breakfast have also been shown to have increased satiety and consume fewer calories throughout the day. Compared to consumption of a bagel breakfast, men who consumed eggs had lower plasma levels of glucose, insulin, and ghrelin – an appetite-regulating hormone. An additional study found that whole egg intake during carbohydrate restriction improves insulin resistance as determined by the homeostasis model assessment of insulin resistance (HOMA-IR) equation. Therefore, eggs represent a nutrient-dense addition to low-glycemic and weight loss diets.

The antimicrobial activity of egg white proteins may also confer anti-inflammatory properties to humans. For example, egg white-derived hen egg lysozyme has been shown to reduce intestinal inflammation in an experimental model of colitis. Egg intake has also been shown to reduce proinflammatory markers in the plasma of overweight and metabolic syndrome subjects, including C-reactive protein, monocyte chemoattractant protein-1, and tumor necrosis factor-α. Conversely, individuals with an egg allergy display hypersensitivity and immune reactivity to egg-derived proteins, thus initiating a proinflammatory immune response.

Lutein and Zeaxanthin

Egg yolks are an important source of two highly bioavailable antioxidant carotenoids, lutein and zeaxanthin. Since lutein and zeaxanthin are embedded in the lipid matrix, these carotenoids have been shown to be more bioavailable in eggs when compared to vegetable sources, despite a concentration of 200–300 μg per egg versus concentrations up to 1500 μg per serving of spinach, broccoli, or kale. Table 2 shows the content of lutein and zeaxanthin in different food sources including eggs.

Biological roles of carotenoids

Egg yolks are an important source of highly bioavailable lutein and zeaxanthin, two carotenoids that are selectively removed from circulation by the eyes and protect against AMD and

Table 2 Lutein concentration in selected foods

Food	*mg/serving*
Kale (raw)	26.5/1 cup
Kale (cooked)	23.7/1 cup
Spinach (raw)	3.7/1 cup
Spinach (cooked)	20.4/1 cup
Collards (cooked)	14.6/1 cup

Green peas (cooked)	4.1/1 cup
Corn (cooked)	1.5/1 cup
Broccoli (cooked)	0.8/1/2 cup
Broccoli (raw)	1.3/1 cup
Romaine lettuce (raw)	1.1/1 cup
Green beans (cooked)	0.9/1 cup
Papaya (raw)	0.3/1 large
Egg (cooked)	0.2/1 large
Orange (raw)	0.2/1 large

Data from U.S. Department of Agriculture, Agricultural Research Service, USDA Nutrient Data Laboratory. http://www.ars.usda.gov/nutrientdata.

cataract formation. This selection is indicative of an important photoprotective role. These carotenoids exert their action by absorbing blue light and reducing its ability to reach the retina by an estimated 40–90%, thereby reducing the generation of reactive oxygen species, which damage photoreceptors and retinal pigment epithelium. The concentration of these carotenoids in the retina can be measured by quantifying macular pigment density in the eye.

Health effects

Epidemiological studies also indicate an inverse relationship between intake of lutein and zeaxanthin and both cataract and AMD. A major clinical trial, Age-Related Eye Disease Study 2 demonstrated that lutein and zeaxanthin are more protective against AMD than other supplements including β-carotene. In addition, studies conducted in animal models have shown potent antioxidant properties of lutein as documented by its effects in decreasing the susceptibility of LDL to oxidation, reducing liver injury, protecting against early atherosclerosis development, and reducing oxidative stress in the liver and eyes. Cell studies have also shown that lutein or zeaxanthin supplementation protect eye lens protein, lipid, and DNA from oxidative damage.

Studies evaluating the effects of egg intake on plasma carotenoids have demonstrated a substantial increase of plasma lutein and zeaxanthin following egg consumption. Lutein and zeaxanthin circulate in plasma transported by LDL and HDL. Egg intake has been demonstrated to result in the formation of larger LDL and HDL particles. These larger particles facilitate the circulation of lutein and zeaxanthin in plasma and support the findings of increased plasma concentrations of these carotenoids. More importantly, studies conducted in both hypercholesterolemic and healthy individuals have demonstrated that macular pigment density is significantly increased following egg consumption indicating that eggs could be used to protect against AMD.

Choline

Choline is a water-soluble organic compound and natural amine that has a wide variety of biological functions. The Food and Nutrition Board of the Institute of Medicine first established Dietary Reference Intakes for choline in 1998 after recognizing its role as an essential nutrient. The body is capable of *de novo* choline synthesis via hepatic catabolism of phosphatidylcholine; however, this process fails to adequately meet daily nutrient needs.

Choline in the diet

Despite choline being essential in our diets, many individuals fail to consume adequate amounts.

According to population-based data from NHANES, 2003–04, it has been estimated that only one in ten Americans (adults and older children) is meeting the adequate intake guidelines for daily choline intake.

Eggs are known to be one of the best sources of dietary choline, in addition to beef and chicken liver, beef steak, milk, cod, and peanut butter. According to the 2010 USDA National Nutrient Database for Standard Reference, one large, raw, fresh egg contains approximately 126 mg of choline. The majority of choline is located in the yolk, which on average is estimated to contain 116 mg of choline, with approximately 0.4 mg in the egg white.

Biological roles of choline

Choline provides structural integrity to cell membranes, in addition to playing roles in cell signaling, muscle functioning, neurotransmitter synthesis, and hepatic transport of lipids to the circulation via lipoproteins. In addition, choline is essential for proper fetal development, particularly in regard to brain and spinal cord development. This is attributed to the role of choline in folate metabolism and its effects on regulating neural stem cell proliferation and apoptosis. However, this biological role of choline has also led to its association with an increased risk of developing certain types of cancer.

Deficiency in choline can result in fatty liver and muscle damage, whereas choline deficiency during pregnancy increases risk of fetal neural tube defects. Reduced intake of choline has also been associated with increased plasma homocysteine due to a weakened capacity to handle methionine, resulting in an increased risk of developing cardiovascular disease. Given its significant neurological roles, choline is also thought to protect against the development of Alzheimer's disease and dementia while promoting integration of learning and memory.

Health effects

A number of health effects have been attributed to diets rich in choline, with eggs often serving as one of the primary dietary sources of choline across the world. Diets higher in choline have been shown to be protective against neural tube defects and cognitive impairments. Choline ingestion from egg intake has also been shown to undergo metabolism to trimethylamine *N*-oxide by gut microflora, which has been associated with an increased risk of major adverse cardiovascular events. However, choline-rich diets are also associated with lower levels of homocysteine, suggesting a protective effect against cardiovascular disease. Diets high in choline, in addition to egg intake, have also been associated with increased risk of developing lethal prostate cancer. Conversely, dietary choline and

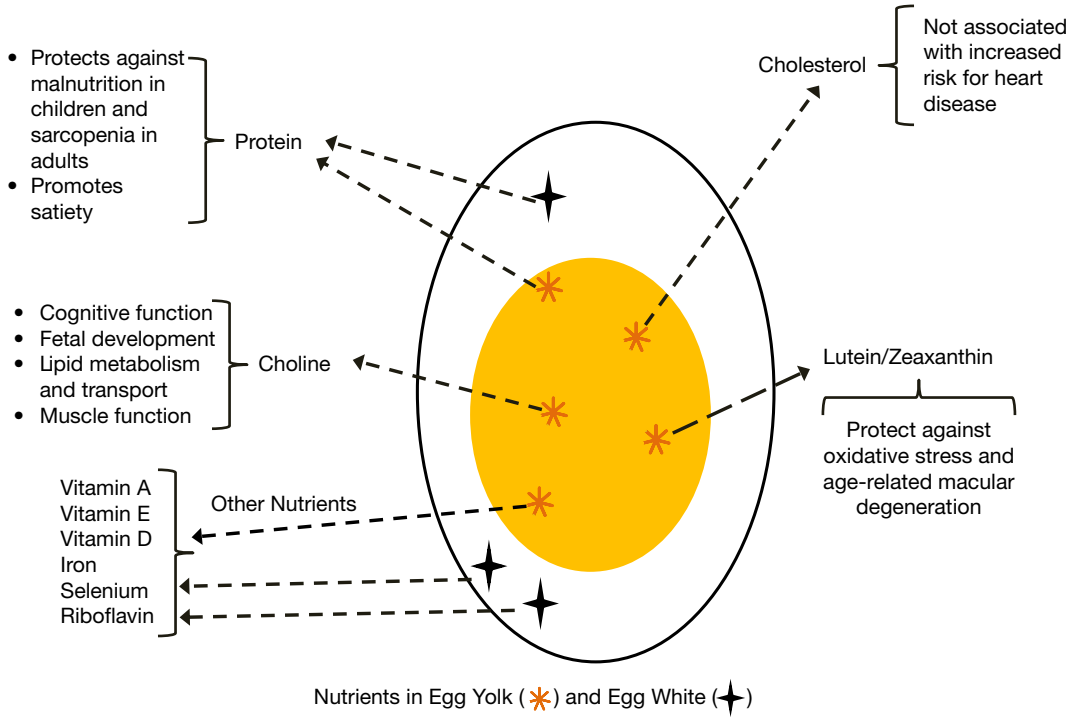

Figure 1 The nutrient content of egg yolk (cholesterol, protein, lutein/zeaxanthin, choline, vitamin A, vitamin E, vitamin D, selenium, riboflavin, and iron (*)) and egg white (protein, selenium, riboflavin, and iron (†)). The specific function of each nutrient as related to health is described.

egg intake has been shown to be protective against the development of breast cancer.

Other Nutrients in Eggs

Eggs are also a good source of fat-soluble vitamins including vitamin A, vitamin E, and vitamin D in addition to iron, all of which are located in the yolk. Since they are part of the lipid matrix of eggs, they can be more easily incorporated into micelles and be absorbed into the intestine where they are incorporated into chylomicrons and distributed throughout the body. Eggs are also good sources of riboflavin and selenium, which are distributed between the egg white and the yolk. One large egg provides 5% of the daily requirements of vitamin A and 5% of the daily requirements of iron. It is also a good source of vitamin E. In a study conducted in children, where they were allocated to consume either two whole eggs per day for 4 weeks or an equivalent amount of egg whites, dietary records indicated that the amount of vitamin E they consumed was almost three times more during the whole egg period.

The nutrients present in eggs and their contribution to nutrition and health are depicted in Figure 1.

Conclusions

Eggs are a rich source of key nutrients and should therefore be considered part of a healthy diet. Not only eggs provide a well-known source of high-quality protein, but also they contain dietary constituents that promote health across the life spectrum, protecting individuals against chronic disease. Evidence derived from epidemiological data and clinical studies support the notion that there is no association between egg consumption and heart disease risk. The yolk is a good source of choline that could be beneficial for pregnant women, for fetal and infant development, and for protection against Alzheimer's disease in the elderly.

All populations of children, young adults, and the elderly should benefit from the excellent protein quality of eggs that supports optimal growth in children and adolescents, while additionally protecting the elderly against sarcopenia. In addition, the carotenoids lutein and zeaxanthin protect against AMD and oxidative stress. Overall eggs should be part of a healthful diet.

Eggs: Use in the Food Industry

CG Belyavin, Chris Belyavin (Technical) Ltd, Newport, UK

© 2016 Elsevier Ltd. All rights reserved.

This article is reproduced from the *Encyclopedia of Food Sciences and Nutrition*, volume 4, pp. 2000–2004, © 2003, Elsevier Science Ltd., with an updated Bibliography section supplied by the Editor.

Introduction

The majority of eggs produced in the world are sold in-shell for consumers to utilize in the home in traditional ways or for baking. In the United Kingdom, only 17% of eggs produced go into egg products, and in the United States, the figure is nearer 30%.

Traditionally, surplus eggs not required for the shell egg market (normally the smaller sizes) and downgraded eggs were turned into egg products. Today, farmers have specific contracts to produce eggs for further processing, and any egg that is damaged cannot be used for this purpose. There are essentially three types of egg products, liquid, dried, and frozen, with small markets for peeled, hard-boiled, and hard-boiled pickled eggs. The main products are used widely in the bakery and confectionery trades along with other industries. Figure 1 illustrates the many uses to which processed whole eggs can be put and also shows the way in which whole eggs can be used to produce value-added products for the food industry without going through the process of pasteurization with or without subsequent drying. Value-added products in the United States are often made with pasteurized eggs.

The world trade in liquid eggs is in excess of 110 000 tonnes traded annually, some 80% of which are traded between EU member countries. Outside of this area, the only significant major market is Japan, which purchases around 15 000 tonnes a year. The Netherlands is the number one exporter closely followed by Belgium, both of them accounting for about 45% of the total world trade.

Some 28 000 tonnes of dried eggs is marketed internationally. Japan and European countries are the major buyers, with the United States being the major seller.

When setting up an egg processing plant, it should ideally be located close to its supply of eggs. A constant supply of eggs is important in the efficient operation of the plant. The correct location enables the eggs to arrive at the plant in good condition, thus ensuring that the resulting product is of good quality.

Liquid Egg Products

The production of liquid egg products takes place in specialist, large plants specifically designed for the purpose. Such a plant could process in excess of 36 million eggs a year. Mechanical equipment is used to break the eggs automatically and, if necessary, separate the egg yolk from the albumen. Such systems can handle up to 108 000 eggs an hour with electronic detectors to make sure that no yolk ends up in the white at the time of separation. A temperature of 10 °C is optimum for breaking and separating.

Further processing of eggs into liquid product is not a means of disposing of poor-quality eggs. In fact, the increasing concern about food safety and quality has meant that only surplus first-quality eggs and uncracked seconds are used in breaking plants.

At the time of breaking, each egg will be visually inspected, either automatically or by an operator, to ensure that no

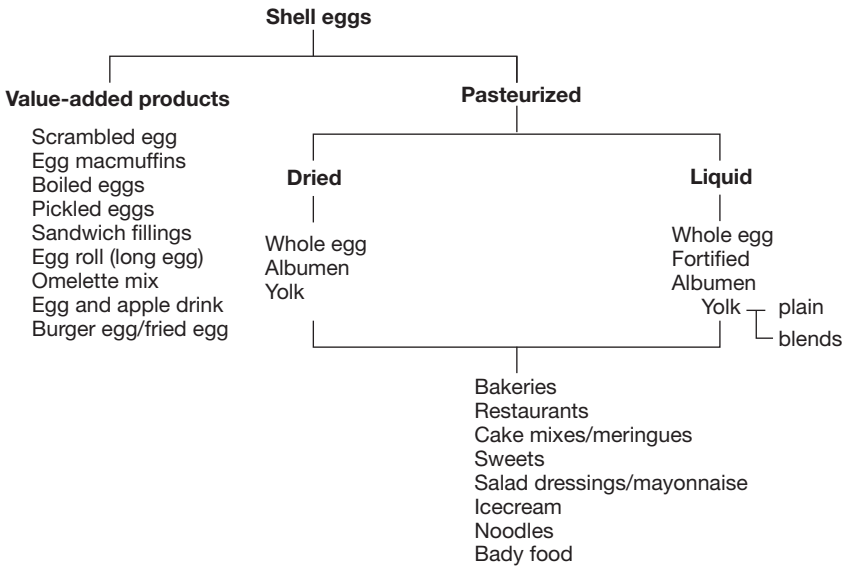

Figure 1 Eggs in the food industry.

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00245-2

undesirable material is passed into the further processing line. Any eggs seen to be unsuitable will be rejected from the system at this stage and disposed of. The contents from the broken eggs are then passed through a sieve to remove any remnants of shell, the chalazae, which are the strands of protein that hold the egg yolk in place, and any other undesirable material.

About 50% of total liquid egg production in the United States is in the form of whole egg (yolk and albumen), and some may be fortified by the addition of extra yolk to increase the ratio of yolk to albumen over and above that found in a normal egg. The balance is divided between production of albumen and that of yolk. Liquid yolks may be sold as plain yolk or special blends such as sugared yolk or salted yolk. Not only such products meet the needs of specific customers but also the addition of these agents to yolk helps to maintain the consistency of the yolk, as without these natural additives, it tends to separate into a thin liquid surrounding a congealed core if it is frozen. The whole egg tends to be standardized to a solids content of 24.7%. The separate egg white should not contain more than 0.03% yolk on a liquid basis, and yolk tends to be standardized to a solids content of 43%.

In the past, all these products would have been frozen rapidly in a blast air freezer and held in this form until used. However, there has been a tendency in large-scale plants to chill the products and handle them as a fresh food, transporting them in refrigerated vehicles to their point of use. In this case, whole eggs and yolk liquids are chilled to 4.4 °C and egg albumen is chilled to <7 °C. In this form, the shelf life of the product is only about 4 days, but the costs of canning and freezing are avoided. Freezing is still adopted for small-scale use of liquid eggs.

Bakeries as a group are the largest users of whole eggs and separate albumen. Mayonnaise manufacturers and salad dressing makers use large quantities of salted yolks, and ice cream makers use sugared yolks. Noodle makers and processors of baby foods use plain yolks.

Liquid eggs or egg products are pasteurized (Figure 2) during their manufacture to prevent organisms such as salmonella from becoming a major health hazard during their subsequent use and particularly after the eggs are removed from storage. Legislation to enforce this was introduced in the United Kingdom in 1964 and in the United States in 1966. The pasteurization process in the United Kingdom involves subjecting the product to a temperature of 64.4 °C (148 °F) for 2.5 min for whole eggs. Comparable figures for the United States are 60 °C (140 °F) for 3.5 min. Albumen is more susceptible to heat, and so, a slightly lower temperature is used, whereas the reverse is the case for yolk, where any salmonella is more heat-resistant. The alpha-amylase test is routinely used to test for adequate pasteurization.

Traditionally, liquid egg products were packed in metal cans or transported by large tankers. Today, modern packaging machinery enables the product to be put in large plastic bags contained in rigid outers, and each bag can contain 500 kg of liquid egg, which is drained from the container by means of a tap inserted at the bottom. The bag is then disposed of and the outer is returned to the manufacturer to be refilled. The product can be put into smaller cartons (Figure 3) that can be supplied to retail outlets for direct sale to consumers or larger cartons for supplying to hospitals and institutions. This is an expensive way of producing liquid eggs because of the cost of the packaging. In these cases, liquid whole eggs would be used for making scrambled eggs and omelets, for example.

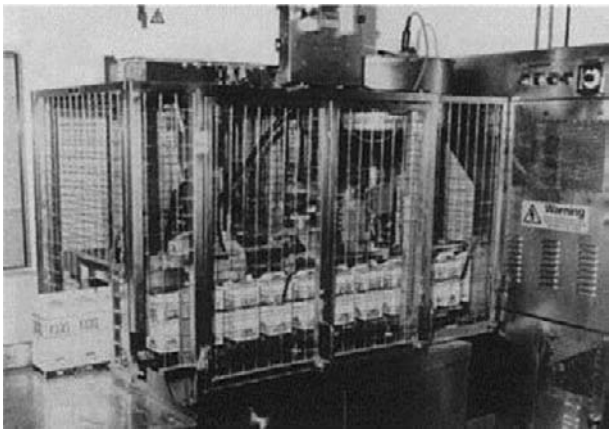

Figure 3 Liquid egg being packed into small cartons for retail sale. Courtesy of Oasters–Fridays (Cranbrook) Ltd.

Over the last 10 years, the production of egg products has been seen as the way in which any decline in egg consumption can be reversed. Consequently, a more diverse range of products are now available, including burger eggs, fried eggs, and meringue mix.

Freezing of Liquid Egg

If the liquid egg is going to be frozen, to maintain a quality product, it is important that the freezing process should be rapid and that the frozen product should be stored at a low temperature. Cans of chilled eggs should be subjected to an air

blast at −30 to −40 °C to ensure total freezing within 24 h, producing a uniform product without coagulation of the yolk. Subsequent storage should be at −10 to −20 °C.

Production of Egg Powder

The production of dried egg products is a further step beyond pasteurization. Spray drying is now the most common method for producing egg powder. However, some egg white is pan-dried and some whole egg is freeze-dried. Dried egg products have a number of advantages, which are listed in the succeeding text.

(1) They can be handled and stored with ease and at low cost.
(2) They are ready to use immediately with no thawing.
(3) They are easy to handle in a hygienic way.
(4) They are easy to remove from the container without scraping.
(5) No bacterial growth can occur in powder at room temperature, provided it is kept dry.
(6) There is good uniformity.
(7) There is precise control over the amount of water used in formulation.
(8) There is no loss when used because the dried egg is usually added directly to the batch.
(9) No special transfer or storage equipment is needed.
(10) Because the moisture content is reduced from around 74% to 2–4% by weight, there is a reduction in weight and volume and a concentration of food value.

A possible disadvantage of powder compared with liquid egg is a loss of 'fresh flavor' and a loss of certain functional properties such as aerating power, unless treated with nonreducing sugars prior to heating. This, however, limits its use because of the sweetened nature of the powder.

There are now several different types of dried egg products available that can be summarized under four major headings: dried egg white, dried plain whole egg and yolk, dried blends of whole egg and yolk with carbohydrates, and special types of dried egg products.

The growth in egg drying is well illustrated by reference to the United States. Prior to 1941, <1% of the eggs produced went to drying plants. Government purchases stimulated drying operations to such an extent that 20 400 tonnes were produced in 1941, 107 000 tonnes in 1942, 118 000 tonnes in 1943, and 146 000 tonnes in 1944. The current annual volume is over 180 000 tonnes. A 30 dozen case of shell eggs will yield about 18 kg of liquid whole egg or 4.5 kg of dried product containing 2.5% moisture.

The handling of shell eggs prior to drying is no different from the handling of eggs that are to be kept liquid. The liquid material is put through a clarifier to remove any bits of shell and is then screened to remove the chalazae and vitelline membranes. Pasteurization is important, not only to control salmonella infection but also to preheat the liquid so as to ensure a low-moisture powder that will not show any scorching. A typical egg-drying plant is shown in Figure 2.

The liquid egg is then pumped under a pressure of 17 250–34 500 kPa (2500–5000 lbf in^{-2}) to nozzles through which it is released into a large chamber where it immediately comes into contact with a stream of air that has been heated to temperatures of 120–175 °C. The enormous surface area created by atomization causes instantaneous evaporation of most of the moisture from the egg material and the formation of powder that falls to the floor as a fine powder, while the moist air passes on out of the drying chamber at a temperature of 65–71 °C. It is important that the spray dryer is designed so that the product stays at relatively low temperatures throughout the drying system and that the dried product is removed from the hot air stream as rapidly as possible.

Modern dryers produce a powder in which the moisture content does not exceed 2%. The temperature of the powder as it leaves the dryer may be 65 °C or higher, and this must be reduced quickly to <29 °C if the product is to have good keeping qualities. Since the powder is extremely hygroscopic, the temperature must be reduced by contact cooling, rather than by exposure to cold air. Two different powder-cooling methods are commonly used: first, pneumatic conveying with cooling air and, second, mixing the powder with carbon dioxide in the form of dry ice. After cooling, the powdered eggs are then packed immediately in sealed containers. Many of them are packed in carbon dioxide to remove the oxygen and lower the pH value in order to improve the keeping quality of the product.

Egg white can be dried in pans, rather than through a spray technique. The pan-dried egg white can be in the form of flake or granular albumen or can be milled to a powder form. This form of egg albumen tends to have good whipping properties once reconstituted.

The chief users of dried egg products are cake mix manufacturers, sweet makers, and manufacturers of meringue powders and, to a lesser extent, mayonnaise makers. Most dried egg products made for commercial use are packed in polythene-lined boxes or drums. A common pack size would contain 25 kg of product.

Quality of Dried Egg Products

The quality of dried egg or dried egg products can be affected by a number of factors. Important are the quality of the eggs broken out to make the original product, handling methods, sanitation practices, conditions during processing, pasteurization procedures, drying, and conditions under which the products are held in storage. Glucose (0.3–0.5%) is removed from the liquid egg white prior to drying by fermentation using a yeast or bacterial culture or by oxidation to gluconic acid using a glucose oxidase–catalase enzyme system. With glucose removed, dried egg whites are completely stable. If glucose is not removed, the product would be unstable because reducing groups from the glucose would combine with amino acids in the protein, leading to a condensation reaction that would be followed by browning and the development of insoluble proteins. There could also be the development of off-odors and the loss of some functional properties during storage. Plain whole egg and yolk can be pasteurized and dried without removal of the glucose, and consequently, these are the least stable of the egg products.

The physical properties important in relation to dried egg products are bulk density, dispersibility, solubility, and reconstituted viscosity.

Storage of Dried Egg Products

One of the real advantages of dried egg products is their ease of storage. Most are relatively stable when stored at room temperature. Dried egg whites can be held under almost any storage condition for an indefinite period of time. Dried products containing whole egg and yolk should be under refrigeration if held for long periods of time. Some of these are relatively stable at room temperature, particularly those where the natural glucose has been removed prior to drying.

Other Uses of Eggs in the Food Industry

Although liquid eggs and dried eggs still account for the majority of eggs used in the food industry, there are other products, which have evolved during the last 10–15 years, that are commercially available.

The mass production of hard-boiled eggs has developed in recent years. Normally, white eggs are used in the process, rather than brown, because the shells can be more easily removed from white eggs than from brown, resulting in less damage to the finished product. In countries where brown egg production predominates, such as the United Kingdom, this means that white eggs may have to be imported for the process from countries such as Denmark. However, in recent years, flocks of white egg-laying hens have been established in the United Kingdom specifically to supply the processing industry.

Again, only good-quality eggs are used in the process so that the final product is also of good quality. Normally, in European Union countries, small eggs would be used (under 53 g) for boiling as there is little demand for these sizes of eggs in the shell egg market.

The eggs are gradually boiled as they move around a trough arrangement containing high-temperature water, with the objective of them being hard-boiled by the time they have completed a single circuit of the trough. The eggs are then removed, deshelled, and cooled. Once hard-boiled, the eggs can be used for a number of products. They can be pickled in jars in plain vinegar or with spices. They can be used in pies or salads and a major use in this form is in airline meals. Eggs damaged during the boiling or shelling processes would not necessarily be discarded. They can be diverted to the manufacture of sandwich fillings, such as egg mayonnaise, which can be packed into 5 kg tubes for distribution to sandwich manufacturers and the catering trade.

Problems associated with large-scale boiling of eggs, apart from that of deshelling, include optimizing the temperature for both the boiling and cooling processes, effluent discharges, and the prevention of black rings occurring at the junction between the yolk and the albumen. This is associated with the breakdown of sulfur-containing amino acids in the albumen producing hydrogen sulfide, which reacts with iron released from the yolk to form iron sulfide.

Hygiene Measures

In all egg processing plants producing egg products for human consumption, a strict code of practice relating to hygiene is essential. Conventional egg products must now meet strict chemical, physical, and functional specifications, which include moisture, fat, protein, ash, glucose, reconstituted viscosity, whipping ability, and functional performance in the foods in which they are used. Also included are microbiological standards for total plate count, coliform, yeast and mold, *Escherichia coli*, salmonella, coagulase-positive staphylococcus, and *Clostridium perfringens*.

Many plants have a resident food technologist responsible for the implementation of a quality control program using an in-house quality control and microbiology laboratory. Every batch of product produced would be tested for contamination, and production plants would be swabbed twice a week to test for the presence of undesirable organisms within such a program.

Elderly: Nutrition Requirements

R Chernoff, University of Arkansas for Medical Sciences, Little Rock, AR, USA

© 2016 Elsevier Ltd. All rights reserved.

Introduction

It is well known that the population of elderly people is expanding rapidly; it has been estimated that by 2030, 70 million people will be age 60 years or older, and, by 2050, the population older than age 65 is projected to be 88.5 million. The 85+ population is anticipated to grow from 4.2 to 6.6 million in 2020, then to 8.9 million by 2030, to 19 million by 2050. An increase in the prevalence of disabilities and diseases is one of the natural consequences that accompany advanced aging.

Functional impairment in older adults is associated with poor nutritional status or malnutrition, which is frequently also associated with the perception of quality of life, particularly among women. Disability is associated with frailty and frailty is linked to loss of muscle strength and weight. Frail individuals are not always cachectic but may be overweight or obese. Data from the Health and Retirement Study, a prospective study conducted by the University of Michigan, demonstrate that excess body weight is associated with less Activities of Daily Living (ADL) and Instrumental Activities of Daily Living (IADL) impairment. The challenge of determining nutritional requirements in elderly individuals is associated with an increasingly diverse impact of physiological aging and a lack of adequate and appropriate standards against which nutritional status can be measured.

Energy Requirements

As humans age, there are changes in body composition; lean body mass, total body water, and bone density decrease over time. Fat stores may increase or remain the same, but fat compartments shift and tend to become denser around major organs. These body composition changes contribute to a decrease in the energy required to maintain homeostasis including body weight and function. To avoid excess weight gain, caloric intake must be reduced. The Baltimore Longitudinal Study of Aging demonstrated a decrease in energy intake from 2700 kcal at age 30 to 2100 kcal by age 80 in male subjects. This observation is important because as basal energy needs decrease and activity becomes more sedentary, less energy substrate is required to maintain lean body mass and support energy expenditure. However, reducing total caloric intake can increase the individual's at risk for a deficient intake of other essential nutrients.

Decreased energy expenditure is associated with chronic disease and increasingly sedentary behavior. There is a decrease in consumption of calories with age as well as a decrease in energy expenditure. However, if older adults do not reduce their caloric intake as they age and become more sedentary, weight gain results. Weight gain may serve to further exacerbate disabling conditions; however, heavier patients may have better survival and recovery from atherosclerotic heart disease, stroke, and other potentially life-threatening conditions.

Requirements for energy to maintain weight are often linked to energy consumption, but research indicates that this might not be reasonable in estimating energy needs for elderly individuals. Prediction equations for energy requirements do not give reliable estimates of energy requirements in elderly people, and indirect calorimetry should be employed when actual energy needs must be defined rather than grossly estimated. The clinical challenge is to continue to meet all nutrient requirements in a smaller caloric base of food consumed regardless of weight.

Data indicate that the relationship between obesity and mortality becomes stronger with age. Perhaps, more pervasive is the role that obesity has in functional consequences; older adults who are physically limited because of obesity (body mass index of ≥ 30) tend to be more sedentary. Sedentariness contributes to weight gain, more severe obesity, and possibly mortality.

Undernutrition

Undernutrition, a deficit of essential nutrients, including energy substrate and protein, is a common finding in older adults. In elderly individuals, measuring nutritional status is somewhat challenging because there are no population reference standards against which to compare. Alternate approaches to measure undernutrition or malnutrition abound, but it has been well documented that undernutrition exists and is a therapeutic challenge in older adults regardless of their health status. In elderly people, loss of reserve capacity is associated with undernutrition. Reserve capacity is the ability of an organism to respond to trauma, acute illness, or other physiological insults; for patients who lose this ability, an insult may lead to a rapid decline. Weight loss has been associated with adverse outcomes.

Calorie Restrictions

Evidence that caloric restriction increases life span in research models ranging from single-cell organisms to nonhuman primates has had positive results. Evaluating the animal calorie restriction models in humans is challenging due to the poorly defined mechanisms of calorie restriction and longevity and the potentially difficult ethical issues in human research. Skepticism about the positive effects of calorie restriction in humans is related to the real-life, nonlaboratory, controlled environment situation under which people live.

Protein Requirements

Protein intake tends to be highest in young adults and progressively declines with advancing age. The decrease in protein intake is likely to be the result of reduced energy intake and not a change in the proportion of energy consumed as protein. Data indicate that although the acceptable macronutrient

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00247-6

distribution range for protein is 10–35% of energy, very few older adults usually consume more than 20% of their energy intake as protein. In normal aging, changes in body composition occur that result in a shift toward decreased muscle mass and increased fat mass.

The loss of fat-free mass with advancing age theoretically results in a relatively lower protein requirement (per kilogram of body weight) compared to a younger adult. However, at present, there is no consensus regarding the protein needs of elderly persons, although there is some research suggesting that the Recommended Dietary Allowances (RDAs) should be higher than the current level. Short-term nitrogen balance studies are inconclusive, whereas the limited longer-term nitrogen balance studies suggest that the RDA is not sufficient to completely meet the metabolic and physiological needs of elderly persons.

Fat Requirements

A minimum of 10% of total energy intake should be derived from fat to ensure an adequate dietary intake of fat-soluble vitamins and essential fatty acids. Recommendations for dietary fat intake are the same for older adults as for younger adults: 30% or less of total diet with saturated fats providing from 8% to 10%, polyunsaturated fats being ~10%, and monounsaturated fats making up the difference. The recommendation for dietary cholesterol intake is 300 mg day^{-1} or less. Total cholesterol is generally considered an important risk factor for coronary heart disease; however, the impact of cholesterol profiles in elderly people is unknown. In a 5-year prospective study of 4066 men and women older than age 71 years, elevated total cholesterol levels were associated with a similar pattern of death from coronary heart disease as seen in younger adults. The subject group with the lowest total cholesterol levels (<160 mg dl^{-1}) had the highest incidence of preexisting cardiovascular disease, the highest risk factors for cardiovascular disease, the highest indexes of poor health, and the highest crude coronary heart disease mortality. Currently, it appears that elevated total cholesterol levels remain a risk factor for death from coronary artery disease in elderly persons. High-density lipoprotein cholesterol fraction values <35 mg dl^{-1} predict coronary heart disease mortality and occurrence of new events in individuals older than 70 years. Specific recommendations for dietary fat modifications must be made on an individual basis based on a complete profile of cardiovascular and stroke risk factors.

Carbohydrate Requirements

Carbohydrate is the third major macronutrient; it includes the simple sugars and complex carbohydrates. Requirements for dietary carbohydrate generally approach 55–60% of total energy intake. The complexity of dietary carbohydrate can be as important as the percentage of calories contributed by carbohydrate-rich food. Consumption of food with the indigestible dietary fiber removed can contribute to gastrointestinal disorders commonly encountered in older adults, including constipation, diverticular disease, diabetes, and hyperlipidemia.

Dietary fiber, mainly composed of plant polysaccharides and lignin, is resistant to human digestive enzymes. One example of such fiber, wheat bran, increases fecal bulk and decreases gut transit time and intraluminal pressure within the colon. These effects help to reduce the incidence of constipation and the formation of colonic diverticula. However, soluble fibers such as gums and pectins increase the viscosity of intestinal contents, increase gut transit time, and decrease the rate of small intestinal absorption. Consumption of fibers such as guar, pectin, and tragacanth leads to reduced insulin secretion in normal subjects, increased carbohydrate tolerance in diabetics, improved lipid profiles, and reduced glycosylated hemoglobin (HbA1c). The mechanism of the positive effect seems to be related to delayed gastric emptying and reduced rate of absorption of carbohydrate in the small intestine. Purified fibers such as guar, pectin, oat bran, and high-fiber foods, including cereals, starchy vegetables, and beans, have been reported to lower serum lipids. Decreases in total cholesterol, LDL cholesterol, and triglycerides without changes in HDL cholesterol have been reported. At present, it seems prudent to have a daily dietary fiber intake of 25–35 g day^{-1} and to include a variety of fibers from fresh fruits, vegetables, legumes, and whole-grain products. Every effort should be made to encourage older adults to have a varied dietary intake of carbohydrate-containing foods daily. This strategy will increase the likelihood of adequate consumption of micronutrients as well.

Fluid Needs in Older Adults

In older adults, fluid intake often does not receive the attention it deserves. Inadequate fluid consumption can lead to rapid dehydration, which has its own potentially risky consequences including hypotension, constipation, nausea, vomiting, mucosal dryness, decreased urinary output, elevated body temperature, and mental confusion. Total body water decreases with age, shrinking from 75% body weight in infants to 55% body weight in elderly adults associated with the reduction in total lean body mass.

Older adults are at risk of dehydration, particularly when there are climate challenges (extreme heat or cold). Water acts as a thermal buffer to protect the individual from hypo- or hyperthermia. Elderly people have decreased sweating and changes in other thermoregulatory responses, making them more vulnerable to periods of environmental shifts in temperature. Insensible losses through skin can range from 0.3 l h^{-1} when sedentary to 2.0 l h^{-1} with exercise; this may lead to a loss as high as 6 l day^{-1} in extreme heat. Decreased plasma volume and osmolality can result in death during periods of extreme environmental heat. Adequate hydration in older adults affects their ability to be physically active; cognition, alertness, and short-term memory are affected by mild dehydration. The challenge comes from the fact that thirst mechanisms and sensitivity are compromised in elderly people. The decrease in fluid intake is the result of alterations in mechanisms that control thirst sensitivity, particularly a decrease in osmoreceptors and baroreceptors and secretion of vasopressin.

Environmental factors, hormonal changes, climate (temperature and humidity), availability of water and food, medical problems, diuretic abuse, polypharmacy, and avoluntary decrease of fluid intake may all affect fluid balance. Along

with disordered thirst control mechanisms and inadequate intake of fluid for maintenance, older adults who have fever, infection, immobility, dementia, coma, fluid loss due to hemorrhage, diarrhea, vomiting, incontinence, or diabetes insipidus or have acute illness can become chronically dehydrated. The kidneys' ability to concentrate urine or efficiently conserve water also can affect fluid balance.

Many older adults, particularly those who are institutionalized, are not consuming adequate amounts of fluid. Although the usual stated requirement for fluid intake is eight 8 ounce glasses of fluid per day, data to support this recommendation are lacking. Actual need is probably in the range of six 8 ounce glasses of fluid per day.

Methods commonly used to determine fluid needs in individuals include 30 ml kg^{-1} body weight with a minimum of 1500 ml day^{-1}, 1 ml $kcal^{-1}$ consumed, or 100 ml kg^{-1} for the first 10 kg of actual weight, 50 ml kg^{-1} of the next 10 kg actual body weight, and 15 ml kg^{-1} of remaining weight. The first method (30 ml kg^{-1} body weight) approximates fluid needs most accurately in institutionalized elderly persons; additional research needs to be conducted to better estimate actual needs of older adults. Strong and chronic encouragement for oral fluid intake might be necessary to maintain hydration status.

Vitamin Requirements

Water-Soluble Vitamins

Vitamin B_1 (thiamine)

Some studies suggest that older adults might have a higher requirement for vitamin B_1, but lower energy requirements for older adults may contribute to an increase in requirement. Based on what is presently known, the recommended amount appears to be adequate for all adults independent of age. Depending on income, race, and socioeconomic status, up to 70% of elderly adults have low levels of vitamin B_1 intake.

Vitamin B_2 (riboflavin)

Vitamin B_2 acts with its coenzymes flavin mononucleotide and flavin adenine dinucleotide in many electron transfer reactions. Because of the many different roles of the flavoenzymes in intermediary metabolism, the important role of riboflavin (such as in antioxidant defense or in the modulation of homocysteine metabolism) is often forgotten. Dairy products and cereal products are, for older adults, the most important sources of riboflavin. In various populations around the world, the high prevalence of riboflavin deficiency is mainly caused by an inadequate intake of dairy products.

There might be a role for riboflavin in the pathogenesis of age-related cataracts because this vitamin might be important as a photosensitizing agent. Despite the potential involvement in some disease states, there is no evidence that there is a higher need for vitamin B_2 in older adults.

Niacin

Data about niacin status in elderly adults are very limited. Niacin intake in elderly adults varies widely and is associated with the variables of socioeconomic background, race, age, health status, and institutionalization. Nutritional intake of niacin is related to the mortality of elderly people; however, this relation does not necessarily imply causality. The nutrient density of niacin was adequate in nursing home diets so that low intakes become the major determinant of recommendations for this vitamin. For niacin, low dietary intake is key to a niacin-insufficient diet. Encouragement of higher energy and protein consumption is the best strategy to increase niacin status because this approach improves niacin and protein intake.

Vitamin B_6

The intake of vitamin B_6 varies widely among elderly persons as a function of age, socioeconomic level, and state of health. Studies report intakes below the RDA in up to 50% or even 90% of elderly populations. Even in healthy, free-living, elderly adults, 61% of women consumed <1 mg of vitamin B_6 per day, and 54% of elderly men consumed <1.1 mg (corresponding to 55% of the 1989 RDA). Between 10% and 50% of the US population older than 51 years consumed less than the Estimated Average Requirement (EAR) of vitamin B_6, <1.4 mg day^{-1} for men and <1.3 mg day^{-1} for women. (The EAR corresponds to the daily nutrient intake that is estimated to meet the requirement of half the healthy population of the corresponding age group.)

It has been suggested that an age-related increase in activity of the alkaline phosphatase, considered to be of major importance in the degradation of pyridoxal-5-phosphate (PLP), and low intakes of vitamin B_6 are the major causes of age-related decline in plasma PLP levels. Abnormalities of vitamin B_6 can be corrected by the ingestion of vitamin B_6 supplements in most elderly persons. A few studies report the inability of some older adults (up to 20%) to correct their biochemical vitamin B_6 status on supplementation. These observations are suggestive of age-related changes in vitamin B_6 requirements of older adults. The effects of diseases and comorbidities seem to be the likely causes of unresponsiveness to supplements. The bioavailability of vitamin B_6 from food is low; the RDA, based on the intake vitamin B_6 from food sources, might be even higher than assumed. The present recommendations do account for these alterations of the metabolism with aging.

Both retrospective and prospective studies have described a relationship between the risk of coronary artery disease, myocardial infarction, and the intake of vitamin B_6. This relationship is, however, strongest for folic acid.

Folate

Since the 1989 RDA was published, the recommended intakes of folate have been increased for older women and men. Folate intakes in older adults vary considerably as a result of diet, but most elderly people ingest amounts close to the RDA. Before fortification of cereal grains with folate (i.e., before 1 January 1998), the prevalence of low folate intakes varied between 0% and 50%. The median intake in the population at large before mandatory cereal folate fortification was 250 μg day^{-1}, which is well below the present recommendation. The average folate intake has increased by $\sim$80–100 μg day^{-1} due to the fortification of cereals.

A high intake of alcohol alone or in combination with an inadequate diet is one of the most important factors contributing to clinical folate deficiency. In elderly subjects, the presence of both low folate intake and elevated plasma homocysteine level represents a rather prevalent clinical situation. Elevated

levels of plasma homocysteine are mainly attributable to an impairment of folate, vitamin B_6, and/or vitamin B_{12} status. In most people, folate seems to be the major determinant of plasma homocysteine levels. Perhaps, homocysteine is only a surrogate factor and its relationship to etiologies of chronic disease is more complicated. Presently, the best strategy to manage progression of chronic disease risk is the consumption of a well-balanced diet.

As a result of the US government-mandated folic acid fortification of cereal grain products, a shift in the distribution of folate intakes and consequently the biochemical status of folate occurred. It has been reported that a higher supplemental folate intake ($>400\ \mu g\ day^{-1}$) was associated with an increased cognitive decline in elderly subjects. This effect was noticeable in older people who also had a vitamin B_{12} deficiency or low vitamin B_{12} plasma concentration as reported in other studies. Adequate intake (AI), whenever possible, from food, based on present guidelines should be more strongly encouraged, but it should be remembered that larger amounts of folate from fortified foods and/or supplements are not good for everyone.

Vitamin B_{12}

Vitamin B_{12} requirements for older persons (i.e., >51 years) can be obtained through consumption of vitamin B_{12}-fortified foods or vitamin B_{12}-containing supplements. Fortified foods and supplements contain crystalline vitamin B_{12} and absorption is not affected by aging. Intake of vitamin B_{12} in free-living elderly people varies, and ~0–50% of older adults have been reported to have (dietary nonsupplemental) intakes below the present recommendation. Dietary intake varies in older adults as a function of food choices. Nearly 70% of vitamin B_{12} intake in elderly subjects is from meat, eggs, and fish.

It has been shown that atrophic gastritis, common among older adults, decreases the bioavailability of dietary vitamin B_{12}. In food, vitamin B_{12} is bound to a protein carrier and must be released before it can be absorbed. Several mechanisms can lead to the malabsorption of protein-bound vitamin B_{12} in atrophic gastritis. Because of decreased or lack of gastric acid production, protein digestion is impaired, and vitamin B_{12} cannot be released from its protein carrier. Another potential factor in atrophic gastritis is that bacterial overgrowth in the upper gastrointestinal tract can bind vitamin B_{12} and make the vitamin unavailable. However, it has been shown that malabsorption of the protein-bound vitamin B_{12} in subjects with atrophic gastritis can be reversed by treatment with tetracycline; the absorption of crystalline vitamin B_{12} is not impaired in atrophic gastritis. Most elderly people can absorb vitamin B_{12} from fortified food. Vitamin B_{12} deficiency could be a major undetected problem in apparently healthy elderly people since the symptoms of deficiency are vague. There is a controversy over the lower limit of normal plasma levels of vitamin B_{12}, so elderly subjects with low plasma levels of vitamin B_{12} should be monitored more closely.

'Pernicious dementia' and other changes in cognitive function caused by a deficiency of vitamin B_{12} have been described in the literature. Patients with different forms of cognitive impairment may have impaired vitamin B_{12} status; however, this is mainly the result of low intakes. It has been reported that anemia in old age is more likely related to folate deficiency than to vitamin B_{12} deficiency. The new Dietary Reference Intakes (DRIs) for vitamin B_{12} have been increased compared to earlier recommendations because a large fraction of elderly people malabsorb this vitamin from food sources (i.e., protein-bound vitamin B_{12}); it is recommended that individuals older than 50 years consume foods fortified with B_{12} or take a B_{12} supplement.

Biotin

Biotin deficiency occurs rarely; the recommendation for the AI for biotin has been set at $30\ \mu g\ day^{-1}$ for all adults independent of age, but there are hardly any data about elderly adults. Since aging and excessive alcohol consumption can be linked to an alteration in biotin metabolism, it is likely that elderly individuals may be biotin-insufficient. Present evidence, although minimal, suggests that biotin status is not a major concern for older adults.

Vitamin C (ascorbic acid)

Vitamin C deficiency disease, scurvy, is rare but as new metabolic properties of vitamin C are described, an AI of vitamin C-rich foods remains a key for health maintenance, especially in elderly adults. There are no age-related changes in absorption and metabolism at median level intakes; it can be assumed that any deficiency is related to poor intake. Dietary vitamin C intakes vary mainly as a function of the presence of illness associated with overall poor nutrient intake, institutionalization, and age.

The intake of different dietary supplements, especially including vitamin C, has increased and contributes considerably to the nutrient intake of large segments of the elderly population. Institutionalization, hospitalization, and illness lead to a decrease of vitamin C intakes contributing to low plasma levels.

It has been reported that lower ascorbic acid levels are seen more frequently in elderly men than in elderly women; sex differences in plasma ascorbic acid concentration might be caused by a lower tubular reabsorption of vitamin C in elderly men. Healthy centenarians had significantly lower vitamin C plasma concentrations because of lower intakes.

Low levels of vitamin C in healthy elderly people can be corrected easily by the administration of oral ascorbic acid supplements, but when stopped, there may be a rapid decrease in the blood levels. Elderly people with low vitamin C levels do not necessarily show clinical symptoms, so it has been concluded that there is no real need to raise the ascorbic acid levels in the blood through supplementation. Because of the functions of vitamin C, this conclusion might be incorrect. In view of what is known or not yet known about the significance of low plasma levels, a continuous, adequate daily intake should be ensured.

Ascorbic acid can be important in the pathogenesis of chronic diseases of aging. Ascorbic acid has been found to be potentially important in the prevention of atherosclerosis, cancer, senile cataract, lung diseases, cognitive function, and various degenerative diseases. Vitamin C supplements are promoted to decrease lipid levels, thereby reducing the risk of atherosclerosis. However, a 5-year vitamin C supplementation trial had no markedly favorable effects on the serum lipid and lipoprotein profile in an adult population.

Vitamin C supplements do not prevent any of the chronic diseases of aging, but neither do pharmacological doses of vitamin C have a protective effect. The current recommendation for ascorbic acid seems to be adequate for older adults, although some individuals might find it difficult to achieve this intake level from diet alone. Nevertheless, intake should be strongly encouraged in elderly individuals who are institutionalized, ill, or of lower socioeconomic status. An increased consumption of fresh fruits and vegetables should be encouraged in elderly people.

Fat-Soluble Vitamins

Vitamin A

Meeting vitamin A needs by an increased ingestion of carotenoids might actually be a safe strategy for older adults. The vitamin A intake of many elderly people is below the present recommendations, but their vitamin A plasma levels remain well within normal limits. Vitamin A intake varies widely, and up to 70% of elderly people, depending on age, income, sex, race, geographic location, and socioeconomic status, have vitamin intakes below two-thirds of the 1989 RDA.

There is evidence that vitamin A status is generally not impaired in elderly people. In the Women's Health Study, vitamin A status was associated with an increased risk of hip fractures only in postmenopausal women with vitamin D deficiency. This is a well-known phenomenon and bone symptoms are a known feature of vitamin A toxicity. Nevertheless, it is probably wise not to encourage high vitamin A intakes in older adults, especially in the presence vitamin D deficiency. A more reasonable strategy for older adults is to get vitamin A from a higher intake of carotenoid-containing foods. An increased intake of carotenoids from fruits and vegetables was found to be associated with a decreased cardiovascular mortality in elderly patients.

High vitamin A supplement use by older adults might contribute to toxicity in elderly individuals. Acute hypervitaminosis A is rare, but chronic toxicity can be seen in this age group. Increased consumption of carotenoids from food and vegetables to improve vitamin A status should be encouraged in older adults.

Vitamin D

For men and women older than 70 years, the AI is 15 μg day^{-1} (600 IU). Skin synthesis is important compared to intake from food sources. Cutaneous synthesis of vitamin D ranges between 80% and 100% of the total vitamin D content of the body. It has been suggested that, with adequate sun exposure, dietary sources of the vitamin become unnecessary. Fortified foods, such as milk, contain considerable amounts of vitamin D, which would cover the needs of older adults. Some of these products are, however, not regularly consumed by elderly people or are consumed only in small quantities. Even a marine-based diet (e.g., salmon, sardines, and mackerel) seems to be insufficient for the maintenance of an adequate vitamin D status.

Data reported from the NHANES III survey indicate that older adults (71 years and older) report low intakes of vitamin D from food. Food fortification can lead to an improved vitamin D nutriture in elderly people.

Dietary vitamin D intake is usually not able to prevent vitamin D insufficiency especially during the winter months when people have low sun exposure. Plasma and serum levels of 25-hydroxyvitamin D_3(25[OH]D_3) decline with age in all populations. Along with low intake, decreased synthesis in the skin, decreased 1-α-hydroxylation in the kidney, decreased sunlight exposure, decreased plasma-binding capacity for vitamin D and vitamin D metabolites, and drug/nutrient interactions all contribute to inadequate vitamin D nutriture. Dietary fortification, enrichment of food, and ingestion of vitamin D supplements have a high potential for improving vitamin D status; the consequences are prevention of bone loss and decreased fracture risk.

Vitamin E

Age-related changes resulting from oxidative reactions are found in most organ systems; vitamin E and other antioxidants would seem to have a role to play in aging and the aging process. However, the consequences of a deficiency do not necessarily imply that pharmacological doses of antioxidant vitamins will have a protective effect on aging and related diseases. Nevertheless, all large supplementation trials have led to disappointing results regarding the role of vitamin E in the modulation of age-related diseases. Current evidence suggests that there is no impairment of vitamin E absorption with aging.

Because of the antioxidative properties of vitamin E, the effects of the vitamin in the prevention of atherosclerosis, cancer, cataracts, central nervous system disorders such as Alzheimer's and Parkinson's disease, immune function, impaired glucose tolerance, and many more conditions have been proposed. Despite all these potential relationships, the intake of high doses of supplements cannot be recommended.

Vitamin K

Data about vitamin K status in older adults are scarce. Poor vitamin K status has been associated with different chronic diseases involving calcification processes (e.g., osteoporosis and atherosclerosis). It is assumed that a dietary intake of 1 μg kg^{-1} of body weight per day should be sufficient to maintain normal blood clotting in adults. Recommendations are based on the maintenance and function of normal clotting mechanisms. In elderly people who have atrophic gastritis with a bacterial overgrowth, vitamin K status does not appear to be affected when assessed by measuring the resistance to warfarin therapy. Intake of vitamin K varies over a wide range, primarily due to diet composition. Studies indicate that up to one-third of elderly adults do not consume the recommended amount of phylloquinone.

Although the function of vitamin K is usually associated with blood coagulation, research conducted during the past few years identified vitamin K as an important factor in bone metabolism and thus in the development of osteoporosis. Combined treatment of vitamin K_2 and bisphosphonates in postmenopausal women with osteoporosis demonstrated that the combination treatment is more effective in the prevention of new vertebral fractures than a single treatment of bisphosphonate alone. A high dose of vitamin K might have positive effects on fracture risk. More studies are needed to clarify the

effect of vitamin K on bone health and at this time do not point to any specific recommendation regarding an ideal intake of vitamin K for bone-related issues.

Minerals

Sodium, potassium, calcium, and magnesium are considered essential minerals for humans. Older people may have challenges in maintaining levels of these minerals within normal limits because of decreases in renal function, by other renal mechanisms designed to conserve or excrete excessive amounts of these minerals, and certain medications or disease states. The DRIs and the *Dietary Guidelines for Americans* serve as guides for the intakes of these nutrients from foods and supplements (e.g., for calcium). It has been suggested that the dietary intakes of sodium are too high and the intakes of potassium, calcium, and magnesium are too low among older adults.

Sodium

Dietary sodium is available through many sources, particularly processed, preserved, and canned foods. It is actually a greater challenge to avoid dietary sodium for individuals on sodium restrictions.

Potassium

Age alone does not appear to affect the ability to maintain the concentration gradient of potassium. Intracellular potassium stores can be depleted in a variety of clinical conditions commonly seen in elderly patients (metabolic and respiratory acidosis, congestive heart failure, cirrhosis, and uremia) with serum potassium concentrations remaining within normal limits. Dietary potassium is found in a wide variety of foods, and there are rarely disturbances of potassium status due to dietary factors.

Calcium

Both hypocalcemia and hypercalcemia occur with more frequency in older adults because specific disease conditions that cause challenges to calcium balance are more common in elderly people. More importantly, the age-related loss of bone calcium occurs in both sexes, but more commonly in women, it is related to a variety of variables such as diet, hormone levels, bone density, and other factors. Nevertheless, this loss leads to the development of osteoporosis and an increased risk of fractures. Dietary factors play an important role in the age-related loss of bone calcium. In older individuals, calcium intake is generally low and is associated with reduced absorption of calcium. Lack of vitamin D (hypovitaminosis D) is often associated with increased age. Because vitamin D is the major regulator of intestinal calcium absorption, the cumulative effect of a calcium intake deficit and an inadequate intake and generation of active vitamin D is a negative calcium balance. This stimulates parathyroid hormone (PTH) release, increasing bone calcium resorption and risk for osteoporotic fractures, a major cause of morbidity and mortality in the elderly population.

Magnesium

Poor magnesium status has been associated with numerous age-related conditions. Gastrointestinal disorders and alcohol consumption are the most commonly encountered problems in older adults. Hypomagnesemia produces neuromuscular and psychiatric symptoms, including neuromuscular hyperirritability, tetany, seizures, muscle weakness, vertigo, gross tremors, and mental changes (e.g., irritability and aggressiveness). Linking these symptoms with hypomagnesemia may be elusive because serum levels will generally remain within normal limits.

Barriers to Maintaining Adequate Nutrition

Ingesting an adequate diet may be affected by a variety of other secondary factors associated with advancing age. Oral health status; swallowing difficulties; changes in vision, smell, and taste; socioeconomic factors; polypharmacy; drug/nutrient interactions; cognitive status (delirium, depression, and dementia); and functional status all constitute potential barriers to maintaining adequate nutritional status and the consumption of a nutrient-dense, nutritionally adequate diet.

For elderly adults who are living on fixed income such as social security or other retirement incomes, food can be a significant part of their living expenses. Living conditions, cooking facilities, transportation, and seasonal variations in the price of specific foods, for example, fresh fruits and vegetables, can have an impact on nutritional status.

Polypharmacy is a problem among many elders who are taking multiple medications. There are often drug/drug, drug/nutrient, and drug/herbal product interactions that may affect appetite, taste, the efficacy of medication treatments and may be the etiology of gastrointestinal disturbances. A review of the prescription, over-the-counter, and herbal remedies is warranted on an annual basis to minimize the effect that drugs may have on the nutritional status of an elderly person.

Cognition may have a profound impact on dietary intake; dementia, delirium, and depression will affect appetite, the perception of food, activity level, and the ability to feed oneself. Activity level, and need for energy calories, may be quite impacted by dementia, with some individuals becoming hyperactive and others becoming very sedentary.

Depression may have a longer and more profound effect on nutritional status than dementia. Depression has an impact on appetite, weight loss, and poor oral intake. It may be associated with a broad range of problems associated with chronic disease, medications, grief, loneliness, and others.

Conclusion

Encouraging older adults to eat more complex carbohydrates rather than simple carbohydrates can contribute to adequate dietary fiber intake. Reduction of saturated fat, with an increased emphasis on consumption of poly- and monounsaturated fats, and decreased overall fat intake compensate for lower basal energy requirements and a decreased activity level often encountered in older adults. Providing adequate protein

of high biological value is essential in older adults as is meeting fluid needs. Attention to overall fluid intake in healthy free-living, chronically ill, functionally dependent, or acutely ill elderly people is key to maintaining optimal health in any person, but particularly important for this age group. Needs for these macronutrients (carbohydrate, fat, protein, and fluid) can be met with awareness of individual requirements, imagination, and attention to daily intake.

Not all micronutrients are affected by aging although chronic disease may be a factor in the adequacy of intake, digestion, absorption, or metabolism of various vitamins and minerals. The water-soluble vitamins (B complex and vitamin C) require attention because they cannot be stored and are involved in many metabolic pathways that affect overall health and nutritional status. Among the fat-soluble vitamins, vitamins A and D require some attention. Vitamin D has been an issue in recent years due to indications that many adults have low levels of dietary vitamin D, particularly older adults.

Barriers to adequate consumption of a nutritious diet including, but not limited to, cognitive status, oral health, deficits in sensory perception and functional status, socioeconomic factors, swallowing disorders, polypharmacy, and other changes that occur with age must all be assessed. Screening older adults for potential risks for nutrition problems is a highly recommended, cost-effective, and preventive strategy.

The specific recommendations concerning nutrient intakes and food-based dietary guidelines for older adults – with particular emphasis on guidelines for promoting physical activity among older and prevention of chronic noncommunicable diseases – can contribute to healthy aging.

Emerging Foodborne Enteric Bacterial Pathogens

SJ Forsythe, Nottingham Trent University, Nottingham, UK

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Compared to clinical infectious diseases, the number of currently recognized foodborne pathogens seems small. In part, this is due to general procedures of food production, for example, cooking, acidification, and dehydration, which over the centuries and in different cultures have been refined and become a self-proved effective means of food preparation. However, with changes in the sourcing of food ingredients, the need for large-scale food preparation practices and longer storage periods along with changes in eating habits has ensured a continuation of food-related illnesses. Such infections are an important cause of morbidity and mortality worldwide and have a major impact on public health. The true worldwide burden of diseases caused by foodborne pathogens is largely unknown. At best, we have data indicating trends in infections for a few pathogens in a few number of developed countries.

The European Food Safety Authority has defined 'emerging risk to human, animal and/or plant health' as a risk resulting from a newly identified hazard to which a significant exposure may occur or from an unexpected new or increased significant exposure and/or susceptibility to a known hazard. Hence, in order to detect such risks, adequate surveillance and monitoring programs need to be in place. There are many food safety monitoring systems at national and international levels. These are summarized in Table 1. Examples are the 'Rapid Alert System for Food and Feed' (RASFF) in Europe and WHO–INFOSAN. In general, these systems identify problems such as the increased reported occurrence of a foodborne hazard retrospectively. Consequently, any intervention is initially reactive instead of predictive.

In order to determine the global health burden of foodborne illness, the WHO set up the Foodborne Disease Burden Epidemiology Reference Group. This is composed of internationally renowned experts in a broad range of disciplines relevant to global foodborne disease epidemiology; http://www.who.int/foodsafety/foodborne_disease/ferg/en/index3.html. They have estimated that in 2005, 1.8 million people died from diarrheal disease, and these were mainly attributable to contaminated food and water sources. In the United States, foodborne illnesses affect up to 80 million people and cost an estimated US$5 billion on an annual basis. Additionally, our understanding of such infections is changing with the recognition of previously unrecognized and previously well-recognized pathogens, which have increased in their prevalence or become associated with new food vehicles.

The major organisms associated with foodborne disease are bacteria due to their ease of isolation and identification compared to viruses and fungi. However, with improved global surveillance systems, as well as improved isolation and identification methods, previously unrecognized foodborne infectious organisms are being recognized. With a global economy and the international transportation of food, the need to attribute human infections to food vehicles is warranted for their control.

The study of emerging foodborne enteric pathogens is both exciting and daunting at the same time. The opportunity to recognize and define an emergent pathogen leading to its control and reduced risk is an admirable goal, yet to publicize the emergence of an enteric pathogen based on limited information and initiate action could be regarded as scaremongering and alarmist. Given the limited number of organisms, which are routinely monitored in food, it may take considerable time before there is sufficient body of evidence of its significant presence such that it might be argued that by the time the link between the clinical presentations and food as a vector has been established, the organism will no longer be 'emerging' and therefore outside the scope of the study. The word 'emerging' implies the emergence *de novo* of the pathogen, yet for some, the term 'recently recognized' is more appropriate as the organism had been previously described, but the link with foodborne disease may be new. Some organisms in this article are 'emergent' or 'recently recognized' pathogens for which food has been established as a vector, but some will not be so strongly associated but could be foodborne. It may be argued that the latter should not be included – however, this begs the question of how will we ever know unless we look. Our powers of microbial epidemiology are still mainly limited to bacteria as we are still largely culture-dependent. In time, next-generation sequencing (NGS) will enable real-time genomic analysis of infections, but for now, our future predictions remain misty and unclear.

Illness caused by foodborne pathogens represents an important economic and public health burden worldwide. Based on a yearly case estimate and recent US census data, an estimated 25% of the US population is affected by foodborne illness each year. Viral foodborne pathogens are thought to contribute to ~50% of all foodborne illness cases in the United States. Rates of foodborne illness in many developed countries are similar. While exact numbers are difficult to estimate, it is thought that the burden of foodborne illness in developing countries is even higher.

Since 1996 in the United States, FoodNet has been an active surveillance program for laboratory-confirmed infections due to seven commonly reported bacterial foodborne pathogens: *Salmonella*, shiga toxin-producing *Escherichia coli* O157, *Shigella* spp., *Vibrio* spp., *Yersinia* spp., *Campylobacter* spp., and *Listeria monocytogenes*. This surveillance covers 15% of the US population. Over the period 1996–2005, there had been 121 536 cases including 552 deaths, for which 215 and 168 were due to were among persons infected with *Salmonella* and *Listeria*, respectively. Useful as this surveillance is, it does not cover the myriad of foodborne pathogens and toxigenic agents.

In the United States, there are an estimated 9.4 million cases of foodborne illness, which can be attributed to 31 known

Table 1 Early identification systems for emerging foodborne hazards

Country	*Organization*	*Activity*
The United Kingdom	FSA	Food Standards Agency (FSA)
The Netherlands	ISIS	Day-to-day changes in frequency of all communicable diseases
European	European Centre for Disease Prevention and Control (ECDC)	Provides a structured and systematic approach to the control of communicable diseases and other serious health threats in partnership with national health protection agencies. Issues warnings to EU member states through the early warning and response system (EWRS)
	Rapid alert system on food and feed (RASFF)	Centralized reporting of food hazards (physical, chemical, biological)
	EU: FVO	Food and Veterinary Office (FVO) promotes effective control systems in food safety and checks on compliance
The United States	CDC: FoodNet	Determines the exact burden of foodborne diseases, monitors foodborne disease trends in the United States, and relates foodborne disease to specific foods
	CDC: eFORS	Electronic Foodborne Outbreak Reporting System
	CDC: PulseNet	National network of public health laboratories that undertake pulsed-field gel electrophoresis analysis of bacteria that may be foodborne
International	WHO: GPHIN	Global Public Health Intelligence Network
	WHO: INFOSAN	International Network of Food Safety Authorities Network disseminates urgent information

After Marvin, H. J. P., Kleter, G. A., Prandini, A., Dekkers, S., and Bolton, D. J. (2009) Early identification systems for emerging foodborne hazards. *Food and Chemical Toxicology* **47**, 915–926.

pathogens (2011 data). Of these, 14 pathogens account for 95% of the illnesses and hospitalizations and 98% of deaths. The associated costs are estimated as $14.0 billion (ranging from $4.4 to $33.0 billion) of which 90% are attributable to five pathogens: nontyphoidal *Salmonella enteric*, *Campylobacter* spp., *L. monocytogenes*, *Toxoplasma gondii*, and norovirus. However, there were an additional estimated 38.4 million cases (80%), which were due to 'unspecified agents, including known agents with insufficient data to estimate agent-specific illness, known agents not yet recognized as causing foodborne illness, substances known to be in food but of unproven pathogenicity, and unknown agents.' These unattributed cases resulted in ~71878 hospitalizations and 1686 deaths. Although this author is not claiming that all these cases are due to emerging foodborne pathogens, the article illustrates that there is still scope for previously unrecognized pathogens to be discovered. Toxin-induced gastroenteritis due to *Bacillus cereus* is a well-recognized foodborne pathogen, yet the lack diagnostic tools means its incidence is highly likely to be underestimated and not an emergent pathogen as such.

The microbiological safety of food is dependent upon multiple variable 'from farm to fork' along the food chain. The combined advances in the Internet and culture-independent (i.e., DNA sequencing) methodologies are enabling improvements in monitoring and surveillance, though the scenario is constantly changing with increased global transportation of foods and food ingredients, aging populations, and changes in eating habits. Against this background, this article reviews the current situation regarding emergent enteric foodborne pathogens. In particular, reference will be made to previously unrecognized vehicles, for example, fresh produce, and serious issues to public health following the acquisition of antimicrobial resistance. Additionally, previously unknown foodborne pathogens, many of which are zoonotic, are being recognized through improved methods of surveillance and identification.

This article will not consider well-recognized foodborne pathogens: *Campylobacter jejuni*, *Salmonella enterica* serovars, *E. coli* O157 and O104, *Vibrio cholerae*, *V. parahaemolyticus*, *Yersinia enterocolitica*, *Listeria monocytogenes*, *Clostridium perfringens*, *Staphylococcus aureus*, and *Bacillus cereus*. For information on these organisms, please consult the specific chapters as listed at the end under 'See also.' Such organisms are often formally controlled via microbiological specifications whether in international policies or producer–distributor agreements. Essentially, improvements in the microbiological safety of foods have been largely driven by public demand in response to disease outbreaks, and consequently, less-recognized pathogens are overlooked. Focussing on a particular potential source of infection will invariably lead to discoveries, as evidenced by the emphasis of bats as vehicles of bacterial disease, which has opened a whole field of previously unrecognized bacterial and virus route of transmissions. Awareness and surveillance of viral foodborne pathogens are generally poor and primarily limited to norovirus, hepatitis A, and rotaviruses. Although many foodborne parasites are recognized, only *Ascaris*, *Cryptosporidia*, and *Trichinella* are effectively monitored in foods. Their epidemiology of such parasites through the food chain is poorly understood. The issues of viral and parasitic foodborne pathogens are not considered in this article due to the lack of information.

Bacterial Enteric Pathogens

Aeromonas Species

Description: *Aeromonas* genus, composed of 17 hybridization groups and 14 phenospecies
Phenotypic differentiated groups: *A. hydrophila*, *A. caviae*, and *A. sobria*
Clinical presentations: Traveler's diarrhea
Sources: Water, fish, shellfish, meats, dairy products, and fresh vegetables
Detection methods: Various culture media, for example, starch ampicillin agar (SAA) and BIBG

The genus *Aeromonas* was first proposed in 1936 for rod-shaped Enterobacteriaceae, which possessed a polar flagellum. Since then, there have been many taxonomic revisions, and currently, it forms the family Aeromonadaceae. They are Gram-negative, rod-shaped, facultative anaerobic, nonspore-forming bacteria, which are widely distributed in the soil and aquatic environments. Members of the genus are divided into three phenotypically differentiated groups: *Aeromonas hydrophila*, *Aeromonas caviae*, and *Aeromonas sobria*. Currently, the genus is composed of 17 DNA hybridization groups or genomospecies and 14 phenospecies.

The *Aeromonas* genus includes psychrophiles and mesophiles and is associated with various diseases of warm- and cold-blooded animals. They have been isolated from fish, shellfish, meats, dairy products, and fresh vegetables. However, only few foodborne outbreaks have been documented. Some studies have shown that some motile *Aeromonas* species are becoming food- and waterborne pathogens of increasing importance. They have been associated with several foodborne outbreaks and are progressively being isolated from patients with traveler's diarrhea.

A. hydrophilia is present in all freshwater environments and in brackish water. It has frequently been found in fish and shellfish and in market samples of red meats (beef, pork, and lamb) and poultry. The organism is able to grow slowly at 0 °C. It is presumed that given the ubiquity of the organisms, not all strains are pathogenic. Some strains of *A. hydrophila* are capable of causing illness in fish and amphibians as well as in humans who may acquire infections through open wounds or by ingestion of a sufficient number of the organisms in food or water. *A. hydrophila* may cause gastroenteritis in healthy individuals or septicemia in individuals with impaired immune systems or various malignancies. *A. caviae* and *A. sobria* also may cause enteritis in anyone or septicemia in immunocompromised persons or those with malignancies.

There is controversy as to whether *A. hydrophila* is a cause of human gastroenteritis. The uncertainty occurs because volunteer human feeding studies (10^{11} cell dose) have failed to demonstrate any associated human illness. However, its presence in the stools of individuals with diarrhea, in the absence of other known enteric pathogens, suggests that it has some role in disease and has been included in this survey of foodborne pathogens. Similarly, *A. caviae* and *A. sobria* are putative pathogens associated with diarrheal disease, but as of yet, they are unproved causative agents. General symptoms of *A. hydrophilia* gastroenteritis are diarrhea, abdominal pain, nausea, chills and headache, dysentery-like illness, and colitis. Additional symptoms may include septicemia, meningitis, endocarditis, and corneal ulcers.

Two types of gastroenteritis have been associated with *A. hydrophila*: a cholera-like illness with severe diarrhea and a dysenteric illness characterized by loose stools containing blood and mucus. The infectious dose of this organism is unknown. *A. hydrophila* may spread throughout the body in the bloodstream and cause a general infection in persons with impaired immune systems. Those at risk are individuals suffering from leukemia, carcinoma, and cirrhosis and those treated with immunosuppressive drugs or who are undergoing cancer chemotherapy.

A. hydrophila produces a cytotonic enterotoxin, hemolysin, acetyl transferase, and phospholipase. Together, these virulence factors may account for the organism's pathogenicity. The detection of genes responsible for *Aeromonas* virulence is a vital tool in establishing the potential pathogenicity of the bacteria, as these virulence genes may act alone or in synergy in the establishment of infections.

A number of selective and differential isolation media have been developed for the recovery of *Aeromonas* species from the environment, foods, and clinical specimens. Since comparative studies demonstrate that no single medium results in the optimal recovery of aeromonads, combinations of different isolation media and methods are used including direct plating, membrane filtration, and multiple tube tests for determining most probable numbers. SAA and bile salts–inositol–brilliant green (BIBG) agar with initial enrichment in alkaline peptone water (APW) or tryptose broth containing ampicillin (TSB-30, ampicillin 30 mg l^{-1}) are recommended simultaneously with commercially available media such as *Aeromonas* medium (Ryan's medium). Starch glutamate ampicillin penicillin (SGAP-10) medium has been used to detect aeromonads from foods. The isolation of aeromonads from contaminated samples such as feces requires the use of selective and differential media such as MacConkey agar, cefsulodin–irgasan–novobiocin (CIN) agar, and blood agar with ampicillin (10 mg l^{-1} ampicillin). To facilitate recovery of aeromonads from highly contaminated samples such as feces, enrichment broths such as APW are incubated overnight and subcultured onto CIN agar and blood agar with ampicillin. Culture plates are then incubated aerobically at 35 °C for 24–48 h. *Aeromonas* species produce distinctive colonies, with or without hemolysis on blood agar. Colonies are screened by carrying out oxidase test and identified using biochemical methods or commercially available bacterial identification kits.

Arcobacter Species

Description: *Arcobacter butzleri*, *A. cryaerophilus*, and *A. skirrowii* are the primary species of interest.
Clinical presentations: Persistent and watery diarrhea.
Sources: Contaminated drinking water and food.
Detection methods: mCCDA and CAT.

Campylobacter jejuni and *C. coli* are well recognized as the major causes of human gastroenteritis. Meanwhile, a number of other *Campylobacter* species and related organisms have also been recognized as causing animal if not human cases of gastroenteritis. These include *Campylobacter concisus* and *Arcobacter* species. While there are a relatively few reported cases of infection

due to *Arcobacter*, this is probably due in part to the lack of routine use of appropriate isolation media.

A number of reviews on *Arcobacter* spp. have demonstrated that the organism is a cause of human pathogen and is associated with food products. One of the first significant studies of *Arcobacter* started in 1995 in Belgium where the WHO Centre for *Campylobacter* specifically looked for non-*jejuni*/*Campylobacter coli*-like organisms (CLOs) in fecal samples. It is plausible that *A. butzleri* and *A. cryaerophilus*, which were first isolated from aborted bovine fetuses and later from porcine fetuses, will in the future be more fully recognized as of significant human importance. Currently, there is increasing awareness of their role as veterinary pathogens, but there are relatively few human cases.

The *Arcobacter* genus was formerly known as aerotolerant campylobacters and CLOs. But improved methods of taxonomic evaluation have led to the recognition of the genus *Arcobacter*. There are currently 17 recognized *Arcobacter* species, and these have been isolated from various sources. Of particular interest are *A. butzleri*, *A. cryaerophilus*, and *A. skirrowii*, as these have been associated with human cases of diarrhea, the probable transmission routes being through the ingestion of contaminated drinking water and food. These three species are also veterinary pathogens causing porcine abortions. *A. butzleri* serotypes 1 and 5 are regarded as the primary human pathogens; however, no epidemiological studies have yet shown the transmission of the organism through the food chain to humans. The situation is, however, reminiscent of *C. jejuni* and *L. monocytogenes*. These organisms were recognized as veterinary pathogens many years before the medical microbiologists used suitable isolation media to samples from patients suffering from gastroenteritis. *Arcobacter* species have been isolated from a range of food sources (**Table 2**) using a range of methods, some of which may favor certain species more than others. Water may also be a vector of *Arcobacter* transmission to animals and humans.

In general, *Arcobacter* spp. are more aerotolerant and have lower growth temperature limit than *Campylobacter* spp. On blood-based agars, *Arcobacter* spp. produce round, off-white or grayish colonies, 2–4 mm in diameter after 3 days of incubation. The colonies are generally small, nonpigmented, and convex with entire edges. Swarming has been reported on fresh agar. Brain Heart Infusion Agar supplemented with 0.6% (w/v) yeast extract and 10% (w/v) blood agar has been used recently for routine culturing.

Table 2 Incidence of *Arcobacter* in animals and animal products

Source	*%*	*n*	*Site*
Pigs	0–89.9	299[a]	Ground pork
	7	100	Pork
Cows	1.5	68	Minced beef
	2.2	90	Beef
Poultry	96.8	125	Chicken carcasses
	24.1	220	Turkey meat
Ducks	50	10	Carcasses
	52	170	Carcasses
Water	100	10(4)[b]	

[a]Only tested for *A. butzleri*.

[b]All samples were positive using FISH, whereas *Arcobacter* was only isolated from four samples.

Adapted from Forsythe, S. J. (2006). *Arcobacter*. In: Motarjemi, Y. and Adams, M. (eds.), *Emerging foodborne pathogens*. Cambridge: Woodhead Publishing, references therein.

Arcobacter isolates can be presumptively identified by their shape (small comma-shaped or spiral rods) and motility (darting or corkscrew motility). They can be easily distinguished from *Campylobacter* and related genera by their ability to grow in air at 25 °C. The main phenotypic traits used for *Arcobacter* species differentiation are catalase activity, nitrate reduction, cadmium chloride susceptibility, microaerophilic growth at 20 °C, and growth on MacConkey agar and in the presence of 3.5% NaCl and 1% glycine. Organic acids and amino acids are used as carbon sources. Hydrogen is not required for growth. All *Arcobacter* isolates hydrolyze indoxyl acetate. A simple diagnostic characteristic useful for the presumptive identification of *Campylobacter jejuni*, *C. coli*, and *Arcobacter* spp. is the cadmium chloride test.

Arcobacters appear resistant to antimicrobial agents typically used in the treatment of diarrheal illness caused by *Campylobacter* spp., for example, erythromycin, other macrolide antibiotics, tetracycline, and chloramphenicol. Isolation of arcobacters requires selective media such as mCCDA and CAT. Identification can subsequently be achieved using 16S rRNA probes and genotyped.

The occurrence of arcobacter-related diseases may be underestimated due to the lack of surveillance and optimized detection procedures. Examination of human and veterinary clinical specimens for the presence of *Arcobacter* species is rarely performed, and in most cases, suboptimal procedures are used. In addition, little is known about the risk factors for human infection. The most extensive study to date on this matter was undertaken on a total of 67 599 stool samples over an 8-year period. *A. butzleri* was the fourth most common CLO isolated. It was more frequently associated with symptoms of a persistent and watery diarrhea than *C. jejuni*.

The isolation of *A. butzleri* was associated with cases of persistent and watery diarrhea and less associated with bloody diarrhea compared to *C. jejuni*. The pathogenicity and virulence mechanisms of *Arcobacter* spp. are still poorly understood and have only been studied in *A. butzleri*, *A. cryaerophilus*, *A. skirrowii*, and *A. cibarius*. Analysis of the *A. butzleri* strain RM 4018 genome shows the presence of several putative virulence genes in the organism, such as *ciaB*, *cj1349*, and *cadF*. These are homologous to genes associated with pathogenicity in other closely related organisms. The *ciaB* gene encodes an invasion protein injected directly into the cytoplasm of the host cells through a secretion system. The *cj1349* gene encodes for proteins that enable adhesion to host cells by binding specifically to fibronectin, and the CadF protein also induces the internalization of bacterial cells by the activation of GTPases.

Campylobacter concisus

Description: *Campylobacter concisus*, a fastidious *Campylobacter* species

Clinical presentations: Isolated from healthy and diarrheal individuals

Sources: Contaminated food and water

Detection method: No specific method available to date

Despite considerable efforts in surveillance and improvements in isolation methods, only about half of the reported intestinal infectious cases are attributable to a named organism. While a large number of cases are related to *C. jejuni* and *C. coli* infections, there is evidence that other *Campylobacter* species may also be causative agents. Epidemiological evidence is poor, but it is reasonable to assume that more fastidious *Campylobacter* species, such as *C. concisus*, will not be recovered as efficiently as the better understood *C. jejuni*. In common with other campylobacters, *C. concisus* is a Gram-negative, curved, microaerophilic bacterium. It can be isolated from the human oral cavity and fecal samples from healthy and diarrheic patients. As a consequence, its primary pathogenic potential is uncertain. In many diarrheal cases, *C. concisus* is isolated as the only potential intestinal pathogen, and hence, the need to determine its role in human enteric disease is evident.

Studies to date suggest *C. concisus* is composed of various genotypes, which may vary in their pathogenic potential. However, considerable further work is needed to determine the risk of *C. concisus* to human health and vehicles of infection. Given the habitat of the organism as being in the intestinal tract of healthy individuals, it is plausible that contaminated food and water could be the sources of infection. The organism has been included here to raise awareness of this emerging pathogen and its possible contribution to foodborne infections.

Cronobacter spp., Formerly *Enterobacter sakazakii*

Description: *Cronobacter* genus. Seven recognized species proposed: *C. condimenti*, *C. dublinensis*, *C. malonaticus*, *C. muytjensii*, *C. sakazakii*, *C. turicensis* and *C. universalis*. Gram-negative, frequently motile, facultative aerobic rods; members of the Enterobacteriaceae.

Clinical presentations: Infections in all age groups, particularly neonates, infants <6 months of age, and the elderly. Life-threatening symptoms in neonates and infants <6 months of age include meningitis, necrotizing enterocolitis, and respiratory infections.

Sources: Infections in neonates associated with contaminated reconstituted powdered infant formula (PIF). Ubiquitous in nature, particularly plant material. Human carriage.

Detection methods: Cultivation on chromogenic agar, followed by sequencing of *fusA* or *rpoB* gene for phylogenetic analysis.

Cronobacter is possibly the archetypal recently recognized bacterial pathogen, which has been associated with foodborne infection, albeit via one particular food source: PIF. The considerable progress in better understanding and control of this organism is undoubtedly due to policy issues. Using seven-loci multilocus sequence analysis, the close relatedness of the *Cronobacter* species is shown in Figure 1. According to phylogenetic analysis, these major divisions formed about 41 million years ago, and further, host adaptation has occurred as will be considered later with the specific case of *C. sakazakii* sequence type 4.

Short timeline: Pre-2002, various outbreaks in neonatal intensive care units and sporadic cases reported.

2002 Outbreak at the University of Tennessee investigated by CDC and FDA. Fatal case linked to the use of powdered formula
FDA *Cronobacter* (and then *E. sakazakii*) detection method; Bacteriological Analytical Manual

2004 1st FAO–WHO risk assessment meeting on microbiological safety of PIF
Development of first chromogenic differential agar

2006 2nd FAO–WHO risk assessment meeting
ISO/TS 22964 method released

2008 3rd FAO–WHO risk assessment meeting
Revised Codex Alimentarius Commission guidelines for microbiological specifications for PIF released, to include *Cronobacter* as a named pathogen
Cronobacter genus defined, composed of 5 species

2009 Open-access seven-loci multilocus sequence typing (MLST) scheme established to replace ambiguous 16S rDNA analysis; www.pubMLST.org/cronobacter

2010 First whole sequence for *C. sakazakii* published; isolate from the University of Tennessee outbreak

2011 *C. sakazakii* sequence type 4 (clonal lineage) association with neonatal meningitis determined
C. condimenti and *C. universalis* recognized

2012 First pan-genome analysis of *Cronobacter* genus based on 14 genomes
Revised FDA method of detection; Bacteriological Analytical Manual

2013 www.pubMLST.org/cronobacter expanded to include the following:
(a) Tax-MLST established, extension of MLST to include genotyping of *ompA* and *rpoB*
(b) *Cronobacter* BIGSdb searchable repository for all published *Cronobacter* sp. genomes established

Before 1980, yellow-pigmented *Enterobacter cloacae*-like strains were called *Enterobacter sakazakii*. Despite earlier sporadic cases of neonatal and infant infections, the organism was highlighted following an outbreak in a university hospital in Tennessee (the United States). One neonate died from meningitis, two died from suspected infections (tracheal aspirate-positive), and seven were colonized (six fecal-positive and one urine-positive) with the same strain according to pulsed-field gel electrophoresis (PFCE) profiling. The source was attributed to powdered formula. Since such neonates only have a limited number of exposure routes, the FAO–WHO instigated three risk assessments that have directly contributed to the 2008 Codex Alimentarius Commission revisions in the microbiological specifications of PIF. Prior to this, the number of Enterobacteriaceae (except for *Salmonella*) permitted in PIF was <100 cfu g^{-1}. These specifications had not been revised since 1979. However, following the concern of the serious implications following *Cronobacter* infections of neonates, the microbiological criteria changed such that *Cronobacter* should not be detectable in 10 g test volume quantities of PIF.

In order to implement the specifications, improved understanding of the organism and development of detection methods are needed. The focussed attention showed *Enterobacter sakazakii* should be regarded as a separate genus and was

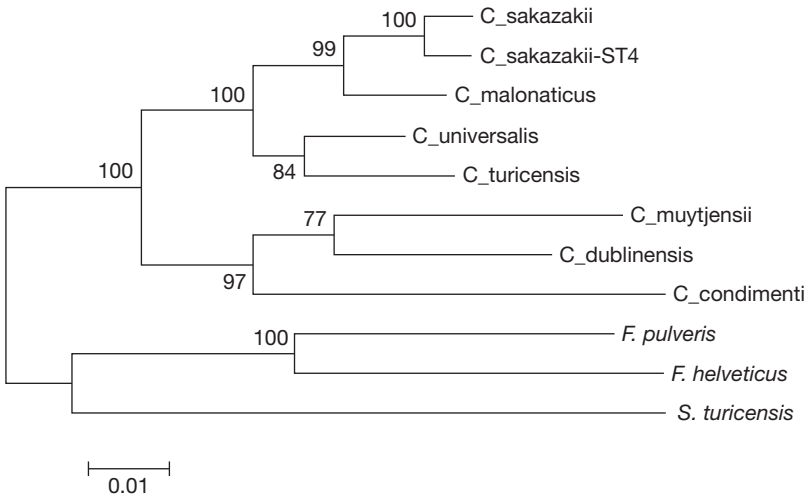

Figure 1 Maximum likelihood tree of the seven-loci multilocus sequence typing (3036 base pair concatenated length) for the members of Cronobacter, Franconibacter, and Siccibacter genus, showing the sequence type for each species type strain and the neonatal meningitis-associated sequence type 4. The tree was drawn using MEGA5.2 (http://www.megasoftware.net) with 1000 bootstrap replicates. Adapted from Holy, O. and Forsythe, S. J. (2014). named *Cronobacter*; in 2013, there were seven recognized species. Only four of which are associated with human infections: *C. sakazakii*, *C. malonaticus*, *C. turicensis*, and *C. universalis*. It is highly probable that the number of infections has probably been unreported due to misidentification. The species can be grouped, with the mostly clinically relevant being group 1 (*C. sakazakii* and *C. malonaticus*, which form the majority of clinical isolates in all age groups) and group 2 (*C. turicensis* and *C. universalis*, which have been less frequently reported). The other species are primarily environmental commensals and are probably of little clinical significance. Table 3 shows an age profile of *Cronobacter* isolated using throat swabs from over 45 000 outpatients during the period 2005–2011. The organism was isolated from every age group, with a higher frequency from children < 14 years of age.

In 2011, Joseph and Forsythe announced the strong association between neonatal meningitis cases and the clonal lineage of *C. sakazakii* ST4. This was established using retrospective study of 41 clinical strains from 1953 to 2008, collected from seven countries. This association was confirmed later in the year by the analysis of a number of highly publicized cases in the United States. The reason for the association of one sequence type out of >200 STs in the genus is unclear as no particular virulence traits have been determined in *C. sakazakii* ST4. However, it is known that this sequence type is frequently (~24% of strains) isolated from the infant formula and milk powder manufacturing plants in Australia, Germany, Switzerland, and Ireland and therefore may represent a particularly persistent clonal variant, resulting in increased neonatal exposure.

Cronobacter can invade human intestinal cells, replicate in macrophages, and invade the blood–brain barrier. The route of infection is probably through attachment and invasion of the intestinal cells. Whole genome sequencing has revealed a large

number of plausible virulence factors, though many require further laboratory studies for confirmation. These are summarized in the succeeding text, and further details can be obtained from the original publications. Due to the increasing number of *Cronobacter* genomes being sequenced, for up-to-date information, the reader should consult the *Cronobacter* BIGSdb, which is a searchable (BLAST) repository of all published *Cronobacter* genomes (see 'Relevant Websites').

A number of fimbria clusters have been identified in the genomes of *Cronobacter* species. Many fimbria clusters are common to all species, though there are two interesting exceptions. *C. sakazakii* is the only *Cronobacter* species encoding for β-fimbriae, whereas the genomes of the other species encode for curli fimbriae. This may reflect evolution to the host ecosystem. A number of iron assimilation mechanisms have been found in *Cronobacter* species, which might enable the organism to utilize iron from breast milk and infant formula. Five putative type VI secretion system clusters have been identified *Cronobacter* sp. genomes. These may be involved in adherence, cytotoxicity, host-cell invasion, growth inside macrophages, and survival within the host. It has been proposed that the outer membrane proteins ompA and ompX have roles in *Cronobacter* penetrating the blood–brain barrier. The mechanism (s) leading to the destruction of the brain cells is unknown and could in part be a host response. The organism also encodes for a number of hemolysins.

C. sakazakii is unique in the *Cronobacter* genus in its utilization of exogenous sialic acid, and this may have clinical significance. The ability to utilize sialic acid could be a major evolutionary host adaptation since the compound is found in breast milk, mucin, and gangliosides. Sialic acid is also an ingredient in PIF due to its association with brain development. *C. sakazakii* is also able to grow on the ganglioside GM1 as a sole carbon source. Levels of endotoxin due to the presence of heat-stable lipopolysaccharide (LPS) have been measured in infant formula. In rat pups, LPS enhances the translocation of *Cronobacter* across both the intestines and the blood–brain barrier and therefore indicates that its presence in infant formula could increase the risk of bacteremia in neonates. It has been speculated that frequent LPS contamination of PIF (known to disrupt tight junctions) might contribute to the invasiveness of *Cronobacter* across the blood–brain barrier. The organism also has a number of heavy metal resistance factors and biofilm formation, which might enable it to resist disinfectants in food production environments.

Due to the high profile and changes in microbiological specifications for PIF for target age <6 months, a number of isolation and identification methods were developed post-2002.

Isolation of the organism from PIF largely resembles that for *Salmonella*, with the use of stages for preenrichment, enrichment, presumptive isolation, and confirmatory tests. It should be noted that the FDA and ISO methods for the detection of *Cronobacter* are not up to date with respect to the taxonomy of the genus and not all species will necessarily be recovered by these techniques. In fact, a well-known phenotyping kit manufacturer still retains the name *Enterobacter sakazakii* instead of *Cronobacter* spp. in its online database. In addition, *E. helveticus*, *E. pulveris*, and *E. turicensis* have been used as negative control cultures as they were regarded as close relatives. In 2013, they were reclassified as Cronobacter and therefore should have been positively detected, however in 2014 there were removed from the genus and formed the new genera Franconibacter and Siccibacter (Figure 1).

It should be noted that the emphasis of controlling *Cronobacter* spp. in PIF has given the false impression that this is the only route of infection. In fact, the *C. malonaticus* type strain was isolated from breast abscess, there is human carriage and the organism is recovered from a wide range of foods (Table 4), and the organism has been isolated from the nasogastric feeding tubes of neonates not receiving reconstituted infant formula.

Enteroaggregative *Escherichia coli*

Description: The enteroaggregative *Escherichia coli* (EAEC) are a pathotype within the *E. coli* species. Gram-negative, facultative rods. The genus is a member of the Enterobacteriaceae family.

Source: Contaminated food.

Clinical presentations: Watery diarrhea with or without blood and mucus, abdominal pain, nausea, vomiting, and low-grade fever can be persistent.

Detection methods: No specific isolation procedures are available.

Table 4 Survey of dry food products and food ingredients from which Cronobacter spp. have been isolated

Adapted from Forsythe, S. J., Dickins, B., and Jolley, K. A. (2014). Cronobacter, the emergent bacterial pathogen Enterobacter sakazakii comes of age; MLST and whole genome sequence analysis. *BMC Genomics* **15**, 1121 and references therein.

The well-known gastrointestinal bacterium *Escherichia coli* includes a number of pathotypes defined according to their clinical presentation or adherence pattern on Hep-2 cell line. EAEC self-aggregate and form a biofilm on intestinal mucosa cells (Hep-2 cell line) with a 'stacked-brick' adherence phenotype. The first EAEC infection case was described in 1987 in a child with acute diarrhea in Lima, Peru. These days, EAEC is estimated to be the second most common cause of traveler's diarrhea. Unconfirmed reports have linked EAEC with the development of irritable bowel syndrome. EAEC is a heterogeneous cluster of *E. coli* strains, which is an important cause worldwide of acute or persistent diarrhea in children and adults. The reason for its inclusion in this article is that since the late 1990s, EAEC has received increasing attention as a cause of acute, often persistent, and watery diarrhea and malnutrition in children and HIV-infected persons living in developed countries.

EAEC outbreaks have been described in children and adults in the United Kingdom and France. The carriage of the organism by children <5 years of age was higher in those with a history of diarrhea. Similarly in Brazil, EAEC was found to be more frequently associated with diarrhea in children <2 years of age. There has been an increasing rise in the proportion of childhood diarrheal cases in which EAEC are implicated, and this indicates that EAEC are important emerging agents of pediatric diarrhea. It is believed that EAEC not only may be causing acute and persistent diarrheal disease but also may be persisting in the human intestine subclinically, inducing chronic inflammation in the absence of dysentery. This persistent infection could result in chronic disruption of gut function resulting in malnutrition and restricted childhood development.

EAEC route of transmission can be through contaminated food. In Italy, two consecutive EAEC outbreaks (affecting 24 individuals) were linked to contaminated unpasteurized cheese. A study of Mexican tabletop sauces identified 44% of sauces from Guadalajara (Mexico) contained viable EAEC cells, compared to 0% of sauces in restaurants in Houston (the United States). In the largest reported outbreak so far, 2697 (40.6%) Japanese children who consumed infected school lunches had severe diarrhea, and EAEC was found in 10% of cases. Serotyping of EAEC is not applicable in the diagnosis of diarrheagenic *E. coli* infections. In the United Kingdom, 97 EAEC strains were serotyped to 40 different O types, and in another study, 93 out of 143 EAEC strains could be serotyped to 47 different serotypes. Finally, many of the EAEC strains autoagglutinate and so are described as nontypable or O rough.

EAEC pathogenesis involves three stages: (1) adherence to the intestinal mucosa by aggregative adherence fimbriae and adherence factors, (2) increased production of mucus that enhances EAEC adherence to the surface of enterocytes, and (3) the release of toxins and elicitation of an inflammatory response, mucosal toxicity, and intestinal secretion. The best-studied virulence factor is *AggR*. This is a transcription activator carried on pAA, a large 60 MDa plasmid. *AggR* controls the expression of fimbriae (adherence factors), a dispersin protein, and at least two pathogenicity islands on the EAEC chromosome. Dispersin is an antigenic antiaggregative protein, which is encoded by the *aap* gene in the pAA plasmid. It is regulated by *aggR*, modulates fimbrial adhesion, and facilitates penetration of the microorganism through intestinal mucus by binding to LPS and altering the electrostatic properties of the EAEC outer membrane surface. Although several other virulence factors are detectable using PCR probes, none exhibit 100% specificity to EAEC strains. Other putative virulence factors include a yersiniabactin system, a complex carbohydrate-specific lectin, enterotoxins, and cytotoxins. The large *E. coli* O104 outbreak in 2011 was due to a hybrid EAEC.

Escherichia albertii

Description: *Escherichia albertii*, species closely related to *E. coli*. Gram-negative, facultative nonmotile rods. The genus is a member of the Enterobacteriaceae family.
Sources: Human feces, birds, animals, and environment.
Clinical presentation: Diarrhea.
Detection methods: No specific isolation procedures are available. May originally be identified by routine diagnostic protocols as enteropathogenic *E. coli* (EPEC) or enterohemorrhagic *E. coli* (EHEC).

Little is known about the host or geographic distribution of *E. albertii;* however, it is carried by ~1% of wild birds and is associated with mass mortality events among birds in the Northern Hemisphere and the cause of mortality in captive birds and poultry. The author does not know of any confirmed cases of foodborne infections due to this organism or even isolation from food. Nevertheless, the organism has been tentatively included in this article as an emerging enteric foodborne pathogen based on its association with poultry and misidentification with EPEC and EHEC in order to raise awareness.

The recognition of *Escherichia albertii* as an emerging human enteric pathogen typifies the value in reevaluating previous identification schemes and anomalies. The organism has previously been misidentified as eae-positive *Hafnia alvei*, as well as strains of eae-positive *E. coli*, *E. coli* serotype O86, EPEC, and EHEC.

In 1991, clinical isolates of *H. alvei* were found to differ from representative *H. alvei* strains by phenotypic and genotypic assays. This variation included the carriage of an intimin gene homologous to the *eae* gene encoding for the attaching-effacing phenotype of EPEC. Following the use of 16S rDNA sequence analysis and DNA–DNA hybridization, the new *Escherichia* species, *Escherichia albertii*, was proposed for the previously *eae*-positive *H. alvei* strains. In addition to the possession of intimin, *E. albertii* also produces a cytolethal distending toxin. Using MLST and virulence gene sequences (*eae* and *cdt*), it is proposed that the *E. albertii* lineage includes *Shigella boydii* (serotype 13) and other previously nontypable clinical isolates. This lineage shared a common ancestor with *E. coli* and *Shigella* pathogenic groups ~28 million years ago (mya), and also the *E. albertii* lineage was established before the radiation of pathogenic *E. coli* and *Shigella*. In essence, *E. albertii* is not a newly emerged pathogenic variant of *E. coli–Shigella*, but a previously unrecognized pathogen, which was confused with other more familiar, closely related organisms.

E. albertii strains are nonmotile, fermented D-glucose (with gas), D-mannitol, and D-mannose, but does not ferment lactose

or other sugars. All strains are positive for the *eaeA* gene, but the presence of other virulence-related genes is variable, namely, *cdtB*, *phoE*, *ehxA*, and *stx2f*. Therefore, there is variability within this lineage, which may cause confusion and hinder accurately identifying *E. albertii* from other members of the *Escherichia* genus. Although the number of accurately recorded outbreaks due to *E. albertii* is uncertain, it is plausible that some outbreaks have been misattributed to *E. coli* as shown in the reassessment of a food poisoning outbreak of gastroenteritis.

Plesiomonas shigelloides

Description: *Plesiomonas shigelloides* is the only recognized species in the genus *Plesiomonas*. Gram-negative, facultative aerobic rods; oxidase-positive. The genus is a member of the Enterobacteriaceae family.
Clinical presentations: Three forms of gastroenteritis, (i) a secretory, watery type; (ii) an invasive, dysentery-like type; and (iii) a subacute or chronic form, lasting between 2 weeks and 3 months.
Sources: Freshwater and estuarine water. Wide range of hosts: amphibians, birds, fish, and animals.
Detection methods: No specific isolation procedures are available.

P. shigelloides is the only species in the genus *Plesiomonas* and is the only oxidase-positive member of the Enterobacteriaceae family. It is recognized as an emerging water- and foodborne enteric pathogen and a major cause of traveler's diarrhea in China and Japan. The organism can cause three types of gastroenteritis: (i) a secretory, watery type; (ii) an invasive, dysentery-like type; and (iii) a subacute or chronic form lasting between 2 weeks and 3 months. There are additional reports of extraintestinal infections: meningitis in neonates, bacteremia, sepsis, and septic shock with high fatality rates. The natural environment for the organism is freshwater and estuarine water. It is also found in amphibians, birds, fish, and animals. Outbreaks are generally related to the consumption of contaminated seafood (crabs, oysters, and fish) or untreated water.

The pathogenicity of *P. shigelloides* is poorly understood, although there are reports of secreted toxins *in vitro*: cholera-like toxin, thermostable and thermolabile toxins, β-hemolysins, and cytotoxin complex. The somatic antigen of *P. shigelloides* may also play a role in pathogenicity, since the gene encoding the most common type, O17, shares almost complete identity with the smooth antigen gene of *Shigella sonnei*. An acute foodborne outbreak in Cameroon was postulated to be due to a preformed toxin in the food, due to the short incubation period.

There is no specific medium for the direct isolation of *P. shigelloides*. In general Enterobacteriaceae media, the organism produces nonlactose-, nonsucrose-fermenting colonies. The organism does not grow on thiosulfate–citrate–bile salts–sucrose medium, but does grow on CIN medium (normally used to isolate *Yersinia* and *Aeromonas* species), producing opaque colonies without a pink center indicating that mannitol is not fermented. It has a minimum growth temperature of 8 °C.

Providencia alcalifaciens

Description: Gram-negative rods. The genus is a member of the Enterobacteriaceae family.
Clinical presentation: Traveler's diarrhea.
Sources: Contaminated food and water.
Detection method: A selective medium has been formulated but possibly not evaluated.

Providencia alcalifaciens is primarily recognized as possible cause of traveler's diarrhea in developing countries. But in 1996, there was a large outbreak of foodborne infection causing acute gastroenteritis, involving 290 patients, in Fukui, Japan. No previously recognized enteropathogens were detected in the fecal samples of the patients. However, PFGE-indistinguishable *P. alcalifaciens* strains were recovered from 7 of 18 samples. Additionally, a specific antibody against the isolated strain was found to be elevated in the patients' sera. *In vitro* virulence studies of the strains using the Caco-2 cell line showed strains could invade human intestinal cells and fluid accumulation in rabbit ileal loop experiments. Together, these results indicate that *P. alcalifaciens* was probably the causative agent of the outbreak.

A selective medium for the recovery of the organism from feces has been published. But to the author's knowledge, no large-scale trials of method evaluations have been undertaken.

Shigella sonnei

Description: Gram-negative facultative aerobic rods. The *Shigella* genus is a member of the Enterobacteriaceae family.
Clinical presentations: Dysentery, fever, and stomach cramps.
Sources: Water and food contaminated with feces and flies.
Detection methods: No specific isolation procedures are available.

Shigella spp. can be regarded as pathotypes of *Escherichia coli* with the ability to invade the human gut mucosa and cause dysentery. Infection is due to the ingestion of the organism via fecally contaminated food or water and can be due to poor personal hygiene by food handlers. *S. sonnei* is well known as a primary cause of dysentery in developed countries and is now emerging as a problem in the developing world. It is replacing the more diverse *Shigella* species *S. flexneri* in areas that are undergoing economic development and improvements in water quality.

Whole genome sequence analysis shows that the current *S. sonnei* population descends from the most recent common ancestor <500 years ago. Evidence to date indicates the species primarily diversified in Europe into four distinct lineages with unique characteristics. This was followed by the spread and establishment of a single, rapidly evolving, multidrug-resistant lineage into Asia, Africa, and America, termed 'pandemic lineage III.' This lineage is now a dominant cause of dysentery in many endemic areas of the world.

The emergence of *S. sonnei* has been attributed to the acquisition of virulence plasmid pINV B, encoding the *Plesiomonas shigelloides*-related O antigen. This has been difficult to confirm since the plasmid is easily lost during laboratory subculturing prior to analysis. Similarly, it has been proposed that previous exposure to *P. shigelloides* (via contaminated water) may offer some protection from *S. sonnei* infection since the O antigens are indistinguishable and cross-react. This could account for the increased incidence in *S. sonnei* infections following improvements in water quality due to the reduced passive cross protection by exposure to *P. shigelloides*.

Ones to Watch

Antibiotic Resistance of Recognized Foodborne Bacterial Pathogens

A detailed consideration of antibiotic resistance and their widespread use in human and veterinary medicine, agriculture, and aquaculture animal husbandry and veterinary usage are outside the scope of this article. Nevertheless, antibiotic-resistant enteric foodborne pathogens are an emerging public risk. Antimicrobial resistance has been described in well-known pathogens, some of which are foodborne: *Salmonella*, *Campylobacter*, *Shigella*, and *Vibrio* spp., methicillin-resistant *Staphylococcus aureus*, *E. coli*, and enterococci. The resistance of animal- and food-associated bacteria to antimicrobial agents has been repeatedly reported. Bacterial resistance inevitably develops to each new class of antibiotics. A variety of different antimicrobial resistance phenotypes result from the acquisition of external genes that can provide resistance to an entire class of antimicrobials. These genes are frequently associated with large transferable extrachromosomal DNA elements, plasmids, on which there may be other mobile DNA elements such as transposons and integrons.

Plasmids in the incompatibility group IncA/C are of considerable interest with respect to multiple antibiotic resistance in enteric pathogens of humans and animals. Although these large, low-copy number plasmids have been known for over 40 years, they appear to be of increasing relevance in the spread of antibiotic resistance. The plasmids have at least three hotspots for the integration of mobile genetic elements. They were first identified from multidrug-resistant *Aeromonas hydrophila* and *Vibrio* spp. in cultured fish. This coincided with the use of antibiotics for cultured fish. A survey of clinical isolates of *Salmonella* newport from 1940 to 2000 revealed that IncA/C plasmids and their multiresistance phenotype emerged after 1980, the reservoir being environmental bacteria, followed by the acquisition of antibiotic gene modules according to antibiotic exposure. IncA/C plasmids which have acquired the bla_{NDM-1} gene encoding the New Dehli metallo-β-lactamase have been disseminated in clinical *E. coli* and *K. pneumoniae*.

Another issue with increasing antibiotic resistance is the coresistance to microbiocides, such as triclosan and quaternary compounds. It has been reported that exposure of *Salmonella enterica* and *Escherichia coli* O157 to sublethal concentrations of antibacterial agents contributed to their development of adaptive resistance to both biocides and antibiotics. Benzalkonium chloride-resistant *Salmonella enterica* serovar Virchow showed elevated resistance to chlorhexidine. *E. coli* O157 acquired high levels of resistance to triclosan after only two sublethal exposures and, when adapted, repeatedly demonstrated decreased susceptibilities to various antimicrobial agents, including chloramphenicol, erythromycin, imipenem, tetracycline, and trimethoprim. However, the specific mechanisms of such coresistance remain poorly understood.

Revelations from Whole Genome Sequencing

Clinical and food microbiology is moving from being culture-dependent to culture-independent. This gives the promise of earlier recognition of attributable organisms. In order to achieve this, there needs to be (a) accessibility to centralized information and (b) consistent interpretation of the DNA sequence. From mid-2013, the FDA has started to sequence 100 000 foodborne pathogens, with 30 completed in December 2013. The genome sequence data will have open access and are being deposited in the National Center for Biotechnology Information and hence shared with other countries for international surveillance.

The major advantages of culture-independent testing are that it is usually faster than culture-based methods and can simultaneously provide subtyping information as required for epidemiological studies and accessible for further analysis. MLST can be predicted from the genome sequence and is not limited to the conventional seven loci. BIGSdb has been implemented for a number of bacterial pathogens such as *Campylobacter jejuni* and *Cronobacter* spp. A number of retrospective foodborne outbreaks have been studied using NGS although as yet few in real time (Table 5).

Conclusions and Future Studies

Compared to clinical infectious diseases, the number of currently recognized foodborne pathogens seems small. In part, this is due to general procedures of food production, which over the centuries have been refined and self-proved effective means of food preparation, for example, cooking, acidification, and dehydration. However, with changes in sourcing of food ingredients, large-scale food preparation practices, longer storage, and changes in eating habits have ensured a continued of food-related illnesses. The major organisms associated with foodborne disease are bacteria due to the ease of isolation and identification compared to viruses and fungi. However, with improved global surveillance systems, as well as improved isolation and identification methods, previously unrecognized

Table 5 Foodborne outbreaks investigated using whole genome sequencing, genomic epidemiology

Organism	*Source*	*Size of outbreak*	*Comment*	*References*
Salmonella Typhimurium	Seven egg farms	193 cases	Retrospective	Hawkey et al.

L. monocytogenes 1/2a	Ready-to-eat meat products	22 deaths and at least 57 illnesses	Retrospective	Gilmour et al.

foodborne infectious organisms are being recognized. With a global economy and transportation of food, the need to continue to attribute human infections to food vehicles is warranted for their control. This article considers a range of viral and bacterial enteric pathogens, which may be foodborne. Some like *Cronobacter* are currently associated with one food product, reconstituted infant formula, and was previously unrecognized as a bacterial genus, whereas others such as *Shigella* are far better understood. Some recently recognized enteric pathogens are due to increased awareness (such as *Cronobacter*); others are adaptations of existing pathogens. Selective pressures due to the use of antibiotics will drive further changes in the microbiota, which may have severe consequences yet in the future. Being able to predict the future emergence of foodborne enteric pathogens is not possible at this time because of their diversity in virulence and pathogenicity properties, their ability to adapt, the diversity of foods, and the variation in susceptibility to infection by the human population. The best available approach to recognizing the emergence of a foodborne enteric pathogen emergence is through improved surveillance schemes leading to prompt, informed, and appropriate level of control. In part, this will be met by the expansion of genomic epidemiology whereby cases and outbreaks are investigated using whole genome sequencing.

The recognition, control, and monitoring of potential enteric pathogens require a reliable and robust detection system. It is probable that as newly described enteric pathogen is studied, then its description and taxonomy are likely to change as hitherto, it was poorly described and any strains in culture collections could be the more easily recovered variants and only a subpopulation of the taxonomic unit.

It is clear that the major challenge ahead is to establish effective communication between public health, veterinary, and food safety experts, which will bring together multidisciplinary skills and multipathogen expertise. Such collaboration is essential to monitor changing trends in foodborne infections, in order to detect emerging pathogens and to predict their risk to human health such that appropriate control measures can be implemented.

Emulsifiers: Types and Uses

R Miller, Kansas State University, Manhattan, KS, USA

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Surfactants, also called surface-active agents, are molecules that migrate to the interface between two phases (solid, liquid, or gas). The three most common two-phase systems in food products are emulsions, foams, and dispersions (Table 1). Emulsions are composed of two immiscible liquids. One liquid is dispersed within the other as individual droplets and is called the discontinuous phase, while the other liquid surrounds the droplets and is called the continuous phase. The emulsion behaves like the continuous phase. The typical food emulsions are oil-in-water (o/w), which consists of discontinuous droplets of oil dispersed in a continuous water matrix, and water-in-oil (w/o), which is composed of discontinuous droplets of water dispersed in a continuous oil matrix. When describing emulsions, the 'oil' component may be actual oil or some other ingredient that is not soluble in water. Examples of o/w emulsions are homogenized milk and ice cream, while common w/o emulsions include margarine, salad dressing, and mayonnaise. Emulsions can be formed mechanically by shaking or stirring; however, they are not stable for long periods of time and will separate into the two separate components relatively quickly. Emulsifiers are a type of surfactant that is used to stabilize emulsions.

Types of Emulsifiers

There are many types of emulsifiers. They are classified according to (1) charge in aqueous systems, (2) solubility, (3) hydrophilic/lipophilic balance (HLB), and (4) functional groups that compose them.

Table 1 Interfaces in food systems

Food system	*Continuous phase*	*Discontinuous phase*
Emulsion	Liquid	Liquid
Foam	Liquid	Gas
Dispersion	Liquid	Solid

Charge in Aqueous Systems

There are four classifications of emulsifiers based on the charge of the hydrophilic group when it solubilizes in water. They may be anionic, cationic, nonionic, or amphoteric. Anionic emulsifiers form negatively charged ions. They are effective in the neutral to alkaline pH range and are also sensitive to ionic strength and so do not function well in high salt-containing systems. The salt shields the negative charges so the anionic emulsifiers become ineffective and the emulsion breaks down rapidly. Sodium stearoyl-2-lactylate (SSL) is an example of an anionic emulsifier. Cationic emulsifiers form positively charged ions in water and are functional in the acidic pH range. They are somewhat toxic and so are not used as food additives. Nonionic emulsifiers have no net charge and form no ions. They are highly effective and are compatible with all other types of emulsifiers. They are relatively insensitive to pH and salt concentrations. Mono- and diglycerides (MDGs) are nonionic. Amphoteric emulsifiers form both positively and negatively charged ions when dissolved in water. They are not affected by pH values except some are not effective near the isoelectric point (pH at which protein is uncharged). Lecithin is an amphoteric emulsifier.

Solubility

The solubility of an emulsifier governs the type of emulsion that will be formed. The phase in which the emulsifier is least soluble becomes the continuous phase. A key attribute of emulsifiers is that they are amphiphilic. This means one end of the molecule is lipophilic and the other end is hydrophilic (Figure 1(a)). The lipophilic end, referred to as the tail, is usually a long-chain fatty acid taken from a food grade fat or oil. It is not soluble in water but is soluble in oil and is called

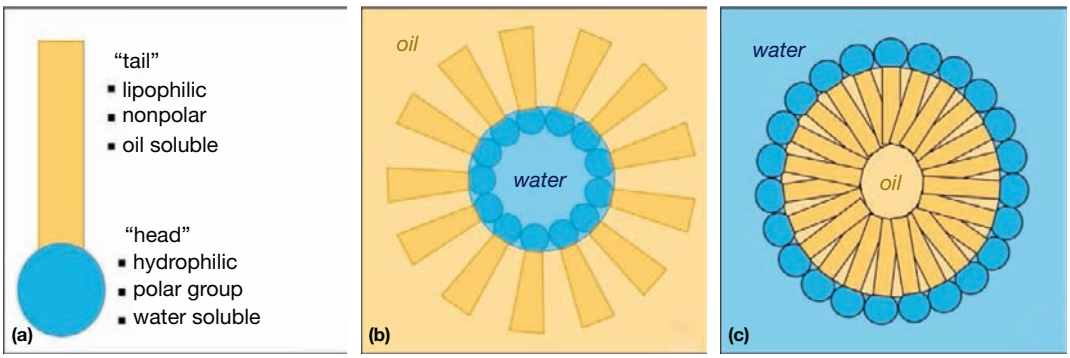

Figure 1 Emulsifier molecules contain a lipophilic 'tail' and a hydrophilic 'head' (a). Orientation of the emulsifier molecules in water-in-oil (b) and oil-in-water (c) emulsions.

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00249-X

oil-loving. The hydrophilic end is often referred to as the head and is polar. Thus, it easily dissolves in water and is termed water-loving. Emulsifiers that are easily soluble in water (more hydrophilic) produce o/w emulsions. The emulsifier interacts strongly with the water, thus reducing the surface tension of the water so that it approaches zero. The water no longer forms droplets and becomes the outer (continuous) phase of the emulsion, leaving the oil dispersed as discrete droplets (inner or discontinuous phase) to form an o/w emulsion (Figure 1(b)). Lipophilic emulsifiers are not water-soluble and interact with the oil phase. As a result, the surface tension of the water is not significantly reduced so it remains as discrete droplets in the oil, producing a w/o emulsion (Figure 1(c)).

Hydrophilic/Lipophilic Balance

Several methods of classifying emulsifiers are available. The most commonly used is HLB. HLB is an index of the solubilizing properties of emulsifiers and indicates the type of emulsion (o/w or w/o) that the emulsifier is best suited for (Table 2). HLB values can be calculated based on the molecular structure of the emulsifier or determined empirically. The values range from 0 to 20, but some emulsifiers have been shown experimentally to have higher values. Emulsifiers with low HLB values are more oil-soluble (lipophilic), while those with higher values are more water-soluble (hydrophilic). In general, emulsifiers with HLB values of 3–6 are lipophilic and best suited for w/o emulsions. Emulsifiers in this range include MDGs and propylene glycol monostearate (PGMS). Hydrophilic emulsifiers with HLB values of 10–18 are best suited for o/w emulsions. Examples include diacetyl tartaric acid esters of monoglyceride (DATEMs) and lecithin. The effectiveness of emulsifiers is affected by processing conditions and ingredients such as sugar, salt, and protein. It has been reported that the strength of the interaction is more important than the number of reactive groups in determining the hydrophilic properties of emulsifiers. However, HLB can provide an estimate of the hydrophilic nature of various emulsifiers and serves as a useful guide for classifying and selecting emulsifier systems. Selecting the ideal emulsifier or combination of emulsifiers often requires experimental work.

Table 2 Hydrophilic/lipophilic balance (HLB) values of common food emulsifiers

Emulsifier	*Abbreviation*	*HLB value*
Mono- and diglycerides	MDGs	4
Glycerol monolaurate		7
Ethoxylated monoglyceride	EMG	13
Diacetyl tartaric acid esters of monoglyceride	DATEMs	9
Succinylated monoglyceride	SMG	5
Lactylated monoglyceride	LMG	3
Sodium stearoyl-2-lactylate	SSL	22
Propylene glycol monostearate	PGMS	3
Sorbitan monostearate		6
Sodium stearoyl-2-lactylate	SSL	15
Polysorbate 65		11
Polysorbate 80		15
Sucrose monostearate		5
Calcium stearoyl-2-lactylate	CSL	8

Functional Groups

Food emulsifiers are created by alcoholysis or direct esterification of edible fatty acids taken from animal or vegetable sources with polyols (i.e., glycerol, propylene glycol, and sorbitol). Further processing by reaction with ethylene oxide or esterification with organic acids produces a wide range of emulsifiers with differing properties. The most commonly used food emulsifiers include MDGs, stearoyl lactylates, sorbitan esters, polyglycerol esters, sucrose esters, and lecithin. They find use in a wide array of food products (Table 3).

MDGs are the most commonly used food emulsifiers, composing about 75% of total emulsifier production. The largest use is in yeast-raised baked goods to increase shelf life, followed by cake and cake icings. Another major use is in margarine manufacture. MDGs are produced by heating triglycerides and glycerol with an alkaline catalyst. The

Table 3 Common food emulsifiers and uses

Emulsifier	*Food products*
Mono- and diglycerides	Bread, cake, pasta, frozen dessert, icing, topping, peanut butter, margarine, dehydrated potatoes, shortening, coffee whitener, and pasta
Glycerol monolaurate	Bread, whipped topping, frosting, glaze, and cheese products
Ethoxylated monoglyceride	Bread, whipped topping, icing, frozen dessert, and coffee whitener
Diacetyl tartaric acid esters of monoglyceride	Bread, extruded products, icing, margarine, and salad dressing
Succinylated monoglyceride	Bread
Calcium stearoyl-2-lactylate	Bread, egg whites, and dehydrated potatoes
Sodium stearoyl-2-lactylate	Bread, pasta, dehydrated potatoes, and coffee whitener
Propylene glycol esters	Cake, whipped topping, dehydrated potatoes, and shortening
Sorbitan esters	Whipped topping, cake, cake mix, cocoa, icing, filling, and coffee whitener
Polysorbate 60	Whipped topping, cake, cake mix, cocoa, icing, filling, coffee whitener, shortening, salad dressing, and edible oil
Polysorbate 65	Ice cream, frozen custard, ice milk, sherbet, frozen dessert, icing, cake, cake mix, whipped topping, filling, and coffee whitener
Polysorbate 80	Ice cream, frozen custard, ice milk, sherbet, frozen dessert, gelatin mix, shortening, baked goods, bakery mixes, filling, icing, topping, and frying oil
Sucrose esters	Bread, bakery mixes, frozen dessert, whipped milk products, and ice cream
Lecithin	Baked goods, chocolate, cooking spray, instant foods, and margarine

resulting product is a mixture of about 45% monoglycerides, 45% diglycerides, and 10% triglycerides. The monoglyceride concentration can be increased to about 90% using molecular distillation to produce distilled monoglycerides. MDGs can also be processed to produce emulsifiers with various functionalities. Ethoxylated monoglycerides (EMGs) are formed by treating monoglycerides with ethylene oxide gas. DATEMs are produced from the reaction of monoglyceride with diacetyl tartaric acid anhydride. Succinylated monoglycerides (SMGs) result from the reaction of distilled monoglycerides with succinic anhydride. Stearoyl lactylates are the reaction products of stearic acid and lactic acid, which are further converted into the calcium or sodium salts and become calcium stearoyl-2-lactylate and SSL. SSL is one of the most common anionic emulsifiers used in the food industry. Sorbitan monostearate, a sorbitan ester, is produced by reacting sorbitol and stearic acid. It can then be reacted with ethylene oxide to produce polyoxyethylene sorbitan monostearate (polysorbate 60), polyoxyethylene sorbitan tristearate (polysorbate 65), and polyoxyethylene sorbitan monooleate (polysorbate 80). Polysorbate 60 is the most widely used in the group. Polyglycerol esters result from reacting fatty acids with polymerized glycerol of three to ten molecules. Sucrose esters are derived from sucrose and edible tallow and consist of the mono-, di-, and triesters of sucrose with fatty acids. Emulsifiers that solidify into the stable alpha crystalline form are called alpha-tending and include acetylated monoglycerides (AMGs), lactylated monoglycerides (LMGs), and propylene glycerol monoesters (PGMEs). Lecithin is a mixture of phosphatides including phosphatidylcholine, phosphatidylethanolamine, and inositol phosphatide. It is a natural component found in animal and vegetable products. Egg yolk, which contains about 20% phospholipid, is well known for its emulsifying ability. It is too expensive to isolate lecithin from egg yolk; therefore, most commercial lecithin is derived from soybeans, which contain about 2% lecithin. Many other emulsifiers and emulsifier blends are available for specific applications.

Mechanism of Action in Food Products

An o/w emulsion will be used as an example of how an emulsion is formed. When water and oil are mixed vigorously (i.e., whipped, stirred, and shaken), the oil will form into individual droplets dispersed within the water. The oil droplets are the discontinuous phase because they are separated by the water. The water (also referred to as the aqueous phase) is the continuous phase where each water molecule is touching another water molecule. Although an emulsion was formed, it is not stable. Within a short period of time, the oil droplets will bump into each other, and the two droplets will merge into a single, larger droplet. This is called coalescence. These larger oil droplets have less surface area and higher surface tension. Ultimately, all of the oil droplets will coalesce and rise out of the water to form into a separate layer floating on top of the water. The rate at which the oil droplets rise out of the emulsion is inversely proportional to their size; thus, larger droplets rise faster than smaller droplets. In the case of a w/o emulsion, the water is present as individual droplets (discontinuous phase) within the continuous oil phase. Emulsifiers are added to promote emulsion formation and stabilization.

Emulsifiers do not create emulsions. An emulsion is typically created using mechanical means such as mixing or stirring. However, one of the roles of emulsifiers is promoting the formation of smaller oil droplets during emulsion creation, which slows the rate of coalescence. When the appropriate emulsifier is added into the oil and water mixture, the molecules orient at the interface between the water and the oil droplets. The hydrophilic heads are attracted to the water, whereas the lipophilic tails are repelled by the water and attracted to the oil. As a result, the lipophilic tail will react with the oil droplet, while the hydrophilic head will react with the water at the surface of the oil droplet; thus, it reacts at the interface between the two immiscible phases. When this happens, the surface tension of the oil droplet decreases considerably, which decreases the surface tension and allows the droplets to be subdivided into smaller droplets during mixing. The effectiveness of lowering surface tension varies between different emulsifiers.

The second role of emulsifiers is stabilizing the emulsion once it has formed. This is the main reason that emulsifiers are used in food systems. Even though smaller droplets are more stable, emulsion stabilization by emulsifiers is not directly the result of their ability to lower interfacial tension and allow for the creation of smaller droplets. Rather, emulsifiers stabilize emulsions by accumulating at the interface of the two phases where they form a barrier that prevents the droplets of the discontinuous phase from coalescing. The mechanism by which the barrier forms is determined by the properties of the emulsifier. One mechanism of stabilization is due to like-charged particles repelling each other. Anionic emulsifiers carry negative charges that repel each other to keep the droplets apart. SSL, SMG, and DATEM are anionic emulsifiers. They are not highly effective in systems with high salt levels because the salt shields the charge, which suppresses the repulsive forces and leads to rapid coalescence and breakdown of the emulsion. Although not used in food systems, cationic emulsifiers carry positive charges that also repel each other to stabilize the emulsion. In nonfood systems, anionic and cationic emulsifiers should not be used in combination as the opposite charges would interact, thus rendering the emulsifiers inactive. Another form of stabilization is employed by emulsifiers that contain a large hydrophilic portion such as EMG. The large hydrophilic head holds a large amount of water and creates a layer of 'bound' water around the droplet, which prevents coalescence. These emulsifiers are not sensitive to salt. Simple steric hindrance is a third type of stabilization. The emulsifier forms a solid layer at the interface, which physically prevents coalescence even if the droplets touch each other. This occurs in alpha-tending emulsifiers such as PGME.

Food Uses of Emulsifiers

In the food industry, the term 'emulsifier' is used generically and includes surfactants that are not technically classified as emulsifiers. Additives categorized as emulsifiers in the food industry provide a broad range of functions in a wide range of food

products including emulsification, stabilization, antistaling, crumb softening, foaming, fat crystal modification, mouthfeel, agglomeration, defoaming, wetting, solubilizing, and stickiness control. Many food products contain emulsifiers that perform many different functions (Table 3). A few are discussed here.

Dairy Products

Emulsifiers are added to ice cream to shorten the freezing time, improve whipping, and produce a dry, stiff texture that melts slowly. The ice cream mix is an o/w emulsion. Emulsifiers stabilize the emulsion and prevent the fat globules from agglomerating in the mix. When the mix is churned into ice cream, the emulsifiers function to destabilize the natural milk protein film that surrounds the milk fat globules so they can surround the air bubbles and stabilize into a frozen foam. MDGs, sucrose esters, and polysorbates are commonly used in ice cream.

Nondairy whipped toppings are whipped cream replacers made using vegetable fats. They may be frozen or in pressurized cans. In these products, emulsifiers are added as destabilizers to promote aeration. In this role, the emulsifier causes the fat globules to agglomerate during whipping. This is done to create a fat network in the continuous aqueous phase, which stabilizes the air bubbles and imparts stiffness to the foam. Polysorbate 60 and alpha-tending emulsifiers such as LMG and propylene glycol monoesters are commonly used in the production of commercial nondairy whipped toppings.

Coffee whiteners are liquid or powdered cream replacers. Emulsifiers are added to improve their dispersion in hot coffee. Typical emulsifiers used include distilled monoglycerides, DATEM, polysorbate 60, and sorbitan monostearate.

Salad Dressings

Mayonnaise is an o/w emulsion that contains at least 65% vegetable oil. The emulsion is stabilized by the high level of lecithin in the egg yolk. FDA standards of identity do not allow the addition of other emulsifiers.

Pourable salad dressings are w/o emulsions that contain at least 30% vegetable oil. Typically, consumers shake the bottle to form the emulsion before pouring the dressing over their salad. Polysorbates and DATEMs are commonly used to enhance emulsification when the bottle is shaken.

Margarine

Margarine is a w/o emulsion containing about 80% fat. It is usually made with MDGs of long-chain fatty acids and lecithin. The MDGs promote the formation of the emulsion, while the lecithin is added to increase the solubility of the MDGs in the oil blend. Distilled monoglycerides with a high concentration of unsaturated fatty acids and lecithin are used in low-calorie spreads, which are also w/o emulsions that contain at least 50% water and 40% fat.

Shortening

Shortening consists of a fat blend that contains emulsifiers. All-purpose shortenings contain about 1% distilled monoglycerides. High-ratio or emulsified shortenings, for use in cakes where the levels of sugar and liquid are present at higher levels than the flour, contain several emulsifiers including distilled monoglycerides, LMG, and PGME. These shortenings allow better air incorporation during mixing and bind more sugar and water.

Pasta

SSL and distilled monoglycerides are added into pasta products to aid in extrusion. They are also used in pasta for soups or canned products to reduce stickiness and improve the texture of the cooked product.

Baked Products

In the baking industry, the term 'emulsifier' is used to describe a broader group of surfactants, which includes those that are active in foams (air-in-water) and dispersions (liquid-in-solid) and in emulsions (liquid-in-liquid). Thus, the term emulsifiers will be used in this section to encompass the common surfactants used in baked products.

Doughs and batters are complex systems that contain multiple interfacial interactions that occur simultaneously, some of which change forms as the products are heated. Emulsifiers play many different roles in these products. Most batters and doughs contain a polar, continuous phase that consists of an aqueous (water) solution of salts, sugars, water-soluble proteins, and other solubilized formula ingredients, which can be a component of an emulsion, a foam, and a dispersion simultaneously in a single batter or dough. For example, the continuous aqueous phase may form an emulsion in which a lipid in some form (oil or solid fat) constitutes the nonpolar, discontinuous phase. It may be the continuous phase in an emulsion with a nonpolar, discontinuous polar discontinuous phase of lipid in some form (oil or solid fat). Almost all batters and doughs contain a foam of the continuous aqueous phase with a discontinuous phase of air bubbles, which are incorporated during mixing. Furthermore, the continuous aqueous phase makes a dispersion with the insoluble formula ingredients, which include the starch and gluten in the flour.

In cake batters, distilled monoglycerides and alpha-tending emulsifiers such as AMG and PGMS function as aerating agents to speed up the whipping rate and facilitate the incorporation of many small air cells. This leads to a more stable emulsion and results in a cake with a larger volume and fine, uniform crumb grain. Alpha-tending emulsifiers are critical in cakes made using a one-stage mixing procedure or prepared from boxed cake mixes where liquid shortening or oil is used because they form a solid film at the oil–water interface, which stabilizes the emulsion and also keeps the liquid oil from breaking the emulsion or foam that is prepared during mixing.

Emulsifiers used in yeast-leavened bread products are also active in the solid–liquid interface (dispersion) where they function as crumb softeners and dough strengtheners. As crumb softeners, they interact with starch granules and gluten protein polymers to impart a softening effect on the crumb grain and extend the shelf life of the product. Monoglycerides are the primary crumb softener used in bread. Other common crumb softeners include DATEM, sucrose esters, and PGMS.

Dough strengtheners interact with the gluten protein and alter the rheology of the dough to produce a stronger gluten structure. Anionic emulsifiers such as DATEM, SSL, SMG, EMG, and polysorbates are good dough strengtheners. Some of the emulsifiers used in baking have only one or the other of the functionalities, while others have both. For example, SSL functions mainly as a dough strengthener, but it also plays a minor role promoting the emulsification, incorporation, and subdivision of air cells during mixing and crumb softening.

Regulation of Energy Metabolism

Energy metabolism represents the most important body function and has an effect on energy expenditure. It is paramount to basal metabolism, growth, and physical activity in humans. Energy derived from nutrients drives the critical cellular functions in humans and is essential for survival. Using complex biochemical pathways, chemical energy stored in the macronutrients (carbohydrate, fat, and protein) is transformed into other forms of energy such as heat and *adenosine triphosphate*. The regulation of metabolism at the cellular level relies on a complex neurohormonal system, which responds to a variety to stimuli and controls the utilization of substrate in individual cells. The overall aim of this regulatory process is to maintain energy balance, and it is important to understand these pathways that convert food into usable fuel.

The importance of the central nervous system (CNS) in the regulation of body weight has been known for the past 100 years. Several factors have been identified, including mechanical, hormonal, neural, and metabolic, that act as peripheral signals in sending information to the CNS to regulate substrate metabolism. The CNS processes these signals and integrates a response to modify the control mechanisms that maintain energy balance. It has been proposed that energy balance is maintained by the regulation of body fat through a feedback mechanism with specific processes mediated. In these processes, the hormones leptin and insulin send signals to the CNS about the body fat stores and participate in body weight control. Both leptin and insulin cross the blood–brain barrier and interact with receptors at the hypothalamus; two types of neurons in this area have been described to have opposite effects (anorexigenic vs. anabolic) to the action of leptin and insulin concentrations, and it is by this mediating effect that energy balance is achieved.

Other factors have been described in the CNS regulation of energy balance, including signals from the gastrointestinal tract and from the nutrients (i.e. glucose, fatty acids, and amino acids). Among the satiety hormones secreted by the gut in response to presence of substrate are cholecystokinin, amylin, peptide YY, apolipoprotein A, glucagon-like peptide-1, and ghrelin. The concentrations of the different substrates send feedback to the CNS about the energy status of the body. The observation that lower or higher blood glucose levels induce changes in feeding behavior led to the well-known fact that the CNS uses several sugar molecules as signals to regulate food intake. Although neurons get most of their energy supply from the oxidation of glucose rather than fat, studies in animals have demonstrated that administration of fatty acid synthase inhibitors produces anorexia and weight loss. Recently, studies have shown the effect of intake of different amounts of amino acids in the central regulation of satiety, with diets high on protein having an effect of decreasing food intake. On the other hand, administration of several amino acids (i.e., leucine and valine) has been shown to have opposite effects on food intake.

In summary, the CNS is an important and vital component of the regulation of energy metabolism. Hormonal secretion and feedback regulation by the CNS, gastrointestinal factors, and substrate intake and metabolism are important in achieving energy homeostasis.

Components of Energy Expenditure

In order to understand energy balance, it is important to review the total energy expenditure (TEE) during health and illness. In healthy individuals, TEE can be partitioned into three main components: basal metabolic rate (BMR), thermogenesis, and physical work. BMR represents 60–70% of TEE, while thermogenesis represents 10%, and physical work accounts for 20–30% of TEE. During conditions of stress, the proportions of these components vary depending on the severity of the insult, amount of substrate intake, and physical activity. Diet-induced thermogenesis (DIT) is the amount of energy required to absorb, process, and store nutrients and represents an increase in energy expenditure with respect to postabsorptive state (Figure 1). BMR is difficult to measure. However, indirect calorimetry (IC) allows a measurement of a close approximation of this value and has been described in more detail later in this article. Resting energy expenditure (REE) is the energy expenditure measure by IC in true resting state. Energy supply greater than two to three times the REE gives rise to a DIT that increases from 10% up to 20% after the first week of illness with resultant increases in energy expenditure and higher ventilatory and cardiocirculatory demands on the patient; therefore, it is important not to supply excessive calories in relation to measured energy expenditure or BMR during the acute phase of the injury or surgical stress. With age, energy expenditure is reduced and this in addition to decreased exercise activity explains the increase in weight gain commonly seen during adulthood. On average, the rate of basal metabolism per body weight is reduced from infancy to adulthood by 1.5–2 times (Figure 2).

For many years, the concept of the increased energy expenditure seen in infants has been attributed to the energy cost of growth. In early infancy, the growth velocity is maximal at approximately 6 months of age; this process slows down considerable by the age of 1 year. It has been described in infants less than 6 months that approximately 7–8% on the energy used by the body is utilized for growth purposes; this amount decreases to less than 2% of the energy expenditure by the time the child becomes older than 1 year of age when the BMR reaches about 55 kcal kg^{-1} day^{-1}. There is a reduction in the rate of basal metabolism that starts after the age of 3 years. This change is explained by changes in body composition and an uneven growth of organs, for example, the metabolic rate of

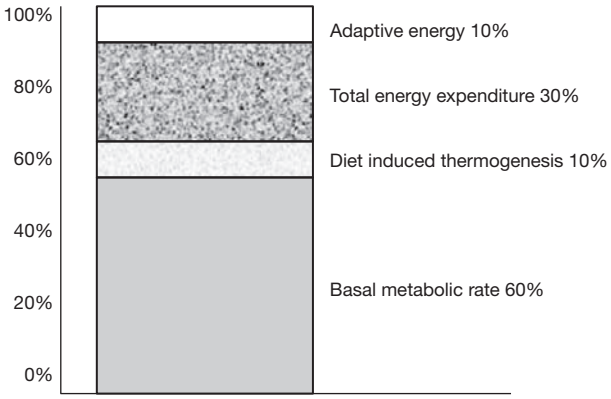

Figure 1 Components of energy expenditure.

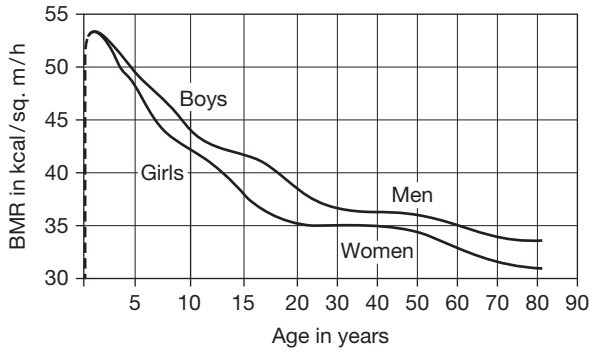

Figure 2 Change in basal metabolic rate with age. Reproduced with permission from Mitchell, H. H. (1962). *Comparative nutrition of man and domestic animals*, vol. 1, pp. 3–90. New York: Academic Press.

the brain represents 12% of the total in the newborn, while in adults, it is only 2% of their body mass. The last peak of BMR occurs at the age of 14 years, and after this period, the BMR is stabilized at the level of an adult.

BMR defined as the energy expenditure after a 12 h fasting period represents 50–70% of TEE, and it does decrease over time by approximately 1–2% per decade. Many studies have reported that the BMR is lower after adjustment for fat-free mass in older individuals. The two changes that could explain a lower metabolic rate during aging is the relative increase of fat mass in relation to the decrease of fat-free mass. Multiple studies have indicated that BMR is lower in the elderly when compared to rates in younger individuals even after taking into consideration changes in body composition associated with age. BMR defined as the energy expenditure after a 12 h fasting period represents 50–70% of TEE, and it does decrease over time by approximately 1–2% per decade. Many studies have reported that the BMR is lower after adjustment for fat-free mass in older individuals. The two changes that could explain a lower metabolic rate during aging are the relative increase of fat mass in relation to the decrease of fat-free mass. Multiple studies have indicated that BMR is lower in the elderly when compared to rates in younger individuals even after taking into consideration changes in body composition associated with age. There is a reduction in the rate of basal metabolism that starts after the age of 3 years. This change is explained by changes in body composition and an uneven growth of organs, for example, the metabolic rate of the brain represents 12% of the total in the newborn, while in adults, it is only 2% of their body mass. The last peak of BMR occurs at the age of 14 years, and after this period, the BMR is stabilized at the level of an adult.

An important component of energy expenditure is the energy dissipated by physical activity; this expenditure in addition to the BMR and the thermal effect of food represents the TEE. The explanation for the decline in TEE with age is not well understood. With aging, there is an increase in body fat mass, making body composition changes an important reason for this change. Another important factor in creating energy imbalances and eventually weight gain is the ability to oxidize fat, with an increase in body fat stores if oxidation of fat is decreased and vice versa.

For many years, the concept of the increased energy expenditure seen in infants has been attributed to the energy cost of growth. Growth velocity (as measured by grams/day or grams/kg/day) is highest in neonates and early infancy and starts to slow down in the second half of infancy. In infants less than 6 months, approximately 7–8% on the TEE is allocated for growth purposes; this amount decreases to less than 2% of the energy expenditure by the time the child becomes older than 1 year of age when the BMR reaches about 55 kcal kg^{-1} day^{-1}.

In summary, multiple studies have shown that dysregulation of energy intake occurs in healthy older individuals increasing the risk of energy imbalance; in addition, studies have indicated a dysregulation of energy expenditure and substrate oxidation associated with aging that results in changes in body weight. In periods of sickness, when energy expenditure varies and the individual is dependent on artificial nutrition, it is important to be aware of the balance between energy intake and requirement.

Metabolic Response to Stress

The profound metabolic response to critical illness, including injury, surgical stress, or inflammation, is not always predictable and varies in intensity and duration between individuals.

The energy cost imposed by this metabolic response may be proportional to the severity and duration of the stress but cannot always be accurately estimated. Importantly, nutritional support itself cannot alter the metabolic stress response. Failure to recognize existing nutritional deficiencies and provide adequate nutrition support during the acute phase of the illness may exacerbate preexisting malnutrition or result in new nutritional deficiencies. Both overfeeding and underfeeding should be avoided in order to decrease metabolic imbalances and development of malnutrition in critically ill patients. The nutritional plan should be individualized and customized to each patient during their hospital admission. A complete understanding of the metabolic events involved in the metabolic stress is essential for planning appropriate nutritional support plans in critically ill patients.

The hormonal and cytokine profile of the stress response to critical illness is characterized by increased serum levels of insulin, glucagon, cortisol, catecholamines, and proinflammatory cytokines. Elevated serum counterregulatory hormone

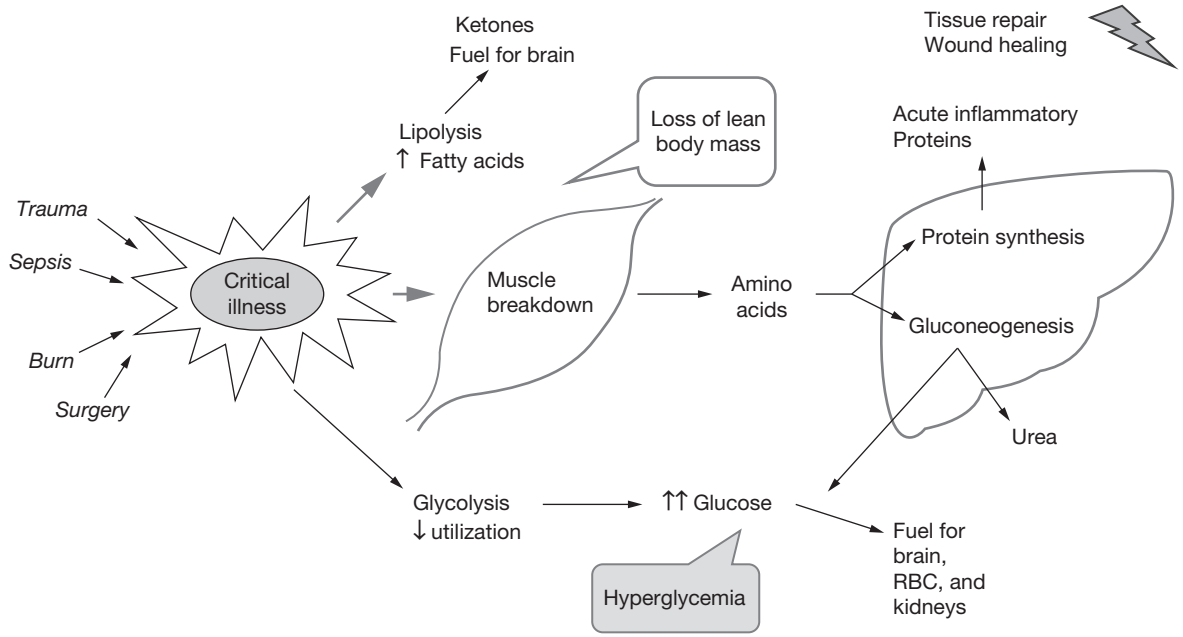

Figure 3 Basic pathways of the metabolic stress response to injury. Reproduced with permission from Mehta, N. and Jaksic, T. (2008). The critically ill child. In: Duggan, C., Watkins, J. B. and Walker, W. A. (eds.) *Nutrition in pediatrics* (4th ed.), pp. 663–673. Hamilton, ON: BC Decker.

concentrations induce insulin and growth hormone (GH) resistance, resulting in the catabolism of endogenous stores of protein, carbohydrate, and fat. This autocannibalism ensures a steady supply of essential substrate intermediates and energy necessary to support maintenance energy and micronutrient needs in addition to driving the ongoing metabolic stress response. The *sine qua non* of this acute metabolic response is a hypermetabolic, hypercatabolic state resulting in the loss of endogenous muscle stores with increased glucose and free fatty acid oxidation, elevated energy expenditure, and increased protein breakdown (Figure 3).

Among the changes at the CNS seen during the acute metabolic response are alterations in the hypothalamic–anterior pituitary axes, resulting in increased cortisol secretion, elevated concentrations of GH, increased reverse T_3 secretion, increased prolactin, and decreased testosterone. The degree of alterations in the levels of these hormones is proportional to the severity of the insult and produces significant changes in body homeostasis. Cytokines are endogenous proteins that act as mediators of local and systemic injury or inflammation. They are synthesized by several tissues and white blood cells in response to stimulation by endotoxin and viral particles. These mediators are critical in modulating a number of responses by promoting tissue repair, prioritization of substrate for protein synthesis, and anti-inflammatory actions. This response when augmented secondary to an overwhelming insult or inadequate response by the host immune response can lead to an increased risk of injury-induced morbidity and mortality. Tissue injury elicits the release of proinflammatory cytokines (TNF-α, interleukin (IL)-1, IL-6, and IL-8). Once these peptides are released by activated macrophages and endothelial cells, signals are enacted to release anti-inflammatory cytokines, mainly IL-10. Many clinical studies have reported the use of drugs aimed to attenuate the proinflammatory response or medications to augment the anti-inflammatory reaction with mixed results, highlighting the inherent difficulties in the control of the inflammatory response.

During the acute metabolic response, there is a significant increase in the concentrations of the counterregulatory hormones (oppose the anabolic effects of insulin) including catecholamines, glucagon, and cortisol. The actions of catecholamines include an elevation of the metabolic rate, hyperglycemia induced by hepatic glycogenolysis, and suppression of pancreatic secretion of insulin. The known actions of glucagon are glycolysis and gluconeogenesis with a resultant elevation in the serum concentrations of lactate and alanine; this results in the endogenous regeneration of glucose. The effects of cortisol are at the muscle level with significant proteolysis and elevation of metabolic rate in conjunction with the action of catecholamines. The other important effect of cortisol is the increase in gluconeogenesis by the incorporation of alanine and glutamine from muscle proteolysis and gut sources, respectively. Also, cortisol has been shown to increase insulin resistance and oppose the anabolic effects of insulin.

It has been postulated that the attenuation of the effects of anabolic hormones during the acute metabolic response represents a compensatory mechanism. Insulin is a potent anabolic hormone with multiple actions including glycogenesis, lipogenesis, and protein synthesis. When a state of increased insulin resistance is present, glucose production, lipolysis, and proteolysis are increased, conditions usually seen in critically ill adults and children. Recent evidence suggests an anti-inflammatory effect of insulin administration; this finding has been reported in animal and clinical studies. GH, also known as somatotropin or somatropin, is a peptide hormone that stimulates growth, cell reproduction, and regeneration in humans and other animals. GH is a stress hormone that raises the concentration of glucose and free fatty acids and stimulates

production of insulin-like growth factor 1 (IGF-1). The actions of GH are aimed toward anabolic conditions, and its synthesis and secretion are stimulated by IGF-1. During stress conditions, the secretory pattern of GH and IGF-1 is suppressed by a cytokine-mediated mechanism. Clinical studies in children with burns have reported that the exogenous administration of recombinant GH has increased protein synthesis and nitrogen balance and improved clinical outcomes.

Substrate Adaptations During the Acute Metabolic Response

The changes in substrate homeostasis seen after the acute metabolic response are aimed to preserve life, despite the fact that in many instances, this response is maladaptive. During periods of starvation not associated with stress, endogenous mobilization of adipose stores is the main source of energy for metabolic purposes. This mobilization of body fat stores is preceded by the use and eventual depletion of glycogen stores; the time it takes for glycogen reserves to be depleted is usually few hours for infants and children and up to 24 h in adults. It is during this initial period of lack of substrate intake that the energy needs are supplied mainly with glycogen and protein. After a period longer than 48–72 h, an increase in fat store mobilization is ensued with subsequent utilization of fat as the sole source of energy, with the exception of tissues that are dependent mainly on glucose for metabolic fuel. Also, a decrease in energy expenditure is seen aimed to preserve lean body mass. Unfortunately, patients with limited or smaller protein stores (i.e., children and malnourished adults) will be metabolically compromised in less time.

The acute metabolic response seen with injury, trauma, and sepsis results in important alterations in substrate metabolism. In addition to the use of glycogen stores, gluconeogenesis is increased and provides the bulk of carbohydrates for the glucose-dependent tissues; protein breakdown provides substrate for the synthesis of acute phase reactants and gluconeogenesis. The hyperglycemic response seen is secondary to the uncontrolled need to synthesize new glucose and to the increased insulin resistance at the peripheral tissues associated to the dysfunction of the intracellular glucose transport protein 4 (GLUT4).

The acute metabolic response in the critically ill subject is hypercatabolic resulting in proteolysis, increased protein turnover, and decreased protein synthesis. These changes have been shown by the use of stable isotopes in studies that included patients with sepsis and extensive burns. The response of the acute ill patient in terms of protein catabolism is different from the subject under starvation conditions in that the former has negative protein balance secondary to an exaggerated proteolysis as opposed to decreased synthesis in the starved subject. This catabolic response is not attenuated by the provision of adequate nutrition support and persists until the acute process is resolved. Much of this loss of lean body mass as it relates to commonly measured outcomes, including length of intensive care unit (ICU) stay and length of hospitalization, has been debated by the experts. Even though the exaggerated catabolic response is not reversed by the provision of substrate in the form of glucose, protein, and fat, adequate supplementation of protein is recommended to increase protein synthesis and attenuate the net negative protein balance.

Glucose is the primary fuel for the CNS and minimal amounts are required to maintain function. Provision of glucose in excess of the capacity of oxidation, usually 8–10 mg kg^{-1} min^{-1} in neonates and 4–6 mg kg^{-1} min^{-1} in adults, has been associated with lipogenesis, hepatic steatosis, and hyperglycemia. It has been reported that up to 150% of the glucose oxidized under stress conditions is provided by gluconeogenesis, and this response is not attenuated by the exogenous administration of glucose. Exogenous administration of insulin does not increase the rate of glucose oxidation in critically ill patients because the rate of maximal glucose oxidation has been reached in addition to increased endogenous levels of insulin. The resultant hyperglycemia seen in these patients is a result of a combination of factors including increased glucose oxidation and hepatic glucose production and decreased peripheral uptake of glucose.

Assessment of Energy Requirement for the Hospitalized Patient

Methods to Estimate Energy Needs

Adequate nutrition support is important giving the high prevalence of malnutrition in the hospitalized patient. Several studies have reported malnutrition rates ranging from 30% to 50% upon admission to the hospital, with more than 50% of these already malnourished patients having a worsening nutritional status if it is left untreated. It has been reported that up to one-third of hospitalized adults patients will develop malnutrition after admission to the hospital. Malnutrition has been reported to worsen outcomes, including immune suppression, infection, longer hospital stay, increased morbidity, and decreased survival. Critically ill children differ in their energy needs from healthy children in terms of underlying metabolism and growth, comorbidities, and preexisting energy reserve, and therefore, it is difficult to estimate energy needs in this population. In addition, frequent monitoring of energy expenditure is necessary to accommodate any variations in energy expenditure throughout the course of illness. In the absence of metabolic equipment to measure energy needs in the ICU, caution should be used when reference values are used to estimate energy needs in this population.

Reference values

The BMR reference values include the following:

1. The Harris–Benedict equation, (Harris–Benedict 1919) one of the most widely used to estimate BMR. This equation is widely used in adults and has never been validated for children.
2. The Food and Agriculture Organization, the World Health Organization, and the United Nations University (FAO/WHO/UNU). These equations were based on data derived from 6100 individuals under a variety of conditions and represent BMR.
3. Talbot published guidelines in 1938 for the estimation of BMR based on measurements made in children. These values were based on studies performed by the author.

Table 1 Prediction equations

Equation	*Gender*	*Age*	*Basal metabolic rate estimate*
Harris–Benedict		Children	[22.1 + (31.05 × Wt) + (11.6 × Ht)]
	Female		[665.0955 + (9.5634 × Wt) + (1.8496 × Ht) − (4.6756 × age)]
	Male		[66.473 + (13.7516 × Wt) + (5.0033 × Ht) − (6.755 × age)]
FAO/WHO/UNU	Female	0–3 years	[(61 × Wt) − 51]
		3–10 years	[(22.5 × Wt) + 499]
		10–18 years	[(12.2 × Wt) + 746]
	Male	0–3 years	[(60.9 × Wt) − 54]
		3–10 years	[(22.7 × Wt) + 495]
		10–18 years	[(17.5 × Wt) + 651]
Schofield	Female	0–3 years	[(16.252 × Wt) + (10.232 × Ht) − 413.5]
		3–10 years	[(16.969 × Wt) + (1.618 × Ht) + 371.2]
		10–18 years	[(8.365 × Wt) + (4.65 × Ht) + 200.0]
		18–30 years	[(13.623 × Wt) + (2.83 × Ht) + 98.2]
	Male	0–3 years	[(0.167 × Wt) + (15.174 × Ht) − 617.6]
		3–10 years	[(19.59 × Wt) + (1.303 × Ht) + 414.9]
		10–18 years	[(16.25 × Wt) + (1.372 × Ht) + 515.5]
		18–30 years	[(15.057 × Wt) − (0.1 × Ht) + 705.8]
Estimated energy requirements	Female and male	0–3 months	[89 × Wt − 100] + 175
		4–6 months	[89 × Wt − 100] + 56
		7–12 months	[89 × Wt − 100] + 20
	Female	3–8 years	135.3 − [(PA × 10 × Wt) + (30.8 × Age) + (934 × Ht)] + 20
		9–18 years	135.3 − [(PA × 10 × Wt) + (30.8 × Age) + (934 × Ht)] + 25
	Male	3–8 years	88.5 − [(PA × 26.7 × Wt) + (61.9 × Age) + (903 × Ht)] + 20
		9–18 years	88.5 − [(PA × 26.7 × Wt) + (61.9 × Age) + (903 × Ht)] + 25

FAO, Food and Agriculture Organization; WHO, World Health Organization; UNU, United Nations University. Basal metabolic rate estimate in kcal per day; weight (Wt) in kg; height (Ht) in cm; physical activity (PA).

4. Schofield equations. These equations were based on data from the FAO/WHO/UNU report with some additional data (Table 1). It is important to mention that the use of these reference values in critically ill patients could lead to underfeeding or overfeeding because of the variability of the metabolic state of patients during their stay in the ICU.

Correction factors

The use of stress and activity factors in addition to the BMR reference values has been reported to overestimate and underestimate energy needs in critically ill patients, reinforcing the concept that IC should be used as a strategy to measure energy needs in this population of patients. Several studies conducted in critically ill patients on mechanical ventilation that used different BMR equations (i.e., Harris–Benedict, Schofield, and Talbot) and correction factors of 1.3 and 1.5 to estimate energy needs were found to have significant differences when compared to measured energy expenditure by IC, emphasizing the concept that IC is the only method to accurately measure energy needs in critically ill patients.

Predictive equations

The use of regression equations based in multiple variables (sex, weight, height, body temperature, heart rate, inotrope dose, sepsis, days of admission to the ICU, minute ventilation, etc.) has been reported in both adults and children admitted to the ICU and has shown to be more accurate than reference values when compared to measured energy expenditure by IC. Caution should be given when using predictive equations because of the dynamic nature of the metabolic condition of critically ill patients.

Methods to Measure Energy Needs

The measurement of energy expenditure in humans has been attempted in the last century by physiologists. These methods include direct calorimetry, IC, and the isotope dilution technique. The use of direct calorimetry requires the measurement of heat produced by the body while the subject is placed in an insulated and tight chamber. The principles used are similar to those in a bomb calorimeter (Figure 4). IC is the method by which metabolic rate and substrate utilization are estimated from respiratory gas exchange measurements and urinary nitrogen excretion. It has been regarded as the gold standard for accurate measurement of REE. IC measures whole body oxygen consumption (VO_2) and carbon dioxide production (VCO_2). Then, the VO_2 and VCO_2 values are converted to a caloric equivalent based on equations developed by Weir: $REE = [VO_2\ (3.941) + VCO_2\ (1.11)] \times 1440$. The use of IC and urinary nitrogen allows the calculation of 'net' oxidation rates for carbohydrates, protein, and fat by the use of the Conzolazio formulas. The VCO_2/VO_2 ratio is known as respiratory quotient (RQ), and it is well known that the conversion of glucose to fat elevates the RQ and reflects the proportion of substrate utilization in the body. The npRQ represents the ratio of glucose and fat utilization by excluding the participation of protein and varies in value from 0.70 to 1.0, with values >1.0 indicating net fat biosynthesis from glucose (lipogenesis).

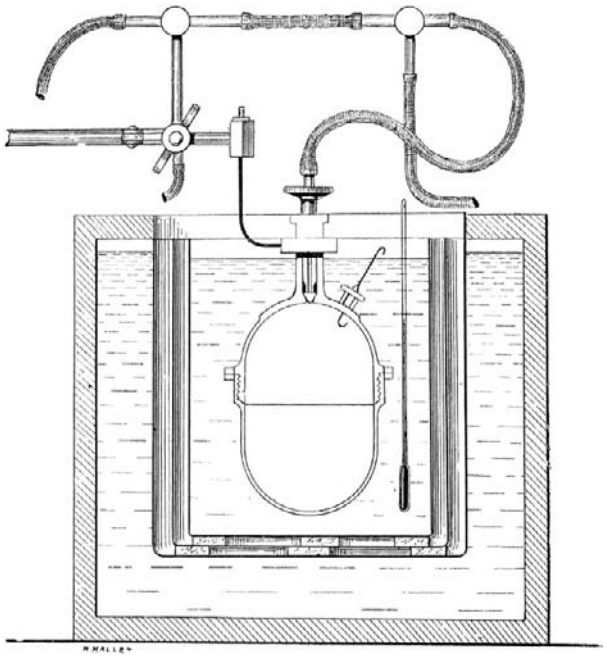

Figure 4 The bomb calorimeter. This diagram shows the bomb calorimeter designed by the French chemist Pierre Eugene Marcellin Berthelot (1827–1907). It is used to measure the heat of chemical reactions. Artwork from the tenth volume (second period of 1892) of the French popular science weekly 'La Science Illustree.' From the Science Photo Library.

The correct interpretation of IC results implies an understanding of the assumptions and technical considerations of this methodology. There are several sources of error and many technical difficulties in applying this methodology in the ICU including (1) model of calculation and assumptions, (2) calorimetric factors used, (3) leak around endotracheal tube, (4) inspired oxygen concentration above 0.60, (5) use of high levels of positive end expiratory pressure, (6) unstable gas analyzers, (7) inability to reach steady state, and (8) human factors. Studies in mechanically ventilated adults and children have concluded that the use of an abbreviated IC protocol of 3–5 min duration is enough to achieve steady state and obtain reasonable accuracy, while other authors have concluded that energy expenditure results of a 30 min IC test are comparable to 24 h test results.

The potential useful clinical applications of IC in critically ill patients can be summarized as follows: (a) assessment of energy expenditure in patients who fail to adequately respond to estimated nutritional needs, (b) assessment of energy expenditure in patients with single or multiple organ dysfunction who need prolonged ICU care and artificial nutritional support, (c) assessment of the effects induced by artificial nutrition on the cardiocirculatory and respiratory systems in mechanically ventilated patients with acute and chronic respiratory failure, and (d) monitoring of VO_2 while weaning from mechanical ventilation. Targeted measurements of REE are currently recommended and are included in the American Society for Parenteral and Enteral Nutrition (ASPEN) Clinical Guidelines: Nutrition Support of the Critically Ill Child. In summary, IC has brought understanding of how energy is utilized during critical illness; this has yet to be translated into improving patient outcomes. Studies examining the role of simplified IC technique, its role in optimizing nutrient intake, its ability to prevent overfeeding or underfeeding in selected subjects, and the cost–benefit analyses of its application in the ICU are needed.

TEE that takes into account physical activity can be measured using doubly labeled water technique (DLW). The isotope dilution technique uses stable isotopes (^2H_2O, $H_2{}^{18}O$, and $NaH^{13}CO_3$) to measure energy expenditure. The DLW method is based on the differences in turnover rates of ^2H_2O and $H_2{}^{18}O$ in body water. The DLW technique has been validated against IC and is now considered to be a gold standard for measurements of TEE under free-living conditions. Sources of measurement error include analytic inaccuracies in the mass spectrometric determination of isotopic enrichment, biological variations in the isotope enrichment, isotopic fractionation during formation of carbon dioxide and during vaporization of water, the calculation of total body water, and the assumption or calculation of the 24 h RQ. The use of the DLW method is not possible in the critically ill child because of the fluid shifts and imbalances.

The carbon dioxide production (VCO_2) during respiration has long been used as an index of substrate oxidation and energy expenditure. The isotopic dilution technique allows the ^{13}C from infused labeled bicarbonate ($NaH^{13}CO_3$) tracer to be diluted by metabolically produced carbon dioxide. By measuring the degree of isotopic dilution in expired air or blood, VCO_2 rates can be calculated. The assessment of energy expenditure must involve knowledge of the amount of energy released per liter of carbon dioxide produced, or the energy equivalents of CO_2, which constitutes the food quotient, which serves as a surrogate for RQ under conditions of nutrient balance. Two important concerns in relying on this technique relate to (1) errors in quantifying the tracer dose of labeled bicarbonate and (2) the possibility that the labeled bicarbonate does not adequately trace total CO_2 formed in the mitochondria. Another limitation is the need to know accurately the labeled bicarbonate correction factor(s) required for the physiological condition investigated (recovery factor). In summary, isotopic tracer techniques and IC should be considered as complementary techniques, in particular since the tracer techniques require the measurement of carbon dioxide production obtained by IC. However, it should be kept in mind that the assessment of substrate oxidation by IC may involve large errors in particular over a short period of time. By using IC, energy expenditure is calculated with less error than substrate oxidation rates.

In summary, energy needs must be carefully evaluated during hospitalization particularly during the course of critical illness by measuring the energy expenditure. If IC is available and the patient meets the conditions for a measurement test, IC provides an accurate way to measure REE. IC could be used in specific patient populations (targeted IC; Table 2) to prevent unintended underfeeding and overfeeding. In the absence of measured REE, equations to estimate energy needs may be used, but caution should be exercised in order to avoid incorrect estimation.

Table 2 Criteria for high risk for metabolic alterations and candidates for targeted indirect calorimetry per American Society for Parenteral and Enteral Nutrition (ASPEN)

1. Underweight (BMI <5th percentile for age) or at risk for overweight (BMI >85th percentile for age) or overweight (BMI >95th percentile)
2. Children with >10% weight gain or loss during ICU stay
3. Failure to consistently meet prescribed caloric goals (for >5 days)
4. Failure to wean or need to escalate respiratory support
5. Need for muscle relaxants for >7 days
6. Neurological trauma (traumatic, hypoxic, and/or ischemic) with evidence of dysautonomia
7. Oncological diagnoses (including children with stem cell or bone marrow transplant)
8. Children with thermal injury
9. Children requiring mechanical ventilatory support for >7 days
10. Children suspected to be severely hypermetabolic (status epilepticus, hyperthermia, systemic inflammatory response syndrome, dysautonomic storms, etc.) or hypometabolic (hypothermia, hypothyroidism, pentobarbital, midazolam coma, etc.)
11. Any patient with ICU length of stay >4 weeks may benefit from indirect calorimetry to assess adequacy of nutrient intake

BMI, body mass index; ICU, intensive care unit.

Energy Provision for the Hospitalized Patient

In the critically ill patient, the goal of nutrition support is to provide adequate needs and prevent underfeeding and overfeeding. Multiple complications do occur attempting to convert a catabolic condition in an anabolic state including increased carbon dioxide production, hyperglycemia, hypertriglyceridemia, and fatty liver. Recent studies in critically ill adults indicate worse outcomes occur with low energy intake in patients with either low or very high body mass index. The inability to deliver adequate energy intake, resulting in negative protein–energy balance, has been associated with increased morbidity and mortality rates in adult ICU patients. Cumulative energy deficit also is associated with an increasing number of complications including increased length of ICU and hospital stay.

The magnitude of the stress response and the presence of malnutrition amplify the complications associated with undernutrition in the management of the critically ill patient admitted to the ICU. Nitrogen deficits accrue over short periods of time; therefore, it is important to remember this situation when malnourished patients in the ICU develop an acute metabolic stress response (i.e., sepsis and injury), because the level of nitrogen deficit to be tolerated is less compared to patients with the same level of stress and normal nutritional status; thus, delaying nutrition support in the malnourished patient beyond 5–7 days can potentially increase morbidity and mortality in this population. Another important aspect in the provision of nutrition support to patients admitted to the ICU is the prescription of overnutrition. This excessive nutrition comes as carbohydrates and protein. Hyperglycemia secondary to increased insulin resistance in addition to oversupply of dextrose can impose additional respiratory work with eventual development of fatty liver. Also, excessive amounts of protein in patients with underlying renal disease increase the risk for uremia-associated complications.

Enteral nutrition should be the feeding method of choice in critically ill patients because it replicates the normal pattern of nutrient consumption and hormonal homeostasis, maintains and improves gastrointestinal integrity, and reduces the incidence of multiorgan failure. Early enteral nutrition appears to be well tolerated in the general ICU population and is associated with early attainment of nutritional goals. The impact of early enteral nutrition and optimal energy balance might be most relevant in patients with preexisting malnutrition, who cannot afford added nutritional worsening during the course of the acute illness. Enteral nutrition is preferable to parenteral nutrition, but if enteral nutrition route is contraindicated or not tolerated, parenteral nutrition should be started after patient condition has stabilized. If enteral nutrition is partially tolerated or the rate of advancement is slow and does not cover energy and protein needs, then supplemental parenteral nutrition should be considered.

Recent studies in critically ill patients have found an association between the use of parenteral nutrition and increased morbidity and mortality. Since critically ill patients are highly dependent on substrate availability, have lower reserves, and are at risk of malnutrition, parenteral nutrition should be considered. Current recommendations agree on initiating parenteral nutrition if enteral nutrition has failed or it is contraindicated. If low-volume enteral nutrition is started and is inadequate to cover nutritional needs, supplemental parenteral nutrition should continue and be gradually decreased as enteral nutrition is advanced until full volume of enteral feeds covering nutritional requirements is achieved.

The use of clinical practice guidelines developed by multidisciplinary expert consensus and based on clinical evidence can help to improve nutrition support practices in the ICU. Most recent clinical guidelines for the critically ill patient by the American Society for Parenteral and Enteral Nutrition recommend to provide energy intake equivalent to BMR; this is based on extensive studies that reported measured energy expenditure in the patient admitted to the ICU. Regarding the provision of protein supplementation during periods of stress, current recommendations are to supplement 15–20% of the total nutrient intake to be provided as protein, with protein intakes of 1.5–2.0 g kg^{-1} day^{-1} for adult patients and 1.5–3 g kg^{-1} day^{-1} for infants and children.

The nutritional assessment of critically ill patient upon admission to the ICU should aim to identify those with existing malnutrition, and a tailored and individualized nutritional plan should be implemented in order to prevent underfeeding and overfeeding in these patients. Serial assessment of energy expenditure, by using IC, will guide energy intake and prevent cumulative imbalances. The most important aspect of the provision of nutrition support during periods of stress is the preservation of lean body mass; the amount of lean body mass has been shown to be associated with mortality. There are multiple barriers to the implementation of adequate nutrition with many of these barriers being preventable. Implementation and utilization of clinical nutrition guidelines may help achieve nutrition goals in the hospitalized patient.

Introduction

Energy intakes (EIs) that meet energy requirements (ERs) can in principle be defined from physiological considerations of energy balance. Thus, when EI from food and drink matches total energy expenditure (TEE), there is energy balance with the body neither gaining nor losing energy. This means that either EI or TEE measured at energy balance could form the basis of a reference EI or ER value. In practice, measurement of either EI or TEE is not a simple task.

Energy Content of Foods

Within the International System of Units (SI), the unit of energy is joule (J) and the energy content of food is normally in kilojoule (kJ = 10^3 J) and megajoule (MJ = 10^6 J). The thermochemical calorie is also still widely used especially in the United States and is equivalent to 4.184 J (1 kcal = 4.184 kJ).

Food energy content can be determined in terms of the maximum amount of potentially available energy by measuring the heat released after its complete combustion to carbon dioxide and water in a bomb calorimeter. This is the gross chemical energy content (GE) of all organic food constituents of which the macronutrients carbohydrate, fat, protein, and alcohol account for the main components. However, not all GE from food is available for human metabolism because of losses during food utilization at the level of digestion, metabolism in the intestine, especially in the colon, and postabsorption metabolism. This means that the available energy to the organism, defined as metabolizable energy (ME), is the difference between GE intake and all losses in feces, in urine, a small amount in sweat, and in postprandial increases in metabolism. Energy losses in feces largely represent incomplete digestion and the energy content of bacteria produced in the colon, whereas energy losses in urine and sweat are due primarily to the urea content, which represents the incomplete catabolism of protein. The value quoted as the energy content of foods on food labels and in the food composition tables is the ME content. Historically, the ME content of food was calculated from the amounts of protein, fat, carbohydrate, and alcohol in the food (determined by chemical analysis) using specific energy conversion factors called the Atwater factors, which are estimates of the energy content of each macronutrient and alcohol, numerically rounded for practical purposes. These energy values are 17 kJ g^{-1} (4.0 kcal g^{-1}) for protein, 37 kJ g^{-1} (9.0 kcal g^{-1}) for fat, 17 kJ g^{-1} (4.0 kcal g^{-1}) for carbohydrates, and either a rounded value of 29 kJ g^{-1} (7.0 kcal g^{-1}) or an unrounded value of 6.9 kcal g^{-1} for alcohol. However, there are several issues that complicate the calculation of ME and that can result in differences between agencies in how ME is calculated.

For fat, the GE content will vary slightly according to the chain length and degree of saturation of constituent fatty acids in dietary triglycerides. Also, the ME will be less than the GE because of some loss as fecal fat. In practice, because dietary fat incorporates a mixture of different fatty acids, these differences, which could influence the GE, are ignored, and it is usually assumed that the digestibility is ≈95%. As a result, ME content of dietary fat is assumed to be 95% of GE, that is, 37 kJ (9.0 kcal g^{-1}), the general Atwater factor.

For carbohydrates, there are two complicating factors. Firstly, the GE of carbohydrates in food varies according to their molecular form, that is, glucose, disaccharides, and starch. The GE per unit weight is 15 kJ (3.6 kcal g^{-1}), 16 kJ (3.8 kcal g^{-1}), and 17 kJ (4.0 kcal g^{-1}), respectively. FAO has recommended that a conversion factor of 16 kJ g^{-1} (3.8 kcal g^{-1}) should be used when carbohydrate is expressed as monosaccharide equivalents and 17 kJ g^{-1} (4.0 kcal g^{-1}) when determined by direct chemical analysis of carbohydrate, that is, the general Atwater factor, and in the United Kingdom, this method is used. However, in the United States, carbohydrate is calculated from total dry weight of food minus protein, fat, and ash, and this will include unavailable carbohydrate (i.e., dietary fiber) and other noncarbohydrate components (e.g., lignin, organic acids, tannins, waxes, and Maillard products) in the calculated value. As a result, for a mixed diet, total EIs can be 12% higher and carbohydrate intake 14% higher when carbohydrate by difference is used in dietary analysis compared with available carbohydrate analyzed directly. Thus, estimates of the extent of underreporting in dietary surveys in the United States are often lower than those in the United Kingdom.

Secondly, carbohydrates include nonstarch polysaccharides (NSPs) and resistant starch; these may also provide energy through fermentation in the colon to form short-chain fatty acids. Some of these products are absorbed into the bloodstream or used locally by colonocytes as energy, and a conversion factor of 8 kJ g^{-1} (1.9 kcal g^{-1}) has been suggested by FAO. However, in the United Kingdom, the food composition tables ignore energy from NSPs and resistant starch and assume all carbohydrates are completely absorbed so that the ME is calculated using the general Atwater factor of 17 kJ g^{-1} (4.0 kcal g^{-1}), which is carbohydrate expressed as monosaccharide.

For protein, the GE can vary according to the amino acid content and the ME according to its digestibility and the amino acid content, which determines its nitrogen content and the amount of urea produced and excreted per gram of protein. These differences especially the digestibility can be large so that highly digestible animal proteins like in egg may yield 40% more ME than less digestible plant proteins. In practice, the ME content of dietary protein is assumed to be 17 kJ (4.0 kcal g^{-1}), the general Atwater factor, on the basis of an assumed loss of urinary energy as urea. This will be a relatively accurate value because dietary protein usually represents a mixture of several animal and

plant protein sources. Because the immediate metabolic fate of amino acids absorbed into the body includes deamination and other reactions such as gluconeogenesis that contribute to the postprandial increase in heat production (the thermic effect of food (TEF)), it has been suggested that this should also be accounted for in a value defined as the net metabolizable energy (NME). However, this value is not generally used and the TEF is usually assumed to be part of energy expenditure.

For alcohol, the ME is assumed to be 29 kJ (6.9 kcal)/g consumed, the unrounded general Atwater factor. Alcohol is oxidized completely and does not directly add to body energy stores. There is a component of postprandial thermogenesis following alcohol consumption with reported values ranging between 9% and 28%, but this is not included in the ME.

Energy Intakes

The amount of food energy consumed is assessed as part of national nutrition surveillance in many countries and in the course of many studies of diet and health interactions. However, it is well known that accurate measurement of dietary EI is difficult. Moreover, the extent of the unreliability of the various methods is not as widely appreciated as it should be. There are a number of ways in which food intakes can be measured, and the likelihood that the various methods are accurate can be tested to some extent by modeling intake values with predicted values of TEE to see if the values are physiologically sensible. This comparison is a valid test because on a daily basis, differences between EI and TEE are likely to be small and not usually measureable.

At the national population level, the FAO compiles data on food balance sheets, converted to per capita overall food energy supply. Clearly, this measure is unlikely to be useful in identifying variation in intakes between subpopulations or influences of age, gender, and lifestyle. Furthermore, food wastage at all points in the food supply chain will result in an overestimate of per capita overall food energy supply. This is most likely to have increased over recent decades through wastage, especially at the prehousehold level. An analysis of these data in the United Kingdom shows little change between 1961 and 1990 (at about 13.4 MJ/day/per capita); thereafter, however, this intake increases by 5% to the year 2000, and by a further 2% to 2009, eventually to reach 14.3 MJ/per capita/day. This value is higher than would be expected and modeling shows it to be an overestimate of EIs by about 40%.

At the household level, records of household food purchases adjusted for number and ages of household members enable a better estimate of per capita EI. In the United Kingdom, such records have been collected annually on a complete cross section of the British population from 1950. This is now the Expenditure and Food Survey, a 2-week diary record of all expenditure by each household member over the age of 7 years in about 5000 UK households. Such records are subject to both underestimation through underreporting of purchases and overestimation through food wastage in the home, although attempts are made to minimize the former and account for the latter error. Currently, reported values are 9.58 MJ/per person/day, which are 20–30% lower than values in 1955. This value is slightly lower than the lower range (25th centile) of the predicted current UK all-adult population TEE.

At an individual level, food EIs can be measured directly from questionnaires of food intakes recorded as the frequency of consumption of lists of individual food types, i.e., food frequency questionnaires; recorded as a recall of intakes over the previous 24 h, as dietary records collected over a number of days (e.g., 4–7 days), or most accurately as records of weighed food intakes over periods of up to 7 days. In national surveys such as NHANES (the US National Health and Nutrition Examination Survey) and NDNS (the UK National Diet and Nutrition survey), a balance is struck between likely accuracy and the numbers of subjects who can be studied. Currently, for the UK NDNS, 4-day dietary records are used with annual measurements in a rolling program collecting anthropometric and biochemical measures of nutritional status as well as food intakes. There has been a downward trend in the mean reported daily intakes for total energy for adult men and women from 1987, with the most recent value indicating 7.86 MJ day^{-1}. In fact, this value is much lower (and unphysiological) than would be predicted by simple modeling of likely TEE, almost certainly due to underreporting.

Energy Expenditure as the Basis for ERs

From the earlier, it is quite clear that measurement of EI is exceedingly difficult and unlikely to provide information that can be reliably transformed into dietary reference values (DRVs) for energy. In any case from what is known about the regulation of energy balance, it is clearly more physiologically appropriate to base the derivation of energy reference values on TEE than on EI. This is because, in humans, it appears that EI is finely regulated through the appetite mechanism to enable EI to match TEE, rather than the other way round. TEE comprises the basal metabolic rate (BMR), energy expended at rest in the postabsorptive state and at thermoneutrality, energy expended in physical activity (physical activity energy expenditure (PAEE)), and other components such as postprandial thermogenesis (TEF) and thermogenesis associated with growth. TEE does not appear to include a significant component of regulatory EE responsive to EI, that is, dietary-induced thermogenesis, apart from the heat increment of feeding that is associated in a near stoichiometric way with postprandial metabolism, mainly amino acid oxidation. The diet-related thermogenesis associated with uncoupled fat oxidation in brown adipose tissue mitochondria, which is a feature of rodent metabolism, is not believed to be quantitatively important in humans after the first months of life apart from a small, recently identified component of cold-induced nonshivering thermogenesis. Thus, it is TEE, mainly a function of size (BMR) and lifestyle (PAEE), that can be identified as the physiological determinant of the ER: that is, the ER can be predicted specifically as the rate of TEE plus any additional needs for growth, pregnancy, and lactation.

ERs for What Purpose and for Whom?

Given the context of target populations exposed to an obesogenic food supply and built and social environment, to which it is genetically susceptible, and that have become overweight, all recent definitions of the ER refer to healthy body weights.

For example, in the United Kingdom, the ER is defined as "the amount of food energy needed to balance energy expenditure in order to maintain body size, body composition and a level of necessary and desirable physical activity consistent with long-term good health. This includes the energy needed for the optimal growth and development of children, for the deposition of tissues during pregnancy, and for the production of milk during lactation consistent with the good health of mother and child." This specifically 'prescriptive' approach involves identifying ER values for infants, children, and adults in relation to best estimates of healthy body weights: for children, growth standards and reference weights that are below current UK values and, for adults, a weight associated with a minimum risk of mortality, that is, W equivalent to a BMI of 22.5 kg m^{-2} at actual heights. This is below the current average UK population BMI of 27 kg m^{-2}. Application of ER values derived in this way to under- or overweight groups will tend to mediate weight change toward the desirable range. The question of including within a prescriptive ER, sufficient EI to balance a 'desirable' level of PAEE, is also an important consideration given that much of the population is thought to be sedentary. Achieving this in practice, however, is much more difficult since any advice to overweight populations to consume more energy carries obvious risk. In practice, advice on desirable physical activity is usually given separately including information on the additional energy needed for various amounts of additional PAEE.

In the public health context, ER values can be defined as DRVs for food energy that provide a best estimate of the food energy needs of a population and its subgroups and represent criteria against which to judge the adequacy of their food EIs. For all nutrients other than energy, the DRV is identified as the reference nutrient intake (RNI), a value at the upper bound of the reference ranges, that is, the estimated average reference value (EAR) + two standard deviations, ensuring low risk of deficiency for any individual. However, for dietary energy, the DRV is defined differently: that is, as the EAR, itself; this is because an RNI defined as earlier would represent an excess EI for the majority of the population, leading to weight gain and obesity in the long term. In contrast, the EAR represents an intake associated with similar probabilities of excessive and insufficient EIs for any individual within the population. Because EIs and the requirement are highly correlated by virtue of the appetite mechanism's adjusting EI to match ER, such probabilities are much lower than would be expected, that is, $<50\%$. Thus, in adults, the DRV for energy is the EAR, that is, the intake associated with a healthy body weight at existing height and levels of physical activity. During infancy and childhood, the requirement also has to meet the needs for healthy growth and development, whereas during pregnancy and lactation, the requirement must meet the needs for development of a healthy baby, supporting adequate lactation while minimizing postpregnancy weight gain.

Utilizing Doubly Labeled Water-Derived Measurements of Energy Expenditure to Derive ERs

Measurement of TEE can be achieved by several methods. Short-term measurements under highly defined conditions can be made by calorimetry with direct calorimetry, measurement of heat loss from the subject in a calorimeter, the most accurate method. Indirect calorimetry, the most commonly used approach, measures oxygen consumption and/or carbon dioxide production from which TEE is calculated using standard formulas. The doubly labeled water (DLW) method is generally recognized as the most accurate measure of free-living TEE currently available. The DLW method is a minimally invasive stable isotopic technique of measuring carbon dioxide (CO_2) production in free-living subjects over a period of several weeks. After a measured dose of DLW (i.e., water containing the stable isotopes of hydrogen, ^2H, and oxygen, $^{18}O_2$), samples of saliva or urine are taken over 2 weeks, and the rate of dilution of the two isotopes in these samples is measured. As water is lost from the body, the two isotopes are lost and the enrichment of both ^2H and $^{18}O_2$ falls. However, $^{18}O_2$ in water exchanges with the oxygen in CO_2 because of the carbonic anhydrase reaction such that there is an additional loss of $^{18}O_2$ as $C^{18}O_2$. As a result, $^{18}O_2$ is lost from the body faster than ^2H with the difference providing a measure of the CO_2 production rate. TEE is then estimated from this rate after assigning an energy value to CO_2 calculated from the assumed average respiratory quotient value. This in turn is estimated from the macronutrient composition of the dietary intake. The method provides more accurate measures of TEE than other noncalorimetric methods such as heart rate monitoring and has dramatically improved our understanding of human energy expenditure.

However, making use of DLW-derived data is not straightforward with either of two main approaches that can be employed. The first involves a definition of the ER in which TEE is expressed in a factorial way. TEE can be considered as comprising three components, BMR, TEF, and PAEE. With TEF assumed to be about 10% of EI, then for subjects at energy balance (TEE = EI), $TEE = BMR + 0.1 \times TEE + PAEE$. However, PAEE will vary not only with the extent of physical activity but also as a result of body weight. Thus, an alternative way of expressing TEE is to normalize it for the BMR assuming this captures influences of weight age and gender by expressing it in terms of multiples of the BMR as the physical activity level (PAL), that is,

$$ER \equiv TEE = PAL \times BMR$$

BMR is predictable with adequate accuracy from anthropometric variables (weight, age, height, and gender). PAL is assumed to include just PAEE although any TEF will also be included. In the past, PAL has been derived from time-allocated lists of activities for which energy costs are known and PAL values or ranges have been identified that equate to lifestyles. Thus, in free-living populations, PAL can range from <1.3 in immobile subjects to between 3 and 4.7 for limited periods of time in soldiers on field exercises or elite endurance athletes, for example. Within the general population, however, the overall range of PAL values for individuals in energy balance and leading sustainable lifestyles is between 1.38 for the most sedentary and 2.5 for the most active. TEE can be predicted from BMR and a lifestyle-related value of PAL. DLW data can identify PAL values in population groups. In this case, BMR can be measured separately or predicted so that the values for TEE determined by the DLW method can be expressed in terms of PAL. This has allowed a much better understanding of the range and variation in PAL as a function of lifestyle.

The second approach models the DLW-derived TEE values against anthropometric characteristics of the reference population in regression equations, allowing TEE and ER values to be predicted for population groups: for example, children or adults. However, regression modeling does not easily allow for inter- and intraindividual variation in PAEE. Because of this, committees using this approach have had to make provision for the likely variation in PAEE within the population group by introducing multilevel ordinal variables derived from PAL data in the regression model to modify the total height and weight contribution to TEE.

Limitations of the Factorial Model of TEE

The increasing amount of reported DLW measurements of TEE has in fact allowed a detailed analysis of the various factorial models, which have all been shown to be unsatisfactory in terms of being able to predict TEE of population groups according to their lifestyles. This is because values predicted for individuals or groups according to their lifestyles do not correspond well with measured, DLW-based values. In fact, most DLW or whole body calorimeter studies show considerable variation in TEE between individuals involved in similar activities. A likely explanation for this is indicated by 24 h calorimeter and DLW studies showing a wide variation in PAL values (from 1.15 to 1.7) in subjects with restricted activity. Furthermore, these 24 h values correlate with free-living DLW-measured PALs (1.35–2.15). Such observations have led to the development of the concept of spontaneous physical activity (SPA). SPA is body movements associated with activities of daily living, change of posture, fidgeting, and 'a propensity for locomotion.' SPA is a highly reproducible, within-individual familial trait; it accounts for a considerable fraction of between-individual variation in TEE and displays an inverse relationship with future weight gain. Nonexercise activity thermogenesis is another term used to describe a somewhat extended definition of this phenomenon. Other individuals have been identified who exhibit marked reductions in activity, that is, to levels approaching the BMR, after periods of intense activity. The extent and variation in SPA, currently not quantifiable within population groups, calls into question the predictability of PAL from lifestyle information as currently collected, especially with the precision previously assumed.

A New Approach to the Factorial Model

The recent UK report on energy DRVs adopted an alternative approach to the use of PAL values in the definition of TEE and the ER of target population groups. In this report, it was concluded that when there are sufficient DLW measurements of TEE available for a particular population group to enable it to serve as a reference, the most useful information is the distribution of PAL values within that reference population. The assumption is made that the reference population groups are sufficiently demographically similar to the target population and that the DLW data are extensive enough and representative of the reference population. In this case, the distribution of PAL values observed in the reference population in terms of 25th, median, and 75th centiles can be used to predict TEE and hence the ER as a function of BMR for the less active, average, and more active members of the target population group. The principle is shown in Figure 1. The restriction of the range of ERs to just three values is clearly a major departure from previous approaches for adults. However, in most cases only the median population value will be used. It is in principle similar to the method adopted by FAO in their recommendations for children. However, it is an approach that recognizes the reality that prediction of rates of TEE for individuals or population groups is inherently uncertain and that, in practice, most health professionals use a very restricted range of ER values.

Identifying Suitable PAL and EAR Reference Values for Adults

Identifying reference, DLW-derived PAL values is difficult because most published studies contain only small numbers of subjects recruited in various ways for various reasons, that is, not necessarily representative. For example, in a recent meta-analysis of DLW data of adults, 4971 individuals were identified. However, these subjects derived from 183 cohorts with a median cohort size of only 14 and with only 10% having >70 subjects. If few of the individual cohorts are representative of the general population, then it cannot be assumed that combined data sets will be representative either. In contrast, DLW studies of energy expenditure have been reported for two large, randomly selected, urban-population cohorts, with a combined population of 929 men and women aged 30–69 years. The two study populations were quite similar, both being recruited from the Washington, DC, metropolitan area. They were judged to be a reasonable match to the UK population in terms of the extent of overweight and obesity (mean BMI values of 27.2 kg m^{-2}: current UK values 27 kg m^{-2}) and ethnicity. PAL was evaluated for the whole cohort and the median and distribution of PAL values within each cohort did not differ and were not influenced by gender. For the combined cohort ($n = 929$), the distribution, shown in Figure 1, was skewed, with subjects clustered at the lower end of the range. PAL values of 1.49, 1.63, and 1.78 were identified for the 25th, median, and 75th centiles, corresponding to sedentary, low, and moderate activity. Neither median value nor distribution of PAL values for BMI categories differed significantly, and the regression of PAL on BMI was nonsignificant ($p = 0.64$ for slope: $R^2 < 0.1\%$). This suggests that with increasing BMI, the decrease in extent of PAEE is matched by its increasing energy cost. PAL fell slightly with age, although age explained only 0.4% of the variance, that is, falling from PAL values of 1.69 at 30 years to 1.63 at 70 years. Although the minimum age was 30, PAL values of the youngest subjects aged ≤35 years did not differ from those aged >35 years suggesting that the lack of 18–30 years of age is unlikely to represent a significant source of bias when the data set is used to represent PAL values for all adults. Derived EAR values for adult men and women are shown in Table 1.

Identifying Suitable PAL and EAR Reference Values for Infants, Children, and Adolescents

For infants, most recent committees have calculated energy reference values from the energy deposited in new tissue plus TEE. The energy costs of tissue deposition have been calculated

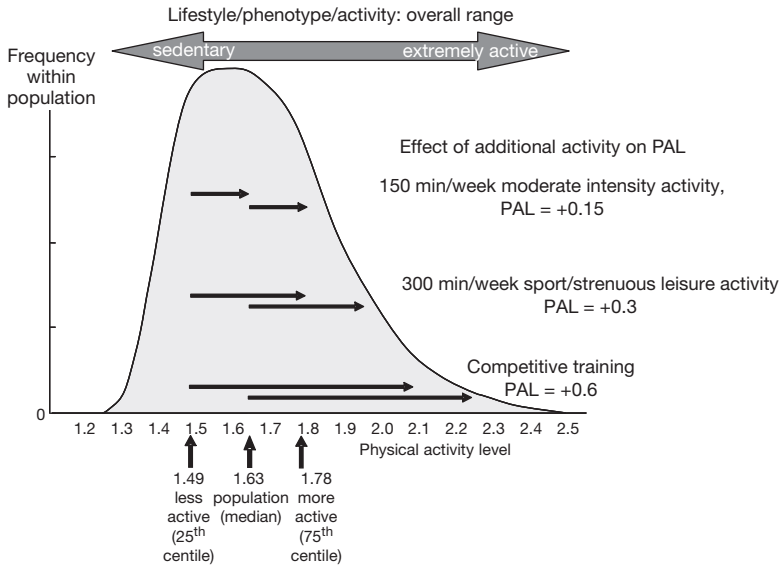

Figure 1 Schematic representation of energy expenditure and consequent energy requirements of the adult population as a function of the physical activity (PAL) value. From the UK report Dietary Reference Values for Energy 2011, Scientific Advisory Committee on Nutrition London TSO 2012. The distribution of PAL values is that of the reference population identified as appropriate to define the UK dietary reference values for energy. The likely increases in PAL (and consequent energy needs) shown for various activities include the current UK recommendations that adults participate in at least 150 min of moderate intensity activity per week: an increase in PAL of 0.15. These increases in activity are shown as they would affect initial PAL values at the 25th centile and median values, with the increases indicated by the length of the arrows. Although for those with PAL values at the 25th centile, the recommendations for increased activity will only increase PAL to the median level, this can still be expected to have health benefits. The increases shown are only approximate. They will vary to a small extent with the initial PAL, that is, with the intensity of the activity replaced, and will be slightly less than the values shown, especially for subjects with high initial PAL values. The equivalent values in terms of energy are shown in **Table 1**.

Table 1 Estimated average energy requirements for adults (MJ day^{-1})

				EAR values (MJ day^{-1})		
	Height (cm)	*Weight (kg)*	*BMR (MJ day^{-1})*	*Less active*	*Population*	*More active*
Men	175	69.2	6.7	10.0	10.9	11.9
+30 min moderate intensity activity, 5 days per week: +PAL = 0.15					+1	
+60 min active sport five times per week: +PAL = 0.30					+2	
+intense aerobic exercise in competitive training: +PAL = 0.60					+4	
Women	162	58.7	5.4	8.0	8.7	9.5
+30 min moderate intensity activity, 5 days per week: +PAL = 0.15					+0.8	
+60 min active sport five times per week: +PAL = 0.30					+1.6	
+intense aerobic exercise in competitive training: +PAL = 0.60					+3.2	

Values shown for illustration are prescriptive aimed for a healthy body weight equivalent to a BMI of 22.5 kg m^{-2} at mean adult heights for the UK population. BMR is calculated from the Henry prediction equations (Henry, C. J. (2005) Basal metabolic rate studies in humans: measurement and development of new equations. *Public Health Nutrition* **8**:1133–1152), based on weight, age, sex, and height. EAR values calculated as BMR × PAL where PAL = 1.49 (less active), 1.63 (population), and 1.78 (more active). Also shown are additional daily energy needs associated with the selective amounts of increased activity shown in **Figure 1**.

Source: Values derived from the UK report, Dietary Recommendations for Energy 2011, Scientific Advisory Committee on Nutrition London TSO 2012.

from an analysis of the body composition of healthy infants during normal growth. Longitudinal DLW studies of TEE over the first 2 years of life have been performed in healthy, well-nourished, nonstunted infants, born at full term with adequate birth weight, who have been either breast-fed or formula-fed. These measurements have allowed the development of simple prediction equations for TEE as a function of weight for breast-fed, formula-fed, and mixed-fed infants, in the latter case by predicting TEE values intermediate between the breast-fed and formula-fed values. EAR values for energy have then been calculated from the sum of TEE and energy deposition for breast-fed, formula-fed, or mixed-fed infants. For the United Kingdom, EAR values are calculated from weights of children growing along the trajectory of the UK-WHO Growth Standards. Although it is recognized that exclusive breast-feeding is highly unlikely to continue beyond the recommended first 6 months of life, in most recent reports, EAR values have been calculated by this model for the first 12 months of life for each mode of feeding (adopted during the first 6 months) and tabulated for boys and girls at monthly intervals. This is because after 12 months, a different calculation of the EAR is used as described later. For boy infants, EAR values increase

from 2.03, 2.36, and 2.17 MJ day^{-1} for breast-fed, formula-fed, and mixed-fed infants at 1 month to 3.2, 3.3, and 3.25 MJ day^{-1} at 12 months, respectively. For girl infants, EAR values increase from 1.82, 2.16, and 1.97 MJ day^{-1} for breast-fed, formula-fed, and mixed-fed infants at 1 month to 2.91, 3.05, and 2.98 MJ day^{-1} at 12 months, respectively.

For children and adolescents, the same principle used to derive EAR values for adults is used based on TEE derived from PAL × BMR. However, because of potential changes in age in both body composition and behavior that may influence TEE, the starting point for derivation of EAR values is an analysis of changes in PAL with age for boys and girls. In fact, while there are a large number of published DLW studies of infants, children, and adolescents, not all of them allow individual PAL values to be calculated, and most of the studies involve small numbers (average $n = 20$). Thus, only a limited analysis of the distribution of PAL values at each age and each gender can be performed. In fact, PAL values were obtained for 170 studies (3502 individual measurements, 2082 females, and 1420 males), with reported values for every age from 1.5 to 18 years allowing mean study values for boys and girls to be examined as a function of age, as shown in Figure 2. PAL values were not influenced by gender, but did increase with age; this effect is driven by low values for preschool children and some groups of preadolescents. As a result, all studies were grouped into three age categories ≤3, >3 to <10, and 10–18 years. Whether this age increase in PAL is a physiologically or behaviorally real phenomenon once children enter schooling is not clear since several studies of children aged 5–10.5 years show individual PAL values that vary markedly (e.g., from 1.19 to 2.34). It is possible therefore that schoolchildren from a very early age exhibit a similar very wide range of activities and PAL values as observed in adults.

EAR values for children also include the cost of energy deposition during growth, which is substantial in the first year of life, tapering off thereafter. Thus, for preschool children, schoolchildren, and adolescents, growth costs are much less, and the energy deposited can be accounted for by a simple +1% adjustment of PAL (PAL × 1.01), which results in acceptably low levels of error. This resulted in adjusted median PAL values for the three age groups of 1.40, 1.58, and 1.75. These values were used to define the population EAR values of children as a function of BMR predicted for age, weight, height, and gender. Population EAR values for energy as a function of age are shown in Figure 3. The gender differences reflect the slightly higher BMR values for boys due to differences in weight and body composition.

Energy Reference Values for Pregnancy

It is customary to calculate the ERs for pregnancy and lactation as increments to be added to the mother's EAR. Ideally, women should begin pregnancy at a healthy body weight, and this raises the question as to whether ER values for pregnant women should be calculated as for nonpregnant women on their healthy body weight (i.e., a BMI of 22.5 kg m^{-2}) or on their actual body weights. It is the case that women who are overweight or underweight at the beginning of pregnancy are at risk of poor maternal and fetal outcomes, although this is not completely understood. Because of this uncertainty, it is usual practice to adopt a precautionary approach and not to make ER recommendations aimed at weight loss for

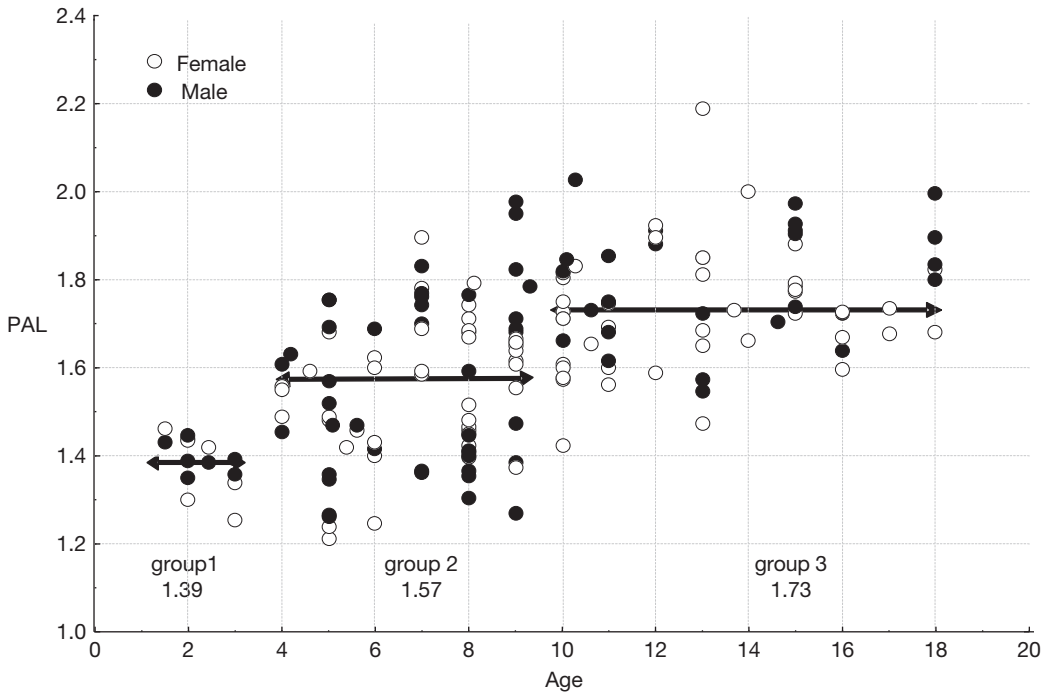

Figure 2 PAL values for energy (MJ day^{-1}) for infants, children, and adolescents. From the UK report Dietary Reference Values for Energy 2011, Scientific Advisory Committee on Nutrition London TSO 2012. Median values for the indicated age ranges are shown. Each point represents a single age group reported in a single publication or in publications, which list mean values for each of several age groups. Boys and girls are shown separately.

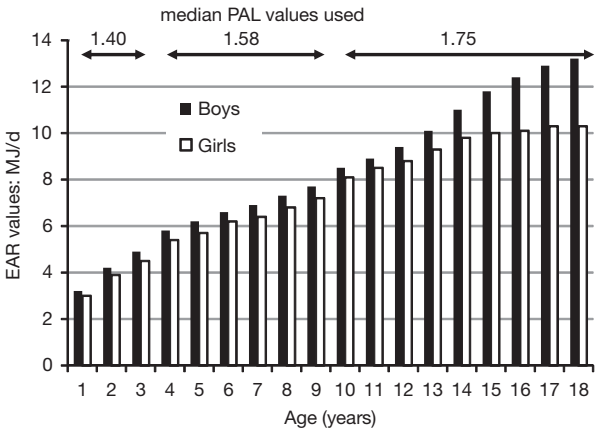

Figure 3 EAR values for energy (MJ day^{-1}) for infants, children, and adolescents. Values derived from the UK report Dietary Reference Values for Energy 2010, Scientific Advisory Committee on Nutrition London TSO 2012. Values are calculated from BMR × PAL values shown for the various age groups and are prescriptive values calculated for healthy weights at each age. PAL values are median values for the published DLW data. BMR values are calculated from the Henry equations (reproduced from Henry, C. J. (2005). Basal metabolic rate studies in humans: measurement and development of new equations. *Public Health Nutrition* **8**, 1133–1152), using weights and heights indicated by the 50th centiles of the UK-WHO Growth Standards (ages 1–4 years) and the UK 1990 reference for children and adolescents (Royal College of Paediatrics and Child Health (2011) UK-WHO Growth Charts: early years. Available at http://www.rcpch.ac.uk/growthcharts).

overweight pregnant women. For this reason, the recent UK report identified EARs for pregnancy and lactation as estimates of the incremental EIs likely to be associated with healthy outcomes for mother and child that should be added to EAR values calculated at actual preconceptional body weights.

As to the amount of extra food energy required for pregnant women, the key issue is that of identifying the extent to which the demands for gestational weight gain (GWG) due to growth of the products of conception and of maternal weight can be met by adaptive physiological and behavioral changes of the mother as opposed to increased dietary EIs. A balance needs to be struck between allowing for optimal fetal growth and avoiding the excessive weight gain likely to occur with overestimates of energy needs. In this context, the recent UK report concluded that, in general, it is unlikely that women require extra energy in the first trimester of pregnancy and compensatory reductions in PAEE during the second and third trimesters are likely to reduce the demand for extra EI at this time. Furthermore, although careful studies of energy expenditure and deposition indicate an apparent need for additional energy, such calculations include maternal fat deposition, which is not a determinant of birth weight. Indeed, on the one hand, longitudinal body composition studies have indicated that some fat deposition remains 6 months postpartum and may contribute to weight gain in women through successive pregnancies. This is undoubtedly undesirable. On the other hand, there is strong evidence that inadequate GWG is associated with decreased birth weight and fetal growth (small for gestational age). Recommendations for constraining weight gain may also be inappropriate for pregnancies in vulnerable groups such as teenagers. On this basis, it was concluded that the EAR for pregnancy should be limited to an additional intake of 0.8 MJ day^{-1} (191 kcal day^{-1}) during the last trimester.

Energy Reference Values for Lactation

The energy needs for lactation can be calculated from DLW measurements of energy expenditure and the amounts and composition of breast milk and estimated energy mobilization from tissue stores. On the basis of a milk energy output of 500 kcal day^{-1} and an average weight loss of 0.8 kg month^{-1}, which is equivalent to 170 kcal day^{-1}, this would imply the need for an increment of 330 kcal day^{-1} (or 1.38 MJ day^{-1}) for the first 6 months during which time exclusive breast-feeding is recommended.

After the first 6 months, the energy cost of lactation will depend on the amount of breast milk consumed by the infant, which is likely to be diminishing. The need for additional maternal EI will also be modified by maternal body composition, so recommendations for additional intakes are generally not identified for this period of the infant's life.

Conclusion

Historically, reference values for dietary food energy needs developed from crude observations of food EIs to an assumed detailed and extensive understanding of the energy costs of human activities. However, the advent of DLW studies of actual energy expenditure has revealed that the assumed ability to predict accurately the energy needs of individuals or population groups with certainty was overly optimistic. Because of this, the most recent national report has markedly simplified the estimation of energy needs identifying only three activity levels for any population group. These are a population EAR value based on a PAL value of 1.63 and BMR at weights equivalent to a BMI of 22.5 kg m^{-2} at individual heights. Given that for UK men and women, mean heights are 175 and 162 cm, respectively; this equates to 10.9 (2605) and 8.7 (2079) MJ day^{-1} (kcal day^{-1}), respectively, as shown in Table 1. For the chronically ill or for immobile elderly men and women, a lower PAL value is appropriate with the 25th centile PAL value (PAL = 1.49), corresponding to ER values of 10.0 (2393) and 8.0 (1915) MJ day^{-1} (kcal day^{-1}). For men or women responding to advice to generally increase activity, the 75th centile PAL value (PAL = 1.78) is more appropriate and corresponds to ER values of 11.9 (2848) and 9.5 (2274) MJ day^{-1} (kcal day^{-1}).

In each case, these values are prescriptive in terms of supporting a healthy body weight. Thus, for the overweight or obese, that is, the majority of the UK population, the population ER values are less than weight-maintaining EIs and should allow for some degree of weight loss. However, the recommendations are not prescriptive in terms of physical activity although the extent to which PAL values will be higher for those specifically engaged in additional physical activity can be predicted as shown in Figure 1, with daily energy increments shown in Table 1. Thus, for those engaged in 30 min of moderate, intensity activity for 5 or more days of the week, 60 min of active sport five times per week, or intense aerobic

exercise associated with training for competitive sport, the ER will increase by an amount equivalent to 0.15, 0.3, or 0.6 PAL units, respectively. Importantly, the principle of a reference population distribution of PAL values as the basis for EAR values allows for simple updates as appropriate DLW data accumulate.

Enteral Feeding

DL Waitzberg and RS Torrinhas, University of São Paulo, São Paulo, Brazil

© 2016 Elsevier Ltd. All rights reserved.

Definition

Enteral nutrition (EN) can be defined as a set of therapeutic procedures applied to solely or partially replace or supplement oral feeding for maintenance or recovery of nutritional status of malnourished or eutrophic patients in hospital, ambulatory or home settings, through the enteral (gastrointestinal tract) administration of commercial or noncommercial diets composed by controlled predefined or estimated amount of isolated or combined nutrients and specially formulated and developed for use by enteral probes or oral intake, aiming at the synthesis or maintenance of tissues, organs, or systems.

Relevance

EN is part of specialized nutritional therapy, which also includes parenteral nutrition (PN) (endovenous nutritional supply). Its main relevance is to restore or maintain the nutritional status of patients in order to prevent malnutrition. It has long been known that malnutrition is associated with increased morbidity and mortality in hospitalized patients.

Both EN and PN allow achieving the protein-calorie requirements and the minimum daily requirement of vitamins and minerals. When the gastrointestinal tract is structurally and functionally intact, it is preferred to use EN. When you cannot reach 60% of caloric needs by EN, we must consider the associated use of PN.

There are metabolic, safety, cost/benefit, and mainly physiological benefits when providing EN. The supply of nutrients through the digestive system maintains intestinal anatomy and its natural microbiota. These benefits allow the improvement of the intestinal immune system and the decrease of infectious complication risk in surgical patients.

Indications

EN should be indicated in situations in which the digestive tract is fully or partially functional and when oral intake is insufficient to reach two-thirds to three-quarters of the daily nutritional needs, mainly in malnutrition conditions. The main indications for EN use are listed in Table 1. In the other hand, EN is relative or temporarily contraindicated in some conditions, such as gastrointestinal tract obstruction, diarrhea and vomiting refractory to drug therapy, short bowel syndrome with severe malabsorption, severe paralytic ileus, high-output intestinal fistulas, massive bleeding from the gastrointestinal tract, severe malabsorption syndrome, and inability to access gastrointestinal tract.

Planning

Route of Feeding

After the indication of the route of feeding, the time by which EN will be required should be estimated to then proceed with the best access choice. Particularly for surgical patients, the estimate must comprise the time of pre- and postoperative or perioperative (both) nutrition. At least 10 days of preoperative EN are associated with improved nutritional status in moderate malnourished patients. However, patients with severe malnutrition associated with other clinical comorbidities may require longer EN treatment, particularly those with benign diseases.

Short-term EN (less than 6 weeks) is achieved using a nasogastric feeding tube (in gastric, duodenal, or jejunal position). Insertion of nasogastric feeding tubes in gastric or postpyloric position can be done manually or with endoscopic or fluoroscopic assistance and at the bedside in most cases. Although rare, complications can occur during the passage of a nasogastric feeding tube, such as pneumothorax, empyema, mediastite, esophageal perforation, bleeding and gastric perforation, injury to teeth, tracheobronchial injury, and arrhythmias.

For long-term EN (more than 6 weeks) gastric or jejunal nutrition ostomies are preferred. Gastrostomy and jejunostomy nutrition can be performed through open or percutaneous surgery using endoscopic, radiological, or laparoscopic techniques. Planning for the nomination and selection of the EN access is provided in Scheme 1.

After the choice of a nasogastric feeding tube or ostomy, it should be decided where the distal end of the feeding tube will be placed in gastric or intestinal position. Gastric access can be obtained with nasogastric or gastrostomy and the postpyloric access through nasojejunal feeding tube, gastrojejunostomy, or jejunostomy. Some criteria applied to determine the placement of a nasogastric feeding tube include the speed of gastric emptying, gastroparesis, use of drugs inhibiting gastric and digestive motility, and risk of pulmonary aspiration.

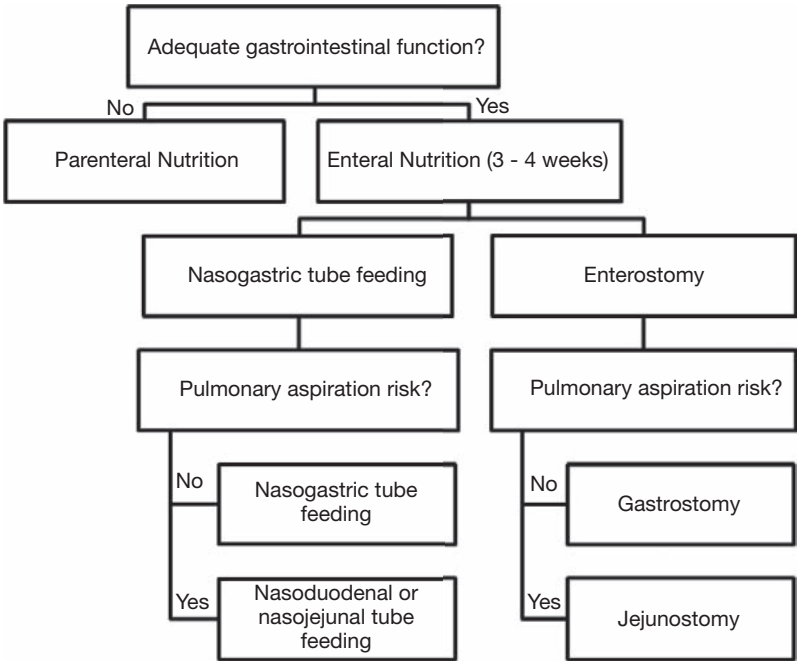
Formulation

The EN can be administered intermittently or continuously. Selection of pathway for EN administration and the type of infusion to be adopted will influence its formulation design. This also involves determining the total period for diet administration, the volume to be infused, infusion rate, if gravity drip will be used, and in which form it will be provided (infusion pump or by bolus). Table 2 outlines the programming of EN according to feeding tube positioning in pre- or postpyloric location.

Enteral formulations should be nutritionally complete when used as exclusive nutrition or as a supplement to patients with normal oral ingestion; or nutritionally incomplete when

Table 1 Enteral nutrition indication for adult patients

Clinical setting	*Recommendation*
Cancer	Less than 60% of energy needs intake for 5 consecutive days
	Dysphagia
Elderly	Severe neurologic dysphagia
	Emotional depression at hyporexia phase
	Contraindicative for terminal dementia
Surgery	High nutritional risk (5–7 preoperative days)
	Head and neck cancer (early – 24 h postoperative)
	Gastrointestinal cancer (early – 24 h postoperative)
	Severe trauma (early – 24 h postoperative)
	Malnutrition at the surgery period (early – 24 h postoperative)
	Insufficient oral intake to achieve basal energy expenditure for more than 10 postoperative days (early – 24 h postoperative)
Heart disease	Loss of body weight (6%) in 6 months (heart cachexia)
Crohn disease or ulcerative colitis	Nutritional supplementation higher than 600 kcal day^{-1} (consider)



Scheme 1 Planning for indication and pathway selection of enteral nutrition.

used only as a supplement nutrition. The evaluation of the digestive and absorptive capacity of the patient should be performed for better enteral formula selection (Scheme 2).

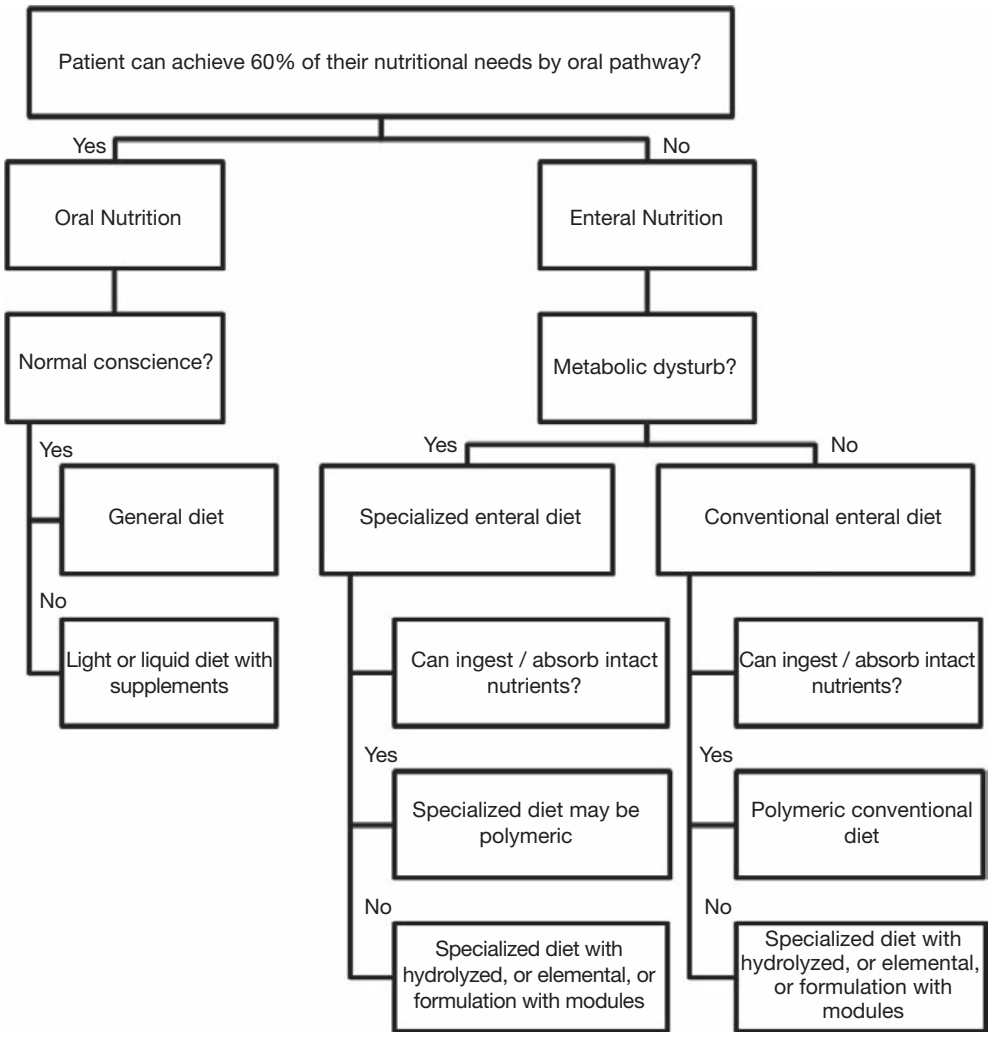
Several enteral formulations are based on fresh food, processed food, or both fresh and processed food. Therefore, nutrients comprising EN are generally the same constituents of a normal diet, consumed by the oral route, including carbohydrate (40–60% total energy needs), protein (14–20% total energy needs), fat (15–30% energy needs), and fiber (40–20 g l^{-1}). Different factors should be considered to facilitate the choice of the most appropriate enteral formulation for patients with EN indication, such as caloric density, osmolarity and osmolality, administration pathway, source and complexity of nutrients, and disease.

The EN caloric density (kcal ml^{-1}) should be based on the patient's total calorie needs versus the volume of enteral diets to be administered per day. Enteral diets with higher energy density have a lower amount of water, which can range from 690 to 860 ml l^{-1} diet. The categorization of enteral formulas, according to its energy density, is shown in Table 3.

Vitamin and mineral supply varies according to the specific needs of the patients and their disease. In the specific nutritional needs, you should evaluate the indication of additional micronutrient supplementation, even when the formulation, per se, achieves those values recommended by the Recommended Dietary Allowance (RDA). Clinical nutritional patient evaluation should include objective and/or subjective indicators to identify, as early as possible, any risk of specific

Table 2 Programming of EN according to feeding tube positioning

Tube feeding position	*Volume*	*Osmolality*	*Fractionation*	*Administration time*
Stomach	Allows high-volume supply	Hyperosmolar solutions are tolerated, but the higher solution osmolality the slower stomach emptying	Depends on the total volume/day and patient tolerance. Lower fractionation (four to six times per day) and higher volume in each supply may be used	About 120 drops per min (or time (min) = total volume (ml)/6) from the beginning of therapy
Postpyloric	During intermittent supply, the volume should not exceed 300 ml h^{-1} in adapted patients	Better tolerance for formulations with less than 550 mOsm l^{-1}; dripping of hyperosmolar solutions should be strictly controlled by using infusion pump	Continuous or intermittent fractionation, generally between six and eight supplies per day in each 3 h	Initial phase: 60 drops/min (or time (min) = total volume (ml)/3); 'adapted' phase: 120 drops per min (or time (min) = total volume (ml)/6)



Scheme 2 Planning for selection of enteral diets.

micronutrient deficiency for it to be immediately corrected and/or prevented.

Some specialized and very specific formulations to particular clinical situation (e.g., renal failure) are insufficient in some vitamin and mineral supply. Therefore, EN dietary planning attends to the need for supplementation or not of these micronutrients. For the long-term use of incomplete enteral feeding, the supplemental vitamins and minerals should be indicated.

Table 3 Categorization of enteral formulas according to its energy density

Energy density	*Value (kcal ml^{-1})*	*Formula*
Very low	<0.6	Sharply hypocaloric
Low	0.6–0.8	Hypocaloric
Standard	0.9–1.2	Normocaloric
High	1.3–1.5	Hypercaloric
Very high	>1.5	Sharply hypercaloric

In patients with malabsorption syndromes, investigate the possible fat soluble vitamins (A, D, E, and K) deficiency to correct it shortly. There is a lack of specific vitamin and mineral recommendations for critically ill patients. However, in such a condition, the needs of antioxidant nutrients are increased due the oxidative stress, and it is recommended to supplement vitamins A, C, and E, zinc, and selenium.

EN osmolality (mmol l^{-1} solution) and osmolality (mOsm kg^{-1} water) are associated with its digestive tolerance. Although the stomach tolerates diets with higher osmolality, more distal portions of the gastrointestinal tract respond better to isosmolares formulations. Therefore, hyperosmolar diets infused by gastrostomy or nasogastric feeding tube have better digestive tolerance when compared with administration by postpyloric or jejunal probes.

The nutrients that most affect the osmolality of a solution are simple carbohydrates (mono- and disaccharides), which have greater osmotic effect than the higher molecular weight carbohydrates (starch); minerals and electrolytes, due the property of its dissociation into smaller particles (e.g., sodium, potassium, and chloride); hydrolyzed proteins; crystalline amino acids; as well as medium-chain triglycerides, because they are more soluble than long-chain triglycerides. The more hydrolysates components contains the formulation, the higher its osmolality.

Enteral diets should not exceed the value of the renal solute load tolerated by the kidneys (800–1200 mOsm, in normal situation). Renal solute load can be calculated by adding 1 mOsm for each mEq of sodium/potassium/chloride, and 5.7 mOsm (adults) or 4 mOsm (children) for each gram of protein from its formula. Special attention should be given to critical clinical situations, such as sepsis, postoperative, polytrauma, and severe burn, where the urine becomes very dense, with high osmolality (around 500–1000 mOsm kg^{-1}), even under appropriate hydration.

Importantly, the influence of the medication osmolality is usually neglected. The mean osmolality of liquid medications administered orally or by feeding tube ranges from 450 to 10 950 mOsm kg^{-1} water. Certain manifestations of gastrointestinal intolerance may be related to the medication, although it is often attributed to enteral formulation.

In specific clinical situations, there may be demands for change in the types of nutrients used; the quantity and/or form these should be presented. In such cases, nutritional therapy becomes more specialized. These adaptations involve changes from simple source of nutrients used until its physicochemical and structural modifications. Thus, specialized formulations for enteral use may provide different sources of vitamins, minerals, carbohydrates, lipids, and proteins, and these nutrients may be presented in their entirety or hydrolyzed (wholly or partly) structure.

Some specialized EN formulations are part of immunonutrition. The immunonutrition is a nutritional intervention that explores the particular activity of various nutrients in alleviating inflammation and modulating the immune system, in which are included the omega-3 fatty acids, arginine, glutamine, nucleotides, and antioxidants. There is a current consensus that perioperative immunonutrition can beneficiate elective surgical patients, especially those malnourished patients submitted to major gastrointestinal surgery. In these patients, administration of enteral diets containing n-3 PUFA, nucleotides and arginine contributes to decrease postoperative infectious and noninfectious complications and must be initiated 5–7 days preop (500–1000 ml day^{-1}) and maintained in the postoperative period.

Although the benefit of using this enteral formula combining different nutrients with immunomodulatory functions is well established in surgical patients, data are lacking to confirm or guide the effective and safe use of enteral diets containing isolated immunonutrients in different clinical populations, including arginine and glutamine. In hemodynamically stable condition, arginine may offer immunologic and metabolic benefits, but its participation in the synthesis of nitric oxide may constitute a potential risk for septic patients. Enteral glutamine should be considered to treat burn patients and trauma victims, but there is not sufficient evidence for its use in critically ill patients with failure of multiple systems.

Other nutrients that may compose specialized EN formulations include the branched chain amino acids (BCAAs). BCAAs provide primary fuel for skeletal muscle during stress and sepsis. Therefore, leucine, isoleucine, and valine may be added to specialized EN formulas as supplemental metabolic sources to attend the metabolic needs of skeletal muscle during hypermetabolic conditions.

Administration

EN should be initiated as soon as possible to prevent intestinal atrophy and its associated complications (mainly infection) due the lack of nutrients, a concept known as early EN. In critically ill patients, EN should be started within the first 24–48 h after admission. Under the metabolic point of view, the use of early EN can prevent excessive secretion of catabolic hormones by inhibiting the increase in serum cortisol and glucagon and maintain nutritional status to prevent loss of body weight and muscle mass and negative nitrogen balance.

However, the benefits of early EN do not extend to all patients, and its efficient use is restricted by the need for hemodynamic stability and adequate tissue perfusion and visceral oxygenation. Therefore, some clinical conditions, such as paralytic ileus, abdominal distention, nausea, and vomiting, may hinder the selection of potential candidates to benefit from early EN. The points that limit the indication of early EN remain to be clearly defined, with consensus and controversy points, which can give rise to different clinical behaviors.

When the nasogastric feeding tube is placed in the stomach, the concern about the dose and infusion rate is not so relevant due the local adaptation mechanisms. Intermittent gastric administration (30–60 min each one) can be initiated with the volume of 60 ml in its total concentration and progress up to 250 ml each four hours, respecting tolerance and nutritional purpose; whereas continuous infusion can be initiated

with the volume of 10–40 ml h^{-1} in its total concentration and progress from 10 to 20 ml every 8–12 h, as tolerated.

For postpyloric (duodenum or jejunum) access, attention must be increased because fast dripping can cause colic and diarrhea, with decreased caloric use and patient injury. With the technique of continuous duodenal infusion, the dose and rate to be employed correspond to those described for the intragastric placement, with the difference that the concentration of the diet should be iso- or hypotonic.

Monitoring

Nasogastric or by ostomy feeding is associated with mechanical, gastrointestinal, infectious, pulmonary, and otorhinolaryngologic complications, which is prevented or treated by monitoring patients appropriately. Aspiratory pneumonia is considered the most serious complication in EN. It can occur due to excessive diet supply, delayed gastric emptying (with potential risk for neurological disability of the reflex mechanisms for vomiting protection) and paralytic ileus.

Aspiration of gastric residue may be useful to evaluate its emptying and to avoid the risk of regurgitation and aspiration, despite a lack of consensus for its routine use. For gastric residues larger than 200 ml (nasogastric feeding tube) or than 100 ml (gastrostomy) associated with abdominal discomfort and distension, the EN must be must interrupted and the patient clinically and radiologically investigated. When not associated with digestive symptoms, it is recommended to delay the diet for an hour and reassess the gastric residual volume. Some drugs, such as erythromycin, metoclopramide, bromopride and donperidona can be used to accelerate gastric motility.

Among the EN-associated complications, diarrhea diagnosed by three or more liquid bowel movements per day also takes a prominent position. Specialized anamnesis can be useful for the differential diagnosis of diarrhea during EN to exclude other potential etiologies, such as infectious and/or inflammatory gastroenterocolites.

Conclusion

As part of specialized nutritional therapy, EN is not free of complications, but its use ensures the maintenance of the intestinal anatomical integrity, tropism, and natural microbiota that would be impaired when providing PN. Moreover, considering that the gastrointestinal tract and liver process the nutrient before its reaching the systemic circulation, EN is very effective for maintaining the homeostasis of amino acids pool, as well as the muscle mass. Currently, EN is preferred to PN because 'when the gut is functioning and can be used, it should be used,' and it is extensively applied around the world to effectively maintain or reestablish patient nutritional status. Furthermore, EN-related complications may be avoided or minimized through the adequate nutritional planning (including suitable choice of enteral access and placement, administration form, and formulation design) and strict patient monitoring.

Enzymes: Analysis and Food Processing

T Haertlé, FIP, BIA, INRA BP, Nantes, France

© 2016 Elsevier Ltd. All rights reserved.

Proteins with catalytic properties are called *enzymes*. They are the key molecules responsible for the correct functioning of living organisms. Because of their catalytic properties, enzymes have long been used as crucial tools in many food technologies. Their deliberate use started in Neolithic times, at the dawn of human food processing, when they were employed in the first intentional fermentation processes (1). Since then, humans have used starters or rennets containing beneficial enzymes.

As with all proteins, enzymes are composed of 20 amino acids linked by peptide bonds, which, from a chemical point of view, are a subtype of the amide bond. The character of the side chains of amino acids (polar, apolar, negatively or positively charged, H-bond donor or acceptor) defines most of the intrinsic and extrinsic interactions of the enzyme molecule and its interactions with the surrounding medium. Thus, the character and spatial arrangement of the amino-acid side chains define the structural and catalytic properties and specificities of enzymes. The classification of enzymes, as proposed by International Union of Biochemistry and Molecular Biology, organizes enzymes according to the reactions they catalyze (3). In this way, enzymes are classified into six main categories:

- EC 1: Oxidoreductases
- EC 2: Transferases
- EC 3: Hydrolases
- EC 4: Lyases
- EC 5: Isomerases
- EC 6: Ligases

According to a study carried out by the Freedonia Group Inc. in 2003 (9), the global enzyme industry was worth $5.8 billion US dollars in 2010, and it is forecast to rise 6.8% annually to $8 billion US dollars in 2015. The Freedonia study covers the total sales of enzymes, including carbohydrases, proteases, polymerases, nucleases, and lipases, for use in various markets, such as biotechnology, food, and pharmaceuticals. It was pointed out in Freedonia study that three important factors drive the growth of the world enzyme market:

- Novel advances made in production biochemistry, fermentation processes, and recovery methods have resulted in the affordable large-scale production of enzymes.
- The development of various applications employing enzymes has greatly increased market demand.
- Enzymes are capable of catalyzing many different reactions, enhancing their collective commercial usefulness.

Despite increased growth in world demand for enzymes, only approximately 200 of the 4000 types of enzymes are commercially available on the global market.

Of these 200 enzymes, about 20 are produced in industrial quantities. The various difficulties impeding the industrialization of enzymes are as follows: (i) it is currently difficult to find enzymes with high yield, high activity, and high stability; (ii) enzymes used for drug and food purposes must pass through multiple phases of clinical trials and government approval, such as those conducted by the U.S. Food and Drug Administration (FDA) and the European Food Safety Authority (EFSA), which is both time-consuming and costly; and (iii) enzymes for other purposes, such as detergents, require strict testing and approval by government sectors dealing with environmental safety. Not all the classes of enzymes are used in food processing with equal intensity. Some of the key food enzymes are described below, grouped according to function (e.g., processing carbohydrates or proteins).

Processing Carbohydrates

α-Amylase, EC 3.2.1.1

Synonyms: 1,4-alpha-D-glucan glucanohydrolase.

α-Amylase catalyzes the endohydrolysis of 1,4-α-D-glucosidic linkages in polysaccharides containing three or more 1,4-α-linked D-glucose units.

Uses and applications: α-amylases of different origins (4, 5) serve as processing aids in the production of alcoholic beverages, starch hydrolysis, brewing, bread- and sugar-making, and fine bakery.

Origins: *Bacillus amyloliquefaciens*, *Bacillus licheniformis*, *Aspergillus oryzae*, barley malt, porcine pancreas.

Amylases are used extensively in the food, textile, detergent, paper, and pharmaceutical industries. α-Amylases are also used as sugarcane or sugar beet processing aids, solving the viscosity and raw sugar filtration problems typical to starches. The specific ability to hydrolyze the internal α-(1,4) links in amylose and amylopectin, yielding shorter, less viscous polysaccharide chains, has made α-amylases attractive for use in sugarcane and sugar beet processing. Although different sources of α-amylase are available, enzymes of microbial origin are generally preferred because of their advantages, such as cost-effectiveness, efficient production, and consistency. Most commercial α-amylases are produced from *Bacillus* species. These amylases are thermophilic, thermostable, and acidic enzymes isolated from *Bacillus* strains, and they are widely used in starch processing.

Their unique activities, efficiencies, and stabilities are typically specific to the *Bacillus* species from which the enzymes originated, unless they were genetically modified or produced. Overall, α-amylase performance is affected by several variables: pH range, calcium requirements, temperature stability, hydrolytic activity, Rt, and resistance to osmotic conditions, that is Brix tolerance. Because of the diverse functionality of commercial α-amylases, their optimal application in the sugarcane industry requires a full understanding of their activities and potential to hydrolyze different forms of starch under various industrial conditions.

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00257-9

α-Amylases [α-1, 4-glucan glucohydrolase] are among the most important enzymes used for the direct conversion of starch to glucose, which can be further fermented into ethanol. It breaks successive bonds from the nonreducing end of the straight chains producing glucose. The production of ethanol from starch requires two steps, enzymatic hydrolysis followed by fermentation, which are performed by two different organisms (bacteria and yeast).

The quantitative increase in glucoamylase secretion and ethanol production requires strain improvement, because the quantities produced by the wild strains are often too low.

Strain improvement in industrial applications is generally achieved by mutation with agents such as methylnitronitrosoguanidine(MNNG), ethidium bromide, and ultra violet light. Production strains that are mostly used in industrial fermentations are developed by repeating random mutations followed by selection.

A common substrate for α-amylase production by solid-state fermentation (SSF) is wheat bran. Enzyme extracted from these substrates contains various impurities, including a significant amount of melanine-like product-coloring matter, which can interfere in the juice clarification process, if the enzymes are used in crude form. Usually, α-amylases are purified from these colored extracts by different purification steps. The purification of the targeted enzymes should be such that the number of steps are minimized in order to be cost-effective, because the yields and the number of operational steps are inversely proportional to each other. Often α-amylases are partially purified by activated charcoal in a single step.

α-Amylases are calcium-containing enzymes, binding at least one calcium ion per monomeric unit. The calcium ions convey the resistance to pH, temperature, proteolysis, and denaturation by different agents and by heat. The thermostability of α-amylase is increased greatly by bound calcium ions. Recently, many calcium-fortified fruit juices have been proposed as healthy and nonfat alternative foods, especially for children. Therefore, many fruit juices are clarified with use of α-amylase in presence of calcium chloride.

α-Amylase has been found to be a possible causative allergen for protein contact dermatitis (PCD), however. Main activity assay: One unit will liberate 1 mg of maltose from starch in 3 min at pH 6.9 and 20 °C. The α-amylase assay uses ethylidene-pNP-G7 as the substrate. Once the substrate has been specifically cleaved by α-amylase, the smaller fragments produced can be acted upon by α-glucosidase, which causes the ultimate release of the chromophore, which can then be measured at 405 nm.

β-Amylase EC 3.2.1.2

Synonyms: 1,4-α-D-glucan maltohydrolase. β-Amylase catalyzes the exohydrolysis of 1,4-α-D-glucosidic linkages in polysaccharides, resulting in the successive liberation of maltose units from the nonreducing ends of the chains.

Uses and applications: Partial delactosylation of milk and other dairy products. B-Amylase is also employed in the starch and alcohol industries.

Sources: *Kluyveromyces lactis*, barley, wheat grains.

β-Amylase is a member of family 14, which comprises glycosyl hydrolases, and it catalyzes the release of successive β-maltose from the nonreducing ends of α-1,4-linked oligo- and polyglucans.

β-Amylase is a major component of so-called diastatic power (i.e., the combined α-amylase, β-amylase, debranching enzyme, and α-glucosidase activities) of malt. Exclusive maltose production is utilized by the industry for the production of maltose-rich syrups and the nondigestible sweetener maltitol.

β-Amylases have been found not only in various plants, such as sweet potato, barley, wheat, and soybean, but also in some bacteria. β-Amylase, alone or the combination with transglucosidase treatment, can also be used to enhance the slow digestion properties of starch. For amylopectin with a higher proportion of short chains, the amylopectin structure itself slows enzymatic digestion, due to its higher branch density and short chain length, which are more difficult for the amylolytic enzymes to digest. Starch is the major reserve polysaccharide of higher green plants, and it is the second most abundant natural biopolymer on earth after cellulose. Starch is also the main energy-providing material in cereal- and tuber-based food products for the majority of the world population. In human nutrition, the proper rate of glucose release and absorption from digesting starch plays an important role in nutrition, helping to maintain adequate energy levels. According to the rate and extent of starch digestibility, starch is generally classified as rapidly digestible starch (RDS), slowly digestible starch (SDS), or resistant starch (RS). RDS induces a fast increase in blood glucose and insulin levels, whereas SDS is slowly digested throughout the small intestine, with a low glycemic response. Recent studies have shown that obesity and related metabolic diseases, such as diabetes mellitus and cardiovascular diseases, may be associated with the long-term consumption of foods with high RDS contents, which is positively correlated to a high glycemic index and will cause a substantial fluctuation of glucose homeostasis regulatory hormones and high stress to the regulatory system. Therefore, improving food quality with higher amounts of SDS is becoming an area of interest for academia and industry. Generally, starches differ in digestion rates. β-Amylase hydrolysis is important for making sugar syrup and brewing beer and liquor derived from starch. Thanks to the application of β-amylolysis, the amount of SDS can be more than doubled.

β-Glucanase from *Talaromyces emersonii* belongs to the family of hydrolytic enzymes. This food enzyme catalyzes the hydrolysis of 1,3 linkages or the β-1,4 glucan of the cereals used in the production of beer, and it helps reduce the viscosity of musts caused by barley glucans.

Main activity test: According to Bernfeld (1955), the rate at which maltose is released from starch is measured by its ability to reduce 3,5-dinitrosalicylic acid. One unit releases one micromole of β-maltose per min at 25 °C and pH 4.8.

Xylanase EC 3.2.1.8

Synonyms: endo-1,4-β-xylanase.

Uses and applications: bread making, special bread, the production of maize starch and alcohol through fermentation.

Origins: *Aspergillus oryzae*, *Bacillus subtilis*, *Bacillus subtilis*, and *Trichoderma longibrachiatum*.

Xylanase hydrolyzes the β-1,4 linkages-D-xylosidic inside of chains of xylans and arabinoxylans releasing reducing sugars.

Hemicelluloses are hydrolyzed by the cooperative action of a group of enzymes, and the main enzyme involved in the depolymerization of xylan is endo-β-1,4-xylanase. The β-1,4-endoxylanases (1,4-β-D-xylan xylohydrolase, EC 3.2.1.8), which are produced by algae, protozoa, molluscs, crustaceans, insects, seeds of terrestrial plants, bacteria, and many fungal species belonging to the genus *Aspergillus*, are commonly found in nature. However, the xylanase enzymes of filamentous fungi are potentially the most interesting for industrial uses, because they are produced in greater amounts compared with those of yeast and bacteria. These enzymes can be used in monogastric feeds in order to hydrolyze nonstarch polysaccharides such as β-glucan and arabinoxylan that are found in vegetables, thus increasing feed conversion, body weight gain, and the yield of production (4, 5). To date their use was broadened to many processing industries, such as pulp, paper, food, and textile. Of the many reported applications for xylanase, its use as a food supplement has played an important role for monogastric animals, because it can improve the utilization of nutrients.

Xylanases are used in the baking industry to stabilize dough, to make dough flexible, and to improve gluten strength. Xylan is the principal hemicellulose, which is the major plant cell wall polysaccharide component. Arabinoxylans are important in the formation of gluten and other networks in dough, and it has been reported that the nonwater-extractable arabinoxylans exert a negative effect on bakery products, whereas the water-extractable forms of arabinoxylans, with medium to high molecular weights, have a beneficial effect.

Xylanases have been added to dough to accelerate the process of bread making by helping to breakdown polysaccharides in the dough. Enzyme activity is effective in dough by cleaving arabinoxylan chains and thus modifying their functions. Moreover, xylanases contribute to the decrease of dryness and stiffness of the dough with increasing elasticity, extensibility, and coherency, as well as increases in volume and decreases in bread density. Xylanase treatments also result in higher moisture retention and the improvement of sensory perception of bread. Dough characteristics and bread quality improve significantly in response to xylanase treatments during tempering, as compared to application during mixing.

Main activity test: Xylanase activity is tested using an assay based on the release of dyed fragments from 4-*O*-methyl glucuronoxylan dyed with Remazol Brilliant Blue dye or p-pydroxybenzoic acid hydrazide measured at 410 nm.

Glucose Oxidase EC 1.1.3.4

Synonyms: β-D-glucose:oxygen 1-oxidoreductase

Uses and applications: gluten strengthening, gelation of the soluble arabinoxylans in the flour.

Origins: *Aspergillus niger*.

Glucose oxidase can be used for strengthening the dough. Glucose oxidase catalyzes the oxidation of b-D-glucose to form D-glucono-1,5-lactone and hydrogen peroxide. Glucose oxidase has a gluten-strengthening effect by inducing the formation of protein–protein bonds that strengthen the protein network and thereby strengthen and stabilize the dough. Glucose oxidase catalyzes the oxidation of glucose into gluconolactone, with the concomitant reduction of the oxygen to hydrogen peroxidase. Five mechanisms are known, concerning the effects of the sugar oxidase enzymes, as follows: (i) generation of disulfide bridges between the proteins, (ii) formation of di tyrosines, (iii) blocking the effect of glutathione, (iv) gelation of the soluble arabinoxylans in the flour, and (v) alteration of the equilibrium between the different enzyme systems present in the dough.

Main activity assay: Glucose oxidase can be utilized for the enzymatic determination of D-glucose in solution. As glucose oxidase oxidizes β-D-glucose to D-gluconolactate and hydrogen peroxide, horseradish peroxidase is often used as the coupling enzyme in glucose determinations. Although glucose oxidase is specific for β-D-glucose, solutions of D-glucose can be quantified, because α-D-glucose will mutorotate to β-D-glucose as the β-D-glucose is consumed by the enzymatic reaction. Thus, this enzyme is also used in biosensors that measure the amount of glucose in blood.

Processing Proteins

Rennet/Chymosin EC 3.4.23.4

Synonyms: chymosin, rennin.

Uses and applications: Rennet or chymosin is used for cheese making and has highly specific milk-clotting activity relative to its proteolytic activity.

Origins: Fourth stomach of the suckling calf and fungi such as *Mucor miehei*, *Mucor pusillus*, and *Endothia parasitica*.

Aspartic proteases (EC 3.4.23.X) are endopeptidases having two aspartic acid residues that are critical for catalytic activity within their active sites. They are an important class of proteases, which are widely used as milk-coagulating agents. Chymosin (EC 3.4.23.4), the principal aspartic protease used for cheese making, has highly specific milk-clotting activity relative to its proteolytic activity.

Chymosin has broad specificity, similar to that of pepsin A, and it clots milk through the cleavage of a single Ser-Phe105-Met-Ala bond in κ-casein. By predominant cleavage of the Phe105–Met106 bond of bovine κ-casein, chymosin has high specificity for splitting the caseinomacropeptide from the casein micelles, and therefore, it induces milk clotting. Because they are responsible for the hydrolysis of the κ-casein chain in casein micelles of milk, these enzymes are used as milk coagulants in cheese preparation. Because cheese consumption is growing all over the world, the production of different cheese varieties has been increased. Consequently, the availability of calf rennet is limited, and now, calf rennet only covers 20–30% of the world demand for milk coagulant.

Calf rennet obtained from the fourth stomach of a suckling calf is used all over the world, except in India, for the manufacture of almost all varieties of cheeses. However, due to the acute shortage of calf rennet, a substitute for calf rennet has been developed from fungal sources such as *Rhizomucor miehei*, which produces acid protease for the manufacture of goat and sheep cheeses. Substitute proteases are also derived from plants such as wild thistle (*Cynara cardunculus*), and recombinant rennet-chymosin is used for milk coagulation. Chymosins can be obtained from various sources, such as animals, plants, and fungi. The properties of different chymosins have been reviewed by Kumar et al. Chymosins, the major component

of rennet (milk clotting enzyme), are the acid proteases produced in the fourth stomach of milk-fed ruminants.

Although the cost has been reduced due to the biotechnological preparation of recombinant chymosins, natural alternatives are still preferable. However, the unavailability of calf stomachs and ethical problems associated with animal slaughter have forced a search for other alternatives to calf chymosin. In this regard, various microbial alternatives are used for chymosin production, but not all of these sources are suitable for the production of quality cheese, because they often generate a bitter taste. Recombinant chymosin production has been achieved in different microorganisms in response to the consumer demand for vegetarian and vegan cheeses. Buffalo, sheep, goat, and rabbit are believed to be good sources of rennet. Bovine (*Bos tarus*), buffalo (*Bubalos bubalis*), and lamb (*Ovis platyurea*) chymosins have been characterized extensively.

Substitutes from microbial sources would be more interesting, considering the stable availability of these sources and the low cost due to the possibility of using cheap substrates for fermentation. It has been reported that microbial coagulants represent 53% of the demand for milk-clotting preparations. Chymosins from microbial origins have found well-defined applications in cheese manufacturing. Some microbial chymosins from fungi such as *Mucor miehei*, *Mucor pusillus*, and *Endothia parasitica* have been purified, and their enzymatic properties have been investigated in detail. These fungal enzymes have been used in large-scale cheese production since the 1960s. Apart from low cost and stable characteristics, chymosins from fungi are also better accepted by people whose eating habits and religious beliefs exclude the use of animal enzymes or recombinant rennets.

Main activity test: Skimmed milk solution is incubated at 35 °C for 10 min. Then 0.5 ml of rennet is added to the solution and mixed immediately. The time from adding rennet to milk coagulation is recorded.

Transglutaminase EC 2.3.2.13

Synonyms: Transglutaminase, factor XIIIa, fibrinoligase, fibrin-stabilizing factor, glutaminylpeptide γ-glutamyltransferase, polyamine transglutaminase, tissue transglutaminase, *R*-glutaminyl-peptide:amine γ-glutamyl transferase, (TGase; protein-glutamine gamma-glutamyltransferase), fibrinoligase, glutaminylpeptide gamma-glutamyltransferase, polyamine transglutaminase.

Uses and applications: Stabilization of the gluten network in dough, reconstitution of matrix meat products.

Origins: Blood coagulation factor XIII, pig/bovine liver, *Streptoverticillium moboarense*.

Transglutaminases are the enzymes used for the stabilization of the gluten network in dough, allowing manufacturers to overcome the lack of emulsifiers and produce good bakery products from frozen dough. It is also used for the reconstitution of meat products.

Transglutaminase is an efficient and promising food enzyme because it catalyzes acyl transfer reactions, deamidation, and crosslinking (polymerization) between protein intra- or interchain glutamine (acyl donor) and lysine (acyl acceptor) peptide residues. The reactions promoted by this food enzyme create profound changes in the proteins composing food matrices, leading to improved texture and stability in terms of temperature, syneresis, emulsifying properties, gelation, and increased water-binding capacity, without changing the pH, color, flavor, or nutritional quality of food.

Protein cross-linking may be carried out with help of transglutaminase (TG) either prior to or simultaneously with the addition of rennet. Enzymatic cross-linking affects both the primary and the secondary stages of rennet coagulation. The impact of protein cross-linking on the primary enzymatic phase is mainly related to increased coagulation times due to the inhibition of caseinomacropeptide release. Consequently, a higher extent of protein cross-linking may lead to reduced gel firmness. The simultaneous reaction of TG and rennet results in significantly increased yield due to the enhanced lactoserum binding of the gel network stabilized by additional covalent bonds resulting from transglutaminase action. In conclusion, cross-linking has a strong impact on the entire coagulation process, leading to rennet gels with modified functional properties.

Transglutaminases may even render food protein more nutritious because of their potential use for the incorporation of essential amino acids in proteic matrices. Microbial transglutaminase (MTGase), an extracellular enzyme from the class of transferases, is produced commercially via traditional fermentation by the microorganism *Streptoverticillium moboarense*. This food enzyme, which acts in a wide range of pH and temperature (pH 5.0–8.0, optimum temperature of 50 °C, but with activity between 40 and 70 °C), is Ca^{2+} independent, and its activation does not require special cofactors. This enzyme was also granted *generally recognized as safe* (GRAS) status by the FDA in 1998, as well as approval from European (French and Danish) food control agencies, making MTGase very attractive for the food industry. According to existing reports, native and MTGase-modified proteins differ only in the number of bonds between glutamine and lysine residues.

Several studies have tested a variety of food proteins as substrates for MTGase: milk and whey proteins, soy globulins, myofibrillar proteins, albumins, and others. One of the main industrial applications of MTGase is in the restructuring and consolidation of meat products. Through the cross-links MTGase catalyzes, the transglutaminase increases stability, improves texture, and decreases losses during cooking, giving the restructured meat product an appearance resembling that of intact muscle. In the dairy industry, transglutaminase has been used in the production of yogurt, in which it has been largely used for the prevention of syneresis during whey separation, because of its capacity to increase the gel water-holding capacity. Despite transglutaminase's innovative potential in the formulation of various food products, it remains underexploited for industrial uses, particularly in products of plant origin.

Considering the food industry's significant interest in using food-grade transglutaminases because of their specificity, mild reaction conditions, and very low risk of toxin formation, understanding how transglutaminases modify the functional properties of food proteins is the most important step in promoting their industrial use in novel, reconstructed food products.

MTGases belong to the class of transferases widely known to modify the functional properties of proteins in food systems. The main mechanisms of their action are polymerizations that result in many functional and biophysical changes, including changes in protein hydrophobicity. MTGases decrease protein

solubility, inducing protein gelation. They also affect emulsification, foaming, viscosity, and water-holding capacity, all of which depend on radical decreases in cross-linked protein solubilities. Because MTGase promotes the polymerization of proteins via decarboxylation of free amino acids, it could be used to suppress the formation of biogenic amines in foods containing high amounts of free amino acid, such as the meat of certain fish (e.g., mackerel, tuna, etc.).

Given that the majority of plastics are nonbiodegradable and their excessive use has led to serious environmental problems, industry is seeking alternative natural sources for those materials. Therefore, reticulated fish skin and scale gelatines, in combination with soya proteins, could be used to produce edible and biodegradable films, improving food product quality and reducing waste.

Among the materials used to prepare edible films, gelatine has been extensively utilized because of its relative abundance and excellent film-forming ability. Recently, edible films based on fish gelatin have received increasing attention due to concerns about mad cow disease and foot-and-mouth disease. Transparent films with good mechanical properties can be prepared from the fish scale gelatin extracted at pH 5. However, gelatin films have poor water resistance properties, because of the highly hygroscopic property of gelatin. Additionally, the mechanical properties of gelatin films decrease when in contact with the surfaces of foods with high moisture contents. These properties restrict the application of edible films prepared from unmodified native gelatin only.

It was reported that the physical properties of protein films could be improved by adding transglutaminase, which is considered to be a safe and effective cross-linking agent. The addition of soy protein isolate (SPI) and its coreticulation with TG could also greatly improve the swelling property of gelatin films.

Main activity assay: Most tests rely on measuring the absorbency caused by OPA-reactive Lys on the casein during the transglutaminase action.

Papain EC 3.4.22.2

Synonyms: Papainase, papaya peptidase I.

Uses and applications: Papain is a processing aid for the production of protein hydrolyzates as aromatic bases, aswell as plant protein hydrolyzates. Papain is also used in the brewery and in meat tenderization.

Origins: *Carica papaya* (papaya), *Ananas comosus* (pineapple).

Papain is a cysteine protease with wide specificity, cleaving the peptide bonds of basic amino acids, such as leucine and glycine. It also hydrolyzes esters and amides. Papain will digest most protein substrates more extensively than the pancreatic proteases do.

The ability of papain to improve beef meat tenderness is attributed to the increased degradation of myofibril proteins and the disruption of muscle fiber structures, because of its proteolytic action. The main components of meat, myofibrils, mainly consist of actin, myosin, and various accessory proteins and connective tissue, which consists of various collagen subtypes and elastin. The relative proportions of these components influence meat structure and texture and, thus, the relative tenderness of a meat. It is known that the disruption of these components of meat structure in various ways, including the partial hydrolysis of meat proteins, contributes to tenderness. The potential of exogenous proteases, such as papain, to tenderize meat has been exploited for a long time.

Main activity assay: A titrimetric determination of the acid produced during the hydrolysis of benzoyl-L-arginine ethyl ester (BAEE) serves to measure papain activity. One unit hydrolyzes one micromole of benzoyl-L-arginine ethyl ester per min at 25 °C and pH 6.2, under the specified conditions.

Asparaginase EC 3.5.1.1

Synonyms: Colaspase.

Uses and applications: Asparaginase is used in the deamidation of food preparations containing L-asparagine and carbohydrates, which are cooked at temperatures above 120 °C, such as bread and other cereal products, as well as fried products based on potatoes, generating polyacrylamide. Asparaginase is an enzyme that catalyzes the hydrolysis of asparagine to aspartic acid.

Origins: *Aspergillus oryzae*.

Main activity assay: Asparaginase hydrolyzes asparagine to generate aspartic acid, which can be detected colorimetrically ($\lambda = 570$ nm) or fluorescently (Ex/Em = 535/590 nm) using a coupled enzymatic reaction.

Processing Lipids

Lipases EC 3.1.1.X

Uses and applications: Cheese production, oil and egg industries, bakeries.

Origins: Pancreas, *Fusarium venenatum*, *Fusarium oxysporum*, hybrid between *Thermomyces lanuginosus* and *Fusarium oxysporum*.

The importance of lipases (triacylglycerol acylhydrolases, E) is undeniable, and the impact of this group of enzymes is clearly seen in their widespread application in many industries, including organic synthesis, paper manufacturing, oleochemistry, dairy, cosmetics, perfume, biosensors, and detergents.

Lipases catalyze the hydrolysis of fats into fatty acids and glycerol at the water–lipid boundary, as well as the synthesis of esters from fatty acids and glycerol at the water-insoluble substrate boundary. The unique capability of lipases to react only at the interface between aqueous and nonaqueous phases distinguishes them from esterases. Lipases hydrolyze the ester bonds in triglycerides, yielding diglycerides, monoglycerides, and fatty acids, and they catalyze the hydrolysis of ester bonds in sn-1 diacyl phospholipids to form 2-acyl-1-lysophospholipid and fatty acids. This improves the properties of dough and the quality of bread, leading to a finer and more homogeneous crumb structure.

Phospholipases are also used in cheese production, as well as the oil and egg industries. Engineered phospholipase C may be used for the efficient degumming of edible vegetable oils; the enhancement of the natural emulsifying properties and heat stability of yolk and/or whole egg; the enzymatic hydrolysis of vegetable lyso lecithins into lecithins in order to improve their emulsifying properties; and the degumming of vegetable oils during refining, which eliminates phospholipids

from the oil during the purification step, in order to obtain satisfactory taste and quality, provide better storage stability, and facilitate the rest of the manufacturing process.

Lipases often have high chemo-, region-, and enantioselectivity, so that they are considered to be one of the most important industrially utilized biocatalysts. The current trend in lipase research is to focus on microbial lipases rather than lipases derived from animals and plants, because lipases from microorganisms have several advantages, including the ability to catalyze diverse reactions, produce high yields, and reduce production costs. In addition, microorganisms have the advantage of relative ease of genetic manipulation. Other major advantages of microbial lipases include (i) structural stability in organic solvents, (ii) independence from cofactors, (iii) catalyze reactions utilizing a wide range of substrates, and (iv) high enantioselectivity. A detailed description of bacterial and fungal lipases, as well as a brief account of lipase purification techniques and screening methods, can be found in a recent review by Nagarajan.

Omega-3 polyunsaturated fatty acids (ω3 PUFA) from fish oils promote well-established health and anti-aging benefits that justify their use as functional ingredients in dietary supplements, healthy foods, and nutraceutical products. Among them, eicosapentaenoic (EPA, C20:5) and docosahexaenoic acids (DHA, C22:6) continue to receive particular attention because of their numerous biological properties and positive effects on human health. In addition to recognized benefits for the prevention of cardiovascular diseases, EPA and DHA were reported to protect from inflammation-mediated disorders, including obesity and diabetes, as well as Alzheimer's and related neurodegenerative diseases.

Human metabolism exhibits a limited ability to synthesize ω3 PUFAs. The dietary supply of preformed compounds therefore appears to be an essential alternative. However, the practical use of such lipids as food ingredients is often limited by their high susceptibility to oxidation, which is responsible for the undesirable off-flavor and odor of rancid oils associated with a loss of nutritional value. Various solutions can be implemented to minimize these degradation pathways, and the pathway most commonly used by manufacturers is the addition of antioxidants. Intensive research has been pursued on natural phenolic antioxidants issued from plants. Many studies reported that such antioxidants are highly effective at protecting ω3-enriched food products from oxidation. In addition, some works pointed out the interest of formulations mixing ω3 PUFAs and phenolic compounds for the prevention of Alzheimer's disease and the treatment of obesity through lipid-lowering effects. Another approach involves bringing together ω3 lipids and phenolic compounds in a single entity. Such an association was shown to improve the stability of highly oxidizable fatty acids, while facilitating the solubilization of phenolic compounds in lipid phases. Additional effects could include the increased bioavailability of phenols, as well as cumulative and even synergistic biological activities. In addition, PUFA phenolic esters were reported to exhibit higher antimicrobial, antioxidant, and antiinflammatory activities than native phenols do.

Fatty-acid phenolic esters are preferentially produced by enzymatic bioprocesses based on the use of lipases that exhibit high selectivity towards polyfunctional substrates and mild reaction conditions, as compared to chemical synthesis pathways. Most often, esterification reactions were carried out in dry organic solvent, but few studies reported the possibility of processing without any solvent.

The synthesis of biodiesel by lipase-catalyzed reactions has also become a matter of great commercial interest due to its environmental friendliness over petrodiesel fuel.

The main advantages of using biodiesel are that it is biodegradable, can be used without modifying existing engines, and produces less harmful gas emissions, such as sulfur oxide. Chemically, biodiesel is a mixture of alkyl esters with long-chain fatty acids, and it is typically made from nontoxic, biological resources such as vegetable oils, animal fats, or even used cooking oils. In this sense, due to the low miscibility of the substrates, the application of ultrasound irradiation to this reaction system may lead to high reaction rates. Although the rates of triglyceride conversion to fatty-acid alkyl esters are known to be slower than the alkali-catalyzed routes, enzymatic catalysis has attracted much attention, because it is more ecofriendly and has the potential for industrial implementation, due to the simplicity of the product-refining process and the use of lower reaction temperatures. In fact, the key advantage of an enzymatic biodiesel process is that triglycerides, as well as free fatty acids, can be efficiently transformed into biodiesel under the same mild conditions, and the byproduct, glycerol, can be easily recovered as part of a high-quality, high-value stream, without any complex process. The high cost of enzyme production remains the major obstacle to the commercialization of enzyme-catalyzed processes, but considerable progress has been made to address it, including the use of solvent-tolerant commercial and noncommercial immobilized lipases and new immobilization technologies, making catalyst reutilization possible.

From *Fusarium venenatum*, *Fusarium oxysporum*, hybrid between *Thermomyces lanuginosus* and *Fusarium oxysporum*

Main activity assay: Lipase hydrolyzes a triglyceride substrate to form glycerol, which may be quantified enzymatically by monitoring a linked change in the OxiRed probe absorbance at 570 nm. Other spectrophotometric methods for lipase activity determination use synthetic lipase substrates transformed via enzyme-catalyzed hydrolysis into spectrophotemetrically detectable products. The predominant substrates are p-nitrophenyl and naphthyl esters of the long chain fatty acids, as well as thioesters. The lipolysis of the p-nitrophenyl esters (e.g., laurates, palmitates, oleates) gives rise to yellow-colored p-nitrophenol measured at 405–410 nm.

Other Food Enzymes

Phytases EC 3.1.3.8 X

Uses and applications: Degradation of antinutritional factors (phytates).

Origins: *Bacillus* spp., *Aspergillus ficum*, *Aspergillus niger*, *plants*.

Phytases catalyze the hydrolysis of phytate molecules, known as antinutrients, which complex certain essential minerals, and it is used in bread making to reduce the content of the bread phytates.

Phytates (myo-inositol-1,2,3,4,5,6-hexakisphosphates) are widely thought to play a significant role in decreasing the bioavailability of minerals by chelating cations and forming complexes, which may be insoluble or otherwise unavailable under physiological conditions. A number of studies, including animal experiments and human trials, have been done on the negative effects of phytates, and these studies clarify that dietary phytate has a negative impact on the bioavailability of mineral ions (i.e., Zn^{2+}, $Fe^{2+}/3^{+}$, Ca^{2+}, Mg^{2+}, Mn^{2+}, and Cu^{2+}). Additionally, phytate has also been reported to form complexes with proteins at both low and high pH values, and the complex formations may alter the protein structure, which induces changes in the physicochemical and functional properties, enzymatic activity, and proteolytic digestibility of proteins (or enzymes). Thus, it is necessary to partially, or even completely, eliminate the antinutritional effect of phytates when phytate-rich products are produced or used. There are several processing techniques, such as soaking, germination, malting, fermentation, ultrafiltration, and ion exchange columns, which can be used to decrease the inhibitory effect of phytate on mineral absorption. In addition, phytase (myo-inositol hexakisphosphate phosphohydrolase), which catalyzes the conversion of phytate to inositoland inorganic phosphate, can also be used to reduce phytate in food processing. Some research studies describe the application of phytase in food processing to reduce phytate in products such as white wheat rolls, cereal porridges, wheat bran flour, glandless cotton flour, bread, corn wet milling, and rice bran protein isolate. It was reported that 85% of phytates in soybean meal and 67% of phytates in cottonseed meal could be hydrolyzed by *Aspergillus ficuum* phytase at 50 °C and pH 4.0–5.5.

Phytic acid (PA) can be degraded by phytase enzymes, leading to an increase in the bioavailability of zinc and other minerals. PA degradation was reported to occur during the fermentation of cereals such as wheat, which contain endogenous phytases, and on the addition of exogenous phytases during the preparation of cereal flours for complementary feeding. Both processes require long preparation in slurry form, however, with adjustments to pH and temperature for efficient dephytinization. A simpler procedure, suitable for in-home fortification mixtures, would be to add the phytase to the cereal porridge at the time of consumption so that PA degradation could take place during the digestive process. This would then have a positive effect on zinc and iron adsorption.

Phytate can be hydrolyzed in the gastrointestinal tract (GIT), at least to some degree, by the intrinsic phytases present in feeds originating from plants, endogenous phytases, or possibly by microbial phytase from the gut microbiota present in the GIT. More recently, however, phytases have been commercially produced from microbial sources and are often included in pig and poultry diets to improve the availability of minerals, such as Ca and P, as well as other nutrients, ostensibly through greater phytate hydrolysis. Several studies have been published examining the efficacy of dietary microbial phytase supplementation on Ca and P availability in pigs, but these studies largely focus on disappearance across the total tract, while largely overlooking apparent ileal mineral absorption. There is a lot of information about the fate of dietary phytate P and total P and Ca throughout the GIT of pigs, particularly in response to the presence of dietary microbial phytase and in relation to corn–soybean meal diets.

Sources: *Aspergillus niger*, plants.

Main activity assay: The assay is based on the enzymatic hydrolysis of sodium phytate under controlled conditions via the measurement of the amount of orthophosphate released. The phytase activity is expressed in phytase units (FTU). One phytase unit (FTU) is defined as the amount of enzyme that liberates 1 µmol of inorganic phosphorus per minute from 0.0051 mol/l sodium phytate at 37 and pH 5.50, under the conditions of the test.

Legislation Concerning the Safe Use of Food Enzymes

With very rare exceptions, largely limited to their allergenic properties, the consumption of most food enzymes does not present a particular danger. However, some of these enzymes in active form, such as certain proteases and lipases, may have detrimental effects on the cell membranes of human skin or the GIT. Thus, safe practice requires that all enzymes used in food formulations should be either inactivated, denatured, or eliminated before the end-product stage. Because the great majority of food enzymes are the mixtures of various components present in their production media including other enzymes, present sometimes in even greater amounts that a desired enzymatic product, and an array of other compounds, the safety of the product should conform to current security and health standards, assuring safety for consumers.

The first legislation addressing security verifications for food enzymes was voted on and enforced in Denmark and in France. These laws, in turn, inspired European legislation for securing the safety of foods created with help of industrially produced enzymes (12, 13). In most cases, if there is no considerable history of safe use, as in the case of rennet, the new enzymatic processing aid should fulfill many sanitary requirements, such as microbiological, toxicologic, mutagenic, carcinogenic, and allergenic safety.

Enzymes: Functions and Characteristics

Enzymes: Concept and History

Enzymes are biological macromolecules that act as facilitators (catalysts) of every metabolic reaction that takes place in or is produced by the action of living organisms. With the exception of a small group of catalytic RNA molecules, all enzymes are proteins, and their activity depends on their native protein conformation. The function of enzymes is to increase the speed (rate) of biological reactions so that they occur in a time scale useful for organisms. An example of enzyme action can be taken from how bread supplies us with energy. The essential component of bread is starch, a polymer of glucose. When we eat bread, digestive enzymes splice starch down to free glucose molecules, which then undergo a chain of enzymatic reactions to be finally converted into CO_2 and H_2O. The overall balance of these reactions is highly exergonic, and the energy liberated sustains our physical and mental activity. However, if we keep a piece of bread in a container, it can remain for years without any noticeable change. The same reactions that occur in our organism are thermodynamically possible and may occur in the container, but in the absence of enzymes they take place at an extraordinarily low speed that makes them useless to sustain life. Enzymes are therefore agents whose role is to reduce the time of chemical reactions.

Although virtually all enzymes are proteins, there are many cases in which the protein needs another chemical component (cofactor) to perform its catalytic activity. This cofactor may be an inorganic ion, such as Fe^{2+}, Mg^{2+}, Mn^{2+}, or Zn^{2+}, or a more complex organic molecule, named coenzyme, such as coenzyme A. When the coenzyme is tightly bound to the protein, it is called a prosthetic group, such as the heme group. The protein part is called apoenzyme or apoprotein, and the complete, catalytically active enzyme with both components is called holoenzyme.

The use of enzymes by humans dates to the earliest times of civilization, far before the time when the concept of enzyme could be conceived. Ancient enzyme uses were associated with the production of certain types of foods and beverages. The use could be indirect, as in the production of foodstuffs resulting from microbial fermentation, such as bread, wine, beer, or vinegar. It could also be direct as in cheese production from milk, using renin obtained from the stomachs of ruminants. Of course, early civilizations were not aware of the nature or function of the substances that they used in the elaboration of enzyme products, which was based on empirical observations and folklore.

It was during the nineteenth century that the development of biochemistry provided an emerging picture of the nature and properties of enzymes. In 1833 Anselme Payen and Jean-François Peroz described the isolation of an amylolytic substance from germinated barley that they called diastase. Two years later, the chemist Jöns Jacob Berzelius coined the term catalysis (1835), referring to the property of certain substances to accelerate chemical reactions. One year later Theodor Schwan discovered the digestive enzyme peptidase. However, it was not until 1876 that Wilhelm Kühne purposed the term 'enzyme' derived from the Greek word 'zymé,' which means ferment. In 1894 Emil Fischer proposed the lock-and-key theory to explain the mechanism of enzyme action. In 1897, the brothers Hans and Eduard Buchner demonstrated that the transformation of glucose in ethanol can be carried out by chemical substances (enzymes) present in cell free extracts.

During the first half of the twentieth century, the chemical nature of enzymes and their mechanism of function were elucidated. In 1903, Victor Henri published the first mathematical model describing the process of enzyme action (enzyme kinetics). Ten years later, in 1913, Leonor Michaelis and Maud Menten published their very well-known mathematical model of enzyme kinetics relating the velocity at which an enzymatic reaction proceeds with the concentration of substrate. In 1926 James B. Summer purified and crystallized the enzyme urease isolated from jack beans. His work provided first evidence that enzymes are proteins. This was confirmed in the next few years by the work of John Northrop with digestive enzymes pepsin, trypsin, and chymotrypsin. Around 1950, two key contributions were determinant for understanding the structure and function of proteins in general, and enzymes in particular. Frederick Sanger's work with insulin showed that proteins are composed by chains of amino acids linked by peptidic bonds. Based on Sanger's discovery, Kaj Linderstrøm-Lang made an accurate description of the shape and organization of the architectural elements that compose protein molecules. Already in the second half of the twentieth century, around 1960, John Kendrew and Max Perutz using X-ray crystallography resolved the first three-dimensional structure of proteins. Although they worked with globular, noncatalytic proteins, myoglobin and hemoglobin, their work pioneered subsequent studies linking protein structure and enzymatic function. Enzyme studies were fostered by the onset and development of genetic engineering techniques in the second half of the twentieth century. As a result of this development, it is possible nowadays to obtain in large amount and pure form almost any enzyme from any organism.

One-Gene–One-Enzyme

In 1941 George Beadle and Edward Tatum published a highly influential article in which they proposed the so-called one-gene–one-enzyme hypothesis. At that time, the principles of Mendelian inheritance were understood, and it was known that enzymes were proteins, but the chemical nature of the genetic material remained a mystery. Beadle and Tatum worked with the bread fungus *Neurospora crassa*, looking for genetic mutations causing metabolic defects. The selected mutants required the addition of a specific supplement,

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00256-7

typically an amino acid (e.g., arginine or leucine) to restore their capability to grow. These, called auxotrophic mutants, were therefore impaired in the metabolic process – pathway – leading to the biosynthesis of the required compound. The genetic analysis of a group of mutants requiring the same supplement showed that they were affected in different genes controlling successive steps – chemical reactions – of the same pathway. From this, Beadle and Tatum concluded that each gene determines the existence of an enzyme that catalyzes a specific biochemical reaction.

Later discoveries rendered this theory an oversimplification. Presently, we know that there are many genes that do not encode enzymes as they have a regulatory function; other genes encode nonenzymatic proteins. There are also enzymes that are composed by more than one polypeptide and are therefore encoded by more than one gene. Nevertheless, with many exceptions, Beadle and Tatum's insight was essentially true and established an early, first connection between the genome and the thousands of biochemical reactions that take place in a living organism.

Structure and Function of Enzymes

The working functionality of a molecule resides in its chemical composition and spatial conformation – structure. Enzymes are molecular machines able to catalyze chemical reactions. They are built by at least one polypeptide chain, and their structure derives from the corresponding particular sequence of amino acids. The general features of protein structure were first proposed by Linderstrøm-Lang and later confirmed by crystallographic analysis of Kendrew, Perutz, and the work of Linus Pauling. The structure of a protein results from a hierarchical organization of the molecule at four levels. The basic level – primary structure – is determined by the specific linear sequence of the amino acids that compose the polypeptide chain. Stretches of amino acids bound in a polypeptide chain, depending on their composition, can take an apparently random conformation – coil or loop – or adopt particular patterns. These may have the shape of a helix – α-helix – or a zigzagged extended conformation of chain segments (β-strands) interconnected laterally with the shape of a sheet – β-sheet. These patterns constitute the following – secondary structure – level. Every polypeptide chain, with its distinct secondary structure elements, adopts a specific three-dimensional arrangement that is referred to as tertiary structure. Often, proteins are made of more than one polypeptide chain – monomer – which can be identical or different. The specific association of two or more monomers in proteins constitutes its quaternary structure (Figure 1). Although the amino acids of a polypeptide chain are linked by covalent union between the amino group of one amino acid and the carboxyl group of the next – peptide bond, the secondary, tertiary, and quaternary structures are maintained by numerous, usually noncovalent, forces such as hydrogen bonds, salt bridges (electrostatic), and hydrophobic interactions. Proteins contain secondary structure (α-helix and β-chain) elements connected by coil regions of different length. Generally, the secondary structure elements cluster at the internal hydrophobic core of the protein, whereas the connecting coils are at the surface. A relatively small three-dimensional pocket within the overall structure of an enzyme constitutes the catalytic site, which is formed by the amino acid residues directly involved in catalysis and those that participate in binding the substrate. In a way, it could be considered that the secondary structure elements, which are evolutionary conserved among similar, phylogenetically related proteins – homologues, are mostly involved in maintaining the protein framework, whereas some of the loops build the catalytic pocket, providing substrate specificity and enough flexibility for the conformational changes occurring in the enzyme during the catalytic process.

Presently, two methods are used for protein structure determination, X-ray crystallography, and nuclear magnetic resonance (NMR). Analysis of X-ray diffraction patterns provides a very accurate picture of protein structures with a resolution up to 1 Å. A drawback of this technique is that it requires the protein to be in crystalline form. Protein crystals are often difficult to grow, and sometimes their quality is not good enough to obtain the three-dimensional structure with sufficient accuracy. Around 1970, NMR was applied to the resolution of protein structures thanks to the work of Kurth Wüthrich. NMR analysis is carried out using protein solution samples, much easier to prepare than crystals; however, the practical use of this technique is still limited to proteins of relatively small size. Progress made during the last decades has yielded a huge number of protein structures, most of them enzymes, available at the Protein Data Bank (http://pdb.org/). A highly useful complement to the experimental techniques are bioinformatics tools, such as SWISS-MODEL (http://swissmodel.expasy.org/) or I-TASSER (http://zhanglab.ccmb.med.umich.edu/I-TASSER/), which allow predicting the three-dimensional structure of a protein from its amino acid sequence, on the basis of existing homology with other proteins of known structure.

Name, Types, and Classification of Enzymes

Enzymes are named by adding the suffix '-ase' to a term describing or referring to their activity. For instance: citrate synthase, peptidase, lactase, etc. Exceptions to this rule reflect the circumstance that the enzyme was named before the specific reaction that catalyzes was known. This was the case for enzymes such as pepsin or lysozyme. Before a systematic way for naming enzymes was adopted, the same enzyme could be named differently according to the context where it was studied. Conversely, different enzymes could receive the same name. This created misunderstanding and made difficult the interpretation of published results. The situation became unbearable when the rapid growth of biochemical research increased enormously the number of enzymes that were identified and characterized. In 1956, the International Union of Biochemistry (IUB) appointed a commission, the International Commission on Enzymes, or simply the 'Enzyme Commission' (abbreviated EC), whose mission was to establish a rational methodology for the classification and nomenclature of enzymes. The adopted classification was based on chemical activity (function). Each enzyme was

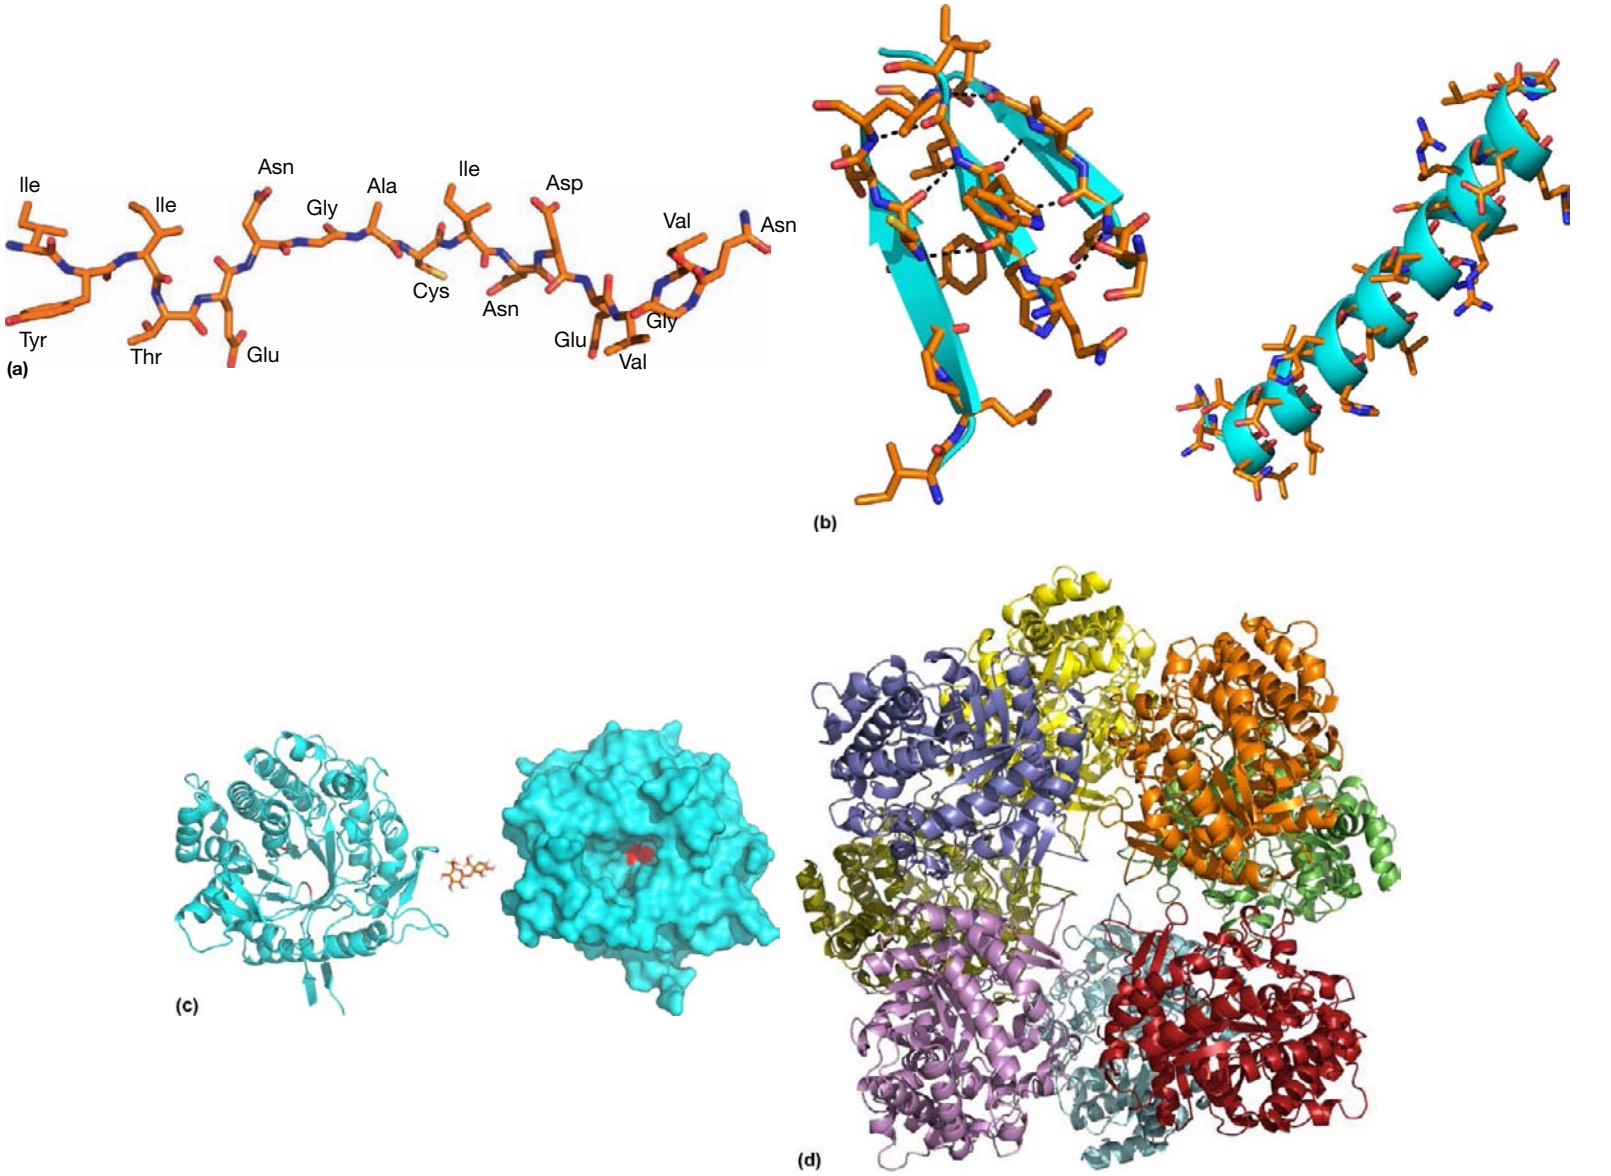

Figure 1 (a) Primary structure fragment of the enzyme β-glucosidase A (BglA) from *Paenibacillus polymyxa*. The amino acidic residues are identified with a three-letter code. (b) Two different secondary structure elements from BglA: a parallel β-sheet (left panel) and an α-helix (right panel). Hydrogen bonds connecting residues of different β-strands in the β-sheet are indicated by dashed lines. (c) Tertiary structure of a BglA polypeptide (monomer). The structure represented on the left is an α/β-barrel, made of an inner cylindrical (barrel-shaped) β-sheet, surrounded by α-helixes. On the right side, a 'surface' representation of the monomer shows the contour of amino acid residues that are fully accessible to the solvent. Catalytic residues are colored in red. A molecule of the enzyme's substrate, the disaccharide cellobiose, is represented in the center of the figure. (d) Quaternary structure of BglA. This enzyme is an octamer of identical monomers (PDB ID: 1BGA).

assigned a classification number (EC number) and a systematic name to identify the reaction that it catalyzes. In addition, for traditional or practical reasons, enzymes often have a common or trivial name. The classification proposed by the EC established three hierarchical levels: classes, subclasses, and sub-subclasses. Six classes of enzymes were considered: oxidoreductases, transferases, hydrolases, lyases, isomerases, and ligases. Within each class, subclasses, and sub-subclasses were established attending specific characteristics of the reaction being catalyzed, such as the nature of the substrate and the chemical groups involved in the reaction. EC numbers are composed of four set of digits, separated by dots. The first, second, and third sets of digits refer to the class, subclass, and sub-subclass. Finally, the fourth digit identifies individual enzymes within a given sub-subclass. As an example, lactase is the common name of the enzyme that breaks the disaccharide lactose, the milk sugar, into its two monosaccharide components, glucose and galactose. The systematic name of the enzyme is β-D-galactoside galactohydrolase and its EC number is EC 3.2.1.23. The number 3 specifies the class name (hydrolase). The second number – 2 – the subclass (glycosylase). The third number – 1 – indicates the enzyme's property of hydrolyzing *O*- and *S*-glycosides. The fourth digit – 23 – identifies this particular enzyme as β-galactosidase. Nowadays, around 6500 enzymes, virtually the full set of enzymes involved in the metabolism of living organisms, are known. An updated view on enzyme names and classification is given by the Nomenclature Committee of the International Union of Biochemistry and Molecular Biology (http://www.chem.qmul.ac.uk/iubmb/enzyme/).

Proteins are classified on the basis of their structural similarity. At the level of tertiary structure, that is, the three-dimensional appearance of the protein, natural polypeptides tend to adopt characteristic shapes that arise from different combinations of secondary structure elements. These shapes can be classified at different levels into a defined number of classes (http://scop2.mrc-lmb.cam.ac.uk/). Enzymes are protein molecules whose functions – catalytic properties – are determined by their structure, which in turn depends on their sequence. On the other hand, resemblance at the primary structure level (amino acid sequence) reflects obvious evolutionary relatedness. Therefore, systematic classification of enzymes on the basis of their structure affords information about both their phylogenetic relationship and their function. A particular case of structural classifications of enzymes is the Carbohydrate Active Enzymes Database (http://www.cazy.org/), which provides comprehensive information about all sorts of enzymes related to carbohydrate metabolism.

How Enzymes Work

Most biochemical reactions are energetically favorable. However, they would take place extremely slowly without the existence of a catalyst. This is because the chemical conversion of a substrate into a product undergoes an intermediate state (transition state), which has a higher energy than the substrate. The term *activation energy* (Ea) is used to describe the energy required to reach this transition state and is related to the reaction rate (the higher the Ea, the lower the reaction rate). It may also be described as a kinetic barrier that needs to be surpassed for the reaction to proceed. The role of enzymes is to supply an environment that greatly increases the chances for the reaction to occur, by decreasing the energy of the transition state and therefore the Ea. The environment for the catalysis is provided by the active site. The interaction between specific amino acid residues of the enzyme, in a particular three-dimensional configuration, and substrate is mediated by multiple weak interactions and allows that the substrate is recognized unmistakably among other similar molecules. Once the substrate is bound to the enzyme, catalytic amino acid residues transiently react with the substrate, assisting its transformation into the final product through a more energetically favorable transition state than that occurring without an enzyme. It is important to highlight that the enzyme, as any other catalyst, is not consumed during the reaction and recovers its original form when the reaction is completed. Enzymes act as molecular machines able to break, ensemble, or transform molecules. They have evolved as highly specialized tools, which explains the existence of as many different enzymes as metabolic reactions.

Enzyme Kinetics

Enzyme kinetics is the discipline that studies how enzymatic reactions take place, the rate at which they occur, and the influence of environmental conditions in the reaction process. The study of the rate of the reaction and its connection with the other most critical factor, the available amount of the substrate, is essential to understand enzyme action. In 1913 Michaelis and Menten published, in German, a paper whose title translated to English is 'The Kinetic of Invertase Action.' In this paper, which became a milestone of biochemistry, the authors established the relationship between the velocity of an enzymatic reaction and the concentration of the substrate according eqn [1]:

$$V_0 = V_{max}[S]/K_m + [S] \quad [1]$$

In this equation, V_0 (initial velocity) is the rate at which the reaction proceeds at a given substrate concentration, V_{max} is the maximal speed that the enzyme achieves (at saturating substrate concentrations), [*S*] is the substrate concentration, and *K*m is the Michaelis–Menten constant, which reflects the affinity of the enzyme for the substrate (the lower the *K*m, the higher the affinity). Its value corresponds to the concentration of substrate at which the reaction rate is half of the maximum. Michaelis and Menten deduced their equation from the study of the enzyme invertase that splits the disaccharide sucrose into its two constituent monosaccharides, glucose and fructose. This reaction was a convenient model system to study the behavior of an enzyme because the conversion of substrate into products was easily monitored by physical techniques. When a beam of polarized light traverses a sugar solution, the polarization plane is rotated, either to the right – dextro rotation – or to the left – levo rotation. This optical activity can be measured with a polarimeter, and the measured value correlates with the concentration of the sugar in the solution. Sucrose and glucose are dextrorotatory, whereas fructose is levorotatory. Because optical activity of fructose is higher than that of glucose, the enzymatic reaction can be followed

by measuring the rotation of light from right to left. Using this procedure, Michaelis and Menten determined the rate at which sucrose was transformed by the action of the invertase. The correlation that they found between the speed of reaction and sucrose concentration fitted a hyperbolic curve. The reaction rate increases as the substrate increases with an asymptotic tendency to a maximum (V_{max}; **Figure 2(a)**) according to eqn [1]. The study of many other enzymes in the following years confirmed the general value of the Michaelis–Menten model, even though there are enzymes that show different kinetics. This is the case, for instance, of allosteric enzymes, in which the interaction between enzyme and substrate is affected by another molecule – effector – that regulates the activity of the enzyme. In 1934, Hans Lineweaver and Dean Burk described a transformation of the Michaelis–Menten equation (eqn [2]). In the graphical representation of the transformation, the function of $1/V_0$ versus $1/[S]$ is a straight line (**Figure 2(b)**), where the intercept with the x axis is $1/V_{max}$ and the slope is K_m/V_{max}.

$$1/V_0 = (K_m/V_{max})\cdot 1/[S] + 1/V_{max} \qquad [2]$$

Linear regression analysis of experimental data by means of the Lineweaver–Burk, or double reciprocal, plot soon became a useful, albeit inaccurate, tool to easily calculate enzyme kinetic parameters (K_m and V_{max}) from experimental determinations. Currently, the availability of computational tools has facilitated nonlinear regression analysis, using directly eqn [1], and this is the preferred method to obtain more accurate values of K_m and V_{max}. However, the Lineweaver–Burk plot is still useful to corroborate the Michaelis–Menten behavior of an enzyme or to study the effect of different types of enzyme inhibitors.

The Effect of Physical and Chemical Agents on Enzyme Activity

Like most chemical reactions, enzyme-catalyzed reactions proceed faster when the temperature increases. This happens because an increase of the system's energy accelerates the molecules in the reaction, increasing the probability of interaction between the chemical components. However, in the case of enzymatic reactions the boosting effect of temperature is limited by the stability of the enzyme. Each enzyme has an optimal temperature at which it shows maximal activity. This is because enzymes structure is maintained by multiple noncovalent weak interactions such as hydrogen bonds, electrostatic, and hydrophobic interactions, which are influenced by physicochemical conditions, such as temperature. High temperature disrupts the network of interactions that holds the molecular architecture of enzymes. If the change is drastic, the protein structure disassembles, and the enzyme losses its activity irreversibly. This process is called heat denaturation. Enzymes show different degrees of sensitivity to temperature. In general terms, as a result of evolution, they are adapted to the temperature conditions in the natural habitat of the producing organism. For instance, human enzymes work at a temperature of around 37 °C. Enzymes from hyperthermophilic archaea function at temperatures of around 100 °C at which virtually all human enzymes are denatured. On the other hand, enzymes from psychrophilic organisms work optimally at temperatures close to 0 °C at which human enzymes are structurally stable but inactive. Another critical parameter for enzyme activity is pH, which affects mainly electrostatic interactions holding the enzyme structure. As happens with temperature, there is a pH at which the enzymes work optimally and a working range at which they remain active. If the pH increases or decreases outside the working range, the enzyme structure can be affected irreversibly.

Chemical compounds can affect enzyme activity. As mentioned earlier, some inorganic ions may be required as cofactors for the activity of some enzymes. Some compounds may bind reversibly or irreversibly to critical sites in the protein structure (within or outside the catalytic pocket), reducing or abolishing enzyme activity. Other compounds can react with a functional group of the enzyme leading to chemical modifications (e.g., oxidation, carbonylation) that may cause (reversible or irreversible) inactivation. A special case of inhibitors are those called 'suicide inactivators.' These are compounds of

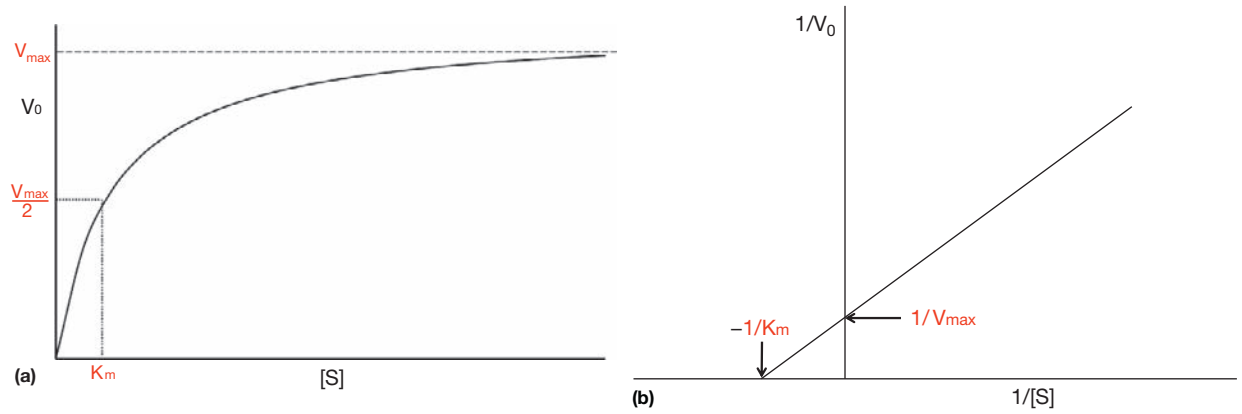

Figure 2 Michaelis–Menten kinetics. (a) Variation of the initial rate of the reaction (V_0) with the substrate concentration ([S]). The asymptote corresponding to maximum velocity (V_{max}), achieved at saturating substrate concentrations, is indicated with a dashed line. The Michaelis constant (K_m) value, which is indicative of the affinity of the enzyme for the substrate, corresponds to the substrate concentration for which the enzyme initial rate is half of V_{max}. (b) Lineweaver–Burk or double reciprocal plot of Michaelis–Menten kinetics.

chemical structure similar to the enzyme's substrate, which bind to the active site and are converted into a reactive molecule, which interacts irreversibly with one of the catalytic residues. These kinds of inhibitors are very useful research tools as they help to explain the mechanism of catalysis, can facilitate the crystallization and structural analysis of enzymes, and in some instances can be used as drugs in therapeutic treatments.

Enzyme Regulation

A simple living organism such as the bacterium *Escherichia coli* contains around 4000 genes that direct the synthesis of a fairly equivalent amount of proteins, most of which are enzymes. In humans, the number of protein-encoding genes is around 35 000. Not all proteins encoded in a genome are needed at the same time or in the same quantity. Because protein synthesis is a highly costly process for living cells, living organisms have developed regulatory mechanisms that supply the cells with the proteins that are required at a certain moment and in a convenient amount. Regulation is exerted at different levels in the flux of information, which goes from DNA to mRNA and from mRNA to protein. Genes can be classified into two categories, according to their expression rate. There are genes required at all times, for example those encoding enzymes acting in central metabolic pathways. These are called housekeeping genes, and they are expressed in a constitutive – continuous – way. For other genes, which are required just at certain stages, the first level of regulation is transcription. The synthesis of a regulated mRNA may be increased in the presence of a signal molecule called inducer. The consequent effect of increasing the encoded enzyme is called induction. An alternative mechanism is gene repression, in which the transcription of a gene is decreased or suppressed by the presence of a molecule called a repressor. As consequence of these two mechanisms the presence or absence of individual enzymes and even the levels at which they are present in the cells is controlled. Another level of regulation takes place on the life span of the mRNA molecule. In some cases, mRNAs translation responds to environmental signals through the interaction of specific sequences (UTRs, for untranslated regions) with protein factors. In other cases, as long as an mRNA is present in the cytoplasm, it continues to be translated by the ribosomes into the encoded protein. Different mRNA species differ in their intrinsic stability. As a general rule, mRNAs from highly regulated genes are more unstable than mRNAs from housekeeping genes and tend to disappear quickly. Even though an mRNA is eliminated, the enzyme resulting from its translation will remain present in the cytoplasm for a certain time, depending on its intrinsic stability. If its action is no longer required, its activity is generally suppressed by a mechanism of inhibition that can be exerted in different ways. One type of competitive inhibition is caused by a molecule that competes with the substrate for the active site of the enzyme. Often the inhibitor is the product of the enzymatic reaction. The action of the inhibitor depends on its concentration and on the affinity that the enzyme has for it. The effect is reversible because an increase on the concentration of the enzyme's substrate will make difficult the access of the inhibitor to the active site. Another type of reversible inhibition is noncompetitive or allosteric. In this case, the inhibitor binds to a region of the enzyme other than the active site, called the allosteric site.

Industrial Enzymes

Since early times of the development of biochemistry, researchers realized the industrial potential of enzymes. In 1907, the German company Röhm and Haas commercialized for the first time an enzyme preparation. The product, marketed with the name OROPON, represented a revolutionary innovation for leather bating, as an alternative to traditional procedures, which used animal excrements in the process. The innovation resulted from the work of Otto Röhm, who had studied the properties of enzymes like trypsin, isolated from pig pancreas, and its digestive effect on skins and furs. A few years later, in 1914, the Röhm and Haas firm launched BURNUS, the first enzyme containing detergent for laundry. One century after these precursory accomplishments, enzymes have innumerable applications in the food, chemical, and health industrial sectors. Enzymes are becoming an advantageous alternative to an increasing number of industrial chemical processes. Enzymes are natural, nontoxic, biodegradable, efficient, and highly specific catalysts that operate under mild conditions. Therefore, the use of enzymes generally represents an eco-friendly – green – alternative to conventional procedures. Current global production of industrial enzymes can be estimated to represent a value between 4 and 5 USD billion. Danish company Novozymes dominates world market with a share that approaches one-half of the total. Currently, other important European players are DSM in The Netherlands and BASF in Germany. In the United States, DuPont has achieved an important role in the enzyme business after the acquisition of Danisco and Genencor. The main area of enzyme application is the food and feed sector, which consumes over one-third of enzyme's production, closely followed by detergents and cleaners. Biofuel (ethanol), pulp and paper, textile, leather, and pharmaceutical industries also make extensive consumption of enzymes. Starch processing represents a major field for enzyme application. Simple sugars, monosaccharides, resulting from the enzymatic hydrolysis of starch carried out by α-amylase and glucoamylase, are used as sweeteners in different types of foods and beverages and are also used by biofuel industries, as fermentable material to produce ethanol. Traditional food industries like bakery and brewery also make extensive use of enzymes. In bakery, amylolytic enzymes are used to increase the amount of fermentable sugars, increasing loaf volume. Xylanases help dough handling and improve crumb structure. Proteases digest the gluten, improving dough texture. Lipases are used to obtain an emulsifying effect that reduces bread staling. In brewing, amylases are used to increase fermentable sugars. Glucan hydrolyzing enzymes (β-glucasases) have an important application in reducing the viscosity of beer, making for easier filtration. Proteases prevent turbidity and chill-haze formation in beer. ALDC (α-acetolactate-decarboxylase) prevents the formation of diacetyl, a compound that is formed as a natural product of yeast metabolism but has undesirable off-flavor characteristics. The detergent industry is the largest single market for

enzymes. Proteases and lipases are included in detergent formulations to eliminate stains of different chemical nature. Cellulases help to remove substances attached to cotton fibers. Enzymes improve different operations in the pulp and paper industry such as bleaching, pitch control, and deinking. Xylanases, lipases, cellulases, and laccases are used for this purpose. Enzymes have numerous applications in the pharmaceutical and health care industries. An example is the use of glucose oxidase in sensor strips to monitor glucose level in serum.

Most industrial enzymes are produced by microorganisms. Producer strains of fungi and bacteria are grown under well-defined conditions in either submerged or solid state fermentation. Genetic engineering techniques are routinely used to achieve homologous or heterologous expression of genes encoding enzymes of interest in suitable host strains and to enhance the performance of the producing strains. Production procedures are different for intracellular and secreted enzymes. In the first case, the cells of the producing microorganism need to be disrupted to release the enzyme, which may require expensive purification methodologies such as preparative chromatography. Secreted enzymes are recovered from the culture medium by filtration. The use of enzymes for food applications requires GRAS (generally recognized as safe) status granted by the U.S. Food and Drug Administration (FDA), the European Food Safety Authority (EFSA), or the views of qualified experts.

Extremozymes

Life thrives in extreme conditions. Living organisms can find niches at temperatures higher than 50 °C (thermophilic), or even higher than 100 °C (hyperthermophilic), below 20 °C (psychrophilic), extreme acid or alkaline conditions at pH lower than 3 (acidophilic) or higher than 9 (alkaliphilic), or under extreme salinity (halophilic). Organisms capable of living in such environments have enzymes that must endure extreme conditions. These 'extremozymes' have unique properties that could be used for many purposes. Thermophylic and hyperthermophylic enzymes show an increased number of interactions (hydrophobic, salt bridges, disulfide bonds) to maintain the protein structure at high temperatures. They are valuable tools for the degradation of complex polysaccharides (such as starch or lignocellulosic materials) or substrates whose solubility is greatly increased at high temperatures. In contrast, psychrophilic enzymes have weaker protein interactions to ensure sufficient flexibility to sustain enzymatic activity at low temperatures. Psychrophilic enzymes are used in detergents and other textile-related applications. Acidophilic or alkaliphilic enzymes usually fall in the thermophilic category and can be used for similar purposes. Production of extremozymes at industrial scale is still a challenge because generally extremophilic organisms are not easily culturable, and often the genes coding for their enzymes are not well expressed in conventional hosts. Nonetheless, this is an active research field because extremozymes may find countless applications in various industrial fields.

Introduction

The family Enterobacteriaceae consists of a heterogeneous group of rod-shaped, gram-negative bacteria, varying in their ecological niche, host range, and pathogenic potential for humans, animals, insects, and plants. Members of the family are aerobes or facultative anaerobes, are motile by peritrichous flagella or nonmotile, do not form endospores or microcysts, and are chemoorganotrophic with both respiratory and fermentative metabolisms, and most grow well at 22–35 °C. Foodborne pathogens in the family Enterobacteriaceae generally do not demonstrate an atypical heat resistance, and they are inactivated at temperatures lower than the pasteurization temperature for milk (72 °C for 15 s). The family Enterobacteriaceae contains more than 50 genera and a large number of species, and there are several human pathogens within this family. Important foodborne pathogens in the family Enterobacteriaceae include *Cronobacter* spp. (primarily *C. sakazakii*), *Escherichia coli*, *Salmonella enterica*, *Shigella* (*boydii*, *flexneri*, *sonnei*, and *dysenteriae*), and *Yersinia* (*enterocolitica* and *pseudotuberculosis*). In the United States, ~3.6 million cases of foodborne illness are caused each year by bacterial pathogens, and ~1.5 million of domestically (the United States) acquired foodborne cases are due to diarrheagenic *E. coli*, *Salmonella*, *Shigella*, and *Yersinia*. Thus, four genera within the family Enterobacteriaceae cause ~40% of bacterial foodborne illness in the United States. The 2011 data from the European Union indicate that the pathogens *Salmonella*, *Campylobacter*, and pathogenic *E. coli* account for 48% of the outbreaks and 27% of the cases of the foodborne disease. This chapter will focus primarily on pathogenic *E. coli* categories, with some discussion also on other foodborne pathogens in the family Enterobacteriaceae.

Intestinal Pathogenic *E. coli*

E. coli is a commensal organism that makes up part of the normal flora of the intestinal tract of humans and animals. *E. coli* belongs to the family Enterobacteriaceae and is a gram-negative, facultatively anaerobic, non-spore-forming, rod-shaped bacterium. Not all strains of *E. coli* are harmless, and some strains have acquired virulence mechanisms, making them pathogens. Some of these strains cause diarrhea and other intestinal diseases, while other *E. coli* pathogens induce disease at nonintestinal sites.

Enterohemorrhagic *E. coli* (Also Known as Shiga Toxin-Producing *E. coli*)

In 1977, Konowalchuk and coworkers in Canada discovered that culture filtrates from some *E. coli* strains produced a cytopathic effect on Vero cells (African green monkey kidney cell line). Since most of the strains producing this effect were from infants with diarrhea, they speculated that the toxin produced by these strains, which they referred to as verotoxin, had a role in the genesis of diarrhea. The *E. coli* that produced verotoxins were referred to as verotoxigenic *E. coli* or VTEC. In 1983, O'Brien and LaVeck purified the toxin from Konowalchuk's prototype strain, *E. coli* O26:H11 H30, and showed that it was structurally and antigenically similar to Shiga toxin produced by *Shigella dysenteriae*, and they named the toxin, Shiga-like toxin. In 1983, there were two outbreaks of hemorrhagic colitis (HC) in the United States, and it was reported by Riley and coworkers that they were linked to eating undercooked hamburgers contaminated with *E. coli* O157:H7, a rare *E. coli* serotype that was later shown to produce verotoxin. Subsequently, a link was established between VTEC infection and development of hemolytic uremic syndrome (HUS). The term enterohemorrhagic *E. coli* (EHEC) was coined by Myron Levine at the University of Maryland and refers to Shiga toxin-producing *E. coli* (STEC)/VTEC strains that have the same clinical, epidemiological, and pathogenic features associated with the prototype EHEC organism *E. coli* O157:H7.

STEC/EHEC O157:H7 and certain non-O157 STEC serogroups are major foodborne pathogens that cause diarrhea, HC, and HUS, and occasionally, death results in infected individuals. A conspicuous feature of STEC O157:H7 and non-O157 STEC intestinal pathology is the intestinal attaching and effacing (A/E) lesion, which is dependent on a type 3 secretion system (T3SS). The secretion system is encoded on a pathogenicity island, the locus of enterocyte effacement (LEE). The T3SS structure forms a pore complex that spans from the inner bacterial membrane to the host cellular membrane and enables the bacteria to inject bacterial effector proteins directly into the eukaryotic host cells following attachment. The effector proteins subvert eukaryotic cell processes and enable the pathogen to modulate the host environment to induce bacterial infection and disease symptoms. Among the non-O157 STEC, there are both LEE-positive and LEE-negative serogroups. For example, STEC serogroups O26, O45, O103, O111, O121, and O145 are generally LEE-positive and T3SS-dependent, whereas serogroups O1, O2, O5, O8, O48, O73, O76, O87, O91, O113, O118, O123, O128, O139, and O174 may be LEE-negative and T3SS-independent. However, only a few of the several hundred non-O157 serotypes have been tested to determine their LEE and T3SS status.

The *eae* (*E. coli* attaching and effacing) gene located on the LEE encodes the production of intimin at the bacterial outer membrane. Tir (transmembrane intimin receptor), also encoded by *eae*, is translocated by T3SS to the host cell membrane; Tir allows attachment of the bacterial intimin protein to the host cell

membrane leading to an intimate attachment of the bacterium with the host cell. The intimate attachment is characterized by the A/E lesion with localized loss of the microvilli (effacement) and an accumulation of polymerized actin pedestals beneath and surrounding the adherent bacterial cell. The bacteria remain extracellular during infection. There are non-O157 STEC that are LEE-negative and do not produce A/E lesions; however, these strains may produce severe diarrhea, HC, and even HUS, but their virulence mechanisms have been poorly studied. Other genes, such as the Saa (STEC agglutinating adhesion) and Iha (IrgA homologue adhesion), are also carried by STEC serogroups that may play a role in attachment; however, additional research is needed to determine the function of these genes.

The most critical virulence factor in STEC is a bacteriophage-encoded cytotoxin similar to the Shiga toxin produced by *Shigella dysenteriae*. In *E. coli*, the *Shigella* Shiga toxin was initially called Shiga-like toxin but was renamed to Shiga toxin 1 and Shiga toxin 2. STEC produce two Shiga toxins: Stx1 and Stx2. Stx2 has ~60% sequence homology to Stx1. There are a number of genetic variants for *stx*1, including *stx*1a, *stx*1c, and *stx*1d, and for *stx*2, there are seven variants, *stx*2a to *stx*2g. Stx2a is a more potent toxin than Stx1; the LD_{50} (in mice) of Stx1 is >1000 ng, whereas the LD_{50} of Stx2a is 6.5 ng. Stx1 and Stx2 are AB_5-type toxins; the B-pentamer of the holotoxin binds to globotriaosylceramide (Gb_3) present on host microvascular endothelial cell surfaces (the kidney, intestine, and brain) followed by endocytosis of the holotoxin. A subunit of the A portion of the toxin is an *N*-glycosidase that acts on the 28S RNA of the 60S ribosomal subunit leading to the inhibition of protein synthesis and apoptosis of endothelial cells, particularly those of the kidneys with resultant damage of the renal endothelial cells. There are swelling of the renal cells and detachment of the cells from the basement membrane and formation of fibrin thrombi in the kidney capillaries. Narrowing of the capillary lumens leads to a reduced blood supply to glomeruli with a loss of kidney function resulting in HUS. HUS is characterized by hemolytic anemia (destruction of red blood cells), acute kidney failure (uremia), and low platelet count (thrombocytopenia).

Early symptoms of STEC infection include watery diarrhea and abdominal cramps. Approximately 90% of confirmed STEC infections result in HC, and 5–15% of the HC cases progress to HUS. The mortality rate for HUS ranges from 5% to 10%. A few patients suffer long-term consequences affecting the gastrointestinal tract, liver, cardiovascular system, or central nervous system (CNS); however, most patients recover without major consequences. Very young and elderly patients show the most susceptibility to complications and death due to HUS. Antibiotics are not recommended in the treatment of STEC-infected patients and can increase the risk for development of HUS due to toxin release from lysed STEC cells. Fluid hydration may be necessary in diarrheic patients. Patients with severe bloody diarrhea may need blood transfusions, and in cases of HUS, dialysis may be necessary.

The main reservoir for STEC is the intestinal tract of cattle. However, other ruminants, including sheep, goat, buffalo, guanaco, deer, and elk, and nonruminants, including cats, dogs, pigs, horses, rabbits, and chickens, also can carry STEC. Contact with cattle, the cattle environment, and food products originating from cattle provides major risk factors for STEC infection to humans. Recreational, drinking, and irrigation waters contaminated with cattle feces can be sources of STEC. Infected individuals can transmit STEC person-to-person, and food may be contaminated by cross contamination or by an infected food preparer. In the United States, STEC O157:H7 was declared an adulterant in beef in 1994 after a large outbreak linked to contaminated ground beef occurred, and recently, STEC serogroups O26, O45, O103, O111, O121, and O145 were declared adulterants, since these serogroups cause the majority of the non-O157 STEC infections and illness similar to that caused by STEC O157:H7. For the period 2009–13 in the United States, O157:H7 STEC outbreaks were associated with foods, including spinach (1 outbreak), Romaine lettuce (1), Lebanon bologna (1), beef (3), hazel nuts (1), cheese (1), and prepackaged cookie dough (1). STEC serogroup O26 was associated with outbreaks linked to ground beef and raw clover sprouts. An outbreak linked to STEC O121 involved frozen food products, and O145 was associated with two outbreaks, one linked to Romaine lettuce and the other due to an unknown source. Outbreaks are often associated with STEC O157:H7, whereas non-O157 STEC are more often associated with sporadic cases and less often with outbreaks. However, it is now estimated that non-O157 strains cause a greater number of illnesses than *E. coli* O157:H7.

Based on the Centers for Disease Control and Prevention's FoodNet program in the United States for the years 2000–10, STEC O157:H7 was the cause of 5688 infections (74.0%), whereas non-O157 STEC caused 2006 infections (26.1%). The top six non-O157 STEC caused 1416 cases (18.4%). Serogroup O26 was responsible for 5.8% of STEC cases, followed by serogroups O103 (5.0%), O111 (4.2%), O121 (1.4%), O45 (1.2%), and O145 (0.8%). However, estimates of the total STEC foodborne infections indicate that the non-O157 serogroups cause 64% of the STEC disease cases in the United States. In the European Union, in 2011, nine STEC serogroups were responsible for 4022 cases of disease. STEC O157:H7/H− was responsible for 54% of the STEC cases, and STEAEC (Shiga toxin-producing enteroaggregative *E. coli*) O104 caused 26% of the disease cases. Serogroup O26 accounted for 7% of the cases. Serogroups O103, O91, O145, O128, O111, and O146 were responsible for fewer cases in the descending order. In 2010, nine serogroups (in the descending order, O157, O26, O103, O145, O91, O63, O111, O128, and O146) accounted for 2110 cases; STEC O157:H7 caused 71% of the STEC illnesses followed by 12% for serogroup O26. There was no report of STEAEC cases in the European Union in 2010. Of 504 isolates of STEC isolated for the period 2001–09 in Australia, the following serogroups were the most common: O157 (58%), O111 (13.7%), O26 (11.1%), O113 (3.6%), O55 (1.3%), and O86 (1.0%). The information on STEC isolates from patients in the United States, the European Union, and Australia indicate that serogroup O157 was the most common cause of STEC illness.

Strict hygiene during animal slaughtering, vegetable and fruit harvesting, product handling, shipping, and food preparation is critical in controlling and preventing STEC-induced disease.

Enteropathogenic *E. coli*

Enteropathogenic *E. coli* (EPEC) are an important cause of persistent and potentially fatal diarrhea in infants and young

children in developing countries. EPEC possess the LEE pathogenicity island similar to the Shiga toxin-producing *E. coli* but do not produce Stx. The formation of A/E lesions is characteristic of EPEC and is dependent on LEE island genes encoding T3SS, which acts in a similar way to the secretory system in STEC and allows intimate attachment of the bacteria to the host cell. LEE genes encode for effector proteins that subvert host cellular processes and induce gastrointestinal symptoms. Non-LEE-encoded genes produce effector proteins that inhibit phagocytosis, activate innate immune responses, and have a role in colonization and pathogenic responses. The *E. coli* adherence factor plasmid (pEAF) has the *bfp* operon, which encodes the bundle-forming pilus. The EPEC strains that carry the *eae* and *bfpA* genes are termed typical EPEC, whereas the atypical EPEC strains have the *eae* gene but lack *bfpA*. The typical EPEC strains are a major cause of infantile diarrhea in developing countries but are rare in the developed world. Diarrhea manifests as a severe watery stool with a large amount of mucus but is rarely bloody. The atypical EPEC induce a less severe illness. Treatment consists of prevention of dehydration induced by diarrhea. Humans appear to be the only reservoir for typical EPEC, whereas both animals and humans are reservoirs for atypical EPEC. Contaminated food and water have been associated with EPEC diarrhea. EPEC infections are generally sporadic, and food vehicles are often unknown. Raw chicken and beef, cold pork, meat pie, and other foods, as well as water, have been implicated in a few outbreaks. However, any foods exposed to the feces of an infected human may induce diarrhea.

Enteroinvasive *E. coli*

Enteroinvasive *E. coli* (EIEC) induce an invasive inflammatory colitis with copious watery diarrhea. EIEC are closely related to *Shigella* species but do not produce Shiga toxin. A number of EIEC strains contain the *sen* gene, which encodes for *Shigella* enterotoxin-2 (ShET-2). ShET-2 is translocated to the host cell via T3SS and may participate in the inflammation of the intestinal epithelial cells. The virulence effector genes, the *sen* gene, and T3SS genes are located on a large plasmid, pInv. EIEC does not carry the LEE pathogenicity island. When ingested, EIEC reach the colon, gain access to the colonic submucosa through the M cells, and are then taken up by macrophages. The bacterial cells escape from the macrophages and invade and replicate in the colonocytes. Bacterial virulence effectors are secreted via T3SS into the host cells, which enable the bacteria to evade the immune system and to promote cell-to-cell dissemination. The role of T3SS in EIEC is internalization of the bacteria into the host cell; A/E lesions are not seen in EIEC infection. EIEC-contaminated food and water are associated with the illness. EIEC infections caused by EIEC are rarely detected in the United States; however, a large outbreak occurred in Texas in 1992 in which 370 people became ill after consuming guacamole. Foods are most likely contaminated by infected food handlers, and EIEC infections may also occur via person-to-person transmission. Outbreaks associated with EIEC in several countries have been reported with water, imported cheese, vegetables, and potato salad as the vehicles of infection. Rehydration therapy and antibiotics are recommended as treatments for EIEC infection. Since humans are the only known reservoir of EIEC, it is probable that most EIEC infections are due to food prepared by an ill individual.

Enterotoxigenic *E. coli*

Enterotoxigenic *E. coli* (ETEC) infection induces a watery diarrhea, which may be a mild, self-limiting disease or a severe purging cholera-like disease. The infection may attack children in developing countries or other areas with poor hygiene and unclean water. In addition, ETEC is a major cause of traveler's diarrhea. The organism colonizes the surface of the small bowel and produces enterotoxins, which induce the diarrhea. ETEC elaborate two types of plasmid-encoded enterotoxins: heat-labile enterotoxins (LT-1 and LT-2) and heat-stable enterotoxins (STa and STb). LT-1 is an AB_5 toxin closely related to cholera toxin. LT intoxication of host intestinal cells leads to permanent activation of adenylate cyclase with increased levels of cyclic AMP (adenosine monophosphate). Cyclic AMP activates protein kinase A, leading to phosphorylation of ion channels and secretion of electrolytes into the intestinal lumen. The increased gut osmolarity leads to a watery diarrhea. STa is a small, single-peptide toxin, which binds to the host cell guanylate cyclase, leading to increased cyclic GMP (guanosine monophosphate) levels. Chloride secretion is increased, and NaCl absorption is inhibited. The increased osmolarity in the intestinal lumen results in diarrhea. ETEC strains may produce LT, ST, or both. Rehydration therapy and antibiotics are recommended as treatments for ETEC infection. Humans are the reservoir of ETEC, and ingestion of food or water contaminated by an infected person is often the likely cause of illness. Foods implicated in infections include Brie cheese, curried turkey, mayonnaise, crab meat, deli foods, and salads.

Enteroaggregative *E. coli*

Enteroaggregative *E. coli* (EAEC) include a heterogeneous population of *E. coli* strains that do not produce LT or ST and that adhere in a stacked brick pattern to HEp-2 cells and to each other. These strains cause a watery diarrhea in both industrialized and third-world countries. Diarrhea can be of relatively long duration ($\geq$ 14 days) in some cases. EAEC infects children and immunocompromised individuals, and these pathogens are an important cause of traveler's diarrhea. The major features of EAEC pathogenesis are colonization of the intestinal mucosa with mucoid biofilm formation, elaboration of enterotoxins, and mucosal inflammation. The plasmid (pAA)-encoded AAF (aggregative adherence fimbriae) and AggR (regulator) are required for colonization; however, AAF is not present in all EAEC strains, and therefore, other adhesins are likely involved in EAEC colonization. Adhesion is followed by secretion of Pet (plasmid-encoded toxin) and EAST1 toxins (plasmid-encoded EAEC heat-stable toxin 1). EAST1 is a small polypeptide enterotoxin that induces diarrhea by secreting cyclic GMP. The *pet* gene is located on pAA and encodes Pet, a heat-labile protein toxin belonging to the serine protease autotransporter family. Pet is an enterotoxin inducing cytoskeletal changes and epithelial cell rounding. In addition, the enterotoxin ShET-1 may be found in some EAEC. However, the role of enterotoxins in EAEC-induced diarrhea is not clear. EAEC strains that show the stacked brick phenotype and that

contain pAA are termed typical EAEC, whereas those strains that have the stacked brick phenotype but lack pAA are termed atypical EAEC. Both atypical and typical strains induce diarrhea. Rehydration therapy and antibiotics are recommended as treatments for EAEC infection. Ingestion of food has been associated with EAEC-induced diarrhea; however, the reservoir of the organism is unknown. Salsa in Mexico, unpasteurized cheeses in Italy, and school lunches in Japan have caused outbreaks of EAEC-induced illness. It is probable that infected food handlers are the source of the organism.

Diffusely Adherent *E. coli*

Diffuse adherence is characterized by uniform attachment of bacteria to HeLa or HEp-2 cells, whereas localized adherence is when bacteria attach in groups to only a few sites on the cultured cell surface. Diffusely adherent *E. coli* (DAEC) are a poorly characterized heterogeneous population of *E. coli* showing diffuse attachment to cell surfaces and are believed to be a cause of diarrhea. The DAEC pathotype colonizes the small bowel and may be responsible for watery diarrhea in children. Diffuse adherence is mediated by both fimbrial (Dr and F1845) and afimbrial (Afa) adhesions. A secreted autotransporter toxin (SAT) has been demonstrated in DAEC strains associated with diarrhea. SAT induces lesions on tight junctions of epithelial cells causing increased permeability and may be a virulence mechanism in DAEC. However, the mechanism of diarrhea induction in DAEC strains is not certain.

Shiga Toxin-Producing Enteroaggregative *E. coli*

The Shiga toxin-producing enteroaggregative *E. coli* (STEAEC) may be a newly emerging pathotype of *E. coli*. The serotype O104:H4 caused a large outbreak associated with close to 4000 cases of illness, over 800 cases of HUS, and over 50 deaths in Europe in 2011. This pathotype is unusual in that the organism carried the pAA-virulence plasmid (and its virulence genes) of EAEC strains and a *stx*2-harboring prophage. Thus, this STEAEC strain presents the stacked brick phenotype of EAEC and production of Shiga toxin. The STEAEC strain is not a pathogenic *E. coli* with new virulence factors but is rather a pathogen that has combined the virulence properties of the EAEC with the production of Shiga toxin of the STEC pathotype. The strong morbidity and mortality induced by this strain may be due to its strong adherence to the host cell leading to higher levels of Stx transfer. The serotype O111:H2 with both Stx2 and EAgg (AggR) was reported in 1997 as a cause of a case of HUS, and in 2012, an outbreak induced by serotype O111:H21 positive for Stx2c and *aggR* occurred in Ireland. Therefore, it is probable that the transfer of the Shiga toxin gene into other EAEC serotypes will produce STEAEC serotypes that may cause serious outbreaks of Shiga toxin-induced HC and HUS in the future.

Recent Outbreaks in the United States due to *E. coli* Pathotypes

For the years 2009–10, the Centers for Disease Control and Prevention reported that there were 58 outbreaks due to STEC serotypes (53 due to STEC O157:H7 and 5 due to non-O157 STEC) with 651 total cases. In 2009, there were three outbreaks due to ETEC with 85 cases, and in 2010, EPEC caused one outbreak with 7 cases. The vehicles of infection were not provided. There were no reported outbreaks caused by EIEC, EAEC, or DAEC for 2009–10.

Nonintestinal Pathogenic *E. coli*

The nonintestinal pathogenic *E. coli*, which are a cause of illness outside of the gut, are termed extraintestinal pathogenic *E. coli* (ExPEC). The intestinal pathogenic *E. coli* (IPEC) are obligate pathogens, whereas the ExPEC are facultative pathogens that reside in the gut of a fraction of individuals and behave as harmless commensal organisms. In general, the IPEC have well-defined virulence traits, whereas ExPEC strains are very diverse and have few common virulence factors among them. Thus, it is difficult to define ExPEC by virulence properties. At the present time, ExPEC and nonpathogenic *E. coli* cannot be differentiated by molecular epidemiological techniques, and therefore, there is a limited understanding of the biology of ExPEC.

Urinary tract infections (UTIs) are common bacterial infections, particularly in women, and extract extremely high health costs in terms of morbidity, treatment, and loss of productivity. Uropathogenic *E. coli* (UPEC) are ExPEC that cause ~80% of community-acquired UTIs and ~30% of nosocomial UTIs. The UPEC reside in the gastrointestinal tract and can be transferred to the urinary tract. Infection of the urethra is termed urethritis, that of the bladder is termed cystitis, and that of the kidneys is termed pyelonephritis. Individuals at risk for acquiring UTIs include the very young, elderly, females, pregnant women, and individuals who are immunocompromised or who are undergoing urinary catheterization. The UPEC possess a number of virulence traits that make them efficient pathogens of the urinary tract such as specific adhesins; several toxins including hemolysin, cytotoxic necrotizing factor type 1 (CNF1), and a protease toxin (SAT); and iron acquisition systems. The primary reservoir for UPEC is the human intestinal tract; however, the original source (e.g., possibly avian, food, or environmental source) of UPEC is not clear.

The pathology leading to UTIs by UPEC includes adherence and colonization, evasion of host defenses, and damage to host cells and tissues. The UPEC are transferred from the rectum to the periurethral area and ascend the urethra into the bladder. Type 1 fimbriated UPEC attach to the bladder epithelial cells and trigger apoptosis and exfoliation, as well as invasion and multiplication of UPEC in the bladder cells. If the UTI is not treated, the organisms may ascend the ureters and induce pyelonephritis. Pyelonephritis can cause irreversible kidney damage, kidney failure, and death. Some individuals may have high bacterial counts in the urine but are asymptomatic. Treatment of UTIs is becoming more complicated due to increased resistance of UPEC to antimicrobial compounds.

Neonatal meningitis *E. coli* (NMEC) strains are ExPEC that represent the most frequent cause of gram-negative meningitis in the newborn. Bacterial meningitis is an inflammation of the meninges with high morbidity and mortality. Severe neurological sequelae occur in 30–50% of infants who survive

meningitis. The neonate (neonatal period is the first 28 days after birth) acquires NMEC during birth or from the environment, and the organisms invade and multiply in the bloodstream. The NMEC pathogen then crosses the blood–brain barrier (BBB). The BBB is a structural and functional barrier made up of the brain microvascular endothelial cells (BMECs), which separates the CNS from the vascular component of the body. The BBB regulates the transition of macromolecules into the CNS and protects the CNS against entry of microbes and toxins that may be present in the blood.

There are several stages of NMEC pathogenesis: bacteremia, binding of bacteria to the surface of the BMEC, and invasion of the BMEC followed by invasion of the meninges and the CNS.

Meningitis is associated with bacteremia counts of $>10^3$ CFU ml^{-1} blood. Outer membrane protein A (OmpA), K1 capsule (carried by the predominant strains of *E. coli* that cause neonatal meningitis), and *O*-lipopolysaccharide are necessary for survival and multiplication of NMEC in the circulatory system. OmpA and FimB (fimbriae) of NMEC bind to BMEC, and the organism invades the BMEC via a transcellular traversal mechanism in which the bacteria penetrate the cells without disrupting them. OmpA, Ibe proteins, and CNF1 induce actin cytoskeletal rearrangement and formation of microvillus-like protrusions, which facilitate entry of the organisms into the BMEC. NMEC leave the BMEC and invade the meninges and CNS, and then, they multiply and induce the release of proinflammatory compounds. In addition, there are brain edema and increased intracranial pressure with meningitis and neuronal injury. Neonatal meningitis is treated with appropriate antibiotics.

Avian pathogenic *E. coli* (APEC) are responsible for a number of economically important poultry diseases. Interestingly, some human ExPEC and some APEC strains have similar phylogenetic backgrounds and share some of the same virulence genes. This relationship between ExPEC and APEC suggests that APEC may be zoonotic pathogens that can lead to human diseases such as UTIs or neonatal meningitis through the ingestion of poultry meat. Recent studies support the role of chicken meat as a potential source of organisms inducing UTIs to humans; however, food has not been shown to be related to neonatal meningitis.

Other Enterobacteriaceae

Cronobacter sakazakii

The genus *Cronobacter* consists of seven species, namely, *C. sakazakii*, *C. malonaticus*, *C. turicensis*, *C. dublinensis*, *C. muytjensii*, *C. condimenti*, and *C. universalis*. *Cronobacter* species are gram-negative, motile by peritrichous flagella, non-spore-forming, facultatively anaerobic, rod-shaped bacteria. *Cronobacter* species are more thermotolerant when compared with other genera in the Enterobacteriaceae family, and they can grow in temperatures over a range of 6–47 °C. The reservoir of *Cronobacter* is unknown; however, plants are a possible source, and the organisms have been isolated from a wide range of food products. Most *Cronobacter* species have been associated with human illness; however, the majority of the infections in infants and neonates have been associated with *C. sakazakii*, and this species has been the most studied. Infants that ingest rehydrated powdered milk formula contaminated with *C. sakazakii* suffer bacteremia, meningitis, and necrotizing enterocolitis; mortality is greater than 50%. Infections among immunocompromised adults, particularly the elderly, have been reported. The outer membrane protein, OmpA, is an important virulence factor in the development of meningitis in newborn rats. OmpA-positive *Cronobacter* cross the intestinal barrier, multiply in the blood, and invade the brain endothelial cells. The pathogen crosses the BBB and eventually causes meningitis. *Cronobacter* lacking the *ompA* gene do not bind to intestinal epithelial cells, do not cross the intestinal barrier, and do not lead to pathology. Other potential virulence factors include biofilm formation and membrane-associated efflux pumps that expel a broad range of inhibitory compounds. However, it is clear that knowledge of the virulence mechanisms of the *Cronobacter* species is limited.

Shigella

The *Shigella* species are small, gram-negative, nonmotile, facultatively anaerobic rods, which do not produce spores or capsules. The optimum growth temperature is 37 °C. The organisms are the causative agents of bacillary dysentery (shigellosis). All of the species except *Shigella sonnei* have several serotypes. Humans are the natural host of the *Shigella* species. The organisms are transmitted via the fecal–oral route by infected individuals and contaminated food and water. Shigellosis is an invasive infection of the colon that ranges from short-term watery diarrhea to inflammatory bowel disease. In inflammatory bowel disease, watery diarrhea proceeds to bloody mucoid stools, abdominal cramps, and tenesmus. In healthy individuals, shigellosis is self-limited and resolves without sequelae. In malnourished infants and young children in developing countries, shigellosis can result in acute, life-threatening complications. HIV-infected and immunocompromised individuals may suffer persistent diarrhea and malnutrition if infected by *Shigella*. Cellular invasion and spread of infection involve invasion of the enterocytes, intracellular multiplication, intra- and intercellular spread, killing of the host cells, and tissue damage. *Shigella dysenteriae*, but not other *Shigella* species, produce Shiga toxin. Shiga toxin is encoded chromosomally in *Shigella dysenteriae*, whereas it is phage-encoded in STEC. Similar to STEC, infection by *Shigella dysenteriae* can induce HUS. The virulence of *Shigella* is dependent on a virulence plasmid encoding T3SS components. T3SS is necessary for invasion and secretion of virulence factors into intestinal epithelial cells leading to inflammatory destruction of the epithelial lining of the intestine. Rehydration therapy and antibiotics are used to treat shigellosis.

Salmonella enterica

Salmonella spp. are rod-shaped, gram-negative, non-spore-forming, predominantly motile with peritrichous flagella, chemoorganotrophic, and facultatively anaerobic. The range of temperature for growth is 2–54 °C, and the optimum is 35–37 °C. There are more than 2000 different serovars based on flagellar, carbohydrate, and lipopolysaccharide characteristics. *Salmonella* causes disease in both animals and humans. Serovars Typhi, Paratyphi, and Sendai cause enteric fever, whereas most

serovars cause enterocolitis and diarrhea. The elderly, infants, and immunocompromised individuals are at the highest risk for *Salmonella* infections. Ingestion of food or water contaminated with nontyphoidal *Salmonella* is followed by crampy, abdominal pain, diarrhea, nausea, and vomiting. Enterocolitis in children is marked by increased severity of inflammation, bloody diarrhea, long duration, and increased risk of complications. Salmonellosis is self-limited in immunocompetent hosts. A small number of infected individuals develop a sequela known as reactive arthritis. Important virulence genes are carried on the *Salmonella* pathogenicity islands (SPI-1 through SPI-5). Other virulence traits include the virulence plasmid (pSLT), adhesins, flagella, and proteins involved in biofilm formation. Antibiotics are recommended in severely ill patients; however, it is important to realize that antibiotic resistance is common in the salmonellae. Hydration therapy is necessary in cases of severe diarrhea.

Yersinia

Yersiniosis is a self-limiting gastrointestinal disease in immunocompetent individuals; however, in young children and immunocompromised individuals, the disease is more severe and may result in death. Sequelae such as reactive arthritis may occur after infection. The organism is rod-shaped, gram-negative, psychrotrophic (can grow at 4 °C), and facultatively anaerobic. Yersiniosis is a foodborne disease caused mainly by *Y. enterocolitica* and *Y. pseudotuberculosis*, and the flea-transmitted *Y. pestis* rarely causes foodborne illness. Pigs are the major reservoir of *Y. enterocolitica*; pig tonsils are a common site of *Yersinia* colonization. The absence of the virulence plasmid (pYV) is associated with lack of pathogenicity in *Y. enterocolitica*. pYV encodes the *Yersinia* adhesin YadA, which mediates mucus and epithelial cell attachment and host cell invasion. A T3SS is also encoded by pYV and is involved in the injection of virulence-related effector proteins, the *Yersinia* outer membrane proteins (Yops), into the host cell. The Yop proteins interfere with host signal induction (evasion of immune responses), disrupt host actin cytoskeleton, and induce apoptosis in host cells. Chromosomal genes encoding the invasion protein (Inv) and the attachment-invasion locus (Ail) have a role in cell binding and invasion by *Yersinia*. The most common vehicle for yersiniosis is contaminated food, including meat, oysters, fish, raw milk, and cheese. Antibiotics are used to treat yersiniosis.

Escherichia coli and Other *Enterobacteriaceae*: Occurrence and Detection

S Fanning, L Rogers, K Power, and P Ó Gaora, University College Dublin, Dublin, Ireland

© 2016 Elsevier Ltd. All rights reserved.

Enterobacteriaceae

All members of the *Enterobacteriaceae* possess some common bacteriological features. They are gram-negative, rod-shaped facultative anaerobes. Bacterial isolates are classified as being either motile by means of peritrichous flagella or nonmotile, being devoid of any flagella. Members of this family are generally 0.3–1.0 × 0.6–6.0 μm in size and are non-spore-forming. They can ferment glucose and are catalase-positive (except for *Shigella dysenteriae*) and oxidase-negative, and they reduce nitrate to nitrite. Table 1 provides a summary of the general characteristics of some of the members of this family.

Enterobacteriaceae family members are associated with a wide range of disease (Figure 1). Illnesses associated with members of the *Enterobacteriaceae* include wound infections, urinary tract infections (UTI), gastroenteritis, meningitis, pneumonia, septicemia, and hemolytic uremic syndrome (HUS). While some of these species are true pathogens, others are regarded as opportunistic.

Members of this bacterial family can grow readily on a variety of microbiological culture media. They are also widely dispersed throughout the environment being found in soil, water, plants, and the gastrointestinal tract of animals and humans.

The Genus *Escherichia*

The genus *Escherichia* was described originally by Theodore von Escherich who first discovered *Escherichia coli* in 1885. This bacterial genus contains five species with *E. coli* being the best known. Other species include *E. albertii*, *E. fergusonii*, *E. hermannii*, and *E. vulneris*. A number of species are pathogenic; however, the majority are commensals or opportunistic pathogens.

Features associated with isolates of the E. coli *genus*

Escherichia coli cells are 0.5 μm in length and 2.0 μm in diameter. Optimal growth occurs at a temperature of 37 °C, though some strains can grow at temperatures up to 49 °C. The optimal range of pH is between 6.0 and 7.0, with few being able to grow at a pH <4 or >9. *E. coli* grown on MacConkey agar forms small, red/pink, smooth, and circular colonies. When further assessed, these are motile by means of peritrichous flagella (Table 1).

Environments known to contain E. coli

These bacteria can be found in the gastrointestinal tract of warm-blooded animals in which it colonizes within hours of birth. Strains can also be found throughout the environment, in water, food, and soil. Most *E. coli* isolates are harmless and play an important role as constituents of the normal biota or microbiome found in a healthy human intestinal tract. They aid digestion in the gut, produce vitamin K_2, and prevent pathogenic bacteria from thriving in the environment of the intestine.

Relevance of E. coli *to public health*

Pathogenic strains of *E. coli* cause a variety of illnesses such as food poisoning with severe stomach cramps, watery or bloody diarrhea, vomiting, and nausea. Severe complications include kidney failure, seizures, and stroke. The main route of transmission is through *fecal–oral contamination*, due to poor hygienic conditions.

E. coli has a very fluid genome that enables the uptake of many different mobile genetic elements. This genomic fluidity has had a large impact on the evolution of pathogenic serovars with phages, plasmids, and pathogenicity islands playing a role in their diversity and evolution. This has resulted in the emergence of pathogenic strains that are associated with their own virulence factors and disease symptoms. Pathogenic strains are classified into a number of pathotypes as follows:

- Verotoxigenic *E. coli* (VTEC)
- Enterotoxigenic *E. coli* (ETEC)
- Enteropathogenic *E. coli* (EPEC)
- Enteroaggregative *E. coli* (EAEC)
- Enteroinvasive *E. coli* (EIEC)
- Diffusely adherent *E. coli* (DAEC)

Pathotypes of *Escherichia coli* Important to Human Health

Verotoxigenic E. coli

VTEC strains are defined by the production of cytotoxins that disrupt protein synthesis within host cells. These toxins are referred to as either verotoxins (*vt*) due to their activity against Vero cells *in vitro* or Shiga-like toxin 1 (*stx*1) and Shiga-like toxin 2 (*stx*2) due to their similarity to the Shiga toxin produced by *Shigella dysenteriae*.

Dissemination of these strains occurs *via* the *fecal–oral* route arising from substandard hygienic conditions. An infectious dose can be as low as 10–100 cells. Ruminant animals are an important reservoir for VTEC. Infections can occur through contact with an infected individual, directly from an animal shedding the organism or its fecal matter, *via* the consumption of a contaminated food containing the bacterium or through the consumption of contaminated water.

Symptoms of a VTEC infection can range from mild diarrhea to severe bloody diarrhea. Potentially fatal complications arising from VTEC infections include HUS and thrombotic thrombocytopenic purpura.

Enterohemorrhagic *E. coli* (EHEC) is a subset of VTEC that is classified as pathogenic to humans. Usually, strains are classified as EHEC when they contain a verotoxin-encoding gene in combination with an *eae* gene that encodes intimin, an outer membrane protein that is involved in attachment to epithelial cells. Some *eae*-negative strains may also be EHEC.

Table 1 Typical characteristics of *Enterobacteriaceae*

Features	*Escherichia coli*	*Salmonella*	*Yersinia*	*Cronobacter*	*Enterobacter*	*Citrobacter*
Size (μm)	0.5 × 2.0	3.4 × 0.7	0.8 × 1–2	3 × 1	0.6 × 2–3	1 × 2–6

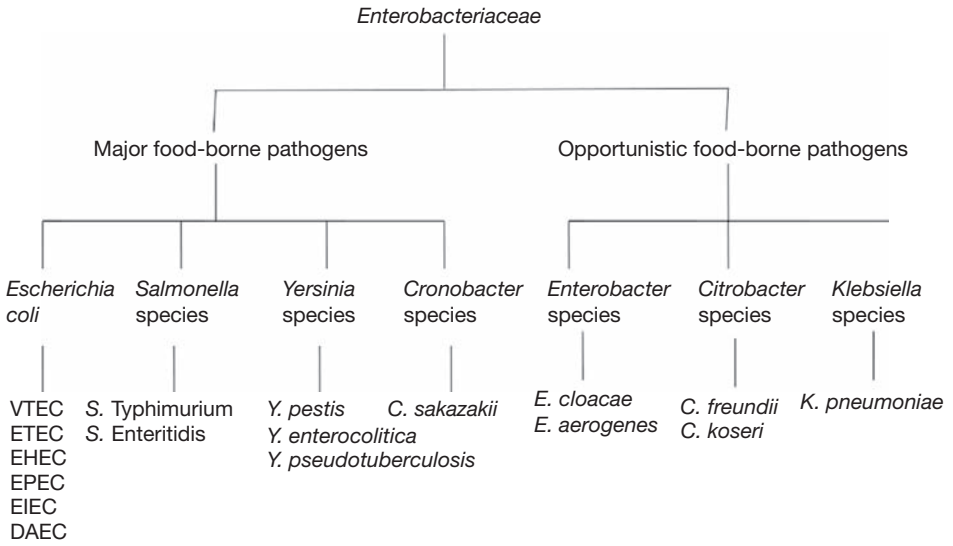

Figure 1 *Enterobacteriaceae* of importance to public health.

They produce highly potent toxins and can form attaching and effacing lesions on epithelial cells, a characteristic typically associated with EPEC strains. In terms of public health, *E. coli* O157 is one of the most commonly detected EHEC serotypes, although other serotypes are also being recognized.

Enteropathogenic E. coli

EPEC strains are noted for their ability to produce attaching and effacing (A/E) lesions. In this case, bacteria attach to the host epithelial cell membrane disrupting the cell surface resulting in the effacement of microvilli at the site of adherence. EPEC contains a 35 kbp pathogenicity island called the locus of enterocyte effacement, which encodes genes responsible for the attaching and effacing lesions.

These strains are further classified into typical enteropathogenic *E. coli* (tEPEC) and atypical enteropathogenic *E. coli* (aEPEC) based on the presence and absence of the *E. coli* adherence factor plasmid that is only found in tEPEC strains. tEPEC is a well-documented cause of gastroenteritis in infants. aEPEC is more prevalent than tEPEC in both developed and developing countries and is an important risk factor in juvenile endemic diarrhea and diarrheal outbreaks.

Outbreaks of EPEC infection have been linked to the consumption of contaminated drinking water as well as some meat products. In the case of tEPEC, humans are thought to be the only reservoir while both animals and humans are reservoirs for aEPEC.

Enterotoxigenic E. coli

ETEC strains are characterized by their expression of enterotoxins and the presence of host-specific fimbriae required for attachment to intestinal cells. Two types of toxins, heat-stable (ST) and heat-labile (LT) toxins, are produced by ETEC. Different strains can harbor either one or both of these toxin-encoding loci. The toxins act to stimulate the intestinal lining leading to an increase in fluid secretion resulting in diarrhea.

These pathogenic *E. coli* are the leading cause of traveler's diarrhea. Symptoms range from mild to severe cholera-like illness characterized by watery stool(s), vomiting, and stomach pains lasting up to 3 days. The infectious dose is estimated at 10^8 cells but is lower in immunocompromised patients.

ETEC is mainly transmitted through food and water contaminated with human and animal feces. In humans, ETEC

infections are widespread though rarely life-threatening and usually self-limiting. It is a major pathogen in animals and can even cause death.

Enteroinvasive E. coli

These bacteria are characterized by their ability to invade epithelial cells and disseminate from *cell to cell* while replicating within. EIEC differ from typical *E. coli* in that they are nonmotile and cannot decarboxylate lysine nor ferment lactose. EIEC strains possess an invasion plasmid that encodes the virulence genes conferring EIEC invasive capacity.

EIEC strains are highly related to *Shigella* species at the genetic, biochemical, and pathogenic levels. They cause a syndrome identical to bacillary dysentery more often linked to *Shigella* species, with profuse diarrhea and high fever. The infectious dose of EIEC is estimated at 10^6 cells whereas that of *Shigella* is similar to EHEC, in the range of ten to several hundred cells.

There are no known animal reservoirs of EIEC. Transmission usually occurs through contact with infected humans through the fecal–oral route. EIEC infections can also occur through ingestion of contaminated food or water.

Enteroaggregative E. coli

EAEC strains are characterized by their ability to adhere to epithelial cells in an aggregative manner resulting in a *stacked-brick pattern*. They do not secrete LT or ST enterotoxins. EAEC pathogenesis involves adherence to the intestinal mucosa resulting in increased production and deposition of a mucus biofilm leading to mucosal toxicity due to inflammation and cytokine release. EAEC strains can cause persistent infection by evading the immune system of the host.

These organisms are associated with acute or persistent diarrhea with little or no fever and no vomiting. They are especially prevalent among children in developing countries. EAEC strains are considered emerging pathogens, as VTEC O111:H2 strains isolated from a HUS outbreak in France also possessed genetic markers of EAEC *E. coli*. EAEC outbreaks have been linked to infant food including formula, milk, and water.

In the summer of 2011, a novel strain of *E. coli* O104:H4 emerged and caused a serious food-borne outbreak in Lower Saxony, Germany. This outbreak was associated with serious illness such as bloody diarrhea with a high incidence of HUS. Epidemiological investigations reported 3816 cases with 845 instances of HUS and 54 deaths. At first, *E. coli* O104:H4 was thought to be an EHEC strain, but it was later identified as an EAEC that had acquired the ability to produce Shiga toxin.

Diffusely adherent E. coli

DAEC strains are characterized by their adherence to Hep-2 cells in a diffuse pattern. Approximately 75% of these bacteria express the Afa/Dr family of adhesins, but not the typical virulence genes of other *E. coli* pathotypes.

DAEC are a major cause of UTI and can cause watery diarrhea typically without blood but with vomiting. Infection is characterized by the growth of fingerlike cellular projections on the surface of infected epithelial cells that envelop the bacteria. Sources associated with DAEC infections include contaminated food such as undercooked beef, contaminated water, and contact with infected animals.

Enterobacteriaceae of Importance to Human Health

The genus Salmonella

This bacterial genus was named after Daniel Elmer Salmon following the discovery of the type strain *Salmonella enterica* in 1885. The *Salmonella* genus contains three species, *S. bongori*, *S. enterica* (including six subspecies), and *S. subterranea*. The genus is subdivided into more than 2500 serovars based on antigenic features. *Salmonella enterica* and its serovars are most commonly associated with human disease.

Features associated with isolates of the Salmonella *genus*

Salmonella cells are 2–3.4 μm long and 0.7–9.0 μm in diameter, with rounded ends. Most have peritrichous flagella, though *S. subterranea* has one lateral flagellum. Optimal growth occurs within a pH range from 6.5 to 9.0 and across a temperature range of 30–37 °C. *Salmonella* species do not grow at pHs <3.5 and >9.5 nor at temperatures <10 °C and >42 °C. *Salmonellae* are acid-tolerant and can grow at lower pH limits of 3.7–4.4. *Salmonella* species can produce hydrogen sulfide from thiosulfate. The motility of *Salmonella* isolates is strain-dependent and specific to the host environment.

Environments known to contain Salmonella

Salmonella species are isolated from aquatic and sedimentary environments where they can multiply though these are regarded as transitional environments between host infections. Some strains such as *S. subterranea* are specifically adapted for living in soil. Salmonellae possess the ability to survive in low-moisture conditions and are associated with many food-borne outbreaks especially in the ready to eat food market.

Relevance of Salmonella *to public health*

Salmonella species cause illnesses including typhoid fever, paratyphoid fever, and food-borne illnesses. These bacteria are zoonotic pathogens, being present in (food-producing) animals from which they can transfer to humans. *S. enterica* subspecies *enterica* serovars Typhimurium and Enteritidis are commonly reported members of this genus. These bacteria can exhibit resistance to one or more antibiotics, compromising treatment in some infected individuals.

Nontyphoidal salmonellosis is food-borne, and consequently, the food chain is an important route of infection for humans. *Salmonella* typhimurium is one of the serovars most often associated with cases of food-borne infections. Clinical signs associated with salmonellosis include diarrhea, dehydration, fever, and abdominal pain that can last for up to 7 days. There is a greater risk of infection in the young, the elderly, and immunocompromised individuals.

The genus Yersinia

Yersinia pestis (the 'plague bacillus') was first identified by Alexandre Yersin in 1894 and classified as *Pasteurella pestis* soon thereafter. Von Logham reclassified *Pasteurella pestis* and *Pasteurella rodentium* into the new genus of *Yersinia* in 1944. The name was accepted as an official genus in 1980. The genus *Yersinia* contains 17 species, of which only 3 are known to be

pathogenic to humans. These include *Y. pestis*, *Y. enterocolitica*, and *Y. pseudotuberculosis*.

Features associated with isolates of the Yersinia *genus*

Yersinia species form gray-white translucent colonies after 24 h of growth on blood agar plates. After 48 h on MacConkey agar, they form clear colonies. *Yersinia* strains are nonmotile at temperatures between 25 and 35 °C (Table 1). Y. *enterocolitica* and *Y. pseudotuberculosis* are psychotropic, being capable of growth at temperatures of 4 °C or even lower.

Environments known to contain Yersinia

Rodents are the natural reservoirs of *Yersinia* species, although other mammals can occasionally serve as hosts. *Yersinia pestis* can be transmitted to humans subcutaneously through flea bites and can become airborne during pandemics. Due to the ability of enteropathogenic *Yersinia* species to grow at low temperatures, refrigerated foodstuffs can become contaminated with these organisms. Swine and wild animals are common reservoirs.

Relevance of Yersinia *to public health*

The pathogenic species of *Yersinia* have been linked with a wide range of illnesses in humans including Crohn's disease, yersiniosis, mesenteric lymphadenitis pseudoappendicitis, and systemic infectious disease, commonly known as plague.

Y. pestis is the causative agent of the plague, which has been responsible for three human pandemics throughout history. These are the Justinian plagues, recorded from the sixth to eighth centuries, the Black Death from the fourteenth to nineteenth centuries, and the modern plague from the nineteenth century to the present time.

Y. enterocolitica is primarily a food-borne pathogen found in some food-producing animals such as pigs and other mammals. After ingestion of contaminated water or food, *Y. enterocolitica* colonizes the intestine causing yersiniosis, an acute gastrointestinal condition. Symptoms include fever, abdominal pain, vomiting, and diarrhea. Treatment usually consists of an aggressive course of antimicrobial chemotherapy.

Y. pseudotuberculosis is the least common of the three *Yersinia* pathogenic strains. It causes an illness characterized by fever and acute abdominal pain arising from mesenteric lymphadenitis, an inflammation of the lymph nodes.

The genus Cronobacter

Originally, members of this bacterial genus were described as yellow-pigmented *Enterobacter cloacae* being subsequently reclassified as *Enterobacter sakazakii* in 1980. A further and more recent reclassification was reported in 2007 with the acceptance of the new genus name, *Cronobacter*, based on a polyphasic study of a large collection of these isolates. Currently, the genus *Cronobacter* contains seven species, namely, *C. sakazakii*, *C. malonaticus*, *C. turicensis*, *C. muytjensii*, *C. dublinensis*, *C. condimenti*, and *C. universalis*.

Features associated with isolates of the Cronobacter *genus*

Cronobacter are 3 μm long and 1 μm in diameter. *Cronobacter* species produce two colony morphotypes, one being described as glossy and the other having a matte texture. Some 80% of strains identified produce a yellow pigment on tryptone soya agar at 25 °C. These strains can grow over a wide range of temperatures from −5 °C to 44–47 °C depending on the isolate. Optimal growth occurs in pH ranging from five to ten with some isolates being more susceptible to acid exposure. *Cronobacter* have a notable tolerance to desiccation, being able to withstand dry conditions for up to 2 years in infant formula. *Cronobacter* strains are motile by means of peritrichous flagella.

Environments known to contain Cronobacter

Cronobacter has been isolated from a variety of food and environmental sources such as dairy products, dried meats, powdered infant formula (PIF), households, livestock facilities, food manufacturers, and PIF production facilities.

Relevance of Cronobacter *to public health*

Cronobacter species are regarded as opportunistic pathogens linked with life-threatening infections in neonates. Clinical presentation can include necrotizing enterocolitis, bacteremia, and meningitis. These organisms can also infect older adults, although these cases tend not to be life-threatening.

The genus Enterobacter

The genus *Enterobacter* was accepted in 1960 with *Enterobacter cloacae* being designated as the type species. With the application of modern typing techniques, nine species are currently recognized in this genus. These are *E. cancerogenus*, *E. aerogenes*, *E. mori*, *E. ludwigii*, *E. kobei*, *E. soli*, *E. asburiae*, *E. cloacae*, *and E. hormaechei*.

Features associated with isolates of the Enterobacter *genus*

Enterobacter species are motile by four to six peritrichous flagella. Some are encapsulated (Table 1). Generally, these bacteria are 0.6–1.0 × 2–3 μm in size. *Enterobacter* species produce round, iridescent, flat, nonpigmented, irregular-edged colonies, when grown on nutritive agar. The optimum growth temperatures are between 30 and 37 °C, though they can grow in temperatures up to 44 °C.

Environments known to contain Enterobacter

Enterobacter can be found on human skin, plants, soil, water, sewage, intestinal tracts of animals, including humans, dairy products; and clinical specimens such as feces, urine, blood, sputum, and wound exudates.

Relevance of Enterobacter *to public health*

Enterobacter species are considered opportunistic pathogens, rarely causing disease in healthy individuals. The species *E. cloacae* and *E. aerogenes* are the main pathogens in the genus. These organisms are associated with bacteremia, lower respiratory tract infections, skin and soft tissue infections, UTIs, endocarditis, osteomyelitis, arthritis, and ophthalmic infections. Outbreaks involving *E. cloacae* have been reported in the ICUs of hospitals.

E. cancerous is rarely associated with human infections and is considered a plant pathogen.

The genus Citrobacter

The genus *Citrobacter* was first proposed in 1932. *Citrobacter* contains 11 species: *C. amalonaticus*, *C. farmeri*, *C. braakii*,

C. freundii, *C. gillenii*, *C. murliniae*, *C. sedlakii*, *C. werkmanii*, *C. youngae*, *C. koseri*, and *C. rodentium*.

Features associated with isolates of the Citrobacter *genus*

Citrobacter species are 1.0 × 2.0–6.0 μm in size. They are found either singly or in pairs, are devoid of a capsule, and are motile. *C. freundii* form small, circular, convex dark pink colonies on MacConkey agar. Rough or mucoid forms have also been reported. *Citrobacter* species grow optimally at a temperature of 37 °C.

Environments known to contain Citrobacter

Citrobacter are found in a variety of environmental sources, including soil and water, and in the human intestines. They are rarely the primary source of illness, though some strains can cause infections of the urinary tract, sepsis, and infant meningitis.

Relevance of Citrobacter *to public health*

Citrobacter species are not regarded as significant etiological agents in human disease. *C. freundii* and *C. koseri* have mainly been isolated from urinary and respiratory tract infections. *Citrobacter* can cause septicemia in patients that display a number of predisposing factors. *Citrobacter* have also been found to cause meningitis, septicemia, and pulmonary infections in neonates and young children, and some of these cases have been linked to contaminated batches of PIF. *Citrobacter* is considered an opportunistic pathogen.

Detection of Members of the *Enterobacteriaceae* Family Using Conventional and Molecular Methods

Conventional microbiology

Conventional microbiological-based techniques make use of morphological and biochemical differences between genera and bacterial isolates recovered from different sources. Selective and differential bacterial culture media for enrichment and isolation of strains have been developed.

Examples of detection using bacterial morphology and reactions on specific culture media

Macroscopic morphology can aid with the identification of features visible to the naked eye. It describes colony appearance in terms of its shape, texture, pigment, speed of growth when incubated, and the growth pattern. Microscopic morphology allows for an examination of individual bacterial cells for their shape, size, Gram stain, and acid-fast reactions to aid identification. The goal is to achieve an initial presumptive identification of the bacterium on the culture plate.

The application of specially designed culture media is a method commonly used to aid the identification of key pathogens of significance to public health. As an example, *E. coli* O157 must be identified quickly due to its association with low infectious doses. Its impact on human health makes it the focus of numerous commercial diagnostic companies. Many of these exploit the inability of VTEC O157:H7 strains to ferment the carbon source contained in sorbitol MacConkey agar. When grown on this media, VTEC O157:H7 produces a colorless colony distinguishing it from other organisms on the same plate. However, more recently, some *E. coli* O157 have been identified with the ability to ferment sorbitol so other means for confirmatory identification must be developed and applied. Non-O157 strains may sometimes be differentiated through the use of Chromocult and Rainbow agar on the basis of their colony color. However, currently, there are no suitable commercial agars available for this purpose.

Similarly, *Salmonella* species are cultured from food (after a period of resuscitation) and from clinical samples directly onto selective agar media, usually xylose–lysine–deoxycholate agar, and incubated at 37 °C for 24 h. Colonies can be preliminarily classified based on their morphology.

Examples of diagnostic biochemical tests

Commercially available biochemical galleries exploit the expression or otherwise of different phenotypic characteristics to identify bacteria. Some of these tests exploit the biochemical capacity of an isolate in terms of its ability to ferment a range of sugars, susceptibility to various antibacterial agents including drugs, and the capacity to metabolize complex polymers. In addition, some strategies will allow for the assessment of the motile nature of an isolate (see **Table 1** in the preceding text).

Molecular-based diagnostic microbiology

Polymerase chain reaction

The polymerase chain reaction (PCR) is an *in vitro* version of the natural DNA replication process that occurs within all living cells. It can be applied to rapidly amplify a discrete segment of genomic DNA. Characteristically, double-stranded DNA is denatured, separating it into two discrete strands. Primers, short oligonucleotide sequences of synthetic DNA, hybridize to opposite DNA strands, and, following the addition of a thermostable DNA polymerase and the four dNTPs, a round of synthesis is initiated, extending the DNA from the synthetic primer on each strand. Up to 30 reiterated cycles of denaturation, annealing, and extension are completed within a typical PCR reaction, amplifying the original DNA target exponentially.

In a more recent development of the conventional PCR approach, quantitative *real-time* PCR (qPCR) emerged. This strategy enables quantification of target-specific amplicons. In this approach, a housekeeping gene is chosen to act as a normalized comparator against which a variable DNA target is measured, resulting in quantification of the latter. qPCR can be applied for the quantification of individual genes and bacteria of importance to human health.

As an example, VTEC organisms can be detected by targeting their unique virulence genes, including *stx* and *eae* (as described earlier). Real-time PCR assays have been developed that allow the detection of the major VTEC-associated genes enabling the differentiation of strains in *real time*. These targets can be combined into multiplex assay platforms that can facilitate the detection of several different VTEC serogroups simultaneously.

Various PCR-based methods for the detection of *Cronobacter* strains exist. These include a conventional 1,6-α-glucosidase-based PCR and a *dnaG*-based qPCR that can detect all seven of the *Cronobacter* species. When used in combination with a species level PCR assay, individual species of the genus can be identified. This PCR method used the *rpoB* gene for which specific primers have been designed for each species.

Pulsed-field gel electrophoresis

Pulsed-field gel electrophoresis (PFGE) makes use of suitable restriction enzymes to digest bacterial DNA at a limited number of sites within the genome, producing large or macro-DNA fragments that can be separated based on their size. The careful separation of these DNA fragments is achieved through the application of a periodical alternating electric field to a gel matrix. Comparison of these restriction profiles can indicate whether or not isolates are epidemiologically linked. PFGE has been used to aid with the tracking of many food-borne outbreaks and is regarded as the *gold standard* in molecular subtyping. PFGE has been standardized between different laboratories allowing for the comparison of PFGE profiles. PulseNet is an initiative that was originally developed at the CDC that facilitates the global tracking of food-borne pathogens.

Multilocus sequence typing

Multilocus sequence typing is a genome-based protocol used for the characterization of bacterial species by sequencing internal regions of typically seven housekeeping genes. To enable accurate sequencing, fragments of between 450 and 500 base pairs are used. Bacterial species display sufficient polymorphism within the chosen genes to assign an identifier to the alleles detected. By combining the sequences of (usually up to) seven loci, a species-specific allelic profile can be generated for each bacterial isolate.

Optical mapping

Optical mapping is a recently developed technique that generates high-resolution, ordered, whole-genome restriction maps from single DNA molecules independently of available sequence information. Purified DNA is isolated from a bacterium of interest and digested with a suitable restriction endonuclease. The DNA is then stained, scanned, accurately measured, and subsequently assembled into a complete genome restriction map. These maps can be compared to discover genetic differences, such as insertions or deletions between strains. Optical mapping can be used to distinguish between different species and isolates.

Optical mapping was applied to distinct *E. coli* O104:H4 German outbreak isolates in order to characterize differences. In this case, regions of differences contributing to the pathogenicity of this unusual strain were identified.

Whole-genome sequencing

Genome sequencing involves the decoding of a bacterium's complete genetic code, more specifically the determination of nucleotide order, within the chromosome. The technology underpinning this approach has evolved following a number of advancements over the years, and it is the most powerful analytic approach to molecular determination.

Next-generation sequencing

Next-generation sequencing (NGS) or high-throughput sequencing describes a number of sequencing technologies in common use. These approaches generate large volumes of sequence data at relatively low cost, thereby facilitating the rapid sequencing of DNA and RNA. This technology is significantly quicker and cheaper than the traditional Sanger-based technology.

A number of NGS technologies now exist for this purpose, such as

- Illumina (Solexa) sequencing,
- Roche 454 sequencing,
- Pacific Biosciences single-molecule real-time sequencing,
- SOLiD sequencing,
- Life Technologies Ion Torrent sequencing.

Despite the differences in the chemistries used, all the methods in the preceding text share some common features such as the random fragmentation of the template DNA, amplification of the target to be sequenced on a solid surface such as a bead or glass slide, and direct *step-by-step* detection of each nucleotide, following incorporation.

Sequencing technologies provide for the determination of the base order from thousands of small fragments that are subsequently assembled to generate a consensus genome sequence. Once assembled, this draft sequence must then be checked to confirm that correct assembly has taken place, followed by careful gene annotation and importantly the discovery of features of interest, including the identification of resistance and virulence genes along with other phenotypic data on a molecular basis.

NGS is a high-resolution and therefore accurate and reliable means of bacterial characterization.

In the 2011 German outbreak mentioned earlier, NGS technology facilitated the whole-genome characterization at an early stage of this incident. An *E. coli* O104:H4 outbreak isolate and a historic *E. coli* O104:H4 HUS isolate from 2001 were characterized using Ion Torrent's NGS in combination with optical mapping. Within 62 h, draft genomes were available enabling the genes to be examined. It was found that the strains carried genes associated with both EAEC and EHEC. Hence, it was proposed that the outbreak strain was a highly pathogenic hybrid of EAEC and EHEC strains.

Essential Oils: Isolation, Production and Uses

CM Cook, Hellenic Agricultural Organization-Demeter, Thermi, Greece
T Lanaras, Aristotle University of Thessaloniki, Thessaloniki, Greece

© 2016 Elsevier Ltd. All rights reserved.

Background

Essential oils are volatile, aromatic components of herbs and spices and have been used since ancient times in flavoring, food preservation, medicine, and perfumery. Some well-known aromatic and spice plants from which essential oils are produced commercially are shown in Table 1. The plant families Lamiaceae and Apiaceae are particularly rich in aromatic plants. The essential oil can be found in the flowers, leaves, roots, rhizomes, fruits, seeds, wood, and resins of these plants. On the surface of leaves and calyces, the essential oil is located in specialized cells called glandular trichomes.

Essential oils are synthesized by plants, as secondary metabolites, and are bioactive compounds with biological properties. They are considered to play a role in plant protection against herbivores making them unpalatable; in the attraction of pollinators; in plant protection against fungal, viral, and bacterial infections; in communication and signaling between other plants; and in allopathy by reducing the competition of neighboring plant species, among others. The essential oil content of plant material can vary with season, bioclimatic zone, growing conditions, and stress.

Essential oils can easily be isolated from plant material by hydrodistillation and are liquids at room temperature. They are a complex mixture of terpenes and terpenoids, which make up the characteristic aroma of each plant, and it is the composite effect of all the constituents present in it. They can be present from a mere trace up to around 95% of the essential oil. Most often, main components are precursors, intermediates, and end products of a particular biosynthetic pathway, and their relative proportions may depend on the time of year or the developmental stage of the plant. Terpenes are chemical compounds of low molecular weight, which are made up of isoprenoid units consisting of 5 carbon atoms, and these can join together to form units of C10 mono-, C15 sesqui-, C20 diterpenes. Oxygenated terpenes or terpenoids can be aldehydes, alcohols, ketones, acids, esters, ethers, and others.

Natural biodiversity is reflected by plants and their essential oils. It is possible to have several different species producing an essential oil with the same composition and major component (same biosynthetic pathway), for example, carvacrol in 'oregano' plants: *Origanum vulgare* subsp. *hirtum* ('Greek'), *O. onites* ('Turkish'), and *Thymbra capitata* ('Spanish' oregano). On the other hand plants of the same species, for example, Mentha spicata can have completely different aromas: 'peppermint' (menthol), 'spearmint' (carvone), 'wild mint' (piperitone and piperitenone oxide), and 'lavender' (linalool and linalyl acetate). These are known as chemotypes, plants of the same species having terpenoids arising from different biosynthetic pathways.

A return to the use of natural products in everyday life has stimulated interest in different aspects of essential oils and prospective uses in medicine, cosmetics, and the food industry. This interest is reflected in the marked increase in research publications on essential oils over the last twenty years (Figure 1) focused primarily on not only essential oil composition and biological properties but also isolation methodologies, species variation, chemotaxonomy, and others.

Isolation

The volatile nature, general insolubility in water, and solubility in organic solvents are properties of essential oils that can be exploited when designing isolation methods. The nature of the plant material and the lability of essential oil components should also be considered. Traditional and commercially most commonly used methods are distillation using water and/or steam, cohobation, maceration, enfleurage, and cold pressing. However, new technologies are continually being developed in order to decrease extraction times and energy costs.

Traditional Technology

Hydrosteam distillation

Distillation using water and/or steam is the most widely used and cost-effective method for the production of the majority of essential oils worldwide. It involves the application of heat and moisture to vaporize and release the essential oils from the plant material followed by the cooling of the vapor mixture and the separation of the oil from the water. Although the boiling point of most essential oil components generally ranges from 150 to 300 °C, they can be evaporated with steam/boiling water at 100 °C, as the combined vapor pressures of two immiscible liquids will be equal to atmospheric pressure at a lower temperature than that at which the essential oil will vaporize.

Hydrodistillation is the most simple of processes and has been used by man for centuries for the extraction of essential oils and is used mostly by small-scale producers. The plant material is almost completely covered by water in the chamber. The water is boiled using an external heat source, and the essential oils together with the steam are condensed and separated. Essential oil content of aromatic plants is determined using a Clevenger-type distillation apparatus, according to the European Pharmacopoeia. Disadvantages of hydrodistillation are that the process is slow and requires energy for heating, distillation rates may vary if the heat source is not controlled, and the direct heat source may cause charring of plant material in the base of the chamber. Prolonged contact of essential oils with the hot water can cause the hydrolysis of some essential oil constituents, for example, esters can hydrolyze to acids and alcohols. However, advantages of hydrodistillation are high yields of essential oil and good recovery of constituents. It is simpler and faster than steam distillation.

In steam and water distillation, direct contact with the boiling water is avoided by supporting the plant material on a grid. Advantages are that the process is faster and requires less fuel

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00261-0

Table 1 Some well-known aromatic plants and spices used commercially for their essential oil

Plant family	*Common (and scientific name)*
Anacardiaceae	Mastic (*Pistacia lentiscus* var. *chia*)
Annonaceae	Ylang-ylang (*Cananga odorata*)
Apiaceae	Dill (*Anethum graveolens*), parsley (*Petroselinum crispum*), anise (*Pimpinella anisum*), coriander (*Coriandrum sativum*), cumin (*Cuminum cyminum*), caraway (*Carum carvi*)
Asteraceae	Chamomile (*Chamaemelum nobile* and *Matricaria chamomilla*), tarragon (*Artemisia dracunculus*), yarrow (*Achillea millefolium*)
Burseraceae	Frankincense (*Boswellia* sp.)
Caprifoliaceae	Valerian (*Valeriana officinalis*)
Lamiaceae	'Greek' oregano (*Origanum vulgare* subsp. *hirtum*), peppermint (*Mentha* x *piperita*), spearmint (*Mentha spicata*), sage (*Salvia officinalis*), lavender (*Lavandula* sp.), rosemary (*Rosmarinus officinalis*), basil (*Ocimum basilicum*), marjoram (*Origanum majorana*), lemon balm (*Melissa officinalis*), pennyroyal (*Mentha pulegium*), thyme (*Thymus* sp.), patchouli (*Pogostemon cablin*)
Lauraceae	Bay (*Laurus nobilis*), cinnamon (*Cinnamomum* sp.)
Myristicaceae	Nutmeg (*Myristica fragrans*)
Myrtaceae	Clove (*Syzygium aromaticum*), eucalyptus (*Eucalyptus* sp.), wintergreen (*Gaultheria* sp.)
Oleaceae	Jasmine (*Jasminum* sp.)
Piperaceae	Black pepper (*Piper nigrum*)
Poaceae	Citronella grass (*Cymbopogon nardus*, *C. winterianus*)
Rosaceae	Damask rose (*Rosa* x *damescena* and *R. centifolia*)
Rutaceae	Lemon (*Citrus limon*), bergamot orange (*C. bergamia*)
Santalaceae	Sandalwood (*Santalum* sp.)
Schisandraceae	Star anise (*Illicium verum*)
Zingiberaceae	Cardamom (*Amomum* sp. and *Elettaria* sp.), ginger (*Zingiber officinale*), turmeric (*Curcuma longa*)

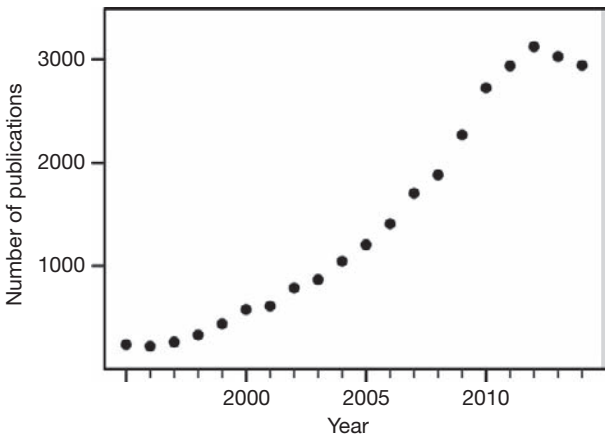

Figure 1 Trends in essential oil publications: 1995–2014. Web of Science (all databases), Thomson Reuters (2015) Thomson Reuters Web of Science. Available online: http://apps.webofknowledge.com (2015) (Accessed 30 January 2015).

than hydrodistillation while giving high reproducible yields. The method is used in developing countries as portable field distillation units, combining simple construction, ease of operation, and low cost with capacities of 100–2000 kg plant material.

In direct steam distillation, steam is generated in a boiler (external source) that is then passed through the plant material, which is supported on a grid in the chamber. Steam at atmospheric pressure has a temperature of 100 °C; however, the use of high-pressure steam correspondingly increases the temperature enabling a more rapid and complete distillation of essential oil. The advantages are reduced fuel costs due to higher thermal efficiency and suitability for large-scale production (1–3 ton plant material). However, setup costs are quite high and stills should be of stainless steel.

Distillation with cohobation: most essential oils have very low solubility in water; however, the solubility of rose oil, for example, is quite high. To avoid the loss in the condensing water, this water is returned to the still when using water and steam distillation for redistillation.

Solvent extraction

In the perfume industry, essential oil production is carried out using volatile solvents such as petroleum ether and hexane at 50 °C. This temperature is lower than that of distillation reducing the possibility of degradation of thermally labile compounds, and thus, essential oils are considered to have a more natural odor. After filtration, the essential oil is recovered by reducing the volume of solvent under vacuum evaporation; however, this can lead to severe losses of essential oil volatile components. Solvent extraction is advantageous when plant material is very limited (e.g., single leaf analysis) or where the major essential oil constituents are of interest rather than the essential oil content. Disadvantages are that nonvolatile compounds may be coextracted and that toxic solvent residues remain in the extract and can then contaminate food and fragrances. The process is also more expensive than distillation and creates waste disposal problems for the used solvents.

Enfleurage

Enfleurage is the extraction of essential oils using cold fat and has been used traditionally in the production of perfumes from fresh flower petals with low essential oil content, for example, jasmine and violets. The process has limited application on a large scale as it is very labor-intensive and has been superseded by modern processes such as extraction with volatile solvents. Dry flower petals are placed on glass plates coated with a thin layer of a high-quality odorless fat. Emitted essential oils are absorbed by the fat, and after extraction (in the order of 24 h or more hours), the petals are removed (defleurage) and replaced by fresh petals. This is an accumulative process that is repeated until the end of the flowering season. The essential oil that is absorbed in the fat is subsequently extracted with alcohol.

Cold pressing (expression)

This mechanical method is almost exclusively used in the production of citrus fruit (e.g., lemon, orange, and bergamot) essential oils. Pressure is used to crush the peel (pericarp) by rolling the fruit against sharp objects. Essential oil glands located in pits on the pericarp are punctured, releasing the essential oil, which is washed away with water. The essential

oil and water are separated by centrifugation. The process is carried out at low temperature so there is no thermal degradation of the essential oil components. Essential oil can be extracted before or after the extraction of the juice. Traditionally, expression was carried out by hand.

New 'Green' Technology

In recent years, research has centered on designing more efficient extraction procedures, which give higher yields (process intensification) with lower energy consumption and lower ambient operational temperatures. Conventional steam distillation and solvent extraction procedures although being generally simple have disadvantages of requiring long extraction times and large volumes of solvents. Industries are moving towards the application of greener nonconventional technologies with an emphasis on safer, sustainable, environmentally friendly, and more economical protocols. These nonconventional technologies include supercritical fluid extraction (SFE), solid-phase microextraction (SPME), ultrasound-assisted extraction (UAE), and microwave-assisted extraction (MAE), which are increasingly finding applications at a pilot and industrial level. It is interesting to see whether the trends in essential oil publications with respect to methods of isolation (MAE, solvent extraction, SPME, SFE, and hydrodistillation) for the period 1995–2014 (Figure 2) follow the trends in the development of new nonconventional technologies. Hydrodistillation is by far the primary isolation method reported in publications that would appear to be a result of the simplicity and low cost of the method. However, rising trends are also observed for SFE and SPME as might be expected.

Supercritical fluid extraction (SFE)

Carbon dioxide is a supercritical fluid when it is subjected to temperatures and pressures above its critical temperature (304.25 K) and pressure (7.39 MPa). It then expands like a gas but has the density of a liquid. Supercritical CO_2 is an important industrial solvent, which is odorless, colorless, nonflammable, and of low toxicity and environmental impact, compared to other organic solvents used in essential oil extraction, such as hexane and acetone, which are toxic and flammable. Other advantages of supercritical CO_2 extraction are relatively low temperature, shorter extraction times, selectivity, solvating power that varies with temperature and pressure enabling fractional extraction, absence of toxic residues that remain in extracts, absence of oxidation of essential oil compounds, ease of isolation of analytes from the supercritical CO_2 by pressure reduction (evaporation), and CO_2 recycling by condensation.

For essential oil extraction by SFE fractionation, supercritical CO_2 at temperatures of 40–50 °C and a pressure of about 11 MPa is passed into a heated extraction column packed with plant material. Usually, the plant material is incubated for a period of time (static mode) followed by a flow of new fluid (dynamic mode). The supercritical CO_2 with dissolved compounds is subjected to pressure reduction to remove the CO_2. Isolated essential oils may contain small amounts of other coextracted compounds such as cuticular waxes.

Solid-phase microextraction (SPME)

SPME is a rapid, solvent-free sample extraction technique. The SPME apparatus consists of a fiber holder and assembly containing a 1–2 cm thin, fused-silica retractable fiber coated with a thin polymeric coating such as polydimethylsiloxane (stationary phase). The sample is placed in a vial sealed with a septum. The fiber is extended through the needle into the headspace above the sample. The volatile analytes establish an equilibrium between the sample matrix, the gas phase above the sample, and the polymeric coating on the fused-silica fiber to which the analytes adsorb. After a given extraction time, the fiber is withdrawn and can be inserted directly into the injection port of a capillary GC column where the volatile analytes are rapidly, thermally desorbed. As no solvent is injected, there is no solvent front to mask component peaks

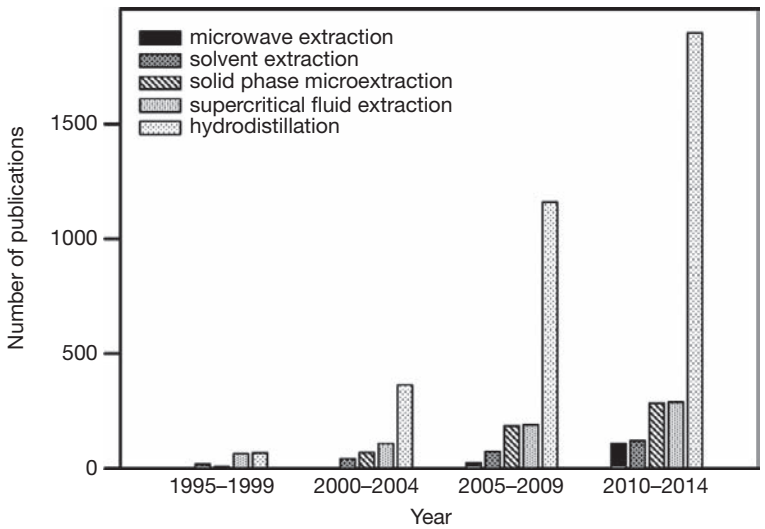

Figure 2 Trends in essential oil publications with respect to methods of isolation (microwave-assisted extraction, solvent extraction, solid-phase microextraction, supercritical fluid extraction, and hydrodistillation) for 5 year periods from 1995 to 2014. Web of Science (all databases), Thomson Reuters (2015) Thomson Reuters Web of Science. Available online: http://apps.webofknowledge.com (2015) (Accessed 30 January 2015).

eluting early from the column improving detection limits and resolution. SPME is used in the analysis of flavor and fragrance components in foods and beverages and is easily automated. It can be applied to very small samples and also to living systems.

Ultrasound-assisted extraction (UAE)

Ultrasound (US) has been used traditionally in biochemistry as a procedure for the production of plant extracts, as it causes the rupture of cell membranes and the release cell contents into the medium. The main factors that cause cell breakage are the water jets and shock waves caused by the collapse of cavitation bubbles generated by US. Part of the US pressure wave is dissipated as heat. The application of US to essential oil isolation enhances the homogenization of the plant material and thereby decreases the extraction time and the total energy consumed in the process. Analytes are more concentrated in the extract. The process is clean with no residues left in the extract. Combined with other extraction procedures, it can improve yield, selectivity, and product quality.

Recently, it has been shown that UAE using large-scale multiple transducer flow reactors operating at high power density ($700\,W\,l^{-1}$) promotes process intensification in the isolation of essential oils as compared to classical maceration in hydroalcoholic extracts. US has also been used to improve hydrodistillation extraction (sono-Clevenger) by greatly reducing extraction time without reducing yield or essential oil quality. Combined US and hydrodistillation extractions have been implemented on an industrial scale.

Microwave-assisted solvent extraction (MAE)

MAE is an extraction technique that combines microwave radiation technology with traditional solvent extraction. Microwave radiation is used to heat the solvent and plant material. Advantages of MAE are shorter extraction times (minutes rather than many hours), the use of less solvent, higher extraction yield, higher-quality products with lower cost, and lower energy consumption and CO_2 emissions when compared to Soxhlet or solvent extraction with stirring. Apparatus is simpler and less expensive than other methods such as SFE. Under optimized conditions (solvent volume, power, and heating time), the quality of essential oil and yield obtained are similar to those obtained by hydrodistillation.

Solvent-free microwave extraction (SFME)

Solvent-free microwave extraction (SFME) combines microwave heating and 'dry' distillation (no added solvent or water) under conditions of atmospheric pressure and 100 °C. Isolation and concentration of volatile compounds are performed in a single step. The internal heating of water within the plant material swells the plant cells and leads to rupture of the essential oil glands. Essential oil is evaporated by the *in situ* water of the plant material, and the distillate is passed through a cooling system outside the microwave. Excess water is returned to the extraction vessel to restore the *in situ* water of the plant tissue. SFME significantly reduces the time, energy, and plant material required for extraction. The reduction in extraction time and small amounts of water utilized decrease the likelihood of the hydrolysis, esterification, and/or oxidation of essential oil compounds.

Production

Production technology should be optimized and standardized in order to improve the overall yield and quality of the essential oil product. Raw plant materials, extraction yield and extraction time, and quality (composition, color, and texture) are important factors for industrial production, which looks for efficient, fast, and economic processes. Subsequently, storage conditions and containers should be optimized for maximum shelf life.

The quality of the raw plant material and an adequate supply for industry can be guaranteed by sustainable agricultural practices. Indiscriminate collection from the wild can lead to the reduction of wild resources, loss of biodiversity, and plant material of inconsistent quality. Cultivation of selected plants with high essential oil and biomass yields and of desired chemical composition (quality) is preferable. Harvesting times and postharvest drying and processing conditions must also be optimized and standardized so as to minimize any deterioration in quality and yield (appearance and loss of essential oil).

Extraction procedures should be carried out in stills and vats made of noncorrosive materials (e.g., stainless steel and glass) of optimal design and under optimal standardized conditions (temperature and time of extraction) for reproducible results. Plant materials such as seeds, roots, and wood may need to be crushed, ground, or soaked prior to extraction. Distilled essential oils with a high moisture content must be clarified using desiccants or on an industrial scale by high speed centrifugation. Moisture, oxygen, high temperature, and light adversely affect the storage life of the essential oil.

Essential oil composition (quality) can be analyzed using gas chromatography (separation of compounds) coupled with detection methods such as mass spectrometry (MS). For example, the gas chromatographic analysis of oregano (*Origanum vulgare* subsp. *hirtum*) essential oil (Figure 3) indicates many component peaks and the presence of four main components p-cymene (5), γ-terpinene (6), thymol (9), and the major component carvacrol (10). Some characteristics of these components are given in Table 2.

The standardization and quality control of essential oils ensure product quality and safety in worldwide markets. Standards are important and aid in the detection of adulterated and synthetic essential oils (addition of synthetic compounds and mixing with cheaper lower-quality oils, or solvents, to increase bulk). Standardization is an important reference for industry providing the properties of the natural components of products.

The International Organization for Standardization technical committee ISO/TC 54, *Essential oils*, has developed 1. specific monographs for quality standardization of all essential oils; 2. standardized analytic methods to control the quality of international standards of analytical methods and specifications; 3. requirements for transport, labeling, and marking; and 4. nomenclature and botanical names, with the aim of expanding global trade in essential oils and ensuring their quality and safety. ISO/TC 54 aims to 1. facilitate the global trade in essential oils, 2. enhance the quality of essential oils on the market, 3. protect the health of essential oil consumers, and 4. enhance the safety of essential oils. Many essential oils (or components) demonstrate toxicity and/or are hazardous in pregnancy and for persons with asthma or epilepsy and thus should be treated as medicines. The

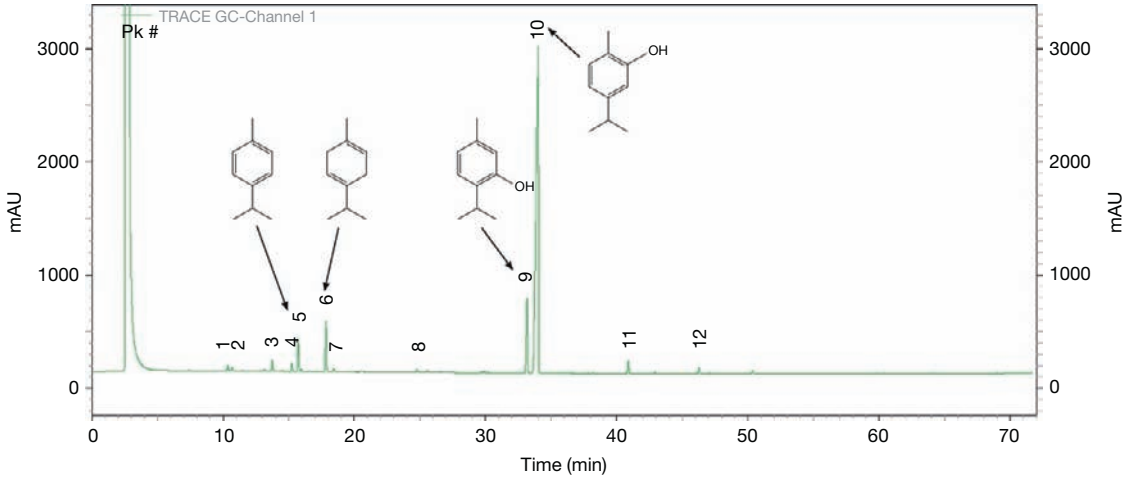

Figure 3 Gas chromatograph of *Origanum vulgare* subsp. *hirtum* (oregano) essential oil. Experimental details: the oil was analyzed by GC-FID using a ThermoQuest Trace GC with an HP-5MS capillary column (5% diphenyl-, 95% dimethyl- polysiloxane, non-polar, 30m × 0.25 mm ID × 0.25 μm film thickness) coupled with a flame ionization detector. Carrier gas: helium. Flow rate: 1.0 ml min^{-1}. Column temperature was 60 °C for 5 min, increased 2 °C min^{-1} until 150 °C and then increased 6 °C min^{-1} until 280 °C. The injector and detector temperatures were 240 °C. Kovats indexes were calculated by comparison of the relative retention times of the separated essential oil components with those of an homologous series of C_8-C_{26} n-alkanes standards.

Table 2 Some characteristics of the four main compounds of oregano essential oil analyzed by gas chromatography (see **Figure 3**)

Peak number	*Compound name*	*Kovats index*	*Molecular formula*	*Formula weight*	*Chemical abstract service number*
5	p-Cymene	1024	$C_{10}H_{14}$	134	99-87-6
6	γ-Terpinene	1059	$C_{10}H_{16}$	136	99-85-4
9	Thymol	1290	$C_{10}H_{14}O$	150	89-83-8
10	Carvacrol	1299	$C_{10}H_{14}O$	150	499-75-2

committee has also participated in the revision of and new European Pharmacopoeia monographs for essential oils.

Uses

Essential oils contain many bioactive compounds (e.g., terpenoids), which, apart from their fragrance and flavor, also show a wide range of biological activities and properties. For example, some of these properties are antibacterial, antifungal, antioxidant, insecticidal, insect repellent, acaricidal, larvicidal, anthelmintic, anti-inflammatory, cytotoxic, antibiotic, anticarcinogenic, analgesic, and local anesthetic. As such, these natural products from more than 300 essential oils are widely used in the food and beverage industry; in the pharmaceutical industry and medicine; in perfumery, cosmetics, and healthcare products (toiletries); and in veterinary science and alternative medicine (aromatherapy). As the uses are many, it is useful to examine them on a general level and then focus on some recent advances relevant to food and health.

Food Industry

About 60 % of essential oil production is used in the food industry primarily for flavoring and seasoning of food products such as cured meats, alcoholic and soft drinks, ice cream, and confectionary, among others. Essential oils also represent a source of natural antimicrobials for food preservation. Carvacrol, a major component of oregano essential oil, has many beneficial bioactivities in the preservation of food, which include antioxidative properties in food (fats and oils); the inhibition of foodborne human pathogenic bacteria, fungi, and parasites in human foods (eggs, meat and poultry products, milk, and leafy vegetables) and animal feed; and also the inhibition of microbial and fungal toxin production. The many health promoting effects of carvacrol create a potential for its use as a multifunctional food in pure and encapsulated form and in edible films.

Pharmaceutical Industry

Essential oils are generally not recommended for internal use undiluted due to their toxicity, nor for direct application to the skin, with the risk of dermatitis, allergic reaction, or skin photosensitization. However, topical application of some essential oils such as lavender and oregano when diluted in plant oils aids in the healing of wounds and burns. Essential oils are used as analgesics, expectorants, decongestants (menthol and eucalyptus), antiseptics, flavors to neutralize unpleasant tastes, and others.

Recently, some essential oil constituents such as geraniol have shown potential antitumor effects, inducing growth inhibition and apoptosis in cancer cells. Mice fed with diets supplemented with geraniol (25–75 mmol kg^{-1}) showed a dose- and time-dependent growth inhibition of tumor growth *in vivo* together with an induction of apoptosis. It also reduced cholesterogenesis. The doses of geraniol were nontoxic to the mice; the mevalonate biosynthetic pathway was inhibited. As such, geraniol could be a potential candidate for cancer chemotherapy.

Animal Feed Supplements and Animal Health

Essential oils have been evaluated for their effects on growth performance and meat quality of animals raised for meat production (e.g., poultry, pigs, and rabbits) as a safe and natural feed supplement alternative to the overuse of nontherapeutic antibiotics (growth promoters) and the subsequent development of antibiotic resistance in bacterial pathogens of humans and animals. For example, the supplementation of quail (*Coturnix coturnix*) diets with juniper oil (100 and 150 mg kg^{-1}) caused a significant increase in live weight, live weight gain, and carcass yields. Further, the dietary juniper oil reduced thiobarbituric acid levels in raw thigh meat samples in storage and exhibited antioxidant activity, preventing lipid oxidation in stored meat. Generally, essential oils as animal feed supplements can protect against the colonization of pathogenic microorganisms in the gut, reduce the fermentation process and the production of toxic metabolites, and have a positive effect on gut microbiota and animal welfare.

Many essential oil constituents (e.g., trans-cinnamaldehyde, thymol, carvacrol, citronellal, neral, linalool, and limonene) are important insect repellents and are effective against mosquitoes, fleas, ticks, flies, and lice, which can transmit infective diseases such as malaria.

Acknowledgment

The authors thank Evaggelia Samara for the technical assistance and acknowledge the financial support of the National Strategic Reference Framework (NSRF) Greece, Research Funding Program, Action ARISTEIA II (NATURAL AROMA-4204), for the essential oil analysis.

Essential Oils: Properties, Composition and Health Effects

G Buchbauer and IM Wallner, University of Vienna, Vienna, Austria

© 2016 Elsevier Ltd. All rights reserved.

Sources and Production

Essential oils are a group of plant secondary metabolites and are obtained only by steam distillation (according to ISO rule 9235) from different plant organs especially from aromatic plants. Those volatile compounds vary in odor and flavor. The manner of this distillation method is important because it determines the quality of the essential oil. Inappropriate production can result in the loss of bioactivity. Essential oils are concentrated liquids of complex mixtures and contain a lot of bioactive compounds.

Patterns of Consumption

Essential oils are lipophilic compounds, which are able to cross membranes very easily. Hence, essential oils are well absorbed not only from the intestine but also through the skin and the lungs. Because of their transdermal and pulmonary absorption, they are used for many medical applications in ointments, balms, and bath additives.

Availability, Absorption, and Metabolism

A high amount of essential oils is rapidly absorbed after dermal, oral, or pulmonary administration and crosses the blood–brain barrier. They are able to interact with the receptors in the central nervous system (CNS) and to affect biological functions such as relaxation, sleep, and digestion. Essential oil constituents can be metabolized by the liver in the form of polar compounds following limited phase I enzyme metabolism by conjunction with glucuronate or sulfate. Furthermore, they can be exhaled via the lungs as volatiles or as CO_2. Sulfate and glucuronide forms have been detected in urine and in plasma. Because of the fast metabolism and short half-life of active compounds, a minimum risk of accumulation in the body is suggested. The respiratory tract exerts the most rapid way of entry, followed by the dermal pathway. Essential oils and their metabolites can also be absorbed and delivered to the body through oral ingestion.

Health Effects

Essential oils and especially their constituents have a lot of health effects such as antibacterial, antiviral, and antifungal activities. Further fields of applications are anticancer therapy and therapies for cardiovascular and nervous system disorders. Additionally, they are used to reduce the level of cholesterol and regulate the glucose level. Besides, they are useful in the treatment of gynecological diseases. Essential oils are commonly used in the food and cosmetic industries.

Antioxidative Properties of Essential Oils

Nutritional properties of foodstuffs are affected by oxidation of oils. Today, the tendency goes towards using natural compounds such as essential oils for producing functional food. A present study has tested *Cinnamon zeylanicum* and *Zataria multiflora* Boiss as two natural preservatives. The use of this essential oil prevents oxidation rate and reduces preliminary and secondary oxidation products compared with butylated hydroxyanisole (BHA). Foods, which contain fat and oils, can be oxidized slowly during storage. As a result, different oxidation products occur, which cause rancidity and reduction of the sensory properties of foodstuffs. Lipid oxidation and fungal growth reduce the shelf life of food products. To solve these problems, manufacturers use antioxidants and preservatives. In the majority of cases, the producers of foodstuff use synthetic additives such as BHA and butylated hydroxytoluene as antioxidants, but the even low toxicity of those products has restricted their use. Recently, aromatic plants and spices serve as a source of biologically active substances such as antioxidants in foodstuffs. Today, the focus is on natural antioxidants that can replace synthetic additives that might be carcinogenic. Cinnamon, which belongs to the *Lauraceae* family, provides a variety of oils with different aroma characteristics. This aromatic plant contains the highest phenolic contents and strongest antioxidant activity. The main components of cinnamon are cinnamaldehyde and methyl eugenol. Studies have shown good antioxidative and antifungal activities of *Cinnamon zeylanicum* compared with control samples. The components that are responsible for antiradical activity of cinnamon are eugenol, cinnamaldehyde, cinnamic acid, and 1,8-cineole. The antifungal nature of cinnamon belongs to the high phenolic contents especially carvacrol, thymol, cinnamaldehyde, and eugenol. Food manufacturers need antioxidants that resist at high temperature during baking. Studies have been shown that concentrations of 500 ppm of *Cinnamon zeylanicum* essential oil can be used instead of BHA. Foodstuff, which contains this oil, might have nutritive and functional advantages compared to BHA. Consumption of foodstuff, which includes natural additives, can help us to prevent health disorders caused by oxidation, for example, aging, atherosclerosis, and cancerogenesis.

Inhibition of Foodborne Pathogens by Essential Oils

Foodborne illness that is caused by microorganisms is a growing public health concern. The percentage of people that are suffering from foodborne illness are up to 30%. Unsafe food is responsible for illness and results in several deaths every year. Nowadays, there are an increased concern of food safety and a demand from customers of natural products, which are free from synthetic additives. As a result, the use of natural antimicrobial compounds, such as essential oils, herbs, and spices for food, is gaining interest. Essential oils offer a relatively safe status and a potential for multipurpose functional use.

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00262-2

Especially essential oils from the *Lamiaceae* and *Apiaceae* families exert bactericidal properties against microorganisms that contaminate food products; therefore, they are considered as natural food preservatives. Additionally, the widest spectrum of action as well as the greatest antibacterial activity is shown by phenolic compounds, for example, thymol and carvacrol. Above all, *Thymus vulgaris* L., *Origanum vulgare* L., and *Satureja hortensis* L. play an important role. The phenylpropanoid eugenol, which is a phenolic compound, is also known for its antimicrobial properties, and eugenol occurs especially in the essential oils of clove and of cinnamon leaves. All these essential oil compounds, especially as carvacrol, thymol, eugenol, cinnamaldehyde, and cinnamic acid, are used in food to control natural spoilage process and to prevent growth of microorganisms.

Moreover, essential oils could be used for the reduction of biogenic amines and as a flavoring agent in Gouda cheese, which has a positive health effect. Biogenic amines affect physiological functions such as immune response, brain activity, and gastric acid secretion. However, if biogenic amines occur in high amounts in food, they can cause health damage. Different concentrations of the essential oil from *Z. multiflora* Boiss (*Lamiaceae*) were added to milk, to test the effect of this oil on biogenic amines production such as tyramine and histamine and microbial counts in Gouda cheese. Thus, the concentration of tyramine and histamine was significantly reduced at the end of the maturation period in comparison with the control group. The higher the concentration of the essential oil, the higher was the decrease in biogenic amines and microbial counts. *Z. multiflora* essential oil was most effective against yeasts, but there was only a low reduction in *Enterobacteriaceae* counts.

Essential oils and spasmolytic activities

Present studies have shown promising spasmolytic activities from *Cuminum cyminum* L. Generally, cumin is used as an antioxidant and flavor compound. Besides these properties, it also acts as an antiseptic, analgesic, anti-inflammatory, and sedative and is used against stomach disorders, diarrhea, and spasms. The antispasmodic activity of the hydrodistilled fruit extract of *Cuminum cyminum* was tested on isolated of guinea pig ileum. At the beginning, concentration-dependent responses of acetylcholine – which induces such spasms – on pig ileum were recorded and then a distinctive antispasmodic activity was shown. The anticholinergic drug atropine was used as the standard antispasmodic agent. These results proved that acetylcholine alone causes contraction of ileum, but when acetylcholine was given in combination with the hydrodistilled fruit extract, a significant decrease of contraction was noted. This high degree of spasmolytic activity was caused by blocking the cholinergic receptors.

Essential Oils and Anticancer Activities

Cancer is a worldwide disease that can occur at any age and it is the second cause of mortality particularly in low-income countries. Until 2030, the cancer mortality could increase by 50% to reach 15 million worldwide. There is a relationship between the production of reactive oxygen species and the origin of oxidation and inflammatory, facts which can lead to cancer. Oxidative stress acts as a DNA-damaging agent, which furnishes an increase of the mutation rate within cells and promotes oncogenetic transformation. ROS can activate signaling pathways that contribute tumor development through the regulation of cellular proliferation, angiogenesis, and metastasis. It is worth to note that many cytotoxic molecules of plant origin that possess a chemopreventive potential are used in chemotherapy, for example, thymoquinone as an active ingredient of *Nigella sativa* L. (*Ranunculaceae*). It should be considered that 30–40% of all kinds of cancer can be prevented with a healthy lifestyle and dietary measures, and it is obvious that nutrition has an impact on the cancer process. There are dietary components, which are able to promote cancer progression, and there are some that act as chemopreventive agents. *N. sativa* exerts a positive effect as mediating inflammation and cancerous cell growth especially to treat colon cancer. Nuclear factor-kappa B activation was decreased by thymoquinone in a dose-dependent manner. The chemotherapeutic effect of this substance is comparable with the synthetic 5-fluorouracil. The inhibiting effect of the essential oil from *N. sativa* on colon carcinogenesis may be linked with the suppression of cell proliferation in the colon mucosa. The essential oil of black cumin seeds is known for its cytotoxic and apoptotic/necrotic properties in a cancer cell line. An animal study has shown that the addition of *N. sativa* seeds to the diet is able to protect against oxidative stress, inflammatory response, and carcinogenesis. Furthermore, this study reported that the daily intake of these seeds (and thus of the volatile oil) results in the reduction of chromosomal aberrations and damaged cells. Additionally, animal models showed that thymoquinone blocked angiogenesis *in vitro* and *in vivo*, thus preventing the growth of cancerous cells. In conclusion, the anticancer and anti-inflammatory properties of *N. sativa* and its essential oil containing thymoquinone may be attributed partly to the suppression of NF-kappa B activation pathway. This essential oil can also be considered as a potential immunosuppressive agent. Because of its nutritional quality, *N. sativa* is a potential source of diet-based strategies, which may play a role in improving human health.

Besides, monoterpenes that are components of nearly all essential oils and especially of citrus fruits can be used to prevent cancer. They show ideal chemopreventive properties, such as antitumor activity, commercial availability, low cost, oral bioavailability, and low toxicity. Because of this reason, monoterpene studies are proceeding in human clinical trials for chemotherapeutic activity. Several dietary monoterpenes are known for their antitumor activity. It has been shown that (+)-limonene exerts chemopreventive activity against rodent mammary, skin, liver, lung, and fore-stomach cancers. (+)-Limonene, the main constituent of orange oil, for example, is widely used as a flavoring agent for fruit juices, soft drinks, ice cream, and so on. The monoterpenes (+)-limonene and perillyl alcohol and their metabolism products showed a high degree of oral bioavailability.

Essential oil constituents such as citral are also known for their anticancer potential. Citral can be obtained from herbs such as lemongrass, melissa, and verbena. Citral consists of two isomeric acyclic monoterpene aldehydes, namely, geranial (*trans*-citral, or citral A) and neral (*cis*-citral, or citral B). This key component is commonly used as a food additive. Studies showed that concentrations of 44.5 μM citral induced

apoptosis in cancer cell lines, a concentration that is comparable to the one of citral in a cup of tea prepared from 1 g of lemongrass. Apoptosis is linked with DNA fragmentation and induction of caspase-3 catalytic activity, whereby the αβ-unsaturated aldehyde group is responsible for this apoptotic effect and might be a core structure for the design of pro-apoptotic drugs.

Essential oils are also able to inhibit the formation of *N*-nitrosodimethylamine in vegetables. Vegetables are rich in nitrate that is a precursor of nitrite. Crops contain different concentrations of nitrate, dependent on the species, genetic, and environmental factors and cultivation conditions, whereas the concentration of nitrite in plants is commonly very low. *N*-Nitroso compounds such as nitrosamines that are formed by *N*-nitrosation of secondary amines with nitrite in an acidic environment act as strong carcinogens. Several foods contain the precursors of this reaction. Meats, cured meat products, and smoked fish are sources of secondary amines. Nitrite often occurs in hams and sausages as an antimicrobial or coloring substance. Essential oil constituents, such as carvone and limonene, are able to activate the glutathione S-transferase that reduces the risk of cancer. The terpene hydrocarbon (+)-limonene, which represents one of the major compounds of citrus essential oils, exhibits anticarcinogenic properties against mammary, lung, stomach, and skin cancer. It has been reported that the essential oils of citrus show an inhibitory effect on the formation of *N*-nitrosodimethylamine. Especially *Citrus junos* Siebold ex Tanaka (*Rutaceae*), also known as yuzu, which is a popular sour citrus fruit in Japan, shows an inhibitory effect on the formation of *N*-nitrosodimethylamine. Because the Japanese diet is richer in vegetables than in other countries, their intake of nitrate is very high, and thus, they have a higher risk to suffer from stomach cancer. Bacteria in saliva have an influence on the *N*-nitrosodimethylamine formation, because they induce the reduction of nitrate. Although the rate of formation of nitrosamines is proportional to the square of nitrite concentration, it has been considered that nitrite in vegetables especially cabbage, celery, spinach, and mint is not mainly responsible for the formation of *N*-nitrosodimethylamine. In most cases, oral bacteria are responsible for the reduction of nitrate into nitrite. Terpene hydrocarbons such as myrcene, α-terpinene, and terpinolene show an inhibitory effect and cause the decrease of *N*-nitrosodimethylamine formation. In conclusion, yuzu oil showed an inhibitory activity on the formation of *N*-nitrosodimethylamine in the presence of vegetables and saliva.

Essential Oils and Diabetes

Essential oils from different plants can also have a positive effect on diabetes and hypertension. Nowadays, there is a tendency to manage type-2 diabetes and hypertension with natural sources. There are two major ways to handle this: the scavenging of free radicals and the inhibition of key enzymes, which are involved in starch digestion such as α-amylase and α-glucosidase. By those enzymes, starch is converted into glucose, thus increasing its concentration. Inhibition of these enzymes leads to a delay of the absorption of glucose followed by a moderate postprandial blood glucose elevation. There is also a relationship between diabetes and an increased generation of free radicals and a defective antioxidant defense system. Additionally, oxidative stress is involved in the diabetogenic process. For that reason, antioxidant-rich foods have a good dietary intervention in the management of this disease. The use of the essential oil of black pepper seeds in relation with diabetes and hypertension is known in folk medicine. Aromatic spice plants such as black pepper show good antioxidant properties, due to phenolic contents of the essential oil, which possesses antimicrobial, antihypertensive, anticonvulsive, and sedative activities. The essential oil is extracted from the seeds and leaves from black pepper and contains mono- and sesquiterpenes, besides phenolic compounds that are effective in preventing diabetes in animal models. The essential oil of black pepper is established for its radical scavenger abilities and its ferric-reducing antioxidant activity attributed to the presence of pinene and 1,8-cineole. Another therapeutic approach is the inhibition of the starch-metabolizing enzymes. In this case, the activity of α-glucosidase is more strongly inhibited by the essential oil than the one of α-amylase. This circumstance has a therapeutical purpose towards synthetic α-amylase and α-glucosidase inhibitors. The use of those natural products is important in preventing some side effects of the synthetic inhibitors. The essential oil of black pepper can inhibit also the angiotensin-1-converting enzyme (ACE) activity. This fact is a therapeutic approach in the treatment of hypertension, which is one of many complications associated with type-2 diabetes. *In vitro*, the ACE activity was inhibited in a concentration-dependent manner by the essential oil, because it is able to block the conversion of angiotensin-1 into the vasoconstrictor angiotensin-2 that causes the hypertension.

Essential Oils and Mood Disorders

Furthermore, some essential oil constituents, such as (*E*)-methyl isoeugenol (MIE), is often used as food flavor. This essential oil from *Pimenta pseudocaryophyllus* (Gomes) L.R. Landrum (*Myrtaceae*) leaf has calming properties. This ubiquitous food additive appears attractive for the treatment of mood disorders. Studies demonstrated the anxiolytic- and antidepressant-like activities of MIE, suggesting the participation of serotonergic pathways. Among psychiatric diseases, mood disorders are most common, that is, widespread with a prevalence of up to 20% worldwide. Because of the low remission rate and the high rate of nonresponse to current treatment, it is necessary to develop new therapeutic agents, such as consumption of functional food. With this basic food nourishment as well as health benefits are covered. Today, aromatic plants have been largely explored as functional ingredients in the pharmaceutical and food industries. The treatment of neural disorders with naturally occurring food flavors, such as MIE, seems to be more acceptable than the use of pharmacotherapies. Oral administration of MIE showed an increase in sleep duration and a soothing activity of the CNS. An antiseizure property of MIE was hypothesized too, because it acts similar to diazepam, a CNS-calming compound. This hypothesis is further supported by the antiseizure properties of aromatic compounds with a similar chemical structure as MIE, such as methyleugenol, eugenol, and 1-nitro-2-phenylethane.

Besides MIE, in diets, the widely consumed essential oil of lemon is also known for its antidepressant-like effect and

therefore acts as functional food ingredient. Because of many side effects, such as nausea and anorexia, by using conventional medicaments against depression, there is a growing interest in the search of new effective antidepressants, such as functional foods that worldwide are used in the kitchen. Animal studies have been shown that the volatile oil from lemon has increased the metabolic turnover of dopamine in the hippocampus and of serotonin in the prefrontal cortex and striatum. The oral administration of lemon essential oil does not show any toxic effects or an influence on weight, blood, and organs of rodents. Upon oral administration of 400 mg kg^{-1} lemon essential oil, the dopaminergic activity in the striatum and the hippocampus was significantly enhanced on account of an increased concentration of dopamine and a decreased turnover. It is known that depressed patients suffer from a dysfunctional 5-hydroxytryptamine (5-HT) system; thus, selective 5-HT reuptake inhibitors enhance the activation of various 5-HT receptor subtypes. In conclusion, the essential oil of lemon has a great potential to be used as an antidepressant functional food ingredient.

Essential Oils and Osteoporosis

Furthermore, essential oils can also be useful in the treatment of osteoporosis. This disease is a major health problem in aging humans – especially women – when low bone mass leads to osteoporotic fractures. The bone turnover is increasing and it comes to a marked decrease in trabecular bone mineral density (BMD) and bone mineral content. Osteoporotic fractures reduce the quality of life of the patient and they are a burden to health care. Hence, it is desirable from medical and economical points of view to prevent the loss of bone mass. A nutritional approach would be an inexpensive opportunity to prevent low bone mass. Studies have shown that essential oils from sage, rosemary, and thyme and essential oils from pine, juniper, and eucalyptus inhibit or at least retard the activity of osteoclasts. The essential oil of pine is the most potent one and also the bitter orange-peel oil is very potent, for which monoterpenes, such as thujone, eucalyptol, camphor, borneol, menthol, and thymol, are responsible. Studies have shown that pine oil reduces the loss of trabecular BMD in animal models, and *in vitro* studies report that these monoterpenes directly inhibit the osteoclast activity. (1*R*,3*R*,4*S*)-(−)-Menthol that is the most widely used monoterpenic alcohol in human nutrition inhibits bone resorption *in vivo* and *in vitro*, but the latter effect is weak. Also, the consumption of monoterpene-rich fruits and vegetables is linked with a greater BMD in humans. Animal studies have shown that vegetables, salads, and herbs, as a part of human nutrition, are able to inhibit bone resorption. Essential oils exert a positive effect on the bone metabolism when they are added to food. Therefore, essential oil-containing herbs are possible candidates for a dietary approach to osteoporosis.

Essential Oils and Their Effect on the Gastrointestinal Tract

Essential oils are also famous for their positive effect on the gastrointestinal tract. *Mentha x piperita* L., which belongs to the *Lamiaceae* family, contains a volatile oil with the major compound (−)-menthol. This essential oil is used against irritable bowel syndrome, because of its influence on gastric motility. Peppermint tea is commonly used against acute and chronic gastritis, enteritis, and disturbances of the GI tract by the antispasmodic effect of menthol. Furthermore, peppermint tea is commonly used as an antiemetic in pregnant women, besides ginger and cannabis. This volatile oil shows the same effect as 5-HT_3 receptor antagonists, 5-HT_4 receptor agonists, and anticholinergics. Those receptors are also involved in the pathogenesis of irritable bowel syndrome. Peppermint oil and (−)-menthol are able to completely inhibit 5-HT_3 receptor in a concentration-dependent manner by relaxing the smooth muscle and antagonizing the serotonin-induced stimulation. This antagonistic effect on the 5-HT_3 receptor channel influences in a positive manner the disturbed motility during symptoms of irritable bowel syndrome and emesis. The cationic influx through 5-HT_3 receptor channels was inhibited by peppermint oil and its main constituent (−)-menthol. The influence of peppermint essential oil and (−)-menthol leads to the reduction of serotonin-induced contraction in animal models. In addition, they possess a direct relaxant effect.

Essential oils often are used as food additives to complement present therapies of gastritis and peptic ulcers. This disease is caused by an increased density of *Helicobacter pylori* in the gastric mucosa. A nutritional approach can help people with asymptomatic gastritis to manage the infection and to decrease the development of the disease. Those essential oils that exhibit the strongest bactericidal potential against *H. pylori* P1 were also active against other *Helicobacter* strains. The most effective single essential oils constituent against *H. pylori* are carvacrol, isoeugenol, nerol, citral, and sabinene. The widespread infection with *H. pylori* is well known as the major etiologic factor in chronic active type B gastritis, gastric ulcers, and gastric cancer. Nowadays, a triple therapy such as the combination of proton pump inhibitor and two antibiotics is common, but increasing antibiotic resistance is also responsible for an eradication treatment failure. Therefore, there is a growing interest to find alternative treatments, for example, the development of new nutritional approaches. Especially patients with an asymptomatic gastritis profit from this nutritional approach.

Essential Oils and Alzheimer's Disease

Essential oils can also be used in the treatment of Alzheimer's disease, the most common cause of dementia in the aged population. It results in cognitive decline and mental deterioration that is the result of massive and progressive loss of neurons from different regions of the brain. Disorders of the CNS are linked with neurotransmitter disturbances and insufficiencies in cholinergic functions. Cholinesterase is responsible for the hydrolyzation of choline, and if there is a high concentration of this enzyme, then a lower concentration of choline in the synaptic gap results. Investigations have shown that there is a relation between increased levels of cholinesterase enzymes and Alzheimer's disease. This fact leads to the hypothesis that this cognitive decline in patients is linked to the progressive cholinergic degeneration. Hence, promising approaches for the treatment of Alzheimer's disease are cholinesterase inhibitors that are able to enhance the level of cholinergic neurotransmitters in the brain. Acetylcholinesterase (AChE) and

butyrylcholinesterase (BChE) are the major cholinesterase enzymes that are responsible for the decreasing choline levels. Today, Alzheimer's disease patients are treated with AChE inhibitors, synthetic compounds that reveal some toxicity during prolonged use. Hence, there is a great demand for alternative drugs to treat Alzheimer's disease. It has been suggested that dietary supplements with antioxidants and free radical scavengers may decrease the mild cognitive impairment of Alzheimer's disease. A high amount of plants has been traditionally used for the enhancement of cognitive function and alleviation of several symptoms linked with Alzheimer's disease. Nowadays, essential oils of edible plants are considered to inhibit AChE and BChE. Those volatile oils are of great interest, because of their availability, few side effects, low toxicity, and their biodegradability. Studies have shown that the essential oils of *Citrus aurantifolia* (Christm.) Swingle (*Rutaceae*), *Alpinia galanga* (L.) Willd. (*Zingiberaceae*), and *Melissa officinalis* L. (*Lamiaceae*) possess the highest inhibitory activity against AChE, whereas *Melissa officinalis*, *Citrus aurantifolia*, and *Ocimum gratissimum* L. (*Lamiaceae*) exhibited the strongest inhibitory properties against BChE. Therefore, the leaf essential oil of *Citrus aurantifolia* with the constituents (+)-limonene, (−)-camphor, citronellol, *cis*-ocimene, and 1,8-cineole is a promise for the prevention and treatment of Alzheimer's disease, because it inhibits both enzymes. 1,8-Cineole that is one of the most potent AChE inhibitors also occurs in other plants such as *Rosmarinus officinalis* L. (*Lamiaceae*).

Essential oils and atherosclerosis

The essential oil of sage could be used as food ingredient with anti-inflammatory and antiatherogenic properties. Cholesterol deposition in the intima of large- and medium-size arteries together with a chronic inflammatory process leads to atherosclerosis. Oxidized low-density lipoproteins play a key role in early inflammation. This type of LDL that is not recognized by the LDL receptor is taken up by the scavenger receptors in monocytes–macrophages and endothelial cells. Hence, it comes to the accumulation of cholesterol in macrophages and to the formation of foaming cells. Moreover, oxidized LDL is able to induce the expression of proinflammatory cytokines such as TNF-α, Il-1β, and IL-6 in macrophages and endothelial cells. Essential oils from spices, which are added to food, present various biological activities, such as antioxidant and anti-inflammatory properties. As mentioned earlier, the oxidation of LDL results in this atherosclerotic lesion and the initiation of the inflammatory cascade. Therefore, oxidized LDL is able to induce the expression of proinflammatory cytokines, such as IL-1β, TNF-α, and IL-6 from monocytes and macrophages. IL-1β and TNF-α play an important role in the initial amplification of the inflammatory response. Moreover, they are able to induce the expression of adhesion molecules by endothelial cells and promote secretion of different cytokines and chemokines by monocytes. Furthermore, they are involved in the process of foam cell formation, especially by means of induction of growth factors. Activated macrophages, lymphocytes, fibroblasts, and vascular smooth muscle cells produce during stimulation IL-1 and TNF-α. The inflammatory cytokine IL-6 plays an important role in the development and progression of atherosclerosis. It has been reported that the essential oil of *Salvia officinalis* L. (*Lamiaceae*) is able to inhibit COX-2, thus exerting anti-inflammatory properties. Also, supercritical extracts of *Salvia officinalis* are effective inhibitors of oxidized LDL and induced proinflammatory cytokines. This sage extract mainly consists of camphor, borneol, and 1,8-cineole that is a strong inhibitor of TNF-α, IL-1β, and IL-6 production. Borneol and camphor also exhibit excellent anti-inflammatory properties. Therefore, sage extract has a great potential to be used as an anti-inflammatory agent to prevent atherosclerosis.

Ethnic Foods

OI Bermudez, Tufts University School of Medicine, Boston, MA, USA

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Consumers of ethnic foods often have distinctive cultural characteristics, including language, social norms, and behaviors that provide them with a sense of connectedness. From a cultural standpoint, ethnic foods serve as the familiar link with the past and help those who are accustomed to them to maintain and promote among peers their ethnic identity.

In countries like the United States, with a very diverse ethnic population, the production, distribution, and consumption of ethnic foods are an integral feature of the overall American culture.

Native Americans are direct descendants from the original population groups distributed throughout the country before the European colonization. Since then, they have contributed to the cultural dimensions of 'ethnic foods' with their food production developed around the 'three sisters' (corn, beans, and squash) system. Moreover, they developed a rich and highly nutritive traditional cuisine with many similitudes to those found in Central America. For example, in Guatemala, the 'three sisters' system was termed as the 'milpa.'

During and after the colonization, several waves of immigrants from Europe, Africa, and Asia brought from their countries of origin their ethnic foods and dishes. Then, their cuisine evolved from the homeland traditional dishes to the modified versions of ethnic cuisines that currently exist in these modern times.

Similarly, more recent waves of immigrants from Central and South America, the Caribbean, and the four corners of the globe contributed to the rich diversity of the foods present today in US households.

Several cooking techniques and eating styles from the original traditions brought by original, earlier, and new American settlers were exchanged and adopted by them. Traditional dishes like tacos, tamales, pizza, and noodles and Chinese dishes (e.g., lo mein) gave origin to new dishes, different from their native, original versions. Those ethnic food transformations are likely to continue as the American population becomes more diverse and interrelated, with evolving sense of taste, flavor, and smell for what they term as 'ethnic foods.'

Ethnic Diversity of the American Population

The United States has a very diverse population. This diversity was long in existence in the precolonial times with more than 300 tribal groups of Native Americans. Since then, the United States had transformed into a 'plurality nation.' This pluralism is reflected in the ancestry of the early settlers in the country, which are those that contributed to the ethnic diversity of the American cuisine. In the current times, those from German (16%), Irish (11%), English (8%), and Italian (6%) descents are the largest ethnic groups that contributed to the diversity of the white population (see **Figure 1**). The Census Bureau defines as white those having origins in any of the original peoples of Europe, the Middle East, or North Africa.

Furthermore, it is the plurality of the more recent immigrants, along with that from the African-American population that has given this country the ethnic diversity observed in the early periods of the twenty-first century. According to the 2010 Census Bureau, the total population reached about 309 million people. The racial and ethnic heterogeneity of this population is represented in **Table 1**. As seen in this **Table 1**, whites were the largest group (75%). Other ethnic groups include black or African-Americans (14%), Asians (6%), American-Indian and Alaska Natives (2%), and Native Hawaiian and other Pacific Islanders (0.4%). Based on ethnicity, which is reported by the Census Bureau as having or not Latino or Hispanic background, 16% of the total US population is of Latino or Hispanic origin.

This diversity of the major racial and ethnic groups in the United States is reflected in the large number of ethnic groups that, because of their geographic, socioeconomic, and cultural origins, have contributed to the rich, mixed, and festive ethnic foods that every day are present in the American households.

Ethnic Foods Present in the American Homes

Based on the geographic, climate, and, particularly, the plurality of the American population, one could find an extraordinarily rich ethnic cuisine in most households across the country. Most ethnic cuisines have been influenced by centuries of food exchanges between indigenous groups and immigrants from all over the world. As result, the American cuisine is a unique multiethnic blend. No single eating pattern has prevailed over all the others, and no ethnic or cultural group has emerged with an unchanged food pattern. However, some ethnic cuisines are more popular than others, mainly due to the high number of immigrants from the latitudes where those ethnic foods and traditions originated.

In general, foods that are regarded as ethnic foods by a cultural group vary over time and with the degree of acculturation of the group consuming them. Even within major race and ethnic subgroups, many variations in ethnic foods exist. Some foods only bear a passing resemblance to the original cuisine from which they were derived. However, all of them fulfill important cultural roles for the diverse American population. For example, in the United States, pizza, tacos, chili with meat, and chicken chow mien are very different from the Italian, Mexican, and Chinese dishes that inspired them. Hispanic-Americans with a Mexican-American heritage differ in their food preferences from Puerto Ricans, Colombians, and Chileans, whose eating patterns involve a blend of Spanish, African, Native Central/South American, and continental North American influences. Similarly, Asian-Americans of Filipino, Japanese, or Chinese ancestry have very different food choices and traditions. Among the over 300 different Native

Table 2 Examples of ethnic cuisines and representatives dishes commonly eaten by the American population

Ethnic cuisine	*Examples of popular dishes*
Puerto Rican	Rice with pigeon peas, tostones (fried green plantains), habichuelas (stewed pink beans), pasteles (similar to tamales), and rice pudding
Mexican	Tamales, tortillas (corn- or wheat-based), tacos, enchiladas, guacamole, and mole poblano
Italian	Pizza, risotto, spaghetti, lasagna, ciabatta bread, cheeses, and wines
Japanese	Sashimi, sushi, soba, sukiyaki, yakitori, and miso soup

American groups, the staples and other foods that they regard as unique and distinctive to their cultures also vary.

The traditional 'Mediterranean' diet varies in terms of foods and seasonings included in their cuisine. These differences are reflecting the European and North African Mediterranean locations and cultural norms of the Mediterranean countries where the Mediterranean diets originated. These traditional diets include liberal amounts of fruits, vegetables, legumes, grains, and fish. High amounts of monounsaturated compared with saturated fats, low amounts of meats, and moderate consumption of alcohol are also observed. Although there is a debate about the extent to which such a regimen is exportable, some 'Mediterranean' ethnic foods have become very popular in America. Examples of those foods include olives and olive oil, breads, couscous, pastas, artichokes, arugula, grapes, dates, figs, almonds, chickpeas, basil, bay leaf, and parsley.

The ethnically diverse cuisines found in the United States include the contributions of most ethnic groups. Those groups brought with them their native recipes and some of their traditional food ingredients. And then, throughout the times, they modified and adjusted those recipes to the availability and cost of foods and seasonings in order to make them acceptable by the general population. Table 2 contains a short list of examples of ethnic cuisines present in the US households.

Germans, for example, brought and modified hot dogs and hamburgers. Italians, with their basic ingredients wheat, tomato sauce, and olive oil, also influenced the American foodways. They introduced classic dishes such as pizza and spaghetti, to the point that the Italian cuisine is the third most popular in the country.

Ethnic cuisines of Asian origins, particularly represented by Chinese and Japanese ethnic dishes, adapted to the American palate. Chinese-American foods represent the second most popular ethnic cuisine in the United States. Those ethnic cuisines contributed with several unique ethnic dishes. Noodles-based dishes and a large variety of vegetable dishes (e.g., broccoli and tomatoes) are part of the incorporation of non-Chinese foods added to satisfy the American preferences.

From Latin America, Mexicans contributed a large variety of ethnic foods. An extensive list of Mexican foods, including chili peppers, chocolate, black beans, tacos, 'burritos,' and tamales, is part of the rich offerings found across the country. Currently, the Mexican cuisine is the most popular ethnic food category in the country. Because the large Mexican population in the United States, along with their rich and varied traditional cuisine, the general American population has incorporated many of those Mexican ethnic foods into their eating habits, diversifying the culinary landscape of 'American' ethnic foods.

Ethnic food preferences and choices are important aspects of the cultural heritage they represent. Some of the many sources available on food-related aspects of culture are summarized in Table 3. It includes the cultural anthropology literature on foodways, reports, and nutrition information materials that describe foods, their uses, and related traditions.

Ethnic Differences in Food Classification Systems

Ethnic groups vary in their foodways, social and physical contexts in which food preparation, serving, and eating occur. Table 4 describes the factors that are thought to be involved in the development of ethnically distinctive cuisines and ethnic foods. Nutritional anthropologists subscribe to various theories on how ethnic food patterns have developed (see Table 5). No one theory appears to predominate over the other.

Individuals in different ethnic groups have different ways of categorizing foods, which are sometimes at variance with medical views of foods as sources of nutrients that are based on physiological and biochemical characteristics. They may also differ in their attitudes toward medical care and their health behaviors and in their beliefs about the therapeutic

Table 4 Factors involved in the development of ethnically distinctive cuisines

Factors	*Examples*
Ecological factors	Geography, climate, range of native plants and unusual species in area
Individual factors	Philosophical, religious, and moral attitudes
Social factors	Social structures, social relationships, social status, migration patterns (both voluntary and involuntary)
Economic factors	Trade, food prices, food distribution, imports, and exports

Table 5 Theories on how ethnic food patterns developed

Theory	*Comments*
Environmentalism	Ethnic food traditions are determined primarily by environmental and external influences
Cultural determinism	Humans mold their environments and diets quite independently of their physical surroundings
Cultural ecology	Both culture and environment are important
Cultural history	Historical influences on how foods have evolved and developed over time
Functionalism	Use of foods to identify or please people socially and how foods are used in society

Table 6 Some ways in which foods are classified in different cultures

Food classification system	*Descriptions*
Food habits	'Core,' secondary core, and peripheral foods
Gastronomic	Foods versus nonfoods, edible versus nonedible
Religious/ philosophical	Sacred versus profane, allowed versus forbidden
Opposing categories or properties	Hot versus cold, yin versus yang, or other ways of 'balancing food intakes to prevent or cure disease'
Medicinal	Foods for the prevention of diseases or as treatment for certain diseases or psychological states
Social	Symbolic of a culture or belief system
Emotional significance	Foods for the sick, party foods
Nutritional	Macro- and micronutrients
Hygienic	Wholesomeness, cleanliness, freedom from environmental contaminants, microorganisms, or other undesirable elements

Source: Kaufman-Kurzrock, D. L. (1989). Cultural aspects of nutrition. *Topics in Clinical Nutrition* **4**(2), 1–6.

and preventive properties of foods and the appropriate balance between different foods. For example, there are systems in various cultures that categorize foods into medicinal versus nonmedicinal, hot versus cold, or yin versus yang. These are classification schemes based on properties other than nutrient content (see Table 6). Food classification systems may affect nutritional status because they cause the exclusion of healthful foods or food groups from the diet, encourage consumption of harmful items, or produce a false sense of security among eaters that all of their nutritional needs are met when in fact they are not.

Dietary Assessment of Ethnic Food Consumption Patterns

Familiarity with ethnic foods is important for dietary assessment, particularly if they are imports from other countries. The foods themselves, their names, composition, portion sizes, and frequency of consumption vary. Accurate assessment of nutrient intakes depends on a good knowledge of these factors. Some ethnic foods may be especially rich sources of nutrients or other food constituents, such as phytochemicals.

During the last 40 years, Americans experienced increases in a series of nutritional and health threats associated with unhealthy eating practices, including obesity, type 2 diabetes, hypertension, cardiovascular diseases, and certain types of cancers. To halt those detrimental effects, people, in general, are responding favorably to the new policies and recommendations to improve eating and health-related practices. For some groups, those recommendations are being implemented with the use of ethnic foods considered healthy alternatives. To confirm those beliefs, food and nutrition experts need to analyze the growing number of ethnic foods that are being incorporated into the already diversified, ethnic cuisine practiced by Americans. The application of tools and techniques for dietary assessment may be needed in order to provide appropriate nutritional guidance for those groups adapting new ethnic foods.

One challenge in evaluating diets that include many ethnic foods is the appropriate choice of methods for dietary assessment. Methods such as semiquantitative food frequency questionnaires are often designed to capture intakes of important nutrients for those who conform to the predominant food culture. These are often inappropriate for subgroups with very different dietary patterns. Subgroup members may call the foods by different names, consume items not included on the food lists, or vary in amount and frequency of consumption. The use of such instruments to assess intakes of individuals with unconventional dietary preferences can lead to highly erroneous conclusions. Subgroup-specific food frequency questionnaires that take account of these factors are sometimes available, and when they are, these should be used. For example, well-validated ethnic-specific food frequency questionnaires have been developed for Japanese and Chinese-Americans living in Hawaii and for Puerto Ricans living in the Northeast.

Another potential problem in the dietary assessment of ethnic cuisines is that nutrient databases for converting dietary intakes into nutrients for ethnic foods may not be available. In research studies on individuals who use many ethnic foods, nutrient databases that include entries for ethnic favorites are needed to obtain complete information about intakes. Whenever possible, food tables that are specific to the country or ethnic group should be used. Country-specific tables of food composition and nutrient databases are becoming increasingly available, and these are the best option. For individuals who eat largely ethnic cuisines in countries where the parent food culture is different, special food composition tables for the ethnic foods that are most popular in mainstream diets are usually unavailable. Even for ethnic foods that are included in nutrient databases, food composition information may be incomplete, inappropriate, or lacking. Moreover, nutrient values for foods that are rarely consumed outside of the ethnic group may be absent, especially if the ethnic group is small. This is a challenge with many local foods consumed by Alaskan natives for which there is a gap in nutrient composition of those foods.

The dietary assessment task is more difficult when no country or ethnic-specific food tables are available. Recipes made from locally available ingredients or imported foods may differ in their food composition from recipe values in food tables used in Western countries. For example, a typical curry dinner as served in India, Ghana, and England varies greatly in its nutrient composition. For this reason, country-specific food consumption tables are needed.

Ethnically Appropriate Dietary Planning and Interventions

The consumption of ethnic foods is usually interpreted as a cultural phenomenon. However, it has physiological implications. Sometimes, alterations in eating habits are necessary to achieve nutritional needs, but this is a difficult goal to achieve. Food habits are among the oldest and most deeply entrenched aspects of many cultures, and they cannot be easily changed.

When they are changed, they often produce unexpected and unwelcome reactions.

There is no simple formula for success, but ethnic specificity and cultural sensitivity are important ingredients in crafting successful nutrition planning and interventions. Table 7 provides some examples from the recent literature of ethnically appropriate nutrition interventions.

The expertise of nutritional anthropologists who specialize in cultural anthropology as it relates to food and foodways is helpful. Some general principles that must be kept in mind are discussed in the succeeding text.

Some foods are more important than others to eaters and are the base of their food systems. Those foods constitute a continuum or gradient that consists of the 'core diet,' which includes universal, regular staple foods, the 'secondary core' of foods that are used widely but not universally, and 'peripheral' foods that are used infrequently or during specific holidays or celebrations. Such groupings are useful in planning nutritional interventions since they often suggest opportunities for making acceptable changes and possible pitfalls that need to be avoided. Food habits are always difficult to change. The most resistant habits of all involve foods in the core diet, especially those that are also viewed by the eaters as ethnically appropriate and vital to group cohesion.

The language used about foods and the names of favorite foods themselves must be used in recruitment. Ethnic-specific nutrition information, recommendations, dietary guidance, and education are also vital if interventions are to be appropriate to the dietary patterns and culture of intended recipients. In many countries, ethnicity, socioeconomic status, educational level, geographic location, and religious and ethical views are often confounded. As these other factors vary, so will the appropriateness of the intervention.

The importance of including ethnic foods in determining the ultimate acceptance of nutrition interventions varies within and between ethnic groups. In general, those who are least acculturated to the larger mainstream society, those with language barriers, the ill, the geographically isolated, the economically disadvantaged, traditionalists, and the religiously conservative may regard ethnic foods as particularly important. Those who are innovators and desire acceptance in the larger culture may regard ethnic foods as less important. The degree to which new foods are incorporated into eating styles varies depending on contact between cultures, food availability, trade, and social status of the group introducing the food and philosophical, religious, and individual factors. Immigrants differ in the extent to which they wish to remain unassimilated in their foodways and true to their native cuisines. Ethnic borrowing and mingling rather than rigid preservation of unique eating traditions often occur.

Ethnic-specific food-based dietary guidelines and graphics to guide food choices present nutritionally appropriate food patterns in a culturally acceptable manner for many ethnic groups. Many guidelines are currently available. They have the advantage of including ethnic foods as a part of overall diets. These guidelines are helpful as starting points for developing population-based nutrition education materials for healthy persons. Graphics that depict appropriate food choices have the additional advantage of being understandable even to those who may be illiterate.

Special attention must be paid to the ethnic appropriateness of nutritional counseling for those who are ill or in especially vulnerable groups from the physiological standpoint. Therapeutic diet manuals are sometimes available or obtainable that can be helpful in designing diets that provide medical nutrition therapy that is culturally appropriate.

Additional useful techniques for crafting nutrition information, education, and counseling interventions include the use of ethnic and regional terms for foods and recipes. Interventions should be adapted to be culturally appropriate. Food preparation and cooking demonstrations can be used to show how to incorporate recommendations into existing food patterns. Nutrition education and counseling should include attention to ethnic issues. Community social structures in the ethnic group are helpful to make contacts with the target ethnic groups.

Those who develop nutritional interventions that involve food enrichment, fortification, or special supplements must also pay attention to the role of ethnic foods and food patterns in the diet. In many cultures, the target groups for such efforts are those who are nutritionally vulnerable because of their age, sex, and socioeconomic status. And they are likely to have eating practices that are deeply embedded in their culture. Nutrition counselors must remember that care of the sick is heavily intertwined with food and health beliefs, social relationships, and acculturation. In summary, nutrition workers must avoid cultural biases and ethnocentricity in dealing with their clients in both dietary assessment and planning.

Extrusion Cooking: Chemical and Nutritional Changes

JAG Arêas, CM Rocha-Olivieri, and MR Marques, Universidade de São Paulo, São Paulo, Brazil

Introduction

The Extrusion Cooking of Foods

Extrusion cooking has become one of the most prominent technologies for thermal processing of food for a number of reasons. It was adapted from the plastic industry and first used for food processing in the 1920s to cook and model cereals in several forms. It evolved in the 1970s to the high-shear, high-pressure, high-temperature machines, which has become ever since the major process used throughout the food industry to generate expanded ready-to-eat products and textured vegetable protein. In the 1990s, modulated double-screw extruders were developed, and more feed materials with distinct water content could be processed. However, the most successful configuration for extrusion cooking is still the one that through a high shear at high temperature and pressure in a single screw creates the final texture by orienting and cross-linking the food macromolecules in a tridimensional stable structure, generating a wide variety of food products. In this extruder configuration, the feed material, rich in carbohydrates and proteins and with a low moisture content, is conveyed through an Archimedes screw within a barrel forming a molten mass that is expelled through a die. During this process, the molten mass experiences elevated shear, temperature, and pressure, with resident times at high temperatures of <5 s. Extrusion is thus a high-temperature short-time (HTST) food process method that inhibits most of the biological events but preserves most of the nutritive value of the processed food. In addition, the elevated pressure, temperature, and shear promote fragmentation of the feed material and orientation of the biopolymers dissolved in the molten mass until the exit of the equipment. The high pressure inside the equipment keeps the overheated water, typically around 150 °C, in the liquid state within the molten mass. At the die exit, it then flashes off because of the sudden drop of pressure, and the mass cools down. The biopolymers' filaments that hitherto flowed into the molten mass undergo an intense cross-linking, creating a supramolecular network that stabilizes the final structure of the extruded product. For this reason, extrusion has been widely used to cook and model food in various shapes, generating a great number of commercial convenient products. These extruded products are usually stable, with a long shelf life, microbiologically safe, and with an imparted texture, which increases their acceptability. They can be ready-to-eat products or ground and becoming ingredients that added to diverse products' formulation.

Because the extrusion cooking process employs elevated temperatures for short periods, usually below 5 s, several beneficial effects are expected in the extruded food. Nonetheless, some concern was also devoted to the potential deleterious effects of this processing to the nutritive value of foods. The reader should refer to the 'Further Reading' section to several reviews, books, and websites on the extrusion cooking technology. This article will describe the most common chemical changes throughout the extrusion cooking process and how they affect the nutritive value of the extruded food.

The More Frequent Chemical Transformations in Extrusion Cooking

Cross-Linking and Chemical Changes in Proteins

The diverse composition of the monomers that make up proteins enables a wide spectrum of interactions between proteins and other macromolecules. In general, the conditions of extrusion cooking promote raw materials' native protein dissociation, denaturation, orientation, and cross-linking at the exit of the equipment. Besides this macromolecular organization and because of the high temperatures that a protein experiences inside the equipment, extrusion cooking has been supposed to produce some potentially toxic amino acid and peptide derivatives, as it was described for other thermal processes. For example, under alkaline conditions, amino acids may cross-link during food thermal processing. As the extrusion cooking process destabilizes the tertiary and quaternary structures of the proteins by a combination of increased shear and temperature within the extruder, protein–protein interactions and amino acid cross-linking may occur. Proteins rich in alanine, lysine, cysteine, and ornithine are more prone to protein–protein interaction under specific conditions.

Thermal alkaline processes transform alanine into dehydroalanine, which may then react either with lysine to form lysinoalanine, or with cysteine to form lanthionine, or with ornithine to form ornithoalanine. Lysinoalanine is the most common of these compounds, which interferes with growth and induces changes in nucleus size and cytoplasm volume of kidney tubules cells in rats. However, all studies on the extrusion cooking process showed that there is less lysinoalanine formed in the extruded foods as compared with similar products prepared by traditional cooking methods. The majority of reactions of protein cross-linking observed throughout the extrusion process participate in the formation of the supra molecular structure that stabilizes and texturize the extruded products. Extrusion is safe as to the production of toxic compounds derived from thermal decomposition of amino acids.

The intensity of these cross-links may also be dependent on the other components from the food matrix and on the protein functionality. The content and type of protein may produce distinct structure resistance after extrusion as observed when amaranth or chickpea flour are treated with sodium glutamate and inosinate. The extrusion cooking of amaranth pasta mixtures may also cause a decrease of protein solubility in different denaturant solvents in the presence of starch; and all this knowledge may be used for technology improvements. However, none of these changes affect the nutritive value of the final extrusion product nor produce any health threat.

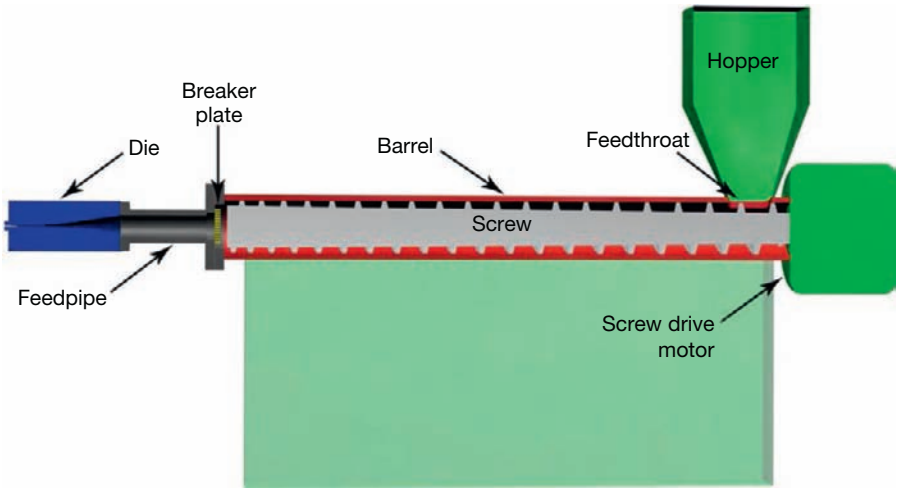

Figure 1 Schematic representation of a typical single-screw extruder. Ambient pressure and temperature built up to the typical maxima of 5 MPa and 150 °C, respectively, from the feed hopper to the die end. The residence time of the feed material at these conditions is typically below 5 s. Public domain picture. Author: Magnus Manske. http://commons.wikimedia.org/wiki/User:File_Upload_Bot_(Magnus_Manske).

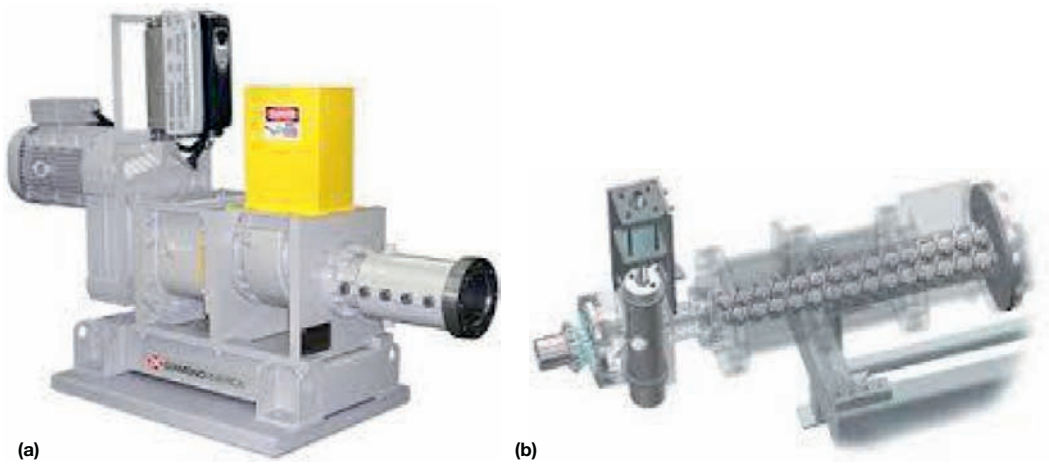

Figure 2 Examples of single-screw (a) and double-screw (b) extruders. From: Schweizer, J. P. (2011) The Right Extruder: Design Considerations - http://www.foodmanufacturing.com/articles/2011/05/right-extruder-design-considerations.

Extrusion of bovine rumen protein with 3.8% of residual lipid, for example, produced more structured extrudates with higher content of disulfide linkages and noncovalent interactions than those with less lipid content. Lung protein shows similar results, indicating an important role of the lipid, especially phospholipid content. These findings are consistent with some of the proteins becoming inaccessible upon thermal treatment and with the reorganization of the macromolecules at the die end favoring disulfide and noncovalent interactions. Again, these changes only affect texture with no effect on the nutritive value of the extruded food.

Chemical Changes in Carbohydrates

Extrusion cooking is a process where occur moderate carbohydrate hydrolysis and intensive starch gelatinization through cleavage of intermolecular hydrogen bonds. For this reason, extrusion causes an increase in water absorption until the rupture of starch granules, which occurs during this process, creating a viscous mass. The action of high pressure, high shear, and high temperature, combined with the moisture content and the amylose of the raw material, may subject the processed material to significant changes.

One of the most important modifications undergone by the material rich in carbohydrates and proteins, after extrusion, is expansion. The rate of expansion is very important for an extruded product, and for most of the cereal starches, such as corn, wheat, and rice, the product has a maximum expansion when subjected to temperatures between 150 and 200 °C. The gelatinized starch, the cellular protein, and the cellulose encompass a complex that decisively influences the product's expansion ability after the mass passes through the die.

The extrusion cooking purpose is to transform starchy raw materials, whose main feature in their original form is an insoluble granular material, in a crunchy, fluffy, expanded final product that easily breaks. Therefore, gelatinization rate

Figure 3 Examples of snacks and biscuits (a), breakfast cereals (b), and pet food (c), produced by single-screw extrusion cooking. Promotional photographs. Source: (a) http://www.kishanagrotech.com/; (b) http://www.clextral.com; (c) http://www.diytrade.com.

measurements and the effects of extrusion are essential. Thus, some physical tests are used, including viscosity, product expansion in the die, shear strength, amylograph tests, consistency index, and expansion ratio. There are also chemical tests, such as gelatinization index, water absorption index (WAI), water solubility index (WSI), and aqueous ethanol-soluble carbonate and water-soluble carbohydrate.

During the extrusion cooking process at high temperatures between 120 and 180 °C and pressures from 3 to 16 MPa, partial starch hydrolysis may occur. It appears that because of thermoplastic treatment, starch flour has a variation in its color; the milk-white flour at temperatures between 120 and 135 °C turns dark brown at 150–180 °C. At temperatures of 120–135 °C, starch becomes completely gelatinized, but at this point, hydrolysis does not occur yet. This will be only achieved at higher temperatures and pressures. The consequence of this high-temperature and high-pressure combination is the cleavage of 1,2-glycoside bonds of sucrose, 1,4-glycoside bonds of raffinose, and 1,4-glycoside bonds of maltodextrins. The higher the extrusion temperature and lower moisture content of the raw material, the greater is the bond cleavage within the molecules with high molecular weight.

For evaluation of the final extruded product, two factors are quite important and shall be taken into account: the WSI and the WAI. The conclusions found by many studies on these properties were that the WAI increases for a wide variety of starch products with the temperature rise in the extruder barrel. The lower is the material initial moisture content used for extrusion, the higher is the extrudates' WSI.

The extrusion of starchy raw materials results in important changes in product viscosity after dissolution in water. This property is relevant for a technological point of view, but its impact on nutritional properties is not clear. All processes that increase starch solubility may increase its glycemic index (GI). However, several cooking processes for amaranth showed that the GI of starch of the extruded amaranth was not the highest one. Even increasing starch solubility, the extrusion produces a complex network made of starch and protein that may hinder access of amylolytic enzymes to the food matrix. A more detailed account of the impact of extrusion on the GI is in Section **Changes in GI** of this article.

Chemical Changes in Lipids

Generally, the raw materials used throughout the extrusion process contain low amounts of lipids. The friction necessary for mechanical energy transfer to the extruded material is essential for food extrusion. Large amounts of lipids cause slippery at the barrel and impair the process.

Some lipid hydrolysis occurs in lipid extrusion by lipase action. However, even high levels of free fatty acids in foods have no toxicological effects on humans, although organoleptic and storage quality of the extruded foods may be impaired. The proper combinations of humidity and heat are responsible for reducing the lipase activity in the extrusion process, decreasing the factors favoring free fatty acids' production. The inactivation of enzymes that occur during the extrusion process promotes increased shelf life of the final product.

Fatty acids' oxidation may also occur in a limited extent. Some conditions in the extrusion cooking process that may affect the rate of lipid oxidation, which are similar to the ones found in any other process, are listed in the succeeding text:

(1) The rate of oxidation increases with the amount of oxygen present and the surface area of the food exposed.
(2) Higher temperatures produce faster reaction rates.
(3) Oxidation rate is retarded at intermediate moisture contents of water activity (Aw = 0.3), but the rate is higher at water activities below 0.1 and above 0.55.
(4) Light and metals act as prooxidants.
(5) The presence of antioxidants reduces the rate of oxidation by terminating free radicals or by sequestering metals.

Chemically, the double bonds of unsaturated fatty acids can easily react with free radicals and oxygen. Oxygen adds to a carbon–carbon double bond in a chain of unsaturated fatty

acids forming hydroperoxides. These compounds break down rapidly in the presence of some substances, factors, and process conditions that affect the rate of lipid oxidation. Contents up to ~5% of total lipids improve expansion ratio and texture, whereas the formation of *trans* fatty acids at this lipid concentration is almost insignificant. As the lipid content of the raw material for extrusion is typically below this content, extrusion negligibly affects lipid oxidation.

Other Chemical Changes

During the extrusion cooking process, there is a strong structural molecular rearrangement. The intense disturbance considerably influences the shape and texture of the extruded products. One such chemical change that occurs is the amylose–lipid complex formation. The interest in amylose–lipid complexes focused on their technological importance in starchy food systems. A consequence of these chemical changes is the low lipid extraction using solvents after extrusion.

At low hydration levels, the linear component of starch, amylose [α 1–4]-glucose-linked polymer, behaves as a flexible random coil with stretches of left-handed helical segments in aqueous solution. Stable secondary conformations, known as A-, B-, and V-amylose, are formed both in ionic solutions and in solvents of lower polarity. In the presence of lipids, the amylose chain undergoes a conformational change to V-amylose, characterized by the interaction of the aliphatic lipid tails with the hydrophobic core of the polysaccharide, forming a very stable imperfect helix.

These amylose–lipid complexes turn up when the material is between its melting and glass transition temperatures. The barrel temperature and moisture within the feed material are determinant in the process; the water acts as a plasticizer, and the decrease of moisture content increases the temperature. The presence of other components in the food matrix increases the melting temperature of starch–lipid complexes, which are also present at high barrel temperatures.

Moreover, the presence of triglycerides, diglycerides, and different fatty acids' saturation in the lipid fraction may result in lower expansion, decreased degree of gelatinization of starch, reduced dough viscosity, distinct dough flow properties, and decrease of the hardness of the extrudate.

Nutritional Consequences of the Chemical Changes

Increasing Digestibility of Amino Acids

Comparable to other HTST processes, extrusion is the preferred choice regarding nutrient retention, destruction of antinutritional factors, microorganisms, and capability of producing different textures. However, the intense high-pressure homogenization can break down chemical bonds and promote new chemical reactions that alter the protein digestibility. Mild heat treatment of vegetable proteins generally improves digestibility, and with increasing severity of temperatures, protein digestibility decreases.

In some studies, the decrease of the true digestibility was evident after extrusion. The process caused protein denaturation with formation of insoluble compounds through new protein–protein interactions that were responsible for the stabilization of the structure. Intermolecular disulfide and other hydrophobic bonds appear to be the major type of linkages that occurs during extrusion and influence extrudate characteristics. These results occurred due to previously hidden amino acid residues becoming exposed and free to react with other food components. The exposure of hydrophobic residues reduces the solubility of extruded protein in aqueous systems, decreasing digestibility.

However, most studies have demonstrated that the protein digestibility improves because of the denaturation of protein, which renders them more susceptible to digestion by proteolytic enzymes. Extruded cowpea beans, a protein-rich legume, showed an increase of 55.9% digestibility measured *in vitro* as compared to the raw grain. Thus, extrusion enhances the digestibility of proteins through denaturation and by inactivation of protease inhibitors.

Loss of essential amino acids

The amount of essential amino acids is an important indicator of nutritional quality of extruded products. Process conditions of extrusion influence the digestibility of the proteins and affect the availability of certain amino acids. Thus, no doubt that lysine is the most unstable amino acid during the extrusion process. Several chemical reactions, combined or not, are responsible for amino acid losses, such as protein denaturation, Maillard reaction, and protein cross-linking.

Increasing energy input and decreasing water cause significant reduction in the availability of several amino acids. Loss of unstable amino acids in the extrusion cooking process was reported in the literature to be 30–40% lysine, 7–21% arginine, 15% histidine, 8–21% cystine, 14% methionine and tryptophan. During extrusion cooking of maize grits, below 14.5% water, there was also a decrease in cystine. Only minor losses were found in other amino acids.

The nature of the extruded protein also influences the extent of the loss of the available amino acids. In meat sources of protein, bovine rumen, for example, extrusion did not affect the concentration of very sensitive essential amino acids like cystine and methionine, and the occurrence of any other limiting amino acid in the extruded protein was not observed.

Maillard reaction

The Maillard reaction is one of many chemical reactions that occur during the extrusion cooking process and has important nutritional and functional consequences. Known as non-enzymatic browning, Maillard reaction is actually a series of reactions with a wide variety of compounds produced as a result. This chemical reaction is characterized by the binding of a reducing sugar (glucose, fructose, lactose, or maltose) and a free amino group on an amino acid, usually the epsilon-amino group of lysine.

Because of this, the main nutritional loss related to this reaction is the quantity of available lysine. Data reported throughout the literature indicated that small peptides from the matrix can also be involved in this reaction. Another indication of Maillard reactions is the dark color of the extruded material, due to the formation of melanoidins and other reaction products; however, a darker color is not necessarily due to the imperative presence of these materials.

Extrusion cooking appears to cause lysine losses that do not exceed those for other methods of food processing (loss range 3–13%), but appears to depend on the raw material used. In semolina pasta, for example, lysine is involved to loss of a greater extent with respect to other amino acids in the range of 43.9–62.0%. In food with lysine limitation, this loss is important for the nutritional quality.

Extreme conditions of temperature (>180 °C) and rotation (>100 rpm) in combination with low moisture (<15%) promote the breakdown of poly- and oligosaccharides and release reducing units of the molecule. On the other hand, an increase in feed rate promotes less lysine loss due to a residence time decrease and heat transfer to the mixture. Conditions of higher pH, reducing sugar hydrolysis in the extrusion of mung bean and cowpea flours, are also favorable for lysine retention.

For quality control purposes, the amount of available lysine in an extrudate may be quantitatively measured through several methods. The reaction of free lysine with fluorodinitrobenzene is one of these. Total lysine may also be measured after acid hydrolysis of the protein, and the amount of unavailable lysine can be calculated.

Although researchers are still unsure of the precise mechanisms by which acrylamide is formed in foods, there is a strong relationship between Maillard reaction and acrylamide formation on extruded products. Temperatures above 120 °C, very low moisture content of 5%, higher asparagine content, and reducing sugars are favorable parameters. It has been suggested that the butanedione, one of the several dicarbonyl compounds formed during the Maillard reaction (Strecker degradation), in the presence of free asparagine can produce high amounts of acrylamide. On the contrary, glycine, L-lysine, and L-cysteine added to formulation can reduce the formation of acrylamide (95%, 91%, and 87%, respectively), and they can be used as additives of the extrusion process.

Hydrolysis of Carbohydrates

Redistribution of soluble and insoluble fiber

Few studies have been performed about the effect of extrusion cooking or other processes on dietary fiber. The degradation of the components of dietary fibers may occur in processes that involve shear. It is known that the glycosidic bonds of cellulose can be broken during dry grinding in ball mill. It is also known that degradation in the colon of the fiber is inversely proportional to its particle size. Therefore, the disruption and homogenization of the particles due to the intense mechanical working during extrusion could leave the dietary fiber more available for fermentation in the colon.

The thermoplastic extrusion causes structural changes in biopolymers, with significant transformation in polysaccharides. Because of this, the structure and composition of the fiber fraction experience a shift in the molecular weight of constituent polysaccharides. In general, one observes an increase between 10% and 15% in the content of the soluble dietary fiber (SDF) fraction at the expense of the insoluble one. Enzymatic or acid treatments can increase this proportion, being an additional tool in achieving higher levels of soluble fiber.

A very important effect brought about by the extrusion process is the degradation of phytic acid, in addition to rearranging components of total dietary fiber (TDF), which would improve the nutritional properties of food after this process. The heat applied during the extrusion process modifies the texture of raw foods, which can consequently alter the composition and the structure of these components.

In some foods, such as oat bran, the extrusion process improves the functional properties of SDF. When one compares the SDF raw oat bran with SDF-extruded oat bran, some characteristics have been changed in the extruded product. They are the increased aggregate formation, the increased gelatinization temperature, the increased solubility index, the water absorption capacity, and water retention solvent. An increase in the apparent viscosity and the consistency coefficient is also observed, besides a decrease in the flow behavior index, a decreased radial expansion, an increased bulk density and breaking strength of extrudates, and an improvement in foam ability.

Studies have also reported an increase in TDF of barley flour after extrusion. This is due to the increase either in one or in both fractions of fiber. These changes in the profile of dietary fiber during the extrusion process can be explained by the resistant starch formation that is determined as dietary fiber, 'enzyme-resistant indigestible glucans,' formed through transglycosidation, and a structural transference from insoluble to SDF.

Digestibility of starch

Many changes may be observed in the functional properties of the starch due to the extrusion process. These changes can be monitored by physical and chemical methods in the starch granules and their components. They include the determination of textural and rheological properties, which are related to the digestibility of the starches and availability of glucose. Among the many food processing methods, the extrusion cooking is the one that mostly increases the rate of starch digestibility, due to a decrease of particle size of the final product. The variation and the digestibility rate will depend on some parameters, such as amylose and amylopectin ratio, the feed material particle size, the process temperature, the moisture of the raw material, and the screw speed and geometry.

During extrusion, starch is exposed to high shear forces that physically cleave glycosidic linkages, forming fragments of lower molecular weight. Inside the extruder, the starch granule is compressed and will slowly turn into a homogeneous and molten mass where the disappearance of granular and crystalline structure is observed. However, the extent to which the starch will break down depends upon the intensity of treatment. The degree of digestibility of starch is an important property of the extrudate, and it appears that the *in vitro* digestibility of starches is significantly higher after the extrusion process.

The structural integrity of the starch granules is lost due to increased shear action and molding in the extruder barrel. This makes the starch more available for enzymatic action. Nevertheless, low levels of starch digestibility observed in some extruded foods with a high starch content can be attributed to the formation of amylose–lipid complex, starch–protein, and the limited availability of water, which impairs the starch digestibility during the enzymatic hydrolysis. The decrease in the grain size distribution results in increased surface area and a higher degree of hydrolysis.

Extrusion potentially produces greater increase in starch digestibility than any other processing methods. However, some studies comparing four processing method – popping, roasting, flaking, and extrusion – found that the rate of hydrolysis of starch is greater by popping, roasting, and peeling than by extrusion.

Changes in GI

Values of the GI of several products and the respective glycemic response can be influenced for many factors; and processing plays a very important role among them. When the cellular structure of the starch granule is preserved even after heat processing, the final product keeps its GI, which is lower than when the starch granule is broken. Nongelatinized starches are less digested by humans, so heat processing is beneficial for a complete starch digestion. After the heating and shearing during the extrusion process, the starch granules are cooked and broken down, and the crystalline structure of the pellet is reduced, resulting in partial gelatinization and depolymerization. This will result in a viscous fluid of starch dispersion in water. Extrusion processing conditions such as temperature, moisture, and screw speed, among others, will affect the physical and chemical structures of starch and, subsequently, the IGs of the final extruded products. Therefore, snack amylaceous products usually have higher GIs than the corresponding raw materials.

Most of the extruded products are basically composed of cereals. Thus, they have a high GI. Various studies have been performed to increase the dietary fiber content after extrusion, thereby lowering their glycemic response. They shed some light on the mechanisms by which dietary fiber lowers the glycemic response. In these studies, the fibers seem to coat the starch granules, protecting them against the action of the amylolytic enzymes and reducing the degradation of starch, eventually producing a low glycemic response. There is also a physiological effect of the soluble fiber fraction, increasing gut fluid viscosity and reducing glucose absorption and hence the GI.

With increased dietary fiber content, it is possible to enhance the amount of slowly digestible starch components in processed food with reduced rate and degree of glycemic response. The use of whole-wheat flour instead of the refined flour in the extrudates reduces the amount of rapidly digestible starch components and increases the quantity of slowly digestible starch in extruded cereal-based breakfast. In the extrusion process, starch is subjected to high shear forces that chemically break glycosidic linkages forming fragments of lower molecular weight. Thus, this smaller branched starch forms new linkages, which are more resilient and, therefore, present lower GI. These structures are considered resistant starch and greatly contribute to the TDF content of the extruded food product.

Loss of Essential Fatty Acids and Vitamins

Extrusion of food can be a possible adverse effect with the destruction of vitamins during processing. The loss or retention of vitamins in extruded foods can vary according to the type of food, screw rpm, die diameter, moisture content, residence time at high temperatures, time and temperature of processing, and throughput. In general, in lower temperatures, the losses are minimal. In usual extrusion conditions at high temperatures for a short time and with quick cooling of the product during output, a relatively small loss of most of the essential fatty acids and vitamins is observed. For example, there are a 95% retention of thiamine and a small loss of riboflavin, pyridoxine, niacin, and folic acid in cereals at temperatures as high as 154 °C.

Vitamins A and C are normally lost by oxidation and heat. The retention of vitamin C is about 70% in extruded foods, while the retention of vitamin A ranged from 50% to 140% after extrusion. These differences are due to the intrinsic susceptibility of each vitamin and because vitamin A fortification of extruded products is performed through a series of β-carotene derivatives with distinct heat stability.

Other Nutritional Changes

Extrusion can maintain the levels of the lycopene in extruded enriched snacks, if the source used to enrich is the tomato skin powder.

The extrusion process can reduce the content of tannin that sometimes is undesirable in food. The extrusion of flaxseed, for example, showed 77% reduction of tannins.

A 13–35% reduction in phytate content occurs after the extrusion of a wheat bran–starch–gluten mix. Phytate is known to reduce absorption of iron and other essential minerals.

Fortification of extruded products must be performed carefully. The added minerals should have high bioavailability, they should also be homogeneously mixed with food ingredients, and these must be compatible with the processing. Calcium salts, for example, reduce the expansion of snacks. The mineral used may also be compatible with the postextrusion storage. The bioavailability of the iron is generally not affected by the extrusion process, and highly bioavailable iron is observed after processing of leguminous seeds.

Overview of the Extrusion Cooking Effects on Nutritional Value

In short, the extrusion process is widely used throughout the food industry during recent years; and there are several nutritional aspects of this thermal processing that should be taken into account.

Among the positive aspects, the following can be featured:

(a) The possibility of developing a vast range of versatile products ready for consumption, with a long shelf life, since various enzymes are inactivated, as lipases and lipoxidase.
(b) The destruction of antinutritional factors and microorganisms is effective and the final product is safe with respect to the production of toxic compounds derived from thermal decomposition of amino acids.
(c) The transformation of starchy materials in a crunchy, fluffy, expanded product that easily breaks with a final pleasurable product with texture.
(d) The enhancement of the digestibility of proteins through denaturation and by inactivation of protease inhibitors.

(e) The promotion of an increase of SDF fraction content and degradation of phytic acid, in addition to rearranging components of TDF.
(f) Extrusion process promotes a greater increase in starch digestibility than any other processing methods.

The negative aspects of extrusion are minimal but should be considered:

(a) Extruded snack products tend to have a higher glycemic response in comparison with the raw materials, although the increase in the dietary fiber content of the extruded products can lower their glycemic response.
(b) Vitamins are destroyed during processing, with vitamin C being the most affected, but in lower temperatures, the losses are minimal.
(c) The availability of several amino acids is reduced; lysine is the most unstable amino acid during the extrusion process.
(d) There is a strong relationship between Maillard reaction and acrylamide formation on extruded products.

Extrusion Cooking: Principles and Practice

L Moscicki, Lublin University of Life Sciences, Lublin, Poland

Extrusion-Cooking Technology

Extrusion technology, which is well-known in the plastics industry can be modified for a wide variety of extrusion-cooking applications in the food and agriculture industries, for which it produces 'engineered' food and special feed. Generally speaking, the extrusion cooking of raw vegetable materials involves the extrusion of ground material under barothermal conditions, with controlled moisture content, so that the shear energy, which is exerted by the rotating screw and/or additional heating of the barrel, heats the food material to its plasticizing or melting point. In this changed rheological status, the food is conveyed under high pressure through a die or a number of dies, and the product expands to its final shape. As a result, the extrudates have physical and chemical properties that are very different from those of the raw materials. Food extruders, which are often called extrusion cookers, belong to the family of high-temperature short-time equipment, because they perform under high pressure (up to 20 MPa) and high temperatures (up to 200 °C) for only a short time (typically tens of seconds). This form of processing restricts unwanted damage to nutrients such as proteins, amino acids, vitamins, and enzymes. The process conditions and raw materials used have a strong impact on the food and feed properties during extrusion cooking, however, and they can drastically influence the final product quality.

A modern food extruder is a process reactor that creates different extrudates by varying screw layout, mixing elements, clearances in the gaps, and the installed motor power and barrel heating, in order to control the dough reaction. For example, altering the process parameters and the combined effects of heat and shear affects the degree of starch gelatinization or denaturation of proteins in the presence of water.

Extrusion cooking is now used for the manufacturing of a diverse array of foodstuffs (Figure 1), including the following:

Figure 1 Various extrusion-cooked foodstuffs and feedstuffs.

- Direct-extruded snacks, such as ready-to-eat (RTE) breakfast cereals, differing in shape, color, taste, and texture
- Snack pellets: products destined for fried or hot air–expanded snacks, precooked pasta
- Baby food, precooked flour, instant concentrates, functional components
- Pet food, aquafeed, feed concentrates, and calf-milk replacers
- Texturized vegetable protein or meat analogs (mainly from soybeans)
- Crisp bread, bread crumbs, emulsions, and pastes
- Confectioneries: different kinds of sweets, gums, and jellies
- Barothermally processed products for the pharmaceutical, chemical, paper, and brewing industries

Extrusion cooking can use raw materials that have not previously displayed great economic importance (e.g., legumes) or have been regarded as waste. Of practical importance, the process can also be implemented with relatively low effort, does not require excessive capital investment, and uses equipment that can be employed for multiple applications. The energy consumption of food extruders is in the range 0.08–0.20 kWh kg^{-1}. Thus, in many cases, food extruders provide a cost-competitive alternative to other machines used for food and feed manufacturing.

The direct extrusion of cereal snacks provides a good example of extrusion-cooking technology. Figure 2 presents the standard installation used in this process.

Preparation of Raw Material

Direct-extruded snacks are most often manufactured from popular cereal-based materials, such as corn, wheat, and rice. Depending on its quality, the material must be properly ground and weighed, according to the recipe, and mixed thoroughly before being fed to the extruder. If preconditioning is required, water and/or steam is added to the material before mixing.

Extrusion Cooking

Extrusion cooking is based on the concept that, after the material leaves the die, the sudden decrease in pressure allows the superheated water in the material to turn into steam, leading to a rapid expansion of the material. This expansion is responsible for the porous structure of the extrudate, with the structure shaped by bundles of molten protein fibers. The melt mass leaving the extruder generally takes the shape of the extruder dies. A rotary knife is installed outside the die, in a lengthwise arrangement, and the appropriate setting of the knife speed controls the product length. This allows for the production of different, fancy shapes of extrudates, such as balls, stars, shells, and rings, even when using a simple single-screw food extruder. The technology for the production of each shape requires an appropriate distribution of temperature, pressure,

and moisture content in the material during processing. Therefore, the operator must be focused on flexibility and precise control, especially in regard to the thermal process. Frequently, the process for the manufacturing of specific products must be developed empirically.

Drying, Coating, and Packing

After extrusion, the extrudates are dried to a moisture content of about 6–8% and cooled when necessary. Drying can be performed with simple rotating drums installed with electric heaters, or it can use a gas-operated hot air installation working at temperatures just above 100 °C. Larger installations rely on belt dryers, heated by gas-fired heat exchangers or steam, with hot air circulating through the unit sections. Cooling takes place at the ambient temperature, as air flows through the perforated belt of the cooler device. The flavor and vitamin-coating step is often integrated in drum dryers. Flavor additives, liquored or powdered, come in a wide variety of forms, from smoked meat flavor to paprika aroma.

Popular direct-extrusion breakfast cereals include coated cereal balls, rings, or shells in an icing sugar coating. The industrial production of this type of product requires the use of an additional high-performance drum dryer or belt dryer, so that the application of the coating is a continuous process, thus maintaining fixed product quality.

Quality Parameters

The literature has described the influence of various extruder variables, such as screw speed, die geometry, screw geometry, and barrel temperature, on product quality. A number of measuring methods are used to obtain the desired physical properties of extrudates. The most important are bulk density, water sorption, wet strength, dry strength, cooking loss, and viscosity behavior after extrusion. A more detailed description of the properties of starches and proteins also requires additional chemical data, including dextrose equivalents, reaction rate constants, and data describing sensitivity to enzymatic degradation. The food engineer and technologist must be able to forecast the relationship between these properties and their dependence on the extruder variables. Therefore, it is necessary to provide a (semi)quantitative analysis of biopolymers in the extrusion-cooking process, which can be done by adopting an engineering point of view, with the extruder considered to be a processing reactor.

Food Extruders

As previously mentioned, extrusion cooking involves machines in which the main operative body is one screw or a pair of screws fitted in a barrel. During barothermal processing, the material is mixed, compressed, melted, and plasticized in the end part of the machine (Figure 3). The range of physical and chemical changes in the processed material principally depends on the parameters of the extrusion process and the construction of the extruder.

There are many conventional methods for classifying food extruders, but the most practical accounts for the following three factors.

- The method of generating mechanical friction energy converted during extrusion into heat: autogenic, isothermic (heated), polytropic (mixed)
- The amount of mechanical energy generated: low-pressure extruders producing relatively limited shear rate and high-pressure extruders generating large amounts of mechanical energy and shear

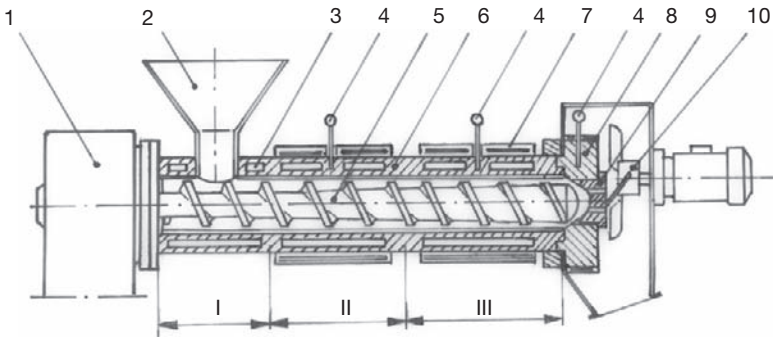

Figure 3 A cross section of a single-screw food extruder: 1, engine; 2, feeder; 3, cooling jacket; 4, thermocouple; 5, screw; 6, barrel; 7, heating jacket; 8, head; 9, dies; 10, cutter; I, transport zone; II, compression zone; III, melting and plasticizing zone.

- The construction of the plasticizing unit, with both the barrel and the screw designed as a uniform, integrated body or fixed with separate modules

In 1946, in the United States, single-screw extruder were developed to cook and expand corn and rice snacks. In combination with an attractive flavoring, this product type is still popular, and the use of single-screw extruder equipment to produce such snacks is, in principle, is still the same. A wide variety of extruder designs can be employed for this purpose. The old method of cutting preshaped pieces of dough out of a sheet with roller-cutters is also still in use, however, because the complicated shapes of snacks require very expensive dies and die heads for cooking and forming extruders. Although modern techniques offer improved control of mass flow in food extruders, new extruders with better mixing and a more steady mass flow often show advantages over the traditional single-screw equipment. In the mid-1970s, twin-screw extruders were introduced for the combined process of cooking and forming of food products, partly as an answer to the restrictions of single-screw extruder equipment, because twin-screw extruders provided a largely forced flow. Twin-screw extruders also tended to produce better results on scale-up from the laboratory extruder types in use for product development.

During the processing of biopolymers, nearly all chemical changes in food are irreversible. Continued treatment after such an irreversible reaction in an extruder should be a process controlled for temperature, time, and shear, leading to a series of completely different functional properties of the produced food. From a rheological point of view, two facts are the most important. First, non-Newtonian flow behavior usually occurs in food extruders. Second, chemical reactions occur during the extrusion-cooking process (e.g., gelatinization of starch or Maillard reactions), strongly influencing the viscosity function. The rheological behavior of the product, which is relevant to the modeling of the extrusion process, has to be defined directly after the extruder screw tip, before expansion has occurred, in order to determine the influence of water losses, the consistency of the material, and temperature effects due to the flashing process that occurs directly after leaving the die.

Today, the food extruder is integrated into the technological line as a single- or twin-screw reactor, with the preheating step performed in a specially built preconditioner. The forming task of the extruder can also be separated from the heating and shearing steps. In this case, the final shaping and forming are done in a second, well-optimized post-die forming extruder, which largely processes the food at a lower water level than is present in the first reactor extruder. This method produces cooked, preshaped, unexpanded food pellets, which can be used for the production of RTE cereal flakes (e.g., popular corn flakes) or as half product in the manufacturing of fried snacks.

Single-Screw Food Extruders

The design of single-screw extruders is relatively simple. In food extruders, sticking effects are prevented by the force of friction between the material and the barrel wall, and this friction is facilitated by the suitable grooving of the inside of the barrel (longitudinal or spiral grooves).

These devices process relatively easy materials characterized by a high friction coefficient, such as maize or rice grits (i.e., basic materials for the production of direct extrusion snacks or breakfast cereals). For these materials, the use of the simplest autogenic extruders is often sufficient, even at a low ratio of screw length L to diameter D (L/D) = 4–6. The main disadvantages of single-screw extruders are poor mixing (as a result, materials should be mixed before feeding) and limited efficiency, especially when multicomponent mixtures of raw materials are used. Smooth positive movement of the material in a single-screw food extruder depends on the actual drag flow, which is caused by the screw geometry and its rotation minus the so-called back flow.

The operator must strictly follow the technological regime during operation, which is determined experimentally or given by expert technicians. A number of issues must be taken into consideration in daily extruder operations:

- The moisture content and particle-size distribution of the raw material mixtures must be properly chosen and homogeneous. This prevents shooting or blocking in the extruder and ensures the desired quality of the extrudates.
- Intensive cooling of the barrel (e.g., with cold water) contributes to a lower processing temperature and increases the friction inside the material. It must be correlated with the quality requirements of the extrudate. A temperature drop in the material raises its viscosity and positively contributes to the extruder's performance.
- The blocking of a few die holes results in a sudden increase in pressure and leads to a powerful back flow, or even

lockout of the machine. In such a case, immediately cleaning the blocked holes with a thin tool might correct the problem. If this does not help, the operator must stop the machine and dismantle the die. Postponing the disassembly of the die with a plasticized material inside it may lead to permanent damage to the equipment during the next start-up.

- The smallest holes in the die cause a higher resistance during the extrusion of the material, because smaller openings increase pressure and reduce the extruder's output, given the higher incidence of back flow.
- Applying a plasticizing screw with a greater L/D ratio can generate more extrusion pressure resulting from a longer fully filled screw, which leads to improved plasticizing of the material and reduced back flow.
- The loss of a defined clearance between the barrel surface and the screw flights hampers the movement of the material, reduces friction and pressure, and causes poor operation of the machine, which means poor product or no product at all.

Twin-Screw Food Extruders

These machines are much more complex in terms of design but much more universal in operation. However they are more expensive. Nonetheless, twin-screw extruders have become very popular with producers of extrusion-cooked foodstuff, because of their ability to process a wider range of materials (e.g., viscous and hard-to-break materials) and their lower energy consumption, broadening the list of products the machines can produce. Corotating food extruders are also used to a greater extent because of their high productivity and efficient material transportation, mixing, plasticizing, and extrusion. The self-wiping and intermeshing flights of the screws effectively force the material forward, and, as a result, no material is locked in the space between the surface of the barrel and the screw. Popular corotating twin-screw food extruders most often produce RTE breakfast cereals, pet food, and aquafeed.

The physical processes and heat exchange associated with material transfer in twin-screw food extruders are more complicated than they are in single-screw extruders. Readers who wish to learn more about the engineering aspects of extrusion can find detailed information in the literature. The extrusion-cooking technique is fairly complicated, and its proper use requires considerable expertise on the part of the operators. Yet, when operators are properly trained, extruders can allow food companies to vastly broaden their product offerings.

Counterrotating twin-screw food extruders are special-purpose devices. In these machines, the screws rotate slowly, but they can mix the material effectively, and their work resembles a positive-displacement pump, generating high pressure on the screws in the barrel's closed C-shaped chamber. This approach is especially suitable for high viscosity material. The back flow of material in these extruders is very small because of the tiny clearances between the screws and the barrel. They are mainly used for the production of confectionery and chewing gum, as well as the processing of fiber- and cellulose-rich materials.

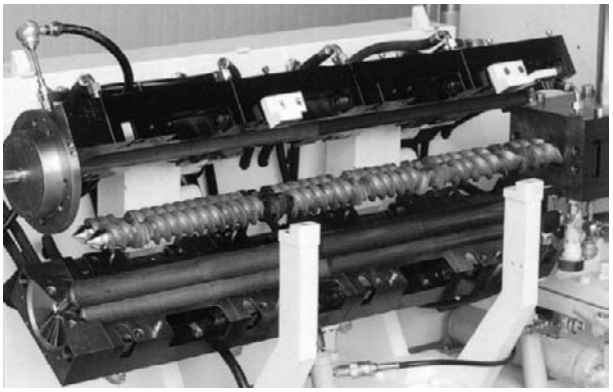

Figure 4 Modern multifunctional corotating twin-screw food extruder with an axially open barrel.

Twin-screw food extruders now have a modular construction, with the screws built from several different elements mounted on the screw shaft. These elements handle transporting, mixing, compressing, and melting the material (Figure 4). By properly setting these elements, the operator can control the behavior of material inside the extruder, thus influencing the scope of the physical and chemical processes during the extrusion-cooking process.

Extruders often produce a wide range of products, from simple maize snacks to protein-based food. Snack production requires high pressure and mechanical energy at a low L/D ratio. Protein-based material needs long processing times, with many intermediate stages applied. Modular screws allow for these possibilities, either by the disassembly of the barrel units in combination with the replacement of the screws or by changes in the screw lay-out. Some food-extruder producers offer a mobile feeder installed on the feed ports between the center and the end of the barrel. In such cases, distance rings are placed on the screw shafts ahead of the final set of screw elements.

During the operation of extruders, the engine load must be maintained at an adequate level (maximum 80–85%). As a result, the screw's rotational speed, torque, and energy consumption (expressed in kWh per 1 kg of product) must be controlled. The proper choice of extruder machinery for the type of production is also important for a successful operation. Yet, no established and strict recommendations currently exists regarding the range of temperature in different zones of the plasticizing section of food extruders. Some temperature ranges can be recommended during the processing of certain raw materials, but, in the case of a particular machine, these ranges should be verified empirically, or they should be based on the manufacturer's recommendations.

In the daily operation of food extruders, the start-up and close-down of production causes difficulties. This is an important job for the operator because it is relatively easy to block the machinery. Cleaning the plasticizing unit, after it has stopped, requires patience and time. If the stop procedure is incorrect, permanent damage to the equipment can occur. On the other hand, the start-up procedure is relatively uniform. After the extruder heats up and reaches the desired temperature in individual zones of the plasticizing section, the engine begins running at one-third of the nominal rpm level. Highly moisturized material is then fed into the machine. Subsequently, the

machine performance is increased step by step, while the operator closely watches the outflow of material and the engine load. After a few minutes, the machine reaches its nominal operation parameters. The close-down must be done in the reverse order, and finally, the operator completely cleans the machine after taking down the die head, using some coarse material (e.g., oats) for the final cleaning of the plasticizing section. The machine will not restart when the working parts and the head are dirty.

Producers of extruded foodstuffs now prefer to fully control the production process. In the case of high-volume production rates, this level of control is indispensable, because only a properly programmed control system is fast enough to govern the production flow, responding immediately to failures of the working equipment. Modern food extruders can easily replace many conventional food-processing units, and these extruders are capable of helping the industry develop new series of products. The market expects new foodstuffs that are fancy in shape, taste, and raw material composition, as well as attractive from an economic point of view. As previously mentioned, extrusion cooking can texturize proteins from vegetable sources to create textures resembling those of meat, allowing for healthier (low fat), palatable, and more sustainable products. Extrusion-cooking technology can meet these expectations, but food technologists need specialized knowledge.

Introduction

At present, the worldwide population is estimated to be around 7 billion people. During the twentieth century, however, it is estimated that more than 70 million died due to food crises. Nowadays, at the height of the twenty-first century, the food crises (famine) continue as a global humanitarian tragedy. These crises are recognized and are mainly located in zones of the African continent, such as in the Horn of Africa where an endemic form persists. This does not mean, however, that other regions of the world are free from the risk of food crises. Generally, the risk persists primarily in developing countries with deficient economic transformations combined with problems of political instability, natural disasters, wars, and/or social conflicts. Moreover, these crises persist in concrete zones that are poorly integrated into worldwide trade, as well as in urban and rural areas whose public services lack the capacity to attend the poorest and most vulnerable groups. However, although these determinants can be found in different parts of the world and in distinct moments, the current food crises concentrate mainly in sub-Saharan Africa and some regions of South Asia.

Hunger, be it transient or endemic, is a historical reality whose incidence continues being decisive at the present time. Although the statistics on malnutrition and food insecurity have greatly improved in the last decade, the most recent reports of the Food and Agriculture Organization of the United Nations (FAO) on the state of food insecurity in the world indicate that much remains to be done. Hunger has fatal repercussions in the life of millions of people; as part of the process, it deprives its victims of health, causes massive migrations to other countries as people seek sustenance, and aggravates and/or causes illnesses such as malnutrition, AIDS, tuberculosis, and malaria. In addition, it is both a source and a consequence of instability, poverty, and underdevelopment as attested to by the fact that the majority of armed internal conflicts happen in countries with precarious food conditions.

One must ponder: Why, if it was possible to end famine in hunger-prone countries such as Russia, China, India, and Bangladesh during the twentieth century, due to the technical advances in food production, do people still to continue dying of hunger? Surely, this is because hunger is a phenomenon much more complex than it seems on its face. In any case, it would be an error to think that death from starvation or famine is homogenous; in fact, the causes and consequences of food insecurity greatly differ between countries and even between different regions within the same country. As such, a general theory explaining the periods of hunger and famine cannot exist, and thus, each one of these periods should be treated in a unique manner.

Definitions for the Discussion of Famine

To better understand the context of famine, it is necessary to clarify some concepts associated to the term. Distinctions need to be made among hunger, malnutrition, famine, and food insecurity.

Hunger

Hunger is defined here as a condition resulting from an individual's inability to eat sufficient food to lead a healthy and active life. It compromises a series of feelings, emotions, and behavioral changes, not easily measurable in themselves that result from disruption in an individual's access to food. Naturally, hunger is a recurring feature of food insecurity of households and their members in developing countries.

Malnutrition

Undernutrition, by contrast, is defined as the measureable nutrient deficiencies in a diet that can lead to illness (lack of energy, retardation, and blindness) or death. The symptoms themselves may not be recognized as indications of nutrient deficiencies since interactions between undernutrition, care behavior, and diseases are complex.

Famine

Famine is a widespread and extreme hunger that for individuals results in a drastic loss of body weight and an increase in morbidity. At the community level (as an interaction of these two symptoms), a rise in the death rate and massive social dysfunction and dislocation result. Famine is a process of socioeconomic crisis, relatively prolonged over time, and consists in the progressive impoverishment of the most vulnerable groups

and the deterioration of their systems of sustenance, with an increase in massive hunger. The process also implies population movements, the propagation of epidemics, community degradation, and, in severe cases, an increase in mortality that results more from related epidemics than to starvation, itself. Therefore, food crises (famine) are a catastrophic split of social, economic, and institutional systems that provide food for production, feeding, and consumption. For many years, these crises have been considered as anomalies, crises that could be resolved in a brief period of time and for which the previous situation existing before the crisis could be reestablished. Nowadays, this vision of a transient stage has been dispelled, as it is known that food crises (famine) can destroy not only lives but also future development of the community/region.

Food Insecurity

Food insecurity is a situation that exists when people lack secure access to sufficient amounts of safe and nutritious food for normal growth and development and an active and healthy life. It may be caused by the unavailability of food, insufficient purchasing power, inappropriate distribution, or inadequate use of food at the household level. Food insecurity, poor conditions of health and sanitation, and inappropriate care and feeding practices are the major causes of poor nutritional status. Food insecurity may be chronic, seasonal, or transitory.

Famine Mortality

The most serious manifestation of starvation is increased mortality, although food crisis does not occur with the same intensity or in the same way in all cases. Mortality data associated with food crises also reveal that they do not affect all people equally. From a biological and socioeconomic focus, the highest mortality rates are seen in vulnerable groups. First affected are children under five and the elderly living in poor conditions and in remote rural areas far from the cities. However, data recorded in the great famines indicate a complex interaction between biological vulnerability and socioeconomic vulnerability. The latter is closely associated with the cultural, social, and economic contexts of each region or country.

The death toll in the severe famines is only approximate estimates. The reason for not being able to set an exact number of deaths is mainly due to the lack of official records of births and deaths in some developing countries as well as basic demographics of the population (population census and mortality rates during nonfamine years). On the one hand, excess mortality rates are estimated for population groups monitored by the national population census, and the rates are compared to the 'normal' population before the famine. On the other hand, mortality is a parameter that does not assess the total demographic impact of famine, as the falling birth rate may have consequences on population size. This increased mortality in famines is due to two main factors. First, there is the effect of starvation that brings about weight loss and the subsequent undernutrition that puts individuals at increased risk for diseases. Second, as a result of undernutrition, there is increased susceptibility to infectious diseases as a result of weakened immune systems. Furthermore, there is increased exposure to epidemics unrelated to food (e.g., typhoid, cholera, measles, and malaria) due to the lack of sanitation and hygienic conditions caused by displacement and overcrowding in unsanitary settings and the lack of potable water. Both circumstances imply that refugee camps are locations that generally register the highest mortality rates.

Although the overall data indicate that famines throughout history have produced a high number of deaths, in relation to the national population of the countries where they occur, this has rarely exceeded 2–3% of the total population. During twentieth century, there were between 70 and 80 million deaths. From the recorded data, a pattern of geographic and seasonal appearance can be established. It seems that over the decades, famines have been happening in the northern hemisphere (Russia) and Asia (China, India, and Bangladesh), moving toward sub-Saharan Africa, where even today, it remains endemic. In addition, this geographic shift has been associated with a decrease in mortality. During the pre-1960 period, the nine famines that occurred in Russia, China, and India led to a total of 66 million deaths. However, the 16 famines that have occurred since the 1960s in Africa have caused 10 million deaths. This reduction is due to several advances made during the twentieth century. In the first half of this period during the colonial administration, vulnerability to famine in Asia, and to a lesser extent in Africa, decreased because of improved communications and transportation. Markets that were previously isolated were linked with larger markets, and warning systems were established and policies implemented to help those affected by famine. In some colonized countries, decolonization brought disparate effects. On the one hand, in countries like India, decolonization produced greater government involvement in the eradication of hunger through policies of job creation or the delivery of humanitarian aid, both of which led to excellent results. On the other hand, in many African countries, decolonization was associated with the *de novo* appearance of famines, induced by increases in political and economic instability and civil wars. Moreover, in many cases, drought and the lack of water for crops worsened the problems of hunger in many of these countries. Thus, during the 1980s and 1990s, some countries that had never been prone to famine such as Sierra Leone, Zaire, Angola, and Mozambique and others that had previously suffered famine such as Sudan and Ethiopia suffered major famines due to armed conflict and/or drought. Today, in the Horn of Africa, the equation *drought + war = famine* is still very much in vogue.

Current State of Global Food Insecurity

FAO's latest estimates indicate that reducing global hunger continues on the right track. It is estimated that approximately 805 million people were chronically undernourished during 2012–14. These figures represent a decline of more than 100 million in the last decade and of about 209 million over the period 1990–92. However, one in nine people worldwide still lacks sufficient food to lead healthy and active lives. The vast majority of malnourished people live in developing countries (791 million people), although it is in these same countries where most of the improvements in the last two decades have occurred (FAO). The decrease in the proportion of hungry people has been approximately 7.4 percentage points from the period 1990–92 to 2012–14, which has reduced the proportion of people affected by hunger from 18.7% to 11.3% (Figure 1).

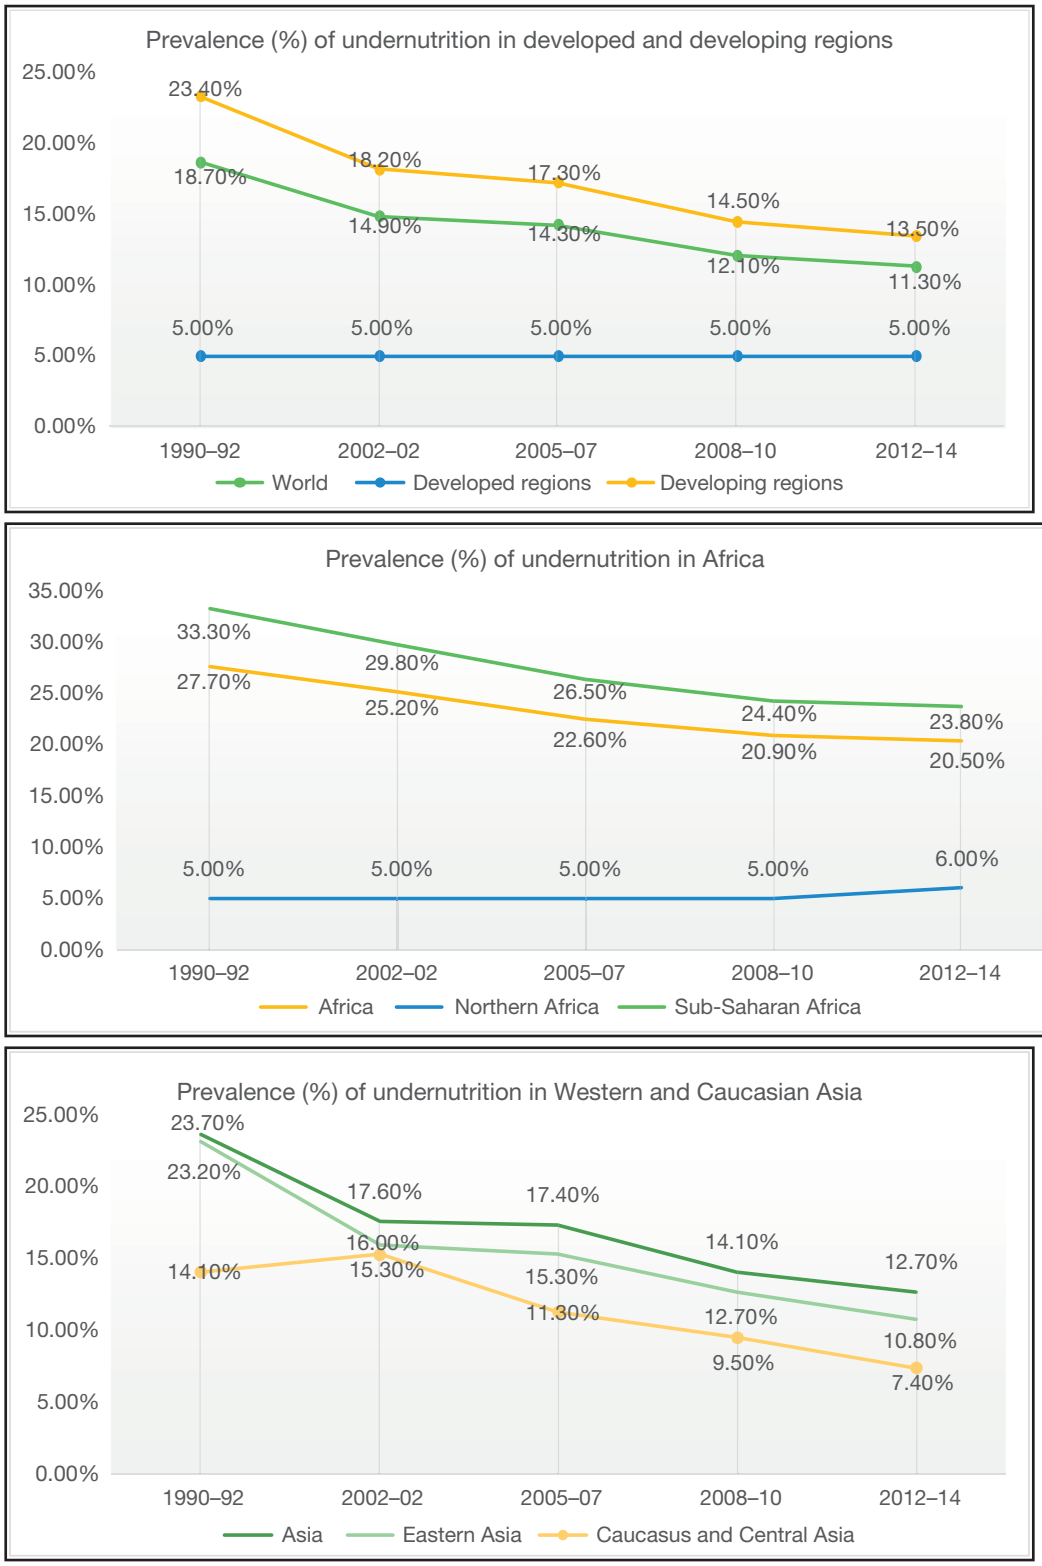

Figure 1 Trends in undernutrition prevalence rates.

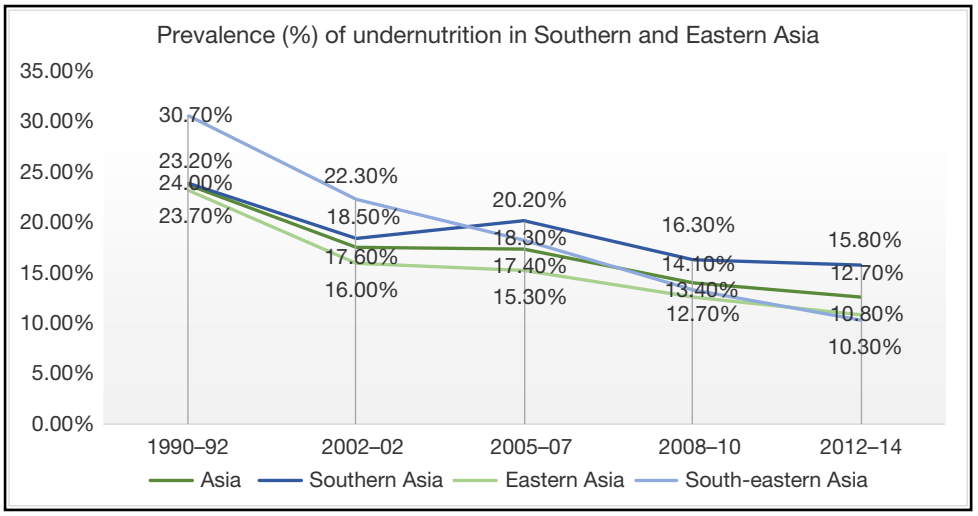
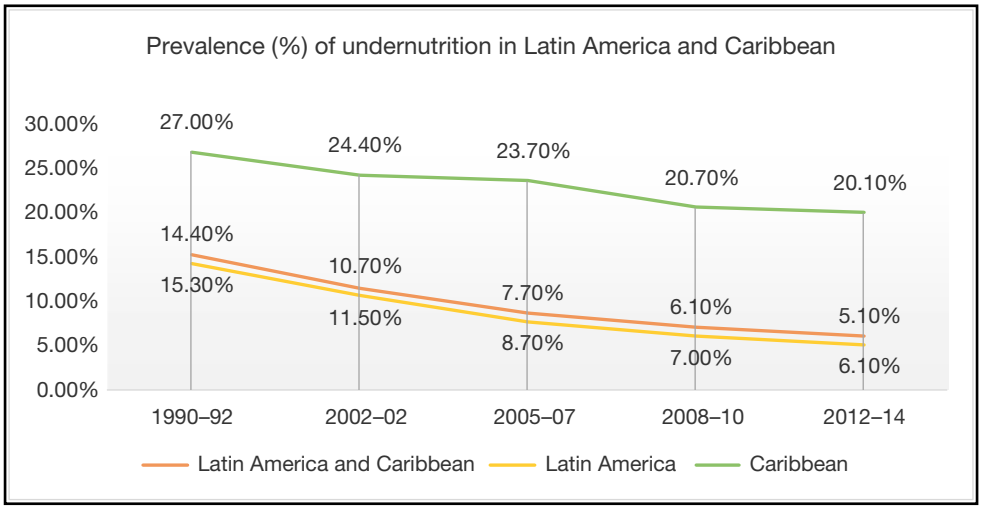
Continued





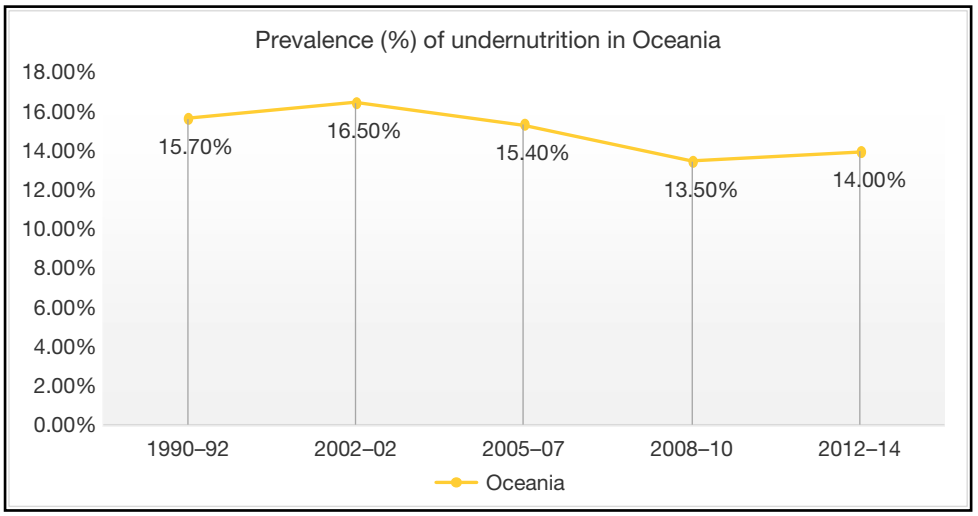


Figure 1—Cont'd

This decline has been much more significant in developing countries, where for the same period, the decrease was almost 10 percentage points (from 23.4% in 1990–92 to 13.5% in the period 2012–14). Therefore, it seems that the hunger goal stated in the Millennium Development Goals (MDGs) for 2015, "reduce by half the proportion of undernourished people" is within reach, but not the objective of the World Food Summit (WFS) of "halving the number of chronically underfed people." According to estimates, it appears that by 2015, the proportion of undernourished people would be 12.8%, a rate 1.1 percentage points higher than that expected by the MDG (11.7%). However, according to experts, increasing efforts in the most affected areas (sub-Saharan Africa and South and West Asia) would make it possible to accelerate the pace of reducing hunger. Nevertheless, the estimate of people affected by hunger in 2015 is around 791 million, a far cry from the 500 million that constituted the goal of 1996 World Food Summit.

Africa

In Africa, there are a total of 226.7 million undernourished people (20.5% of undernourished people worldwide). The data show that progress in reducing hunger in Africa, mainly sub-Saharan area, has not been sufficient. Still, there have been significant improvements from the period 1990–92 when the prevalence of undernutrition in sub-Saharan area was 33.3% and the prevalence for the period 2012–14 was 23.8%. In total, it is estimated that in the period 2012–14, the number of undernourished people in sub-Saharan area was 214.1 million people. The lack of political stability and wars are the major causes for less progress in sub-Saharan Africa compared to other at-risk regions. A different situation is observed in North Africa, where the prevalence of undernutrition was observed to be less than 5% in all periods since 1990–92; during the period 2012–14, there was an increase in undernutrition reaching 12.6%, for a total of 12.4 million undernourished people. This increase rate can be attributed mainly to the inclusion of Sudan into the region of North Africa.

Asia

Globally, Asia has a total of 525.6 million undernourished people, representing 65% of the world's undernourished population. Although globally, Asia is close to meeting the Millennium Development Goals on hunger, it is the area with the highest numbers of undernourished individuals, and there are significant differences between the regions that make up this area. The Caucasus and Central Asia, East Asia, and Southeast Asia are the regions where most progress has been observed over the last 20 years. The decreases in undernutrition rates have been over 50% for West Asia (from 23.2% in the period 1990–92 to 10.8% in 2012–14). In Caucasus and Central Asia, the decreases had been from 14.1% in 1990–92 to 7.1% in 2012–14, and a 66.5% decrease was observed in the case of Southeast Asia (30.7% in 1990–92 and 10.3% in 2012–14). Still and all, it is worthy to note that in the West Asia region, there is a total of 161.2 million undernourished people.

Moreover, the worst scenarios are observed in West and South Asia. In the region of South Asia, although progress since 1990–92 has been seen, undernutrition rates of 15.8% (with a total of 276.4 million people having food access problems) are still far from the Millennium Development Goals. The situation is worse in West Asia where, albeit undernutrition rates are not as alarming, there is much concern about the developments in recent periods where rates have gone from 6.3% in 1990–92 to 8.7% in 2012–14. This increased prevalence of undernutrition is also reflected in the number of undernourished people, increasing from 8 million in 1990–92 to 18.5 million in 2012–14, showing an increase of more than 10 million undernourished individuals. Deterioration of the economies and high political instability are the main causes of the increase in rates in recent years in the West Asia region.

Latin America and the Caribbean

The Caribbean and especially Latin America presented the most progress of all the developing regions in relation to increased food security. This region has already met the Millennium Development Goals and is close to achieving the target set by the WFS. In total, the region has in 2012–14 an undernutrition rate of 6.1% (a total of 37 million undernourished people), a decrease from the 68.5 million in 1990–92. Latin America's progress in improving food security has been faster than in the Caribbean. In Latin America, the prevalence of food insecurity for 2012–14 is 5.1%; in the last 20 years, the total number of undernourished people has decreased from 60.3 million in 1990–92 to 29.5 million in 2012–14. In the Caribbean, this reduction has been slower, declining from 27% in 1990–92 to 20.1% in 2012–14.

Oceania

Oceania is the region that has the least number of undernourished people in the world (1.4 million representing 0.17% of the world's undernourished population). The prevalence of undernutrition has varied little since 1990–92, showing only a 1.7% decrease. The main concern in the area is that the rates of undernutrition have been accompanied by a greater burden of overweight and obesity. As such, the region suffers from a considerable double burden of malnutrition.

Theories of Hunger

Hunger as a collective phenomenon has always existed, which throughout history has involved different regions of the planet and during given periods of time. It is a result of various factors: poor harvests, wars, economic crises, and natural disasters. The hunger of our time has the peculiarity that it is concentrated in certain regions and countries; it now can be considered as chronic and endemic, that is, not only due to natural disasters or wars. For this reason, it is important to study the theoretical frameworks that have been developed to explain the worldwide phenomenon. In recent decades, several different explanatory paradigms have emerged, attempting to explain the causes of famines. These can be grouped into five distinct models:

Model 1. Demographic Theories (Malthusian and Neo-Malthusian Theories)

The relationship between hunger, production and food availability, and the population is the core of the reductionist

Box 1 Criticisms of the Malthusian Theory

(a) Malthus wrote thinking of the English agricultural situation in the eighteenth century when it was based on subsistence agriculture.
(b) Malthus failed to foresee the agricultural, transport, industrial revolution, and demographic transition.
(c) Geographically marginal land is not necessarily less fertile, even if it is the furthest away.
(d) Famine did not act as a 'Malthusian leveler.'

theories of Malthus and the neo-Malthusians. The focus of these theories was based on the fundamental consideration that the amount of food production (production or food availability) and the number of people (population) are the only two variables that determine the global food situation and therefore the existence – or not – of hunger in the world. From the relationship between both elements, the acceptance of hunger as a fact that has to happen consistently was derived, since the number of people grows geometrically, whereas the amount of available food grows arithmetically. In this formula, Malthus affirmed that in order to avoid hunger, a decrease in the growth rates of the population was essential so as to increase food availability. Currently, there are some authors who keep the Malthusian theory alive, and they conceive hunger as a result of the competitive relationship between the two variables mentioned earlier: food production and population growth and poverty. In other words, according to these principles, the causes of hunger are the lack of food and high rates of population growth. Based on these theories, the balance between food availability and population would be restored through famines, epidemics, mass migration, and reduced fertility. These theories were popular in the 1960s and 1970s when the perception that the world was running out of food resources was on the rise. Today, Malthusian theories have evolved with new arguments that differ from the original theory. New proposals differ from the original Malthusian argument because the constraint on population growth is represented not only by arable land and food scarcity but also by the availability of water, energy supply, and raw materials, as well as by land and air pollution. From this point of view, the neo-Malthusian approach is strongly supported by increasing the awareness of the need to protect the environment and its resources. The Malthusian approach is susceptible to four criticisms outlined in Box 1.

Despite these critiques, these theories could still be considered quite current as they focus on the safety and availability of natural resources and on nonpolluted air and water, thus emphasizing the environmental and social constraints of our planet.

Model 2. Climatic Theories (Based on the Decrease in the Availability of Food or Food Availability Decline)

The food availability decline (FAD) approach assumes that famines are caused by a sudden reduction of per capita food supply. It is usually triggered by natural disasters (drought, floods, pest infestation, etc.), wars, and epidemics that lead to a contraction of the food supply. As a consequence, food prices go up and people, who are not able to bear such an increase, consume less calories and nutrients. Consequently, the most vulnerable individuals start reducing their food consumption because of rising prices. In the case of prolonged exposition to a crisis, this may culminate in increased mortality due to starvation and infectious diseases. This model points out the insufficient production and availability of food as the main causes of famines and starvation. This approach implicitly assumes an equal division of the available food, but unfortunately, such an assumption fails to reflect reality. The FAD hypothesis implies that food security is essentially a matter of expanding food availability. As a solution, it argues to increase the supply and consequently the availability of food. This solution has been strongly criticized by Amartya Sen. However, he recognizes that famines can be caused by food availability decline and he also assumes this hypothesis for its entitlement approach.

Model 3. Food Intervention Decline

This new framework, the so-called food intervention decline (FID), originates from the recent and growing awareness that governments, and more generally political institutions, humanitarian agencies, and nongovernmental organizations (NGOs), have the responsibility to protect all citizens by promoting direct public interventions. This model approach argues that people starve because food policies and services fail to guarantee a sufficient level of nutrition. When these policies and services decline or disappear, persons start suffering and severe undernutrition may occur and consequently famine appears. This approach identifies as main actors all those institutions that are responsible for the production and implementation of measures to secure nutrition and healthy feeding.

The FID approach suggests a number of different policies that may be broadly grouped into two categories, depending on their target. One constitutes the policies established to prevent undernutrition in at-risk zones. Examples are improving the conditions of public health and the warning systems to prevent the crisis, reducing social inequalities and social cohesion, applying policies of price protection for basic foods, and fortifying the systems of education, health, and social services. The other category includes policies establishing fast-responding systems to deal with the appearance of food crises. Examples consist of introducing free or price-reduced food consignments into markets, establishing policies to control prices and subsidize the food supply, creating food reserves (i.e., cereals), carrying out direct interventions, and improving communication and transport infrastructures.

All these interventions should be implemented in a planned and carefully thought-out manner in accordance with the nature of the problems and the underlying causes of the famine. One of the main risks is to damage economies with abundant food supplies, further depressing food prices affecting agricultural incomes; the outcome could be further reducing the disadvantaged population's purchasing power.

Model 4. Sen's Food Entitlement Approach

As a response, mainly to the theories of Malthus and the neo-Malthusians, some authors elaborated theories that determined that famines and hunger were not produced by a lack of food in the market, but rather by the poverty of given social sectors that deprived them of food access. These criticisms gave

place to a new approach, known as food entitlement, proposed by the Indian economist Amartya Sen in his famous 1981 work *Poverty and Famines*. This was decisive for the formulation of the concept of household food security, which focused more on families than on countries (the concept of national food security was changed to household food security). The entitlements are the capacities that a family has to access food by legal means, be it by production, purchase, or receiving food in the form of donations from the state or the community. Sen demonstrated in diverse studies that famine was not frequently due to a lack of supplies, but rather to a sudden loss of entitlements in poor families, until reaching a point that food requirements could not be met. He understood famine as a temporary convulsion of the economic system. According to this theory, the political answer to famines resided in the struggle against the poverty. One of the advantages of Sen's theory on famine is that it is not a simple theory, but a model that is generalizable and can explain different models of famine. In some way, Sen's model assumes as its own the models of FAD and of FID. In the first case, it understands that the descent in food availability can increase the price of foods and, as such, leads to impaired food entitlements. FAD's role is assumed to be one more factor out of many that are related to entitlements. In the same way, when Sen's model suggests to adopt measures to improve food purchases and food assistance, it assumes the hypotheses of the food intervention decline (FID) model.

The fundamental criticism of Sen's theory is that it assumes that famine is like a sudden collapse in food consumption that causes a particularly virulent form of starvation and involves widespread death. That is to say, it would be considered as a onetime and sporadic event, which is distinct from hunger and whose appearance is characterized by an increase in mortality due to starvation. In contrast, authors like Amrita Rangasami and Alex de Waal have shown that famine is not so different from hunger, but rather is a process that begins with hunger as its starting point and, in the most severe cases, can lead to massive death. In fact, the majority of famines nowadays are characterized by a not so extreme starvation, thanks to the palliative mechanisms of the family's distinct coping strategies. At present, it is not the increase in mortality that is the most worrisome factor, but rather the misfortune and social perturbation that is caused. As such, the victims perceive hunger not so much as a life-threatening biological process but rather as a socioeconomic process of impoverishment that threatens their systems of livelihood. Therefore, it understands that Sen's definition of famine only refers to the last phase of the famine and not to the entire process. In fact, authors like Purusottam Nayak criticize Sen for limiting his explanation to the immediate cause of famine, such as the loss of entitlements, but not including background causes or dynamics once the process is initiated. That is to say, Sen explains how famines are produced but does not explain why or what causes them to happen.

Another critical vision of his theory addresses the excessively economic vision of the problem, which centers only on the loss food access and on subsequent starvation, but omits other essential factors of famines like the impact of epidemics on increased mortality, violence, wars, and population movements or social destruction. Sen also contemplated famine victims as passive subjects, ignoring their own capacities for implementing coping strategies to mitigate the effects of famine. Sen himself indicated that his theory had some limitations, which could be summarized in two aspects: on the one hand, a failure to recognize individuals as socially embedded members of households, communities, and states and, on the other hand, a failure to recognize that famines are political crises as much as they are economic shocks or natural disasters.

Sen's theory, when centering on circumstantial economic appearances, specifically on the relationship between markets and people, tends to ignore the structural, historical, and political factors. Therefore, his theory is soundly criticized for limiting itself to measures of a technical nature, suggesting solutions such as providing employment. Thus, resources are generated to help those that have temporarily lost their entitlements or both, but it does not contemplate structural transformations that would eliminate the underlying structural vulnerability.

Model 5. Complex Emergencies (Humanitarian and Political Emergencies)

From the mid-1980s, certain authors posed a distinct vision of the etiology of famines, based on political causes instead of economic or demographic determinants. Authors such as Alex de Waal, David Keen, and Mark Duffield are the maximum exponents of this explanatory political model of famines. For these authors, the victims of the famine are defined not by a lack of economic but rather political power. Famines are seen as political phenomena derived from the lack of government initiatives and even of policy practices causing famines, such as ethnic persecution, forced population displacement, and denying humanitarian aid.

Famine is a result of the failure of a 'political contract' between the country's leaders and the population. This agreement would impose obligations on the politicians, certain obligations to guarantee the right to food. When this tacit agreement exists, the apparition of famine can generate grave political consequences, even including the downfall of government or sanctions for its leaders; and as such, there is keen interest in impeding the appearance of famines. In those countries that do not guarantee the civil rights of their citizens, famines do not concern governing leaders, and therefore, the fight against hunger is not a priority. This phenomenon has mainly been observed in countries with authoritarian regimes like Russia, China, or Ethiopia in the decades of the widespread famines or in civil wars where such a political agreement does not exist, as seen in distinct countries of the Horn of Africa. Besides, these authors indicate that in any famine, there are some sectors that become impoverished, but there are also those that become wealthy, such as traders, landowners of big agricultural farms, and soldiers taking advantage of the hunger-weakened poor. Therefore, the analysis of famines should also be done from the perspective of those that exert political, economic, or military pressure, to benefit from the transfer of resources.

When famine appears as a result of military conflicts, it may be the case where hunger in this context is being used as a weapon of war. Thus, war becomes the main cause of famines, as it destroys crops and food production systems, generates massive migrations, paralyzes health services, prevents or hinders possible family coping strategies, and prevents the distribution of humanitarian aid. From this perspective, famine is

not so much the unavoidable consequence of a crisis, but rather a deliberate aim caused and sustained by determined social powers for taking ownership of resources from the most vulnerable. This allows for the clear definition of political responsibilities in famines and goes beyond the mere economic factors proposed by Sen or the demographic changes defended by Malthus. This new approach understands that the famines are unleashed by a lack of political responsibility on the part of governments and for their noncompliance with fundamental human rights, especially the right to food.

Synthesis of the Famine Models

In short, none of these approaches are sufficient in and of themselves to explain the nature of famines. On the one hand, the Malthusian and neo-Malthusian explanations have lost strength due to the fact that their suppositions are no longer valid, although it is true that the concern for the environment and resources of the planet is in the center of current political debate.

On the other hand, the economic approach is for the time being what dominates among the authors. The vision of famine is seen as a form of economic disaster heightened by some natural catastrophe (drought, floods, etc.) and facilitated by the lack of policies to protect markets, prevent hunger, and intervene in states of emergency. By not considering the political aspects in relation to wars or the related violence of armed conflicts and by not respecting human rights, the vision of famine is reduced to a technical problem that requires technical measures for improving the efficiency of food systems.

Finally, the political approach goes beyond mere economic circumstances and deals with famine as a political problem of not respecting fundamental human rights, of power conflicts and wars, of repressing designated population groups, and of the passivity of the international community in confronting the issues. In these cases, the solution demands interventions not only that are of an economic nature and addressing productive market shares but also that focus on the international level to respect human rights.

Conclusions

Nowadays, already well into the twenty-first century, many people from different parts of the world continue suffering from famine. The famine seen today is different from the widespread famines of the past, as political, economic, and social contexts have changed. Although the triggers and effects are similar, the causes are much more extensive and much more complex. Famine appears as a complex phenomenon of factors, distinct in nature: economic, political, environmental, and social. This multiplicity of factors confirms the high complexity of the problem and therefore also hampers the election of the best responses in each case. Therefore, the policies of prevention and action against famine should take on a holistic approach and consideration for all these aspects. For this reason, although nowadays, famines are more predictable (as they are processes that occur over months or even years, this allows for early detection) and preventable (since they are a result of economy or policies and, as such, are a product of human factors that can be corrected), they are much more difficult to resolve or counteract simply by means of developing structural policies that guarantee the disappearance of hunger.

Introduction

Although many nutrition recommendations remain controversial, there is consensus among health and nutrition professionals in the developed world that the ratio of saturated fatty acids to poly- and monounsaturated fatty acids in the diet should be decreased, and intake of dietary cholesterol should be limited. It is further agreed that consumption of calories from fat should not be more than 30% of the daily total and that consumption of cholesterol should be restricted to <300 mg day^{-1}. It is suggested that those with elevated Low-density lipoprotein (LDL) cholesterol levels or cardiovascular disease should restrict saturated fats to 7% of calories. Prominence is also given to increasing the intake of fruits, vegetables, and grains and modifying the type and amount of fat consumed. The emphasis is on achieving an overall healthful pattern of eating rather than on limiting the focus to merely achieving goals for macronutrient composition.

In the food supply, 30% of the total fat comes from meat, poultry, and fish, and 25% comes from baked goods and other processed grain products. Milk products and fats/oils account for 18% and 11% of the total fat, respectively. Collectively, these food categories account for 84% of the fat in the food supply. Although the type of fat in these contributors to fat intake varies, the effort to reduce total fat and calorie intake has focused largely on reducing the fat content of foods in these categories. The effects of fat on cardiovascular disease are so well documented that they have been recognized as major factors in the etiology of cardiovascular disease. Dietary treatment to prevent obesity and high blood cholesterol levels have become the cornerstone of the National Cholesterol Education Program, which has been designed to help prevent coronary heart disease. Advocates of this program are boosted by reports that coronary heart disease rates can be decreased by dietary interventions and by a recent report that changes in lifestyle, including diet, can bring about regression of severe coronary atherosclerosis after a year without the use of lipid-lowering drugs. Obesity is strongly associated with the development and severity of both diabetes and hypertension, both of which are major risk factors for cardiovascular disease. Due to this, the consumer demand for low-fat foods has encouraged research on reducing the fat content of foods. Problems of inferior organoleptic and physical properties in these products suggested the use of fat replacers (FRs) to provide the desirable qualities.

Definition of FR

FR is defined as a carbohydrate-, protein-, or fat-based compound that replaces one or more of the functions of fat to reduce calories in foods. A broader scheme of FR is presented in Table 1.

FR can be classified as synthetic fat substitutes (FS), emulsifiers or surface active agent, starch derivatives, maltodextrins, hemicelluloses, β-glucans, bulking agents, microparticulates, composites, and functional blends. FR can be further categorized into the following groups:

FS: a synthetic compound designed to replace fat on a weight-by-weight basis, usually having a similar chemical structure to fat but resistant to hydrolysis against digestive enzymes.
Fat mimetics (FMs): a substance that can imitate physical or organoleptic properties. FMs are also referred to as 'texturizing agents.' It requires a high water content to achieve its functionality.
Fat analogs: are compounds with many of the characteristics of fat but have an altered digestibility and altered nutritional value.
Fat extenders: optimize the functionality of fat, thus allowing a decrease in the usual amount of fat in the product.

Some of the applications of FR along with their usage levels are given in Table 2.

Carbohydrate-Based FRs

Carbohydrate-based FMs incorporate water into a gel-type structure, resulting in lubrication and flow properties similar to that of fat. Carbohydrate-based FRs are categorized into starch-derived, cellulose-based, fiber-based, gum-based, and others.

Starch-derived FRs

Native starch is widely used in food and industrial applications as a thickener, colloidal stabilizer, gelling agent, bulking agent, and water-retention agent. Starches from different plant sources such as wheat, maize, rice, and potato have received extensive attention.

Resistant starch

Commercial resistant starches contain about 20–60% total dietary fiber. Resistant starch is insoluble, having a low water-holding capacity (WHC) and is most suitable for cereal-grain-based products with lower levels of moisture content. Resistant starch is generally used as an FR in baked goods, extruded snacks, pasta, breakfast cereals, and beverages.

Maltodextrin

Maltodextrin is a nonsweet, nutritive saccharide polymer, with a dextrose equivalent (DE) of <20. Starches from botanical sources like corn, potato, wheat, rice, tapioca, sago palm, barley, and sorghum can be used as raw material. Maltodextrins

Table 1 Classification of fat replacers by nutrient source, functional properties, and use in food

Type of fat substitute	*Nutrient source (energy density)*	*Functional properties*	*Use in food*
Derived from carbohydrate			
Polydextrose	Water-soluble polymer of dextrose (1 cal g^{-1})	Bulking and retaining moisture	A wide range of foods, including baked goods, confections, and frozen desserts
Modified food starch	A variety of starch sources (1–4 cal g^{-1})	Modifying texture, gelling, thickening, and stabilizing	Processed meats, salad dressing, baked goods, frozen desserts, etc.
Dextrin and maltodextrins	A variety of starch sources (4 cal g^{-1})	Modifying texture and bulking	Baked goods, dairy products, salad dressing, sauces, and spreads
Gums and pectin	Xanthan, guar, locust bean, carrageenan, alginates, and fruit	Retaining moisture, mouthfeel and modifying texture	Wide range of products, including baked goods, sauces, and salad dressings
Cellulose	Various plant sources (virtually noncaloric)	Modifying mouthfeel, texture, and pourability	Dairy products
β-Glucan	Soluble fiber extracted from oats (1–4 cal g^{-1})	Adding body and texture	Baked goods and a variety of other food products
Derived from protein			
Microparticulated protein and modified whey	Denatured or microparticulated protein from egg/milk (1–4 cal g^{-1})	Modifying mouthfeel	Dairy products, spreads, and bakery products
Derived from fat			
Olestra	Sucrose polyester with triglycerides (noncaloric)	Modifying texture and mouthfeel	Savory snacks (stable for fried foods)
Caprenin and salatrim	Caprylic, capric, behenic acid, and glycerine, or triglyceride of short- and long-chain fatty acids (5 cal g^{-1})	Simulating properties of cocoa butter	Confections, baked goods, and dairy foods
Mono- or diglycerides	Derived from vegetable oil and emulsified with water (9 cal g^{-1})	Adding moisture and modifying texture and mouthfeel	Baked goods, vegetable dairy replacers

Table 2 Fat replacers and their food applications

Type of fat replacer	*Usage level (%)*	*Food application*
Modified starch (potato)	21	Bakery dough
Maltodextrin	40–45	Chocolate
Maltrin M040	20	Low-calorie pudding
Maltrin M100	10–28	Butter-like product
Polydextose	20	Peanut butter
HPMC	13	White chocolate bar
Pectin	0.18	Nonfat frozen dessert
Pectin (Slendid) and maltodextrin	0.5–3 + 0–10	Fruit spread
Microcrystalline cellulose + pectin	0.05–0.5 + 0.1–10	Fruit spread
Microcrystalline cellulose + κ-carrageenan (93:7)	25	Yogurt and cottage cheese
Carrageenan gels	15	Frozen dessert
κ-carrageenan	10–14	No-fat coffee creamer
λ-carrageenan	0.2	Whipped toping
Carrageenan + maltodextrin	1–3 + 0–10	Fruit spread
Xanthan gum	0.18	Fat-free cookie
	0.3	Low-fat spread
Pectin + xanthan gum	0.63 + 0.28	Fat-free fruit bar
Starch, pectin, guar gum, and gelatin mixture	1.29	Low-calorie yogurt
Simplesse	2–20	Fruit spread
Sucrose fatty acid polyester (Olestra)	10	Low-calorie cheese
Ethoxylated glucoside tetraoleate	13	Cake mix
	10	Icing mix
	56.25	Mayonnaise
	50	Salad dressing
	80	Margarine
Ethoxylated glucoside tetrastearate	25	Plastic shortening
	13	Cake mix

Table 3 Maltodextrin-based fat replacers

Trade name	*Type*	*Usage level (%)*	*pH stability*	*Temperature stability (°C)*	*Applications in food products*	*Manufacturer*
Paselli A2	Potato	20	3–7	25–212	Dressings, sauces, spreads, frozen desserts, toppings, cakes, and butter	Avehe American Inc., NJ, USA
Stellar, Instant-Stellar	Corn	20–25	4–6	25–200	Baked goods, frostings, fillings, gravies, sauces, and dairy products, confectionary	A. E. Staley Manufacturers, USA
Maltrin M040, M100, M150	Corn	20	3.5–7.5	300	Bakery and snack foods, beverages, confectionary, dairy products, and salad dressings	Grain Processing Corporation, USA
Amalean I, Amalean II-Instant	Corn	1–8	3–7	25–200	Cheesecake, spoonable salad dressings, icings, cheese spreads, and desserts	American Maize Product Co., USA
N-oil, Instant-N-oil	Tapioca	25	3–8	25–225	Confectionary, soup, frozen desserts, spoon/pourable sauces, gravies, and puddings	National Starch Manufacturers, USA
N-Lite LP, N-Lite B/L, N-Lite D, N-Lite CL	Maize	25–30	3–8	25–200	Salad dressings, soups sauces, bakery products, dairy products, yogurt	National Starch Manufacturers, USA
Oatrim	Oatflour	3–6	>3	Retort	Dairy products, cereal, baked goods, and meat products	Rhone-Poulenc Food Ingredients, USA
Oat-fiber White Tan (770, 780, 782)	Oat fiber	3–6	All	All	Processed meats, ice-cream, butter-coated products and deep fried foods, and chocolate	Williamson Fiber Products, County Cork, Ireland

Compiled from various sources: Roller (1996), Sharma and Ganeshkumar (1996), Akoh (1998), Sharma et al. (1998), Sandrou and Arvanitoyannis (2000), Chavan and Prajapati (2009), Tiwari (2005).

are used as an FR in dairy products, confectionary, frozen desserts, cereal baked goods, and meat products due to their ability to form soft, spreadable, thermoreversible gels with melt-in-the-mouth properties. Low-DE maltodextrin is usually added at a level of 1–5% in liquid foods to impart a full-bodied texture and mouth coating, whereas it can substitute about 25–35% of fat in cookies. Starches are usually hydrolyzed to a DE's value from 0 to 100, and as the DE increases, browning reaction, freezing point depression, hygroscopitity, sweetness, solubility, and osmality increase, whereas viscosity, cohesiveness, film-forming ability, and ability to prevent large crystal formation decrease. Maltodextrin with low DE has similar properties to those of native starch and can be used as an FR (Table 3).

Maltodextrins based on potato are low DE ($\leq$5), are cold soluble, and provide low viscosity in the form of solution, but at high concentration (>20% w/w) they are unstable and tend to gels, which are plastic, and spreadable, which provides shortening-like texture. Potato maltodextrin is produced by solubilizing the slurry by jet cooking and treating it with enzymes until the required degree of hydrolysis is achieved (Paselli SA2, C* Pur 01906). Potato starch contains amylose molecules with longer chains as compared to corn and wheat, which retrograde less readily, thereby reducing the tendency to cause turbidity and an undesirable texture in foods. Paselli SA2 is applied in products such as low-fat mayonnaise, sauces, imitation cheese, and frozen desserts, whereas C* Pur 01906, is used in baked goods. Preprepared gels consisting of one part maltodextrin and three parts water provide 1 kcal g^{-1}.

Corn maltodextrin is obtained from limited hydrolysis of cornstarch. Maltrin M040, a product of Grain Processing Corp., Muscatine, Iowa, is a spray-dried corn maltodextrin (DE=5) and is able to partially or totally replace fat in margarine, frozen desserts, salad dressings, and extruded cereals and snacks. Tapioca maltodextrin is obtained by heating tapioca starch in the presence of hydrochloric acid, which yields a gel and is characterized by a bland flavor, smooth mouthfeel, and a texture similar to that of hydrogenated fat, for example, N-oil, N-oil II. N-oil is used as a 20–35% aqueous solution, contributes only 1 kcal g^{-1}, and is used in products like salad dressings, puddings, and margarine.

Oat maltodextrin is obtained by partial enzymatic hydrolysis of oat flour, oat fiber, or oat-bran. Oat maltodextrin (Otrim-1, Otrim-5, Otrim-10) gels are useful for fat sparing in food and food products like yogurt, baked products, and meat products. Oatrim-5, invented and patented by the USDA at the National Center for Agricultural Research, is the only carbohydrate-based FS and contains the unique combination of β-glucan and low-DE maltodextrin. Wheat-based maltodextrin is produced by microfibrillation of wheat fibers and maltodextrin, for example, Vitacel, produced by Rettenmaier, is composed of 70% wheat fibers and 30% maltodextrin. Vitacel can be used instead of hydrocolloids as a thickening and binding agent for stabilization of emulsions, foams, and liquid media.

Disadvantages associated with the usage of maltodextrins is that the amylopectin present in it has a tendency to retrograde slowly, giving rise to a phenomena of setback in low-fat spoonable salad dressings. Low-DE maltodextrins also suffer from freeze–thaw stability and unreliable heat and acid stability. Energy output of all the maltodextrin-based FMs is about 4 kcal g^{-1}.

Polydextrose

Polydextrose was invented by Hans Rennhard at Pfizer Central Research Laboratories, United States, in the mid-1970s.

Table 4 Microcrystalline cellulose and polydextrose-based fat replacers

Trade name	*Type*	*Usage level (%)*	*pH stability*	*Applications in food products*	*Manufacturer*
Avicel RC/CL	Cellulose gel	2–5.0	>3.5	Salad dressings, dips, spreads, bakery, products, dairy products, meat products	FMC Co., PA, USA
Tabulose	Powdered MCC	0.5–20	–	Mayonnaise, salad dressings, sauces, dietary products, bakery products, imitation cheese products	Blanver Farmoquimica Ltd., USA
Novagel RCN-10; RCN-15	MCC + Guar gum	0.5–5.0	–	Bakery and snack foods, beverages, confectionary, dairy products, salad dressings	FMC Corporation, PA, USA
Polydextrose, Litesse, Litesse II	Polymer of glucose with sorbitol and citric acid (89:10:1)	5%	5–6	Pastry, confectionary products, dressings, spreads, bakery fillings, toppings, chilled desserts	Pfizer Inc., New York, USA
Sta-Lite	Polydextrose (fast dissolving)	–	–	Confectionary and bakery products	A. E. Staley Manufacturing Company, IL, USA

Compiled from various sources: Roller (1996), Sharma and Ganeshkumar (1996), Akoh (1998), Sharma et al. (1998), Sandrou and Arvanitoyannis (2000), Chavan and Prajapati (2009), Tiwari (2005).

Polydextrose is composed of randomly cross-linked glucose polymers with all types of glucosidic bonds, although 1–6 bonds are predominant (min. 90%), sorbitol end-groups (max. 2%), and monoester bonds with citric acid. Polydextrose exists in five forms viz., coarse powder, fine powder, type N, type K, and type F. Polydextrose is used as a low-calorie bulking agent that can replace all or part of the sugars and some of the fats in foods while maintaining a pleasant texture and mouthfeel. Polydextrose can also be used as a humectant, texturizer, thickener, stabilizer, and cryoprotectant (Table 4). Litesse®, a white- to cream-colored powder that has a pH (10% solution) of 2.5–3.5 and melts above 130 °C, is clear, bright, and nonsticky; exhibits no crystallization; and supplies only 1 kcal g^{-1}. According to the FDA, Litesse® may be used in frozen dairy desserts, baked goods, confections, frostings, salad dressings, gelatins, puddings, fillings, hard and soft candy, and chewing gum. Litesse® II, specifically developed for light foods, provides a higher level of sugar and fat replacement. The FDA has recognized polydextrose as a 'carbohydrate.'

Cellulose-based FRs

Cellulose is a polymer based on β-(1→4)-linked D-glucose. The most widely available cellulose-based FR are microcrystalline cellulose (MCC) and methylcellulose (MC) gums.

Microcrystalline cellulose

Developed in 1964, is a nonfibrous form of cellulose, ranging in size from 25 to less than 1 μm. MCC is composed of anhydroglucose units linked through a β (1–4) glycosidic bond, which is hydrophilic, linear, and high molecular weight, and it accounts 75–95% by weight. The remaining 5–20% is soluble in nature (Table 4).

MCC is produced using α-cellulose, which is composed of paracrystalline and crystalline regions of microfibrils by employing acid depolymerization and agglomeration, which is followed by drying to give porous particles of MCC. In case of colloidal grade, soluble hydrocolloids such as carboxymethyl cellulose, xanthan gum, or alginate are added to prevent aggregation during drying. On proper dispersion, the cellulose crystallites set up a three-dimensional network that is highly thixotropic, is temperature stable, and adds body, while imparting a clean mouthfeel. Functionality of MCC is affected by different factors like adequate shear, order of addition, hard water/electrolytes presence, and pH of the food. MCC, when used in cakes at levels from 2% to 4%, improves the sponginess, increases cake volume, provides better handling properties, and creates improved product appearance. In doughnuts, powdered grade MCC (1–3%) can reduce the fat absorption. MCC is indigestible, and FDA regulations permit a maximum addition of 1.5% (w/w) of finished ice cream, with an exception in the case of fruit sherbets, wherein a maximum of 0.5% (w/w) can be added.

MC gums

Hydroxypropylemethyl-cellulose (HPMC) and MC are gums derived from chemical modification of cellulose derived from wheat, maize, potato, and/or rice. The cellulose is made soluble by adding sodium hydroxide and then treating with methyl chloride to form MC and along with propylene oxide to give HPMC, which is further dried using hot air, followed by grinding and packaging. MC and HPMC are described in terms of degree of substitution (DS) and molar substitutions (MSs). DS is the amount of substituent groups on the anhydroglucose units of cellulose, and MS is the average number of molecules of substituent that have been substituted per anhydroglucose unit. DS and MS affect physicochemical properties of MC gums like water retention, sensitivity to electrolytes, dissolution temperatures, and gelation characteristics. Methoxy substitution in MC and HPMC corresponds to a DS range of 1.49–2.00 and 3.0–12.0%, respectively. In fried foods MC and HPMC cause reduction in fat uptake, lower caloric value, improve cooking economy, provide more moisture retention, and provide improved yield. In cake and yeast-leavened doughnuts, oil reduction of about 26–28% can be achieved along with enhancement of air entrainment and promotion of uniform and fine cell size in crumb structure. In liquid foods like sauces

and dressings, MC gums act as a stabilizer and provide pourability, texture, and viscosity. In frozen dairy products, their film-forming property, thickening capability, and lubricity mimics the feel of fat. MC is labeled either as 'methylcellulose' or E-461 and HPMC as 'hydroxpropyl methylcellulose' or E-464.

Dietary fiber-based FRs

Dietary fibers can be used to replace fat due to their wide range of technological functionalities, and soluble fibers, such as pectin and gums, possess a higher WHC of almost 20 times their weight of water as compared to cellulosic fibers. WHC is affected by concentration, temperature, presence of certain ions, and pH of the food system. Fibers, such as pectin, gums, β-glucans with mixed bonds, and polysaccharides extracted from algae, form highly viscous solutions, whereas that of inulin is minimal. The capacity of a fiber to bind fat depends on the porosity, which is useful for avoiding excessive absorption of frying fat in batters. Dietary fiber also acts as a protective agent against cardiovascular diseases, diverticulosis, constipation, irritable colon, colon cancer, and diabetes.

Pectin

Pectin is a complex mixture of polysaccharide composed of a galacturonan backbone of which variable proportions can be methyl-esterified and is usually obtained from citrus fruit and apple. D-galacturonic acid units are linked by α-(1, 4)-glucosidic bonds. Commercial pectins are divided according to the degree of esterification into low methocxyl (LM) pectins and high methoxyl (HM) pectins. HM pectins can also be chemically amidated to obtain low methyl-esterified and amidated (LMA) pectins. HM pectins are used mainly in sugar-acid gels, whereas LM and LMA pectins are used in pectate gels. Functionality of pectin is influenced mostly by the molecular weight and the level and distribution of methyl-esters. Slendid®, manufactured by Copenhagen Pectin, Denmark, is produced by extraction from plant, purification, and isolation of the pectin followed by a controlled desertification with the help of either acid or base. Currently, it is used for fat sparing in confectionary products, dairy products, and bakery fillings. To mimic the physical and sensory characteristics of emulsified fat, the particle size of 25–50 μm and usage level of 1.5–4.0% is recommended. It is possible to reduce the fat content in a frankfurter from 25% to 35% to 3–5% by using a wet preparation of 2% Slendid® 110. Pectin gives a trophic effect, increases villus height and crypt depth in the small intestine, stimulates intestinal cell proliferation and activity of brush border membrane enzymes, and stimulates short-chain fatty acid production in the cecum. Pectin gives a net energy of 9 kJ g^{-1} on digestion. In the United States, pectin is given a Generally Recognized As Safe (GRAS) status, whereas in the European Union it is given a designation of E440 as a food additive.

Inulin

Inulin is an oligomer found in plants such as *chicory* and *Jerusalem artichoke* and has a sweetening power of 30–65% that of sucrose and a high degree of polymerization (DP) of 2–60. Inulin is produced by extracting inulin from chicory roots by diffusing the roots in hot water followed by refining and last spray-drying the concentrate. At a concentration of 40–45%, it forms a gel or crème having a fatty creamy feel with characteristics like high water binding, stability against freeze thaw, and inhibition of syneresis in mayonnaise and salad dressings. Inulin with lower a DP of 25 is generally available for high-performance fat replacement. Inulin crème has been successfully applied in fat-reduced table spreads, frozen desserts, cheese products, meat products, fillings, sauces, and meat replacers (Table 4).

β-glucan

β-glucan is a cell wall polysaccharide present in oat, barley, and other grains, and recently yeast β-glucan has been used as a FR in mayonnaise. β-glucan preparation is used to partially substitute for vegetable oil in low-fat products such as salad dressings, ice creams, yogurts, and cheese. β-glucans can also be used for their therapeutic values, as they are found to be immunomodulators, antitumorogenic, and antiviral agents for treatment of hypercholesterolemia and stabilization of glycemia.

Bacterial cellulose

It is produced by some *Acetobacter*, which is a high-value raw material for producing dietetic and dessert foods due to its high WHC. Instead of xanthan gum, bacterial cellulose at a concentration of 3% can be used in ice creams. Bacterial cellulose improves the quality of pastry products by reducing their stickiness.

Z-trim

Z-trim refers to zero calories and can be used for replacing fat and some of the glycemic materials (starches, sugars, and syrups). It provides an aqueous gel fiber structure without taste and imparts a smooth texture. Z-Trim gels also provide insoluble fibers to be used separately or with other fibers such as Oatrim. Z-Trim gel can be used for considerable reduction in calories depending on the amount of fat and carbohydrates replaced in food formulations.

Gum-based FRs

Gums are hydrocolloids, which are long-chain, high-molecular-weight polymers that dissolve or disperse in water. These gums are used along with a combination of other ingredients viz. starches, bulking agents, emulsifiers, and flavor to yield a finished product similar to a full-fat system. Viscosifying and gelling property are affected by temperature, pH, solvent quality, ionic strength, and presence of specific ions. Hydrocolloids usually come from: (a) plant materials such as seaweed, seeds, roots, and tree exudates; (b) microbial biosynthesis; and (c) chemical modification of natural polysaccharides.

Locust bean gum

It is derived from carob seed, *Ceratonia Siliqua* and consists of D-Mannopyronosyl backbone with attached D-galactopyranosyl units existing in a ratio of 4:1. It is having a limited solubility in cold water but on heating to 80 °C for 10 min it hydrates fully, resulting in a highly viscous pseudoplastic solution. Prolonged heating, high rate of shear, and the time of heating can irreversibly degrade the locust bean gum solution.

Guar gum

Guar gum or guran is the endosperm of the seed *Cyampsis tetragonolobus* containing a backbone of (1→4)-β-D-mannopyranosyl units, with every second unit bearing a (1→6)-α-D-galactopyranosyl unit. Lower mannose:galactose ratio (1.5–2) in guar gum indicates that there are few intermolecular interactions, and consequently, less heat is required for solubilization (i.e., at 25–40 °C). Guar gum is usually utilized at a concentration <1% and is stable between pH 3.5 and 9.0.

Protein-Based FRs

Protein-based FR is derived from proteins found in eggs, milk, and other foods (Table 5). The concept of using proteins as FRs is related to proteins with a particular spheroidal structure, ranging from 0.1 to 2.0 μm in size and is usually produced by microparticulation process.

Simplesse® (NutraSweet, Deerfield, IL) was the first FR developed with protein and has received a GRAS status to be used in frozen dessert. It contains 53% protein and is a microparticulated spray-dried powder that mimics emulsified fat by forming a dispersed phase of particles that are free to move independently. It is a multifunctional dairy ingredient made from whey protein concentrate (WPC) that undergoes a unique microparticulation process that results in uniform, spherical, and deformable protein particles, much like fat globules, which range in size from 0.1 to 3 μm. This process helps to reduce the tendency to aggregate the spherical droplets and form gel on heating. These droplets roll around on the tongue, providing a smooth, creamy texture without chalkiness or graininess. Simplesse increases the opacity of the product by forming small spherical droplets of protein that allow more scattering of light. Simplesse retains the biological property of the protein used, so individuals who are allergic to egg or milk proteins can experience allergic reactions to it.

'Dairy Lo,' a thermally denatured WPC, interacts with water and prevents iciness, provides opacity, controls viscosity, and stabilizes air cells along with a fat-sparing effect in dairy product when used at a level of 2–5%. The formulations supplemented with WPC showed greater elasticity, firmness, chewiness, and gumminess compared to the control sample, thus contributing to the texture of the fat-free dairy desserts. Some of the other protein-based FRs available in the market are K-Blazer®, Ultra-Bake™, Ultra-Freeze™, and Lita®.

Fat-Based FRs

Fat-like substances, which are resistant to hydrolysis by digestive enzymes, comprise another major category of materials being promoted as partial or full replacements for oils and fats in bakery and other food products.

Structured lipids

A structured lipid is a triglyceride obtained by the hydrolysis and random transesterification of medium-chain triglyceride (MCTs) and long-chain triglyceride. Structured lipids provide approximately half of the calories of the normal edible oil. Caprenin, an MCT derived from coconut, palm kernel, and canola oil, mimics the physical properties of cocoa butter or confectionary fat. Another example of MCT is Neobee M-5, derived from coconut oil, which prevents bloom formation in chocolate and sticking of uncoated nutritional bars to packaging material by migrating to the surface of these products. Salatrim (short- and long-chain acyltriglyceride molecules) is a 'family' of triacylglycerols produced by the interesterification of highly hydrogenated vegetable oils with triacylglycerols of acetic and/or propionic and/or butyric acids. Salatrim preparations are available to emulate cocoa butter, as well as for use in baked products and filled dairy products.

Table 5 Protein-based fat replacers

Product name	*Type*	*Applications in food products*	*Manufacturer*
Simplesse®	Microparticulate whey protein concentrate	Dairy products, spreads, bakery product, salad dressing, dips, mayonnaise, frostings, sauces, soups	CP Kelco
Dairy-Lo®	Modified whey protein concentrate	Milk/dairy products, baked goods (cheesecake), frostings, salad dressing, mayonnaise-type products	Cultor, New York, NY
K-Blazer®	A blend of protein, food starch, gums, and emulsifiers	Salad dressing, mayonnaise, frozen dessert, sour cream, baked goods, and dairy products	Kraft Food Ingredients Corp, Memphis, TN
Lita®	Corn zein	Baked goods	Opta Food Ingredients, Inc., Cambridge, MA
Leancreme™	Microparticulated whey protein	Baked goods	SPX-APV brand
Optipep™	Hydrolyzed whey protein concentrates and isolates	Yogurts, ice cream, cheese, and drinking milk	Carbery
N-Flate	Nonfat milk, gums, emulsifiers, and modified starch	Sports nutrition products and nutrition bars	
ULTRA-BAKE™	Starch, modified vegetable protein, and xanthan gum	Cake mixes, salad dressing, icings, glazes, desserts, ice cream, and ground beef	
ULTRA-FREEZE™	Egg-white, milk protein, corn syrup solids, and modified starch	Baked goods	

Compiled from various sources: Roller (1996), Sharma and Ganeshkumar (1996), Akoh (1998), Sharma et al. (1998), Sandrou and Arvanitoyannis (2000), Chavan and Prajapati (2009), Tiwari (2005).

Sugar polyesters

Olestra is a mixture of hexa-, hepta-, and octaesters of sucrose prepared by esterifying sucrose with long-chain fatty acids isolated from edible fats and oils. Olestra can be liquid or solid at room temperature based on the fat source in the sucrose polyester. Olestra has the organoleptic and thermal properties of fat and thus it can serve as a zero-calorie replacement for fat in a variety of foods like savory snacks such as potato and corn chips.

Esterified propoxylated glycerol

Esterified propoxylated glycerol (EPG) is a family of propylene oxide derivatives with a structure similar to that of natural fat. It is been claimed that EPG is resistant to enzymatic hydrolysis and that it can be substituted for fats and oils in products such as table spreads, frozen desserts, salad dressings, and bakery products.

Dailkyl dihexadecymalonate

A fatty alcohol ester of malonie and alkylmalonic acids, dailkyl dihexadecymalonate (DDM) in combination with soybean oil has been used to produce potato and tortilla chips. DDM has also been tried in products like mayonnaise and margarine.

Trialkoxytricarballate

A tricarballylie acid, esterified with fatty alcohol, is being evaluated as an oil substitute to produce acceptable margarine and mayonnaise-based products.

Safety of FRs

The use of FRs as a food additives to reduce the fat content in food products also raises the concern of consumers' safety. The safety of the currently used FRs is ensured by the GRAS status by the FDA. FRs could be used and consumed by the consumers in large quantities in fat-less or reduced-fat products. Many of the carbohydrate-based, protein-based, and fat-based FRs have not shown major health concerns except for polydextrose and Olestra. Polydextrose can have a laxative effect, which requires a labeling disclaimer when present at specified levels. Olestra may cause leaky and fatty stools and loss of fat-soluble vitamins. In general, there is limited evidence at the present time on the long-term adverse consequences associated with the consumption of these or any other reduced-fat foods by adults. However, further research is required to study the safe use of these products by children and adults and to evaluate fully their long-term health effects.

Conclusion

Due to the increasing demand for low-fat food products, reduced-calorie and low-fat food markets are showing a dynamic growth. As pointed out in the beginning of this article, the FR can mimic one or more roles of fat in food products. Classification of an FR usually is based on the nutrient source. They provide the functional and sensory qualities of fats in foods and are absorbed and metabolized normally. The introduction of olestra, which is a nonabsorbable FS that can affect nutrient absorption, raises questions about its potential effect on overall health. Some research suggests that individuals who consume a diet that is reduced in fat and calories and includes use of fat-modified products have a better overall nutrient profile than do individuals who do not use any fat-modified products. The recent increase in the availability of FRs in the market raises questions about the cumulative impact of using them in multiple food products and the potential interaction with medications and food ingredients. Within the context of a healthy dietary pattern, FRs, when used judiciously, may provide some flexibility in dietary planning, although additional research with clinical trials is needed to fully determine the longer-term health effects.

Fats: Classification and Analysis

M Narváez-Rivas and M León-Camacho, Instituto de la Grasa (C.S.I.C.), Seville, Spain

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Fats are essential nutrients and concentrated sources of energy of the diet, supplying about 9 kcal g^{-1}. They are soluble in most organic solvents, such as hexane and ethyl ether, but basically insoluble in water.

By classical definition, fats are referred to total lipids, which can be classified into two different fractions depending on if they form or fail to form soaps when blended with sodium hydroxide, considered as saponifiable and unsaponifiable fractions, respectively. The different compounds that can be part of the saponifiable fraction are shown in the next scheme.

The unsaponifiable matter contains terpenic (sterols, 4-methylsterols, 4,4′-dimethylsterols, carotenoids, tocopherols, and tocotrienols) and aliphatic compounds (saturated and unsaturated hydrocarbons and fatty alcohols).

The different ways of analysis of the fat compounds are going to be described in the succeeding text.

Saponifiable Fraction

Triacylglycerols

Triacylglycerols consist of the trihydric alcohol glycerol esterified with fatty acids. They represent the main lipid fraction of foods. For the analysis of molecular species of triacylglycerols, chromatographic and spectrometric methods are available. However, stereospecific determination of positional distributions of fatty acids in them remains a substantial technical challenge. Nowadays, the most used methods for their analysis are HPLC and GC.

Reversed-phase HPLC

Good resolution of triacylglycerols by reversed-phase high-performance liquid chromatography is possible. The retention times are dependent on the total number of carbon atoms of the three fatty acids of the molecule, with each double bond reducing the effective chain length of the species by the equivalent of about two carbon atoms.

The most frequently used columns have been those with phases of the octadecylsilyl (C18, ODS, or ODS-2) type, since stationary phases similar in chain length to the fatty acyl chains maximize the interactions and give a higher efficiency. Silver ion HPLC has been also used. The 250×4.6 mm column with 5 μm packing, the 100×3 mm column with a 3 μm packing, and the 100×2.1 mm column with 1.7 μm packing have been used, the last one being used in terms of saving time and solvent and with no loss of resolution.

Referring to the mobile phases, the most used are

- acetonitrile–acetone,
- acetonitrile–isopropanol,
- acetonitrile–dichloromethane,
- acetonitrile–ethanol–hexane,
- acetonitrile–tetrahydrofuran.

They improve the solubility of triacylglycerols and have an effect on the selectivity and efficiency of the separation. The detector used and the nature of triacylglycerols may determine the choice of mobile phase and the choice of an isocratic or a gradient system. For example, acetonitrile–acetone mixtures are not well suited to saturated components of higher molecular weight, since they tend to precipitate out of solution. For such purpose, the acetonitrile–dichloromethane combination may be the best available. Isocratic eluants are utilized with detectors in which the change in the composition of the mobile phase affects the obtained signal, as in the case of the refractive index (RI) detector. The gradient of elution can be used with detectors such as UV and evaporative light scattering detectors (ELSDs).

The column temperature should be fixed and controlled to achieve reproducible retention times. With low temperatures, solubility effects may come into play, and the more saturated molecular species may precipitate out of solution.

The detection systems for quantitative analysis of triacylglycerol species separated by HPLC have been RI, UV, evaporative light scattering, and mass spectrometry detectors.

One of the most used for the mentioned purpose is the RI detector, in which the RI changes with the chain length and with the unsaturation number. The response factor is considered the same (1) for all triacylglycerols in the practice. This detector is affected by the temperature and composition of the mobile phase, and due to this, the analysis needs to be carried out with thermostated cells and isocratic elution. In some cases, flow gradients can be used. Another limitation of this detector is its low sensitivity. However, RI detection gives good results and is one of the most adequate for the quantitative analysis of these compounds.

It has been reported that UV detection can be used to get good quantitative data at wavelength between 200 and 220 nm, where the ester bond absorbs. This detector shows the highest sensitivity. Nevertheless, the absorption of several solvents used in the mobile phase, like acetone, the unsaturations, and the conjugation of these unsaturations are a problem for the use of this detector in triacylglycerol analysis.

An alternative to the detectors mentioned is the ELSD, which is universal and simple. This shows the disadvantages that a calibration method must be taken into account and that the linear range is between 50 and 250 μg. Below 50 μg, the sensitivity decreases, which is a problem for the analysis of the minor compounds. But this detector shows the advantages that no solvent peak appears and the resolution of the peaks is good and it is not affected by the changes in the solvents of the mobile phase.

For both detecting and identifying molecular species of triacylglycerols, mass spectrometry is used, showing a good sensitivity, although a careful calibration is also needed.

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00274-9

The choice of injection solvent is another important practical point that should be mentioned. Samples should be injected in a small volume of the mobile phase (5–10 µl). Hexane is not employed as injection solvent because a single component can emerge as double peaks due to its properties, which are so similar to those of the stationary phase that it competes with this for the solute molecules.

High-temperature GC

Nowadays, the use of high-temperature GC with flame ionization detection for the separation and quantification of triacylglycerols is a good alternative to HPLC, solving its problems.

Triacylglycerols are not at all easy to volatilize for gas chromatography purposes since their molecular weight is quite high. The injection procedure is of great importance to avoid any sample discrimination and achieve good quantification. Modern gas chromatographs usually come equipped to achieve such purposes with cold on-column injection, split injection, and/or programmed temperature vaporizer injection. The use of cold on-column injection is one of the most desirable to reduce or eliminate thermal decomposition (e.g., the pyrolysis of the most unsaturated triacylglycerols), mass discrimination, and other undesirable effects associated with classical split/splitless injection. Using this injection technique, the injector temperature should be lower than the solvent boiling point. The new split/splitless injectors minimize mass discrimination loss and make possible to apply this technique to triacylglycerol analysis with similar results to those obtained by using cold on-column injection.

Another aspect that needs to be addressed is the nature of the stationary phase. The temperature stability of this is highly important. The most stable to high temperatures is the nonpolarity phases of the dimethylpolysiloxane type, which permit separation by chain length. However, high-polarity or polarizable phases allow remarkable separations by both carbon atom number and degree of unsaturation, but they are less stable to high temperatures. Columns coated with polar stationary phases, such as cyanopropyl silicone, are capable of resolving triglyceride mixtures even better than nonpolar phases, but they cannot reach temperatures over 300 °C. The polarizable phenyl methyl silicone phases are capable of enduring temperatures of about 360–370 °C for a long time, separating triacylglycerols by both chain length and the number of unsaturation. The fused silica capillary DB-17ht column (30 m × 0.32 mm i.d. and 0.15 µm film thickness) shows a really good resolution for the different molecular species of triacylglycerols.

Detection is carried out by using a flame ionization detector (FID), and the response factors need to be considered, which depend on a certain extent on the ratio of the carrier gas.

The purity and nature of the carrier gas, flow rate, rate of temperature change, and whether the carrier gas is maintained at constant flow or constant pressure rate are other practical factors that have to be considered.

An example of triacylglycerol analysis by GC-FID is shown in Figure 1.

Diacylglycerols and Monoacylglycerols

Diacylglycerols are esters of the trihydric alcohol glycerol in which two of the hydroxyl groups are esterified with fatty acids, and they are found as 1,2- and 1,3-isomers. They are generated by acidic and enzymatic hydrolyses of triacylglycerols during the transformation and storage of fats, and 1,3-isomers can be generated from 1,2-diacylglycerols due to an isomerization process, since the 1,3 species is more thermodynamically stable. In tissues, 1,2-diacylglycerols can also be generated from phosphatidylinositol (PI) by the action of phospholipase C. The determination of molecular species of diacylglycerols in fats can be accomplished by a previous extraction and purification by column chromatography or solid phase extraction (SPE) and a subsequent chromatographic method, GC being the most appropriate for that purpose. An aliquot of the fat in hexane and a suitable internal standard (e.g., 1,3-dipalmitoyl-glycerol and dinonadecanoine) are added prior to

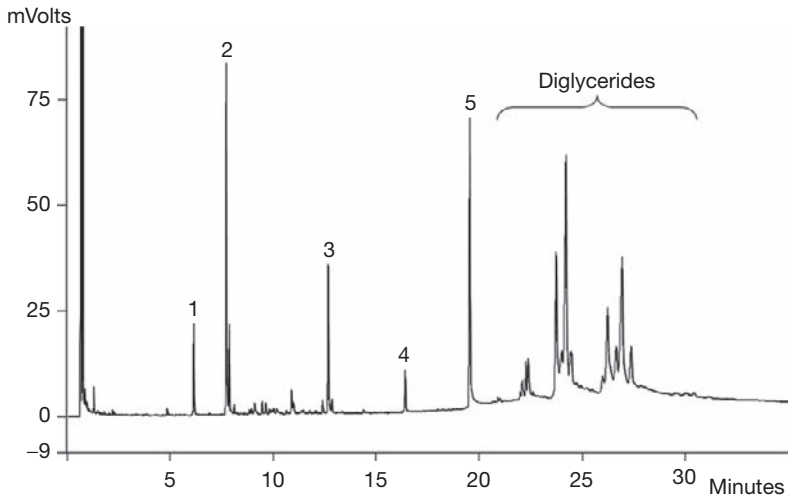

Figure 2 Gas chromatogram of the polar fraction from 0 to 35 min corresponding to the subcutaneous fat of Iberian dry-cured ham. Labeled peaks are identified as follows: 1, palmitic acid; 2, oleic acid; 3, 1-monoolein; 4, cholesterol; 5, 1,3-dimyristin (IS). Reproduced from *Journal of Agricultural and Food Chemistry*, 2007, **55**, 10953–10961.

the purification step, in which silica or diol SPE columns are utilized.

Purification comprises several steps using different solvent systems. The first is carried out passing a solution to eliminate the major compounds (e.g., hexane/methylene chloride/ethyl ether (89:10:1)) through the column, which is discarded. In the second step, the diacylglycerol fraction is obtained by passing a solution, generally chloroform/methanol (2:1), that is evaporated to dryness in a rotary evaporator under reduced pressure, and the residue is treated with 200 µl of the silylating reagent and left at room temperature for a few minutes, obtaining the corresponding trimethylsilyl derivatives of 1,2- and 1,3-diacylglycerols. Monoacylglycerols are also extracted with the diacylglycerol fraction, and they can be analyzed together by GC using a proper temperature program and a proper column. An example of this is shown in Figure 2.

The analysis of the silylated fraction is performed by GC-FID using thermostable midpolarity GC columns (e.g., fused silica capillary DB-17ht polyamide-coated column, 50% phenyl methylpolysiloxane, 65% phenyl- and 35% dimethylpolysiloxane, and 65% methyl phenyl silicone). The peak of 1,2-diacylglycerols appears before their corresponding 1,3-isomers.

With respect to monoacylglycerols, they are at trace levels in fats, and their analytic determination is carried out with a procedure similar to diacylglycerols, trimethylsilyl derivatization, and GC-FID analysis but with nonpolar capillary columns, or their combination as it has been mentioned in the preceding text.

Phospholipids

Phospholipids are a class of lipids that have two fatty acyl molecules esterified at the sn-1 and sn-2 positions of glycerol and a head group linked by a phosphate residue at the sn-3 position. They have amphipathic property since the head group forms a hydrophilic region that determines the type of phospholipid, and the fatty acyl side chains are hydrophobic.

Two different categories are distinguished: glycerophospholipids (phosphatidylethanolamine (PE), phosphatidylcholine (PC), phosphatidylinositol (PI), phosphatidylserine (PS), and cardiolipin (CL)), the derivatives of glycerol, and sphingophospholipids (sphingomyelin: SPH), those that do not contain glycerol.

Phospholipids have been determined traditionally by gravimetric methods and spectroscopic methods, like molecular or atomic absorption spectroscopy. However, these are not usually used nowadays.

The thin-layer chromatography (TLC) technique using adsorbent (silica) coated on glass strips is used for the separation of phospholipids as a separation technique previous to the quantification of these by another procedure or even for their direct quantification by densitometry or thincography. The type of mobile phase used and whether the TLC is in one or two dimensions are critical in the separation of the different groups. This technique has some disadvantages, such as a limited capacity to resolve the phosphatides in their different molecular species, techniques of detection more or less complex with significant errors in the quantification, and a relatively long time period required for analysis.

Nowadays, the method used for the separation and determination of phospholipid classes is the HPLC. Silica columns are the most used for such purposes since this can give excellent results and is relatively inexpensive and robust. Nevertheless, amino columns have been also used, but they need to be periodically regenerated with ammonia solutions. So, they are not widely used.

The most used detectors in the study of phospholipid classes are the UV and the ELSD. The response of UV detector is dependent on the degree of unsaturation in the molecule, and different wavelengths have been used, but the most frequently used are 205 and 208 nm (absorption of the ester bond). Besides, in these detectors, another problem is the absorption of some mobile phases at these wavelengths. That is why there are solvents that cannot be used with these detectors, like chloroform and acetic acid. So, the quantification of

phospholipids using this detector is difficult. On the other hand, ELSD gives a stable flat baseline and is very sensitive, and its response is not dependent on the number of double bonds in the molecule, showing the advantage of simplicity and universality. To use this detector in quantitative analysis, the response factors of the phospholipids must be calculated, due to the minor components.

Referring to the mobile phases used, an isocratic eluant has rarely been used. With a UV detector, an isocratic mode or a linear gradient can be applied. Binary gradients can be employed using ELSD, and the following have been used in several works: (a) chloroform–methanol–ammonium hydroxide and (b) chloroform–methanol–water–ammonium hydroxide. More complicated gradients of elution with three or four eluants have been used, but to a lesser degree than the binary ones. A wide range of different mobile phases have been used to separate the different phospholipid classes, since unfortunately not all phases have the same effectiveness for the different types of samples and the composition of the mobile phase can become critical for each type of matrix. Binary gradients that have been successfully used with different types of matrix are (a) chloroform–methanol–ammonia solution and (b) chloroform–methanol–triethylamine–water. An example is shown in Figure 3.

The use of reversed-phase HPLC allows the separation of the different molecular species of each phospholipid class. Normally, the different phospholipid classes are separated and collected by HPLC or TLC. One or two columns in series can be used depending on the resolution desired and the mobile phase used. Acetonitrile–methanol–water is the most commonly used mobile phase in reversed-phase HPLC using an RP18 column.

The last thing to mention about phospholipids is that they can be purified previously to their chromatographic analysis using SPE to isolate them, and the best results are obtained when silica columns are employed, allowing a high recovery.

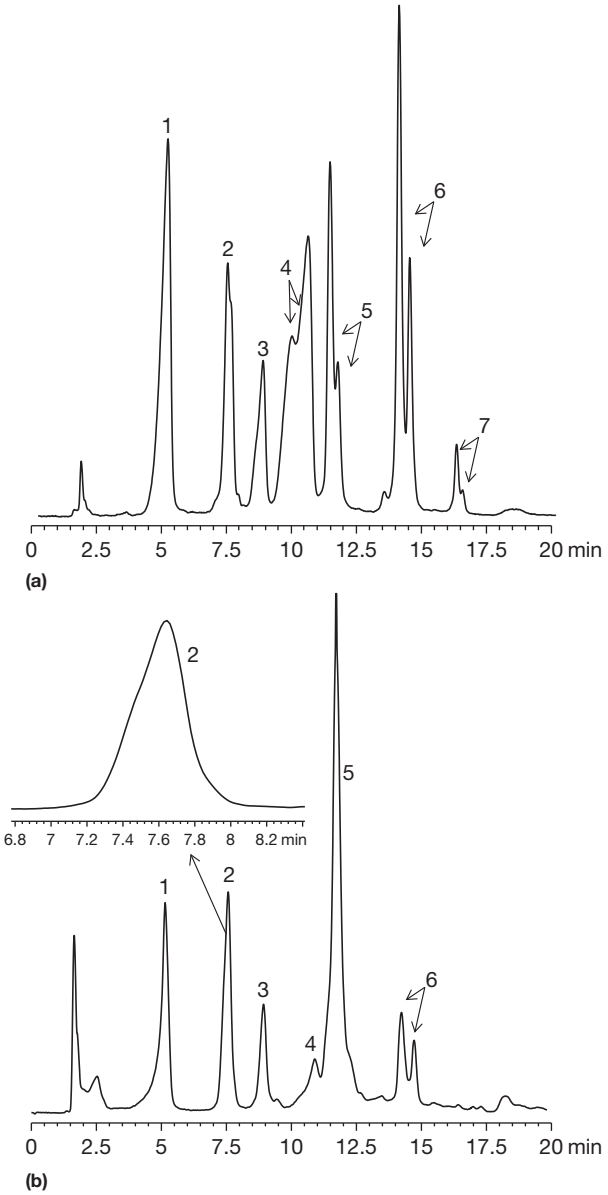

Figure 3 HPLC chromatogram of phospholipid fractions (a) from the standard solution and (b) from the subcutaneous fat of Iberian pig. 1, Cardiolipin; 2, phosphatidylethanolamine; 3, phosphatidylinositol; 4, phosphatidylserine; 5, phosphatidylcholine; 6, sphingomyelin; 7, lysophosphatidylcholine. Waxes

Waxes are organic compounds that consist of long alkyl chains. They are insoluble in water but soluble in organic nonpolar solvents. The waxy material of the fats can include primary and secondary alcohols, diols, ketones, β-diketones, triacylglycerols, hydrocarbons, sterol esters, and aliphatic aldehydes.

Silica gel column chromatography, TLC, SPE, and HPLC (using silica) have been used to separate them from other lipid constituents and to isolate individual classes of waxes for more detailed analysis. On the other hand, high-temperature gas chromatography following trimethylsilylation has been used in recent works, often in combination with mass spectrometry, to achieve simultaneous identification and quantification of the various molecular species.

Semipolar columns can be used for their analysis, although a better resolution is obtained with phenyl methyl silicone columns, which can endure higher temperatures.

All the methods for the determination of waxes consist of a separation from other lipid constituents using silica gel column chromatography, SPE, or HPLC and subsequent quantification using GC. In the official method, the waxes are determined by separating them according to the number of carbon atoms. The fractionation step is carried out by chromatography on a hydrated silica gel column after the addition of the internal standard (e.g., lauryl arachidate). The eluted fraction is recovered and subsequently injected on-column in a GC capillary column. SE-54 or SE-52 semipolar columns can be used, although a better resolution can be achieved with phenyl methyl silicone columns, which can tolerate higher temperatures.

Waxes can be determined simultaneously with fatty acid methyl esters and fatty acid ethyl esters by capillary gas chromatography, which is a method widely applied in laboratories.

A method based on through oven transfer adsorption–desorption (TOTAD) interface is another analytic

alternative. The lipid extract, with an internal standard diluted in *n*-heptane, is injected directly with no sample pretreatment step other than filtration. The wax ester fraction is separated from the triglycerides by normal-phase liquid chromatography, and the TOTAD interface transfers it to the GC to be analyzed. This method allows an automatic analysis of different wax esters, being simpler and faster than other methods, although its resolution is poorer.

A method in which samples are prepared by normal-phase liquid chromatography has also been proposed for the analysis of wax esters, but the precolumn is attached to the inlet of the column in the GC × GC instrument by means of a press-fit connector, the first dimension being performed with a PS-255 column (20 m × 0.25 mm i.d.) and the second dimension with a SOP-50 (50% phenyl polysiloxane) (1.5 m × 0.15 mm i.d.).

Unsaponifiable Fraction

The main classes of compounds that constitute the unsaponifiable fraction of food are hydrocarbons, carotenes, tocopherols, tocotrienols, linear fatty alcohols, triterpenic alcohols, methyl sterols, and sterols. Other components that are part of the unsaponifiable fraction are carotenoid pigments, triterpenic dialcohols, diterpenic alcohols, and phytol, but they are not always present in food matrices.

The unsaponifiable fraction is got doing a saponification with ethanolic potassium hydroxide at high temperature. After this, distilled water is added to the solution, and the mixture is extracted several times with portions of a nonpolar solvent such as hexane, heptanes, diethyl ether, chloroform, or their mixtures thereof. The unsaponifiables will remain in the nonpolar phase, while the fatty acid salts will partition to the polar phase. The nonpolar extracts are combined and washed several times with portions of a mixture of ethanol–water (1:1), until the wash reaches neutral pH. Finally, the hexane solution is dried under a stream of nitrogen or by rotoevaporation and redissolved in an appropriate amount of solvent for cleanup by either TLC or SPE or directly for derivatization. The fractionation of the different classes present in the extract can be carried out by HPLC. In Figure 4, there is an example of the fractionation using the HPLC technique. The same preparative procedure is utilized for the analysis of all unsaponifiable components. The trimethylsilyl derivatives (except for the hydrocarbons) of the purified fractions are analyzed using nonpolar capillary gas chromatography columns. On the other hand, a direct analysis of the silylated unsaponifiable components obtained from different food products can be carried out using a thermostable polar gas chromatography column (65% phenyl–35% dimethylpolysiloxane).

Hydrocarbons

In the natural lipid systems of food matrices, hydrocarbons are present in quite small amounts, and most of them have an odd number of carbon atoms. Cyclic, polycyclic aromatic, and ramified hydrocarbons are also present in small amounts.

A good separation of hydrocarbons is provided by silica TLC of natural lipids using a mobile phase of *n*-hexane-diethyl ether (7:3, v/v), eluting just after the solvent front. To improve the isolation of the unsaponifiable fraction of lipids, TLC and liquid chromatography are being replaced by HPLC methods, and HPLC-GC off-line methods that allow isolation and quantification of the hydrocarbon fraction have been reported. The column used for such purposes is a silica column and the mobile phase is hexane/ethyl acetate. SPE is also used, like in the case of polycyclic aromatic hydrocarbons, which are considered as contaminants.

After their purification, the hydrocarbons are analyzed by GC-FID or GC-MS, the last technique allowing their simultaneous identification. For polycyclic aromatic hydrocarbon analysis, low-bleed and low-polarity columns have been used, like DB-XLB columns. Linear, branched, and terpenic hydrocarbon analyses are performed using nonpolar columns of (95%) dimethyl–(5%) diphenylpolysiloxane type. An example of hydrocarbon analysis by GC-FID is shown in Figure 5.

Alcohols and Sterols

Linear alcohols are constituted by a homologue series of primary fatty alcohols that generally contain 20–30 carbon

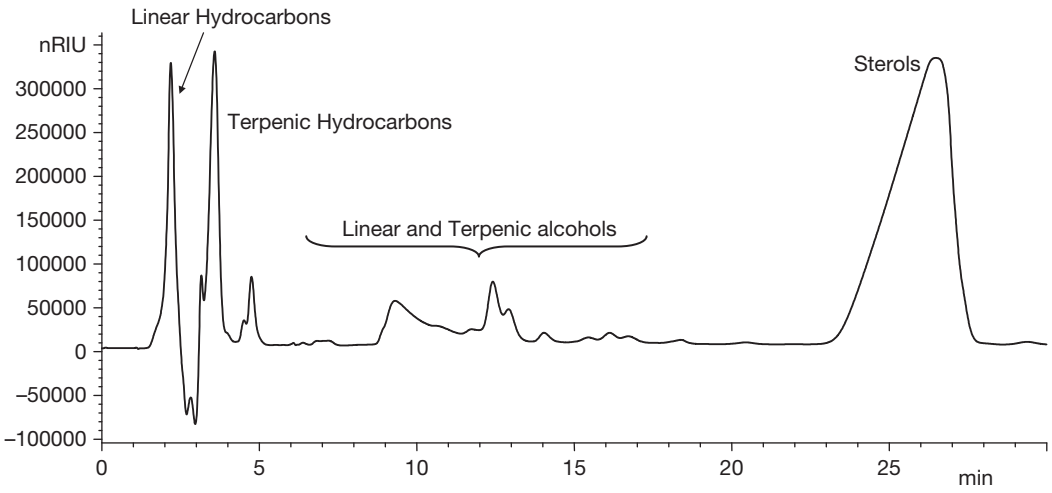

Figure 4 HPLC chromatogram of unsaponifiable fraction from the subcutaneous fat of Iberian pig.

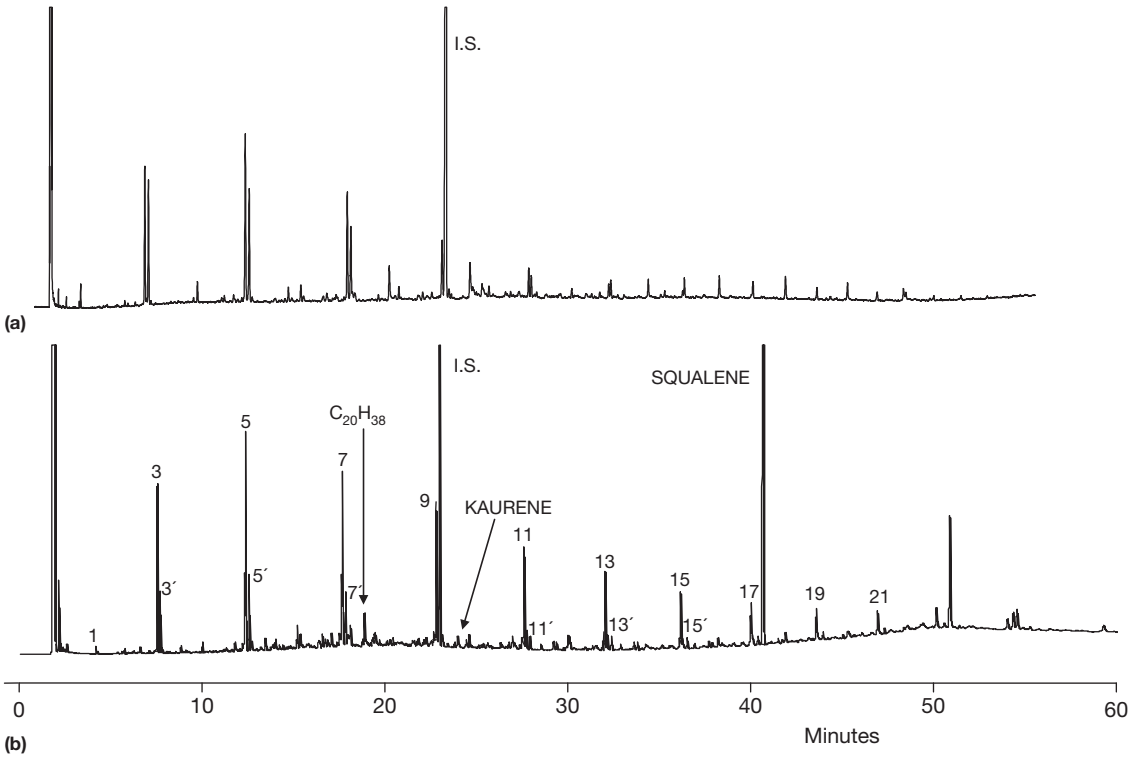

Figure 5 Chromatograms of hydrocarbons obtained from the subcutaneous fat of Iberian pig by LC (a) and HPLC (b). Peaks: 1, 1-dodecene; 3, 1-tetradecene; 3′, tetradecane; 5, 1-hexadecene; 5′, hexadecane; 7, 1-octadecene; 7′, octadecane; 9, 1-eicosene; 11, 1-docosene; 11′, docosane; 13, 1-tetracosene; 13′, tetracosane; 15, 1-hexacosene; 15′, hexacosane; 17, 1-octacosene; 19, 1-triacontene; 21, 1-dotriacontene.

atoms. The triterpenic alcohols have a steroid structure and are present at different levels in vegetal lipids. These are also known as 4,4′-dimethylsterols.

Both linear and triterpenic alcohols are often badly separated in silica TLC. To achieve a better TLC separation, a multiple development technique with a slightly different mobile phase for the second development can be carried out. Then, they are determined using the GC technique.

Sterols are steroid alcohols and they occur naturally in plants (phytosterols), animals, and fungi. Cholesterol (cholest-5-en-3β-ol) is by far the most abundant sterol in animal tissue. This can be esterified to long-chain fatty acids (cholesterol esters). These cholesterol esters are much less polar than free cholesterol. Cholesterol oxidizes slowly in tissues or foods forming a range of different products with additional hydroperoxy, epoxy, hydroxy, or keto groups. These compounds are called oxysterols, cholesterol oxides, or cholesterol oxidation products (COPs). Enzymatic methods from commercially available kits are used to determine the cholesterol content. It is necessary to hydrolyze the cholesterol ester fraction to determine the total cholesterol content.

In the analysis of sterols, these are first isolated from lipid extracts by TLC or column chromatography, following hydrolysis if necessary. Individual components can then be determined by GC, often after conversion to trimethylsilyl ether derivatives to give sharper peaks. The addition of an internal standard allows obtaining accurate qualitative and quantitative results by GC. The most common internal standards for sterol quantification are 5α-cholestane, dihydrocholesterol (5α-cholestan-3β-ol), epicoprostanol (5β-cholestan-3α-ol), and betulin. The internal standard is typically added to the sample prior to alkaline or acidic hydrolysis, undergoing the same extraction conditions as the sterol fraction, or it can be added after extraction but prior to derivatization.

Acidic hydrolysis is necessary to free the sterols when the sample has a complex protein or carbohydrate matrix and/or steryl glycosides. If this is needed, the internal standard is added to the weighed sample, and then, it is hydrolyzed with hydrochloric acid at 100 °C. After the acidic hydrolysis, lipids are extracted using a nonpolar solvent. After solvent removal, saponification of the lipid fraction is carried out as described in the preceding text.

Once saponification has been done, the unsaponifiable fraction may contain other lipids besides sterols including hydrocarbons, carotenoids, tocopherols, free fatty acids, and other triterpenes. For the unsaponifiable fraction of a refined fat or oil sample, it is usually acceptable to proceed with derivatization and GC analysis without further sample cleanup, and no problems with interference by these compounds are presented. However, in other types of samples, the sterol fraction needs to be purified. For such purpose, silica, C18, and aminopropyl SPE cartridges have all been used.

Nowadays, sterols are usually analyzed as trimethylsilyl ethers, since their volatility, peak shape, and response factors improve. Direct injection of nonderivatized sterols results in broader peaks and a lower FID response. The silylating reagents used are N,O-bis(trimethylsilyl)trifluoroacetamide (BSTFA) and N-methyltrimethylsilyltrifluoroacetamide (MSTFA), as well as mixtures of pyridine, hexamethyldisilazane, and trimethylchlorosilane (9:3:1, v/v/v). Derivatization reactions may proceed

completely in several minutes (about 15 or 20 min) at room temperature or heated to complete the reaction when the hydroxyl group on the sterols is hindered in any way.

After derivatization, sterols can immediately be analyzed by GC or after carefully evaporating the derivatization reagents with nitrogen at low temperatures to prevent any sterol ethers and redissolving them in an organic solvent, like chloroform, to an appropriate concentration before injecting. Split mode injection is usually used and the injector temperature usually set from 250 to 300 °C. Fused silica capillary columns with polysiloxane phases of low to midpolarity are used for their analysis. The most common column phase used for sterol analysis is composed of (95%) dimethyl–(5%) diphenylpolysiloxane. A nonpolar phase of (100%) dimethylpolysiloxane can be used, but a good separation of sterol peaks and their respective stanol peaks is not achieved with this column phase. Midpolarity columns (14% cyanopropyl-phenyl-methylpolysiloxane) have been suggested for a better resolution of Δ5-saturated and Δ5-unsaturated sterols.

For the identification of individual components of sterol fraction, mass spectrometry may be required.

HPLC can be employed for the analysis of sterols, using UV and mass spectrometric detection for their quantification and identification, respectively. An HPLC-/atmospheric pressure chemical ionization-MS method has been developed for the analysis of these compounds, in which no previous derivatization is needed. Several stationary reverse phases (C8, C18, and zirconia-based adsorbent) have been studied for this purpose, and the best separation of sterols has been obtained with the C8 phase. Increasing the column temperature accelerates their elution markedly. Nevertheless, different mobile phases have been used.

Rigorous attention in the analysis of the COPs should be attempted because they tend to be present at rather low levels, and there is a danger of further oxidation or side reactions during the analytic process. Both hot and cold saponifications, using either ethanolic or methanolic potassium hydroxide (KOH), have been used in the analysis of COPs. Their enrichment can be carried out using either silica or aminopropyl SPE. Besides, the sample should be protected against light, oxygen, and high-temperature exposures, since they promote lipid oxidation. HPLC and GC techniques have been used for the analysis of COPs, but GC has given better results than HPLC. Samples are derivatized to trimethylsilyl ethers using BSTFA, Tri-Sil reagent (Pierce Chemical Co., Rockford, IL), or the mix of hexamethyldisilazane–trimethylchlorosilane–anhydrous pyridine (3:1:9, v/v/v) prior to GC and GC-MS analyses. Fused silica open tubular capillary columns coated with (5%) phenyl methyl silicone and columns coated with (100%) dimethylpolysiloxane, such as DB-1, have been used for their analysis. Similar results are obtained using DB5-MS and DB1-MS columns. Although GC has been the most used technique for the analysis of COPs, some HPLC methods have been reported. A method using reversed-phase LC/atmospheric pressure chemical ionization mass spectrometry for the successful determination of cholesterol and its oxidized compounds in processed foods such as pork, beef, chicken, and eggs has been described. Diode array ultraviolet detection and laser light scattering detection (LLSD) have been compared, concluding that the use of LLSD in the HPLC of cholesterol and its oxidized products could provide a reliable tool for the determination of these compounds, since the use of this allowed the detection of cholestanetriol and α- and β-epoxides. Between the different internal standards used for their quantification are 5α-colestane, betulin, 19-hydroxycholesterol, and betamethasone-17, 19-dipropionate.

4-Methylsterol and 4,4-dimethylsterol fractions are analyzed in a similar way to other sterols.

Tocopherols and Tocotrienols

These compounds consist of a polar chromanol ring and a hydrophobic 16-carbon side chain attached to the ring via the C2 atom. The difference is that tocopherols contain saturated phytyl side chains, while tocotrienols have isoprenyl side chains with three double bonds. They display antioxidant properties and are active as vitamins (vitamin E), making them particularly important for human health. They are amphipathic and lipid-soluble and are easily oxidized when subjected to heat, light, and alkaline conditions. Tocotrienols are present in small amounts in food lipids. However, palm oil, grape-seed oil, and the annatto lipid fraction contain a relatively high amount of these components.

The determination of the tocopherols and tocotrienols as trimethylsilyl derivatives can be carried out on a short GC column of medium polarity (OV-17), with both flame ionization and mass spectrometric detection, within a short time of analysis, achieving a very good separation of the two classes of components. However, the methods that are usually recommended involve HPLC with fluorescence detection.

These compounds can be extracted using solvent or alkaline hydrolysis extractions. Supercritical fluid or pressurized liquid extractions are alternative techniques to traditional solvent extraction methods that may be used to extract tocopherols and tocotrienols.

HPLC is the most widely used technique for the analysis of these compounds since they are stable under HPLC conditions and easy to dissolve in appropriate solvents, and there are several detectors that can be combined with this technique to detect them, fluorescence detection and UV ($\lambda = 290–300$ nm) detection being the most commonly used. Aside from this, both normal-phase chromatography and reversed-phase chromatography can be applied.

Normal-phase using silica columns is commonly applied when all eight tocopherols and tocotrienols need to be separated, achieving better selectivity when hexane is used with a relatively strong polar modifier 1,4-dioxane in the mobile phase than with a weak modifier such as tert-butyl methyl ether.

However, reversed-phase might also be utilized when only some vitamins are of interest or when mixtures of fat-soluble vitamins and free and esterified tocopherols and/or tocotrienols have to be separated.

The external standard method is usually used to quantify tocopherols and tocotrienols because it is difficult to find a compound that would not interfere with their analysis.

Fats: Production and Uses of Animal Fats

Introduction

The composition of lipids in fatty tissues of meat varies in response to diet, the time at which the lipids are deposited, and adipose tissue depot. The fatty acid composition of pork is especially sensitive to dietary manipulation, whereas that of beef and lamb is affected primarily by the age of the animal and fat depot, although fatty acid composition of ruminant tissues can be modified by dietary means. For example, pasture or grass feeding causes fat depots to be high in saturated fatty acids, whereas grain feeding increases the concentration of monounsaturated fatty acids.

Between 45% and 50% of the entire live weight of livestock species does not enter directly into the human food chain. The by-products of animal slaughter and fabrication include muscle trim and a large quantity of the carcass fat (especially subcutaneous and internal fat depots) that are not used in processed meats. In addition, many internal organs are included in total by-products. Altogether, these by-products contain approximately 20% extractable fat. With rendering, some of this extractable fat can be recovered and converted into more useful and profitable materials such as lard or tallow, allowing part of carcass fat to reenter the human food chain. The quality, and especially the fatty acid composition of the rendered materials, determines the fate of the finished product.

Sources of Lipid in Meat

There are four sources of lipid in meat that are used for meat processing or rendering: the muscle fibers; subcutaneous fat; intermuscular (seam) fat between muscle groups; and intramuscular (interfascicular and marbling) fat. Very lean beef, pork, or lamb, in which all subcutaneous and intermuscular fat has been removed, contains approximately 1% extractable lipid. At the other extreme, even lean trim from Japanese Black (or wagyu) cattle can contain over 40% extractable lipid. This extraordinary concentration of lipid can be attributed largely to lipid within the muscle.

Fatty Acid Composition of Subcutaneous, Intramuscular, and Muscle Lipids

Lipids from fat, lean trim, and organs destined for rendering contain the saturated fatty acids palmitic acid (16:0) and stearic acid (18:0) and their delta-9-desaturase products, the monounsaturated fatty acids palmitoleic acid (16:1$n-7$) and oleic acid (18:1$n-9$). Palmitic acid is produced by the combined activities of acetyl-coenzyme A carboxylase and fatty acid synthase, whereas stearic acid is produced by the addition of two carbons to palmitic acid via a fatty acid elongase. Palmitoleic acid and oleic acid are the products of the delta 9 desaturation of palmitic acid and stearic acid, respectively, catalyzed by the enzyme stearoyl-CoA desaturase (SCD). Palmitic, palmitoleic, stearic, and oleic acids are always present in all tissues of animals (Figures 1 and 2), but the relative concentration of each fatty acid is dictated primarily by the activity of the enzyme SCD.

The polyunsaturated fatty acids typically consumed by livestock species consist primarily of linoleic acid (18:2$n-6$) and α-linolenic acid (18:2$n-3$). In the rumen of cattle, sheep, and goats, polyunsaturated fatty acids are extensively isomerized to *cis*-9, *trans*-11 conjugated linoleic acid (CLA) and other CLA isomers (Figure 3). However, the concentration of CLA isomers in ruminant tissues does not exceed 2% of total fatty acids because CLA is almost quantitatively hydrogenated to stearic acid in the rumen, although small portions of *trans*-vaccenic acid and other fatty acid *trans*-isomers escape the rumen and are absorbed in the gastrointestinal tract. For this reason, ruminant tissues are relatively high in stearic acid and naturally occurring *trans*-fatty acids.

The contribution of both *de novo* fatty acid synthesis and fatty acid desaturation to the fatty acid composition of fat depots is especially apparent in bovine fat (Figure 1). Stearic acid constitutes more than 80% of the fatty acids available for absorption from the duodenum in beef cattle, yet the most abundant fatty acids in bovine fat are palmitic acid (the product of *de novo* synthesis) and oleic acid (from desaturation of stearic acid). Typically, abdominal fat is more highly saturated than subcutaneous or intramuscular fat. In beef cattle, intramuscular fat is also higher in stearic acid than is subcutaneous fat (Figure 1). Unlike the situation for beef, intramuscular fat from pork contains less stearic acid than does subcutaneous fat (Figure 2).

As monogastrics, swine have adipose tissues with fatty acid composition that more closely resembles that of dietary fatty acids. Thus, diets enriched with oleic or linoleic acid will cause the lipids associated with pork to become similarly enriched with these fatty acids. Polyunsaturated fatty acids are especially susceptible to oxidation during long-term storage or rendering. This results in the formation of undesirable aldehydes and ketones, causing the rendered fat to be less acceptable. Feeding pigs diets enriched with polyunsaturated fatty acids also causes the carcasses to be oily and may lead to production problems such as soft pork bellies. Enrichment of carcass lean trim and fat with oleic acid, which is a solid at typical freezer temperatures, does not appear to accelerate lipid oxidation.

The majority of the fatty acids are stored as highly nonpolar triacylglycerols (Figure 4). Triacylglycerols coalesce into the large lipid vacuoles that are the central features of adipocytes. The triacylglycerol structure consists of a glycerol (i.e., three-carbon alcohol) backbone containing three fatty acids in ester linkages. The glycerol primarily is derived from glycerol-3-phosphate, which in turn is derived from the metabolism of glucose or, in the liver, from the phosphorylation of free

glycerol by glycerol kinase. In adipose tissue and intestinal mucosal cells, 2-monoacylglycerol (derived from partial hydrolysis of triacylglycerols) provides a portion of the carbon backbone for triacylglycerol synthesis.

Desaturation of Fatty Acids

Whereas ruminal hydrogenation of unsaturated fatty acids makes it difficult to enrich beef with unsaturated fatty acids, desaturation of fatty acids available for digestion in the duodenum ensures that the plasma, muscle, and fat depots are not overly enriched with saturated fatty acids, especially stearic acid. The activity of SCD has been demonstrated in the liver, muscle, subcutaneous fat, and intestinal mucosa of pigs and cattle. The greatest SCD activity is located within the subcutaneous fat. However, substantial activity also is observed in intestinal mucosal cells, where it may function to reduce the concentration of stearic acid in chylomicrons and very-low-density lipoproteins produced within mucosal cells. In this manner, SCD activity within mucosal cells largely influences the composition of fatty acids available for deposition in other tissues.

Fatty Acid Composition and Melting Points of Lipids

Longer-chain fatty acids have higher melting points than shorter-chain fatty acids, and more saturated fatty acids have higher melting points than unsaturated fatty acids. Because of the abundance of stearic and palmitic acids, animal fats are typically solids at room temperature. At 90–100 °F, rendered pork fat will separate with a liquid upper layer and solid material in the lower layer. The solid portion is known as stearin (from the Greek for animal fat) and is composed primarily of triacylglycerols enriched with stearic acid. The liquid portion is composed of the glycerol backbone in the form of esters with the less saturated fatty acids, primarily oleic acid, and is known as lard oil or olein (from the Latin for oil).

Due to differences in fatty acid composition, the melting points of fat from different species vary. Lamb fat typically has the highest melting point, followed by beef fat and then pork fat. With a high polyunsaturated fat content, poultry fat has the lowest melting point of the four species (80–110 °F). Related to the higher internal temperature, the internal fats have higher saturated fatty acid content and correspondingly higher melting points. The fat in the outer layers of the animal body is less saturated with lower melting points. This corresponds to the lower temperature near the body surface and the need to maintain a more liquid state. For example, beef kidney fat has a melting point of 104–122 °F, whereas the external subcutaneous fat has a melting point of only 89–110 °F. Beef brisket subcutaneous fat has an unusually low melting point (77 °F), due to its high concentration of oleic acid. Pork leaf fat has a melting point of 110–118 °F; pork back fat has a melting point of 86–104 °F. Tallow and lard melting points are standardized as titers, which are the minimum temperature at which fat congeals. For edible tallow, the minimum titer is 105 °F, whereas for edible lard, the minimum titer is 100 °F.

Major differences in fatty acid composition are observed across fat depots of beef carcasses (Figure 5). Brisket fat contains over 6% palmitoleic acid and less than 10% stearic acid, whereas subcutaneous fat overlying the flank contains less than 3% palmitoleic acid and more than 15% stearic acid. The highly consistent, negative relationship between palmitoleic acid and stearic acid demonstrated in several studies indicates that the concentrations of these fatty acids are coordinately

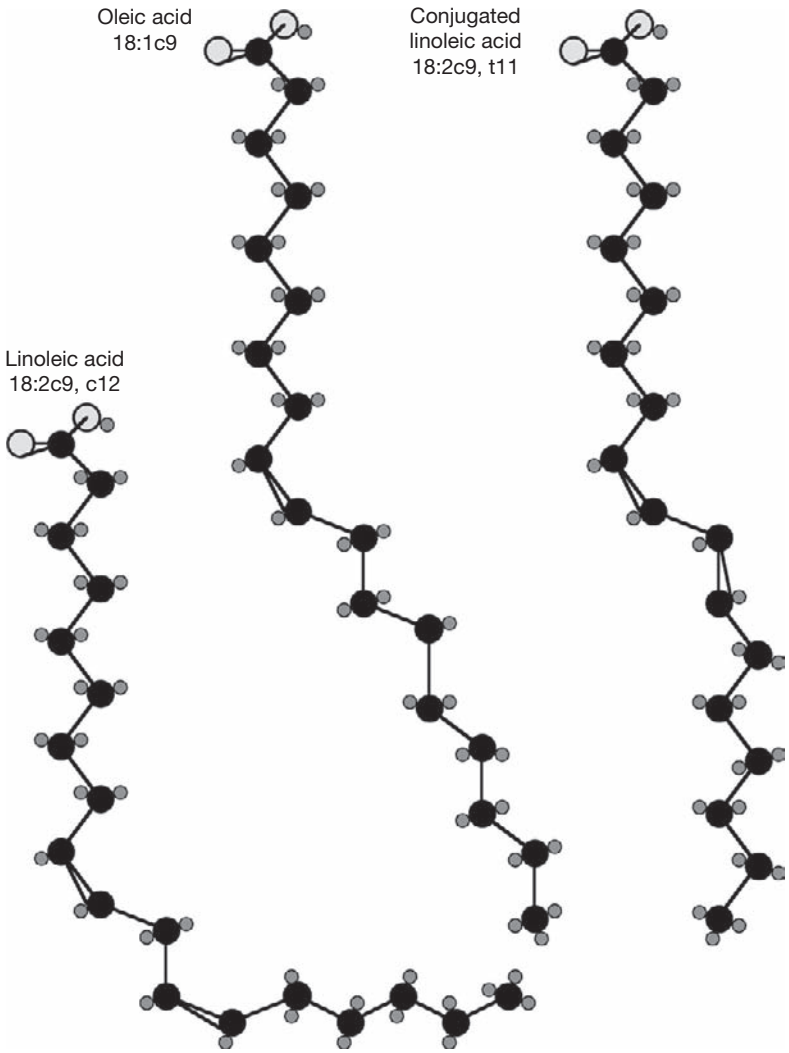

Figure 3 Structures of linoleic acid, oleic acid, and the *cis*-9,*trans*-11 isomer of conjugated linoleic acid. Large filled circles represent carbon; large shaded circles represent oxygen; small shaded circles represent hydrogen.

controlled by SCD. The concentration of stearic acid in adipose tissue lipids is the primary determinant of lipid melting points (Figure 6), and even lipids extracted from fat depots of the same carcasses can exhibit a remarkable range of melting points. These differences in lipid melting point can have major practical importance.

Procedures for Rendering Fats

Early rendering involved the addition of water to the by-products in an open kettle or the injection of steam into a sealed autoclave. This type of process is referred to as 'tanking' and could be used for both edible and inedible products. The fat produced by this method was relatively light in color, but the increased presence of added water resulted in an elevation in the free fatty acid content, reducing the quality and making the product more susceptible to oxidation. Therefore, for economic reasons, dry rendering is most commonly used today.

In the past, each slaughter facility had its own steam-jacketed kettle and rendered its own fat. Although the kettle was jacketed in steam, the by-products were cooked in their own juices with no added water, and therefore, this was considered a dry rendering method. Currently, in the United States, there has been a general shift to centralized rendering operations that collect animal by-products and ship them to a central rendering facility.

Rendering fat involves applying heat, extracting moisture, and separating the fat. To accomplish this, by-products are first ground into a consistent particle size and then cooked at 115–145 °C for up to 90 min. With the heating process, microorganisms such as bacteria and viruses are inactivated (an advantage over other waste product disposal methods). While the by-products are cooked, the jacket steam pressure must be controlled, the mixture agitated, and the temperature monitored for the desired end point. Over the years, there have been advances in the uses of the rendered products and in the rendering methods. Today, more energy-efficient, continuous

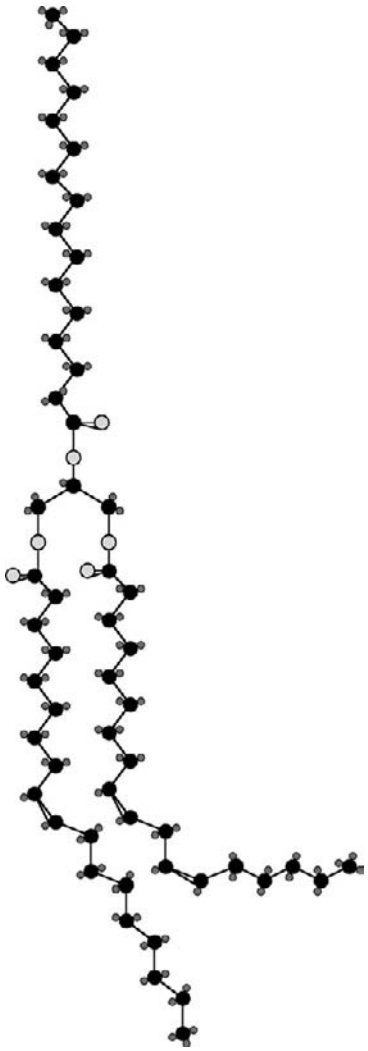

Figure 4 Typical structure of a triacylglycerol: *sn*−1 fatty acid (on left), oleic acid; *sn*−2 fatty acid, palmitic acid; *sn*−3 fatty acid, linoleic acid. This triacylglycerol would be common in porcine adipose tissue. In bovine and ovine adipose tissues, palmitic acid would occupy the *sn*−1 position and stearic or oleic acid would occupy the *sn*−2 position. Large filled circles represent carbon; large shaded circles represent oxygen; small shaded circles represent hydrogen.

processes are used to allow the reuse of process vapors to preheat or dry the materials. Filtering and bleaching systems, as well as refining equipment to remove free fatty acids, may be part of the rendering process.

During rendering, the melted fat floats to the top of the unit by virtue of its lesser density, whereas protein and bone solids settle to the bottom of the rendering kettle. Traditionally, the rendered fat then was skimmed from the top of the rendering kettle. This has been replaced with a screw press that draws off the melted fat, and the melted fat is stored and/or transported in tanks.

Chemistry of Rendered Fats

Rendered fats consist primarily of triacylglycerols (Figure 4). The characteristics of the rendered fat are determined by the composition of fatty acids attached to the glycerol backbone,

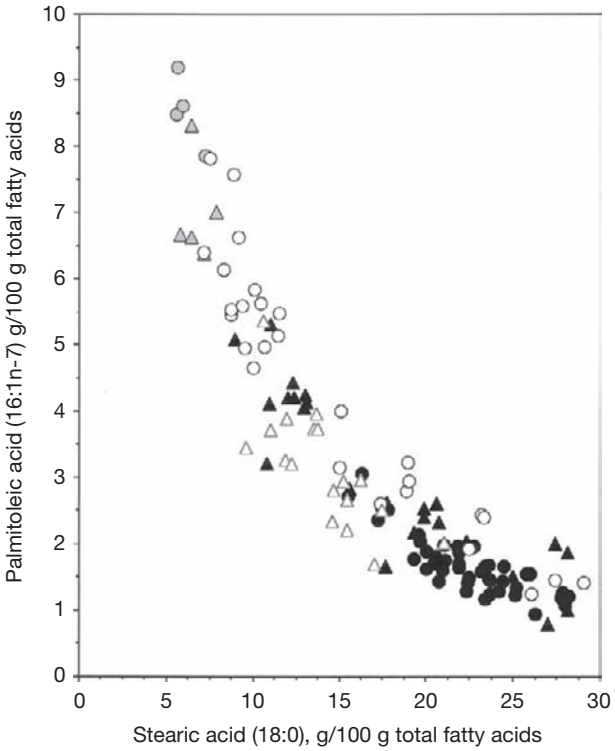

Figure 5 Palmitoleic acid (16:1*n*−7) plotted as a function of stearic acid (18:0) in subcutaneous fat. Lipids were extracted from eight subcutaneous fat depots, taken from 50 carcasses of unknown background. Lipids from brisket fat contained the greatest concentration of palmitoleic acid and least stearic acid, whereas lipids from flank fat contained the least palmitoleic acid and the most stearic acid. Reproduced with permission from Turk, S. N. and Smith, S. B. (2009). Carcass fatty acid mapping. *Meat Science* **81**: 658–663.

which in turn is determined by the source of the raw materials used in rendering. The most abundant fatty acids of animal fat triacylglycerols are palmitic, stearic, and oleic acids, typically comprising 20–25%, 10–30%, and 30–55%, respectively, of the total fatty acids in lean and fat trim. Significant quantities of linoleic and α-linoleic acids are contained in triacylglycerols, especially in rendered poultry fat. Lipids from ruminant tissues also contain measurable amounts of odd-chained fatty acids, branched-chain fatty acids, *trans*-fatty acids, and conjugated fatty acids, all of which are products of ruminal fermentation. Lard and tallow also contain free fatty acids (primarily oleic acid), but these must be no more than 0.5% in edible lard and 0.75% in edible tallow.

When the rendered fat contains more saturated fatty acids, the fat is referred to as hard fat. It is more solid at room temperature and has a higher melting point due to its high concentration of stearic acid. When the rendered fat contains more unsaturated fatty acids, the fat is referred to as a soft fat, which is not as solid at room temperature due to a greater abundance of oleic acid.

Oxidative Rancidity

Rendered fat high in polyunsaturated fatty acids will react chemically with oxygen, resulting in off-flavors and odors

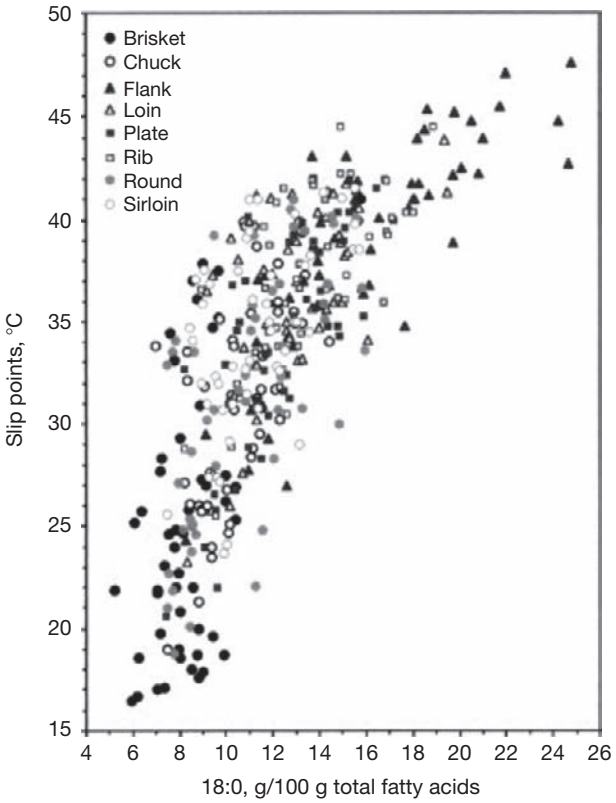

Figure 6 Lipid melting point (slip point) plotted as a function of stearic acid (18:0) in lipids from eight subcutaneous adipose tissue depots. Lipids from brisket adipose tissue had melting points less than 17 °C, whereas lipids from the flank had melting points greater than 45 °C. Reproduced with permission from Turk, S. N. and Smith, S. B. (2009). Carcass fatty acid mapping. *Meat Science* **81**: 658–663.

known as rancidity. Oxidative rancidity is catalyzed by the presence of heat, light, salt, and iron, as well as other elements. Because rancidity is not chemically defined or quantifiable, measurements of oxidation products are often used to indicate quality of the product. One such test is the peroxide value test that measures the milliequivalents (me) of peroxide per kilogram fat. A low peroxide value (<10 me) indicates a nonrancid fat. Lard and leaf lard (from pig abdominal fat) should have a peroxide value no higher than 5 to be considered high quality.

Fate of Rendered Fats

The US rendering industry produces an estimated 0.9 billion kg edible tallow, 1.5 billion kg inedible tallow, 0.6 billion kg yellow grease, 0.1 billion kg lard, and 0.6 billion kg poultry fat. Tallow is primarily derived from rendered beef fat. Choice white cooking grease is derived from pork fat. Yellow grease (not to be confused with off-colored white cooking grease) is restaurant-quality grease or cooking oil and may be from blended sources. Rendered fat provides concentrated sources of energy for use in feed for poultry, aquaculture, and pets. Other uses of rendered fat include soap, candles, and biodiesel.

Conclusions

Fatty acid composition of animal fats varies with animal species, diet, and fat depot. Stearic acid is the primary determinant of lipid melting points, although high concentrations of linoleic acid can effectively reduce melting points. Rendered fats have a great deal of functionality, depending on the source of the fat and the separation techniques. Rendering provides an outlet for animal by-products that would otherwise be unusable. Differential rendering of fat trims that vary in melting points improves the functionality and usefulness of the rendered fat.

Fatty Acids: Determination and Requirements

M Narváez-Rivas and M León-Camacho, Instituto de la Grasa (C.S.I.C.), Seville, Spain

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Fatty acids, with a few rare exceptions, are the main components of oils or fats. Generally, fatty acids are combined as esters, and they are the main compounds of lipids. The most common ester composed of fatty acids is the triacylglycerol, which is a combination of glycerol and three fatty acids.

According to the last definition, acetic acid would be the first of the fatty acids, but most scientists do not consider it that way. They start the monocarboxylic aliphatic series of saturated fatty acids with the propanoic or butanoic acid. That series extends to an acid with 30 carbon atoms (melissic acid). Usually, fatty acids have an even number of carbon atoms, but there are fatty acids that have an odd number of carbon atoms, such as the common margaric acid, with 17 carbon atoms. In general, the aliphatic chain is linear, but in some cases, fatty acids have branched chains: isoacids and anteisoacids. The unsaturated fatty acids are very important along the aliphatic chain, and we can distinguish them based on characteristics of the double bond: *cis* or *trans* (oleic acid or elaidic acid), position, number (linoleic acid, arachidonic acid), and possible conjugation. Most of the unsaturated fatty acids are *cis* and they have no conjugation. The *trans* form appears more or less frequently in the comestible oils and/or fats when they have been subjected to high temperatures (the energy supplied to the *cis* fatty acids allows isomerization). Because of this, the degree of thermal change in oil and/or fat can be measured using *trans* fatty acid content. Natural oils and/or fats with *trans* fatty acids exist, and an example is the fat of ruminants' milk.

Some of the natural fatty acids show different unsaturation to the double bond: ethylenic bonds, a cycle of three (cyclopropane or cyclopropene) or five (cyclopentene) carbon atoms (sterculic acid and Chaulmoogric acid). Between the fatty acids with saturated cycles, the most common have structures of the type: dihydrosterculic ([9-10] methylen, octadecanoic; 9D, 10L, *cis*). The ring of three carbon atoms makes a plane, and the substituents can be put above or under it. In that case, the first carbon atom of the cycle has four valences linked to four different radicals: —H, $-(CH_2)-COOH$, $-CH_2R_1$, and $-CHR'_1(CH_2)[(CH_2)_7CH_3]$. The next carbon atom bonds in a similar manner: —H, $-(CH_2)_7CH_3$, $-CH_2R_2$, and $-CHR'_2$. The two hydrogens attached to these carbon atoms can be on the same side of the plane (*cis*) or on opposites sides (*trans*). Moreover, two different forms exist for the same isomer, one being the mirror image of the other, depending on the position of the radicals of each carbon atom.

Most of the fatty acids only have the acid role. Nevertheless, in nature, fatty acids with other roles exist, because an organism has synthesized them through a specific biochemistry (e.g., ricinoleic acid, with an OH group; licanic acid, with a ceto group). Due to the action of the oxygen, the mechanics of oxidation and autoxidation produce oxidized fatty acids. The oxygenated functional groups that are part of natural fatty acids are hydroxy, ceto, oxo, and epoxy. Among the components of the natural wax, we can find α-, or 2-, hydroxy acids and β-, or 3-, hydroxy acids, which are also part of bacteria lipids. Among the monohydroxy natural acids, there are acids with different chain lengths and saturations, such as the mentioned ricinoleic acid. Among the polyhydroxy acids, there are fatty acids (most of them saturated) with chain lengths between 14 and 24 carbon atoms (most of them from 16 to 18 carbon atoms), having 2–5 OH groups. The most common positions for these groups are the Ω carbon and the positions adjacent to the unsaturations, when the fatty acid includes them.

Fatty Acid Analysis

Classical Methods

Before the emergence of gas chromatography (GC), the methods for determining the fatty-acid composition and the attributes of fat were basically volumetric methods based on some physical–chemical attribute of the fatty acids that were part of fats. Since the advent of GC, some of these analytical methods are still in use. The determination of fatty acids is the primary goal of fat analysis.

Saponification value. This value is defined by the quantity (in milligrams) of potassium hydroxide needed to saponify 1 g of fat. The value shows us the total amount of fat that is contained in the sample, or the combined volume of free an esterified fatty acids, and, in some ways, this value also shows us the lengths of fatty acids in oils and fats.

Reichert–Meissl index and Polenske index. The first index is a volumetric method that denotes the amount of sodium hydroxide needed to neutralize the fatty acids included in 5 g of fat, which can be dissolved into and swept away by water vapor. So, this index indicates the type and quantity of volatile fatty acids (with short chains). The second index refers to insoluble fatty acids in water.

Iodine value. Organic compounds with unsaturation show the property of adding halogens, as well as other compounds, in double bonds. This property is used for the quantitative determination of unsaturation; determining the number of double bonds identifies the type of unsaturated fatty acids contained in an oil or fat. This parameter is determined by using sodium thiosulfate to titrate the iodine excess that remains after the addition to the double bond, with clear starch serving as the indicator.

Chromatographic Methods

We have seen that some of these rates are connected to chain length and the number of double bonds, in the fatty acids.

After the advent of chromatographic methods, such as GC, the previous methods went out of favor, because GC can

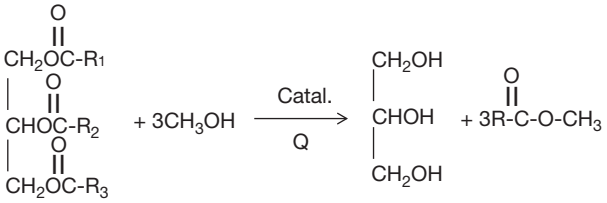
provide more information than the volumetric methods can. GC can also be applied to the analysis of fatty acids and their esters. In general, for fatty acids, direct GC is not commonly used. Instead, a fatty-acid derivatization using methyl esters is carried out, followed by their chromatographic analysis. It is only used for very short-chain acids that are very difficult to be esterified, such as formic acid, acetic acid, propionic acid, butyric acid, and valerianic acid.

The knowledge of the composition, both in quantity and quality, of the fatty acids in oil and fat has always been one of the main issues, because of its importance in oil and fat characterization and the determination of their possible adulteration. The methods for isolating and derivatizing these compounds and the selection of the most appropriate techniques for their determination have been discussed in many scientific publications. The following section describes the GC analysis of these compounds and how they should be prepared for such analyses.

Most of the time, the fatty acids are not free; when they are, they occur only in small amounts. They usually form esters, most often with glycerol, to produce glycerides (mono-, di-, and tri-acylglycerols) and phospholipids. They can also form esters with aliphatic alcohols of linear structure (waxes) or terpenic structure (terpene and sterol esters).

Derivatization of fatty acids

For fatty acid analysis by GC, these compounds have to be analyzed as volatile esters (usually methyl). The usual way to derivatize fatty acids is by forming their methyl esters, because they are more volatile and less polar than free acids, and this makes them easier to elute in chromatographic columns. The reaction that takes place is as follows:



This interesterification reaction involves slow kinetics. The presence of water slows down the reaction ratio and decreases the output. The reaction has to be accelerated by means of catalysis and/or by increasing the temperature to be efficient. The most common methods for preparing the fatty-acid methyl esters use a methanolic medium with alkaline catalysis, with acid catalysis, with alkaline and acid catalysis, or with diazomethane.

Methylation in a methanolic medium with alkaline catalysis

Methylation with sodium methylate is the most widely used method. A solution of sodium methylate in methanol, prepared via the direct reaction of metallic sodium with methyl alcohol, is added to the oil sample. Reflux heating cleans and homogenizes the solution, thus dissolving the methyl esters in the reaction medium. Then, they are extracted by adding a solvent, such as hexane or diethyl ether, and a watery solution of sodium chloride at 10% to separate both phases without their emulsioning. This method presents some drawbacks. Even though the reaction takes place with high yield, there is always the danger that the sodium salts of fatty acids (soaps) might form in the alkaline medium. In addition, free fatty acids do not methylate properly when this procedure is used. To overcome this disadvantage, the fatty matter can be treated with sodium methylate in a methanol solution inside a closed tube and heated. Because of the increased pressure inside the tube, the temperature rises above the boiling point of methanol, up to 85–90 °C. This increases the reaction yield. The heating has to take place for a period of no less than 2 h, however.

Another procedure that gives good results is methylation with potassium hydroxide. It consists of treating a solution in hexane of fat with a KOH 2N methanol solution, shaking it, and letting it decant. It is rapid and has the advantage of not needing heating, which requires eliminating the volatilization losses of acids with chains shorter than C12. This method is used for the methylation of milk fat, and it is widely used to avoid the isomerization of unsaturated fatty acids (analysis of *trans*-isomer fatty acid), but free acids do not derivatize well when this technique is applied; therefore, its use is not advisable for high-acidity oils.

Methylation in a methanolic medium with acid catalysis

Transesterification with methanol can also be catalyzed in an acidic medium. A common procedure consists of making oil react with a hydrochloric acid solution in methanol in a proportion of 2–3%. The acid has to be previously dried in a closed tube at 100 °C for about 1 h. Also with this procedure, it has been observed that the reaction is not complete. The esters are extracted with hexane before being injected.

A variation of the method involves adding a sulfuric acid solution in methanol and hexane and then heating by reflux for 90 min. This method increases the output of the reaction, thanks to the dehydrating action of the sulfuric acid, shortening the time employed in preparing the sample.

Lewis's acidic catalysis is another procedure that efficiently uses methylation with methanol that has been catalyzed with boron trifluoride. The sample is reflux-heated with a methanolic solution of sodium hydroxide until it is homogenized (complete formation of soaps). Next, a methanolic solution of boron trifluoride is added, and the heating continues for a few moments. The esters are extracted by adding a saline solution with heptane, and, thus, the saponification process is not necessary for fatty acids.

Methylation in a methanolic medium with alkaline and acid catalysis

As noted above, methylation in an alkaline medium, besides being incomplete, has the disadvantage that oil or fat can produce soaps (to saponify), and free acids do not methylate well in the alkaline medium. On the other hand, glycerides do not methylate properly in an acidic medium. Thus, a widespread method to improve the yield of the methylation reaction consists of combining both forms of catalysis.

Usually, the sample first undergoes alkaline methylation with reflux heating. The medium is then neutralized and subsequently acidified by means of the methanolic solution of sulfuric acid, before being reheated by reflux. This process

guarantees the hydrolysis of the soaps that might have been formed during the first step and the esterification of the free acids.

Another procedure consists of first treating the sample with a methanolic solution of potassium hydroxide, heated by reflux. Then, dimethyl sulfate is added, and the solution is shaken and heated again. The reaction is monitored using bromocresol green as the indicator. When the reaction is complete, the indicator changes from blue to yellow. Finally, a methanolic solution of sulfuric acid is added to separate the phases. The extract of methyl esters can be injected after purification with alumina.

Methylation with diazomethane

The apparently fast methylation using the diazomethane procedure has been used for free acids. The sample, after being dissolved in methanol, is treated with an ethereal solution of diazomethane, which has been prepared at the very moment of the reaction and under a nitrogen stream. The process is fast, but it requires the previous preparation of the diazomethane from *N*-methyl-*N*-nitroso-*p*-toluene-sulfonamide and 2-(2-ethoxyethoxy) ethanol in an alkaline medium. Diazomethane is toxic and explosive; therefore, some safety measures must be taken.

Formation of methyl esters without the previous extraction of the fat

In some cases, the analyst might be in trouble when undertaking the study of the composition of fatty acids, either because the amount of oily material on hand is minimal or because of extraction selectivity. Another factor to be considered is the possibility that the alteration of the fat during the study itself can induce the analysts to make serious mistakes in their conclusions. Some techniques have recently been developed in order to carry out the interesterification of some oily materials without the previous extraction of the fat. Even though this method can also be useful for oil transmethylation, its main advantage is that it can be directly applied to fresh tissues containing a considerable amount of water, such as olives, without the need for them to be previously dried, as in the aforementioned methods. In this method, both methylation with methanol and acid catalysis are carried out during a dissolving phase. The following reactive mixtures have been successfully used:

1. Methanol:heptane:benzene:2,2-dimethoxypropane:sulfuric acid (37:36:20:5:2, by volume)
2. Methanol:heptane:toluene:2,2-dimethoxypropane:sulfuric acid (39:34:20:5:2, by volume)
3. Methanol:heptane:tetrahydrofurane:2,2-dimethoxypropane:sulfuric acid (31:42:20:5:2, by volume)

The working temperature is 80 °C, and the process takes place in a closed tube. Both extraction and transmethylation are carried out in a single phase because the working temperature is the same for both. After the reaction takes place, the sample is cooled at room temperature, and two different phases occur. The organic (superior) phase containing the methyl esters is then ready for chromatographic analysis. This method is extremely interesting and allows for a great deal of possibilities, such as system automation when there are many samples to be analyzed.

GC analysis of the methyl esters of fatty acids

Once fatty acid methyl esters have been obtained by means of any of the methods mentioned previously, GC analysis can be undertaken with different aims. The first focus, however, is the study of the different types of chromatographic columns and the analysis of the results that can be obtained by using each of them.

The material used to prepare packed columns is the main factor determining the nature of the separations that can be achieved. Liquid phases, such as SE-30, OV-1, JXR, or OF-1, separate fatty acids according to their molecular weight; when the amount in the stationary phase is low, however, fatty acids can also be separated by their unsaturation. Phases such as Apiezón-L separate by unsaturation for the same chain length, with the previous elution of the unsaturated components.

The polyester liquid phases are quite appropriate because they allow for the separation of esters of the same chain length, from 0 to 6 double bonds, eluting the unsaturated components after their corresponding saturated compound. These phases can be classified into three groups:

1. High-polarity phases, such as polymers of ethylene glycol succinate (EGS), diethylene glycol succinate (DEGS), and copolymers of the former with a methylsilicone (EGSS-X™), CP-Sil 84™, and CP-Sil 88™
2. Medium-polarity phases, such as polyethylene glycol adipate (PEGA), polybutanediol succinate (BDS), and EGS copolymers with a high proportion of methylsilicone (EGSS-Y™)
3. Low-polarity phases, such as polyneopenthylglycol succinate (NPGS), EGS with a phenyl-silicone (EGSP-Z™), Carbowax 20M™, and Silar 5CP™

EGSS-X™, EGSS-Y™, and newer phases of equivalent polarity are widely accepted as the most useful representatives of the first and second groups, respectively, because of their relatively high thermal stability, particularly in work with packed columns. The phases from the group of highest polarity are stable at temperatures above those possible with EGSS-X™, and they produce excellent separations of polyunsaturated fatty acids. **Figure 1** shows the analysis using columns of 15% of EGSS-Y™ in a 100–120 mesh silanized and acid-washed support.

The low-polarity phases are mainly utilized in wall-coated open tubular (WCOT) and support-coated open tubular (SCOT) capillary columns because the saturated and monoenoic compounds of the same chain length are separated rather poorly when these phases are used in packed columns. At the same time, the quality and nature of the separations are related to the quantity applied to the stationary phase support. For example, low polyester levels are advisable for eluting the methylesters of long-chain polyunsaturated fatty acids at low temperatures. The relative retention time of fatty acid esters (generally 16:0 or 18:0) tends to shorten as the amount of liquid phase in the support decreases. Unfortunately, variation in the retention times for the esters of fatty acids is inevitable when the column ages through use, as the stationary phase polymerizes further from the column.

The nature of the support also influences the quality of the separations. Silanized and acid-washed materials are inert, and the separations are controlled only by means of the liquid phase. A minute particle size (160–120 mesh) is the best for analytical columns.

Some losses of esters of polyunsaturated acids partly respond to the use of very active supports or aged columns and to the transesterification by the polyester liquid phase, which is caused by the remnants of the catalyzer used in the fabrication of the polyester.

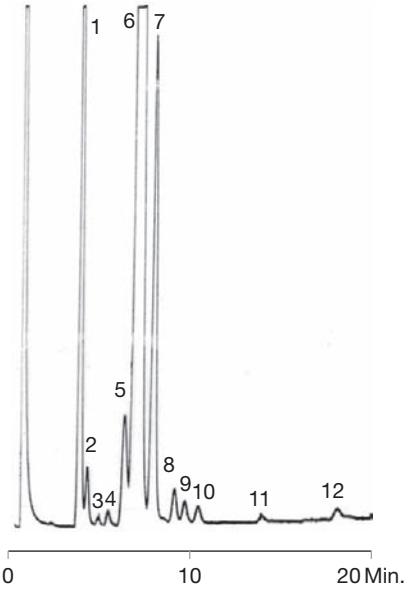


Figure 1 Chromatogram of fatty-acid methyl esters in packed column EGSS-X. 1: Palmitic; 2: palmitoleic; 3: margaric; 4: margaroleic; 5: stearic; 6: oleic; 7: linoleic; 8: linolenic; 9: arachidic; 10: gadoleic; 11: behenic; 12: lignoceric.

The use of WCOT columns of fused silica has led to remarkable improvements in separations with higher resolution, higher analytical precision in quality and quantity, and a higher sensitivity, as well as a shortening of analysis time and a reduction in the preparation of analysis procedures. Polyglycol phases based on Carbowax 20M™, FFAP™, Supelcowax-10™, and SP-1000™ seem to have been the most utilized in recent years. Figure 2 shows a chromatogram of olive oil fatty acids carried out in a SP-2380 capillary column (60 m, 0.25 mm, i.d. 0.25 μm film thickness).

Stationary phases are the same as those used in packed columns; the only difference is that, instead of impregnating a support, they wet the interior wall of the capillary tube. Most phases are now chemically bonded to the tube wall, which decreases loss in the column and, in turn, increases duration and temperature resistance and improves the resolution.

Trans-*fatty-acid determination*

Trans-fatty-acid isomers should be almost completely absent in oils and fats, because they are formed during technological treatments such as partial catalytic hydrogenation; the content and distribution of the *trans* isomers depend on the hydrogenation parameters (i.e., temperature, hydrogen pressure, and the kind of catalyst). Thus, the quantification of *trans* fatty acids is of great relevance to the authentication of oils and fats.

Thin-layer chromatography with silver nitrate

Since its introduction in 1962, thin-layer chromatography (TLC) using silica gel coated with silver nitrate has been very useful for lipid analysis, because fatty acids can be separated according to the number of unsaturations, the geometric configuration of the double bonds, and even the position of the double bond. Mobile phase systems using diethyl ether or

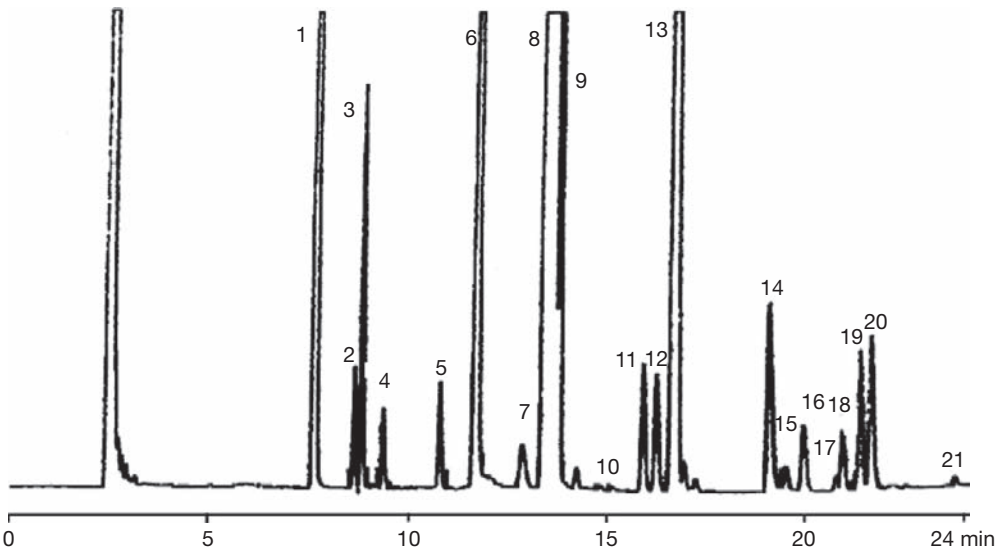

Figure 2 Chromatogram of fatty-acid methyl esters in capillary column SP-2380, 60 m. 1: palmitic; 2: *trans* palmitoleic; 3: *cis* palmitoleic; 4: margaric; 5: margaroleic; 6: stearic; 7: elaidic; 8: oleic (ω9); 9: oleic (ω7); 10: linoleic (9t, 12t); 11: linoleic (9c, 12t); 12: linoleic (9t, 12c); 13: linoleic (9c, 12c); 14: arachidic; 15: linolenic (9t, 12c, 15t); 16: linolenic (9c, 12c, 15t); 17: linolenic (9c, 12t, 15c); 18: linolenic (9t, 12c, 15c); 19: linolenic (9c, 12c, 15c); 20: gadoleic; 21: behenic.

hexane are more useful for separating general kinds of methyl esters of the fatty acids, although it is not possible to resolve them if they have three or more double bonds.

In fact, separations with more than four double bonds are not easy, and mixtures of hexane/ diethyl ether 90:10 (v/v) divide compounds with two double bonds. The obtained bandwidths are visualized under ultraviolet light, after revealing them with 2′,7′-dicloroflurosceine, and the compounds with zero to two double bonds are eluted with diethyl ether or chloroform. The chloroform/methanol 9:1 is necessary to recover completely unsaturated compounds.

Monoenoic natural fatty acids, which contain *trans* double bonds, can be studied through separation of *cis* compounds by TLC with silver nitrate eluted with hexane/diethyl ether (9:1, v/v) as a mobile phase and eluted together with saturated compounds. With care, it is also possible to separate positional isomers of the unsaturated fatty acids by TLC with silver nitrate. With a high concentration of silver nitrate (in the order of 30%) and developing with toluene at low temperatures (−5 to 25 °C), the methyl esters 6-; 9-y 11-*cis*-octadecenoic are well-separated.

Infrared spectroscopy methods

Infrared spectroscopy was used to determine the amount of *trans* isomers of fatty acids, replacing chromatographic absorption methods with silver nitrate, until the appearance of capillary columns of great length (60–100 m) and very polar stationary phase, which have allowed the determination of these compounds. First, to carry out analysis using infrared spectroscopy, fatty-acid methyl esters must be produced using some of the mentioned procedures, before measuring absorption at wavelengths of 10.36 μm. Before any measurements are carried out, it is necessary make a calibration with standard solutions, however.

GC methods

The determination of *trans* fatty acids has been carried out by infrared spectroscopy. However, the use of GC with great-length capillary columns allows the determination of the percentage of *trans* fatty acids, as well as the separation of individual fatty-acid esters of a given chain-length that differ in degree of unsaturation and in the positions of the double-bonds (e.g., two isomers of 18:1 and of 18:3 are separated). In the analysis of the methyl esters of polyunsaturated fatty acids in oil, it is important to note that the shorter the distance between the last double bond and the end of the molecule, the longer the retention time of the isomer. A good correlation exists between the data supplied by GC and infrared instruments.

To determine the composition of *trans* fatty acids by GC, fatty-acid methyl esters should be prepared by means of any previously mentioned procedure. However, it has been observed that, for samples with low *trans*-isomer contents, methylation methods using heating produce an increase in those isomers. Therefore, for this determination, cold methylation with methanolic potassium hydroxide or diazomethane is recommended. In addition, different injection temperatures have been studied because there is always the possibility that *cis*-fatty-acid isomerization might occur in the chromatographic injector. The results of the analysis of a virgin olive oil sample with low *trans*-isomer content (Table 1) are similar for methods B and C, whereas method A yields results that are slightly higher in elaidic acid (18:1t), which is in agreement with the preference for isomerization in an acidic medium. On the other hand, a remarkable increase in elaidic acid seems to occur as the injection temperature increases.

Table 1 Effect of injection temperature and methylation method on the elaidic and linoleic (9c, 12t) acid content of a virgin olive oil

	Method[a]		*Method*[b]		*Method*[c]	
T °C injector	200	300	200	300	200	300
C18:1 9t	0.026	0.042	0.017	0.030	0.016	0.024
C18:29c,12t	0.012	0.090	0.012	0.013	0.015	0.013

Source: León-Camacho, M. and Cert Ventulá, A. (1994). Recomendaciones para la aplicación de algunos métodos analíticos incluidos en el reglamento cee 2568/91 relativo a las características de los aceites de oliva y de orujo de oliva. *Grasas y Aceites* **45**, 395–401.

After numerous injections, an analyst might also observe an increase in the amount of elaidic acid that results from the catalytic action of the residues accumulated in the injector. On the contrary, the cleaner the injector, the lower the amount of acid that will result. Consequently, cold methylation is used, with a solution of potassium hydroxide in methanol at a temperature no higher than 225 °C.

Regarding GC analysis, the methods indicate that the amount of injected sample must be such that a peak of arachidic acid (C20:0) should represent over 20% of the full scale, although it must not be higher than 50%. It has been proved that overlapping between the peaks corresponding to both elaidic and oleic acid and a quantitative distortion, either through discrimination or saturation of the detector, can occur.

The column used by GC analysis should show a chromatographic profile similar to that presented in Figure 2, because the linolenic acid has a slightly inferior retention time than the eicosenoic acid. The use of columns of lesser polarity produces the appearance of peaks that interfere in the determination of the *trans* isomers of linolenic acid. These peaks can resemble ethyl or other esters. The position of the *trans* isomers, therefore, has to be precisely determined by means of the analysis of a refined oil sample.

An HP-88 capillary column, coated with 88% cyanopropyl aryl siloxane (100 m × 0.2 mm i.d × 0.2 μm film thickness), or a Varian Chrompack CP-Sil 88 column, coated with cyanopropyl polysiloxane (100 m × 0.25 mm i.d. × 0.2 μm film thickness), is able to provide an accurate quantitation of *trans*-fatty-acid isomers previously derivatized as methylesters. A better peak resolution is obtained if the carrier gas is hydrogen instead of helium. Furthermore, no silver-ion prefractionation of *trans* fatty acid (by TLC, SPE, or HPLC) is required prior to GC analysis.

Free-fatty-acid determination

Acidity

Acidity was determined through a volumetric method based on fatty-acid neutralization using a nonaqueous solution of sodium or potassium hydroxide and an acid–base indicator

(usually phenolphthalein) to determine the final point of the titration.

Gas-chromatographic method

Free fatty acids, together with mono- and diacylglycerols, form a part of the fat polar fraction, and their analysis can be carried out using a methodology for suitable separation and quantification. This fraction is isolated by solid-phase extraction using diol columns and 1,3-dimyristin as the internal standard. A solution of hexane:methylene chloride:ethyl ether (89:10:1 v/v) is first applied to the column to eliminate triacylglycerols. Subsequently, a portion of chloroform:methanol (2:1 v/v) is applied to the column and collected. This fraction contains free fatty acids and mono- and diacylglycerols, and it is evaporated to dryness in a rotary evaporator under reduced pressure. The residue is silylated and left at room temperature for 15 min. Then, the residue is injected into the GC system using a DB-17HT column and a flame ion detector. In the chromatogram, the free fatty acids appear in first place, followed by monoacylglycerols and subsequent diacylglycerols. An example of this can be observed elsewhere in this encyclopedia.

Fatty Acids: Essential Fatty Acids

The Nature of Staple Foods

As human society slowly changed from hunter-gatherer lifestyles to more agricultural and urban lifestyles, food from capture or culture remained the source of nutrient energy needed for physical activity and of essential amino acids (EAAs) and essential fatty acids (EFAs) needed for growth and healthy tissue functions. Plants make all of these needed nutrients, and they also contain the vitamins and minerals that sustain healthy human life. Local community decisions about soil and climate conditions have influenced the shift from opportunistic capture to deliberate culture of a food, but the logical basis by which people selected a regional staple is not appreciably evident in any written history. Eventually, domestication of plants and animals led to regional foods that were available on a more reliable basis with less expenditure of human energy. Having sufficient food energy (in carbohydrate or fat) is one obvious feature of a staple food plus its stability on storage over time. Awareness of EFA actions seems to have played no role in creating the markets for staple foods that were well established by the mid-twentieth century.

Vitamins and essential nutrients were not discovered until the twentieth century after trial and error experiences had already led to established staple foods with adequate protein (EAA) to successfully support healthy human growth and development. However, knowledge of EFA abundance and action remains a topic of growing awareness and concern among the biomedical community in the twenty-first century. Current knowledge of metabolism and physiology of EFAs indicates that some traditional ethnic lifestyles unknowingly developed healthier daily supplies of EFA than others. Now, careful use of recent information about EFA is likely to give new insights and priorities for current staple foods.

Plants make the essential 18-carbon polyunsaturated fatty acids (PUFAs) that are essential for growth, development, and function of healthy animals and humans. Figure 1 shows how two different desaturases (not found in animals) convert nonessential omega-9 ($n-9$) oleic acid into the omega-6 ($n-6$) and omega-3 ($n-3$) acids. The 18-carbon polyunsaturated acids, predominantly linoleic acid (LA) and alpha-linolenic acid, are made and stored in plant tissues. They are not made in animals for which they are essential vitamin-like nutrients. Small amounts of two other EFAs, stearidonic acid and gamma-linolenic acid, are formed in a few plants by the action of a $\Delta 6$ desaturase on the $n-3$ or $n-6$ precursor. A similar desaturase enzyme occurs in animals.

Table 1 shows recent annual worldwide production of major plant food staples along with the balance of their $n-3$ and $n-6$ EFAs. The Omega-3–6 Balance Scores are derived from the difference in milligrams per kilocalorie (kcal) of eleven different $n-3$ and $n-6$ nutrients in a food item. A negative value means that there is more $n-6$ than $n-3$ nutrient, whereas a positive value indicates more $n-3$ than $n-6$ nutrient. The grains listed at the top of Table 1 have high contents of carbohydrates, which provide food energy. Grains also have sufficient protein to provide needed EAAs. Importantly, the dry forms of grains are stable over long storage times and can be transported fairly easily. The legumes in the center of Table 1 have twice the amount of protein. The dried seeds also are stable over long storage times and can be transported fairly easily. The plant foods at the bottom of the table have a higher water content and lower nutrient density that limits their distribution away from local markets. In the absence of a scientific rationale favoring any particular staple food, convenience, historical precedent, and financial marketing considerations tend to drive the choice of staples among different communities.

Ethnic Food Traditions Affect EFA Intakes

The low magnitudes of many Omega-3–6 Balance Scores in Table 1 show that most major plant staples have relatively balanced amounts of $n-3$ and $n-6$ EFAs. However, the very large negative values (-36 and -59) for the processed oils from these staples indicate a presence of much greater amounts of $n-6$ than $n-3$ nutrients. These values show how important nutritional differences can occur between a food and its processed product. Later sections in this article note some unintended consequences of processing staple foods into forms not used earlier during the development of human societies.

The ability of plants to make their own carbohydrates, amino acids, fatty acids, and vitamins from their surrounding supply of nitrogen, carbon dioxide, minerals, and solar energy allows each plant staple to have gene-determined predictably consistent composition. The nutrient composition of most plant-based foods has remained fairly constant throughout the transition from prehominid times to the present. However, some cultivars developed by selective breeding have specialized differences in composition and yield. Some high-oleic, low-linoleic seed oils come from selected sunflower and safflower strains, but they are not yet widely marketed. The major change in staples as human populations increased was a shift from the plant foods at the bottom of Table 1 toward increased use of the staple commodities near the top. Plants at the bottom of Table 1 were more common in tropical Africa during early hominid times and may have been major foods during early human evolution. Humans began to culture grains as staples only about 10 000 years ago.

Soybeans and peanuts have much more fat than the other plant staples, and they provide a profitable opportunity to separate the oil from the protein to be stored and marketed separately. Food oils also can be recovered as by-products from other commercial activities (e.g., cottonseed oil or lard). Over 150 million tons of food oils were produced in 2012 (Table 2).

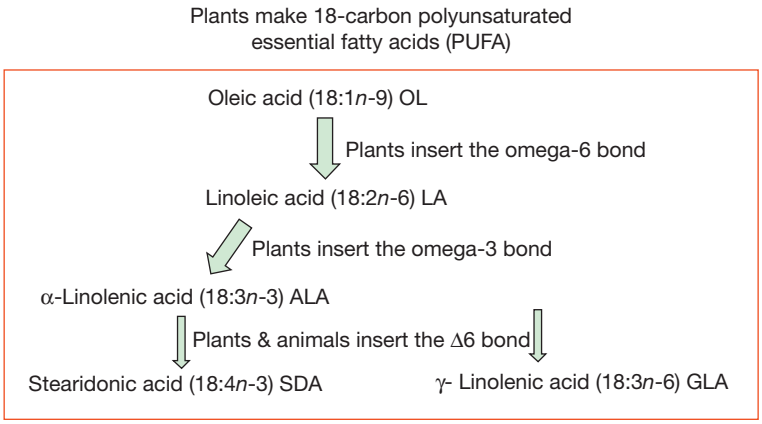

Figure 1 Plants make 18-carbon polyunsaturated essential fatty acids (PUFAs).

Table 1 Production and composition of plant staples

Staple food name	*Annual production (million tons)*	*Protein (%)*	*Carbohydrate (%)*	*Fat (%)*	*Omega-3–6 Balance Scores*
Corn, maize	823 Mt	9.4	76	4.7	−3 oil, −59
Rice, white	690 Mt	7.1	79	0.7	−0.3 oil, −36
Wheat	685 Mt	12.6	71	1.5	−2 oil, −54
Sorghum	66 Mt	11.3	79	3.3	−4
Millet	30 Mt	11	73	4.2	−5
Oats	24 Mt	17	66	6.9	−6
Soybeans	231 Mt	36	30	20	−17 oil, −59
Peanuts	45 Mt	26	16	49	−29 oil, −36
Beans	23 Mt	22	62	1.4	−0.3
Peas	11 Mt	24	64	1.2	−1
Cassava	233 Mt	1.4	38	0.3	−0.1
Sweet potato	110 Mt	1.6	20	0.1	−0.5
Yam	52 Mt	1.5	28	0.2	−0.4
Plantain	34 Mt	1.3	32	0.4	−0.1
Taro	7 Mt	0.5	26	0.1	−3

Table 2 Production and composition of food oils and fats

Staple food name	*Annual production (million tons)*	*Omega-3–6 Balance Scores*
Palm oil	53	−10
Soybean oil	41	−59
Rapeseed oil	24	−12
Sunflower oil	15	−74 (−4, high oleic)
Margarine	14	−69 to −21
Cottonseed	5	−59
Butter	5	−1
Coconut oil	3	−2

The introduction of hydrogenated vegetable oils at the start of the twentieth century began providing cheap semisolid shortenings and margarines (Omega-3–6 Balance Scores = −21 to −69) that partially replaced lard (−10) and butter (−1) for household and commercial food preparation. Food marketing messages about food oils built new cultural lifestyles by the late twentieth century, and regional ethnic differences in food habits gave way to global corporate marketing priorities. Importantly, the new staple food oils and fats continue to be adopted without open public discussion and rigorous evaluation of the health impact of the relative contents of $n-3$ linolenate and $n-6$ linoleate EFAs.

Animal Metabolism Has Competing Actions of $n-3$ and $n-6$ EFAs

When humans and animals eat plants, the EFAs are metabolized by desaturase and elongase enzymes (see Figure 2) that convert the 18-carbon PUFAs into 20- and 22-carbon highly unsaturated fatty acids (HUFAs). Most of the enzymes are indiscriminate, allowing the $n-3$ and $n-6$ forms of EFA to compete similarly for reaction during each metabolic step. As a result, the relative abundance of a competitor affects the amount of conversion that occurs. The proportions of $n-3$ and $n-6$ in the HUFA accumulated in human and animal tissues predictably reflect the proportions of competing $n-3$ and $n-6$ PUFA in the foods eaten. In contrast to what occurs in plants, the EFA composition in human and animal tissues is determined by both genetics and environment.

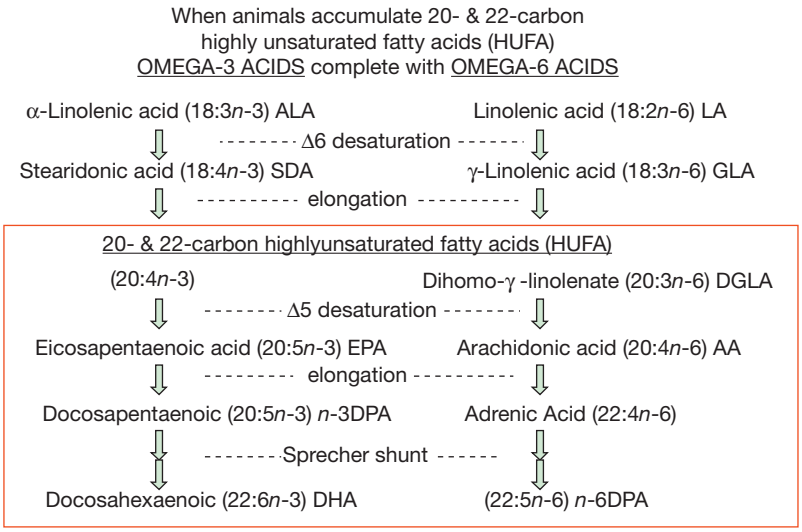

Figure 2 When animals accumulate 20- and 22-carbon highly unsaturated fatty acids (HUFAs), the omega-3 acids compete with omega-6 acids.

Table 3 Production and composition of animal staples

Staple food name	*Annual production (million tons)*	*Protein (%)*	*Carbohydrate (%)*	*Fat (%)*	*Omega-3–6 Balance Scores*
Meat, pig	109	22	0	4	−4
Meat, chicken	93	20	0	3	−8
Meat, cattle	63	20	0	9	−3
Cheese	17	23	3	30	0
Fish, carp	25	18	0	6	+14
Fish, freshwater	7.5	19	0	1	+18
Clams	5.0	15	0	1	+14
Oysters	4.7	6	3	2	+50
Fish, tilapia	4.5	20	0	2	+7
Shrimp	4.3	20	0	1	+19
Salmon	3.2	20	0	6	+73 (+28, farmed)

The Sprecher shunt noted at the bottom of Figure 2 involves an elongase that acts faster with the $n-3$ than the $n-6$ intermediate during a complex set of multiple metabolic steps coordinated between subcellular regions, which gives 22-carbon acids with a Δ4 double bond. This process leads to a greater abundance of 22:6$n-3$ (DHA) than 22:5$n-6$ ($n-6$DPA).

An interesting human genetic haplotype that has faster Δ6 and Δ5 desaturation activities was apparently selected favorably among humans in central and western Africa where plant staples were like those at the bottom of Table 1. Faster conversion of $n-3$ and $n-6$ PUFAs to tissue HUFAs makes African-Americans more responsive than Caucasians or Asians to the high proportions of $n-6$ nutrients in typical American diets. Health-related consequences of these different nutrient responses are noted later in this article.

By domesticating animals, agriculture provided a continual supply of animal-based staple foods that do not require wide-ranging efforts of hunting and gathering. Rather, the meat, milk, and cheese acquired from livestock are eaten with short storage times. However, one important (and often ignored) nutritional aspect of these foods is that the EFA present in domesticated animals is controlled by the EFA that the farmer provides to the animal. As a result, different farming environments produce different balances of $n-3$ and $n-6$ EFAs in the animal product. The food chain that provides EFA to humans merits continuing careful attention and management.

Public attention to animal-based staple foods (Table 3) is focussed primarily on protein content, even though plants do provide appreciable protein. Animals store little carbohydrate, and their energy reserves are mainly stored in fats that have mostly nonessential palmitic, stearic, and oleic acids. Farmers feeding grains to their domesticated animals are adding EFA that accumulate in the animal fat. The negative Omega-3–6 Balance Scores for pig, chicken, and cattle reflect the impact of feeding grains (scores near −3 to −6) in contrast to leaves, grass, and foliage (scores near 0 to +3). The milk, cheese, and yogurt produced in high alpine meadows have more positive scores than those from Japan (where there is limited pasture acreage).

In the same manner, high positive scores for aquatic animals reflect the impact of the algal-based food web in the aquatic environment. At present, wild and domestic fisheries worldwide annually provide fish at a level of 91 million tons (Mt) by capture and 67 Mt by culture plus aquatic plant capture of 1 Mt and culture of 24 Mt. Fisheries remain the

last large hunter-gatherer enterprise on Earth, and they are increasingly being 'managed' by people hoping to sustain some suitable level of capture for the growing human population.

Eating captured seafoods provides humans with much more $n-3$ than $n-6$ EFAs, and those $n-3$ EFAs are predominantly long-chain $n-3$ HUFAs rather than the 18-carbon PUFAs found in domestic plants. However, modern large-scale intensive culture of seafood can involve feeding grain and plant foods that shift EFA proportions away from those normally found in the less intensive natural algal-based food web of oceans and lakes. These commercial, financial factors strongly affect the scores for the cultured staples listed in Table 3. As a result, scores in the table are conditional average values subject to differing environmental variations. As wild-caught seafoods continue to have increasing societal pressures to diminish their capture, the issue of what balance of $n-3$ and $n-6$ EFAs occurs in cultured animal staples will become an increasingly serious topic to manage carefully.

Highly Unsaturated Fatty Acids Form Bioactive Mediators

While linolenic acid is not a dietary essential for plants, it has important physiological actions in plant survival. This occurs by a lipoxygenase-catalyzed oxidative conversion of the acid to the plant hormone, jasmonate, which optimizes plant growth, development, and immunity. For animals and humans, the linolenic acid and LA obtained in foods also undergo oxidative conversion to many potent bioactive derivatives that optimize growth, development, and immunity in animals.

One of the first recognized signs of severe EFA deficiency in laboratory animals was an impaired epidermal water barrier essential to effective growth and survival in low humidity. Two lipoxygenases, ALOX12B and ALOXE3, participate in forming ceramide and hepoxilin derivatives that strengthen the epidermal barrier. Fortunately, the amount of EFA in the diet needed to prevent deficits in the barrier and in growth is $<0.3\%$ of food energy. Because nearly all edible staples can provide this amount, EFA deficiency is very rare among humans.

An associated biomarker of EFA deficiency is the occurrence of more than 50% of tissue HUFA in the form of the $n-9$ HUFA, eicosatrienoic acid. This happens when the supply of dietary 18-carbon EFA is too low to compete effectively with the large amount of endogenous oleate for the elongation and desaturation enzymes that form the $n-3$, $n-6$, and $n-9$ HUFAs. Again, most dietary staples provide enough EFA to maintain the $\%n-9$ in HUFA of tissues below 2% of HUFA. In fact, the frequent occurrence of undetectable levels of $n-9$ HUFA in blood samples from Americans may indicate that they are eating much more EFA than is needed for good health.

One of the most important features of EFA action in humans is the oxidative conversion of HUFA into a large group of potent hormonelike mediators called eicosanoids. These induce signaling actions by many different specific receptors that occur on nearly every cell and tissue of the body. Such signaling is essential for coordinating tissue responses, and excessive signaling can shift healthy physiology toward pathophysiology. Potent hormonelike mediators formed by the oxidative action of cyclooxygenases are prostaglandins (PGs) and thromboxanes (TXs). Mediators formed by lipoxygenases include leukotrienes (LTs), hydroxyeicosatetraenoic acids (HETEs), hydroxyoctadecadienoic acid (HODE), lipoxins (LXs), resolvins (Rv's), hepoxilins (Hx's), maresins (Ma's), and protectins (PDs). Cytochrome P450 enzymes oxidize HUFA to bioactive epoxides (EET, EEQ, and EDP). Also, endocannabinoids are EFA derivatives with potent actions that regulate neural signaling functions.

After the recognition of EFAs in 1929, biomedical research on their actions progressed slowly until the introduction of sensitive gas chromatographic methods by 1960 that gave detailed insights to EFA occurrence and metabolism. Soon thereafter, the 1964 discovery that $n-3$ and $n-6$ HUFAs can form eicosanoids with potent physiological impacts led to an explosive expansion of biomedical research as shown in Figure 3. This interest was fueled by intensive pharmaceutical company interest in developing new drugs to moderate excessive actions of $n-6$ bioactive mediators formed by a set of metabolic steps called 'the arachidonic acid cascade.' While the pace of publication of papers on eicosanoids per se slowed after 1990, interest in the physiological impacts of $n-3$ and $n-6$ essential nutrients on a wide range of human health conditions continues to expand.

The Balance of $n-3$ and $n-6$ HUFA Actions Affect Health

The essential $n-6$ linoleic acid is a very potent and effective nutrient at very low intake levels. However, in the absence of $n-3$ nutrients, it seems to have a very narrow therapeutic window that moves readily from healthy physiology to pathophysiology. The window of safe efficacy is widened by dietary $n-3$ nutrients. That makes the balance between $n-3$ and $n-6$ EFA nutrients a vital aspect of healthy human physiology. The

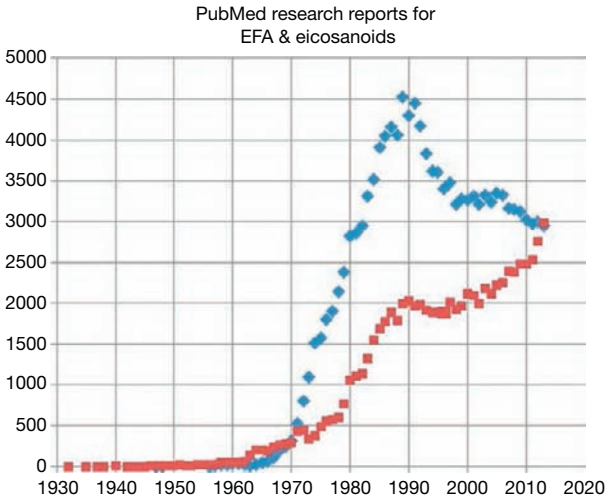

Figure 3 Research reports for EFA and eicosanoids. Squares indicate annual reports retrieved by PubMed for the combined terms: essential fatty acids or linoleic or linolenic or arachidonic or eicosapentaenoic or docosahexaenoic. Diamonds indicate annual reports retrieved for the term eicosanoids.

paradox of a therapeutic window involves both benefit and harm from an agent.

Such a situation is apparent in dose-related actions of aspirin-like NSAIDs. Increasing amounts diminish harmful actions of $n-6$ eicosanoids, whereas doses above the level that gives benefit can begin to impair needed eicosanoid-mediated actions and increase the risk of adverse side effects. While low-dose aspirin is widely used to decrease the risk of $n-6$ thromboxane-mediated heart attacks, high doses of NSAIDs have well-recognized adverse actions. In the case of dietary $n-6$ linoleate, intakes from 0.05 to 0.50 en% increasingly meet the need for essential tissue functions, whereas intakes above those amounts increase the likelihood of $n-6$-mediated overreactions with well-recognized adverse side effects that we treat with medications. Such a transition from benefit to harm is not evident for the dietary $n-3$ nutrients that compete with and moderate the $n-6$ nutrients.

Figure 4 gives the context for the impact on health conditions by $n-3$ and $n-6$ nutrients and their accumulated tissue HUFA. The proportions of $n-3$ and $n-6$ nutrients determine the proportions of $n-3$ and $n-6$ accumulated in tissue HUFA. This makes the $\%n-6$ in HUFA a useful biomarker for average dietary EFA intakes. When the stored $n-3$ and $n-6$ HUFAs are released in the tissues, they are converted by cyclooxygenases to prostaglandins. Slower rates of the formation of $n-3$ than $n-6$ prostaglandins and weaker actions of the $n-3$ than $n-6$ mediators at selective receptors cause greater proportions of $n-3$ than $n-6$ HUFA to give less severe signaling (and pathophysiology). These dynamics are evident in cardiovascular disease (CVD) and heart attacks that are so prevalent in Americans. Excessive $n-6$ mediator signaling leads to greater inflammation and oxidative stress in atherosclerotic vascular wall plaques and in greater thromboxane-activated platelet-mediated thrombosis. Such conditions are less frequent in people with 50% $n-6$ in HUFA than with a typically American value of 78% $n-6$ in HUFA. In this way, the $\%n-6$ in HUFA is a useful biomarker for health risk assessment (HRA).

When stored $n-3$ and $n-6$ HUFAs are released in the tissues, they are also converted by lipoxygenases to leukotrienes. A 10- to 20-fold slower formation of $n-3$ than $n-6$ cysteinyl leukotrienes gives less intense signaling in bronchopulmonary conditions like asthma and chronic obstructive pulmonary disorder. Also, the 50-fold weaker actions of the $n-3$ leukotriene B5 (LTB5) compared to $n-6$ LTB4 at its selective receptor give much less intense amplification of inflammatory conditions in people with 50% $n-6$ in HUFA than with 78% $n-6$ in HUFA. The potent amplification of immune-mediated inflammatory conditions by $n-6$ LTB4 (rather than $n-3$ LTB5) causes many widespread and diverse impacts on human health. These effects are mediated by increasing the formation and action of inflammatory cytokines and chemokines, which can further amplify many harmful health conditions.

A growing number of biomedical research reports (Figure 3) link imbalanced $n-3$ and $n-6$ EFA intakes and excessive $n-6$ eicosanoid actions to unwanted health conditions, including arthritis, asthma, atherosclerosis, bone loss, cancer growth, heart attacks, depression, and suicide; length of hospital stays; classroom disruptions; oppositional behavior; unproductive workplace behavior; and annual healthcare costs.

Three examples in Figure 5 show how the biomarker for the balance of EFA intake, the $\%n-6$ in HUFA, provides a useful HRA measurement for predicting the risk of several unwanted conditions. Coronary heart disease (CHD) mortality rates per 100 000 people are much higher for people with more than

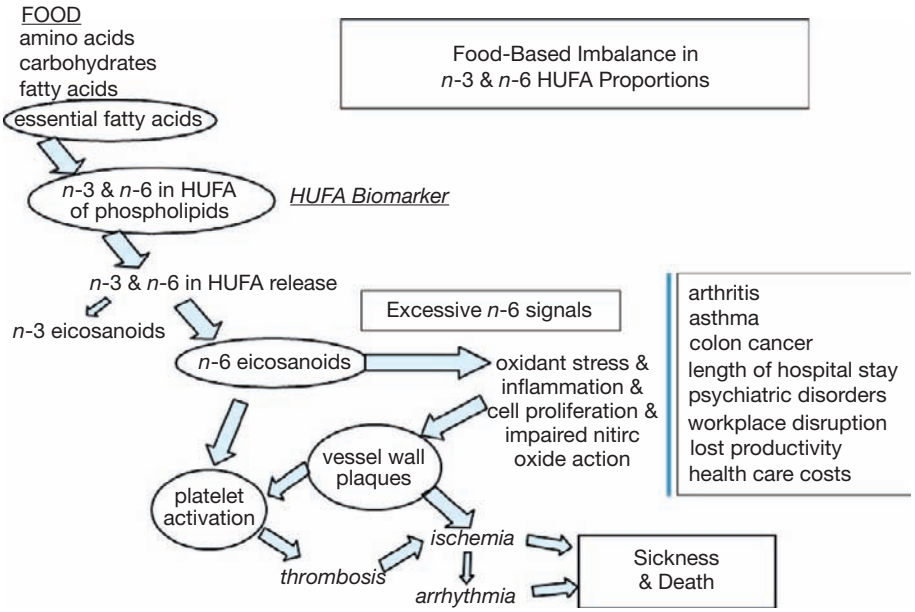

Figure 4 Food-based imbalances in $n-3$ and $n-6$ HUFA proportions. The HUFAs accumulated in phospholipids are released by phospholipase and form eicosanoids that amplify oxidative and inflammatory processes, which lead to many unwanted health conditions. Modified from Lands, B. (2014). Historical perspectives on the impact of $n-3$ and $n-6$ nutrients on health. *Progress in Lipid Research* **55**, 17–29. Internet: http://www.sciencedirect.com/science/article/pii/S0163782714000253, with permission.

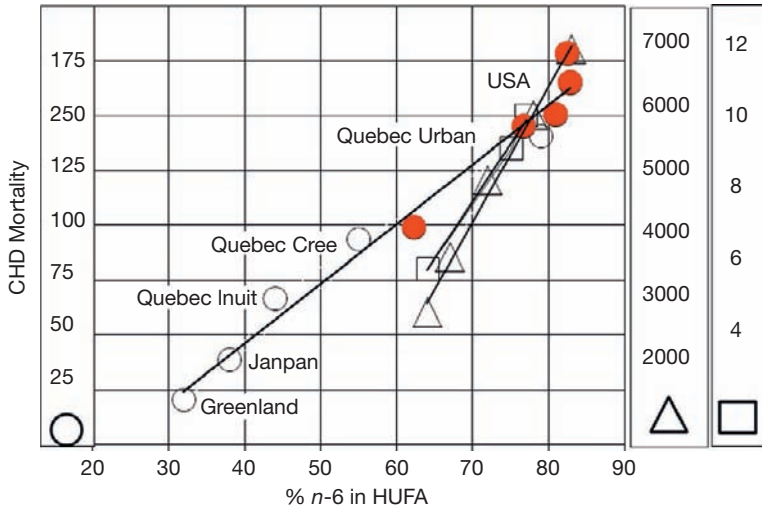

Figure 5 The risk of adverse conditions is higher for people with more than 50% *n*-6 in HUFA CHD mortality rates (per 100 000 people) for different ethnic groups, indicated by circles, with closed circles representing the quintiles in the large US MRFIT study. Annual healthcare claims (in $US) from diverse American groups are noted with triangles. Average hours per day of pain in a randomized, controlled clinical trial are noted with squares.

50% *n*−6 in HUFA than for those with less. People in the lowest quintile of the large US MRFIT study had an estimated HRA value near 62%, and they had nearly half the incidence of CHD as those in the upper four quintiles. A similar relationship was seen for CVD in two large clinical studies. Fragmentary evidence of annual healthcare claim costs from diverse American groups with HRA values ranging from 82% to 64% shows lower annual expenses for people with lower HRA values. In a recent randomized, controlled clinical trial that carefully lowered the intake of competing omega-6 nutrients while increasing the omega-3 nutrients, the HRA value went from 77% to 61% *n*−6 in HUFA, and the average hours of pain per day was lowered by 44% in 3 months.

Omega-6 Eicosanoids Amplify Transient Insults into Chronic Injuries

The chronic inflammatory damage to the blood vessels during atherogenesis is a well-recognized precursor of thrombotic heart attacks. These conditions are known to be made worse by the actions of *n*−6 eicosanoids. However, the contribution of *n*−6 EFA to this situation has not been widely recognized in public health messages that focus on predictive risk factors related to food energy toxicity. High food energy density and caloric imbalances were recognized long ago to accompany higher risks of CVD, although explicit causal mechanisms that need to be prevented remained uncertain. Decreasing associated predictive factors without removing the major causal factor seems unethical as it creates a sense of risk removal while leaving the causal factor undiminished to continue causing harm and a need for treatment.

Many people regard obesity, the visible biomarker of an imbalance in food energy intake and expenditure, to have a causal role in the risk for CVD. Elevated blood cholesterol levels, long recognized to be associated predictively with CVD, are also regarded by many to be a cause of CVD. Massive financial investments in biomedical studies have gathered evidence to support or disprove both hypotheses. However, a clear causal mechanism by which these two biomarkers cause death has not yet been identified and prevented.

Food energy per se poses little health problem if it enters the body's metabolism at a rate slow enough to be expended by the normal biological actions of work, exercise, or building body tissues. Unfortunately, modern lifestyles include much time spent sleeping, eating, driving a car, riding public transit, standing in line, using computer or Internet, reading, and watching television, activities that tend to burn only 200 cal $3\,h^{-1}$. As a result, a 1200 kcal meal (commonly consumed when eating out) will provide an extra 1000 kcal during the next 3 h that the liver will likely convert to triacylglycerols and cholesterol (Figure 6). An important dimension of food is energy density (kcal g^{-1}) that causes an apparently small amount of food to deliver many calories per mouthful and easily give many more kcal per hour than is expended. Figure 6 shows some of the biomarkers and mediators for the resulting food energy toxicity and how the food energy per hour interacts with the food *n*−6 per *n*−3 nutrients.

The 1984 NIH Cholesterol Consensus Conference noted that elevated blood cholesterol results from a food energy imbalance. The conference urged that the first step in the treatment of people who have blood cholesterol levels between 220 and 280 mg dl^{-1} should be diet therapy and caloric restriction, because weight loss and moderate physical exercise can lower the blood cholesterol biomarker. It also urged that the use of drugs to lower blood cholesterol should be used only after using the most rigorous diet modification appropriate for the individual. The conference added that "even when use of drugs seems appropriate, it is important to stress that maximal diet therapy should be continued."

Because high food energy density is associated with both CVD and elevated blood cholesterol levels, blood cholesterol has a logical predictive association with CVD. Even though the association does not prove causality, the public perception is that cholesterol causes CVD deaths. However, results from a large, long-term multiethnic study indicate that cholesterol's predictive relationship may occur only to the degree that people have more *n*−6 HUFA than *n*−3 HUFA and the resulting

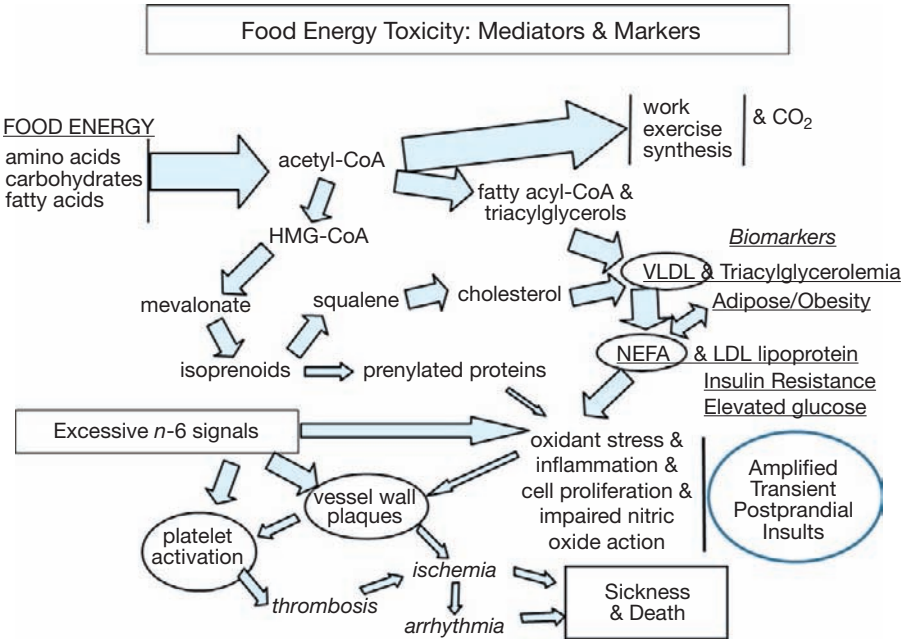

Figure 6 Food energy toxicity: Markers and mediators. Food energy that is not converted to work and CO_2 forms cholesterol and triacylglycerols that are released to plasma as very-low-density lipoproteins (VLDLs). Hydrolysis of VLDL produces nonesterified fatty acids that cause transient postprandial insults that are amplified into fatal chronic disorders by excessive *n*-6 eicosanoid actions. Modified from Lands, B. (2014). Historical perspectives on the impact of *n*-3 and *n*-6 nutrients on health. *Progress in Lipid Research* **55**, 17–29. Internet: http://www.sciencedirect.com/science/article/pii/S0163782714000253, with permission.

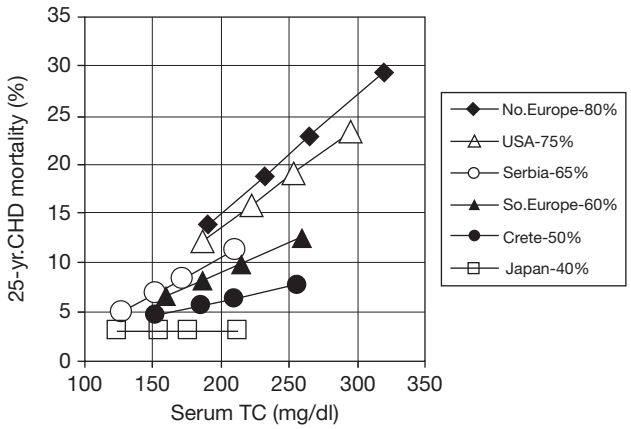

Figure 7 HUFA imbalance controls risk prediction by a food energy biomarker. Fatal heart attack risk may be predicted by blood cholesterol levels only to the degree that *n*-6 exceeds *n*-3 HUFA. Modified from Lands, B. (2014). Historical perspectives on the impact of *n*-3 and *n*-6 nutrients on health. *Progress in Lipid Research* **55**, 17–29. Internet: http://www.sciencedirect.com/science/article/pii/S0163782714000253, with permission.

excess of *n*−6 eicosanoid mediators amplifies transient insult of food energy toxicity into chronic inflammatory plaques with their prothrombotic actions. Figure 7 shows that blood cholesterol levels have no clear relationship to death rates in Japan, where the *n*−3 and *n*−6 HUFAs are well balanced.

Cholesterol has a strong relationship with CVD for people in northern Europe or the United States, where dietary habits maintain the HUFA balance near 75–80% *n*−6 in HUFA. In these people, every large meal with its transient postprandial insult (Figure 6) has a higher probability of producing chronic inflammatory conditions. This evidence can help the public turn its attention away from decreasing the noncausal predictive biomarker of cholesterol toward decreasing the causal biomarker of the %*n*−6 in HUFA. This will likely lead to a successful preventive nutrition intervention, which has eluded the public for so long.

Using Knowledge of EFA Contents for Effective Preventive Nutrition

The previously mentioned discussion of causal mechanisms by which EFA balance affects health creates a high priority for informing individuals of their current HUFA balance and the

balance of $n-3$ and $n-6$ nutrients in the foods they typically eat. With such information in hand, people can begin to reverse the unintended consequences that come from including certain staples in their diet. An important step in this approach was to describe the quantitative way by which eleven major dietary $n-3$ and $n-6$ EFAs affect the accumulated balance of HUFA in tissues. An empirical equation describing this process was developed in 1992 and followed in 2011 by the development of Omega-3–6 Balance Scores. The scores compress data on milligrams per kilocalorie for 11 different EFAs in a food into a single value that indicates the likely impact of the food on the HRA measure, $\%n-6$ in HUFA. Positive values indicate that the food will increase the $\%n-3$ in HUFA, and negative values indicate that the food will increase the $\%n-6$ in HUFA.

Hundreds of vegetables like potatoes, onions, and cabbage have scores near 0, indicating a balance between $n-3$ and $n-6$ nutrients. However, potato salad (-21), potato chips (-33), fried onion rings (-11), and coleslaw (-14 to -33) provide much more $n-6$ than $n-3$ because of added food oils (-36 to -80) and mayonnaise (-32 to -68). While most staple foods have balanced EFA, current processing and marketing procedures have unknowingly altered the balance toward harmful health consequences. Of the top 100 foods eaten by Americans (average score $=-6.2$), eleven have high negative scores between -17 and -50, and only five foods have positive scores ($+2$ to $+5$). No seafood (e.g., solid white tuna, $+46$; wild salmon, $+73$; and herring, $+70$) is on the list.

A hundred legumes (peas and beans) have scores near 0, but soybeans (-17) and peanuts (-29) have very negative scores plus a high energy density from their oil content (**Table 1**). These two legumes and their oils may cause Americans to have 76–80% $n-6$ in HUFA in contrast to a value near 60% for people in Mediterranean coastal villages. Some unintended consequences of such regional food habits that affect HRA values are reflected in **Figure 5**. Annual healthcare costs may be much less for people with HRA values near 50% compared to those with values near 80%. Public health experts estimate that more than half of American healthcare costs are for preventable health conditions, and many of those conditions are worsened by excessive $n-6$ eicosanoid actions. Public recognition that dietary $n-6$ linoleate in the absence of $n-3$ nutrients has a very narrow (to almost nonexistent) therapeutic window may begin to build a broader awareness of benefits from foods that help people NIX the 6 and EAT the 3.

From Dietary Fats to FAs

Fatty acids (FAs) are the compounds of animal and vegetable fats and oils, also found in cell membranes as a component of phospholipids. They represent a class of long hydrocarbon chain molecules (C4 to C28 atoms) with a terminal carboxylate group. The common dietary source of FAs is dietary fats, which are degraded to the final digestive products monoglycerides and free FA. In the body, most FAs are stored as triacylglycerols (TGs), the uncharged esters of glycerol and three FAs.

The term fats or lipids is a common name for large spectra of chemical compounds, including TGs, phospholipids, and cholesterol, originating from the organism or from food. The main lipids in humans, such as TGs or less abundant glycerophospholipids, glycoglycerolipids, and sphingolipids, are the esters of FAs and different alcohols. TGs constitute 90% of dietary lipid and provide 30–40% of daily energy intake in the Western world. In addition, ordinary diet contains a small amount of phospholipids and cholesterol esters (also having FAs in their structure) and free cholesterol.

The digestion of TGs is dynamic and complex process supported by water-soluble digestive enzymes, bile acids, and motion of the digestive tract, predominantly taking place in the small intestine. Lingual lipase from saliva is the first enzyme meeting fats in the mouth. Its enzymatic activity, together with physical action of chewing, and emulsifying activity of phospholipids represent the first step in the digestion of TGs. As a result, the fats form the tiny droplets and become more accessible to the digestive enzymes. Aided by stomach's churning and contractions, gastric lipase stars with the breakdown of TGs into diglycerides and FAs, but almost complete TGs digestion occurs in the small intestine. Due to the action of the bile, lipid droplets in the intestine became emulsified increasing the surface area over a thousandfold and therefore being more exposed to lipase activity. Pancreatic lipase is the most important fat digestive enzymes. It acts on TGs at water–lipid interfaces of bile micelles and with the assistance of colipase accesses the TGs in the inner lipid core to hydrolyze the ester links in positions 1–3. The final products of fat digestion are monoglycerides and free FAs, which are absorbed into intestinal epithelial cells.

Triacylglycerols, Phospholipids, and Cholesterol

TGs are the uncharged esters of glycerol and three FAs. On one hand, they are the predominant type of lipid ingested by humans and consequently the primary source of free FAs; on the other, they are synthesized in humans by two main biosynthetic pathways, the *sn*-glycerol-3-phosphate pathway in liver and adipose tissue and a monoacylglycerol pathway in the intestines. FAs derived from triacylglycerols are absorbed into enterocytes to be reesterified into TG. Packed with proteins and phospholipids, TGs in the form of lipoprotein particles, chylomicrons, enter the lymphatic system and the blood to be transported from the small intestine to other tissues.

The phospholipids, the main component of biomembranes, are present in different foods but mostly in fats, oils, meats, nuts, wheat germs, and egg yolks. Their structure is similar to TGs, with a phosphorus molecule in the location of one FA. Phospholipids from the diet are cleaved at position 2 by pancreatic phospholipase A_2, releasing the lysophospholipids and the free FAs.

Ordinary diet also contains a small amount of cholesterol, originating from animal sources (meat, egg yolks, diary fats, and butter). Cholesteryl esters, in which cholesterol is esterified with long-chain FAs (usually linoleic acid (LA)), are the main form of cholesterol in the diet. The pancreatic enzyme cholesterol esterase hydrolyzes cholesteryl esters to free cholesterol and FA. Cholesterol by itself is a steroid compound that does not contain FAs, but shows some physical and chemical characteristics of fat, like fat origin and fat-like metabolism. Comparing to phospholipids and TGs, it is poorly absorbed from the diet.

There are plenty of different FAs occurring in dietary fats, as well as in plant and animal tissues. To be better described, they are named and classified according to their composition, structure, and properties.

FAs Nomenclature

The nomenclature of FAs relies on three main FA characteristics:

- The length of the hydrocarbon chain
- The degree of unsaturation (double bond)
- The position of the double bonds in the chain

The systematic name for a single FA is the name of its parent hydrocarbon with the final 'e' substituted with 'oic.'

Parent hydrocarbon	Fatty acid
Octadecane	Octadecanoic C18

The number of double bonds is given with the prefix 'en,' 'dien,' 'trien,' 'tetraen,' and so on, before 'oic.'

C18 with:	Name
No double bond	Octadecanoic
One double bond	Octadecanoic
Two double bonds	Octadecadienoic
Three double bonds	Octadecatrienoic

The position of double bond is derived from numbering of FA carbon atoms that starts at the carboxyl terminus as a C1. Carbon atoms 2 and 3 are often referred to as α and β, respectively. In the same manner, the carbon farthest from carboxyl terminus (C atom from methyl group) is called the ω (**Figure 1**).

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00277-4

The symbol Δ with the superscript number (Δ^n) is used to represent the position of double bond, where n indicates lower-numbered carbon of each pair. For example, the *cis*-Δ^9 means that there is a *cis*-double bond between carbon atoms 9 and 10; *trans*-Δ^2 means that there is a *trans*-double bond between carbon atoms 2 and 3.

Altogether, the systematic name for a single FA (common name arachidonic acid (AA) and scientific name 5,8,11, 14-eicosatetraenoic acid) is derived like this:

Total carbons	20
Double bonds	4
Double bonds positions	$\Delta^{5,8,11,14}$
Systematic name	$20{:}4\Delta^{5,8,11,14}$

Alternatively, FA could be named according to a double bond distance from the ω carbon atom, which is in that case numbered as 1. The known examples are ω-3 and ω-6 FAs.

FA Composition and Structure

FAs vary in the length of their carbon chains, mostly having an even number of carbons, typically between 12 and 24. Their hydrocarbon chain may be saturated or it may contain one or more double bonds separated by at least one methylene group (Figure 2).

Based on the number of carbon atoms, FAs are as follows:

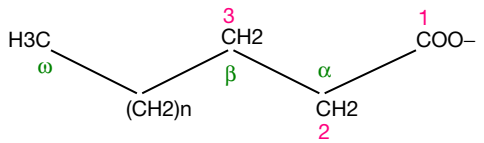

Figure 1 The numbering of carbon atoms in fatty acid hydrocarbon chain.

Short-chain fatty acids	<8 carbons
Medium-chain fatty acids	8–14 carbons
Long-chain fatty acids	≥16 carbons
Very-long-chain fatty acids	>22 carbons

According to the degree of desaturation, FAs are as follows:

Saturated fatty acids (SFA)	No C–C double bonds
Unsaturated fatty acids (USFA)	At least one C–C double bond
Monounsaturated fatty acids (MUFA)	Only one C–C double bond
Polyunsaturated fatty acids (PUFA)	Two or more C–C double bonds

All double bonds in naturally occurring FAs are in the *cis*-conformation, with two pieces of the carbon chain on the same side of the molecule, both 'up' or both 'down.' Thus, due to *cis*-double bond (Figure 3), the carbon tails of unsaturated FAs have the kinks.

The *trans*-conformation mostly appears by the conversion of naturally occurring *cis*-bonds, when unsaturated plant oils are used for frying. In *trans*-bond, two pieces of the molecule are on opposite sides of the double bond, one 'up' and other 'down,' across from each other. The most common SFAs, MUFAs, and PUFAs are listed in Table 1.

There is also a group of FAs, *branched-chain FAs*, with acyl branch(es) connected to the hydrocarbon chain (Figure 4). Normally, their carbon chain is saturated with an odd number of carbon atoms, and the branch is a methyl group usually giving an even number of carbons in total. Branched-chain FAs are common constituents of the bacterial lipids. They also represent the 1–2% of total FAs in mammalian tissues, derived mainly from bacteria from ruminant intestine, while they are very rarely found in the integral lipids of higher plants.

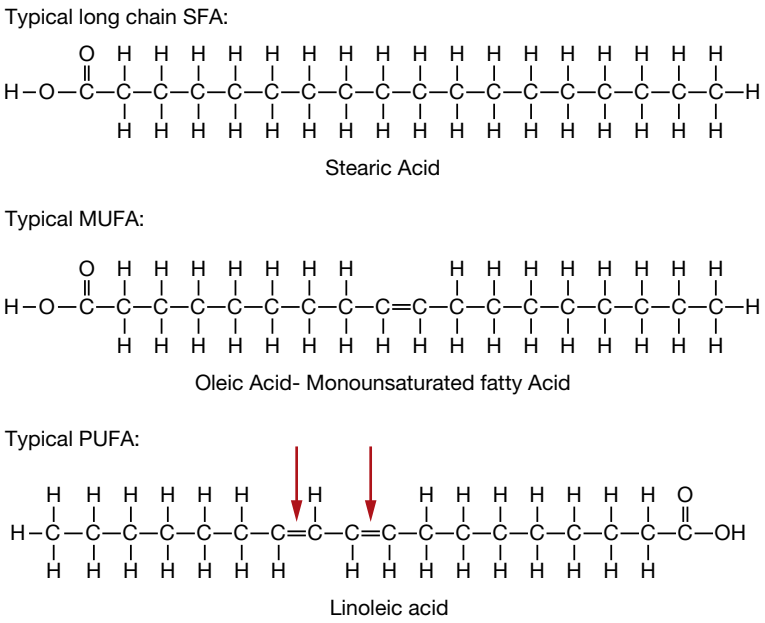

Figure 2 The structural formulas of typical long-chain saturated fatty acid, monounsaturated fatty acid, and polyunsaturated fatty acid.

FAs with the ring in the carbon chain structure are *cyclic FAs* (Figure 5). They are derived from appropriate monounsaturated FAs, such as oleic, linoleic, and linolenic acids. The ring is commonly cyclopropene or cyclopentene. Cyclopropane FAs (CPA-FAs) and cyclopropene FAs (CPE-FAs) have three-member carbocyclic ring. They are found in bacteria and some plants, especially in the seeds of plants belonging to families: Bombacaceae, Malvaceae, Sterculiaceae, Leguminosae, and Ranunculaceae.

Properties of FAs

The properties of FAs and lipids derived from them are markedly dependent on their structure, especially on FAs' chain length and degree of desaturation. The difference occurs in the temperature of melting point, fluidity at room temperature, water solubility (or hydrophobicity), and susceptibility to oxidation and reduction.

The temperature of melting point is influenced by FA structure in the way that it is lower for unsaturated FA compared with saturated FA of corresponding size. For example, the melting point of palmitic acid (C16) is 63 °C, whereas that of palmitoleic acid (C16, which contains one *cis*-double bond) is 0 °C. It happens because the straight hydrocarbon chain of saturated FA favors highly ordered molecules packing, increasing the melting point of FA. On the other side, the *cis*-double bond(s) introduces a kink in the shape of unsaturated FAs, preventing FA molecules to be closely packed and therefore leading to melting point decrease. In opposite, due to its different orientation, the *trans*-double bond favors again linear molecular shape, which helps molecules to pack together in a stable repeating array, resulting in the higher melting point of *trans*-double bond isomers. For example, the *trans*-double bond isomer of oleic acid (elaidic acid) has a melting point of 45 °C and *cis*-oleic acid 13 °C. The fatty acyl chains interact more strongly as the chain length extended with each newly added –CH_2-, increasing the melting points of long-chain FAs compared with shorter-chain FA. In addition, the FA melting points decrease with chain branching, being higher for FA with odd-number carbon chains than for FA with even-number carbon chains. The FA fluidity at room temperature is in strong connection with their melting point. SFA and their derivatives are usually in solid state at room temperature, while MUFA, PUFA, and their derivatives are liquid.

Table 1 Examples of saturated, monounsaturated, and polyunsaturated fatty acids

Common name	*Chemical structure*	*Scientific notation C: double bonds*
Caprylic acid	$CH_3(CH_2)_6COOH$	8:0
Capric acid	$CH_3(CH_2)_8COOH$	10:0
Lauric acid	$CH_3(CH_2)_{10}COOH$	12:0
Myristic acid	$CH_3(CH_2)_{12}COOH$	14:0
Myristoleic acid	$CH_3(CH_2)_3\mathbf{CH}=\mathbf{CH}(CH_2)_7COOH$	14:1*n*−5
Palmitic acid	$CH_3(CH_2)_{14}COOH$	16:0
Palmitoleic acid	$CH_3(CH_2)_5\mathbf{CH}=\mathbf{CH}(CH_2)_7COOH$	16:1*n*−7
Stearic acid	$CH_3(CH_2)_{16}COOH$	18:0
Oleic acid	$CH_3(CH_2)_7\mathbf{CH}=\mathbf{CH}(CH_2)_7COOH$	18:1*n*−9
Vaccenic acid	$CH_3(CH_2)_5\mathbf{CH}=\mathbf{CH}(CH_2)_9COOH$	18:1*n*−7
Linoleic acid	$CH_3(CH_2)_4\mathbf{CH}=\mathbf{CH}CH_2\mathbf{CH}=\mathbf{CH}(CH_2)_7COOH$	18:2*n*−6
α-Linolenic acid	$CH_3CH_2\mathbf{CH}=\mathbf{CH}CH_2\mathbf{CH}=\mathbf{CH}CH_2\mathbf{CH}=\mathbf{CH}(CH_2)_7COOH$	18:3*n*−3
Arachidic acid	$CH_3(CH_2)_{18}COOH$	20:0
Arachidonic acid	$CH_3(CH_2)_4\mathbf{CH}=\mathbf{CH}CH_2\mathbf{CH}=\mathbf{CH}CH_2\mathbf{CH}=\mathbf{CH}CH_2\mathbf{CH}=\mathbf{CH}(CH_2)_3COOH$	20:4*n*−6
Eicosapentaenoic acid	$CH_3CH_2\mathbf{CH}=\mathbf{CH}CH_2\mathbf{CH}=\mathbf{CH}CH_2\mathbf{CH}=\mathbf{CH}CH_2\mathbf{CH}=\mathbf{CH}CH_2\mathbf{CH}=\mathbf{CH}(CH_2)_3COOH$	20:5*n*−3
Behenic acid	$CH_3(CH_2)_{20}COOH$	22:0
Erucic acid	$CH_3(CH_2)_7\mathbf{CH}=\mathbf{CH}(CH_2)_{11}COOH$	22:1*n*−9
Docosahexaenoic acid	$CH_3CH_2\mathbf{CH}=\mathbf{CH}CH_2\mathbf{CH}=\mathbf{CH}CH_2\mathbf{CH}=\mathbf{CH}CH_2\mathbf{CH}=\mathbf{CH}CH_2\mathbf{CH}=\mathbf{CH}CH_2\mathbf{CH}=\mathbf{CH}(CH_2)_2COOH$	22:6*n*−3
Lignoceric acid	$CH_3(CH_2)_{22}COOH$	24:0

The water solubility of FA also depends on the length of hydrocarbon chain. In general, FAs are poorly soluble in water, with the increase of hydrophobicity parallel to chain extension. Even more, the solubility of FA is additional hindered by their tendency to form micelles and monolayers in aquatic environment. However, FA became more water-soluble when present in the form of potassium or sodium salts, as well as in the medium with increasing pH. At the same time, FAs will be well dissolved in nonpolar solvents such as ethanol and chloroform.

In terms of the chemical susceptibility, SFAs are very stable, whereas USFAs react more easily. Here states the rule: the more double bonds, the greater reactivity.

Like other carboxylic acids, FAs can be esterified due to the exchange of groups attached to the FA carboxyl. In biological systems, this type of reactions converts FA to TGs and vice versa. Ester exchange reactions, with TG as a starting point, are also used in the manufacture of TGs enriched in medium-chain FAs, methyl esters, glycerol, or biodiesel.

Despite hydrophobicity, in aquatic environment, at suitable temperatures and pressures, FA can undergo hydrolysis, as used for the industrial production of glycerol and soaps. However, FA hydrolysis usually needs to be catalyzed by acid, base, or lipase. Lipases are enzymes that hydrolyze FAs from lipid species (e.g., TGs and phospholipids) *in vivo*. They favor the reaction of FAs with Δ9 double bond, when compared to Δ4, Δ5, or Δ6 double bond. Being active in milder conditions (less solvent and lower temperature and pressure), lipases are used for large-scale reactions in the manufacturing of confectionary fats and nutritional products (cocoa butter).

Both the double bonds and adjacent allylic carbons of FA alkyl chain are susceptible to oxidation, with higher susceptibility following higher degree of unsaturation. When exposed to air (oxygen), unsaturated FAs undergo a process of auto-oxidation, which is a free-radical chain reaction giving the allylic hydroperoxides as a final product. The process becomes much faster in the presence of light (photo-oxidation), natural pigments (chlorophyll, hematoporphyrins, and riboflavin), and dyes (erythrosine and methylene blue). *Ex vivo*, oxidation leads to the deterioration of unsaturated oils and fats, reducing their nutritional quality. Still, due to antioxidants in their content (tocopherol), most vegetable oils can resist this process. *In vivo*, enzyme-catalyzed oxidation is the initial step in the production of eicosanoids and jasmonates.

The FA alkyl chain is susceptible to reduction at both carbon–carbon double bond and the carboxyl group of FA. From nutritional point of view, attention should be given to catalytic partial hydrogenation. This is a process introducing H atoms in the double bonds, accompanied by a variable degree of *cis*- to *trans*-isomerization. Edible vegetable oils are transformed by partial hydrogenation to the solid form of margarines. The arising content of *trans*-FA in margarines is a subject of concern because of their atherogenic properties.

There are some other reactions involving FAs but mainly used for specific industrial handling and therefore not additional disused.

FA Metabolism

FAs in the body are organized in two forms: free or unesterified and esterified. In the plasma, free FAs (5% of total FA) are bound to albumin and to a lesser extent to globulins and lipoproteins. Most of the FAs in circulation (95% of total FA) are in the form of triglycerides, cholesterol esters, and phospholipids. In biological systems, FAs usually contain an even number of carbon atoms, mostly 14–24.

Synthesis of Saturated FA

Synthesis of FAs takes place in the cytosol of the liver, adipose tissue, lung, and brain. Precursor of all carbon atoms is acetyl CoA generated by oxidative decarboxylation of pyruvate, degradation of amino acids, and β-oxidation of FA.

Prior to the FA synthesis, malonyl CoA is formed from acetyl CoA by the action of acetyl CoA carboxylase, which has biotin as prosthetic group. The reaction of carboxylation is carried out in two stages. The first step is the formation of a carboxybiotin with the presence of ATP and the second step involves CO_2 transfer to acetyl CoA and formatting of malonyl CoA:

$$HCO_3^- + ATP + Enzyme - Biotin \rightarrow Enzyme - Biotin - CO_2^- + ADP + P_i$$

$$Enzyme - Biotin - CO_2^- + acetyl\ CoA \rightarrow malonil\ CoA + Enzyme - Biotin$$

After synthesis of malonyl CoA, a series of four reactions in repeating cycle follows: condensation, reduction, dehydration, and reduction, which lead to the extension of the FA chain.

The FA synthesis starts with covalently binding of acetyl CoA and malonyl CoA to the sulfhydryl group of an acyl carrier protein (ACP) and formation of acetyl ACP and malonyl ACP. Enzymes that catalyze these reactions are acetyl transacylase and malonyl transacylase. Afterward, the reaction of condensation follows, in which acetyl ACP and malonyl ACP form acetoacetyl-ACP (β-ketoacyl ACP) under the action of acyl-malonyl-ACP synthase (β-ketoacyl-synthase) and CO_2 is released. In the third step, acetoacetyl-ACP is reduced to D-β-hydroksybutyryl-ACP, with NADPH as a reductant, by the action of β-ketoacyl-ACP reductase. The following is the process of dehydration: D-β-hydroksybutyryl-ACP to α, β-*trans*-butenoyl-ACP (crotonyl-ACP) in the presence of 3-hydroxyacyl-ACP dehydratase. Finally, crotonyl-ACP is reduced to butyryl-ACP by enoyl-ACP reductase (Table 2). In the following reactions, butyryl-ACP reacts with malonyl-ACP and the cycle is repeated.

The synthesis of FA is continued up to palmitoyl-ACP (a total of 7 cycles) that is then cleaved to palmitate and ACP under the influence of thioesterase:

$$Palmitoil - ACP + H_2O \rightarrow palmitate + ACP$$

The syntheses of SFA, of up to 16 carbons in length, are catalyzed by the enzyme system that is called the fatty acid synthase (FAS). Mammalian FAS is a homodimer, found in the cytoplasm, consisted of the 250-kDa subunits containing three domains each. Domain 1 includes enzymes acetyl transacylase, malonyl transacylase, and acyl-malonyl-ACP, while domain 2 contains ACP, β-ketoacyl-ACP reductase, β-hydroxyacyl-ACP dehydratase, and enoyl-ACP reductase. Domain 3 contains thioesterase enzymatic activities. Unlike the eukaryotes where FAS is a large polypeptide chain with seven different enzymatic activities in two catalytic centers, in bacteria, FAS is a multienzyme complex consisting of six different enzymes plus a separate ACP.

Table 2 Reaction in fatty acid synthesis

Reaction	*Enzyme*
Acetyl CoA + ACP ↔ acetyl − ACP + CoA	Acetyl transacylase
Malonyl CoA + ACP ↔ malonyl − ACP + CoA	Malonyl transacylase
Acetyl − ACP + malonyl − ACP ↔ acetoacetyl − ACP + ACP + CO_2	Acyl-malonyl-ACP synthase
Acetoacetyl − ACP + NADPH + H^+ ↔ D-β-hydroxybutyryl − ACP + $NADP^+$	β-Ketoacyl-ACP reductase
D-β-Hydroxybutyryl − ACP ↔ crotonyl − ACP + H_2O	3-Hydroxyacyl-ACP dehydratase
Crotonyl − ACP + NADPH + H^+ → butyryl − ACP + $NADP^+$	Enoyl-ACP reductase

The final product of FA synthesis by FAS complex, which utilizes NADPH as reductant, is palmitate. In summary, stoichiometry for synthesis of palmitate can be presented with the following reaction:

$$8\ \text{acetyl CoA} + 14\ \text{NADPH} + 7\ \text{ATP} \rightarrow \text{palmitate} + 14\ \text{NADP}^+ + 8\ \text{CoA} + 7\ \text{ADP} + 7\ \text{Pi}$$

FA synthesis occurs in the cytosol using acetyl CoA, which is generated in the mitochondria. Since the transport of acetyl CoA through the mitochondrial membrane is not possible, acetyl CoA is transferred to the cytosol with the use of citrate. Citrate, formed in the mitochondrial matrix, in reaction of acetyl CoA and oxaloacetate, passes across the inner mitochondrial membrane and enters the cytosol. In the cytosol, under the influence of ATP citrate lyase, citrate is cleaved to acetyl CoA and oxaloacetate.

Synthesis of Long-Chain FA

FAs in the cells, produced by FAS or taken up from the diet, may be elongated into long-chain FAs containing 18 carbon atoms or more. Synthesis of long-chain PUFA in mammalian tissues is performed in the endoplasmic reticulum using 4 enzymes; three of these are on cytosolic side of the ER membrane and the fourth is embedded in the membrane. The formation of long-chain FAs starts the same as with FAS, with the reaction of malonyl CoA and acyl CoA and formation of β-ketoacyl CoA, in the presence of elongases. This is followed by the reactions of reduction, dehydration, and repeated reduction to form the acyl chain that is extended with 2C atoms. *Three enzymes are involved*: 3-ketoacyl CoA reductase, 3-hydroxyacyl CoA dehydratase, and 2,3-*trans*-enoyl CoA reductase. In mammals, condensation reaction is catalyzed by enzymes of elongation, known as elongases of very-long-chain fatty acids (ELOVLs). There are seven ELOVLs including elongases 1, 3, 6, and 7 involved in the elongation of SFA and MUFA and elongases 2, 4, and 5 involved in the elongation of PUFA. Microsomal cell vesicles containing the endoplasmic reticulum fraction possess the highest enzyme activity for acyl CoA elongation.

Unsaturated FAs are synthesized by introducing a double bond at a specific position on the acyl chain of long-chain FAs, using the enzyme acyl CoA desaturase. These desaturases are present in the membrane of endoplasmic reticulum and use fatty acyl CoA as substrates and cytochrome b_5 as an electron donor. The desaturases can be divided into two distinct families referred to as stearoyl CoA desaturases (SCDs) or Δ9 desaturase and FA desaturases (FADS), which included Δ6 and Δ5 desaturases.

The conversion of saturated to monounsaturated FA is carried by Δ9 desaturase. This enzyme introduces the first *cis*-double bond at position 9, 10 from the carboxyl end of FAs. The reaction is catalyzed by three enzymes: NADH-cytochrome b_5 reductase, cytochrome b_5, and Δ9 desaturase:

$$\text{NADH} \rightarrow \text{FAD} \rightarrow \text{cyt } b_5 \rightarrow \text{desaturase}$$

$$\text{Stearoyl CoA} + \text{NADH} + H^+ + O_2 \rightarrow \text{oleoyl CoA} + \text{NAD}^+ + 2H_2O$$

The syntheses of PUFA are catalyzed by Δ6 desaturase and Δ5 desaturase. The Δ6 desaturase can introduce a double bond at position Δ6 of the essential FAs of the $n-6$ (LA C18:2$n-6$) and $n-3$ family (α-linolenic acid (ALA) C18:3$n-3$) (Figure 6). After the reactions of desaturation and elongation by Δ6 desaturase and elongase, Δ5 desaturase introduces another double bond at position Δ5 of 20-carbon chain in 20:3$n-6$ and 20:4$n-3$ (Figure 6). The synthesis of docosahexaenoic (DHA) (22:6$n-3$) is carried out from the 22:5$n-3$ through two successive elongations, accompanied by Δ6 desaturation of 24:5$n-3$ in 24:6$n-3$, and followed β-oxidation in peroxisomes to DHA (Figure 6).

Opposite to plants, mammals lack Δ12 and Δ15 desaturases, which introduce double bonds at carbon atoms beyond C9 in the FA chain, and cannot synthesize LA and ALA *de novo*. Thus, these FAs are essential for mammals and must be obtained from food.

Catabolism of FAs

FA Activation

FAs primarily enter a cell via FA protein transporters on the cell surface. FA transporters include FA translocase, tissue-specific FA transport proteins, and plasma membrane-bound FA-binding protein. Depending on the tissue and its metabolic demand, FAs in cell can be converted to either triacylglycerols or membrane phospholipids or oxidized in the mitochondria for energy production. Before this processes, FAs must be activated to acyl CoA. The reaction of activation, taking place on the outer mitochondrial membrane, is catalyzed by acyl CoA synthase (or FA thiokinase) to form an acyl adenylate. In the second reaction, sulfhydryl group of CoA attacks the acyl adenylate and forms acyl CoA and AMP:

$$\text{R} - \text{COO}^- + \text{ATP} + \text{HS} - \text{CoA} \leftrightarrow \underset{\text{acyl adenilate}}{\text{R} - \text{CO} - \text{AMP}} + \text{PPi}$$

$$\text{R} - \text{CO} - \text{AMP} + \text{HS} - \text{CoA} \leftrightarrow \underset{\text{acyl CoA}}{\text{R} - \text{CO} - \text{CoA}} + \text{AMP}$$

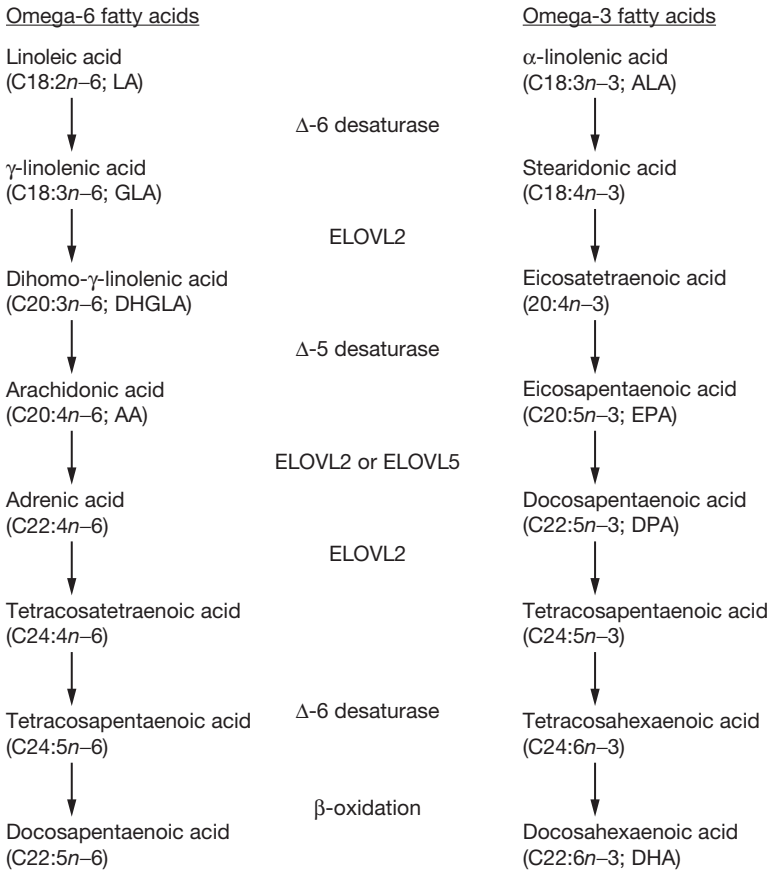

Figure 6 Biosynthesis of long-chain fatty acids.

Transport of FA into Mitochondria

The process of FA activation occurs at the outer mitochondrial membrane, whereas the process of β-oxidation of FA takes place in the mitochondrial matrix. Short- and medium-chain acyl CoA are transported into the mitochondrial matrix directly, but the transfer of long-chain acyl CoA through inner mitochondrial membrane requires a special transport mechanism. Carnitine and three proteins are included in the FA transport into mitochondrial matrix. In the first reaction, the acyl CoA reacts with carnitine and forms acyl carnitine. Reaction is catalyzed by carnitine acyltransferase I (also called carnitine palmitoyltransferase I, CTP-I) located in the outer mitochondrial membrane. An acyl carnitine is transported across the inner mitochondrial membrane by a translocase, with simultaneous transfer of carnitine from the matrix to cytosolic side. In the mitochondrial matrix, acyl carnitine is converted back to acyl CoA in a reaction catalyzed by carnitine acyltransferase II (CTP-II), releasing the carnitine. The acyl CoA then undergoes the process of β-oxidation.

Oxidation of FA

FA β-oxidation is the process by which FAs are broken down to produce energy. The β-oxidation of SFA is a process that involves a cycle of four repeated reactions: oxidation by flavin adenine dinucleotide (FAD), hydration, oxidation by NAD^+, and thiolysis by CoA, resulting in FAs shortened for two C atoms. The first step is the oxidation of the acyl CoA to *trans*-Δ^2-enoyl CoA catalyzed by enzyme acyl CoA dehydrogenase. The second reaction is the hydration of the *trans*-double bond in the presence of enoyl CoA hydratase and the formation of the L-3-hydroxyacyl CoA. The third reaction leads to the conversion of hydroxyl group at C3 into a keto group by L-3-hydroxyacyl CoA dehydrogenase and generates NADH. The final step is the cleavage of Cα-Cβ-bond in the reaction of thiolysis (Claisen ester cleavage), by using a thiol group of the second molecule CoA, in the presence of β-ketothiolase and the formation of acetyl CoA and acyl CoA shortened by two C atoms (Table 3).

Acyl CoA then undergoes another process of β-oxidation. At the final step of this cycle, an FA with an even number of carbons yields two molecules of acetyl CoA. The complete oxidation of palmitoyl CoA requires seven repeated cycles and stoichiometry of oxidation is as follows:

$$\text{Palmitoyl CoA} + 7\text{FAD} + 7\text{NAD}^+ + 7\text{CoA} + 7\text{H}_2\text{O} \rightarrow 8 \text{ acetyl CoA} + 7\text{FADH}_2 + 7\text{NADH} + 7\text{H}^+$$

The $FADH_2$ and NADH produced during the process of FA β-oxidation are used in the electron transport chain to produce ATP. Thus, the complete oxidation of a molecule of palmitate yields 106 molecules of ATP.

Additional enzymes, isomerase and reductase are needed for oxidation of USFA. The process of MUFA degradation begins the same way as degradation of SFA. However, *cis*-Δ^3-enoyl CoA that is formed in the third round cannot be

Table 3 Reaction in fatty acid oxidation

Reaction	*Enzymes*
Acyl CoA + E − FAD → *trans* − Δ^2 − enoyl CoA + E − $FADH_2$	Acyl CoA dehydrogenase
trans − Δ^2 − enoil CoA + H_2O ↔ L-3-hydroxyacyl CoA	Enoyl CoA hydratase
L-3-Hydroxyacyl CoA + NAD^+ ↔ 3-ketoacyl CoA + NADH + H^+	L-3-Hydroxyacyl CoA dehydrogenase

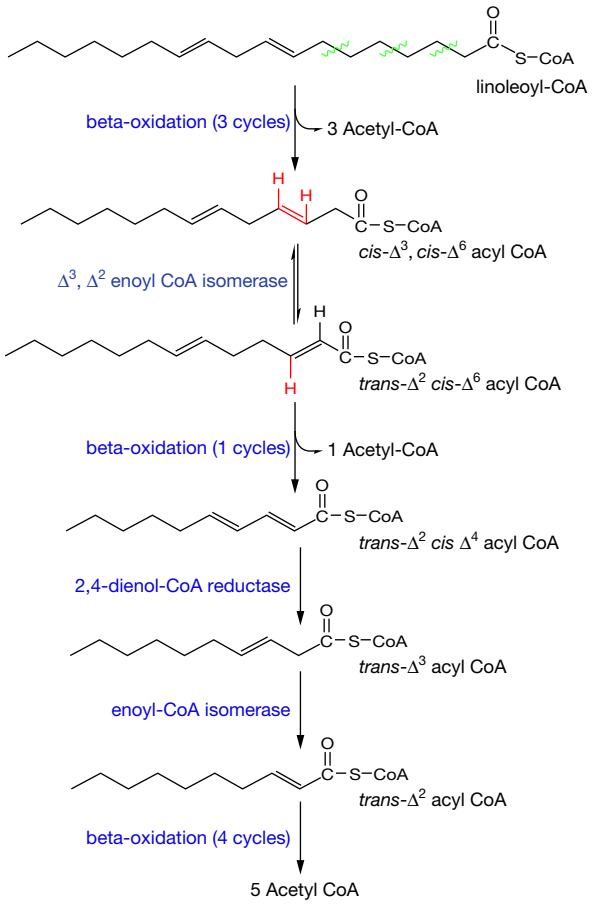

Figure 8 β-Oxidation of polyunsaturated fatty acid.

substrate for acyl CoA dehydrogenase. Therefore, isomerase catalyzes *the conversion* of *cis*-double bond between C3 and C4 into *trans*-Δ^2 double bond and forms *trans*-Δ^2enoyl CoA (Figure 7). This product is a regular substrate in FA oxidation pathway and the process can be continued.

For oxidation of PUFA, a reductase is needed. After three cycles of β-oxidation of linoyl CoA *cis*-Δ^3, Δ^6-enoyl CoA is formed. The *cis*-Δ^3 double bond is converted into a *trans*-Δ^2 double bond by an isomerase. In another round, an acyl CoA with a *cis*-Δ^4 double bond is produced, and its dehydrogenation yields a 2,4-dienoyl intermediate. This intermediate is not a substrate for enoyl CoA isomerase, therefore it must first be converted into *trans*-Δ^3-enoyl CoA by the enzyme 2,4-dienoyl CoA reductase, in the presence of NADPH. In the next step, enoyl CoA isomerase converts *trans*- Δ^3-enoyl CoA into the *trans*-Δ^2 form, a common intermediate in the β-oxidation pathway. (Figure 8). In the FA, β-oxidation pathway produces one acetyl CoA from each cycle of β-oxidation. This acetyl CoA then enters the citric acid cycle. The citric acid cycle, also known as the tricarboxylic acid (TCA) cycle or the Krebs cycle, is the final common pathway for the oxidation of acetyl CoA derived from carbohydrates, fats, and proteins into CO_2 and H_2O to generate a form of usable energy. The NADH and $FADH_2$ produced by both β-oxidation and the TCA cycle are used by the electron transport chain to produce ATP.

The final products of β-oxidation of FA with odd-number C atoms are the 3-carbon propionyl CoA and acetyl CoA. Propionyl CoA enters the citric acid cycle and is converted into succinyl CoA.

Acetyl CoA, which is formed in the process of β-oxidation, enters the citric acid cycle and forms citrate with oxaloacetate, if it is available. In cases of increased lipolysis, as in unregulated diabetes mellitus or in fasting, when oxaloacetate is used to form glucose, the molecules of acetyl CoA form acetoacetate and 3-D hydroxybutyrate, known as ketone bodies. Synthesis of ketone bodies, acetoacetate, hydroxybutyrate, and acetone occurs normally under all conditions, but their production is dramatically increased during starvation. Ketone bodies produced in the mitochondria of liver cells diffuse into the blood that then transports them to peripheral tissues. They are

normal fuels of respiration and very important as sources of energy. The acetoacetate is a major fuel source for the heart muscle and kidney cortex and has the advantage over the glucose, as energy source. Also, under conditions of starvation, the brain may provide even 75% of the energy from the acetoacetate, by using β-ketoacyl CoA transferase, which converted ketone bodies back to acetyl CoA.

The process of β-oxidation is also performed in the peroxisomes that have a major role in the degradation of very-long-chain FAs. In these vesicles, the end product of oxidation is octanoyl CoA. Therefore, the products of β-oxidation are transferred from peroxisomes to mitochondria and this transport is provided by carnitine. Acyl CoA oxidases in peroxisomes are different from those in mitochondria because they transfer the hydrogen to oxygen to produce H_2O_2 instead of producing $FADH_2$. The H_2O_2 is broken down to water by catalase. In peroxisomes, enzymes for α-oxidation, which are necessary for oxidation of some FAs with methyl branches, are also present. Peroxisomes lack the Krebs cycle and cannot degrade the acetyl CoA to produce CO_2 and water.

In microsomes, very-long-chain FAs are oxidized to form eicosanoids and epoxy and hydroxy FAs. Thus, prostaglandins, thromboxanes, and leukotrienes known as eicosanoids are formed from arachidonic and eicosapentaenoic acid by enzymes cyclooxygenases and lipoxygenase. Eicosanoids act as paracrine and autocrine hormones and each has specific effect in the cells. They are involved in the regulation of local inflammation, but they also modify the blood pressure, aggregation of blood platelets, and cardiac function. Additionally, eicosanoids inhibit the mobilization of FAs from adipose tissue and are included in the functions of the central nervous system and the contraction of smooth muscles.

Regulation of FA Metabolism

The availability of free FAs and the rate of utilization of acetyl CoA are the crucial factors that control FA oxidation. The release of FAs from adipose tissue is stimulated by glucagon and epinephrine and inhibited by insulin. The metabolic process that FA will undergo depends on cellular energy state.

If the energy charge of the cell is low, FA will be degraded by β-oxidation reactions to yield acetyl CoA, $FADH_2$, and NADH. The process of β-oxidation is mainly allosteric-regulated, which means that each of the β-oxidation enzymes is inhibited by the specific fatty acyl CoA intermediate it produces. Malonyl CoA is an essential metabolic intermediate in the regulation of FA oxidation. A decrease in malonyl CoA level results in an increased activity of CPT-I in mitochondria in the heart and muscle, while an increase in malonyl CoA level inhibits CPT-I activity. CTP-I catalyzes the commitment step in FA oxidation, which links acyl CoA molecules to the hydroxyl group of carnitine. In addition, activities of two other enzymes included in β-oxidation pathway are allosteric-regulated; 3-hydroxyacyl CoA dehydrogenase is inhibited by NADH and thiolase by acetyl CoA.

The synthesis of FA is carried out if the energy charge is high in the cells and when the level of FAs is low. Enzyme acetyl CoA carboxylase plays an essential role in regulating FA synthesis and degradation. This process is hormone-regulated. Insulin activates carboxylase, while its activity is inhibited by glucagon and epinephrine. In addition, levels of citrate, palmitoyl CoA, and AMP within a cell also control acetyl CoA carboxylase. The most important regulator of FA synthesis is the level of citrate in the cytosol. Citrate stimulates acetyl CoA carboxylase to form malonyl CoA and allows the synthesis of FAs. On the other hand, palmitoyl CoA, as the end product of FA synthesis by FAS, inhibits acetyl CoA carboxylase. AMP is also included in the regulation of an acetyl CoA carboxylase activity. AMP activates AMP-dependent protein kinase, which then performs the phosphorylation of carboxylase and inhibits its enzymatic activity.

There is adaptive control of FA metabolism regulation. The rates of synthesis and degradation of the enzymes involved in the FA synthesis change within a few days, depending on dietary habits, such as fasting and low-fat or high-carbohydrate intakes.

FAs, Human Nutrition, and Health

The general grouping of FAs as SFA, MUFA, and PUFA is usually applied, when their effects on human health are discussed. This approach is based on the assumption that major groups of FAs are associated with different health effects. However, despite the similarities of chemical structure, individual FAs within the same group may have distinct biological properties and physiological activity.

Major SFAs in the diet are myristic acid (14:0), palmitic acid (16:0), and stearic acid (18:0) that originate mainly from animal fats. When predominant food sources of total fats are milk and coconut oil, most SFAs range from C4 to C18. The SFAs with shorter chain, such as butyric (C4:0), caprylic (C8:0), capric (C10:0), and lauric (C12:0) acids, have positive health effects through the prevention of cancer and antiviral and antibacterial activity. On the other side, lauric, myristic, and palmitic acids are known to have thrombogenic and atherogenic effect. Long-chain SFAs are abundant in animal fats. Their negative effect is related to increase in total and LDL cholesterol leading to obesity and/or coronary disease. However, in the case of stearic acid, no atherogenic effect has been shown. Moreover, recent results indicate the proapoptotic effect of stearic acid in some cancer diseases.

Predominant MUFA in the diet is oleic acid (C18:1$n-9$), mostly supplied from olive oil. Oleic acid demonstrates large spectra of biological activities being connected to many health beneficial effects. On the cellular level, as a compound of membrane phospholipids, oleic acid increases membrane fluidity and transport, stimulates enzymatic activity, and regulates the activity of membrane receptors and signal transduction and transcription of some genes. It is associated with the decrease of plasma total cholesterol, LDL cholesterol, and triglyceride concentrations, having positive effect in coronary artery disease. The reduced risk of cardiovascular and neurodegenerative diseases as found in Mediterranean diet is also connected to higher oleic acid content in this type of feeding. Even it is much less present in ordinary diet, the palmitoleic acid (16:1$n-7$) is interesting because of its pro-lipogenic activity in the adipose tissue. Due to this activity, palmitoleic acid could be beneficial in the protection of other tissues and organs from fat accumulation and consequent lipotoxicity. On the other side, its

antiapoptotic activity is undesirable in uncontrolled proliferation of cancer cells. In diets with common use of rapeseed and mustard seed oil, the major MUFA is erucic acid (C22:1$n-9$). No negative health effects of erucic acid consumption have been reported in humans.

Major PUFAs in the diet are LA, ALA, and long-chain PUFA such as AA, eicosapentaenoic acid (EPA), docosapentaenoic acid (DPA), and DHA. LA and ALA are essential FAs, which must be supplied from dietary sources. LA, usually found in sunflower and soybean oil, is significant as a precursor of PUFA $n-6$ family, while ALA, abundant in linseed oil, is precursor of $n-3$ PUFA. At the same time, long-chain PUFA can be provided from the dietary sources. The main foods containing $n-6$ PUFA AA are meat, poultry, and eggs, while fatty fish and fish oils are the main sources of $n-3$ PUFA, EPA, and DHA. The $n-6$ and $n-3$ PUFAs have different roles in human's physiology and health. The AA is involved in the biosynthesis of pro-inflammatory eicosanoids, having pro-inflammatory activity in stress and injury. In opposite, eicosanoids derived from $n-3$ PUFA and EPA are anti-inflammatory, protecting organism from inflammatory diseases (lupus, arthritis, and asthma), heart attack, and stroke. In addition, EPA acts as an inhibitor of synthesis of pro-inflammatory cytokines. Due to the stimulatory effect on neuro- and synaptogenesis, DHA is crucial for optimal neural function. Even more, $n-3$ PUFAs by decreasing lipid level and blood pressure, improving cardiac and endothelial function, and manifesting antiplatelet and anti-inflammatory effects have a crucial role in the control of cardiovascular risk factors. In general, effects of PUFA are dependent on $n-3$ and $n-6$ PUFA ratio, which is about 1:10 in modern dietary habits compared with 1:4 as recommended in terms of the health benefits. One or two fish meals weekly could probably improve this situation.

The human diet contains a certain amount of *trans*-FA, mostly 18:1 *trans*-isomers, derived from partially hydrogenated or high-heat-treated vegetable oils, as well as produced by bacteria from ruminant intestine. The increased intake of *trans*-FA is associated with the HDL cholesterol decrease, an increase of LDL cholesterol, and the higher risk of coronary heart disease and atherosclerosis. The minor proportion of 'unusual' FA, as FA with branched-chain or non-methylene-interrupted double bond structure, is also present in the diet. In the case of increased concentration, the overall effects could be potentially harmful for human health.

Fatty Acid Structure, Classification, and Nomenclature

A fatty acid is a hydrocarbon (acyl) chain with a carboxyl group at one end and a methyl group at the other. A large number of fatty acids exist in nature because the hydrocarbon chain may be of varying lengths (i.e., containing a varying number of carbon atoms linked together) and may have different degrees of unsaturation (unsaturation refers to the presence of double bonds between carbon atoms within the hydrocarbon chain). The terminal carboxyl group is reactive and readily forms ester links. Ester links between fatty acids and alcohol groups on glycerol or cholesterol produce acylglycerols (e.g., mono-, di-, and triacylglycerols are often called mono-, di-, and triglycerides) and cholesteryl esters, respectively. Traditionally, the carbon of the terminal carboxyl group has been referred to as carbon 1 with the carbon next to it (carbon 2) being referred to as the α carbon and the methyl terminal carbon as the ω (sometimes called *n*) carbon. The most abundant fatty acids in the human diet and in the human body have straight hydrocarbon chains of an even number of carbon atoms, although branched-chain, odd-numbered, and substituted fatty acids do exist. Fatty acid chain lengths vary from 2 to 30, and based upon chain length, fatty acids are classified as short chain (2–6 carbon atoms), medium chain (8–12 carbon atoms), and long chain (14 or more carbon atoms); sometimes, fatty acids of 20 or more carbon atoms are referred to as very long chain. Fatty acids are also classified according to the degree of unsaturation (i.e., the number of double bonds in the hydrocarbon chain). Fatty acids containing double bonds in the hydrocarbon chain are called unsaturated fatty acids; a fatty acid containing two or more double bonds is called a polyunsaturated fatty acid or PUFA. Saturated fatty acids do not contain double bonds in the hydrocarbon chain.

Fatty acids have systematic names that are based upon the number of carbons in the hydrocarbon chain (Table 1). However, complications arise for the naming of unsaturated fatty acids because there are multiple possibilities for the position of double bonds within the hydrocarbon chain and because each double bond may be in the *cis* or *trans* configuration. Therefore, when naming an unsaturated fatty acid, it is important that the exact positions of double bonds and their configurations be specified. Traditionally, the position of double bonds was denoted by identifying the carbon number (counting from carbon 1 (the carboxyl carbon)) on which each double bond occurs. Thus, octadecadienoic acid, an 18-carbon fatty acid with *cis* double bonds between carbons 9 and 10 and carbons 12 and 13, is correctly denoted as *cis*-9, *cis*-12-octadecadienoic acid or as *cis*, *cis*-9,12-octadecadienoic acid. More recently, an alternative shorthand notation for fatty acids has come into frequent use, particularly within the nutrition community. This relies upon identifying the number of carbon atoms in the hydrocarbon chain and the number of double bonds and their position. Thus, octadecanoic acid is notated as 18:0, indicating that it has a hydrocarbon chain of 18 carbons and does not contain any double bonds. Unsaturated fatty acids are named simply by identifying the number of double bonds and the position of the first double bond counted from the methyl terminus (with the methyl, or ω, carbon counted as number 1) of the hydrocarbon chain. The way the first double bond is identified is as ω−*x*, where *x* is the carbon number on which the double bond occurs. Therefore, *cis*, *cis*-9,12-octadecadienoic acid is also known as 18:2ω−6. The ω−*x* nomenclature is sometimes referred to as *n*−*x* (e.g., 18:2*n*−6). In addition to these nomenclatures, fatty acids are often described by their common names (Table 1), which sometimes reflect a common origin of the fatty acid, for example, palmitic acid (16:0) from palm oil and oleic acid (18:1*n*−9) from olive oil. In most PUFAs, each double bond is separated by a methylene (–CH_2–) group. However, this is not always the case, and in some PUFAs, the double bonds are conjugated (i.e., the two double bonds are separated by only one single bond). Figure 1 shows the structure of several 18-carbon fatty acids indicating the position of the double bonds in the hydrocarbon chain and how this is reflected in their naming.

Most commonly occurring unsaturated fatty acids contain *cis* rather than *trans* double bonds. *Trans* double bonds do occur in some intermediates in the fatty acid biosynthetic pathway, in ruminant fats (e.g., cow's milk), in plant lipids, and in some seed oils, and they may also be introduced by exposure of *cis* unsaturated fatty acids to high temperatures such as when oils are used for deep fat frying. *Cis*, but not *trans*, double bonds produce a kink in the molecule so that the molecular shape of unsaturated fatty acids containing *cis* double bonds is distinct from that of saturated (and *trans* unsaturated) fatty acids. This has an effect on the physical properties of the fatty acid. The melting point of a fatty acid is affected by its chain length, its degree of unsaturation, and whether the double bonds are *cis* or *trans*. Fatty acid melting point increases with increasing chain length and decreases with increasing degree of unsaturation. Thus, among the 18-carbon fatty acids, stearic acid (18:0) has a higher melting point than oleic acid (18:1*n*−9) and oleic acid has a higher melting point than linoleic acid (18:2*n*−6). For a given chain length and number of double bonds, a *trans* fatty acid has a higher melting point than a *cis* fatty acid. Thus, elaidic acid (*trans* 18:1*n*−9) has a higher melting point than oleic acid. Therefore, the fatty acid composition of a fat-rich substance will determine whether that substance is solid or liquid at room temperature. Consequently, lard, beef tallow, and butter are solid at room temperature because they contain a high proportion of long-chain saturated fatty acids, while coconut oil and corn oil are liquid at room temperature because they contain a high proportion of medium-chain saturated fatty acids and PUFAs, respectively. Melting point can be altered by the modification of fatty acid composition. Hence, to produce margarine from

[a]Commonly called eicosapentaenoic acid.
[b]Commonly called docosapentaenoic acid.
[c]Commonly called docosahexaenoic acid.

vegetable oil, the process of hydrogenation is used to 'harden' the oil: vegetable oils are hardened by reacting them with hydrogen gas at about 60 °C in the presence of a catalyst, which results in the conversion of some of the double bonds to single bonds. This process can also convert *cis* to *trans* double bonds.

Fatty Acid Biosynthesis

Biosynthesis of Saturated Fatty Acids

Saturated fatty acids can be synthesized from carbohydrates and from proteins because the basic building block is acetyl-coenzyme A (acetyl-CoA) produced from sugar and amino acid metabolism. Acetyl-CoA is usually produced within mitochondria, while fatty acid biosynthesis occurs in the cytoplasm. Thus, there is a transport system whereby mitochondrial acetyl-CoA condenses with oxaloacetate to form citrate (catalyzed by citrate synthase) – this is actually a reaction within the citric acid (Krebs) cycle – and the citrate is transported across the mitochondrial membrane to the cytoplasm. Here, citrate is cleaved to produce oxaloacetate (which is converted to malate and transported back into the mitochondria) and acetyl-CoA.

De novo synthesis of fatty acids is catalyzed by a multienzyme complex called fatty acid synthase. The growing fatty acid hydrocarbon chain is built up by successive addition of two-carbon units. These are donated by malonate – a three-carbon intermediate – linked to acyl carrier protein (ACP) through the latter's sulfhydryl group. Malonyl-ACP is formed from malonyl-CoA that is, in turn, formed from acetyl-CoA. Acetyl-CoA carboxylase catalyzes conversion of acetyl-CoA to malonyl-CoA (Figure 2). This is the rate-limiting step of fatty acid biosynthesis and is subject to hormonal regulation (e.g., it is upregulated by insulin). The malonate group of malonyl-CoA now condenses with ACP to produce malonyl-ACP. In the

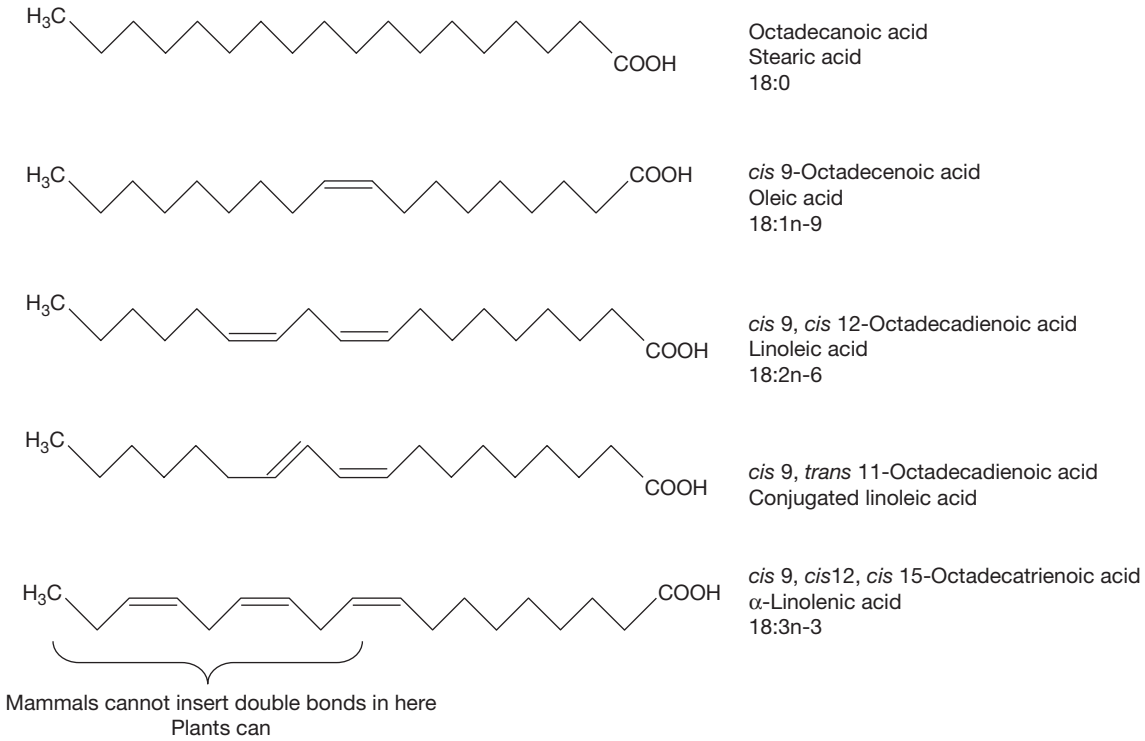

Figure 1 Representation of the structure of five different 18-carbon fatty acids demonstrating the basis of different nomenclatures.

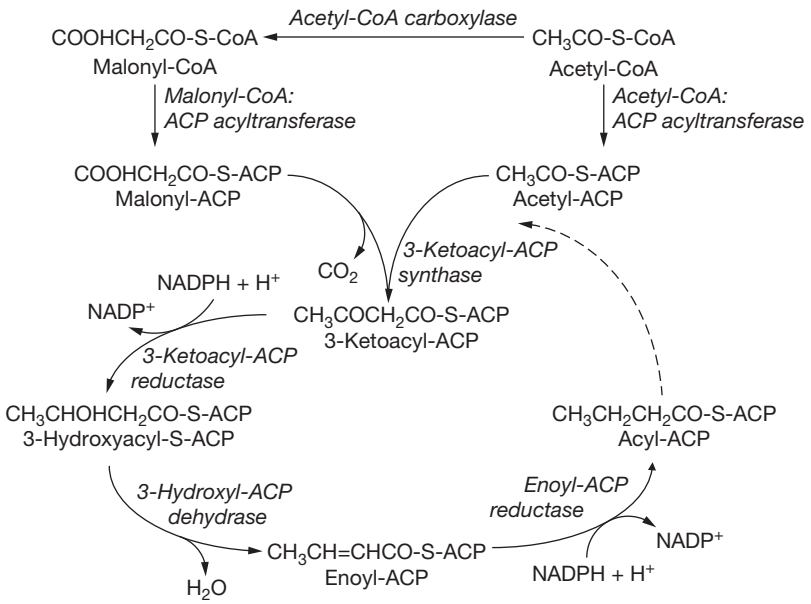

Figure 2 The pathway of *de novo* fatty acid biosynthesis catalyzed by the multienzyme fatty acid synthase complex. Malonyl-ACP (acyl carrier protein) acts as the donor of a two-carbon unit to the growing acyl chain. The acceptor in the first step is acetyl-ACP, and in the subsequent steps, it is the acyl-ACP produced during the previous round of reactions. The usual end product of the process is palmitoyl-ACP.

initial step of fatty acid biosynthesis, malonyl-ACP is condensed with acetyl-ACP to form the four-carbon acetoacetyl-ACP with the loss of one carbon as CO_2 (Figure 2). There follows a sequence of hydrogenation (reduction), dehydration, and hydrogenation (reduction) steps to produce the four-carbon butyryl-ACP (Figure 2). The cycle is now repeated with butyryl-ACP taking the role of acetyl-ACP from the first cycle to ultimately produce a six-carbon acyl-ACP. The cycle is repeated seven times to produce the 16-carbon palmitoyl-ACP, which is hydrolyzed from the ACP to yield palmitic acid. The

reductive steps in the fatty acid biosynthesis pathway use NADPH derived from the pentose phosphate pathway. The overall reaction for palmitic acid biosynthesis is

$$\text{Acetyl-CoA} + 7\ \text{malonyl-CoA} + 14\text{NADPH} + 14\text{H}^+ \rightarrow \text{palmitic acid} + 7\text{CO}_2 + 8\text{CoA} + 14\text{NADP}^+ + 6\text{H}_2\text{O}$$

It is important to note that enzymes exist in some tissues that act to release fatty acids of shorter chain length than palmitic acid from the *de novo* biosynthetic pathway. For example, in the mammary gland of some species, there are enzymes that are responsible for the release of the medium-chain saturated fatty acids such as caprylic acid (8:0) and capric acid (10:0) that are characteristic of the milks of those species.

In eukaryotes, longer-chain saturated fatty acids (actually the fatty acyl-CoA esters are formed) are produced from palmitic acid (actually palmitoyl-CoA is the substrate) by elongation reactions (the enzymes catalyzing these are termed elongases), which occur on the endoplasmic reticulum or in mitochondrial membranes. The mitochondrial system uses acetyl-CoA as the two-carbon donor, and there is a requirement for NADH or NADPH or both depending upon the tissue location. However, the main location for fatty acid elongation is the endoplasmic reticulum and this system uses malonyl-CoA as the two-carbon donor and NADPH. Elongation converts palmitic acid to stearic acid, and in neuronal tissue, large amounts of behenic (22:0) and lignoceric (24:0) acids are produced through elongation reactions. Thus, a large number of fatty acid substrates may be elongated, and seven elongase enzymes, which differ in their selectivity for fatty acids of different chain lengths and degrees of unsaturation, have been identified. Elongases 1, 3, 6, and 7 preferentially catalyze the extension of saturated and monounsaturated fatty acids, while elongases 2, 4, and 5 act mainly on PUFAs (see Further metabolism of linoleic and α-linolenic acids). Elongation of palmitic acid to stearic acid is catalyzed by elongase 6. Elongases 1, 3, and 7 catalyze the elongation of stearic acid to lignoceric acid, while only elongases 1 and 3 can further elongate lignoceric acid.

Biosynthesis of Monounsaturated Fatty Acids

The endoplasmic reticulum is a site for the introduction of double bonds ('desaturation') into fatty acids. The pathway used is almost universal, having been identified in bacteria, yeasts, algae, higher plants, protozoa, and animals. Examples are the conversion of stearic acid (18:0) to oleic acid (18:1$n-9$) and of palmitic acid to palmitoleic acid (16:1$n-7$) by insertion of a *cis* double bond between carbons 9 and 10; once again, it is the fatty acyl-CoA that is the substrate for these reactions that use NADPH and molecular oxygen. Because the double bond is inserted between carbons 9 and 10 counting from the carboxyl end of the hydrocarbon chain, the desaturase enzyme is known as delta-9 desaturase (Δ9-desaturase), although sometimes, this enzyme is referred to as stearoyl-CoA desaturase or SCD.

Biosynthesis of PUFAs

Biosynthesis of linoleic and α-linolenic acids

All eukaryotes and some bacteria can produce PUFAs. Plant enzymes normally introduce a new double bond between an existing double bond and the terminal methyl group of the hydrocarbon chain, whereas animal enzymes normally introduce a new double bond between an existing double bond and the carboxyl group (see Figure 1). Insertion of a double bond between carbons 12 and 13 (counted from the carboxyl carbon) of oleic acid yields linoleic acid (18:2$n-6$). The enzyme that catalyzes this reaction is called Δ12-desaturase (Figure 3). Linoleic acid can be further desaturated by insertion of a double bond between carbons 15 and 16 (counted from the carboxyl carbon) by Δ15-desaturase to yield α-linolenic acid (18:3$n-3$) (Figure 3).

Linoleic and α-linolenic acids are the simplest members of the $n-6$ and $n-3$ families of fatty acids, respectively. As indicated earlier, mammals lack the enzymes that introduce double bonds at carbon atoms beyond carbon 9 in the acyl chain (counting from the carboxyl carbon). Because these include the Δ12- and Δ15-desaturases, this means that mammals cannot synthesize linoleic or α-linolenic acids. Since these fatty acids are required by mammalian cells, they are termed essential fatty acids, and there is a need for their consumption in the diet.

Further metabolism of linoleic and α-linolenic acids

Although mammalian cells cannot synthesize linoleic or α-linolenic acids, they can metabolize them by further desaturation and elongation; desaturation occurs at carbon atoms below carbon number 9 (counting from the carboxyl carbon). Linoleic acid can be converted to γ-linolenic acid (18:3$n-6$) by Δ6-desaturase, and then, γ-linolenic acid can be elongated (by elongase 5) to dihomo-γ-linolenic acid (20:3$n-6$) (Figure 3). Dihomo-γ-linolenic acid can be further desaturated by Δ5-desaturase to yield arachidonic acid (20:4$n-6$) (Figure 3).

Using the same series of enzymes as used to metabolize $n-6$ PUFAs, α-linolenic acid is converted to timnodonic acid, which is more commonly known as eicosapentaenoic acid (20:5$n-3$) or EPA (Figure 3). In mammals, the pathway of desaturation and elongation occurs mainly in the liver, although it is also likely to occur in other cells and tissues that have specific requirements for very-long-chain PUFAs. The desaturation enzymes use NADPH and molecular oxygen and are located on the endoplasmic reticulum. The genes encoding Δ6- and Δ5-desaturase are known as fatty acid desaturase 2 and 1 (*FADS2* and *FADS1*), respectively.

It is evident from the pathway shown in Figure 3 that there is competition between the $n-9$, $n-6$, and $n-3$ fatty acid families for metabolism. The Δ6-desaturase reaction is rate-limiting in this pathway. The preferred substrate for Δ6-desaturase is α-linolenic acid, followed by linoleic acid followed by oleic acid. However, because linoleic acid is much more prevalent in most human diets than α-linolenic acid, metabolism of $n-6$ fatty acids is quantitatively the more important. In the absence of intake of linoleic and α-linolenic acids, metabolism of oleic acid is enhanced resulting in the accumulation of mead acid (20:3$n-9$), which is normally only found in tissues in trace amounts (Figure 3). Appearance and accumulation of mead acid are taken to indicate dietary essential fatty acid deficiency. The activities of Δ6- and Δ5-desaturases are regulated by nutritional status, hormones, and feedback inhibition by end products; for example, high-fat diets and insulin downregulate the activities of these enzymes.

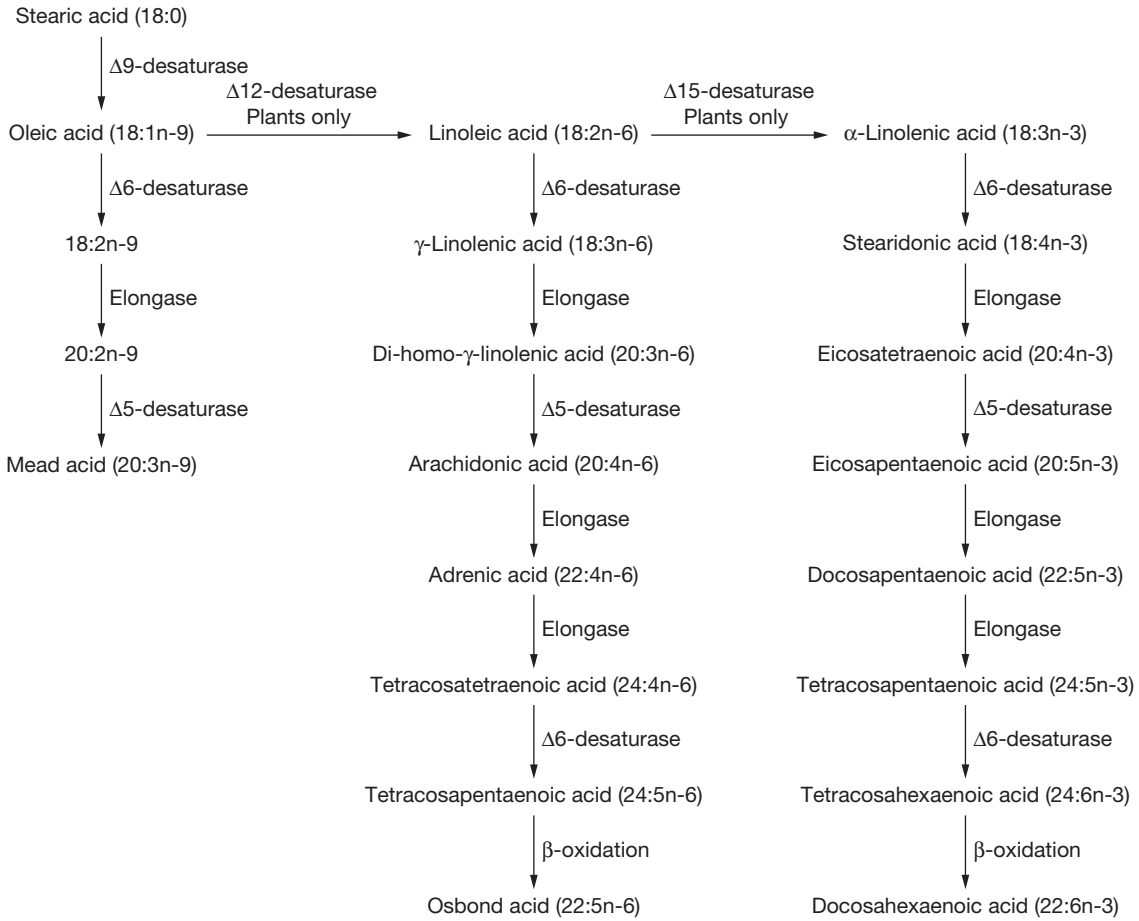

Figure 3 The pathways of biosynthesis of *n*−9, *n*−6, and *n*−3 unsaturated fatty acids.

Furthermore, polymorphisms in the *FADS1* and *FADS2* genes have been associated with differences in the status of *n*−6 and *n*−3 PUFAs, presumably due to the polymorphisms resulting in different capacities of the pathway.

Further conversion of arachidonic acid to osbond acid (22:5*n*−6) and of EPA, to cervonic acid, more commonly known as docosahexaenoic acid (22:6*n*−3) or DHA, occurs by a complex pathway. This involves chain elongation catalyzed by elongase 5, a second chain elongation catalyzed by elongase 2 or 5, desaturation by Δ6-desaturase, and then removal of two carbon atoms as acetyl-CoA by limited β-oxidation in peroxisomes (Figure 3).

Fatty Acid Incorporation into Complex Lipids

Fatty Acids Are Esterified into Complex Lipids

Fatty acids do not usually exist in high concentrations in 'free' form; most often, they are esterified into acylglycerols like mono-, di-, and triacylglycerols, into phospholipids or similar complex lipids, or into cholesteryl esters. Fatty acids in foods are mainly present in triacylglycerols, since this is how plants and animals store fatty acids, although some dietary fatty acids are present in phospholipids since these make up cell membranes and many foods (e.g., meat) include intact cells. Humans and other mammals store fatty acids esterified into triacylglycerols in adipose tissue. Phospholipids are important structural components of all cell membranes and phospholipids contain fatty acids esterified at their s*n*−1 and s*n*−2 positions. Fatty acids circulate in the bloodstream mainly as esterified lipids within lipoproteins. For example, dietary fatty acids are carried in the bloodstream mainly as triacylglycerols within chylomicrons, while very-low-density lipoproteins carry triacylglycerols of hepatic origin (e.g., carrying fatty acids from hepatic *de novo* biosynthesis that have been incorporated into triacylglycerols). Low- and high-density lipoproteins are the main cholesterol-carrying lipoproteins in the bloodstream, and the majority of this cholesterol is present as fatty acid cholesteryl esters. Within these lipoproteins, the hydrophobic triacylglycerols and cholesteryl esters are within the core, which is surrounded by a phospholipid monolayer, which serves to solubilize the particle within the aqueous environment of the bloodstream.

Incorporation of Fatty Acids into Triacylglycerols

The glycerol 3-phosphate pathway

Glycerol 3-phosphate is produced from glycerol in a reaction catalyzed by glycerol kinase:

$$\text{Glycerol} + \text{ADP} \rightarrow \text{glycerol 3-phosphate} + \text{ADP}$$

There follows stepwise transfer of fatty acyl groups from fatty acyl-CoA onto position 1 and then position 2 of glycerol 3-phosphate (Figure 4). The first acylation is catalyzed by acyl-CoA/glycerol phosphate 1-*O*-acyltransferase, known as GPAT, while the second acylation is catalyzed by acyl-CoA/1-acyl glycerol phosphate 2-*O*-acyltransferase, known as LPAT (because 1-acylglycerol 3-phosphate is also called lysophosphatidic acid, hence lysophosphatidate acyltransferase). GPAT has marked specificity for saturated fatty acyl-CoA, whereas LPAT shows specificity toward mono- and dienoic fatty acyl-CoA. Different isoforms of GPAT and LPAT are found on the endoplasmic reticulum and outer mitochondrial membrane, and this distribution differs between tissues. The product of these two reactions is 1,2-diacylglycerol 3-phosphate (also known as phosphatidic acid). Phosphatidic acid can also be formed by phosphorylation of 1,2-diacylglycerol by diacylglycerol kinase using ATP as the phosphate donor. The next step of the glycerol 3-phosphate pathway of triacylglycerol synthesis is the formation of 1,2-diacylglycerol by the hydrolysis of phosphatidic acid by phosphatidate phosphohydrolase. The final step of this pathway is fatty acylation of the now vacant third position of the diacylglycerol catalyzed by diacylglycerol acyltransferase, known as DAGAT. This enzyme has a broad specificity for fatty acyl-CoAs.

The dihydroxyacetone phosphate pathway

Dihydroxyacetone phosphate is an intermediate in glycolysis. The first reaction in the dihydroxyacetone phosphate pathway for triacylglycerol synthesis is fatty acylation at position 1 catalyzed by dihydroxyacetone phosphate acyltransferase (Figure 4). Although this enzyme is found in mitochondria, peroxisomes appear to be a more important location. The next step is the reduction of the keto group to form 1-acylglycerol 3-phosphate, linking into the glycerol 3-phosphate pathway of triacylglycerol synthesis. This reduction occurs on the cytosolic side of the peroxisomal membrane and uses NADPH. Further acylation requires transfer of the 1-acylglycerol 3-phosphate to the endoplasmic reticulum.

The monoacylglycerol pathway

The main function of this pathway appears to be resynthesis of triacylglycerols of dietary origin following their partial digestion in the intestinal lumen. The 2-monoacylglycerol produced during this hydrolysis is fairly resistant to further digestion and appears to be absorbed intact. The pathway involves stepwise transfer of fatty acyl groups from fatty acyl-CoA to positions 1 and 3 of the 2-monoacylglycerol (Figure 4). The first reaction is catalyzed by monoacylglycerol acyltransferase, which appears to have a preference for esterifying position. The second reaction is catalyzed by diacylglycerol acyltransferase, which is specific for 1,2-diacylglycerols (i.e., for esterifying position 3).

Enzyme: 1, glycerol 3-phosphate acyltransferase (GPAT); 2, dihydroxyacetone phosphate acyltransferase; 3, acyl-dihydroxyacetone phosphate reductase; 4, lysophosphatidate acyltransferase (LPAT); 5, phosphatidate phosphohydrolase; 6, monoacylglycerol acyltransferase; 7, diacylglycerol acyltransferase. R_1 and R_2 represent fatty acyl chains; P represents phosphate.

Incorporation of Fatty Acids into Phospholipids

Cell membrane phospholipids and related structures

All cells are bordered by a membrane composed of a lipid bilayer that has both structural and functional roles. The most common membrane lipids are based upon a glycerol backbone with various moieties linked to the hydroxyl groups on the glycerol; these are termed glycerolipids or glycerides. In higher animals, phosphoglycerides (these are usually called 'phospholipids') predominate, whereas in plants, glycosylglycerides are more important. In mammalian systems, the most common phospholipids are the 1,2-diacylphosphoglycerides, which have fatty acyl groups esterified at positions 1 and 2 of the phosphoglyceride and usually another moiety (termed the 'head group') esterified to the phosphate group, which is at position 3. These include phosphatidic acid, phosphatidylcholine (also called lecithin), phosphatidylethanolamine, phosphatidylserine, and phosphatidylinositol. Phospholipids with ether, rather than ester, linked fatty acids at position 1 (and sometimes at position 2) also exist. These include plasmalogens, which have an ether linkage at the s$n-1$ position and an ester linkage at the s$n-2$ position. In mammals, the s$n-1$ position is typically derived from 16:0, 18:0, or 18:1$n-9$ fatty alcohols, while the s$n-2$ position is most commonly occupied by a PUFA. The most common head groups present in mammalian plasmalogens are ethanolamine (called plasmanylethanolamines) or choline (called plasmanylcholines). Platelet-activating factor has an s$n-1$ ether-linked acyl group, an s$n-2$ acetyl group, and choline as the head group. Sphingolipids are membrane lipids based on sphingosine rather than glycerol. These may include fatty acyl groups or fatty acyl derivatives as side chains.

The fatty acid compositions of membrane lipids are usually characteristic for the cell and membrane type, but may change with the cell cycle, with age, in response to stimuli or to changes in the environment or the diet; these changes may have functional consequences. As many as 40 different fatty acids can be incorporated into the s$n-1$ or s$n-2$ positions of a phospholipid. Under normal conditions, the membrane bilayer is in a 'fluid' state, meaning that membrane proteins and lipids can migrate within the plane of the membrane. The fluidity of a membrane is strongly influenced by the fatty acid composition of its constituent lipids. In turn, membrane fluidity may affect cell function. This may be because fluidity, and hence protein movement, is required to establish appropriate interactions between proteins or between proteins and lipids.

Phospholipid biosynthesis

Phospholipids are formed from the parent compound phosphatidic acid, mentioned earlier as an intermediate in the pathway of triacylglycerol biosynthesis. There is variation in the way in which the polar head groups are attached to the phosphate of phosphatidic acid. Phosphatidic acid is the precursor of phosphatidylglycerol, phosphatidylinositol, and diphosphatidylglycerol, while the dephosphorylated derivative of phosphatidic acid 1,2-diacylglycerol is the precursor of phosphatidylcholine and phosphatidylethanolamine (Figure 5).

Fatty Acid Release from Complex Lipids

Fatty Acid Release from Triacylglycerols

Lipases are enzymes that hydrolyze fatty acids from acylglycerols; lipases are a subclass of esterases and they are widespread in nature being found in microorganisms, plants, and animals. Because there are a large number of possible acylglycerol substrates that have different tissue distributions, there are a number of different lipases with differing specificities and locations. Triacylglycerol lipases typically split the fatty acids esterified at positions 1 and 3 leaving the 2-monoacylglycerol intact. Hydrolysis of the latter will usually require a 2-monoacylglycerol lipase. Different triacylglycerol lipases have different fatty acid specificities, meaning that different triacylglycerol substrates are hydrolyzed at different rates and to different extents. In animals, triacylglycerol lipases can be classified as either extracellular or intracellular. Extracellular lipases are secreted from the cells in which they are synthesized and they are involved in hydrolyzing triacylglycerols present in the extracellular environment enabling cellular uptake of the liberated fatty acids. Extracellular lipases include pancreatic lipase, involved in hydrolyzing dietary triacylglycerols in the intestinal lumen; lipoprotein lipase, involved in hydrolyzing lipoprotein triacylglycerols in the circulation; hepatic lipase, involved in hydrolyzing lipoprotein triacylglycerols in the hepatic sinusoids (the liver's equivalent of capillaries); and endothelial lipase, which has both triacylglycerol lipase and phospholipase activities. The best characterized intracellular triacylglycerol lipase is hormone-sensitive lipase found in adipocytes. Hormone-sensitive lipase acts on the surface of the triacylglycerol droplet stored in the adipocyte to release stored fatty acids that can be delivered to the circulation as 'free' fatty acids (or more correctly as nonesterified fatty acids (NEFAs)) from where they are made available to tissues for β-oxidation (see succeeding text). As its name suggests, hormone-sensitive lipase is under tight regulation by various hormones, including adrenaline, noradrenaline, glucagon, and insulin. Insulin acts to inhibit its activity. In contrast, adrenaline and glucagon increase the activity of lipoprotein lipase. Therefore, through its concerted actions on the activities of lipoprotein lipase and on hormone-sensitive lipase, insulin acts to make available fatty acids from circulating lipoproteins for storage in adipose tissue and to retain those fatty acids held there in stored triacylglycerols (Figure 6). Note too that through its actions on glucose transport into adipocytes, insulin makes available the precursor for the synthesis of the glycerol 3-phosphate that is required for triacylglycerol synthesis. In contrast, an increase in adrenaline or noradrenaline concentration, for example, during exercise, or in glucagon concentration, for example, during fasting, enhances the activity of hormone-sensitive lipase, thus promoting release of NEFAs from adipose tissue (Figure 6). The bulk of these will be transported in the bloodstream noncovalently bound to albumin and will be destined for energy generation via β-oxidation in tissues like the skeletal muscle, heart, and liver (see succeeding text). Hormone-sensitive lipase also has cholesterol esterase activity. Adipose tissue also contains a lipase that is more active on monoacylglycerols than triacylglycerols.

Fatty Acid Release from Phospholipids

Phospholipases are enzymes that selectively remove different components of the phospholipid molecule including the fatty

acyl groups at positions 1 and 2 or the base ('head group') or the entire phosphobase moiety. Phospholipases are classified according to their site of action on the substrate phospholipid (Figure 7). Type A phospholipases yield a monoacylphosphoglyceride. Phospholipase A_1 removes the fatty acid at the s*n*−1 position, while phospholipase A_2 removes that at the s*n*−2 position. The phospholipase A_2 enzymes are divided into four groups based upon their properties. Phospholipase C yields a 1,2-diacylglycerol and the phosphobase moiety, while phospholipase D yields 1,2-diacylglycerol 3-phosphate (phosphatidic acid) and the base. Type B phospholipases can remove fatty acids from both s*n*−1 and s*n*−2 positions, but these enzymes are quite rare. Phospholipases are important in the digestion of dietary phospholipids, in cell membrane remodeling, in generation of second messenger molecules, and in provision of PUFAs for the production of bioactive lipid mediators (see later section).

Fatty Acid β-Oxidation

β-Oxidation is the major metabolic pathway by which energy is released from fatty acids. The rate of fatty acid β-oxidation is controlled by the intracellular concentration of 'free' (i.e., unesterified) fatty acids, which in turn is determined by their concentration in the blood, so that a rise in the concentration of circulating NEFAs increases fatty acid oxidation in the tissues that can use them (most aerobic tissues but not the brain). NEFAs become important energy sources during starvation, endurance exercise, and other situations where carbohydrate supply is limiting.

Prior to β-oxidation, the fatty acid substrate is converted to its CoA ester derivative:

$$\text{Fatty acid} + \text{ATP} + \text{CoA} \rightarrow \text{acyl-CoA} + \text{AMP} + \text{PPi}$$

This reaction is catalyzed by a cytosolic acyl-CoA synthase; there are several such synthases with different specificities according to fatty acid chain length.

Fatty acid β-oxidation occurs in the mitochondrial matrix, and therefore, the fatty acid substrate (in the form of fatty acyl-CoA) needs to be transported across the outer and inner mitochondrial membranes that are not permeable to fatty acids or fatty acyl-CoAs with a hydrocarbon chain longer than 12 carbons. Shorter-chain fatty acids can cross both the outer and the inner mitochondrial membranes. Medium- and long-chain acyl-CoAs require a special transport mechanism to cross the mitochondrial membranes. Translocation of these is a carnitine-dependent process involving the coordinate action of isoforms of carnitine palmitoyltransferase (CPT) on the mitochondrial outer and inner membranes (Figure 8). CPT1 forms the fatty acylcarnitine at the outer mitochondrial membrane, and this is then transported to the intramembrane space via porin. The fatty acylcarnitine is transported through the inner mitochondrial membrane via acylcarnitine translocases in exchange for free carnitine. Once across the inner mitochondrial membrane, the fatty acyl-CoA is reformed by CPT2 (Figure 8). CPT1 is the rate-limiting step for mitochondrial β-oxidation. It is inhibited by malonyl-CoA, and thus, conditions that promote malonyl-CoA synthesis (e.g., the fed state) suppress fatty acid β-oxidation (and promote *de novo* fatty acid biosynthesis). Conversely, conditions that promote a decline in malonyl-CoA concentrations (e.g., fasting, starvation, exercise, and insulin resistance) will act to promote fatty acid β-oxidation (and suppress *de novo* fatty acid biosynthesis). These actions at the level of CPT1 form part of integrated whole body metabolic responses to changes in prevailing hormonal conditions, for example, in fasting-to-fed and fed-to-fasting transitions.

Fatty acid β-oxidation itself involves the progressive removal of two-carbon units, as acetyl-CoA, from the carboxyl end of the fatty acyl-CoA substrate in a series of four reactions that act sequentially and repeatedly (Figure 9). Each round of the cycle generates $FADH_2$ and NADH in addition to acetyl-CoA and an acyl chain that is two carbons shorter than the original. The latter reenters the cycle. Thus, complete β-oxidation of palmitoyl-CoA will generate eight acetyl-CoA, seven $FADH_2$, and seven NADH molecules:

$$\text{Palmitoyl-CoA} + 7\text{CoA} + 7\text{FAD} + 7\text{NAD}^+ + 7\text{H}_2\text{O} \rightarrow 8\ \text{acetyl-CoA} + 7\text{FADH}_2 + 7\text{NADH} + 7\text{H}^+$$

The acetyl-CoA produced by β-oxidation is normally oxidized in the citric acid (Krebs) cycle, while the $FADH_2$ and

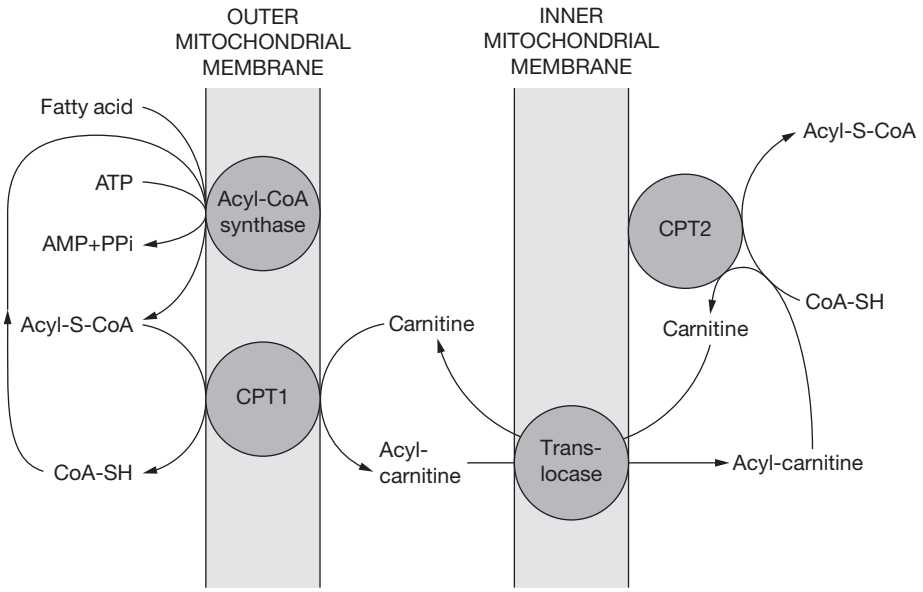

Figure 8 The carnitine palmitoyltransferase (CPT) system for transport of fatty acyl-CoA across the mitochondrial membranes into the matrix prior to β-oxidation.

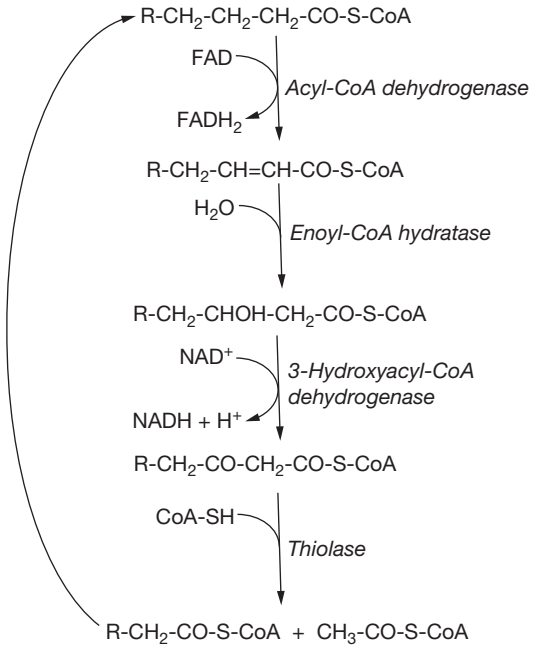

Figure 9 The pathway of β-oxidation of fatty acyl-CoA. Each cycle of four reactions produces acetyl-CoA and an acyl-CoA shortened by two-carbons that then reenters the cycle.

NADH pass their electrons to the mitochondrial electron transport chain. Hence, fatty acid β-oxidation generates a large amount of ATP per mole of fatty acid and per mole of fatty acid carbon oxidized:

$$\text{Palmitoyl-CoA} + 23O_2 + 131\text{Pi} + 131\text{ADP} \rightarrow \text{CoA} + 131\text{ATP} + 16CO_2 + 146H_2O$$

Because the activation of palmitate to palmitoyl-CoA consumes two ATP equivalents, the net gain per molecule of palmitic acid oxidized is 129 ATP. This is equivalent to approximately 37 kJ or 9 kcal of energy per gram of fatty acid oxidized, over twice the energy yield for carbohydrate or amino acid oxidation.

Entry of acetyl-CoA into the citric acid (Krebs) cycle releases CoA, and this is needed to maintain β-oxidation. This entry of acetyl-CoA requires a supply of oxaloacetate for it to condense to so producing citrate (the 'first' reaction of the cycle catalyzed by citrate synthase). The supply of oxaloacetate comes from pyruvate via the enzyme pyruvate carboxylase. Pyruvate carboxylase is activated by acetyl-CoA, which indicates a lack of oxaloacetate. In turn, the pyruvate is produced by glycolysis. Thus, some glucose metabolism is required to support continued fatty acid β-oxidation. The conversion of pyruvate to oxaloacetate is a type of anaplerotic reaction and, because of this requirement for some glucose metabolism to support fatty acid β-oxidation, it is said that "fats burn in the flame of carbohydrates."

The β-oxidation pathway outlined earlier operates for straight-chain saturated fatty acids with an even number of carbon atoms in the chain. Other specific enzymes are required for the oxidation of branched-chain, odd-numbered, or unsaturated fatty acids. β-Oxidation of odd-chain fatty acids yields propionyl-CoA.

Although the process of β-oxidation was originally thought to occur exclusively in mitochondria, a second β-oxidation system occurs in peroxisomes. Fatty acid transport into peroxisomes involves the CPT system, which similar enzymes to mitochondrial CPT2 and regulation via malonyl-CoA. Compared with mitochondrial oxidation, peroxisomal β-oxidation has a much broader substrate specificity and is especially active toward very-long-chain fatty acids and also toward many fatty acids with less common structural features, fatty acid derivatives, and more complex lipids. Acyl-CoA oxidase is an important enzyme involved in catalyzing the first step of peroxisomal β-oxidation. Peroxisomal β-oxidation is involved in

the biosynthesis of DHA from its precursor 24:6*n*−3 (Figure 3) and in the conversion of DHA to EPA, a process sometimes called retroconversion. Peroxisomal β-oxidation also seems important in metabolism of other very-long-chain fatty acids like erucic acid. Defects in acyl-CoA oxidase or in peroxisomal β-oxidation cause clinical features such as mental retardation, seizures, and leukodystrophy because of the inability to metabolize certain very-long-chain fatty acids that become elevated in the circulation if not metabolized.

Ketone Body Synthesis

Ketone bodies are produced using acetyl-CoA derived from fatty acid β-oxidation in the liver under specific metabolic conditions. The two ketone bodies are acetoacetate and β-hydroxybutyrate. Ketone body biosynthesis occurs in mitochondria and the pathway is shown in Figure 10. Two molecules of acetyl-CoA are condensed to form acetoacetyl-CoA, which is then conjugated to another molecule of acetyl-coA to form 3-hydroxy-3-methylglutaryl-CoA (HMGCoA), which is also an intermediate in *de novo* cholesterol biosynthesis. HMGCoA is then cleaved to release one molecule of acetyl-CoA and one molecule of acetoacetate. Some of the acetoacetate is reduced to β-hydroxybutyrate. Both acetoacetate and β-hydroxybutyrate are readily soluble in the bloodstream and are easily taken up by extrahepatic tissues, including the brain. Some acetoacetate may be nonenzymatically decarboxylated producing acetate, a volatile ketone that can appear in the breath.

In target tissues, β-hydroxybutyrate is oxidized back to acetoacetate, which is then converted to its CoA ester. This is cleaved to yield two molecules of acetyl-CoA, which can enter the citric acid (Krebs) cycle for complete oxidation. Thus, hepatic ketone body synthesis allows the transfer of fatty acid carbon to other tissues for oxidation and energy generation. This is especially important for the brain, which cannot utilize NEFAs as an energy source, but which can readily use ketone bodies.

Hepatic ketogenesis is promoted in times of carbohydrate shortage. As described earlier, glucose metabolism is required to support continued entry of acetyl-CoA into the citric acid (Krebs) cycle. However, during times of limited carbohydrate availability, the liver diverts pyruvate and oxaloacetate into gluconeogenesis (i.e., synthesis of glucose) and away from the citric acid (Krebs) cycle; hence, anaplerosis is not supported. This creates a metabolic challenge to supporting the recycling of CoA from acetyl-CoA back to fatty acids to enable their β-oxidation. A solution to this is to divert acetyl-CoA into another pathway that frees up the CoA to enable continuation of β-oxidation. Ketogenesis, which converts acetyl-CoA to acetoacetate and β-hydroxybutyrate, is this solution, and furthermore, it produces metabolic substrates that are able to be used by the brain when glucose is limiting.

Ketone bodies are synthesized during fasting (even after overnight fasting), starvation, and prolonged exercise; in

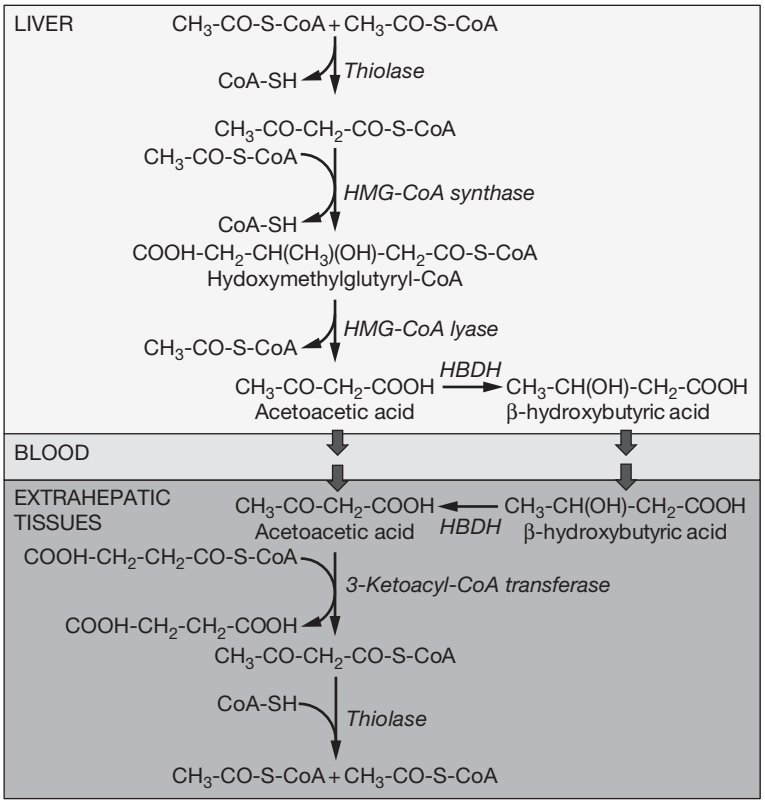

Figure 10 The pathways of ketone body synthesis (ketogenesis) and oxidation. HMG, hydroxymethylglutaryl; HBDH, β-hydroxybutyrate dehydrogenase.

response to high-fat, low-carbohydrate diets (these are sometimes called 'ketogenic diets'); and also by people with diabetes. In the latter case, the marked elevation in blood and brain ketone body concentrations can be pathological.

PUFAs as Substrates for Synthesis of Bioactive Lipid Mediators

One of the key functional roles of PUFAs is as substrates for the biosynthesis of bioactive mediators. These are oxidized derivatives of PUFAs that are usually produced by enzyme-catalyzed reactions, although some of them can be formed non-enzymatically. Linoleic, dihomo-γ-linolenic, arachidonic, eicosapentaenoic, osbond, clupanodonic, and docosahexaenoic acids have all been shown to give rise to such mediators, and it seems likely that all 18-, 20-, and 22-carbon PUFAs can act as substrates for their formation.

Among the possible PUFA precursors, arachidonic acid is usually the most prevalent in cell membranes, and consequently, the most well described of these families of PUFA-derived mediators are the eicosanoids formed from arachidonic acid (eicosa is a prefix that denotes that a structure contains 20 carbons). These include prostaglandins (PGs) and thromboxanes (TXs), which together are termed prostanoids, and leukotrienes (LTs), lipoxins (LXs), hydroperoxyeicosatetraenoic acids (HPETEs), and hydroxyeicosatetraenoic acids (HETEs). Prior to synthesis of eicosanoids, arachidonic acid is released from the s*n*−2 position of membrane phospholipids usually by the action of certain phospholipase A_2 enzymes (often cytosolic group IV phospholipase A_2), although pathways involving phospholipase C and diacylglycerol lipase also release arachidonic acid. The free arachidonic acid then acts as a substrate for cyclooxygenase (COX; e.g., COX-1 and COX-2), lipoxygenase (LOX; e.g., 5-LOX, 12-LOX, and 15-LOX), or cytochrome P450 enzymes (Figure 11). COX enzymes lead to PGs and TXs (2 series when formed from arachidonic acid), LOX enzymes to LTs and LXs (4 series when formed from arachidonic acid), and cytochrome P450 enzymes to HETEs and other derivatives (Figure 11). Eicosanoids act through binding to specific receptors, usually G protein-coupled receptors, and thus, they act in a hormonelike manner working to control cell and tissue responses. The range of activities of the eicosanoids produced from arachidonic acid is extremely broad and includes actions involved in controlling platelet aggregation, blood clotting, inflammation, immune function, smooth muscle contraction, renal function, neuron function, bone turnover, and tumor cell proliferation. The physiology and pathophysiology of arachidonic acid-derived eicosanoids are widely explored.

One feature of increased dietary intake of the very-long-chain *n*−3 PUFAs EPA and DHA is that they partly replace arachidonic acid at the s*n*−2 position of cell membrane phospholipids. The consequence of this is decreased availability of arachidonic acid as a substrate for eicosanoid synthesis. EPA and DHA may also inhibit arachidonic acid metabolism. These effects of EPA and DHA are thought to be important in preventing adverse pathological effects of eicosanoids produced from arachidonic acid like thrombosis (excess blood clotting), chronic inflammation, and tumor promotion and are thought to underlie several of the health benefits of EPA and DHA and foods that contain them like fatty fish. EPA is also a substrate for the synthesis of PGs and TXs (3-series) and LTs (5-series) but, in general, these are biologically weak compared to the arachidonic acid-derived eicosanoids.

Although PGs, TXs, and LTs have been known for decades, a relatively recent discovery has been of new families of bioactive oxidized derivatives of EPA and DHA. These derivatives,

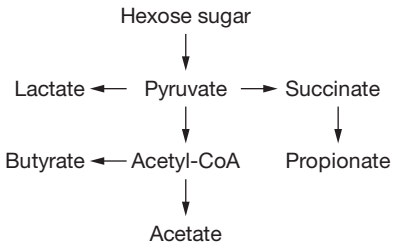

Figure 12 Brief overview of the pathway of biosynthesis of short-chain fatty acids from fermentation of simple sugars.

termed resolvins, protectins, and maresins, have been most thoroughly explored in the context of inflammation, where they have potent activity in resolution ('turning off') of ongoing inflammation. Hence, they have been termed specialized proresolving mediators. E-series resolvins are produced from EPA and D-series resolvins, protectins (sometimes called neuroprotectins), and maresins from DHA. Synthesis of these mediators involves the COX and LOX pathways often across more than one cell type, with different epimers being produced in the presence and absence of aspirin, and they act via specific G protein-coupled receptors. The full range of the biological activities of resolvins, protectins, and maresins has not yet been explored.

Short-Chain Fatty Acid Metabolism

Short-chain fatty acids are volatile fatty acids produced mainly by microbial fermentation. Their principal relevance to human physiology is that they are produced in the proximal colon by microbial fermentation of oligo- and polysaccharides that have escaped digestion by mammalian enzymes further up the gastrointestinal tract (**Figure 12**). There are also some short-chain fatty acids in ruminant milks. The major short-chain fatty acids are acetic, propionic, and butyric. They are very soluble and are absorbed easily from the gut lumen into the bloodstream. In humans, acetate is usually the major short-chain fatty acid present in the circulation. Increased dietary intake of substrates for short-chain fatty acid producing microbes increases their production resulting in higher concentrations in the gut contents and in the bloodstream. Short-chain fatty acids can be oxidized to produce energy, which is considered important for cells of the gut lining, while they can also be used as substrates for the synthesis of longer-chain fatty acids and ketone bodies.

Introduction

The relationship between dietary fat type and cardiovascular disease risk was first identified soon after the turn of the twentieth century. Since that time, the predominance of data indicates that saturated fat is associated with the increased risk of cardiovascular disease, whereas unsaturated fat (monounsaturated or polyunsaturated) is associated with the decreased risk of cardiovascular disease. These conclusions come from both observational studies and interventional studies and have mechanistic underpinnings. However, within the category of unsaturated fatty acids, there are two subtypes that have been demonstrated to have unique effects with respect to cardiovascular disease risk: fatty acids with the first double bond in the omega-3 position of the acyl chain, associated with decreased risk, and fatty acids containing one or more double bonds in the *trans* configuration, associated with increased risk. The focus of this article will be restricted to fatty acids containing at least one *trans* double bond.

Terminology

The term '*trans* fat' typically refers to edible fats that contain *trans*-fatty acids. The term '*trans*-fatty acid' refers to fatty acids that have at least one double bond in the *trans*, as opposed to the more comment *cis*, configuration, in their acyl chain (Figure 1). *Trans* double bond containing fatty acids can be either monounsaturated or polyunsaturated. Edible fats contain a wide range of *trans*-fatty acid isomers, varying in the location of the *trans* double bond(s) and the number of *trans* double bonds in each acyl chain.

Food Sources of *Trans*-Fatty Acids

Ruminant Fat

Trans-fatty acids occur naturally in animal fat as a result of anaerobic bacterial fermentation in the rumen. These *trans*-fatty acids are absorbed from the gut and ultimately distributed throughout the fat depots of the animal. Hence, animal fats, such as meat and dairy fats, contribute to the *trans*-fatty acid content of the diet. Of note, currently dietary guidelines to reduce cardiovascular disease risk recommend limiting intake of animal fat due to the relatively high concentration of saturated fat. When these guidelines are adhered to, so too is *trans*-fatty acid intake from this source limited.

Partially Hydrogenated Fat

Another major dietary source of *trans*-fatty acids is from partially hydrogenated fat. The *trans* double bonds are formed during the partial hydrogenation of liquid oil, typically vegetable oil, which result from the breaking of *cis* double bonds and their random reformation, some of which form *trans* double bonds. In their unmodified state, vegetable oils are made up of fatty acids with only *cis* double bonds. Vegetable oils are partially hydrogenated to increase their viscosity by changing them from a liquid state to a semiliquid or solid state and to extend their shelf life by decreasing their susceptibility to oxidation. Both of these properties are favorable to the food industry.

Appearance of Partially Hydrogenated Fat in the Food Supply

The initial impetus for developing the process of partial hydrogenation of fat was to find an inexpensive substitute for butter. The French chemist Paul Sabatier first developed the process of partial hydrogenation around the turn of the twentieth century. This process involved a nickel catalyst. Shortly thereafter, the German chemist Wilhelm Normann developed a fat hydrogenation process that involved hydrogen gas.

The use of partially hydrogenated fat accelerated from the 1960s to the 1980s as food producers responded to public health recommendations to shift away from saturated fatty acids, particularly animal fats and tropical oils, to unsaturated fatty acids. At the time, partially hydrogenated fats appeared to be a good substitute for fats high in saturated fatty acids because their starting materials, vegetable oils, particularly vegetable oils high in polyunsaturated fatty acids. In addition, relative to vegetable oil in its natural state, partial hydrogenation resulted in a product with more favorable stability and functional properties, similar to that of solid animal fat. The incorporation of these fats into the food supply led to an increased *trans*-fatty acid intake. During this period, there was little concern about the effects of *trans*-fatty acids on lipoprotein profiles.

Estimating *Trans*-Fatty Acid/Partially Hydrogenated Fat Intake

The *trans*-fatty acid content of foods is incompletely captured in most nutrient databases, in part due to the rapidly changing use of partially hydrogenated fat. Changes in use of partially hydrogenated fat, primarily their decline, have been prompted by evolving labeling regulations and legislative mandates. Hence, there is likely a systematic misestimation of *trans*-fatty acid intake when using food frequency questionnaires or food records.

Plasma total *trans*-fatty acid, plasma phospholipid *trans*-fatty acid, and erythrocyte membrane *trans*-fatty acid concentrations have been used as a biomarker of *trans*-fatty acid intake, from both rudiment and partially hydrogenated fat sources. The usefulness of this approach is limited to estimating relative intakes within or among populations. An

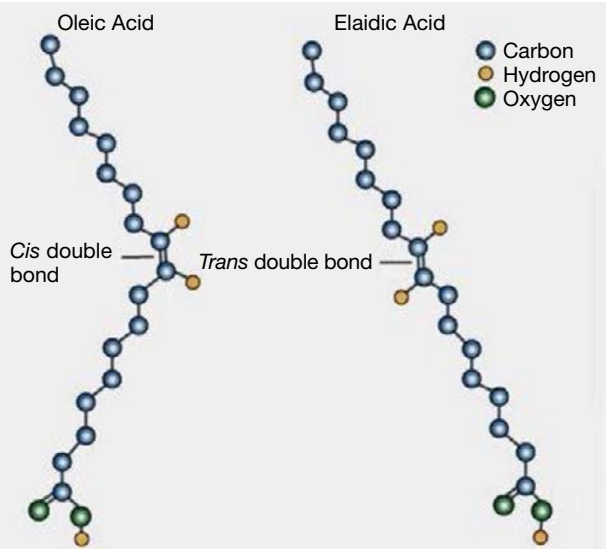

Figure 1 Structure of fatty acids containing a *cis* (left) and *trans* (right) double bond.

additional option for estimating relative *trans*-fatty acid intake from partially hydrogenated fat is to measure plasma dihydrophylloquinone concentrations. Dihydrophylloquinone is the hydrogenated form of vitamin K and not naturally present in vegetable oil. It is formed as an unintended consequence of partial hydrogenation. However, as with biomarkers for *trans*-fatty acid intake in plasma or erythrocyte membrane, the data only provide an assessment of relative intakes within and among populations.

More recently, an attempt to distinguish between the effects of ruminant and partially hydrogenated fats using the plasma proteome is being considered. At this time, it has met with limited success. In the development phase are attempts to identify potential protein biomarker panels for specific *trans*-fatty acids. This approach is based on changes in the regulation of proteins elicited by the addition of elaidic acid to HepG2 cells.

Current Sources and Trends in Dietary *Trans*-Fatty Acid Intake

Sources

The major source of *trans*-fatty acids in the food supply has come from foods made with partially hydrogenated fat, primarily commercially prepared fried and baked products. Over the past decade, the *trans*-fatty acid intake in the United States has declined. This trend has been prompted by a number of factors, including legislative changes at the federal and local levels and grassroots pressure to remove partially hydrogenated fat from the food supply. In the mid-2000s, the Food and Drug Administration mandated that by 2006, the *trans* fat content of packaged food must be listed in the Nutrient Facts label. This ruling appears to have prompted a re-formulation of some products. Between 2005 and 2010, the US Department of Agriculture documented a dramatic decline in the *trans* fat content of newly introduced foods and a rise in the use of 'no *trans* fat' claims on food packages. By 2011, it was estimated that about 66% of the products surveyed had lower *trans*-fatty acid content than previously. Of those, the vast majority, 82%, had <0.5 g per serving of *trans*-fatty acids. Overall, the mean *trans*-fatty acid content of the products surveyed decreased by 49% between 2007 and 2011. Of note, at the time mandatory *trans* fat labeling was enacted, the Food and Drug Administration ruled that products containing <0.5 g *trans* fat per serving could be labeled as 0 g *trans* fat or *trans* fat-free.

Around that same time that the FDA mandated *trans* fat labeling on packaged foods, some US localities restricted the use of partially hydrogenated fats by restaurant chains. As a result, in one such city (New York City), between 2006 and 2008, the proportion of restaurants using partially hydrogenated fat declined from 51% to 2%. More recently, in late 2013, the Food and Drug Administration published a preliminary determination that partially hydrogenated fat, which is currently included on the Food and Drug Administration's 'generally recognized as safe' list, will be removed. A final ruling is expected to become available in 2015. If put into effect, this ruling will likely precipitate additional product reformulation in a variety of food categories and result in a further decline in the *trans*-fatty acid content of commercially prepared foods.

Trends

Although it is difficult to assess the potential public health impact of changes in the *trans*-fatty acid content of the food supply, fragmentary data suggest that the legislative mandates in Scandinavia and the United States have contributed to a secular decline in *trans* fat intake in those places. For example, it has been estimated that between the years 2000 and 2009, plasma *trans*-fatty acid concentrations in non-Hispanic, white adults living in the United States declined by 50%. In the Framingham Offspring Study cohort, between 1999 and 2006, erythrocyte *trans*-fatty acid content declined by 23%. Similar downward trends have been seen in Canada, the United Kingdom, Costa Rica, and Western Europe, but *trans*-fatty acid intake remains high in Eastern Europe and appears to have increased in Greece, North Africa, the Middle East, and South Asia.

Trans-Fatty Acids and Lipoprotein Profiles and Metabolism

Lipoprotein Profiles

Early work in the 1950s through 1970s evaluating the effect of *trans*-fatty acids on plasma cholesterol concentrations suggested a neutral effect. When differences were observed, they were attributed, in part, to decreases in the level of polyunsaturated fatty acids and increases in saturated fatty acids. In the early 1990s, reports started to appear suggesting that, similar to saturated fatty acids, *trans*-fatty acids increased plasma low-density lipoprotein (LDL) cholesterol concentrations and, in contrast to saturated fatty acids, *trans*-fatty acids did not increase high-density lipoprotein (HDL) cholesterol concentrations. Taken together, these changes resulted in a less favorable LDL cholesterol/HDL cholesterol ratio with respect to cardiovascular disease risk. Subsequent work confirmed these findings and, with few exceptions, demonstrated a dose–response relationship between dietary *trans*-fatty acids and LDL cholesterol concentrations. A trend toward increased triglyceride concentrations resulting from *trans*-fatty acid intake has been reported in some studies.

Other Cardiovascular Disease Risk Factors

Small, dense LDL particles have been associated with a higher risk of cardiovascular disease than large, buoyant LDL particles. Dietary partially hydrogenated fat, compared to saturated or polyunsaturated fat, has been reported to shift LDL particle distribution from the large, buoyant particles toward small, dense LDL particles. Changes in fasting insulin and glucose concentrations resulting from dietary partially hydrogenated fat have been reported to be small and, hence, would not be predicted to have a large impact on glucose homeostasis. No significant effect of partially hydrogenated fat intake on C-reactive protein concentrations, lipoprotein (a), blood pressure, visceral adiposity, metabolic syndrome, inflammatory factors, and susceptibility of LDL particles to oxidation has been reported. When effects have been observed, they tend to be small and occur at relatively high intakes of *trans*-fatty acids, and the data are not as consistent as the effects on LDL and HDL cholesterol concentrations.

Trans-Fatty Acid Metabolism

Changes in *trans*-fatty acid intake are associated with proportional changes in tissue levels. For example, plasma and erythrocyte *trans*-fatty acid content declines when intake declines, making these useful measures for assessing trends in *trans*-fatty acid intake. These data also suggest that humans have adequate capacity to metabolize *trans*-fatty acid isomers.

Early work that focussed on identifying the mechanism by which *trans*-fatty acids elevate LDL cholesterol concentrations led to the conclusion that higher rates of *de novo* cholesterol synthesis were not a contributing factor, leading to the speculation that an impairment in the catabolic pathway was involved. This speculation was confirmed with the use of stable isotope-labeled leucine to characterize lipoprotein kinetics in response to partially hydrogenated fat intake. Relative to butter (saturated fatty acids) and soybean oil (polyunsaturated fatty acids), partially hydrogenated fat increased LDL concentrations by decreasing the catabolic rate, resulting in a larger pool size. Little effect of partially hydrogenated fat on LDL production rate was observed. In contrast, partially hydrogenated fat lowered HDL concentrations by increasing the catabolic rate, resulting in a smaller pool size. Again, little effect on HDL production rate was observed. Additional work on the effect of *trans*-fatty acids on HDL metabolism indicated that differences in cholesteryl ester transfer protein activity, phospholipid transfer protein activity, or the fractional esterification rate of cholesterol in HDL did not account for the differences in observed concentrations.

In some cases, dietary partially hydrogenated fat has been reported to increase plasma triglyceride concentrations. In an attempt to determine the mechanism by which *trans*-fatty acids alter plasma lipoprotein profiles, the effect of partially hydrogenated fat on triglyceride uptake by adipose tissue was estimated by measuring plasma acylation-stimulating protein (ASP) concentrations. The data indicated that a diet high in partially hydrogenated fat resulted in lower plasma ASP concentrations compared with a diet high in polyunsaturated fat. Differences in remnant-like particle concentrations, measured in both the fasting and nonfasting states, did not account for differences in triglyceride concentrations.

Trans-Fatty Acid and Cardiovascular Risk

The negative effect of partially hydrogenated vegetable oil and the resulting *trans*-fatty acids on plasma lipoprotein profiles bears out consistently in multiple research studies conducted throughout the 1990s. A meta-analysis of prospective cohort studies and retrospective case-controlled studies resulted in an estimated 2% increase in energy intake from *trans*-fatty acids is associated with a 23% increase in the relative risk of coronary heart disease. Similar estimates on the basis of multiple trials have been made for the substitution of *trans*-fatty acids for saturated, monounsaturated, and polyunsaturated fatty acids, all of which appear to have a more favorable effect on LDL cholesterol and HDL cholesterol concentrations, and the total cholesterol/HDL cholesterol ratio.

The relationship of dietary *trans*-fatty acids and cardiovascular disease risk has been well documented and reviewed. Recent work supports these earlier findings. *Trans* 18:2 isomer intake has been associated with less favorable indexes of heart rate variability in adults from two cohorts: the Cardiovascular Heart Study, involving older subjects (mean age 72 years), and a cohort of younger Portuguese subjects (mean age: 19 years). *Trans* 18:1 isomers were associated with more favorable heart rate variability in the older, but not the younger, cohort. Similarly, a study of middle-aged and older Chinese volunteers concluded that higher erythrocyte 18:2 *trans*-fatty acid concentrations were associated with dyslipidemia, whereas higher 18:1 *trans*-fatty acid concentrations were associated with lower risk of type 2 diabetes. In the Nurses' Health Study, *trans*-fatty acid intake, estimated from food frequency questionnaires, was not associated with sudden cardiac death. However, when the data were assessed on the basis of women with and without coronary heart disease, *trans*-fatty acid intake was positively associated with sudden cardiac death in those women who had clinical atherosclerosis. Data from the Reasons for Geographical and Racial Differences in Stroke (REGARDS) cohort, a US-based prospective cohort study of white and black women and men, indicate that *trans*-fatty acid intake, as assessed using food frequency questionnaires, was associated with higher all-cause mortality. Using plasma phospholipid profiles from two cohorts, the Cardiovascular Health Study and the Estrogen Replacement and Atherosclerosis Study, *trans*-fatty acids were associated with increased cardiovascular disease risk.

Ruminant Versus Partially Hydrogenated Fat and Cardiovascular Disease Risk

Some observational data have suggested that dietary *trans*-fatty acids derived from partially hydrogenated fat are more closely associated with cardiovascular disease risk that dietary *trans*-fatty acids derived from ruminant fat. However, these data have not been consistent.

The difference between ruminant and partially hydrogenated fat sources of *trans*-fatty acids is reflected in the relative distribution of *trans*-fatty acids isomers. Conjugated linolenic acid and vaccenic acid predominate in ruminant fat. The results of clinical studies comparing these two sources of *trans*-fatty acids have been mixed. Some have reported no or only small differences between ruminant and partially

hydrogenated fat sources of *trans*-fatty acids on lipoprotein profiles, whereas others have reported that partially hydrogenated fat results in less favorable lipoprotein profiles than ruminant fat. Interpreting these data can be challenging, because in many studies, the level of ruminant fat *trans*-fatty acid isomers achieved in the test diets could not be achieved with current forms of ruminant fat in the food supply.

Conclusions

The data supporting a negative effect of dietary *trans*-fatty acids on cardiovascular disease risk are consistent. The primary dietary sources of *trans*-fatty acids include partially hydrogenated fat and ruminant fat. Due to legislative changes and public pressure, intake from the former source has declined over the past decade. Adherence to current recommendations to restrict the intake of saturated fat from meat and dairy products would result in reduction in *trans*-fatty acid intake from the latter source. These factors have contributed to a secular decrease in the United States and some other countries worldwide. The adverse effect of *trans*-fatty acids on plasma lipoprotein profiles is consistent; the effect of *trans*-fatty acids on other cardiovascular risk factors is less clear. Observational data consistently demonstrate an adverse effect of *trans*-fatty acids and partially hydrogenated fat on cardiovascular disease risk. Yet to be resolved is the issue of whether *trans*-fatty acid isomers predominating in ruminant and partially hydrogenated fats have differential effects in terms of health outcomes. This uncertainty should not detract from a clear and consistent public health message to restrict the intake of *trans*-fatty acids. Recent trends in the food supply toward less use of partially hydrogenated fat have accelerated this change.

Fermented Foods: Composition and Health effects

D Ansorena and I Astiasarán, University of Navarra, Pamplona, Navarra, Spain

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Fermentation is a biotechnological process used by man since, at least, the Neolithic period (around 10 000 years BC). The fermentation process is carried out by microorganisms (filamentous fungi, yeast, bacteria, or a combination of them) in anaerobic conditions and consists of the conversion of fermentable carbohydrates into end-metabolites such as organic acids, alcohols, and carbon dioxide. Louis Pasteur defined the fermentation process as 'la vie sans l'air,' which means 'life without air.'

Although the main aim for its application was initially food preservation and an increase in the shelf life, other effects such as the improvement of safety, nutritional value, and organoleptic quality of the foods are simultaneously achieved.

The discovery of microorganisms in the nineteenth century enabled the improvement of the production of fermented foods using specific starter cultures that can be added in a large number to accelerate and steer the fermentation process and to obtain a broad variety of fermented foods with different organoleptic and nutritional properties. Spontaneous fermentation is still used in some cases, such as in traditional foods and foods in which the microorganisms responsible for the fermentation are not well known. The microorganisms that can be used as starter cultures because of their proved safety, technological role, and/or beneficial use are gathered in lists elaborated by different institutions such as the International Dairy Federation (IDF), the European Food and Feed Cultures Association (EFFCA), the European Food Safety Authority (EFSA), and the Food and Drug Administration (FDA). Recently, an updated inventory of microorganisms used in food fermentations covering a wide range of food matrices (dairy, meat, fish, vegetables, legumes, cereals, beverages, and vinegar) was presented. The inventory of microbial food cultures (live bacteria, yeasts, or molds used in food production) contains 195 bacterial species and 69 species of yeasts and molds. There are two main fermentation processes: alcoholic fermentation, which results in the production of ethanol and is carried out predominantly by yeasts, and lactic acid fermentation, which gives rise to a great variety of products, occurs mainly in dairy products and cereals, and is carried out by lactic acid bacteria (LAB). Also, acetic acid and alkali fermentation processes take place in alcoholic products and in fish and seeds, respectively.

In the last years, special attention has been paid to the nutritional and health effects of fermented foods derived from microbial metabolic activities. This article is mainly focussed on these aspects. A brief revision of the composition of the different groups of fermented foods and the currently known main health aspects related to the biocompounds resulting from the fermentation process is reported.

Fermented Foods: Composition and Nutritional Value

Approximately one-third of human food intake corresponds to fermented foodstuffs. The major groups of fermented foods worldwide are dairy products, beverages (beer, wines, cider, coffee, and tea), and cereal-based products (bread, pancakes, and donuts) and several fermented foods derived from meat, fish, fruits, and vegetables.

The nutritional and organoleptic properties that characterize each type of these products depend on the composition of the food matrix, the type of microorganism responsible for the fermentation, and the processing conditions.

Dairy Products

The group of dairy products encompasses some of the most typical fermented foods, especially in Europe, North America, and the Middle East and also in Africa and Southeast Asia. The most common subcategories are cheeses and acid-fermented milks.

There are more than 1000 different types of cheeses elaborated with milk from different animal species (cow, sheep, goat, camel, and buffalo) and different maturation degrees, giving rise to a wide variety of textures and flavors. From a nutritional point of view, cheeses are in general high-density products with high energetic value and significant fat, protein, vitamin B, and calcium contents. Also, if they are subjected to large ripening processes, high amounts of biogenic amines (BAs) might be present. These compounds, resulting from microbial decarboxylation of amino acids, may generate toxic effects such as headache and hypertensive crisis and also act as inhibitors of histamine-detoxifying enzymes (as monoamine oxidase). Selection of appropriate starter cultures (decarboxylase-negative activity) has been suggested as a good strategy to try to reduce BA formation during fermentation processes.

Acid-fermented milk (e.g., yogurts and kefir) have different nutritional profiles depending on the ingredients used: type of milk (full fat vs. skimmed milk), added sugars or flavors, etc. The LAB responsible for their fermentation give rise to a degree of acidity that inhibits the growth of other types of microorganisms. In addition, they can also produce several bacteriostatic compounds and compounds responsible for the characteristic organoleptic properties of these types of products. One of the main changes that occur during the fermentation of milk is the conversion of lactose (milk sugar) into the more digestible lactate. Effectively, there are a growing number of individuals that are intolerant to lactose, which benefit from the fermentation of milk. There are other beneficial effects related to the intake of LAB (*Lactobacillus* and *Streptococcus*) and *Bifidobacterium* that are also used as starter cultures in fermented milk. Some of these microorganisms are considered as probiotics and can be positively related to an improvement of the intestinal tract health, an enhancement of the immune system, a decrease in the prevalence of allergy in susceptible individuals, and even a risk reduction of certain cancers. As for cheeses, fermented milk are also rich in calcium and B vitamins.

Fermented Beverages

Different beverages result from the fermentation process of vegetable products. Wines, beers, and cider have a rich composition that is dependent on the fermentation process (predominantly carried out by yeasts) and also on the raw materials (grapes or fruit juice and barley or other cereals) that serve as substrates. Ethanol is a common end product in beverage fermentation and has been classified as carcinogenic to humans by the International Agency for Research on Cancer (IARC). However, there are several epidemiological studies suggesting that moderate consumption of alcohol reduces overall mortality, mainly from coronary diseases. In general, the positive effects of alcoholic beverages are due to the presence of multiple polyphenols, bioactive compounds present in the vegetables or even their metabolites as a consequence of the fermentation process. Wine, being the richest in very active polyphenols such as resveratrol, is associated, when consumed in moderate amounts, with a decreased incidence of cardiovascular disease, hypertension, diabetes, and certain types of cancer. These positive effects could also be due to the presence of other phytochemicals, such as melatonin and phytosterols. Additionally, moderate consumption of beer has been associated with these effects to a lesser degree, probably because of its lower amount of polyphenols. Nevertheless, beer is rich in nutrients such as carbohydrates, amino acids, minerals, and vitamins. In the case of distillate drinks (spirits), they hardly have other interesting compounds apart from ethanol and the aromatic compounds responsible for their organoleptic properties. However, it is worthy to note that favorable changes in several cardiovascular biomarkers (higher levels of high-density lipoprotein cholesterol and adiponectin and lower levels of fibrinogen) provide indirect pathophysiological support for a protective effect of moderate alcohol use on coronary heart disease, independently of its source of supply.

Tea and coffee constitute another interesting group of fermented beverages characterized by their supply of stimulating compounds. It should be pointed out however that, although microorganisms (basically fungi) are involved in their processing, the main changes are due to endogenous polyphenol oxidase activity and other biochemical reactions that take place during fermentation. Although the intake of caffeine, theophylline, and theobromine has been associated with lifestyles related to risk of cancers, those beverages have shown some beneficial effects. Tea is the second most popular beverage in the world after water. Around 75% of tea consumed worldwide is black tea (obtained from the fermentation of green tea). There are many studies demonstrating protective effects of tea over chronic diseases as cardiovascular pathologies, and also, there are some studies, although not conclusive, demonstrating a chemopreventive effect. These effects are related to the high amounts of polyphenolic compounds, especially catechins. Effectively, during the fermentation process to obtain black tea, catechins are converted in a great extent to polymeric complexes known as theaflavins and thearubigins, which seem to be also effective in the prevention of cardiovascular disease. Coffee is very rich in several biological compounds as caffeine, diterpenes, chlorogenic acids, and melanoidins, which may affect human health. The health benefits of coffee consumption regarding the cardiovascular system and metabolism mostly depend on its antioxidant compounds; meanwhile, diterpenes and caffeine may produce harmful effects by raising lipid fraction and affecting endothelial function, respectively. The variety of coffee species, roasting degree, and brewing method determine the final composition and the derived effects.

Fermented Meat and Fish Products

Meat fermentation processes in combination with drying and smoking probably developed empirically over 5000 years ago and have given rise to a broad variety of products: dry, semidry, mold-ripened, and undried products all around the world. The fermentation process is carried out basically by LAB and coagulase-negative staphylococci. Fermented meat products have the nutritional advantages related to the intake of meat, which is a significant amount and quality of proteins depending on the type and percentage of raw meat used in the formulation, iron (50–60% in the heme form), zinc, and vitamin B. On the other hand, they have some arguably negative aspects related to a generally high amount of fat (with a high saturated fat proportion), cholesterol, and sodium. Moreover, the presence of nitrites/nitrates used as nitrificants (curing process) in their formulations has to be taken into account. As the result of the fermentation process (due to proteolytic and lipolytic activities of microorganisms in concertation with the action of meat enzymes), a wide variety of compounds with significant impact on the sensory properties are formed: amino compounds, aldehydes, alcohols, acids, alkanes, alkenes, ketones, and even BAs. Some of these compounds have been pointed out as functional compounds, in particular some of the peptides. Furthermore, there are studies that have pointed out that fermented sausages could be considered as probiotic foods although much more studies are needed to establish the actual health benefits. Moreover, different studies trying to improve the composition of fermented sausages in order to get healthier products are being carried out.

Fermented fish products are especially consumed in Asia and Oceania countries. These products include very popular sauces and pastes, which are used as condiments and ingredients in a great variety of processed foods. They are rich in proteins and amino acids but sometimes also in BAs, which have to be controlled. Also, they have in general high amounts of salt (around 20–25%, except for a traditional product sikhae, which contains 6–8%).

Cereal-Based Fermented Products

Cereals are a good microbial substrate, so the fermentation process takes place in a natural way involving mixed cultures of yeast, bacteria (in general LAB), and fungi (*Aspergillus*, *Fusarium*, *Penicillium*, and *Trichothecium*, among the most frequent). Fermentation of cereals gives rise to very interesting changes in composition, namely, a decrease in the level of carbohydrates and nondigestible oligosaccharides, a synthesis of some amino acids, an increase in the availability of the vitamin B group, and a degradation of phytate (a quelant of iron, zinc, and calcium). As a consequence of the fermentation of wheat and rye flour by LAB (sourdough process), a reduction in the starch digestibility is noticed, leading to a lower glycemic

index. This effect is mainly attributed to the formation of organic acids (lactic acid), to the greater release of peptides and amino acids, or to the increment in the amount of free phenolic compounds, among other factors. All these changes improve the nutritional properties and even can lead to the development of functional products. Effectively, the products formed as a consequence of the fermentation process and the presence of some compounds with health beneficial effects, as it is the case of β-glucan (especially present in oat), make fermented cereals a group to be taken in consideration in the context of functional foods. Moreover, cereals have also been evaluated as good substrates for the growth of probiotic strains, giving rise to some new probiotic foods (e.g., Yosa and Dogik) with supposed beneficial effects, although these aspects are still a research challenge. Furthermore, the fact that cereal-based fermented products are major contributors to energy intake in developing countries has to be considered.

Fermented Fruits and Vegetables

Fresh vegetables and fruits are recommended in a healthy diet because they are fundamental sources of vitamins, minerals, dietary fiber, and biocompounds as phytosterols (hypocholesterolemic effects) and polyphenols (antioxidant properties). However, there are some traditional and emerging fermented products resulting from lactic acid fermentation that represent a suitable way for increasing the consumption of vegetables and fruits. For instance, kimchi is a traditional fermented vegetable product of Korea, which is consumed in winter when the dietary intake of fresh vegetables might be more difficult. Other examples include sauerkraut, cocoa, fermented olives, pickles, and fermented radish.

Bioactive Compounds Derived from the Fermentation Processes

Fermentation leads, among other changes, to the release and/or synthesis of different bioactive compounds that are responsible for some of the health benefits attributed to this type of foods.

Table 1 gathers some of the most common bioactive compounds resulting from fermentation processes and the foods in which they are present.

Bioactive Peptides

Fermentation is one of the mechanisms by which bioactive peptides can be present in foods. Effectively, a number of papers describe the release of these compounds during fermentation of a wide variety of foods, ranging from milk, legumes, meat, soybean, to sourdough. These compounds, formed by 2–20 amino acid sequences, have been related to several physiological functions able to influence health.

Antihypertensive properties have been described for IPP (isoleucine–proline–proline) and VVP (valine–proline–proline) tripeptides released during the fermentation of milk by different proteolytic strains of *Lactobacillus helveticus* (CP790, LBK-16H, and ASC474), *Streptococcus thermophilus*, and *Saccharomyces cerevisiae*. The formation of these and other peptides can be affected by fermentation time and temperature and by pH and calcium concentration in medium. The main mechanism involved in their biological activity deals with the inhibition of ACE (angiotensin-converting enzyme). It has been postulated, for instance, that after a 2-week consumption of 150 ml day^{-1} of fermented milk, hypertensive patients reduced systolic blood pressure approximately by 7 mmHg. Other studies do not clearly support this finding. Nevertheless, according to the EFSA, more studies are needed to conclude about the cause–effect hypotensive activity. In addition, not only the production but also the stability of bioactive peptides has to be taken into account during fermentation.

Antioxidant, antimicrobial, and immunomodulatory properties and anti-inflammatory potential have also been described for peptides formed during the fermentation of milk and other dairy products such as kefir or cheese.

Soybean is also an important source of bioactive peptides. Thus, the proteases and peptidases of *Bacillus*, *Aspergillus*, and *Rhizopus* strains have been shown to hydrolyze soy proteins into active hypotensive peptides. In addition, soy-fermented products such as nattō and tempeh have yielded antioxidant peptides. Less explored sources of bioactive peptides are lentils or porcine skeletal muscle proteins, whose fermentations by *Lactobacillus plantarum* or *Lactobacillus sakei* and *Lactobacillus curvatus*, respectively, were able to release also ACE inhibitory peptides during *in vitro* studies.

Exopolysaccharides

Exopolysaccharides (EPSs) are homopolymers or heteropolymers with a wide diversity of structures, capable of modifying the sensory properties of foods. Some strains of LAB species (*Lactobacillus acidophilus*, *Lactobacillus delbrueckii* subsp. *bulgaricus*, *Lactococcus lactis*, *Lactobacillus plantarum*, *Lactobacillus casei*, etc.) are EPS producers, and in fact, one of these bacteria, *Leuconostoc mesenteroides*, excretes dextran, authorized as a novel food ingredient to be used in bakery products (Decision 2001/122/EC). Besides its technological property as thickener in bakery and dairy products, prebiotic potentialities have been associated with this polymer, as gut microbes metabolize it to produce propionic acid, which is able to reduce cholesterol and triglyceride levels. In addition, EPSs have generally been suggested as blood cholesterol reducers, antioxidants, immunomodulators, and antitumor and antiulcer agents. One of the most studied strains for the antitumor activity of its EPS has been *Lactobacillus plantarum* 70 810, whereas the EPS from *Lactobacillus helveticus* MB2-1 with whey as matrix was associated with strong scavenging activity in *in vitro* tests. Kefir grains are also able to release EPSs from soy milk. However, there is a lack of clinical evidence demonstrating these putative prebiotic characteristics and beneficial effects after oral administration of EPS in functional foods.

Arabinoxylans

During the fermentation of cereal-derived processed food such as bread or beer, the enzymatic hydrolysis of arabinoxylans, yielding arabinoxylan oligosaccharides, can occur. These compounds have been associated with prebiotic and other health effects (improved gut transit, reduced serum triglyceride and

Table 1 Nonexhaustive list of examples of compounds produced during fermentation of foods

cholesterol levels, and immunomodulating and antioxidative effects), although they have not been extensively studied yet.

Polyphenols and Flavonoids

Health beneficial effects are attributed to polyphenols and flavonoids present in vegetable products. These compounds are predominantly found as glycosides in nature. However, their bioavailability in the organism increases when they are not glycosylated. Some food-fermenting LAB can remove glycoside residues by means of enzymatic activity (α-rhamnosidase, β-galactosidase, and β-glucosidase), resulting in increased bioavailable bioactive compounds. Some examples of LAB causing the hydrolysis of healthy phenolic compounds are the following: *Lactobacillus plantarum*, *Lactobacillus pentosus*, *Lactobacillus brevis*, and *Pediococcus pentosaceus*. Strains of these

LAB species have been shown to hydrolyze oleuropein, the most prevalent polyphenol present in olives, to which some of the beneficial effects of unrefined olive oil are attributed. It has been described as an antioxidant and with antitumor and anti-inflammatory properties.

Soy fermentation induces a relevant increase in free isoflavones (daidzein, glycitein, and genistein) from their conjugated forms (daidzin, glycitin, and genistin). β-Glucosidase activity during soy fermentation has been described for selected strains of *Lactobacillus rhamnosus*, *Lactobacillus acidophilus*, *Lactobacillus casei* and *Enterococcus faecium*. As soy isoflavones are structurally similar to estrogen, similar health effects to these compounds have been reported. They have been postulated to play a role in the prevention of cardiovascular disease, metabolic syndrome, and type 2 diabetes; in relieving postmenopausal symptoms such as osteoporosis; or in the decrease in risk of breast and prostate cancers. However, in addition to evidences from *in vitro* biochemical tests and also from epidemiological studies, mostly done in populations consuming high amounts of soya, long-term interventional studies are needed to conclude on the health effects of these compounds. In this sense, the EFSA has considered that, based on the currently available studies, the following claimed beneficial health effects lack a clear enough cause and effect relationship: maintenance of normal blood LDL cholesterol concentrations, protection of DNA, proteins and lipids from oxidative damage, maintenance of bone mineral density, and reduction of vasomotor symptoms associated with menopause.

In the case of cereals, it has been shown that fermentation by *Lactobacillus rhamnosus* and *Saccharomyces cerevisiae* can increase antioxidant activity and total phenolic content of buckwheat, wheat germ, barley, and rye as compared with their unfermented counterparts. Thus, tailored fermentation to improve the antioxidant capacity of resulting foods can be accomplished.

γ-Aminobutyric Acid

γ-Aminobutyric acid (GABA) is a nonprotein amino acid that has several well-known physiological functions including antioxidant, antihypertension, and antidepression effects. Although most of the clinical applications of GABA are theoretical, based on data extrapolated from drug interventions, there are some experiments in humans and mostly in animal studies, in which fermented foods have shown these physiological effects. A significant decrease in blood pressure was noticed after the administration of fermented milk rich in GABA to mild hypertensive patients (using *Lactobacillus casei* strain Shirota and *Lactococcus lactis* YIT 2027) and also in rats (with *Lactobacillus paracasei* subsp. *paracasei* NTU 101 and *Lactobacillus plantarum* NTU 102). Administration of products fermented with the fungus *Monascus* to rats demonstrated their antidepressant effect.

LAB are known food-associated GABA producers, based on their glutamic acid decarboxylase activity, which is the *enzyme* that catalyzes the decarboxylation of glutamate to GABA. *Lactobacillus brevis* gives particularly high GABA production yields compared with other LAB. A wide range of GABA-enriched fermented food products have been described, including cheeses and other dairy products (e.g., koumiss and diverse fermented milk), soy sauces, kimchi, sourdough, black raspberry juice, red seaweed beverage, and fermented fish and meat. Also, model fermentation systems aiming at an increase in GABA and other bioactive compounds have been successfully assayed using lentils and kidney bean extracts as matrices.

Conjugated Linoleic Acid

Conjugated linoleic acid (CLA) (C18:2, with c9, t11 and t10, and c12 being the most common isomers) is naturally present in milk. In addition, several *Lactobacillus*, *Propionibacterium*, *Bifidobacterium*, and *Enterococcus* strains extensively synthesize CLA during the fermentation of milk, whereby the final concentration is influenced by the processing conditions. Often, CLA is considered as a healthy compound, to which several potent physiological properties were attributed, including anticarcinogenic, antiobese, antidiabetic, immunomodulator, and antihypertensive effects. However, other studies point out as well an increase in oxidative markers after CLA supplementation, and controversial results on glucose metabolism or liver function problems have been obtained. Thus, safety concerns regarding the use of CLA in humans persist and need further investigation, with better experimental designs that will clarify the mechanisms of CLA activities. In this sense, the EFSA has considered that, with the studies currently available, the previously mentioned claimed beneficial health effects for these molecules have no clear-enough cause–effect relationship.

Vitamins and Cofactors

The (over)production of vitamins by LAB provides a very attractive approach to improve the nutritional composition of fermented foods. Fermentation can indeed modulate the vitamin content of foods in diverse ways, via either increases or decreases. For instance, yeast fermentation has been shown to increase the folate content in the production process of bakery goods based on wheat, oat, and rye. In the particular case of rye, the level of folate was increased up to sevenfold and that of free phenolic acids up to tenfold after germination and fermentation by *Saccharomyces cerevisiae*. Not only yeasts but also LAB (*Lactobacillus plantarum* riboflavin-overproducing strains) have been successfully used for the preparation of bread and pasta with enhanced levels of vitamin B_2. In milk, folate levels can significantly increase after fermentation with different LAB, as shown for milk fermented with *Lactobacillus acidophilus* ATCC 4356 and *Streptococcus thermophilus* MC. Also, higher amounts of ubiquinone have been found in Korean and Japanese fermented foods than in unfermented foods, due to their diverse microbiota during the process of fermentation (LAB, yeast, and fungi). Foods such as kimchi and jeotgal (a fermented fish) may show high values of this compound. The deficiency of CoQ10 has been implicated in several clinical disorders, including chronic heart failure and hypertension.

Polyols

Other beneficial compounds that might result from fermentation processes are polyols. Modulation of the redox balance

during sugar metabolism by LAB can result in the synthesis of sorbitol, mannitol, and xylitol, which play an important role in foods as reduced caloric sweeteners and anticariogenic agents.

Fermented Foods as Probiotics

Probiotics are 'live microorganisms that, when administered in adequate amounts, confer a health benefit on the host.' Several *Lactobacillus* and *Bifidobacterium* species have been investigated and even commercialized, and certain strains of *Enterococcus*, *Propionibacterium*, and *Bacillus* species and also from the yeast *Saccharomyces boulardii* have been considered as microorganisms with probiotic properties. Some of the health benefits traditionally associated with probiotic consumption include the improvement of intestinal tract health (contributing to the control of irritable bowel syndrome and inflammatory bowel disease, the suppression of pathogens, and the control of travelers' diarrhea or antibiotic-caused diarrhea), enhancement of the immune system, synthesis and enhancement of the bioavailability of nutrients, reduction of symptoms of lactose intolerance, reduction of serum cholesterol levels, and reduction of the risk of certain cancers. Several specific criteria should – arguably – be fulfilled by a microorganism to be considered a probiotic: it should remain viable during the shelf life of the product, withstand transit through the GI tract, and stabilize the intestinal microbiota.

One of the difficulties dealing with confirming the health benefits associated with probiotics is the fact that their biological effects are strain-specific, which makes the data comparison among studies difficult. In addition to this, the lack of evidence for cause–effect relationship has caused the EFSA to reject probiotic health claims. In many of the opinions given by the EFSA on probiotics, it was argued that the outcomes measured did not equate a beneficial physiological effect. Nevertheless, some EU member states have national nutrition guidelines or recommendations that include either probiotics or fermented milk with live bacteria.

Due to the fact that some fermenting microorganisms have probiotic properties, they have been used as starter cultures in attempts to formulate healthier foods. A consensus document elaborated in 2014 makes a reflection about whether the probiotic framework should include traditional fermented foods containing live microbes or not. According to the latter opinion, it is not always possible to clearly distinguish the health contribution of the pure cultures from that caused by the consumption of fermented foods. Consequently, it has been concluded that conventional fermented products are best described as 'containing live and active cultures' but should not be called probiotic. Nevertheless, fermented foods containing live cultures might also qualify as a 'probiotic' if they meet the criteria for that category.

Conclusion

Fermented foods include a wide variety of foodstuffs, whose composition strongly determines their nutritional value. Additionally, several metabolites resulting from fermentation processes are currently being researched as potential functional compounds that contribute to the health properties of this type of foods. Among others, compounds such as bioactive peptides, EPSs, arabinoxylans, polyphenols and flavonoids, and GABA can be highlighted.

Fermented Foods: Fermented Meat Products

F Leroy and L De Vuyst, Vrije Universiteit Brussel, Brussels, Belgium

© 2016 Elsevier Ltd. All rights reserved.

Introduction: From Necessity to Delicacy

Fermented meat products have been known as highly appreciated foods throughout the ages. They are found in many regions worldwide as a part of traditional diets, where they are perceived as attractive gastronomic entities contributing to cultural and geographic distinctiveness (Table 1). In Europe, fermented meats can be traced back to, at least, classical antiquity where they served to preserve meat after slaughter. The production of dry-fermented sausages, consisting of seasoned and salted minced meat that is stuffed into intestinal casings, has been documented in historical sources as a Roman craft. The technique was, however, largely based on the art of dry ham production developed by the Celts and Gauls, consisting of the salting and drying of hind legs of wild boars and pigs. Over the years, fermented meats came to exist in an overwhelming variety, characterized by large differences in ingredients, shape and caliber, and processing conditions. Several types of meat have been applied, including pork, beef, horse, donkey, deer, poultry, and ostrich. Well-known examples of dry-fermented sausages include different types of *salami* (e.g., *salame Brianza*), *chorizo* (e.g., *chorizo de Pamplona*), and *saucisson sec* (e.g., *rosette*). In addition, some fermented meats are semidry or even moist, such as German *mettwurst*, which have distinctive texture properties but are generally displaying a decreased stability. Besides Europe and its expansion to the New World, Asia also has a remarkable tradition of meat fermentations, although this has been less documented and explored. Yet, all local fermented meat specialties have origins in more or less remote pasts, with unique stories to tell, but eventually trace back to the same ancestral need for meat preservation. In fact, meat fermentation originally took off as an empirical preservation method of a primary commodity, in a similar manner as the preservation of milk led to the production of cheese and fermented milks of all sorts.

Due to its highly proteinaceous, energy-dense, and overall nutritious character, meat originating from hunted or domesticated animals has been a strategic foodstuff for most of human history and continues to be so. Nonetheless, before the introduction of the cold chain, the perishable nature of meat made it difficult to achieve prolonged storage in times of scarcity. The stabilization of meat through salting and fermentation therefore led to large logistic benefits. The end products became stable to such a degree that they could even be used as trading goods and provisions for travelers and soldiers, widely circulating throughout the European continent and facilitating expeditions and military campaigns. Clearly, preservation is no longer the most important *raison d'être*, at least in the Western world. Still, the convenience factor and unique sensory properties of fermented sausages continue to provide them with a steady share of the meat market. Over the centuries, the basic ingredients have remained the same, that is, minced meat, fat, curing salt, and spices. These ingredients are stuffed into casings, from either intestinal or synthetic origin, and subsequently subjected to a microbial fermentation process, in most cases followed by a drying stage for further stabilization and maturation of flavor complexity (Figure 1).

Meat Fermentation as a Spontaneous Process

As for all raw and salted meat products, the endogenous activity of meat enzymes, in particular proteases and lipases, contributes to the aging and ripening of the product being subjected to drying. In contrast to dry-salted hams, the original production of dry-fermented sausages involved a desirable and spontaneous acidification of the meat matrix that serves as an extra preservation hurdle in addition to the primary salting and drying, mostly because a comminuted mixture of meat trimmings and fat particles is less stable than whole muscle. Fermentative acidification to pH values that are usually situated between 4.8 and 5.2 inhibits the growth of undesirable microorganisms that are present on the raw meat and denatures the salt-solubilized protein fractions to a characteristic sliceable and gel-like texture.

Under appropriate temperature conditions (e.g., between 18 and 28 °C), the combination of curing salt and anaerobic conditions that are prevailing in the sausage casings strongly select for specific and desirable microorganisms. As a result, the initial microbial species diversity that is present on the raw materials is narrowed down within a couple of days to a few persistent microbial groups. Largely dominating bacteria are certain mesophilic species of *Lactobacillus*, in particular *Lactobacillus sakei* and, albeit to a lesser extent, *Lactobacillus curvatus* or *Lactobacillus plantarum*. Other lactic acid bacteria that may occasionally be present but do not or only marginally affect the production process of most traditional, spontaneously fermented sausages include enterococci, lactococci, pediococci, and leuconostocs. In addition to the dominance of meat-associated lactobacilli, a considerable subdominant population consists of catalase-positive cocci, mostly coagulase-negative staphylococci and sometimes kocuriae. Depending on the applied raw materials and processing conditions, different species of catalase-positive cocci may be encountered during spontaneous meat fermentations. In most cases, *Staphylococcus equorum*, *S. saprophyticus*, and/or *S. xylosus* are prevailing. Yet, minor levels of, for instance, *S. carnosus*, *S. sciuri*, *S. simulans*. *S. succinus*, and *S. warneri* are not uncommon. Whereas lactic acid bacteria chiefly cause acidification through lactic acid production, catalase-positive cocci prevent oxidative deterioration, generate stable nitrosomyoglobin pigments via nitrate reductase activity, and contribute to an attractive aroma via amino acid and fatty acid conversions. These precursor amino acids and fatty acids are liberated via protease, peptidase, and lipase activities by muscle enzymes, although minor contributions by bacteria have also been described.

Table 1 Illustrative but nonexhaustive list of some different types of well-known fermented sausages and their particularities

Type	*Country of origin*	*Particularities*
Mediterranean dry-fermented sausages	Italy (e.g., salami), France (e.g., rosette), Spain (e.g., fuet), etc.	Large variety of recipes and types, often heavily seasoned with pepper, garlic, and herbs; mildly fermented, extensively dried and matured, and mostly molded
Chorizo	Spain	Contains paprika; variable drying periods and moist contents but often semidry and smoked; high-end variants contain Iberico pork
North European dry-fermented sausages	Germany, Norway, Belgium (saucisson d'Ardennes), etc.	Large variety of recipes and types; usually rather acid and often heavily smoked without molding, although salami-type sausages are also produced
Teewurst, mettwurst	Germany	Moist and spreadable pork sausages that are only moderately or not dried; usually smoked and no molding; highly perishable
Hungarian salami	Hungary	Salami-like but with an unusual combination of intense smoking and molding
Lap Cheong	China, Vietnam, etc.	Different types of dried and usually smoked pork or poultry sausages; sometimes containing rice and seasoned with soy sauce, rose water, or sake

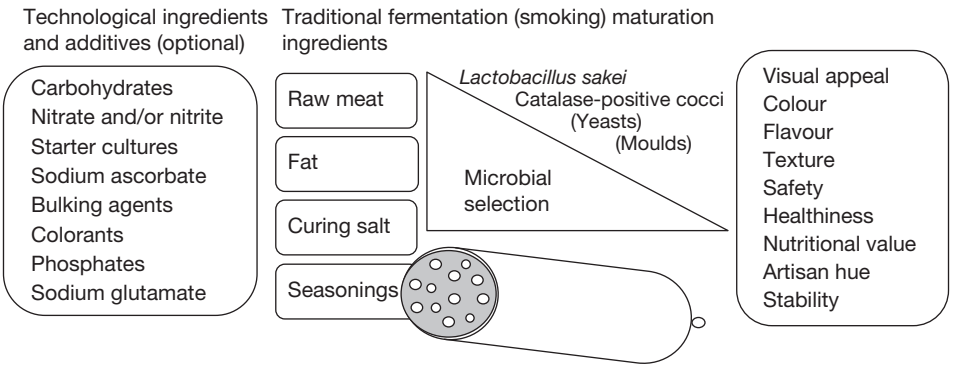

Figure 1 Common ingredients used in the meat fermentation process and targeted quality characteristics of the end products.

Flavor maturation of fermented sausages thus correlates with the amounts of branched-chain aldehydes and alcohols from the conversion of branched-chain amino acids and branched-chain and straight-chain methyl ketones derived from microbial β-oxidation of fatty acids.

Besides bacteria, yeasts and molds can be present in some sausage types. Yeasts, such as *Debaryomyces hansenii*, are probably of a rather minor importance in flavor development but could accentuate certain aromas. In contrast, molds are crucial elements in the elaboration of south European fermented sausages where they develop as a desirable outside layer on the product surface after fermentation, during which they generate additional aroma and contribute to color stabilization through catalase activity, oxygen consumption, and shelter against light. The mycobiota of fermented sausage is diverse, but *Penicillium* is usually the predominant genus (e.g., *Penicillium nalgiovense*). In traditional northern European fermented sausages, molds are mostly undesirable. This is due to the rather humid climate conditions in these regions, which are unsuitable for proper, controlled, and safe mold development. As a consequence, such products are frequently smoked after fermentation, as an empirical manner to add additional preservative action and to prevent the unbalanced growth of detrimental molds. Meanwhile, the smoked flavor became a desirable sensory attribute for northern European consumers. In addition, northern European varieties of fermented sausages are generally more acidified to obtain enhanced microbial inhibition, since they are usually more moist and, hence, more vulnerable to hazards than their drier southern counterparts.

Technological Optimizations

Over the years and particularly since the mid-twentieth century, several technological adaptations have been introduced, as to adjust the traditional meat fermentation process to the requirements of an ever industrializing and globalizing world. This led to the emergence of large factories in the 1960s, producing fermented meat products of consistent quality and safety on an industrial scale. Adaptations range from the simple addition of ascorbate as an antioxidant and of sugar and manganese as bacterial stimulants, over the introduction of climate chambers and microbial starter cultures for improved control, to a multitude of cost reduction attempts via the use of artificial casing and additives of all sorts. Also, technological adaptations have been brought in to reduce the potential generation of toxic compounds, for instance, by dipping sausages in a sorbate solution to avoid undesirable mold growth and by optimizing potentially hazardous smoking procedures.

One of the key breakthroughs has been the gradual introduction of controlled-climate chambers in the 1950s, which enable a rigid control of temperature and relative humidity. Accordingly, the unpredictability of fluctuations in weather

conditions can be ruled out, and a more precise tuning to optimal process requirements can be obtained. This is particularly important not only for a correct drying process but also to steer fermentation and molding.

More or less in the same period, another major advancement has been achieved through the development and addition of starter cultures. In the 1940s, Jensen and Paddock explored the use of *Lactobacillus* cultures onto raw meat, which was followed by inoculations with *Pediococcus cerevisiae* in the United States and *Micrococcus* M53 in Europe. Such starter cultures permit to mostly overcome the problem of failed fermentations, which may be occurring in traditional processes where producers rely on a spontaneous development of the indigenous meat microbiota. Meat starter cultures nowadays usually consist of a predefined microbial consortium of lactic acid bacteria for acidification purposes, mostly *Lactobacillus sakei* and/or *Pediococcus* species, accompanied by selected catalase-positive cocci, mostly *S. xylosus*, *S. carnosus*, and/or *Kocuria varians*. These combined cultures are usually lyophilized and added as a powder that has been resuspended in water to the meat batter prior to stuffing and fermentation. In addition, a surface mold culture may be applied to control the molding process during maturation. As a result of starter culture addition, the production process is accelerated, and end products are more uniform. In North America, further speeding up has been achieved by increasing the fermentation temperature from the traditional range below 28 °C toward temperatures above 35 °C. As a result of this enhanced fermentation temperature, pediococci take over from the mesophilic lactobacilli. Even faster processes have been obtained with chemical rather than microbial acidification, mostly by using glucono delta-lactone or encapsulated lactic acid as acidulants.

Yet, the ever-increasing attempts to speed up fermentation and maturation and to minimize ingredient and processing costs have been counterbalanced by severe losses in product quality. Flavor, for instance, is the result of a complex and delicate interplay between endogenous meat enzymes, microbial action, and physicochemical effects. The dynamics of this interplay depend strongly on the process conditions, in particular the allowed time frame for biochemical conversions and the rate of acidification. On the one hand, cathepsin D, which is a major meat proteinase acting on the myosin and actin fractions, is activated by acidity (with optimal activity at pH 4.5). On the other hand, low pH values strongly inhibit the metabolic performance of meat microorganisms, including their production of peptidyl peptidases and aminopeptidases and their enzymatic conversions of amino acids and fatty acids. With respect to the postfermentation processing, too short maturation periods may impede the proper flavor-generating chemical changes that lead to fatty acid oxidation products and Strecker degradation of amino acids.

In conclusion, excessive acceleration of the production process, on the level of both fermentation and maturation, is known to compromise flavor development to a large extent, despite the obvious advantages related to standardization and cost reduction. As a technological response to partially conceal cost-induced quality losses on the level of texture, color, and flavor, several additives have been introduced in the meat fermentation process. Commonly applied examples include the use of bulking agents (e.g., milk powder), phosphates, sodium glutamate, added flavors (e.g., liquid smoke flavorings), colorants (e.g., cochineal), and sorbates.

From a safety point of view, controlled use of nitrite and/or nitrate salts as additives to fermented meats has become a common practice, as these curing compounds contribute to the inhibition of meat-associated pathogens. Moreover, they are involved in the generation of a typical cured flavor, inhibit lipid oxidation, and lead to stable color formation via the nitrosylation of myoglobin. Yet, because of their involvement in carcinogenic nitrosamine formation, maximum levels have been introduced by regulation. In addition, their chemical conversions can be tuned technologically, for instance, by adding the reductant ascorbic acid, which is to be added in levels exceeding 550 ppm in the United States.

Understanding the Metabolic Functioning of Meat Microorganisms

Improving the meat fermentation process to yield even more attractive end products is a matter not only of muscle biochemistry but also of a better insight into the microbial community dynamics and metabolism. Although the overall roles of the fermented meat microbiota are well understood, the more subtle aspects of their metabolism need further exploration. For instance, recent whole-genome analyses of fermented meat bacteria have identified specialized metabolic repertoires that may explain why certain community members are so strikingly dominant. The specialized adaptation by *Lactobacillus sakei* to the fermented meat environment has been linked to specific metabolic properties via genome analysis, metabolite kinetics, modeling, and gene expression studies. Consequently, the use of arginine and nucleosides by *Lactobacillus sakei* as alternative, nonglucose compounds as energy sources that naturally occur in meat has been suggested as relevant for bacterial dominance. This property has also been shown for coagulase-negative staphylococci, possibly explaining differences on the inter- and intraspecies levels. Variability in competitiveness between coagulase-negative staphylococci is particularly intriguing, since this forms the basis for the eventual selection of a specific bacterial diversity associated with a certain product. As a result, repercussions on the overall bacterial metabolic activity and hence the final sensory quality are to be expected. It has, for instance, been shown that differences in sensitivity to pH lead to different growth or survival kinetics, when comparing *S. carnosus* to the more acid-sensitive *S. xylosus*. Also, the replacement of a smoking treatment by molding may cause a shift from *S. saprophyticus* to *S. equorum*, possibly because of pH increases. As different staphylococcal species display variations in both the absolute and specific production of volatile compounds, this can affect sausage aroma measurably. Enhanced technological control on the staphylococcal community could thus represent an opportunity for tailored flavor modulation.

Interactions between microorganisms, the enzymes of the muscle tissue, the applied ingredients, and the process technology determine the quality, safety, and stability of the end products. New metabolic insights will thus contribute to process optimization and the further development of the so-called functional starter cultures, which should lead to improved

sausage fermentation with respect to flavor, safety, processing, technology, or health, as compared with traditional starter cultures that are merely aiming at standardization and processing speed. Such novel insights are to be obtained from the use of state-of-the-art methodologies, for instance, omics approaches, which are increasingly being used in the domain of food science and technology.

Toward a New Generation of Fermented Meat Products?

Although the meat fermentation process has been dramatically optimized through technological innovations, several challenges are still to be undertaken. Preferably, these strategies need to make use of 'natural' options, avoiding the use of commonly shunned chemical additives. Some of the existing concerns have to do with the safety and health implications upon consumption of the end products.

First, several incidences with foodborne pathogens have been reported despite the fact that acidification, salting, and drying are important microbiological hurdles. Problems are sometimes encountered due to the presence and ingestion of *Salmonella* and *Escherichia coli* or enterotoxins produced by *Staphylococcus aureus*. *Listeria monocytogenes*, although not linked to foodborne illness by fermented meat consumption till now, is also of concern. Several countries, such as the United States, have adopted a zero-tolerance policy with respect to the presence of this bacterium in ready-to-eat foods. This is problematic because *Listeria monocytogenes* has been shown to survive several meat fermentation processes and can sometimes be recovered from nonheated European end products. In general, the presence of foodborne pathogens may be due to high loads in the raw materials or failing production processes. Novel strategies that could eliminate potential residual levels of undesirable bacteria are being sought for. The use of lactic acid bacteria starter cultures that produce natural antimicrobials, in particular bacteriocins, has been frequently explored. Although this mode of action offers considerable potential against *Listeria monocytogenes*, bacteriocins by lactic acid bacteria are generally inefficient toward gram-negative pathogens. Meat-compatible microorganisms with targeted antimicrobial actions, in particular toward *Salmonella* and *E. coli*, would thus offer considerable food safety advantages. Other microbial concerns are related to the use of the fermentative microbiota itself, since certain lactobacilli, staphylococci, and enterococci present during fermentation may be producing biogenic amines. Likewise, surface molds may in principle be toxicogenic. This is particularly of concern during meat spontaneous fermentation processes, since commercial starter cultures have normally been screened to demonstrate the absence of biogenic amine, mycotoxin, and antibiotic formation.

A second major concern is related to the potential implications of fermented meat consumption on human health. Although meat products are characterized by a high intrinsic nutritional value, mostly due to their high contents of quality protein, iron, zinc, and vitamins, some unease has been expressed with respect to their fat and sodium contents. Although the mostly pork-based fat fraction is rather unsaturated and not necessarily problematic, high-fat products are energy-dense and do not meet the current market demand for low-fat foods. More importantly, fermented meat products have been charged for their potential association with the risk of colon cancer. The World Cancer Research Fund specifically advises to avoid all processed meats as part of its ten recommendations to combat cancer. The mechanisms for this association are not fully understood, but a part of the effect could be due to the use of mostly red muscle and the presence of nitrate and/or nitrite in the curing salt. Several attempts have already been made to partially counter all aforementioned concerns, although this frequently implies loss of sensory excellence. Reduction of sodium results in a loss of flavor intensity and texture development, whereas the replacement of potassium and/or magnesium may sometimes lead to metallic or bitter taste defects. Likewise, fat reduction leads to poor mouth feel and aroma losses, whereas fat replacement by, for instance, vegetable oils often results in texture setbacks. Also, the increased production of poultry-based fermented meat products or products based on meat replacers, as an attempt to counter the consumption of red muscle, is leading to end products that display weaker hedonistic profiles. Up till now, attempts to lower the added nitrite levels have been limited to the indirect addition of nitrate via vegetal fractions such as celery or spinach extracts, which is then further converted to nitrite by the meat staphylococci. Although this may be useful for labeling purposes, this approach is mainly aiming at concealment and does not contribute to the health debate.

In an endeavor to counter the negatively perceived health status of fermented meats, several trials have been made to include health-promoting compounds in the original formulations. Examples include the use of probiotics, prebiotics, and other fibers, lycopene, antioxidants, olive oil, and calcium and attempts to increase the content of conjugated linoleic and linolenic acids. Although commercial examples exist, technological and legislative bottlenecks often remain, and questions arise on the conceptual and nutritional relevance of such products.

Paradoxically, part of the innovation of fermented meat products is based on the reintroduction of artisan features. Such features are increasingly used in marketing strategies for contemporary fermented meat products, in a process that can be categorized as 'reemergence of tradition.' The use of labels that claim artisanship and tradition is largely employed to give a feel of trustworthiness in a globalizing food market in crisis.

Conclusions

Despite the fact that fermented meats are rooted in an age-old tradition, several innovations and technological adaptations have been introduced over time. The advent of modern food technology has greatly improved processing speed and efficiency, although in many cases, a too pronounced focus on cost reduction has resulted in inferior sensory quality. As a result, several opportunities can be identified to improve the quality of fermented meats, especially when produced on a cost-effective industrial level. Further research, based on state-of-the-art methodologies and taking into account the combined disciplines of microbiology, meat science, and

processing technology, is needed if any breakthroughs are to be achieved. In addition, the nutritional aspects of fermented meat consumption will likely become more important in the future. Finally, sociological approaches and consumer studies may help to better understand the complex relationship between apparently conflicting demands for traditional characteristics and innovative elements in fermented meats.

Introduction

A chronological appraisal of the origin of fermented milks (FMs) (e.g., Bulgarian milk, Yogurt, Kefir, Koumiss, Laben, Dahi, Skyr, and sour milk) shows that they date back to early civilizations around 10 000 BC. As the way of life of humans changed, it led to the domestication of the cow, sheep, goat, buffalo, and camel. A wide range of indigenous FM products are traditionally made in rural areas worldwide. Most of these products rely primarily on spontaneous fermentation due to the presence of indigenous microflora (mainly lactic acid bacteria, LAB) in the milk. In the Asiatic Steppes, containers made from animal hides containing microorganisms from the previous production batch are used during the manufacture of traditional Koumiss, Bulgarian milk, etc. This reliance on containers or utensils to provide an initial inoculum of starter organisms is widespread.

During the past 90 years, considerable attention has been directed sporadically on benefits derived from the consumption of milk products containing LAB. The role of FM in human nutrition is well documented. Man knew the virtues of fermented foods even during the early days of civilization. In earlier days, these foods were produced by natural fermentations with the main objective of preserving milk.

In many areas of the world, the fermentation process is initiated by the adventitious indigenous microorganisms or through 'backslopping' with mixed or unknown cultures. Often, this type of fermentation may be slow or unpredictable. Nevertheless, it affords a vital means of preserving highly perishable foods, especially where refrigeration is lacking. In Europe, Asia, and Africa, sour milk was known as being more stable and advantageous than fresh milk. It preserved the high-quality nutrients present in milk in a relatively more stable form.

From prehistoric times, man learned to use milk as food. Though the origin of the art of preserving milk by lactic acid fermentation has been lost in antiquity, the biochemical and microbiological knowledge of fermentation is of comparatively recent date. In Indian subcontinent, the conversion of milk into Dahi in every household by souring with the leftover of previous day's sour milk has been a common practice ever since the Aryans inhabited the land. In this way, the life and utility of milk nutrients were extended.

Today, the practice of preserving milk by fermentation has become a routine household technology, and FMs are almost compulsory in this subcontinent. In developed countries, fermentation is initiated with pure starter cultures, which have predictable performance potentials. Recent scientific and technological advances in starter culture management and process control have yielded a variety of products. These products are with superior chemical, physical, nutritional, and sanitary qualities.

A number of FMs, cereal-based products, and beverages are prepared through the action of LAB. Nearly every civilization has consumed FMs. Over the past two decades, the per capita consumption of FMs has increased more than 45-fold due to their image as nutritious and healthful foods. Likewise, the per capita production and consumption of cheese have recorded notable growth in the United States, Europe, and Indian subcontinent. Thus, FMs have been and still are of extreme importance in the nutrition of people throughout the world. The FMs like Acidophilus milk, Bifidus milk, Yogurt, Kefir, Koumiss, Leben, and Skyr are also used as dietary adjuncts. The FMs represent an important component of functional foods and value-added probiotic products.

Nowadays, intense research efforts are under way to develop dairy products into which probiotic organisms are incorporated to make them more valuable. This article provides an overview of the different types of FMs and the starter cultures used in their preparation and health benefits, which can be derived by the consumers through their regular intake.

Raw Materials

The milk of several species, including cow, buffalo, goat, sheep, mare, camel, and reindeer has been used for the preparation of FMs. Each type of FM has its own characteristic texture, body, flavor, and composition, depending on the type of milk used, the type of starter cultures (LAB, with or without aroma producers, and yeasts), and the procedures followed in its preparation. The FMs popularly used in various countries may be classified broadly into four categories: (1) moderately sour types with a pleasant aroma associated with diacetyl, for example, cultured milk; (2) sour and very sour types owing to high acid production, for example, yogurt and *Dahi*; (3) ethanol in addition to lactic acid, for example, Koumiss and Kefir; and (4) probiotic FMs, for example, acidophilus milks especially prepared with human strains of *L. acidophilus*.

Definition

FM is a milk product obtained by the fermentation of milk, where milk may have been manufactured from products obtained from milk with or without compositional modification as limited by the provisions in law, by the action of suitable microorganisms resulting in reduction of pH with or without coagulation (isoelectric precipitation). These starter microorganisms shall be viable, active, and abundant in the product to the date of minimum durability. If the product is heat-treated after fermentation, the requirement for viable microorganisms does not apply.

Types of FM

Concentrated FM

Concentrated FM is an FM of which the protein has been increased prior to or after fermentation to minimum 5.6%. Concentrated FMs include traditional products such as Stragisto (strained yogurt), Leben, Ymer, and Ylette.

Flavored FMs

Flavored FMs are composite milk products, which contain a maximum of 50% (m m^{-1}) of nondairy ingredients (such as nutritive and nonnutritive sweeteners, fruits, and vegetables as well as juices, purees, pulps, preparations and preserves derived therefrom, cereals, honey, chocolate, nuts, coffee, spices, and other harmless natural flavoring foods) and/or flavors. The nondairy ingredients can be mixed in prior to or after fermentation.

Drinks Based on FM

Drinks based on FM are composite milk products, obtained by mixing FM with potable water with or without the addition of other ingredients such as whey, other nondairy ingredients, and flavorings. Drinks based on FM contain a minimum of 40% (m m^{-1}) FM. Other microorganisms than those constituting the specific starter cultures may be added.

Starter Cultures Used in the Preparation of FM

Although the evolution of the process was strictly intuitive, the production of FM products became an established pattern of preservation; since the early 1900s, defined microorganisms have been used to prepare these products on a large industrial scale. The microorganisms that are employed in FMs (including probiotic products, alcoholic/lactic beverages, cultured cream, and products containing molds) and the cheese industry are used singly, or in pairs or multiples, or in a mixture, thus giving the industry the opportunity to manufacture different products. Certain FMs are characterized by specific starter culture(s) used for fermentation; Table 1 depicts the starter cultures used in preparation of FM.

Nutritional Significance of FMs

Lactobacilli use the nutrients in milk for their own metabolism and growth and multiply from 1 to 10 million cells per milliliter. The microorganisms are present in the FM not only as viable cells but also as autolyzed cells, which give rise to primary and secondary metabolites and enzymes, which they have produced during fermentation and storage.

The nutritive value (NV) of an FM depends on the availability and digestibility of nutritive constituents and the changes in these constituents due to microbial growth and fermentation processes (Table 2).

Similarly, the NV of a fermented food also depends on the nutrient content and bioavailability of the nutrients. Impact of fermentation of milk on its constituents is depicted in Table 3. Generally, the energy value of FM is similar to that of the milk from which it was prepared, yet it is claimed that the FM is more nutritious (the composition of milk and yogurt is given in Table 4). Fermentation enhances availability of some of the nutrients for absorption, as shown below:

Effect of Fermentation on Milk Constituents

Milk Proteins

The proteins in milk are of excellent biological quality, and both caseins and whey proteins are well endowed with essential amino acids (EAA). The fact that the protein content of FM, like yogurt, is often elevated by concentration or addition of skim milk solids means that it is an even more attractive source of protein than liquid milk. It is important that the proteins in FMs are totally digestible due to the fact that the starter organisms cause some degree of initial proteolysis. The extent of this breakdown depends on the strains of bacteria being employed, but, in general, at least some release of amino acids and peptides can be expected during incubation and storage.

FM products contain significantly higher levels of free amino acids than milk, due to the heat treatment and proteolytic activity of the starter organisms. The native milk proteins, which form a hard curd in the stomach, are converted into a soft curd containing finely dispersed casein particles resulting from the action of starter organisms in the FM. The FM proteins are useful for children, old people, and those with stomach ulcers, because the soft curd in FM is easier to digest than the milk (Table 3).

It has been observed that the rats fed with diets containing FM products had higher feed consumption, greater weight gains, and a more efficient utilization of their feed. Some medical practitioners advocate the use of *Dahi* and buttermilk by children not only for treatment of common intestinal ailments but also for their general nutrition. In tropical countries like India, where milk is exposed to heavy bacterial contamination, it is better to convert it into FM in order to preserve its NV.

Milk Fats

Although much of the FM sold in industrialized countries is produced from skim milk, traditional materials have always contained some 3–4% milk fat. It has been proposed that the digestibility of fat is improved via the action of the bacteria present during the fermentation process, but whether this effect really exists is highly debatable. The overall energy content of FM reflects both the fat content of the milk from which it was made and whether or not there has been the addition of ingredients such as cream and sugar. Humans have a double requirement for lipids. It acts as storage fat, which is composed of saturated fatty acids, and serves as a source of energy or protection for vital organs.

In addition to this, it also plays an important role by acting as structural fat, which, with proteins, forms many of the essential membranes in animal cells, particularly in areas like brain and nerve cells. These are essential to many physiological processes. Some essential nutrients are fat-soluble and are

Table 1 Starter cultures used for various fermented milks

Sr. no.	*Fermented milks*	*Starter cultures used*
1.	Yogurt	Symbiotic cultures of *Streptococcus salivarius* subsp. *thermophilus* and *Lactobacillus delbrueckii* subsp. *bulgaricus*
2.	Acidophilus milk	*L. acidophilus*
3.	Kefir	Starter culture prepared from kefir grains, *L. kefir*, species of the genera *Leuconostoc*, *Lactococcus*, and *Acetobacter* growing in a strong specific relationship. Kefir grains constitute both lactose-fermenting yeasts (*Kluyveromyces marxianus*) and nonlactose-fermenting yeasts (*Saccharomyces unisporus*, *Sac. cerevisiae*, and *Sac. exiguus*)
4.	Koumiss	*L. delbrueckii* subsp. *bulgaricus* and *Klu. marxianus*. Other microorganisms than those constituting the specific starter culture(s) specified above may be added
5.	Bulgarian buttermilk	*L. delbrueckii* subsp. *bulgaricus*
6.	Dahi	Thermophilic lactic cultures *Str. salivarius* subsp. *thermophilus* *L. delbrueckii* subsp. *bulgaricus* Mesophilic lactic cultures *Lactococcus lactis* subsp. *lactis* *Lac. lactis* subsp. *cremoris* Citrate fermentators *Leuconostoc mesenteroides* subsp. *citrovorum*, *Leu. dextranicum*

9.	Cultured buttermilk	*Lac. lactis* subsp. *lactis* or *Lac. lactis* subsp. *cremoris* and *Str. cremoris* subsp. *diacetylactis*
10.	Leben	*Lac. lactis* subsp. *lactis* *Str. salivarius* subsp. *thermophilus* *L. delbrueckii* subsp. *bulgaricus* Lactose-fermenting yeasts
11.	Cheese(s)	*Lac. lactis* subsp. *lactis*, *Lac. lactis* subsp. *cremoris*, *Lac. lactis* subsp. *diacetylactis* *Str. salivarius* subsp. *thermophilus* *L. delbrueckii* subsp. *bulgaricus* *Propionibacterium freudenreichii* subsp. *shermanii* *Penicillium roqueforti*, *Pen. camemberti*, etc.
12.	Yakult	*L. casei* strain Shirota
13.	Filmjolk	*Lac. lactis* subsp. *lactis* or *Lac. lactis* subsp. *cremoris* and *Leu. mesenteroides* subsp. *citrovorum* or *Leu. mesenteroides* subsp. *dextranicum*
14.	Viili	*Lac. lactis* subsp. *cremoris* *Lac. lactis* biovar. *diacetylactis* *Leu. mesenteroides* subsp. *cremoris* and *Geotrichum candidum*
15.	Skyr	*Str. salivarius* subsp. *thermophilus* *L. delbrueckii* subsp. *bulgaricus*

Table 2 Fermentation induced changes in milk constituents

Constituents	*Changes*
Milk proteins (3–4.5%)	Coagulated into a smooth curd with casein particles finely dispersed. Partially peptonized (0.1–0.7%) and utilized for microbial growth, resulting in the buildup of microbial cell proteins, increase in nonprotein nitrogen, and release of peptides and amino acids
Lactose (4.5–5%)	Partially utilized (1–2%) by starter bacteria producing mainly lactic acid (0.6–2%), volatile acids, flavor compounds, and CO_2 may also be formed by heterofermentative types. Alcohol and CO_2 may be produced by lactose-fermenting yeasts
Milk fat (3.5–7%)	Fermentation leads to partial digestion of lipids
Mineral matter (0.7–0.8%)	No direct appreciable change
Vitamins	No change in fat-soluble vitamins A, D, E, and K. Slight decrease in B-complex vitamins depending on the strains used

found primarily in foods that contain fat. These nutrients are essential fatty acids and fat-soluble vitamins. The LAB possess lipase activity evidenced by the lipids in the cultured products being partially digested. Their assays for lipase activity, however, were performed using culture organisms with tributyrin emulsions as substrate, and they did not prove that the bacterial lipases acted on lipids in the cultured products. A significant increase in free fatty acids over the starting milk has been observed in FM. The lactic acid fermentation and enzymatic action on amino acids also produce small quantities of volatile fatty acids (Table 3).

Milk Carbohydrates

The milk carbohydrate, lactose, causes intestinal problems in a number of persons who are lactose-intolerant. These persons are deficient in the intestinal enzyme, ß-galactosidase, and thus must restrict their intake of milk and dairy products. Milk does not contain this enzyme. Lactose intolerance is normally defined as the occurrence of gastrointestinal symptoms after administration of single test dose, about 50 g lactose in aqueous solution. In a large proportion of world's population, ß-galactosidase activity is low or absent. This enzyme is present in sufficient quantities in lactic FMs. Consequently, the lactose level in FM can be lower than milk, although this is not always the case, as skim milk powder or nonfat milk solids are sometimes added during the manufacture of some of these products.

During fermentation, 20–50% of the lactose in milk is hydrolyzed to its component monosaccharides, glucose and galactose, by the starter culture organisms. The production of ß-galactosidase increases during the fermentation of yogurt, reaching a maximum after four hours of incubation. This enzyme may be released from the microbial culture during digestion, indicating that it may be present in the intestine of persons consuming FM. Lactose-intolerant subjects had a much lower rise in blood glucose and thus a much lower lactose utilization efficiency. A lower lactose content would presumably help tolerance of the product to those with a reduced ability to digest lactose. But clearly the explanation is not this simple because FM with fairly high lactose content is also better tolerated by such individuals than the equivalent amount of lactose in milk. Lactic acid is produced as a by-product of the fermentation process. It acts as a preservative. It influences the physical properties of casein curd by inducing a finer suspension, which promotes digestibility of casein. It also improves utilization of calcium and other minerals and inhibits the growth of potentially harmful bacteria.

Milk Vitamins

Milk is a rich source of vitamins, particularly A, D, and some B-complex vitamins. Breed, diet, climate, geographic location, age and stage of lactation, and other factors can influence the vitamin content of the milk. This, in turn, will affect the vitamin content of the FM. There is conflicting evidence about whether there is an increase, decrease, or no change in level of vitamins during the fermentation of milk. The various manufacturing treatments may affect the content of labile vitamins while there is metabolism of vitamins by the LAB during the log phase of their growth and subsequent synthesis by the same bacteria. International Dairy Federation gave an indication of the changes due to heat treatment, fermentation, and storage.

The vitamin content of FM varies with the type of milk used (particularly the fat content of the milk, which influences the amount of vitamin A and other fat-soluble vitamins present), the strain of bacteria, and the fermentation conditions. Vitamin C is heat- and light-labile, but it is more stable in the acid

conditions of FM than normal milk. Levels of some B-complex vitamins are reduced due to the requirement of some of the LAB. Losses of up to 90% of vitamin B_{12} have been reported with specific bacterial strains, but losses are not always so large and can be reduced considerably by the use of 'supplementary culture' capable of synthesizing significant amounts of vitamin B_{12}. On the other hand, several cultures are able to synthesize the B vitamin, folic acid, increasing the level of this vitamin present in the final product, for example, *Prop. freudenreichii* subsp. *shermanii*, which is used as a starter culture in some of the cheeses, is known to synthesize vitamin B_{12}.

In the current scenario, when there are concerns about the folate intake of women during the early stages of pregnancy, this aspect may prove to have nutritional advantage. Increase in vitamin B and P (riboflavenoid) group vitamins has been observed in Kefir due to the activity of yeasts and acetic acid bacteria. Fermentation has been reported to increase folic acid in buttermilk, sour cream, Yogurt, Bifidus milk, Koumiss, *Dahi*, lassi, laben, skyr, and kefir. Effect of fermentation on the vitamin content in some of the FMs is given in Table 4.

Milk Minerals

Most experiments performed recently did not confirm the improved absorption of calcium because of the more acidic pH in the intestine following consumption of FM. When bioavailability of essential minerals and trace elements was investigated in rat experiments using diets based on milk, yogurt, and pasteurized yogurt and a commercial diet, it was observed that bioavailability (as measured by intestinal absorption, urinary excretion, and bone content) of calcium, phosphorus, magnesium, and zinc from all diets was superior than the commercial diet. In experiments with albino rats, availability of calcium and phosphorus from FM was increased by about 7% and 11%, respectively, compared to milk. The results are explained by the fact that colloidal calcium complexes and lactic acid, both present in FM, enhance calcium absorption.

Bioactive peptides derived from the tryptic hydrolysates of casein known as caseinophosphopeptides (CPP) possess physicochemical properties that enable chelation of various bi- and trivalent minerals to be carried out, thereby enhancing mineral solubility in the lower small intestine. It has been suggested that moderate and exchangeable binding of calcium to CPP is responsible for the high absorbability of calcium from milk. Results of experiments conducted at Melbourne Dental School, the University of Melbourne, have proved that there is a significant reduction in the tooth decay in laboratory animals that are fed with CPP (Table 3).

Formation of Single-Cell Proteins in FMs

In recent years, the nutritional importance of microbial single-cell proteins (SCPs) has received considerable attention. When FM is consumed, a large number of bacterial cells (about 10^7–10^9 CFU g^{-1}) and the products released from these cells enter the digestive tract. Most of the living cells are inactivated in the stomach by the action of hydrochloric acid and pepsin. It has been estimated that about 60% of the SCP nitrogen content (excluding cell wall material and nucleic acids) can be utilized by the body. The EAA content of SCP in FM ranges from 2.0 to 6.5 mg/100 g of product. The SCPs of some bacteria were found to be rich in methionine, lysine, and cystine. Studies on amino acid patterns of acid hydrolysates of SCP have revealed the presence of all the known amino acids. The SCPs of mixed cultures contained higher concentrations of many amino acids than those found in cells of individual cultures.

There were also considerable species variations in the pattern of amino acids in the SCP. When the cells were subjected to proteolytic enzymes simulating to some extent the conditions during passage in the gastrointestinal tract (GIT), significant differences were found between species with regard to the extent of hydrolysis and concentration of EAA released. Cells of *L. acidophilus* and mixed cultures of *Str. salivarius* subsp. *thermophilus* and *L. delbrueckii* subsp. *bulgaricus* released the highest concentrations of EAA. The biological activity of many EAA in FM protein is much higher than that of corresponding amino acids in milk. These results indicate that the SCPs of starter bacteria consumed along with FM are likely to be hydrolyzed partially or fully in the digestive tract, releasing EAA, and some of the starter cultures are most useful than others in this respect.

Biological Value of FMs

The cumulative effect of the available EAA from milk proteins and SCP is reflected in the protein quality (biological value) of the total protein content isolated from FM prepared with different cultures. The protein quality of *Dahi* was assessed by microbiological assay procedure using *Str. zymogenes* as the test organism. It was found to be higher (3–30%) than that of milk used for preparing *dahi*. Samples prepared by using mixed cultures of *Lac. lactis* subsp. *lactis*, *Lac. lactis* subsp. *cremoris*, *Str. salivarius* subsp. *thermophilus*, and *L. delbrueckii* subsp. *bulgaricus* gave higher values than those containing other cultures. Incorporation of the culture of *Prop. freudenreichii* subsp. *shermanii* along with the starter cultures caused a further improvement in protein quality. It has also been found that there is an increased secretion of digestive enzymes by salivary glands when stimulated by the curd particles and that the FM proteins are twice as digestible as milk proteins.

Biopeptides in FMs

Several of the peptides derived from milk proteins represent 'extranutritional' substances, which display significant physiological influence. There are several modes of release of these peptides from precursor proteins or synthesis thereof from simpler molecules. The starter and nonstarter bacteria are commonly used in the manufacture of fermented dairy products. They take advantage of their proteolytic system, which contains at least 16 peptidases. During the microbial fermentations involved in the manufacture of FM, milk proteins undergo controlled proteolysis under the combined influence of native microflora (comprising of some spore producers) and the starter bacteria.

Additionally, proteinases produced by the starter organisms could complement the complex enzyme system of starter microorganisms, leading to the accumulation of beneficial peptides. The angiotensin-I-converting enzymes inhibiting peptides derived from casein are termed as casokinins, whereas those derived from whey proteins are called as lactokinins. Cheeses and processed cheese products, therefore, offer the potential for developing specialized functional food products displaying prophylactic properties, besides their natural nutritional virtues. This represents a hitherto unexplored area of food research, which has tremendous future potential, in both academic and commercial perspectives.

The folklores regarding the nutritional, healthful, and therapeutic aspects of FM have been fully substantiated through recent biochemical, nutritional, and physiological research. With the growing awareness of beneficial attributes of FM products, there has been a tremendous growth of market for probiotic FM products in the European countries, Japan, and developing countries. Prospectus for the genetic modification of starter organisms to enhance the NV and probiotic attributes has opened challenging vistas for the new product development and diversification. The FM, as a potential carrier for natural source of biological peptides, is a fascinating area for technological development.

FMs in the Health-Aware Era

When milk is fermented to obtain any FM, it has billions of live microbial cells, some of which can sustain the drastic conditions in the stomach and impact the GIT microflora. The human GIT microbiota, has been investigated since the beginning of microbiological studies, when Antonie van Leeuwenhoek, the father of microbiology, investigated the microorganisms in his own stools. The human GIT microbiota comprises trillions of microbes distributed in various niches throughout the intestinal tract and is one of the most complex microbiological ecosystem on Earth. The host and its microbiota have coevolved together and considering the staggering numbers and diversity.

There have been major scientific advances especially in human intestinal microbiology in the recent past. Early studies were limited to description of the culturable microbes, which, as we now realize, made up only a minority of the GIT microbes. Due to the development of molecular biological techniques over the last two decades, microbes can now be detected and studied to a large extent, without the need for culturing.

The vast extent of human GIT microbiota is only being revealed by virtue of the advancement of modern molecular biological tools. It is stated that 90% of the DNA of GIT is contributed by this microbiota. The number of microorganisms within the intestine greatly exceeds human cells, resulting in one of the most diverse and dynamic microbial ecosystems. Associations among the microbes and between the microbiota and the host have a profound influence on all concerned. The GIT offers various alcoves with nutrients, those ingested and spawned by the host, and a relatively nonhostile environment to the microorganisms. The microbiota plays essential roles in a wide variety of therapeutic, nutritional, developmental, and immunologic processes and therefore notably contributes to the well-being of the human beings. During the last two decades, specific bacterial isolates capable of surviving and establishing in the GIT known as probiotics have been extensively used to modulate the microbiota of GIT to benefit the consumers. Today, there is swaying evidence for probiotics in prevention and/or treatment of a number of GIT-related ailments, especially for reducing attack of diarrhea, providing relief for lactose-intolerant human beings and also atopic diseases. In order to rationally use synbiotics or other functional foods as therapeutic agents, in-depth knowledge of the structure, dynamics, and function of the bacterial populations of the GIT microbiota is crucial.

Studying the microbial ecology of the intestinal content involves the determination of the abundance and diversity of the microorganisms present, their activity within this niche, and their interactions with each other and their host. The GIT microbiota have been extensively investigated by culture-based methods, but our knowledge about the culturable fraction of this community is limited. It is due to the challenges of obtaining pure cultures of GIT inhabitants, which are hindered by the largely anaerobic nature of this community and the paucity of suitable enrichment strategies to simulate intestinal conditions.

The advent of molecular techniques based on 16s ribosomal (rRNA) gene analysis is now allowing a more complete assessment of this complex microbial ecosystem by unraveling the extent of diversity, abundance, and population dynamics of this community. The techniques like metagenomics have extended our view of those microorganisms that have proved difficult to culture and that play an important role in gut physiology. This huge intestinal microbial reservoir is estimated to contain above 1500 bacterial species and as much as 10^{14} cells. Besides studying the diversity, it is essential to identify these microbes based upon their ecophysiological traits, that is, those that are functionally active versus those that are effectively redundant and play little or no role at a particular time or at a given site of the intestinal tract. Thus, in the present era of health consciousness, the FMs have opened a new vista for multifarious development of these products as dietary adjuncts.

Future Developments in FM Industry

Mechanization and Automated Controls

In the era of aggressive marketing, a strong trade name and a good company image are of utmost importance in order to succeed as a food producer in the increasingly competitive global food market of the FMs. One of the essential aspects when building and protecting a brand name is to produce and deliver a product that is consistent in quality. Consumers expect their favorite product to have the same taste and texture every time it is consumed, regardless of when or where it was purchased and under what circumstances it was manufactured.

In just a few decades, the fermented dairy product industry has developed from small production units operated by a number of skilled dairy personnel, performing most of the operations manually, to large-scale production lines where predetermined product quality and production efficiency are

equally essential for success. Mechanization and the introduction of automation and production management systems have major roles in these developments. The main advantage of having an automated FM production line is that each procedure in the operation is repeated in exactly the same controlled manner every time, which ensures high precision of repeatability and safety.

At present, the rapid developments in computer-assisted information technology and electronics facilitate much more than just the process control to be built into an automated production system, for example, production management systems with work execution, data collection and data analysis, and integration to local or global business systems. The benefits from such developments in the FM industry are not only improved quality, safety, and control but also increased possibilities to map, visualize, analyze, develop, and optimize the product and the process as well as the production management and the production facilities.

Food Safety Aspects

The LAB are ubiquitous in fermented and nonfermented foods and are common components of the human commensal microflora. This long history of human exposure and consumption has led to the reasonable conclusion that they are generally safe. Attention has also been focussed on their possible role as probiotic bacteria, promoting beneficial health effects. There have, however, been a number of reports of human infections caused by LAB and these are reviewed. In most cases, the source of the infection was the commensal LAB flora rather than ingested bacteria, and the patient had some underlying disease or predisposing condition.

Even opportunistic pathogens, the LAB, with the notable exception of the enterococci, are much less successful than a number of other members of the commensal microflora. The use of new strains for probiotic use is likely to require more detailed evidence for their safety, particularly if the strains have been genetically modified or have been derived from animals. Procedures that have been proposed for assessing the safety of new strains are described. Consumers around the world are raising their voices on this issue, and local health authorities are introducing regulations that require all food producers to ensure that food is handled appropriately and safely. All these demands from a global consolidating food industry drive the development of tools that are accurate, competent, and effective that can assist the human brain and body when it comes to managing a food processing enterprise in most advantageous way.

Future Prospectus

Anyone walking around a supermarket will notice the prominence given to dairy products like cheeses, and FMs appear to be prominent dietary components. The sheer variety and consistent quality of such products soon become evident as well and attribute to the technical and scientific expertise of the manufacturers. How markets will develop in the future remains to be seen, for the consumers' tastes are not always predictable. In order to meet such changes in demand, what is important is that fundamental knowledge about the fermentation of milk continues to expand, for only then can product diversity and quality achieve the standards that consumers deserve.

Lactic Acid Bacteria as Cell Factories for the Production of Health-Promoting Compounds

Food fermentations are typically driven by microbial consortia, which may lead to significant changes in the health-promoting properties of fermented foods. Besides the potential direct role of food-borne microorganisms on the gut microbiota ecosystem, their indirect role in the modification of the bioavailability of certain food elements may also have a biogenic effect. The latter depends on the specific metabolic traits of the microorganisms, whereby several biochemical mechanisms allow them to fulfill the role of efficient cell factories for the synthesis and release of health-promoting compounds. As a result, fermentation may lead to a marked increase of the concentration of vitamins or amino acids, a higher bioavailability of phytochemicals and minerals, and an improvement of the nutritional qualities of foods by increasing digestibility and removing antinutrients (e.g., oxalate, protease and α-amylase inhibitors, lectins, condensed tannins, and phytic acid). The proteolytic system of lactic acid bacteria may also contribute to the liberation of bioactive peptides. Based on the previously mentioned considerations, lactic acid fermentation represents a simple and valuable biotechnology to exploit the health-promoting properties of fruits and vegetables.

Fruits and Vegetables as Carriers for Probiotic Microorganisms

Raw, minimally treated, and, especially, fermented vegetables are the vehicles of high-value nutrients and new lineages of commensal bacteria that interact with the gastrointestinal resident microbiota. Few and, in some cases, controversial *in vivo* studies have shown the direct causal relationship between microbes conveyed by fermented vegetable foods and gut microbiota. The consumption of fermented kimchi, for instance, delivers ~8 log cfu g^{-1} of autochthonous lactic acid bacteria and can lead, after administration of about 60 g day^{-1} for 2 weeks, to a positive effect on the number of beneficial human intestinal microbiota (*Lactobacillus* sp. and *Leuconostoc* sp.). *In vivo* intervention studies based on short-term consumption of diets, consisting entirely of plant foods, have shown that food-borne bacteria associated to diet can transiently colonize the gut. Although there is still debate on the link between fermented vegetables and other fermented foods on the one hand and the gut microbiota on the other hand, it is conceivable that ingestion of fermented foods is a source of beneficial microbes that remain viable during transit and at least interact with the gastrointestinal microbiota. More than other food ecosystems, raw fruits and some vegetables possess intrinsic chemical and physical parameters that, for some traits, mimic those of the human gastrointestinal tract, such as the very acid environment, buffering capacity, presence of antinutritional factors (e.g., tannins and phenols), and high concentration of indigestible compounds (fiber, inulin, and fructo-oligosaccharides). Indigestible molecules protect probiotic microorganisms from the acidic environment of the stomach and are a source of nutrients for the microbiota, which positively influences bacterial survival. Plant tissues have a microstructure composed of intercellular spaces, stomas, lenticels, capillaries, irregularities naturally occurring on the surface tissue, and tissue lesions. These sites favor microbial internalization and offer protection. Thus, raw fruits and vegetables may harbor functional strains able to survive gastric and intestinal fluids and capable of adhering to the gut epithelium and hydrolyzing dietary constituents, which cannot be metabolized by the host.

Microbiota of Raw Vegetables and Fruits

Vegetables and fruits, providing a variety of nutrients, are attractive hosts for microbes that colonize surfaces (epiphytes) and tissues (endophytes). Type, availability, and concentration of substrate; buffering capacity; competing microorganisms; and natural plant antagonisms provide a unique environment harboring a rather constant microbiota. However, farming and storage conditions may influence the composition and abundances of microbial communities found on raw vegetables and fruits. The microbial population of these raw matrices fluctuates between ~5 and 7 log cfu g^{-1}, which may include spoilage (e.g., *Erwinia carotovora*), pathogenic (e.g., *Listeria monocytogenes*), and beneficial (i.e., lactic acid bacteria) microbes. As also shown by deep sequencing approaches (high-throughput pyrosequencing analysis of the 16S rRNA gene), the microbiota of fruits is dominated by yeasts and fungi, and that of vegetables mainly consists of bacteria, especially aerobes (e.g., pseudomonads, enterobacteria, and coryneforms). Lactic acid bacteria are only a relatively small part (2–4 log cfu g^{-1}) of the autochthonous microbiota of raw vegetables and fruits. Hetero- and homofermentative species belonging to species of *Leuconostoc*, *Lactobacillus*, *Weissella*, *Enterococcus*, and *Pediococcus* have been variously identified, depending on the species of vegetables. Nevertheless, *Weissella cibaria*/*W. confusa* and, especially, *Lactobacillus plantarum* are the most frequently found species. *Lactobacillus plantarum* is considered to be a ubiquitous and metabolic versatile bacterium, which is largely found in fruits and vegetables. Recently, fructophilic lactic acid bacteria (FLAB) were described as bacteria that prefer fructose to glucose as growth substrate. They are found in fructose-rich niches such as fruits and fermented foods made from fruits and flowers. Only two *Lactobacillus* spp. have been classified as fructophilic until now, that is, *Lactobacillus plantarum* and *Lactobacillus kunkeei*. The latter has originally been isolated from grape juice. All other FLAB were grouped into the genus *Fructobacillus*, which contains *Fructobacillus durionis*,

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00284-1

F. ficulneus, *F. fructosus*, *F. pseudoficulneus*, and *F. tropaeoli*. All these species are phylogenetically related to the genera *Leuconostoc*, *Oenococcus*, and *Weissella*. *F. pseudoficulneus* was isolated from figs and banana. FLAB species are separated into two groups: obligately and facultatively fructophilic. Obligately FLAB grow well on fructose, whereas external electron acceptors such as fructose, pyruvate, and oxygen are needed for glucose metabolism. Molecular typing of lactic acid bacteria isolated from vegetables and fruits is useful to group them into clusters that reflect their distribution in the raw matrix and, presumptively, their way of entry. Besides, intraspecific differentiation is the important preliminary step to select starter cultures.

Fermentation of Vegetable Products

When favorable conditions of anaerobiosis, water activity, salt concentration, and temperature occur, raw vegetables and fruits may be subjected to spontaneous lactic acid fermentation. Alcoholic fermentation may take place concomitantly. Usually, Gram-negative bacteria are inhibited starting from the early stage of fermentation. Spontaneous fermentation may be optimized through back-slopping, commonly used for sauerkraut production (i.e., inoculation of the raw material with a small quantity of a previously performed successful fermentation). Hence, back-slopping results in the dominance of the best-adapted strains and represents a way of using a selected microbial consortium to shorten the fermentation and to reduce the risk of fermentation failure. The same effect is achieved through the use of starter cultures, especially when these are selected within the autochthonous microbiota. In either cases (spontaneous and with starters), the composition of the microbiota completely changes, showing high cell densities of lactic acid bacteria towards the end of the fermentation ($\sim$9 log cfu g^{-1}). Under these conditions, humans are solely exposed to beneficial bacteria without the need for drastic processing.

Nowadays, the use of starter cultures is increasing in vegetable fermentation technology. Yet, contrary to other fermented foods (e.g., dairy, meat, and baked goods), only few cultures are used for fruit and vegetable fermentations, with *Lactobacillus plantarum* as the most frequently used one. It has been shown that the use of selected autochthonous lactic acid bacteria as starters, when contrasted to allochthonous/commercial cultures or to spontaneous fermentation, guaranteed the prolonged shelf life of fermented vegetables and fruits and maintained agreeable nutritional, rheological, and sensory properties. These effects may be the consequence of the modified profile of organic acids, the synthesis of lactic and acetic acids, and the metabolism of free amino acids. Recently, a number of vegetables and fruits were successfully subjected to fermentation by selected autochthonous lactic acid bacteria (Table 1). Adaptation to the intrinsic features of the raw matrices guarantees high survival ($\sim$8–9 log cfu g^{-1}) during fermentation and storage (c.40 days), whereas allochthonous strains show longer latency phases of growth and acidification with respect to selected autochthonous strains. Autochthonous cultures may also synthesize bacteriocins to improve competitiveness and contribute to food safety.

Main Fermented Vegetable Products

Many fruits and vegetables are processed through lactic acid fermentation for the production of a wide range of traditional fermented products in various worldwide regions, mainly in the Mediterranean area. Sauerkraut, kimchi, and fermented cucumbers are the most studied lactic acid-fermented

Table 1 Examples of vegetables and fruits successfully subjected to fermentation by selected autochthonous lactic acid bacteria

Vegetables and fruits	*Autochthonous lactic acid bacteria*	*Effects*
Almagro eggplant	*Lactobacillus brevis*, *Lactobacillus plantarum*	Synthesis of most preferred end products with regard to sensory properties
Leek	*Leuconostoc mesenteroides* and *Lactobacillus plantarum*	High microbiological quality, extensive consumption of carbohydrates, and synthesis of various end products
Carrots, French beans, or marrows	*Lactobacillus plantarum*, *Leuconostoc mesenteroides*, and *Pediococcus pentosaceus*	Rapid decrease of pH, marked consumption of fermentable carbohydrates, and inhibition of Enterobacteriaceae and yeasts
Red and yellow peppers	*Lactobacillus plantarum*, *Lactobacillus curvatus*, and *Weissella confusa*	Rapid decrease of pH, marked consumption of fermentable carbohydrates, inhibition of Enterobacteriaceae and yeasts, high firmness, high color indexes
Pineapple	*Lactobacillus rossiae* and *Lactobacillus plantarum*	Inhibition of yeasts, maintaining agreeable sensory and nutritional features
Sweet cherry puree added of stem infusion	*Pediococcus pentosaceus* and *Lactobacillus plantarum*	Evident consumption of organic acids (e.g., malic acid) and free amino acids, especially throughout storage and preservation of phenolic compounds
Tomato juice	*Lactobacillus plantarum*	Synthesis of exopolysaccharides and high viscosity; preservation of elevated values of ascorbate, glutathione, and total antioxidant activity during storage; synthesis of volatile compounds having a positive log odor value (e.g., 3-methyl-3-butan-1-ol, 2,3-butanedione, and 3-hydroxy-2-butanone)
Kimchi	*Lactobacillus sakei*	Mild acidifying properties, synthesis of volatile compounds (diacetyl, acetoin, acetaldehyde, secondary alcohols, esters, and lactones) affecting the sensory properties

vegetables mainly due to their commercial importance. The manufacturing protocols for some traditional fermented vegetables are described in the following.

Fermented Olives

Table olives are one of the main pickled products with industrial importance. The trade standard applying to table olives of the International Olive Oil Council defines table olives as "the sound fruit of varieties of the cultivated olive trees (*Olea europaea* L.) that are chosen for their production of olives whose volume, shape, flesh-to-stone ratio, fine flesh, taste, firmness and ease of detachment from the stone make them particularly suitable for processing; treated to remove their bitterness and preserved by natural fermentation; or by heat treatment, with or without the addition of preservatives; packed with or without covering liquid." Table olive processing has been a very old tradition in all Mediterranean countries and, from the beginning of this century, has become popular all over the world. The high nutritional value of table olives is well known, since they contain several nutritional components (e.g., vitamins E and A and polyphenols), which largely depend on the olive variety, the maturation stage of the olive fruit, the cultivating conditions, and the processing method. Because of the bitterness caused by the phenolic glycoside oleuropein, raw olives are not suitable for consumption without any processing step. The main commercial preparations, namely, (a) treated green olives (Spanish style), (b) naturally black olives (Greek style), and (c) ripe olives processed by alkaline oxidation (Californian style), are among the first three processing methods defined by the standard. Spanish-style olive manufacture combines a lye treatment with a NaOH solution (1–3.5% w/v) and a fermentation step. It has been generally established that lactic acid bacteria are responsible for the fermentation of treated olives. However, lactic acid bacteria and yeasts compete for the fermentation of natural olives. The predominant bacterial genus is *Lactobacillus*. Other genera of lactic acid bacteria have also been isolated to a lesser extent (e.g., *Weissella*, *Pediococcus*, *Enterococcus*, and *Leuconostoc*). Yeasts play a minor role, though they may contribute to the flavor and aroma of table olives. According to the Greek-style process, the fermentation occurs in a brine solution with high NaCl content (6–15% w/v), which promotes the growth of yeasts (mainly *Candida* spp., *Debaryomyces* spp., *Pichia* spp., and *Rhodotorula* spp.). The predominant lactic acid bacteria genera are the same as the ones involved in Spanish-style processing. Californian-style processing is based mostly on a lye treatment to remove the bitterness and may include only a weak fermentation step.

Microbial starter selection, bacteriocin production, availability of nutrients, probiotication, and adjustment to determinants affecting the fermentation process (e.g., pH, temperature, NaCl, and polyphenol content) are some of the main current challenges for the table olive industry.

Sauerkraut

Sauerkrauts, widely consumed in many European countries and in the United States, are manufactured by spontaneous lactic fermentation of white cabbage (*Brassica oleracea* L. var. *capitata*). After removal of the core and outer leaves, fresh cabbage is shredded and mixed with 2–3% (w/w) salt before allowing for natural fermentation. Cabbages are quickly surrounded by brine and covered with plastic sheeting draped over the tank, to ensure air exclusion. Sauerkraut production typically relies on a sequential microbial process that involves hetero- and homofermentative lactic acid bacteria, such as *Leuconostoc* spp. and *Weissella* spp. in the early phase and *Lactobacillus* spp., *Lactococcus lactis*, and *Pediococcus* spp. in the subsequent phases. *Lactobacillus plantarum* prevails during late fermentation, leading to further acidification and a final pH of ~3.5–3.8. Sauerkraut brine is an important by-product of the cabbage fermentation industry and may be used as a substrate for the production of carotenoids by *Rhodotorula rubra*. Sauerkraut fermentation lasts several weeks, depending on the fermentation conditions, sensory attributes, the autochthonous microbiota of cabbages, and the related sugar contents. Secondary fermentations, such as those carried out by yeasts, are undesirable.

Kimchi

Kimchi is a Korean traditional fermented vegetable made from Chinese cabbage (beachu), radish, green onion, red pepper powder, garlic, ginger, and fermented seafood (jeotgal), which is traditionally made at home and served as a side dish at meals. Kimchi is a generic term indicating a group of traditional lactic acid-fermented vegetables in Korea. Kimchi fermentation traditionally represents an efficient method of preserving the fresh and crispy texture of vegetables during winter, when fresh vegetables are not available. Actually, kimchi is a globally popular food, and its market size is gradually increasing. Thanks to the physiological effects of its ingredients and its microbial metabolites, kimchi is widely perceived as a health-promoting food. Vegetables are soaked with water, cut, and placed in the salt solution (5–7%) for 12 h, until the salt content in the tissues reaches the value of ~2.0–4.0% of the total weight. Further, vegetables are rinsed several times with freshwater and drained. The mixed ingredients are then placed in fermentation vessels, covered with macerated cabbage leaves, and pressed by stones to ensure anaerobic conditions. Kimchi fermentation is a temperature-dependent process. It ripens in 1 week at 15 °C but takes only 3 days at 25 °C. Low temperature (2–6 °C) is nevertheless preferred in kimchi fermentation to prevent the production of strong acidity and overripening, as well as to extend the period of optimum taste. The time for the fermentation of kimchi may thus vary from few days to several months, depending on the temperature and concentration of NaCl. Kimchi fermentation is carried out by various autochthonous microorganisms. The microbiota is largely affected by the fermentation conditions (e.g., anaerobiosis, ingredients, salt concentrations, and temperature). Generally, *Leuconostoc mesenteroides* and *Lactobacillus plantarum* have been identified as the predominant species, but several studies suggest that lactic acid bacteria contributing to kimchi fermentation also include *Leuconostoc citreum*, *Leuconostoc gasicomitatum*, *Lactobacillus brevis*, *Lactobacillus curvatus*, *Lactobacillus sakei*, *Lactococcus lactis*, *Pediococcus pentosaceus*, *W. confusa*, and *W. koreensis*.

Pickled Cucumbers

The manufacture of pickled cucumbers requires that fully ripe cucumbers are washed and drained and, in some cases, sliced.

Further, regular-shaped cucumbers are dipped into brine (5–7% of NaCl). Industrial fermentations are carried out by the spontaneous growth of lactic acid bacteria. The fermentation lasts 2–3 weeks, depending on the temperature (20–27 °C), which allows to reach a final pH of ~3.1–3.5. Because of the high concentration of NaCl, the growth of *Leuconostoc mesenteroides* and other less salt-tolerant species is inhibited. Only homofermentative lactic acid bacteria, such as *Pediococcus pentosaceus* and *Lactobacillus plantarum*, are responsible for fermentation. Strictly heterofermentative species are undesirable. The synthesis of CO_2 leads to texture defects and bloater damage, with serious economic losses. Since CO_2 results also from the cucumber respiration or the malolactic fermentation by *Lactobacillus plantarum*, fermentation vessels are sometimes purged with inert nitrogen gas. Salt, consumption of fermentable carbohydrates, and low values of pH prevent undesirable secondary fermentations by yeasts and other lactic acid bacteria (e.g., *Lactobacillus buchneri*), which often cause cucumber spoilage. Blanching of cucumbers is also used to decrease the concentration of NaCl (4% or less), partially inhibit the autochthonous microbiota, and improve the texture, through the inactivation of endogenous pectin esterase and glycosidases. Partial or complete replacement of NaCl by $CaCl_2$ has been suggested as an efficient method to prevent softening.

Household-Level Fermentations and Traditional Products

Besides the semi-industrial and globally popular products, a large variety of fermented vegetables are manufactured around the world at household level as fundamental components of the daily diet, representing a culture heritage. Perishable and seasonal raw plant substrates are fermented into edible products using indigenous methods of biopreservation. Lactic acid fermentation is the simplest way to preserve fruits and vegetables and helps in solving with the issue of food security. A brief description of some traditional fermented vegetable products from different regions of the world is reported later in the text.

Africa

Fermented foods have a long history in Africa. Substrates used in fermented plant food production include vegetables, fruits, seeds, cereals, roots, and tubers. Some fermented products, usually obtained from carbohydrate-rich raw matrices, serve as main course meals or as beverages, while others, resulting from the fermentation of protein-rich seeds, are used as food condiments.

Fermented seeds are an important cheap source of dietary protein. Examples of traditional fermented seeds used as flavoring agents include iru (fermented *Parkia biglobosa* seeds), ogiri (fermented *Citrullus vulgaris* seeds), dawadawa (fermented soybean (*Glycine max*) seeds), and okpehe (fermented *Prosopis africana* seeds). Often, *Bacillus* species are predominant during these fermentations.

Pickled lemons are widely consumed in North Africa. Fermentation helps in dealing with the issue of seasonality. Cured lemon, called msayer or msir, is consumed in Morocco, while lamoun makbouss are pickled lemons consumed in Libya and Egypt. According to Moroccan style, the salted lemons are stored in sealed glass container, kept in a cool dry place for 4–6 weeks, to allow the leakage of the lemon juice and the dissolving of salt. The resulting strongly salty and acidic brine promotes the growth of lactic acid bacteria and yeast (e.g., *Candida parapsilosis* and unclassified Saccharomycetales).

Cassava (*Manihot esculenta* Crantz) is one of the most important root crops in many African countries and ensures the energetic food security for many millions of people. Sweet varieties of cassava may be consumed directly, whereas bitter varieties are traditionally processed into a wide range of traditional products: gari (partially gelatinized granular cassava meal), fufu (pounded boiled cassava), lafun (fine powdery cassava), kokonte (dried cassava flour), kivunde (retted cassava), and cingwada (retted cassava). Lactic acid fermentation may significantly prolong the short shelf life (only 5 days after harvesting) of raw cassava and may have a role in cyanogen reduction in bitter cassava. *Lactobacillus plantarum* typically dominates the fermentation. Some *Lactobacillus plantarum* strains isolated from fermented cassava are able to hydrolyze resistant starch, thereby increasing the energy density.

Asia

Plant-based foods represent the core of the daily diet in Asian countries, which are the first in the world for per capita consumption of fruits and vegetables. Food fermentation in Asia is strongly dependent on the availability of seasonal vegetables. Ethnic fermented foods are linked to the Asian culture and tradition, and hundreds of different forms of fermented vegetables are prepared by the different ethnic groups. A wide range of substrates is subjected to fermentation, which includes vegetables, fruits, legumes, rice, and bamboo shoots. Processing is still carried out at household-scale through spontaneous fermentations (e.g., alcoholic, lactic, propionic, and acetic acid fermentations).

Gundruk is a fermented leafy vegetable commonly prepared by the Nepalis of the Himalayan region prepared during the months of December to February, when the weather is less humid and there is a wide supply of vegetables. For gundruk preparation, fresh leaves of local cabbage, mustard, and cauliflower are wilted for 1–2 days. The dried leaves, after a mild crushing procedure, are soaked briefly in hot water and hand-pressed in an earthen pot to remove surplus water. Then, they are kept in a warm and dry place for 15–22 days. Generally, a spontaneous fermentation is started by *Lactobacillus brevis* and *Pediococcus pentosaceus* and dominated by *Lactobacillus plantarum* in the late stage. After a desirable fermentation, gundruk is removed and sun-dried. Other examples of Asian fermented leafy vegetables include hum-choy, produced in the south of China from a local vegetable called gay-choy; anishi, goyang, and ziang-sang, made in northeast India from local leafy vegetables; sunki, prepared from red turnip leaves in Japan; and pak-gard-dong, produced in Thailand from mustard.

Khalpi is a fermented pickle consumed in the Himalayan region. For its preparation, mature and ripened cucumbers are cut and sun-dried for 2 days. Then, they are fermented into sealed bamboo vessels for 4–7 days at room temperature.

Khalpi is eaten as a pickle after mixing with mustard oil, powdered chilies, and salt. The microbiota of khalpi is characterized mainly by *Leuconostoc fallax*, *Lactobacillus brevis*, and *Pediococcus pentosaceus* in the early stage and *Lactobacillus plantarum* in the last stage of fermentation.

Sinki is prepared from radish taproots, and it is very popular in Nepali communities. The protocol for its manufacturing is similar to that of gundruk. The fermentation may last up to 30–40 days and is commonly started by *Lactobacillus fermentum* and *Lactobacillus brevis* and later replaced by *Lactobacillus plantarum*.

Pickled fruits, such as lime, lemon, and mango, are very popular in Asia. Burong mangga is a green mango pickle produced in the Philippines. For its manufacturing, peeled and sliced fruits are fermented in brine for ~3 days. Lactic acid bacteria involved during burong mangga fermentation include mainly *Leuconostoc mesenteroides*, *Lactobacillus brevis*, *Pediococcus cerevisiae*, and *Lactobacillus plantarum*.

Tempoyak is a traditional Malaysian fermented condiment made from the pulp of the durian fruit (*Durio zibethinus*). Fermentation is carried out by lactic acid bacteria, such as *Lactobacillus brevis*, *Lactobacillus mali*, *Lactobacillus fermentum*, *Lactobacillus* durianis, and *Leuconostoc mesenteroides*.

Kombucha is a refreshing beverage obtained by the fermentation of sugared tea by a symbiotic mixture of bacteria (acetic acid and lactic acid bacteria) and yeast. Native of China, kombucha is currently common around the world. The many benefits of kombucha for health were reported, such as anticancer activity, detoxifying effects, and antibiotic activity. Its properties are mainly attributed to the acidic composition, to the capacity of glucuronic acid to bind to toxin molecules, and to the content of B-complex vitamins and phenols.

South America

Water kefir, also known as tibicos or sugar kefir, is a probiotic beverage native of Mexico and currently common worldwide. Water kefir is obtained through fermentation of sweetened water with a symbiotic culture of lactic acid bacteria, bifidobacteria, and yeast. Figs and lemons are traditionally added for additional flavor and nutrients. Microorganisms are introduced through water kefir grains (polysaccharide matrix in which microorganisms are imbibed), handed down from household to household. Water kefir grains are thought to have originated from fermented sap on the pads of the *Opuntia cactus*.

Eastern Europe and Middle East

Researchers and food manufacturers have become increasingly interested in Turkish fermented nonalcoholic beverages due to their value as probiotic source. Shalgam, for instance, is a lactic acid-fermented beverage that is very popular in Turkey. Its manufacturing requires that bulgur flour, sourdough, and salt are mixed with water and left to ferment by lactic acid bacteria and yeasts for 3–5 days at room temperature. Then, vegetables (e.g., carrots) and water are added to the fermented product of the first stage. Fermentation is carried out in wooden barrels for 3–10 days, mainly by *Lactobacillus plantarum*, *Lactobacillus paracasei* subsp. *paracasei*, *Lactobacillus fermentum*, and *Lactobacillus brevis*, although yeasts such as *Saccharomyces cerevisiae* may contribute to flavor development. Hardaliye is a Turkish grape-based nonalcoholic traditional beverage. Pressed grapes and cherry leaves are mixed with pressed mustard and fermented in barrels at room temperature for 5–10 days. After incubation, the mixture is filtered and kept in a cool place. The predominant lactic acid bacteria species are *Lactobacillus paracasei* subsp. *paracasei* and *Lactobacillus casei* subsp. pseudoplantarum.

Innovative Plant-Based Fermented Products

During the last decade, innovation in food biotechnology has led to an increase in the number of new products with functional claims for an estimated growth rate of 28% per year. This is paralleled by a rise in the amount of scientific papers dealing with this topic. The global market of functional foods is a growing field of the food industry, driven by modern consumer's demand for foods that may improve well-being and reduce the risk of disease. The ongoing trend of vegetarianism, the increasing prevalence of lactose intolerance, and the cholesterol effects of dairy products drive the research towards nondairy functional foods. The suitability of several vegetables and fruits as raw materials for the manufacturing of functional products has opened new perspectives. There is a strong interest in the development of plant-based functional foods, as juices, smoothies, and yogurt-mimicking beverages. Lactic acid fermentation represents an innovative and attractive approach to improve the nutritional, functional, and hedonistic features of plant material, although several applications often originate from or are inspired by ethnic food (e.g., Asian). In order to develop novel fermented functional foods, implementation strategies relate to the exploitation of microbial functionalities, the testing of novel formulations with ingredients that either are of natural origin or originate from industrial by-products as functional ingredients, and the fortification with probiotics and prebiotics.

Fruit and Vegetable Juices

One of the most attractive opportunities is the development of lactic acid-fermented fruit and vegetable juices, also named 'lacto-juices.' Since the latter have flavor profiles that are pleasing to all age groups and are perceived as healthy and refreshing beverages, they promise a considerable market value. Fruit and vegetable juices are ideal substrates for functional beverage making, due to their content of essential nutrients. Furthermore, formulation with different substrates may provide different combinations of health-promoting components (e.g., antioxidants, dietary fiber, minerals, and vitamins). The technological options for the production of fermented vegetable juices mainly include (i) spontaneous fermentation by autochthonous microbiota, (ii) fermentation by selected starter cultures added to raw vegetables, and (iii) fermentation of mildly heat-treated vegetables by starter cultures. Selection of lactic acid bacteria that are able to adapt to the inherent features of each raw material (e.g., availability of nutrients and physicochemical features) may assure fermented vegetable juices with optimal characteristics. Fruits and vegetables tested in novel lacto-juices include watermelon, sapodilla, carrot, beetroot,

pepper, parsley, lettuce, lemon, cabbage, spinach, tomato, pomegranate, blackcurrant, orange, grapes, and sweet potatoes. Pomegranate juices fermented with selected strains of *Lactobacillus plantarum* have, in general, improved health-promoting and sensory properties. Besides higher phenolic concentration and antioxidant activity, a positive immunomodulation activity distinguishes fermented pomegranate juices from unfermented ones. Fermentation by autochthonous lactic acid bacteria also positively affects the health-promoting and sensory properties of tomato juice, leading to improved viscosity, color, and, especially, ascorbic acid, glutathione, and total antioxidant contents. A fermented juice based on vegetables, seeds, and sprouts of germinated lentils and cowpeas was proposed as potential functional beverage, due the content of ACE-inhibiting substances, bile acid-binding activities, and hemagglutinating activities. Fermented carrot juice, in addition to being microbiologically stable, has good sensory properties and a potentially high nutritional value, due to the improved iron solubility and overall mineral availability. The preservation of pigments and the synthesis of health-promoting substances, such as aglycones and β-carotene, have been shown in lactic acid-fermented beetroots and sweet potatoes. Red beets were also evaluated as a potential substrate for the production of probiotic beet juice by four species of lactic acid bacteria (*Lactobacillus acidophilus*, *Lactobacillus casei*, *Lactobacillus delbrueckii*, and *Lactobacillus plantarum*). Although the probiotication of several fruit and vegetable juices with lactic acid bacteria and bifidobacteria seems promising, some cultures may negatively affect the sensory properties of the juices or show sensitivity towards the low pH of the raw matrices and postfermented products, fermentation metabolites, processing temperature, and gastrointestinal tract conditions. The addition of yeast autolysate (e.g., spent brewer's yeast) into the juices may increase the number of lactic acid bacteria during fermentation, reduce the time of fermentation, and enrich the juices with amino acids, vitamins, minerals, and antioxidants. Thus, a proper selection of the fruit matrices and probiotic strains and, if required, the addition of other ingredients are decisive steps to produce a palatable beverage that may be consumed regularly, providing functional benefits.

Fruit and Vegetable Smoothies

As an alternative to the consumption of fresh fruits and vegetables, the food industry offers the manufacture of smoothies, which consist of mixtures of fruits and vegetables processed to pulp or puree. Recently, a novel protocol for the manufacture of smoothies was set up, based on lactic acid fermentation of white grape juice and *Aloe vera* extract mixed with fruit and vegetable purees. Lactic acid fermentation by autochthonous selected starters positively affects the content of antioxidant compounds and enhances the sensory attributes of smoothies. An alternative technological option for processing sweet cherries involves the lactic acid fermentation of cherry puree supplemented with cherry stem infusion, as to exploit the nutritional, antioxidant, and sensory features of the raw materials. Likewise, broccoli puree fermented by *Lactobacillus* spp. for the production of functional foods is enriched in phenolic derivatives with increased bioavailability and biological activity.

Minimally Processed Fruits and Vegetables

Minimally processed fruits and vegetables are products obtained by trimming and/or peeling and/or cutting and packaging and are characterized by convenience and ability to maintain their freshness. Fermented pineapple slices by autochthonous lactic acid bacteria, also without any heat treatment, is an example of a shelf-stable minimally processed fruit with elevated numbers of viable lactic acid bacteria and agreeable nutritional and sensory properties. Lactic acid fermentation may promote the storage of peppers at room temperature for extended shelf life. A protocol that includes blanching at 85 °C for 2 min, fermentation at 35 °C for 15 h in brine (1%, w/v) with selected autochthonous starters, and heat treatment at 85 °C for 15 min allows the storage at room temperature for 30 days with better texture and sensory properties compared to the 'unstarted' peppers. Moreover, the survival of *Lactobacillus plantarum* and *Lactobacillus fermentum* strains on pineapple pieces has been demonstrated throughout storage. A protective effect against relevant food-borne pathogens was also successfully reported. Artichokes may act as a valuable vector, as they are capable of supporting viable bacteria for at least 90 days. The anchorage of strains to artichokes also improves the survival of probiotic microorganisms during gastrointestinal digestion.

Fruit- and Vegetable-Based Yogurt-Like Products

The so-called vegetable milks might be used as raw materials to develop yogurt-mimicking products. They are mainly obtained from soy, cereals, and nuts. Other minor raw materials may be hemp, sunflower, lupin seeds, and tubers (e.g., tiger nuts). Although the production of yogurt-mimicking products may differ according to the raw material and the microbial starters, the main steps are (i) milk conditioning to the optimal growth temperature of the starters, (ii) inoculation and incubation procedures, and (iii) cooling to 4 °C. Protein coagulation and serum separation during storage may cause physical stability problems. The addition of hydrocolloids, such as xanthan gum, modified starches, pectin, and cellulose derivatives, promotes physical stability. *In situ* production of oligosaccharides and exopolysaccharides by lactic acid bacteria positively affects the texture, since these compounds act as emulsifiers or stabilizers and increase viscosity and mouthfeel. Prebiotic compounds (e.g., starch and fibers) are sometimes added to promote the survival of probiotic starters, due to their nutritional contribution and protective action, since they act as protective barriers within the human gastrointestinal tract. The most popular vegetable milk derives from soy. Soy-based beverages have a huge potential as functional foods, since they may have a role in the prevention of some chronic degenerative diseases, are poor in cholesterol and saturated fats, and contain high levels of quality protein and amino acids, dietary fiber, magnesium, phosphorus, vitamin K, riboflavin, thiamine, folic acid, isoflavones, and other flavonoids. The low concentration of soluble carbohydrates of soy milk may limit the growth and acidification of lactic acid bacteria and make the addition of glucose and fructose indispensible. Probiotic bacteria have been successfully incorporated in soy milks, with a positive impact on the intestinal ecosystem. Nut-derived milks also represent suitable raw substrates to develop healthy yogurt-mimicking beverages, since they are

rich in mono- and polyunsaturated fatty acids, proteins, dietary fibers, phytosterols, phenolics, vitamins, and minerals. Probiotication of hazelnut milk through fermentation with *Lactobacillus rhamnosus* and *Streptococcus thermophilus* has been successful, ensuring high probiotic survival throughout cold storage (≈ 108 cfu ml^{-1}) and an *in vitro* simulation of the digestion process (≈ 105 cfu ml^{-1}). Minor raw materials, such as tuber milk, may also be exploited for the production of yogurt-mimicking products. Fermented tiger nut milk with good nutritional, chemical, and sensory properties was produced through pasteurization at 90 °C for 15 min and fermentation at 45 °C for 18 h using mixed cultures of *Lactobacillus plantarum*, *Lactococcus lactis*, and *Lactococcus thermophilus*.

Conclusion

Fermented fruits and vegetables are associated with several social and cultural aspects of different human communities. Due to their high nutritional value, fermented vegetable foods and beverages are estimated to constitute about one-third of the foods daily consumed worldwide. Studies have shown that fruits and vegetables may serve as a suitable carrier for probiotics. In addition, fermented fruits and vegetables contain a large range of prebiotic compounds that can stimulate the growth of beneficial bacteria. Therefore, exploitation of the axis 'fermented foods – human health' based on plant fermentations is a promising and conceivable strategy for the future. Basic understanding of the relationship between food, beneficial microorganisms, and human health can be important to improve food quality and to prevent disease.

What Is Fermentation? Food Fermentation Versus Biochemical Fermentation

Fermentation is one of the oldest methods of food preservation and preparation; however, the word has many meanings. It is derived from the Latin word *fermentum*, which is the past participle of *fervere* (to boil). A first microbiological definition relied upon the expression 'la vie sans air' by Louis Pasteur (life in the absence of air, in particular oxygen). In biochemistry, fermentation is thus a microbial metabolism that produces energy from carbohydrates in the absence of oxygen. Alternatively, fermentation can be defined as an incomplete oxidation of sugars in the absence of oxygen that uses an internal organic compound as an electron acceptor. In 1957, Prescott and Dunn defined it "a process in which chemical changes are brought about in an organic substrate, whether carbohydrate or protein or fat or some other types of organic materials through the action of biochemical catalysts known as enzymes, elaborated by specific types of living organisms." Based on the latter broad definition, fermentation describes any biological process whether oxygen is present or not, that is, the production of wine, vinegar, yogurt, beer, table olives, and many other foods, as well as of different organic fine chemicals (e.g., antibiotics, amino acids, citric acid, and monosodium glutamate). The main trait of a fermentation is the conversion of complex organic substrates into simpler compounds with the production of chemical energy as adenosine triphosphate.

At least three kinds of fermentation can be distinguished: (i) solid-state (e.g., tempeh), (ii) liquid-state (or submerged) (e.g., fermentation of corn steep liquor), and (iii) semisolid-state, where the product is submerged (e.g., *shoyu* or soy sauce). Moreover, fermentation can be spontaneous and uncontrolled (raw materials get fermented by microbiota that are indigenous or that originate from the equipments and environment) or controlled and inoculated (the fermenting microbiota mostly originates from the inoculation of starter cultures). Controlled fermentation is based on either a monoculture (using a single and pure strain) or multiculture (using biculture or multiculture strains of microorganisms or mixed inocula). The definition of spontaneous or controlled fermentation is closely related to the definition of starter cultures; a starter culture consists of microorganisms that are inoculated directly into food materials to overwhelm the existing microbiota and bring about desired changes in the finished product. These changes may include novel functionality, enhanced preservation, reduced food safety risks, improved nutritional or health value, enhanced sensory qualities, and increased economic value. Table 1 lists the most important microorganisms of starter cultures.

Fermentation is at the basis of the production of fermented foods, which can be defined in different manners:

1. Foods that are fermented until at least one of the constituents has been subjected to the action of microorganisms for a period, so that the final products have often undergone significant changes in physicochemical composition and sensory scores, due to microbial and enzymatic changes
2. Foods that have been subjected to the action of microorganisms or enzymes, so that desirable biochemical changes cause significant modification
3. Palatable and wholesome foods prepared from raw or heated materials by microbial fermentation

There are at least 5000 major and minor or ethnic fermented foods; they generally bear the 3A or A^3 connotation that pinpoints acidic, alkaline, or alcoholic traits. Thus, the most important sensory and physicochemical properties of fermented foods are as follows:

1. Acidic taste (low pH and lactic acid fermentation) (e.g., yogurt, fermented milks, gundruk, kimchi, and table olives)
2. Alkaline nature (high pH) (e.g., kinewa, dawadawa, and pidan)
3. Alcoholic taste (moderate-to-high concentration of ethanol) (e.g., wine, beer, sake, and pulque)

There are different classifications of fermented foods, relying upon different criteria. Hereby, we propose a simple classification (Table 2) based on three questions:

1. Is the fermented food an alcoholic product/beverage?
2. What is the raw material?
3. Which kind of starter culture was applied?

Historical and Cultural Aspects

Our ancestors already consumed food products that had been subjected to food fermentation; they did not know the role of microorganisms, but they recognized the preservative and nutritional qualities of fermented foods, as well as their palatability. We do not know when humans began to use fermentation intentionally, but archaeological data suggest an intentional fermentation of honey, fruits, and rice about 10 000 years ago. Moreover, we have some evidence of bread and cheese making, as well as of grape fermentation, around 6000–7000 BC.

One of the first descriptions of a fermented food is the Hymn to Ninkasi by Sumerians; it dates back *c.*1900 years BC and describes the production of beer. Fermented foods were widespread in all the ancient populations and there is an important document for the production of fermented foods by ancient Indian: the sacred book Rig Veda reported on the production of a fermented beverage to gain immortality. For centuries, fermentation has been an empirical process until Louis Pasteur described the role of microorganisms in 1857. Table 3 proposes a short historical overview of fermentation from the Neolithic era to the twentieth century.

Table 1 Starter cultures

Bacteria	Lactic acid bacteria (*Lactobacillus* spp., *Lactococcus* spp., *Streptococcus* spp., *Leuconostoc* spp., *Pediococcus* spp., *Leuconostoc* spp., *Oenococcus oeni*), *Propionibacterium* spp., *Bifidobacterium* spp., acetic acid bacteria (*Acetobacter* spp., *Gluconobacter* spp.), *Bacillus* spp., *Brevibacterium linens*, catalase-positive cocci (coagulase-negative *Staphylococcus* spp., *Kocuria* spp.)
Yeasts	*Saccharomyces cerevisiae*, *Sacc. pastorianus*, *Zygosaccharomyces* spp., *Candida* spp., *Pichia* spp.
Molds	*Penicillium camemberti*, *P. roqueforti*, *P. chrysogenum*, *P. nalgiovense*, *Aspergillus oryzae*, *Rhizopus microsporus* subsp. *oligosporus*

Table 2 Classification of fermented foods

Nonalcoholic fermented foods	*Alcoholic fermented foods*
Fermented vegetables	Nondistilled mild alcoholic beverages produced by amylolytic starters[a]
Fermented soybean and legumes	Nondistilled and filtered alcoholic beverages produced by amylolytic starters
Fermented cereals	Distilled alcoholic beverages produced by amylolytic starters
Fermented milks	Alcoholic beverages produced using human saliva as amylolytic starter
Fermented fish	Alcoholic beverages produced by mono-fermentation
Fermented meat	Alcoholic beverages produced from honey
Fermented root/tuber products	Alcoholic beverages produced from plants
Miscellaneous products	Alcoholic beverages produced from malting or germination
	Alcoholic beverages produced from fruits without distillation
	Distilled alcoholic beverages without amylolytic starters

[a]Ethnic preparations containing filamentous fungi able to hydrolyze starch.

Table 3 Historical overview of fermentation

When	*What*
7000 BC	Cheese- and breadmaking practiced
6000 BC	Winemaking
3500 BC	Breadmaking in Egypt
2000–3000 BC	Beer fermentation in Egypt and Near East
1900 BC	The Hymn to Ninkasi by Sumerians describes the production of beer
1500 BC	The sacred book of Hindus (Rig Veda) describes Soma, a fermented beverage for immortality, although in Indian subcontinent, fermentation has been used since 6000 BC
1000–2000 BC	Preparation of fermented meat by Babylonians
300 BC	Preparation of fermented vegetables in China
54 BC	Julius Caesar reports cheddar cheese being produced in Britain
48 BC	Sausage making introduced into Rome by Caesar
277	Emperor Probus introduces wine in Alsatia
617	Kumyss, an ethanol-containing fermented mare's milk product, is introduced in Asia
1070	Roquefort cheese discovered
1383	A brewery, later named as Löwenbräu in 1552, opens in Bavaria
1637	The Gekkeikan Sake Co. begins producing sake in Kyoto, Japan; today, it is the world's largest producer of sake
1697	Introduction of white grape in Southern California
1698	Dom Pierre Pérignon (a French monk) develops a method to retain carbon dioxide in wine (production of Champagne)
1857	Pasteur realizes that fermentation is a microbial process
1864	Production of Heineken beer in Amsterdam by using a customized yeast
1873	Lister isolates *Lactococcus lactis* from milk
1881	Publication of some papers on the preparation of koji and the production of sake
1907	Publication of book *Prolongation of Life* by Metchnikoff describing therapeutic benefits of fermented milks
1900–30	Use of defined cultures for fermentation
1950	Identification of bacteriophages in New Zealand
1996	*Saccharomyces cerevisiae* genome sequenced
2001	*Lactococcus lactis* genome sequenced

Not surprisingly, the ancient roots of fermented foods have led to the incorporation of the concept in cultural and religious frameworks. For instance, fermented foods are mentioned in many parts of the Holy Bible, thus suggesting that they must be already known by those civilizations that lived during that time. In the Bible, we found that Noah planted a vineyard immediately after the floodwaters had receded; later, he was described as drunk and naked (Genesis 9, 20). Later in Genesis (18, 8), three angels visited Abraham who offered them some refreshments, including curds. The most important mention of

fermented foods in the Bible was in the Passover story: Hebrew slaves were thrust out of Egypt and could not tarry; therefore, dough could not rise. Fermented foods also played a major role in the New Testament. The first miracle of Jesus was at a wedding in Cana (John 2, 1–11), where he turned water into wine. Another important miracle was the feeding of 5000 men with five loaves of bread and two fishes (John 6, 5–15). Finally, the sacrament of Holy Communion is represented by bread and wine.

Effects of Fermentation on Food Properties

Biosafety and Preservation

As mentioned earlier, food fermentation originally emerged as a way to preserve perishable foods when few other preserving methods existed (e.g., salting). However, even today, preservation is still an important feature of fermented foods. Often, this effect is related to the microbial end products of fermentation (lactic acid, acetic acid, ethanol, etc.), the resulting decrease of pH up to the threshold value of 4.5 in the case of acidic fermentations, the production of specific antimicrobial compounds (such as bacteriocins and antibiotics), and competition for nutrients. Fermentation is thus responsible for the inhibition not only of spoiling microorganisms, such as *Pseudomonas* spp. but also of foodborne pathogens. The latter include *Staphylococcus aureus*, *Clostridium botulinum*, *Salmonella* spp., *Listeria monocytogenes*, *Escherichia coli*, *Yersinia enterocolitica*, *Campylobacter jejuni*, *Bacillus cereus*, *Mycobacterium tuberculosis*, *M. bovis*, *Brucella abortus*, and *Br. melitensis*.

Safety of fermented foods is also linked to the ability of fermenting microorganisms to remove or decrease the content of harmful compounds from the raw materials. Examples include the hydrolysis of limarin (a cyanogenic glucoside found in the leaves and roots of plants such as cassava) by *Lactobacillus* spp. and the degradation of mycotoxins (e.g., aflatoxins and ochratoxin A) by lactic acid bacteria and *Saccharomyces cerevisiae*.

Flavor Generation

Aroma compounds produced throughout fermentation comprise different molecules, synthesized through the degradation of proteins, lipids, and carbohydrates by the concerted actions of microorganisms and the endogenous enzymes of the raw materials. The most important groups include acids, alcohols, aldehydes, esters, lactones, amines, pyrazines, and sulfur compounds.

Acids

This group comprises fatty acids from the hydrolysis of lipids, short-chain fatty acids (SCFA) produced from the degradation of amino acids or carbohydrates, and organic acids (lactic, acetic, and succinic acid), which are the major or minor products of some pathways of carbohydrates.

Long-chain fatty acids ($C > 12$) do not contribute to aroma because they have a high threshold in the perception value, while aroma is strongly affected by SCFA and organic acids. Besides their effects on aroma, acids also contribute to taste and overall flavor complexity.

Alcohols

The contribution of primary and secondary alcohols is very important to aroma development; they can be produced throughout different pathways: (i) carbohydrate metabolism (ethanol is the end product of the primary metabolism in many yeasts and a minor end product in some heterofermentative lactobacilli), (ii) amino acid metabolism (amino acids undergo an oxidative deamination and produce α-keto acids, which are the intermediate compounds to produce aldehydes and alcohols), (iii) reduction of methyl ketones from fatty acid metabolism, and (iv) degradation of long-chain fatty acids (linoleic and linolenic acids) by lipoxygenase and hydroperoxide lyase enzymes.

Aldehydes

Aldehydes are usually produced through two different routes: (i) amino acid deamination or transamination, giving rise to α-keto acids, which are then decarboxylated into aldehydes; and (ii) Strecker degradation of amino acids. Aldehydes are generally intermediate products, as they are converted into alcohols or acids; however, their contribution to aroma is significant.

The most important aldehydes recovered from fermented foods are ethanal, 2-methyl-propanal, 2-methyl-butanal, and benzaldehyde.

Esters

Esters are produced through the esterification between SCFA and alcohols (generally ethanol). They play a significant role in fermented beverages, as they have a very low perception threshold in water (some ppb). The most important notes are melon, pear, banana, apricot, pineapple, floral, rose, honey, and wine.

Lactones

Lactones are cyclic esters produced by the condensation of an alcohol and acid function of the same molecule. They play a significant role in the aroma development of some fermented fruit, dairy, and meat products. They are generally described as fruity notes (peach, pear, apricot, and coconut) or yielding a milky and creamy flavor; the most important compounds are δ- and γ-octalactone, δ- and γ-decalactone, and δ- and γ-dodecalactone.

Amines and nitrogen compounds

Amines come from the decarboxylation of amino acids; these pathways could be a great threat as they can produce biogenic amines, whose toxic effects are well known. An important pathway is the synthesis of L-glutamine from L-glutamic amino acid, reported in yogurt and *miso*.

Pyrazines

Pyrazines are heterocyclic compounds containing nitrogen; they are responsible for different flavors (nutty, roasty, and toasty), depending on the alkyl group. The two most important pyrazines in fermented foods are 2,5-dimethylpyrazine (abundant in Camembert cheese) and tetramethylpyrazine (abundant in Chinese black vinegar); threonine is the precursor of 2,5-dimethylpyrazine, whereas tetramethylpyrazine is produced from acetoin and ammonium.

Sulfur compounds

Sulfur compounds are end or intermediate products of the routes of degradation and synthesis of some amino acids, mainly methionine. The flavor of these compounds has been described as similar to garlic, cabbage, cooked cabbage, cauliflower, and cooked cauliflower; moreover, they have a very low perception threshold.

Color

Optical perception is one of the main sensory traits of importance for food quality, as many consumers decide to buy a product for its appearance. It is related to three different categories: color, cesia, and spatial properties. Color is linked to the optical power spectral properties of the stimulus detected by observers, while cesia includes transparency, translucence, gloss, luster, haze, lightness, opacity, and matt and depends on the properties of reflecting, transmitting, or diffusing light. Finally, spatial properties rely upon the angle of observation and the optical properties of surface.

The color of a fermented food is strongly affected by its composition, storage, and physical parameters (e.g., pH and Aw). Microorganisms can also play an important role. The latter is, for instance, clear in the case of dry-cured fermented sausages; their bright red color is due to nitrosylmyoglobin ($MbFe^{II}NO$) formation, in which an axial ligand nitric oxide (NO) is coordinated to the central Fe^{II} in the myoglobin heme group. In such products, color development depends on the reduction of nitrate into nitrite and subsequently into NO. Meat-associated coagulase-negative staphylococci are able to reduce nitrate contained in the curing salt into nitrite, using a membrane-bound nitrate reductase. This nitrite is then further reduced to yield NO, which takes place under acidic conditions or can be performed by some coagulase-negative staphylococci. Thus, nitrate reduction is an important trait for the selection of strains of *Staphylococcus xylosus* and *Staphylococcus carnosus* intended as starter cultures for dry-cured fermented sausage production.

Aside from fermented meats, starter cultures or indigenous microbiota play a significant role in the color development of different types of fermented foods. For example, microbial metabolism is important for the color of mozzarella cheese, surface-ripened cheeses, and blue-veined cheeses. Some kinds of mozzarella cheese are used for baking (pizza); thus, the presence of residual galactose (a monocarbonyl) can modify the color of melted cheese due to its participation to Maillard reactions. The selection of galactose-positive lactobacilli could thus minimize mozzarella browning. As another example, *Brevibacterium linens* is associated with smear surface-ripened cheeses; it produces yellow-to deep-orange colonies, due to the synthesis of carotenoids. Some other important microorganisms for cheese color are the following: *Brevibacterium aurantiacum*, *Corynebacterium casei*, *Microbacterium gubbeense*, *Staphylococcus saprophyticus*, *Debaryomyces hansenii*, *Candida* spp., *Penicillium roqueforti*, and *P. camemberti*.

Rheology

Fermentation can significantly affect the rheological properties of foods through some main routes, including the production of exopolysaccharides (EPS) and the gelation of casein and other proteins. EPS are extracellular polysaccharides of microbial origin; they might be both bound to the surface of microbial cells and secreted in the extracellular environment in the form of suspension or mucilage. They exhibit thickening, thixotropic, and pseudoplastic properties in yogurt and in some other fermented (dairy) products (e.g., desserts, and dressings). Another important effect of fermentation on rheology relies upon the gelation of casein and whey proteins; this change is associated with the isoelectric point, but the changes in the electric charges may affect the overall structure of proteins and consequently their functionality.

Fermented Foods and Health

Food fermentation is often associated with the production of some biologically active compounds with a potential impact on health, usually referred as nutraceuticals. They can be synthesized through different pathways, for example, oxidation, reduction, hydrolysis, condensation, and isomerization. Table 4 reports some examples of biologically active compounds produced throughout fermentation.

Table 4 Nonexhaustive list of biologically active compounds and their producer microorganisms in fermented foods

Compound	*Producer microorganisms*
EPS: homopolysaccharides (α-D-glucans, β-D-glucans, fructans, polygalactan) and heteropolysaccharides	*Leuconostoc mesenteroides* subsp. *mesenteroides*, *Ln. mesenteroides* subsp. *dextranicum*, *Streptococcus mutans*, *Str. sobrinus*, *Str. thermophilus*, *Pediococcus* spp., *Lactobacillus kefiranofaciens*, *Lb. delbrueckii* subsp. *bulgaricus*, *Lb. casei*, *Lb. acidophilus*, *Lb. helveticus*, *Bifidobacterium* spp.
Angiotensin-1-converting enzyme (ACE)-inhibiting peptides	*Lactobacillus. helveticus*, *Lb. rhamnosus* GG, *Lb. delbrueckii* subsp. *bulgaricus*, *Lactococcus lactis* subsp. *diacetylactis*, *Str. thermophilus*, *Saccharomyces cerevisiae*
Bacteriocins (e.g., reuterin, nisin, sakacin, and plantaricin)	*Lactobacillus reuteri*, *Lb. acidophilus*, *Lb. brevis*, *Lb. delbrueckii* subsp. *bulgaricus*, *Lb. helveticus*, *Pediococcus* spp., *Lb. sakei*, *Lb. plantarum*, *Lactococcus lactis* subsp. *lactis*
Peptides with cholesterol-lowering activity	*Bifidobacterium* spp.
Conjugated linoleic acid (CLA)	*Lb. acidophilus*, *Bifidobacterium* spp.
Vitamins (group B)	*Lactobacillus* spp., *Bacillus* spp., *Saccharomyces cerevisiae*
Phenolic antioxidants	*Acetobacter* spp., species of *Saccharomyces*, *Schizosaccharomyces*, *Kloeckera*, *Zygosaccharomyces*, *Brettanomyces*, *Pichia*
Antibiotics	*Streptomyces* spp.

An interesting topic is the effect of fermentation on health. Some authors found that health disorders were characterized by chronic and low-grade oxidative stress; moreover, they suggested the existence of an 'intestinal inflammatory microbiome,' significantly contributing to altered mood via intestinal permeability, systemic LPS burden, and even direct-to-brain microbe communication. This kind of inflammatory microbiome is enhanced by some Western habits, for example, high-fat and high-sugar or low-nutrient-value foods. 70–80 years ago preliminary studies in rodents and humans pinpointed the consequences of inflammatory microbiome on health; nowadays, it is possible to find some answers toward the potential of fermented foods. It is well known that fermentation can magnify protein quality and the bioavailability of vitamin B, zinc, and magnesium; these compounds exert a significant effect on mental health as they act on mood regulation. Moreover, there is a strong evidence on the fact that some lactic acid bacteria, mainly some strains of *Lb. plantarum*, provide a strong protection toward oxidation. Fermentation of herbal extracts by *Lb. plantarum* was shown to preserve phenols and vitamin C, thus enhancing the free scavenging effect of fermented foods; a similar phenomenon was also found in fermented soy milk by lactobacilli and/or bifidobacteria.

A frontier goal is the production of bioactive compounds; some of these compounds act on immune system, influence glycemic index, possess anti-inflammatory activities, and to some extent can show beneficial mental activities. One of the most important compound is GABA (gamma-aminobutyric acid); the use of synthetic GABA has a limited benefit due to adsorption issues, while the consumption of fermented foods containing GABA produced in situ by *Lb. hilgardii* contributes to the reduction of blood pressure and of anxiety. In addition, GABA-rich red yeast rice has been reported as a strong antidepressant.

Fermentation could act on health toward its effect on flavonoids; some authors suggested the ability of some starter cultures to produce a biotransformation of phenols and this phenomenon is the leading cause of a beneficial shift in growth stimulation of 'good bacteria,' mainly bifidobacteria.

A particular promising aspect is provided by the possible influence of fermented foods on mental health, related to the emerging and promising trend of nutritional psychiatry. The effects of fermented foods on mental health could be due to three leading factors: (i) the presence of specific nutrients, (ii) the ingestion of beneficial microorganisms, and (iii) the modulation of the intestinal microbiota. Ingestion of beneficial microorganisms may have the potential to affect and improve the body responses to some stressful conditions via a whole set of direct and indirect actions, including the following:

1. Direct protection of intestinal barrier
2. Influence on local and systemic antioxidant status and reduction in lipid peroxidation
3. Production of neurochemical compounds, such as GABA
4. Indirect influence on neurotransmitter or neuropeptide production
5. Prevention of stress-induced changes in the intestinal microbiota
6. Activation of neural pathways between the gut and brain
7. Reduced production of cytokine
8. Modulation of neurotrophic chemicals
9. Limitation of carbohydrate malabsorption
10. Improvement of nutritional status
11. Inhibition of gastric and intestinal pathogens
12. Limitation of overgrowth of bacterial growth in the small intestine
13. Analgesic properties

Moreover, some placebo-controlled researches suggest that beneficial microbes can influence mood and fatigue, decrease anxiety and perception of stress, and improve mental outlook; these effects could be linked to their ability to increase peripheral tryptophan levels and alter dopamine and serotonin turnover in the frontal cortex and in the limbic system. Besides the mere ingestion of beneficial microorganisms as such, fermented foods can also display the ability to modulate the qualitative composition of the intestinal microbiota. In 1986, one of the first studies focusing on the effect of traditional dietary patterns examined the differences in the fecal microbiota of rural Japanese versus Canadian urbanites. The researchers found higher counts of *Lactobacillus* spp. and *Bifidobacterium* spp. in the Japanese group that maintained a traditional diet rich in fiber, fermented foods, fish, and vegetables. Several studies have confirmed these preliminary data and have reported a high diversity of fecal microbiota in people consuming fermented foods, whereby the improvement of intestinal balance has been linked directly or indirectly to brain functionality.

A final remark on the most important result on the effect of fermentation on mental health: 3 years ago, some authors were able to show a direct correlation between the administration of a strain of *Lb. pentosus* var. *plantarum* (isolated from kimchi, a traditional fermented cabbage) and hippocampal production of brain-derived neurotrophic factor in mice with a protective effect toward scopolamine-induced memory deficit. This result is a challenge for the future, as it shows that the effects of fermented foods on mental health are not hypothesis, but possibilities.

Concluding Remarks

Fermentation is one of the oldest method of food preservation; moreover, the consumption of fermented foods affects both well-being and cultural traits of life, as it is a part of religion, society, and tradition all over the world. Apart from the effect of fermentation on safety and quality of foods, a new trend is the focus on the link between fermentation and mental health; the expected outcomes of this frontier goal could be a great threat and a challenge for future. We are only scratching the surface in our understanding of the relationship between potentially beneficial microbes and brain health; going inside this phenomenon could lead to some interesting findings and possibilities.

In conclusion, fermented foods are a significant part of our life and culture, and we could presume that discovery, optimization, and focus on fermentation were and will be some leading factors of mankind evolution.

Background

Fermentation has been used to extend the shelf life of foods for over 6000 years. Fermented foods have played an important role in the diets of almost every society throughout the world and are known to offer a variety of benefits. While initially utilized for food preservation, fermentation has numerous benefits that include the improvement of sensory characteristics, acceptability, nutritional value, and safety of foods while also providing diversification to the diet. The number of fermented food products is nearly limitless.

Fermentation is the anaerobic metabolism of carbohydrates by microorganisms. The production of many frequently consumed foods and beverage such as bread, cheese, yogurt, sauerkraut, beer, and wine involves fermentation. Numerous lesser known fermented foods are used in cultural foods throughout the world. The popularity of fermented foods is increasing due to their health benefits and technological advancements that allow for their production on an industrial scale.

A starter culture is a preparation of microbiological cultures that performs or initiates fermentation. Starters usually consist of a cultivation medium, such as grains, seeds, or nutrient liquids that have been well colonized by the microorganisms used for the fermentation. Initially, starter cultures needed to be prepared just prior to use; today, they may be frozen and lyophilized or dried and prepared on an industrial scale.

The choice of starter culture is dependent upon the substrate or raw material being fermented. A starter culture may consist of bacteria, molds, yeasts, or a combination thereof. Lactic acid bacteria are of critical importance in fermentation. Desirable properties of starter cultures include rapid acidification, predictable fermentation processes, desirable sensory characteristics (including taste, texture, aroma, and consistency), and the reduction of harmful microbiota. The first isolation and cultivation of starter cultures occurred in 1890 for cheese and sour milk in Denmark and Germany. Modern technological advancements have led to the development of functional starter cultures. A functional starter culture provides at least one functional characteristic to improve the food safety, nutrition, or quality of the food product.

Purpose of Fermentation

Fermentation serves five primary purposes:

Preservation: Historically, fermentation has predominantly been used as a method of food preservation. Fermentation allows the preservation of substantial amounts of food through lactic acid, alcohol, acetic acid, and alkaline fermentations.

Diet enrichment: Fermentation enriches the diet through the development of a diversity of flavors and textures in food substrates. Examples of this include carbon dioxide production by fermentation in leaven bread and the formation of eyes in cheese or foam in beer and buttermilk.

Biological enrichment: Fermentation enables biological enrichment of food substrates with protein, essential amino acids, and vitamins.

Detoxification: Fermentation can reduce toxic or undesired food components in foods, such as cyanide, phytic acid, and oxalic acid.

Efficiency: Unlike other means of food preservation, fermentation decreases cooking times and cuts back on fuel requirements.

Types of Fermentation

There are three primary types of fermentation most used in traditional and industrial fermentation practices around the world: lactic acid fermentation, alcohol fermentation, and alkaline fermentation.

Lactic Acid Fermentation

Lactic acid fermentation, commonly referred to as lactofermentation, is one of the most common and easiest methods of home preservation. Lactic acid fermentation was a method used to preserve dairy products, vegetables, and meat for extended periods of time before the advent of refrigeration and modern canning practices and today is also utilized in industrial fermentation. Lactic acid bacteria such as *Lactobacillus* spp., lactococci, *Streptococcus thermophilus*, and leuconostocs are examples of lactic acid bacteria that have the ability to convert sugars into lactic acid. Lactic acid inhibits the growth of subsequent and potentially harmful bacteria of other species. It also creates favorable conditions for yeast activity, a property that is utilized in the production of wine and beer.

The chemical reaction of lactic acid fermentation can be written as

$$C_6H_{12}O_6 \rightarrow 2C_3H_6O_3 + 2CO_2 + 2ATP$$
$$\text{Glucose} \rightarrow \text{lactic acid} + \text{carbon dioxide} + \text{energy}$$

Alcohol Fermentation

Alcohol fermentation, also referred to as ethanol fermentation, is the anaerobic process in which yeasts convert simple sugars such as glucose, fructose, and sucrose into cellular energy where ethanol and carbon dioxide are produced as metabolic end products. While yeasts typically function under aerobic conditions, they are also capable of anaerobic respiration, in which sugars are metabolized in the absence of oxygen.

The net amount of alcoholic fermentation by yeast can be written as

$$C_6H_{12}O_6 + \text{zymase} \rightarrow 2C_2H_5OH + 2CO_2$$
$$\text{Glucose} + \text{zymase} \rightarrow \text{ethanol} + \text{carbon dioxide}$$

The first step in alcoholic fermentation involves the process in which the enzyme invertase breaks the glycosidic linkage between glucose and fructose molecules. Each glucose molecule is then broken down into two pyruvate molecules via the chemical process known as glycolysis. Glycolysis causes the reduction of two NAD^+ molecules to NADH. Lastly, two ADP molecules are converted to two adenosine triphosphate (ATP) and two water molecules via substrate-level phosphorylation. The last step uses the enzymes pyruvate decarboxylase and alcoholic dehydrogenase. Zymase is the enzyme complex that catalyzes ethanol fermentation.

Yeast fermentation

The most commonly used microorganism for food production domestically is *Saccharomyces cerevisiae*, also known as 'baker's yeast.' This species was selected due to its ability to produce a large volume of carbon dioxide and a pleasant flavor and to be shelf-stable during storage. When mixed with bread dough, the resulting product is sugar-ferment. Pure cultures of *S. cerevisiae* are isolated and maintained in a laboratory and then inoculated into a medium that often contains molasses and corn steep liquor. (Corn steep liquor is a by-product of wet-milling corn. It is a viscous substrate that contains carbon, nitrogen, and mineral salts.) The inoculated medium is then incubated and aerated, and yeast cells are removed by centrifugation and then washed and mixed with starch or cornmeal. They can be pressed into yeast cakes or freeze-dried to extend their viability.

Yeasts are common epiphytic residents on the surfaces of fruits, vegetables, and cereals. It is the fermentation activity of these yeasts that will lead to their eventual spoilage. Storage and drying decrease the amount of yeast present. Dry flours can also harbor yeasts, though less than whole grains (cereals) that have not had their hull removed.

Alkaline Fermentation

Alkaline fermentation occurs when the protein in a food is broken down into amino acids and peptides. During alkaline fermentation, ammonia is released and pH increases. Alkaline fermented food products are primarily found in Asia and Africa. Examples include natto, Thai thua-nao (and kinema–Thai thua-nao), kinema (made from cooked soybeans), dawadawa (made from African locust beans), ugba (made from African oil beans) kawal (made from fresh legale leaves), and pidan (made from fresh poultry eggs). Spontaneous cultures are most frequently used to make these foods; however, pure cultures can also be used.

Combination Fermentation

Combination fermentation results from the presence of multiple fermentative organisms. Mold-ripened cheeses and salami, cocoa, vinegar, certain fermented milks, and sourdough bread are examples of products that use multiple types of fermentation. Specifically, vinegar is produced using both yeast and acetic acid bacteria. Sorghum beer in Africa is made through lactic acid and alcoholic fermentation. Cocoa is made using lactic acid bacteria, acetic acid bacteria, and yeast.

Traditional Versus Commercial Fermentation

The earliest record of fermentation dates as far back as 6000 BC, long before microorganisms were discovered. Nearly every civilization since has included at least one form of fermented food in its culinary heritage. In some cases, fermentation is a critical component of food safety beyond preservation. Links between food fermentation and human health have been found as early as ancient Rome and China. As cultures and times have changed over the centuries, so have the ways in which we process and preserve foods through fermentation.

Traditional Fermentation and Starter Cultures

Fermentation can occur either through traditional methods or via industrial production. Early methods of fermentation occurred in small batches and involved spontaneous fermentation from microorganisms present on raw goods (i.e., vegetables, fruits, milk, meat, and grains) under the proper conditions. The outcome and taste of the fermented product in traditional fermentation is dependent on the quality and range of microbiota contained in the natural starter culture. For other fermentation processes, inoculation is necessary and a small sample of a previously fermented product is saved and used as inoculate for new raw material. Referred to as backslopping, this method is still used today in the making of some artisanal cheeses, kombucha, sourdough, and sauerkraut.

Commercial Fermentation and Starter Cultures

While methods of traditional fermentation are still being used in various cultures today, the majority of fermented goods are now produced through large-scale industrial techniques. With the discovery of microorganisms, recent insight into their genetics, metabolism, and interaction with raw material has allowed for the ability to improve products and the process of fermentation by using specifically designed and isolated starter cultures. Bread, alcohol, and vinegar were among the first to be 'produced' from starter cultures in the nineteenth century, later leading to the industrialization of the process. Dairy and meat fermentation followed a century later. Today, manufacturers of fermented foods can either use highly concentrated ready-to-use starter cultures or propagate the starter culture in factory production. The decision to use one starter culture method over another depends on various factors including economic value, the number of products produced, the degree of automated fermentation, and the level of microbiology expertise. Variations in commercial starter cultures include direct vat inoculates, frozen or freeze-dried cultures, or starter cultures formulated with stabilizer and carrier genes. Lactic acid bacteria constitute the majority of the volume and value of modern starter cultures. A commercial culture starter with direct inoculation results in the highest level of safety and yield flexibility.

Fermented Foods and Starter Cultures

Due to the variation of raw materials, starter cultures, and fermentation conditions, there are a wide array of fermented food products available. Fermented products are often categorized by the food category of the raw material. See Table 1.

Health Benefits

Fermented foods, as a group, are known to be highly nutritious, and a vast number of health benefits associated with consuming fermented foods are well documented.

Predigestion

As bacteria and yeast feed on the food in their immediate environments, they release enzymes that break down molecules into smaller ones, releasing energy for cellular metabolic use in the form of ATP along the way. Thus, as the larger polysaccharides and protein molecules that hold cells together are degraded, large food particles are ultimately digested into usable pieces. In this way, microorganisms partially digest and physically break down food before it is consumed. Different types of foods are metabolized and broken down in different ways. With grains, gluten is cleaved to nonallergenic fragments. With dairy, predigestion occurs as lactic acid bacteria convert lactose into lactic acid. (For those with a milk allergy, while lactic acid is acceptable to consume, lactic acid starter cultures may contain milk.) With bean ferments such as soy products, enzymes convert proteins into amino acids, which are more digestible and readily assimilated by humans. Lastly, with meats and fish products, bacterial and fungal enzymes help tenderize foods.

Removal of Antinutritional Factors

Fermentation is known to remove a number of harmful and toxic compounds from foods by several means of detoxification. Most notably, fermentation increases the nutritive quality of plant foods by metabolically reducing certain types of antinutrients found in foods such as cyanide, phytic acid, and oxalic acid. For example, the fermentation process that produces kawal, a Sudanese meat substitute, removes harmful toxins from cassava leaves, ensuring them safe for human consumption. Phytates, or phytic acids, are the phosphorus-bound organic acids that protect grains, beans, nuts, and other seeds from premature germination and are well-known antinutrients that can cause mineral deficiencies and digestion issues over time. Common health effects of a phytate-rich diet include tooth decay, lack of appetite, digestive problems, and nutrient deficiencies. For regular consumption of phytate-containing foods in the absence of negative health effects, it is necessary to remove the phytates and other antinutrients through processing techniques such as sprouting, soaking, and fermenting.

Table 1 Nonexhaustive list of types of fermented foods, including the final product, raw material, and type of starter culture

Food category	*Product*	*Raw material*	*Starter culture*
Bean	Tempeh	Soybean	Molds (*Rhizopus oryzae* or *Rhizopus oligosporus*)
	Miso	Soybean	Koji (*Aspergillus oryzae*)
	Natto	Soybean	*Bacillus subtilis* var. natto
	Soy sauce	Soybean	Mold (*Aspergillus*), lactic acid bacteria
Grains/cereals	Bread	Various cereals	Yeast, lactic acid bacteria
	Injera	Teff	Lactic acid bacteria and yeast
	Beer	Various cereals	Yeast (*Saccharomyces*)
	Sorghum beer	Sorghum	Yeast (*Saccharomyces cerevisiae* and *K. marxianus*), lactic acid bacteria
	Sake	Rice	Lactic acid bacteria, yeasts (and occasionally mold)
Vegetables	Kimchi	Cabbage	Lactic acid bacteria
	Sauerkraut	Cabbage	Lactic acid bacteria
	Pickled vegetables	Cucumbers, olives, and more	Lactic acid bacteria
Fruits that underwent alcoholic fermentation	Wine	Grape juice	Yeast, lactic acid bacteria
	Hard cider	Apple juice	Yeast
	Vinegar	Grapes	Acetic acid bacteria (*Acetobacter*)
Meat	Fermented sausage	Sausage	Lactic acid bacteria, catalase-positive cocci (and sometimes molds)
Dairy	Yogurt	Milk	Lactic acid bacteria
	Kefir	Milk	Lactic acid bacteria and yeast
	Cheese	Milk	Lactic acid bacteria (and sometimes propionic acid bacteria, brevibacteria, and molds)
	Pima	Milk	Lactic acid bacteria
Tea	Kombucha	Tea	Lactic acid bacteria and yeast
Honey	Mead (honey wine)	Honey	Yeast
Root	Tanzanian kivunde	Cassava	Lactic acid bacteria

Probiotics and Gastrointestinal Immune Function

Probiotics refer to microorganisms that when ingested in adequate amounts offer health benefits to the host and host physiology. Lactic acid bacteria and bifidobacteria are thought to promote healthy gut bacteria; this is why lacto-fermented foods (fermented dairy foods such as yogurt and dietary supplements) containing these bacteria are considered to have probiotic characteristics. Research suggests that ingestion of probiotic-containing 'health' and functional foods can alter and improve the human gastrointestinal microflora and host immunity. In the absence of mechanistic data, exactly how particular bacterial species contributes to immune system function is not completely understood; however, improvements may include nonspecific defenses against infection, regulation of the balance of T-helper type 1 and T-helper type 2 cells, and increased activity of white blood cells. Some probiotics have been shown to produce antimicrobial compounds, affect immune response or prevent autoimmunity, and/or alleviate lactose intolerance in humans.

Enhancement of Micronutrients and Functional Compounds

During the process of predigestion, vitamins are produced and excreted by the yeast and/or bacteria. In particular, fermentation can increase the amount of several vitamins (e.g., niacin, thiamine, and biotin) in some plant and animal products. In addition to increasing vitamins and their absorption availability in humans, fermentation produces a unique array of micronutrients or functional compounds not found in raw foods. One example of this involves the phytochemical glucosinolate, which is broken down into anticarcinogenic compounds as a result of cabbage fermentation.

While the literature on the health benefits of fermented foods continues to grow, there is still much to be understood. For example, the understanding of how ingestion of live cultures affects, mediates, and regulates physiological processes in the human body is still elementary.

Risks of Fermented Food Consumption

Although the benefits of fermented food consumption have been well documented, biogenic amine content, the possibility of antibiotic resistance in fermented meat products, and the uptake of ethanol and high sodium content are among the risks associated with the overconsumption of fermented foods.

Biogenic Amines

While lactic acid bacteria produced during food fermentation are typically considered to be nontoxic and nonpathogenic to humans, some species of lactic acid bacteria have been found to convert amino acids into potentially harmful amine-containing compounds referred to as biogenic amines. Overconsumption of foods containing a high level of amines is known to have toxicological effects. High levels of biogenic amines are found in a wide array of foods including fermented food products (fish, meat, dairy products, and vegetables) and fermented beverages (wine, beer, and cider). Of the many biogenic amines, histamine and tyramine are thought to be the most important amines occurring in fermented foods. Minimizing or avoiding the presence of amine producing organisms can be achieved through the use of fresh, hygienic raw food materials and, if applicable, addition of microbial controls. Furthermore, precautions should be taken against organisms intended for use in starter cultures confirming non-production of biogenic amines and the ability to withstand production and storage conditions.

Antibiotic Resistance

The emergence and rise in antibiotic-resistant bacterial strains in food products, specifically in meat products, is an ever-increasing public health concern. Starter cultures help drive fermentation in meat products by decreasing fermentation time and improving the overall quality and safety of the products. However, bacteria used as starter cultures, including lactic acid bacteria, are known to pose safety risks by way of transmission of antimicrobial resistance genes. Fermented meat meant for consumption is typically not heat-treated and thus can serve as a direct route for antimicrobial-resistant bacterial transmission from food to human gut microbiota. Studies have found antibiotic resistance in lactic acid bacteria from meats and meat products, with particular mention of strains involved in sausage fermentation such as *L. plantarum*, *L. curvatus*, and *L. sakei*.

Other Risks

As foods ferment, or decompose, certain waste by-products are produced by the bacteria that break down our food. Of the various by-products, alcohol is one by-product that can lead to ethanol uptake due to overconsumption of fermented foods. Fermented foods may also contain excess sodium and not be appropriate for individuals on a low-sodium diet.

Future Possibilities

Biotechnology is advancing the understanding of fermentation and starter cultures rapidly. Pangenomics, or the analysis of the genetic sequences of members of the same species, is now possible with the reduction in cost and time of DNA sequencing. Pangenomics compares complete genome sequences of members within the same species. This opens vast new possibilities to understand and improve industrial starter cultures, which can help with strain screening, strain improvement, safety, and process improvements. For example, thousands of tons of commercial starter cultures are used every year to produce cheese, yogurt, and other dairy products. Further developments and understanding fermentation and starter culture technology will deepen our awareness of this fascinating field.

Introduction

Fats and lipids constitute an important part of the daily diet, and they have a number of essential biological functions. Lipids have an important structural function in cell membranes, they act as energy storage in the cell, they work as signaling molecules, and some of them even act as a kind of hormones. Lipids and fats constitute a broad range of molecules among which triacylglycerols (TAGs) and phospholipids are the most important in our diet. TAGs are composed of a glycerol backbone on which three fatty acids are esterified. Phospholipids can be divided into three classes: glycerophospholipids, ether glycerolipids, and sphingophospholipids. Glycerophospholipids represent the most widespread phospholipid class, and they differ in their polar head groups esterified to the sn-3 position of the glycerol backbone. Fatty acids occupy the two other positions (sn-1 and sn-2) on the glycerol backbone. Fatty acids can be classified into saturated, monounsaturated, and polyunsaturated fatty acids (PUFAs), depending on the number of double bonds in the fatty acid. PUFA can be classified into omega-3 and omega-6 fatty acids, which can be further subdivided into various subclasses. Marine lipids are a major source of the two very long-chain omega-3 fatty acids eicosapentaenoic acid (EPA; C20:5 n-3) and docosahexaenoic acid (DHA; C22:6 n-3), while plant oils such as flaxseed oil are a major source of alpha-linolenic acid (ALA; C18:3 n-3), which has a shorter carbon chain and fewer double bonds. The molecular structure of EPA and DHA is shown in Figure 1. EPA and DHA are not naturally found in plant oils. These two fatty acids have a wide range of well-established health benefits including lowering of triglyceride levels in the blood and reducing the risk of arrhythmia. ALA can be converted to EPA and DHA in the human body, but for people on a normal Western diet with a medium to high intake of omega-6 fatty acids, this only happens to a low extent. The conversion of ALA to EPA and DHA is particularly low in men. This article will provide an overview of the major sources of EPA and DHA and will also discuss the health benefits of marine oils in the different stages of life.

Sources and Production

Sources of Fish Oils

Marine oils refer to fish body oils, fish liver oils, crustacean oils, marine mammal oils, and cephalopod oils. Fish body oils are the predominant product in this category representing almost all of the production with small amounts of marine mammal and squid oils. The fish body oils are sourced from pollack, salmon, tuna, hoki, sand eel, mixed white fish, catfish, dogfish, sprat, horse mackerel, sardines/pilchards, and mackerel, among others. The fatty acid compositions of some of the important fish body oils are shown in Table 1. These fish oils are usually extracted from fatty fish in connection with the production of fish meal. The fish that are processed to produce crude fish oil (and fish meal) can usually be categorized as follows:

(1) Offal and waste from the edible fisheries, for example, cutting from filleting industry. The cuttings or trimmings from the edible fisheries constitute ~50% of the fish biomass intended for food use. These by-products are composed of 15% heads, 14% frames, 4% skin, and 17% viscera (including the livers), and they represent a potential of about 42–44 million tons of waste. Only a portion of that potential resource is currently utilized.
(2) Fish of a quality that is not high enough to make the fish suitable for human consumption.
(3) Fish types that are not considered acceptable or aesthetically pleasing for human consumption. The latter are caught especially for reduction to fish meal and fish oil. This category represents 15–20% of the landings or approximately 16–21 million tons of fish. This raw material, which is landed for direct production of marine oil and fish meal, is 100% utilized.

In the EU, the so-called hygiene legislation requires that fish oils intended for human consumption must be produced from fish that are fit for human consumption, meaning that some of the raw materials that have previously been used for fish oil production for human consumption can no longer be used.

The predominant source of fish liver oils is cod liver. Other sources are hake, halibut, and shark. Fish liver oils constitute <3% of the total production of fish oils.

The other species used for the production of marine oils include krill, squid, and to a lesser extent marine mammals.

The main producers of marine oils are Japan, Scandinavia, Chile, Peru, and Japan (Table 2). The most important countries in the 'Others' category include Russia, Vietnam, and China.

The total annual world production of fish oil during the last 10 years has been ~1–1.25 million tons. The annual production in Chile and Peru and thereby also the total world production are greatly affected by the El Niño events, which can reduce production significantly.

Most of the fish oil is going into salmonid production in Norway, Chile, Canada, and various European countries, but an increasing proportion is being used for dietary supplements and functional foods as will be discussed later. Due to the growth in both aquaculture and direct human consumption of fish oil, it is expected that the total demand for fish oil may soon exceed the production. However, as already indicated earlier, a large proportion of the cuttings and trimmings from the fish industry are currently being wasted and could be utilized for fish oil production. Moreover, ~25–30 million tons of fish is discarded annually and it represents another potential source of fish oils.

Other Sources of EPA and DHA

Anchovy and sardine oils are the major sources of EPA and DHA products. These two species are currently responsible for 80% of the omega-3 products on the market. Fish liver oils, salmon, tuna, algae, or single-cell oils, krill, and yeast account for the remaining 20%. However, the production of EPA and DHA from alternative sources such as microorganisms and plants is expected to grow and is therefore further discussed in the succeeding text.

Several microorganisms are capable of producing EPA and DHA including lower fungi, bacteria, and marine microalgae. Marine microalgae are able to accumulate high amounts of omega-3 PUFAs and they are therefore regarded as a very promising source. Algal oil contains higher levels of DHA, for example, up to 52% compared to fish oil.

Microalgae are cultivated either in photoautotrophic or in heterotrophic production systems. EPA and DHA produced in heterotrophic production systems have been available on the market for several years. Currently, DSM uses *Schizochytrium* sp. and *Crypthecodinium cohnii* for the production of DHA. They have obtained novel food approval from the European Commission for using the *Schizochytrium* sp. oil in products such as dairy products, spreads, dressings, breakfast cereals, and food supplements. The *C. cohnii* DHA oil is used in several infant formula products. The advantage of the heterotrophic production system is that it can take place in closed fermentation systems. In contrast, photoautotrophic algae have to be produced in open systems as they require the presence of light. If the production is carried out in closed photobioreactors, the scale-up of the production is to some extent limited by the ability to effectively introduce light. However, recent development in photobioreactor technologies has reduced this problem, and commercial EPA and DHA products produced in photobioreactors or a combination of photobioreactors and raceway ponds are available.

Genetically modified organism (GMO) plants that can produce EPA and DHA are an alternative source that is being

intensively investigated these years. A major challenge is to obtain satisfactory yields. Commercial products are expected to occur on the market within the next 5 years. The biotech company Monsanto has developed a GMO soybean plant that can produce stearidonic acid (SDA) (C18:4 n-3). The advantage of this fatty acid is that it has one double bond more than ALA. This means that SDA is more efficiently converted in the human body to EPA than current plant sources (ALA) because it bypasses a step in the conversion process. The SDA oil is the first step towards EPA and DHA from GMO plants.

Patterns of Consumption

Among the different omega-3 fatty acids (EPA, DHA, and ALA), marine oils were the most used form in 2007. It thus constituted ca.86% of the ingredients market. A consumer study conducted in 2008 showed that 67.0% of the existing users of omega-3 products identified marine oils as the most preferred source of omega-3.

The marine oils were mainly consumed as dietary supplements, that is, gelatin capsules and to a lower extent liquid supplements. The total consumption of EPA- and DHA-rich oils was ~100 000 metric tons in 2010 and increased to 123 800 tons in 2013. It has been predicted that total global human consumption will increase to 241 000 tons by 2020.

Among the marine oils, fish oils are consumed as triglyceride oils (80% of total sale), low concentrates (2.3% of total sale), middle concentrates (5.2% of total sale), and high concentrates (2.6% of total sale).

As previously mentioned, commercial algal DHA oils are now on the market. However, in 2007, algal DHA oils only accounted for 1.3% of the volume share in omega-3 fatty acid market. However, with more producers entering the market and thereby increasing availability, the consumption of algal oil is expected to increase. Algal oils are primarily used in infant formulas as this application sector accounts for ~70% of the volume. The remaining 30.0% is consumed as dietary supplements and functional foods.

The most natural way of consuming EPA and DHA is of course via fish consumption, and therefore, a few comments on the contribution of fish consumption to EPA and DHA intake are given in the succeeding text. A single lean fish meal, such as one serving of cod, could provide about 0.2–0.3 g of EPA and DHA. On the other hand, a single oily fish meal, such as one serving of salmon or mackerel, could provide 1.5–3.0 g of these fatty acids. However, in most Western countries, the fish intake is low and the intake of lean fish is more common than of oily fish. For example, the median intake of fish was only 16 g fish per day in Denmark during the period from 2003 to 2008. Among the Danes, ~25% eat <5 g fish per day. Consequently, intakes of EPA and DHA among adults in several Western countries may be as low as 0.1–0.2 g day^{-1}. The International Society for the Study of Fatty Acids and Lipids suggests a minimum intake of 500 mg day^{-1}. In Australia and New Zealand, the recommended intake is 430–610 mg day^{-1}. Recently, the Food and Agriculture Organization (FAO) of the United Nations and the European Food Safety Authority (EFSA) recommended a minimum intake of 250 mg EPA + DHA per day for adult males and for nonpregnant/nonlactating adult females. For pregnant or lactating females, the minimum intake was recommended to be 300 mg EPA + DHA per day of which at least 200 mg should be DHA. They also made recommendations for DHA intake for infants aged up to 2 years. For children, the recommendations for EPA + DHA in mg per day were 100–150 for those aged 2–4 years, 150–200 for those aged 4–6 years, and 200–250 for those aged 6–10 years.

Absorption and Metabolism

Absorption and metabolism of omega-3 fatty acids that have been orally consumed follow the same routes as other dietary fatty acids. In brief, they are hydrolyzed from the TAGs or phospholipids, absorbed into enterocytes, and reesterified back into TAGs that are assembled into chylomicrons (lipoproteins). The chylomicrons are released into the lymphatic circulation and then enter the bloodstream. Omega-3 fatty acids from chylomicron TAGs will primarily be stored in adipose tissue, but a minor part of the omega-3 fatty acids will be cleared by the liver. Here, they may be oxidized, metabolized to other omega-3 fatty acids, or resecreted into the bloodstream.

Several studies have investigated whether EPA and DHA from fish are more available than from fish oil supplements in the form of TAGs or ethyl esters. In a recent study, the bioavailability of EPA + DHA (3.1–3.6 g day^{-1}) as reesterified triacylglycerides, ethyl esters, or free fatty acids was compared with that of natural fish oils (triacylglycerides) in a human study. Omega-3 fatty acids were taken as capsules. EPA and DHA contents were lowest in capsules with natural fish oils, but this was adjusted for by the number of capsules taken per day. The bioavailability was highest (124%) in the reesterified triacylglycerides compared with natural fish oil, whereas the bioavailability from ethyl esters was inferior (73%). Free fatty acid bioavailability (91%) did not differ significantly from

natural fish oils. The availability of EPA and DHA from TAG has also been compared with that from phospholipids. Although several studies seem to suggest that EPA and DHA may be more bioavailable when ingested from phospholipids, more studies are needed to finally confirm this conclusion.

In the human body, different cells and tissues have different fatty acid compositions. The EPA and particularly the DHA contents differ significantly among these pools. EPA content is usually lower than the DHA content. Tissues such as parts of the brain and eye have a particularly high level of DHA. This is due to the fact that DHA plays an important role in maintaining a normal function of these tissues. Importantly, supplementation with omega-3 PUFA results in the increased amounts of EPA and DHA in plasma lipids, platelets, erythrocytes, leukocytes, colon tissue, cardiac tissue, etc. Several studies have reported an almost linear relationship between EPA and DHA intake and the resulting EPA and DHA contents of plasma phospholipids and of platelet phospholipids.

Health Effects

Mechanisms of Action

This section will discuss the health beneficial effects of EPA and DHA in the different stages of human life. As an introduction, the different mechanisms through which these fatty acids may exert their effect will be reviewed. Figure 2 provides an overview of the most well-understood mechanisms, but more studies are needed to fully understand the mechanisms behind all the known health beneficial effects of EPA and DHA.

Several studies suggest that the beneficial role of EPA on inflammatory response and platelet aggregation is related to eicosanoids produced in the body from EPA. Eicosanoids are potent chemical messengers that have well-established roles in the regulation of inflammation, immunity, platelet aggregation, smooth muscle contraction, and renal function. EPA is a precursor of the 3-series prostanoids TXA_3 and PGI_3, whereas the omega-6 fatty acid arachidonic acid is a precursor of TXA_2 and PGI_2. TXA_2 and TXA_3 are both prothrombotic, but TXA_3 is less prothrombotic than TXA_2. In contrast, PGI_2 and PGI_3 are equally antithrombotic. Hence, an improper balance between omega-3 eicosanoids and omega-6 eicosanoids can lead to an imbalance in inflammatory response and thrombosis.

EPA and DHA are also precursors for another group of metabolites, namely, resolvins. These lipid mediators have been demonstrated in cell culture and animal feeding studies to have potent anti-inflammatory, inflammation resolving, and immunomodulating effects. A higher intake of EPA and DHA will lead to increased synthesis of resolvins.

The EPA and DHA content of membrane phospholipids influences physical structure and fluidity of the membrane and the structure and composition of important regions of the membranes, which are called rafts. These rafts play a role for receptor action and for the initiation of intracellular signaling pathways. Together, the fluidity of the membrane and raft structure influences the activity of membrane proteins including receptors, transporters, ion channels, and signaling enzymes. In turn, intracellular signal transduction and transcription factor activation may be altered and gene expression modified. This may affect the regulation of inflammatory

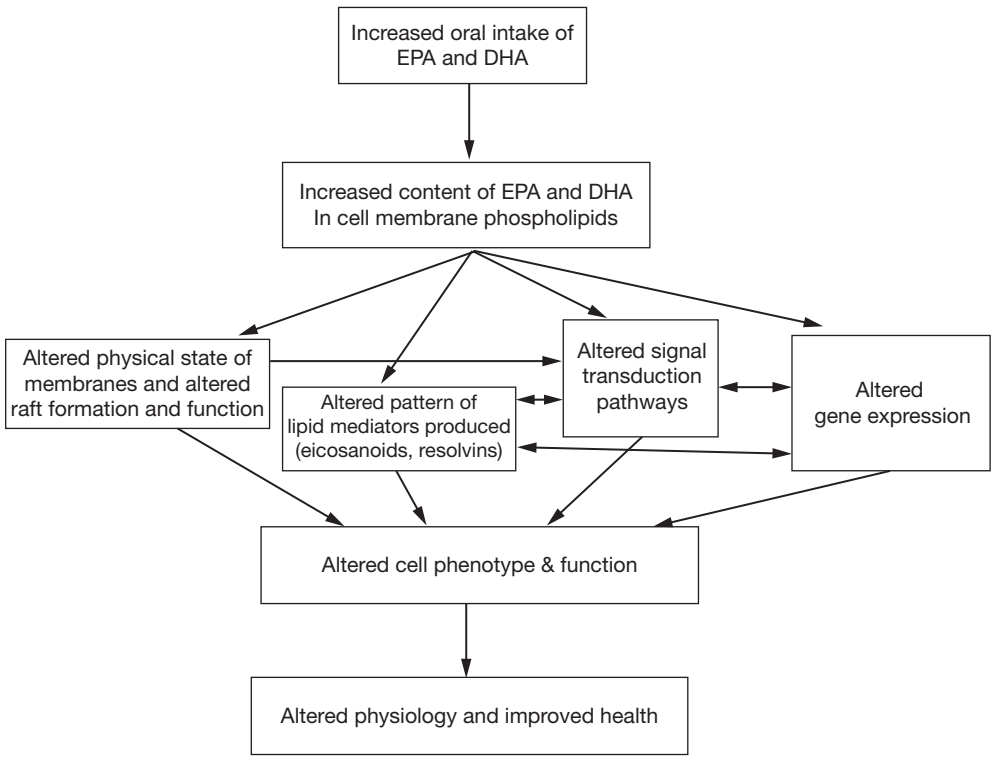

Figure 2 Overview of underlying mechanisms behind health beneficial effects of EPA and DHA. Reproduced from Calder, P. C. (2012). Mechanisms of action of (n-3) fatty acids. *The Journal of Nutrition* **142**, 592S–599S.

processes, the regulation of lipid metabolism, and insulin sensitivity.

The anti-inflammatory effects of EPA and DHA may also be related to their binding to the membrane G protein-coupled receptor called GPR120, which is a lipid-sensing receptor highly expressed in proinflammatory macrophages. When macrophages are stimulated to activate their proinflammatory pathways, this can be inhibited by pretreatment with EPA and DHA via GPR120. A similar receptor dependency for the insulin-sensitizing, anti-inflammatory effects of EPA and DHA was observed in mice deficient in the *GPR120* gene. This suggests that GPR120 is the functional receptor/sensor for these effects of omega-3 PUFA. The same signaling system functions in the hypothalamus. This results in decreased food intake, weight reduction, and improved insulin sensitivity.

Effects of EPA and DHA during Pregnancy and Lactation

PUFAs are preferentially transferred to the fetus at the expense of the mother's own physiological stores. This preferential transfer is termed biomagnification. Maternal arachidonic acid is preferentially consumed by the fetus primarily in early pregnancy followed by DHA in the third trimester and postpartum during lactation. DHA is important for the development of the nervous system including the brain of the fetus. The primary rationale for supplying sufficient intakes of omega-3 PUFA for mothers during pregnancy is therefore to support the optimal health and brain development of the baby during the neonatal period as well as providing for the health and physiological needs of the mother. Maternal omega-3 PUFA intake under the present dietary conditions seems to be inadequate to keep up with the increased demand for omega-3 PUFA during pregnancy. Therefore, it has been suggested that pregnant women should increase their intake of DHA and that infant formulas for both preterm and term infants should contain DHA. Infant formulas with DHA are now available in several countries.

As previously mentioned, high levels of DHA are needed in the brain and retina (eye) for optimal neuronal functioning (learning ability and memory) and visual acuity. Therefore, high levels of DHA in breast milk are necessary in order to ensure proper development of these functions in the infant. The amount of DHA in breast milk is dependent on the intake of the mother during lactation. Hence, consumption of DHA provides a fairly rapid and marked improvement in the DHA level found in breast milk.

Effects of EPA and DHA during Infancy

The body of literature suggests that long-chain PUFAs are important to the growth and development of infants. Fleith and Clandinin concluded in a review that a target DHA level of 0.4% of total fat for preterm infants is desirable and that slightly higher levels than necessary for term infants may be needed. Several studies have demonstrated that addition of omega-3 PUFA to infant formula results in better performances in various tests for visual acuity, mental development, and motor activity including body control, large muscle coordination, manipulatory skills of the hands and fingers, and ability to recognize objects by touch.

Effects of EPA and DHA during Childhood

Unfortunately, there are limited reports on the relationship between fatty acid consumption and health outcomes in children >2 years. One study found that toddlers consuming formula with 130 mg DHA per day for 60 days had fewer adverse events (e.g., strep throat, cough, and upper respiratory infection) and a lower incidence of respiratory illness compared with toddlers consuming the formula without DHA. Other studies of the impact of maternal fish or omega-3 consumption on childhood outcomes have not been able to demonstrate any effects. The relationship between cognitive development of 4-year-old children and their DHA levels has recently been studied, and no association between umbilical venous plasma or red blood cell phospholipid DHA and arachidonic acid levels and cognitive outcomes was observed. There are methodological limitations of the existing randomized controlled trials and epidemiological studies. These limitations include the challenges in quantifying fatty acid exposure and measuring neurodevelopmental outcomes. Therefore, more studies are required to understand the importance of omega-3 intake during childhood.

Effects of EPA and DHA during Adulthood

In adults, low intake of omega-3 PUFAs has been associated with many disease states, including cardiovascular, inflammatory/autoimmune, neurodevelopmental, and psychiatric disorders.

Several studies have demonstrated a beneficial effect of omega-3 PUFA intake on fatal and nonfatal myocardial infarction. An overall decrease of risk of suffering a cardiovascular event of any kind of 10%, a decrease of risk of cardiac death of 9%, and a decrease of coronary events (fatal or nonfatal) of 18% upon intake of omega-3 PUFA have been reported, and it was concluded that marine omega-3 PUFAs are effective in preventing cardiovascular events, cardiac death, and coronary events, particularly in persons with high cardiovascular risk. Moreover, marine omega-3 PUFA may positively affect coronary disease risk factors by decreasing plasma TAG levels, improving platelet function, and lowering blood viscosity.

Omega-3 PUFA has also been found to reduce incidence of joint tenderness and morning stiffness in patients suffering from rheumatoid arthritis. Intake of omega-3 PUFA also appears to offer some protection against asthma, cystic fibrosis, and Crohn's disease. These diseases are all related to a malfunctioning immune system.

The ability of omega-3 PUFA to prevent and treat cancer has been much discussed. A recent review concluded that omega-3 fatty acids are likely to have multifaceted roles in both prevention and treatment of colorectal cancer and other cancers. A review by Gerber was less conclusive. Thus, it concluded that there is only limited evidence from observational studies on colorectal, prostate, and breast cancers on a possible role of omega-3 fatty acids in cancer prevention. Nonetheless, the author stated that there is an increasing biological plausibility of the beneficial anti-inflammatory effect of omega-3 fatty acids on cancers.

Several studies have investigated the role of DHA in Alzheimer's, schizophrenia, and mood disorders. A review by

Hegarty and Parker found that studies investigating the efficacy of omega-3 fatty acid supplementation for mood disorders have provided inconsistent results. They concluded that more research is required before omega-3 supplementation can be firmly recommended as an effective treatment for mood disorders. It has been reported that both arachidonic acid and DHA levels were low in the brain of patients with schizophrenia but that there is only limited evidence that supplements may reduce symptoms. Despite the limited level of evidence for the potential preventative effects of omega-3 fatty acids in mental diseases, the role of DHA in brain function is recognized and a cause and effect relationship has been established as concluded by the EFSA. This also means that health claims on the role of DHA in brain function are allowed. Foods bearing such a claim should contain 250 mg DHA in one or more servings. EFSA has recognized a similar role of DHA in maintaining normal vision, and also, in this case, foods must contain 250 mg DHA in one or more servings to bear the claim (EFSA).

Negative effects of omega-3 PUFA have also been reported. In a recent case–cohort study on 834 men diagnosed with prostate cancer, of which 156 had high-grade cancer, it was found that when compared with men in the lowest quartiles of blood plasma EPA, DPA, and DHA, men in the highest quartile had increased risk of low-grade and high-grade prostate cancer. The reported increased risk of low-grade prostate cancer was 44%, and the reported increased risk for high-grade prostate cancer was 71% for the highest quartile blood plasma omega-3 PUFA group. However, this study has been criticized for not being specifically designed to look at the exact relationship between omega-3 fatty acid intake and prostate cancer as it was an observational study and not a cause/effect study. Another criticism was that plasma phospholipid fatty acids, as measured in this study, are not a good index for long-term intake and can be influenced dramatically by a single meal or even the timing of a fish oil supplement. Moreover, there was no standardization of the omega-3 PUFA quality or quantity consumed by the study subjects. Some were dietary and some were supplementation. Therefore, more research is needed to further study if high intakes of EPA and DHA can promote prostate cancer.

Effects of EPA and DHA during Aging

Studies investigating the role of omega-3 PUFA in healthy older adults are limited. However, there are studies showing that elderly people who consume higher levels of fish as a source of DHA/EPA exhibited a slower rate of decline in their cognitive scoring with age. Other studies have shown that aging individuals who utilized fish oil supplementation appeared to show improved retention of their cognitive functioning in old age. Studies in elderly individuals (65–98 years of age), who were free of known cerebrovascular disease at baseline, exhibited a significantly lower risk of developing a stroke during 12 years of follow-up with increased fish consumption as a source of DHA/EPA. The lowest risk (by 30%) was found in those aging individuals who consumed fish at least five times per week. Moreover, omega-3 PUFAs have been demonstrated to inhibit hepatic triglyceride synthesis, decrease inflammation, and inhibit platelet aggregation in the elderly. Another study suggested that elderly women may be more sensitive to the immunologic properties of omega-3 fatty acids. They found that fish oil supplementation (2.4 g day^{-1} for 3 months) reduced interleukin (IL)-6 in young women (aged 23–33 years) by 30% and in older women (aged 51–68 years) by 60%. Total IL-1β synthesis was reduced by 48% in young women in comparison to 90% in older women, whereas tumor necrosis factor was reduced by 58% in young and 70% in older women.

Conclusions and Future Trends

Consumer awareness about health beneficial effects of omega-3 PUFA is increasing, and this is expected to lead to increasing consumption and thereby increasing demands for marine oils in the coming years. The production of fish oils from traditional resources has stagnated, and therefore, increasing supply must come from new resources such as by-products and discards from the fish industry as well as from microalgae, bacteria, yeast, and GMO plants.

The health benefits from omega-3 PUFA are many and in several cases well documented. However, more studies are needed to obtain more documentation for possible beneficial effects on the prevention of diseases such as mental disorders and cancer particularly in healthy subjects. Likewise, more research is needed to understand the long-term effects of omega-3 PUFA during pregnancy, infancy, and childhood.

Fish Oils: Production and Properties

AK Carvajal and R Mozuraityte, SINTEF Fisheries and Aquaculture, Trondheim, Norway

© 2016 Elsevier Ltd. All rights reserved.

Introduction

The total world fisheries and aquaculture production was 158 million tons in 2012, of which 136.2 tons were used for human consumption and 21.7 million tons of the catch and aquaculture production was used for fish oil and fish meal production. The global fish oil production is estimated to be about 1 million tons per year (0.980 tons in 2012 according to FAO). Out of the estimated 1 million tons of fish oil, about 70 000 tons is estimated to be used for human consumption.

Peru and Chile are the largest producers of fish oil (around 295 000 tons in 2012), followed by Norway and Denmark (140 000 tons in 2012) and Iceland (around 176 tons in 2012). Norway is the largest global importer of fish oil (approximately 200 000 tons) followed by Chile, United Kingdom, and Canada.

Marine Sources for Fish Oil Production

Marine sources used for fish oil and fish meal production can be divided into four categories:

(1) Fish caught especially for the production of oil and meal. This includes species such as anchovy, jack mackerel, capelin, menhaden, and blue whiting. By-catches from other fisheries can also be included in this category.
(2) By-products/rest raw material from the processing industry (both fisheries and aquaculture).
(3) Cod liver (from *Gadus morhua* L. or other gadidae species).
(4) Other marine resources such as seal, krill, micro algae, etc.

Raw Material Quality

The quality of the fish oil depends on the sorting, storage, and handling of the raw material. Fish rest raw material is especially vulnerable to spoilage and degradation because it contains fractions like viscera and blood with high amounts of endogenous enzymes. Lipases and phospholipases will lead to formation of free fatty acids (FFAs) and reduction in quality and stability of the lipids. Prolonged storage of the rest raw material before processing has been shown to lead to an increased concentration of FFA, thus lowering the quality of oil produced from herring and pollock rest raw material. Proteolytic enzymes will cause a reduction in the molecular weight of protein, thus reducing the functional properties. Rest raw materials are also susceptible to microbial spoilage and it is important that they are handled as a raw material intended for human consumption. To ensure high quality oil, it is important to process the raw material within a short time.

There are some regulations for the raw material for fish oil if it is going to be used for human consumption or feed. If the whole fish is going to be used for fish oil production for human consumption, the freshness criteria are based on the total volatile basic nitrogen (TVB-N), which shall not exceed 60 mg of nitrogen/100 g.

Storage and transport must be carried out under hygienic conditions by using tanks of stainless and mild steel construction. The catch has to be chilled within 24 h. Fishing of pelagic species used for fish oil and meal production is mainly done by purse seiners and the fish is stored in bulk in refrigerated sea water (RSW) tanks at −1.5 °C on-board. Whole fish being processed within 36 h must have an acceptable freshness criteria based on TVB-N. Rest raw material may be used directly after production at the slaughter lines to produce oil or may be chilled and transported in containers to the production site. Organic acids can be added to the rest raw material to conserve the raw material before further processing (production of silage). However, the use of non-food-grade acids will result in fish oils that can be used in feed and not for human consumption.

Fish Oil Production

Fish oil and fish meal are traditionally produced by the wet rendering method. The first step is mincing of the raw material (whole fish or by-products), followed by cooking. The cooked material is separated into different fractions, resulting in production of crude fish oil and fish meal. A simplified scheme of the oil and meal production is given in Figure 1.

Cooking

Minced whole fish or by-products are transferred to a continuous cooker and steam heated to 90–95 °C for approximately 10–20 min. The heating will cause protein coagulation and rupture of fat depots, resulting in liberation of oil and water. The cooker usually consists of a long, steam-jacket cylinder where the raw material is moved by a heated rotary screw conveyer. The procedure normally takes around 20 min; however, if a scraped surface heat exchanger is used, the heating time can be reduced to less than 2 min.

Pressing

After cooking, the heated material is transferred to a screw press where the liquid ('press liquor') is squeezed from the solid phase ('press cake') in order to remove as much liquid as possible. Optimal pressing will lead to a higher oil yield and a lower amount of oil in the press cake; thus, a fish meal with low oil content. The press cake liquid consists of water, dissolved material, and oil, while the press cake consists of

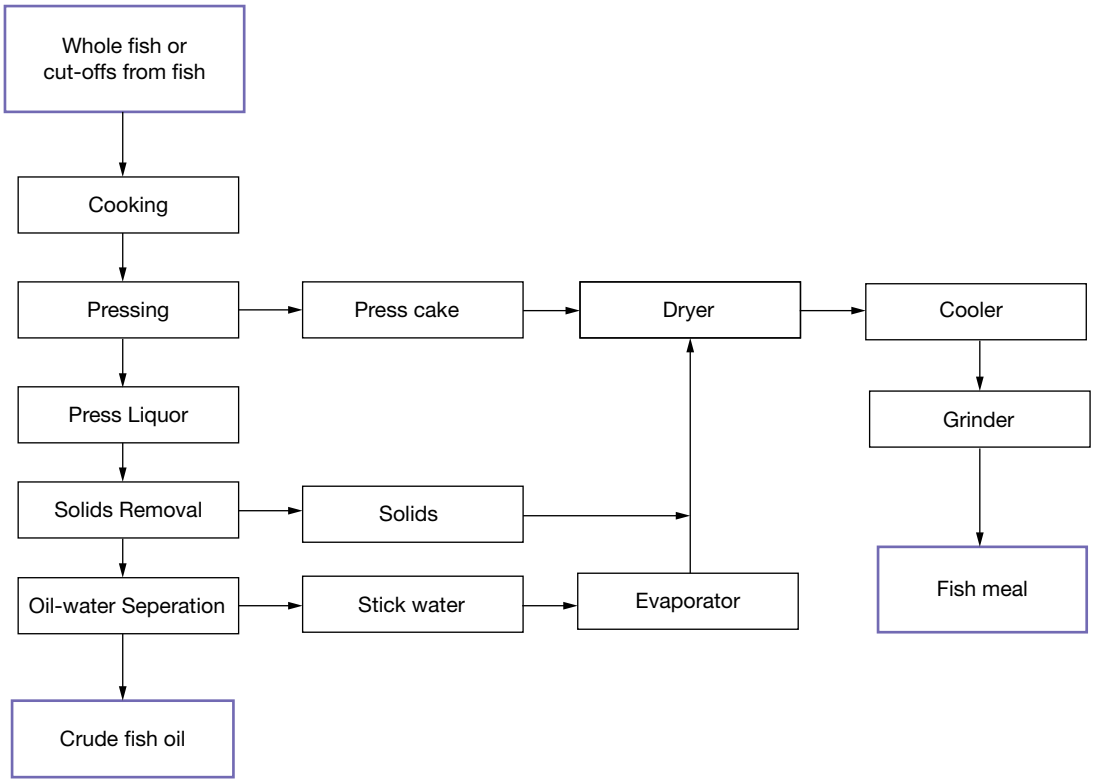

Figure 1 Simplified scheme of oil and meal production.

60–80% of the oil free dry matter. The press cake is further processed into fish meal.

Separation of Press Liquid

Before the oil and water is separated, the press liquid is passed over a vibrating screen (with 5–6 mm perforation) to remove unwanted coarse particles of fish and bones. Different processing solutions based on the fractions' different specific gravity can be used for separation of the press liquid (oil, water, and remaining solids). First, a decanter (horizontal centrifuge) can be used to remove fine suspended solids from the liquor in order to obtain an oil and water phase suitable for further separation. The oil and water phase is transferred to a centrifuge for separation into oil and stick water (water soluble components). The oil is pumped to a polishing centrifuge while the stick water is transferred to the evaporator.

An alternative separation technique is to use a tri-canter which enables the separation of three fractions (sludge, oil, and stick water) at the same time. However, industry experience indicates that it is difficult to produce three high quality fractions and in many cases one of the fractions has to be downgraded in order to produce the other high quality fractions.

Oil Polishing

A polishing centrifuge can be used to remove the final traces of moisture and impurities in the oil. This reduces the amount of pro-oxidants in the oil, thus increasing the oil stability during storage. After polishing, the oil is pumped into storage tanks. The produced oil is called *crude fish oil*.

Drying of Press Cake

Sludge separated from the press liquor is mixed with the press cake together with the concentrated stick water. The press cake is then dried to reduce the moisture content to a level low enough to hinder microbial growth. Two types of driers are used in the fish meal industry: direct and indirect driers. In direct driers, the press cake is in direct contact with the hot gases, while in indirect driers the heat is transferred to the cake through a retaining wall. Indirect driers are mainly used in the fish oil industry.

Enzymatic Protein Hydrolysis

New processes for production of oil based on enzymatic protein hydrolysis are being developed and applied in the industry. Enzymatic protein hydrolysis is based on the use of commercial proteases for proteolytical cleavage of peptide bonds, facilitating the degradation of fish tissue and release of oil. The advantages of using enzymatic hydrolysis compared to the wet rendering method could be a protein product with better biological, digestible, and functional properties. In addition, the use of lower cooking temperature (50–60 °C) compared to the wet rendering method (90–95 °C) can

give an oil of higher quality (low oxidation status) and stability.

For processing of whole fish and by-products by enzymatic hydrolysis, a hydrolysis stage has to be implemented after the material is minced. The reaction can take place in either a tank reactor or a screw-mixing pipe reactor. Heated minced raw material is transferred to a hydrolysis tank and mixed with water (usually in a 1:1 ratio) and commercial proteolytical enzymes (0.1–1 wt% of raw material weight). The reaction proceeds for 30–90 min (hydrolysis time), followed by enzyme inactivation at 90 °C for several minutes.

Several factors can influence the hydrolysis process: substrate type and properties, enzyme type and properties, and processing conditions including temperature, pH, hydrolysis time, and amount of added water. These factors are important for product yield and quality and need to be controlled during processing.

Krill Oil Production

The krill oil industry has developed and optimized the production process for krill, resulting in different processing steps and end products (oil, meal, pasta, etc.). Processing details are often confidential and little is published in the literature. The most common process is to pump live krill onboard the factory trawler were the krill is frozen or directly processed into krill meal. The dried meal can be transported to shore and used to extract krill oil by solvent extraction.

Production of Refined Fish Oil

Crude fish oils contain minor amounts of water and unwanted substances as phospholipids, mono- and diacylglycerols, FFAs, cholestereol, proteinaceous compounds, trace metals, pigments, and primary and secondary oxidation products. The crude oil needs to go through different refining steps before it can be used for human consumption. The general objective of refining of oils is the removal of impurities and unwanted products which cause the crude oil to have an unattractive color or taste or can cause harmful metabolic effects. The refining process can include the following steps:

- Neutralization by addition of citric acid or caustic soda: removal of mainly FFAs, but also oxidation products, phospholipids, pigments, trace metals, and residual soaps
- Washing with hot water: removal of water-soluble material, oxidation products, trace metals, and soaps
- Winterization
- Bleaching by using bleaching earth and activated carbon: removal of pigments, peroxides, phospholipids, soaps, trace metals, sulfur compounds, persistent organic pollutants (POPs), polycyclic aromatic hydrocarbons (PAHs), retinol, tocopherol, and astaxanthin
- Deodorization (steam stripping): removal of volatile compounds, aldehydes, ketones, POPs, FFAs and pigment decomposition products
- Short path distillation (SPD): further reduction of POPs, removal of cholestereol, primary and secondary oxidation products, FFAs, and polymeric materials

Which refining steps are included and in which order can vary between the different fish oils processors.

Neutralization

Neutralization is carried out to remove FFAs (lowering the oils' acid value) and reduce the content of phospholipids, pigments, and trace metals. FFAs can cause darkening of the oil, foaming, and possible smoke during heating. During neutralization, the oil is mixed with caustic soda, resulting in the formation of soaps that can be separated from the crude oil. The oil is heated to the optimum processing temperature of 80–95 °C before caustic soda is added. Hot water is then added to the solution, mixed, and the soapy wash water is removed by using a separator. Washing with water will also remove any water-soluble components present in the oil such as decomposition products of proteins, free amino acids, trimethyl amines and histidine, oxidation products, and phospholipids.

Winterization

Winterization is carried out to reduce the amount of high melting point triacylglycerols and waxes in the crude oil. The process is carried out in tanks with inert conditions and the oil is slowly chilled to 0–2 °C allowing the formation of triacylglycerol crystals with higher melting points to settle and be removed by filtration. The winterization process prevents clouding of the oil at refrigeration temperatures.

Bleaching

The bleaching step removes pigments, but will also further reduce the content of FFAs, residual trace metals, and oxidation products (peroxides) that are left in oil after neutralization. In addition, the process will also remove soaps and sulfur-containing materials. Bleaching by using activated carbon reduces the residual traces of environmental pollutants such as dioxins, furans, and PAHs. However, the process will also reduce the content of desirable natural antioxidants present in the oil as retinol, tocopherol, cholecalciferol, and astaxanthin. The process is carried out by adding bleaching earth and/or activated carbon to the oil through a dosing unit. It is performed at 130–150 °C for 30–60 min under vacuum.

Deodorization

The deodorization step is carried out to remove as much as possible of the unwanted volatile compounds (secondary oxidation products such as aldehydes, ketones, etc.) that are responsible for the unwanted odor and taste of the oil. However, possible nonvolatile secondary and tertiary oxidation products that are formed during processing will not be removed

by deodorization. The oil is steamed under vacuum at a high temperature (150–250 °C) to remove the volatiles. The process is also called stripping, desorption, or steam distillation when oil is mixed with stripping gas to facilitate the mass transfer of the volatiles to the gas phase. The gas phase is continuously removed from the liquid phase. Deodorization should be carried out at a maximum temperature of 180 °C to reduce the risk for polymerization and geometrical isomerization.

Molecular (Short Path) Distillation

An additional step can be added to the refining line to reduce trace amounts of POPs such as dioxins, PCBs, and furans. The use of short path distillation will also lead to the reduction of odor compounds, FFAs, oxidation products, and polymers formed during decompostion/oxidation of the oil. Short path distillation is also used in the production of omega-3-acid ethyl esters.

Fish Oil Properties

Physical Properties

Many of the physical properties of fish oil are dependent on the composition of fatty acids and on the nature of their incorporation into acylglycerols. Density is one of the characteristic that determines quality of the oil and is usually in the range 920–930 kg m^{-3}. Density increases as the mean molecular weight decreases (i.e., with higher saponification values) and the degree of unsaturation increases. Fish oil is a liquid above 10 °C and can solidify below this temperature. The viscosity of fish oils at 20 °C ranges between 60 and 90 cP and decreases exponentially with increasing temperature, the regression equation being $121e^{-0.028T}$ where T is in the range of 20–90 °C.

Fish color can vary depending on the species of fish used and processing conditions.

Chemical Properties

Fish oil is usually made up of triacylglycerols, which often account for more than 95% of the lipids in the oil. The characteristic of a specific triacylglycerol is dependent on the fatty acids composition. However, some fish oils, for example, shark oil, can comprise 40–50% ether linked glycerides. Some fish species can have wax-esters as dominant storage lipids. Wax ester–rich oils generally contain lower levels of omega-3 LC PUFA.

Fatty Acid Composition

The fatty acid composition of fish oils is complex and variable. The composition of fish oils in terms of fatty acids is usually determined by chromatographic methods. The fatty acids tend to contain an even number of carbon atoms and double bonds are of the 'cis' configuration.

The most abundant fatty acids in fish oils are: 14:0 – myristic; 16:0 – palmitic; 16:1 $n-7$ – palmitoleic; 18:1 – oleic acid, 20:1 $n-9$ gondoic, 22:1 $n-11$ – cetoleic, 20:5 $n-3$ – eicosapentaenoic and 22:6 $n-3$ – docosahexaenoic fatty acids. The triacylglycerols consist of fatty acids esterified at three different positions on a glycerol molecule. This distribution of fatty acids in the glycerol molecule is more or less unique for different types of natural fat. An indication of approximate composition of various fish oils are given in Table 1. In most of the fish oils the omega-3 LC PUFAs, mostly EPA and DHA, generally make up 10–35% of the total fatty acids. Fatty acids such as 20:1 and 22:1 are present in significant parts in oils produced from fish such as herring, mackerel, and capelin, caught in northern waters.

Other Chemical Constituent

Fish body and liver oils contain other chemical components such as vitamins. Vitamin D tends to concentrate in the liver of fish. Therefore, body oils contain less vitamin D compared to liver oils. The content of vitamin D depends on the species, age, size, sex, nutritional conditions, and spawning state of the fish. The liver oils also contain vitamin A. Vitamin E is not synthesized by fish; therefore, vitamin E content is dependent on the fish diet. The most abundant form of vitamin E is alpha tocopherol with the concentration being higher in the liver than body oils. The level of tocopherol in fish oil is reduced during refining and deodorization and generally less than 100 ppm is found.

Oxidative Stability

Because fish oils usually contain long chain polyunsaturated fatty acids, they are highly susceptible to oxidation. In addition to fatty acid composition, the oxidative stability of oils also depends on the amount of prooxidants and antioxidants in the oils and storage conditions such as temperature, light, and oxygen availability. Anoxic production and storage of oils prevent against oxidation. Generally, each 10 °C decrease in storing temperature doubles the shelf-life of the oil. Trace amounts of prooxidants (catalysts of lipid oxidation) such as transition metals are usually present in fish oils. Therefore, in order to reduce oxidation, antioxidants that inactivate metals or lipid radicals are added to the fish oils. Encapsulation of n-3 fatty acids reduces the contact between lipids and oxygen and contributes to protection against oxidation. Packaging in material nonpermeable for light and oxygen also contributes to protection against oxidation.

Lipid oxidation is a dynamic process creating a complex mixture of primary, secondary, and tertiary products. Because several products are intermediate; they are formed and then broken down again during marine oil processing, and there is not always a linear increase in the oxidation-products with time of oxidation.

The oxidative state of oil is defined as the sum of all oxidation products present. Traditionally, an estimate of primary (peroxide value) and secondary products (anisidine value) is applied.

PV analysis usually is performed using the iodometric titration method—that is, the one referred to both by Ph. Eur.

Table 1 Composition of major fatty acids of selected fish

(Monograph 2.5.5 Method A) and by GOED (AOCS procedure Cd 8–53).

Anisidine value (AV) determines the amount of aldehydes (secondary oxidation products) formed as a result of breakdown of lipid peroxides in the oils. The method is based on the color reaction between the aldehydic compound and the p-anisidine (AOCS procedure Cd 7–58, Ph.Eur. Monograph 2.5.36).

Oxidative stability of oils is usually difficult to determine. The effect of different antioxidants on the oxidative stability of fish oils can be determined by accelerated oxidative stability methods such as the oxidative stability index (OSI). The OSI method is an American Oil Chemist Society (AOCS) approved method that determines the relative resistance of fat and oil samples to oxidation. The instrument measures the conductivity increase in deionized water as a result of the secondary products' formation during the oxidation of the oil. The Schaal oven test is another accelerated method for determining the stability of lipids and the effect of antioxidants. The test is based on the measurement of weight gain of lipid samples over time at a chosen temperature. The increase in the weight is a result of oxygen binding to the unsaturated fatty acids (i.e., peroxidation). Active antioxidants will delay the onset of peroxidation and, therefore, the weight gain, compared to a control (no antioxidants).

Quality Criteria for Marine Oils for Human Consumption

The chemical composition and quality of crude oils depend on both the production process and the quality of the raw material. This will influence the properties of the oils in regard to edible properties and technical applications. No standard quality criteria are set for the crude oils, but an overview of the typical chemical and physical properties of the crude oils has been reported by Bimbo in 'Guidelines for Characterizing Food-grade Fish Oil' shown in Table 2. Several tests are used to evaluate the quality, moisture content, and impurities. The quality criteria for crude oils are mainly set by the buyer of the oils depending on their range of application; feed, nutraceuticals, functional foods, or pharmaceuticals.

Table 2 Chemical properties of crude oils

Quality guidelines for crude oils	
Moisture and impurities (%)	Usual basis 0.5 up to maximum of 1
Fatty acids (% oleic acids)	Range 1–7, usually 2–5%
Peroxide value (mequiv. kg^{-1})	3–20
Anisidine value	4–60
TOTOX (2PV + AV)	10–60
Iodine value	95–200 (depending on fish source)
Color (Gardner scale)	Up to 14
Iron (ppm)	0.5–7.0
Copper (ppm)	Less than 0.7
Phosphorus (ppm)	5–100

According to the European Food Safety Authority (EFSA), it is difficult to give an exact recommendation for the maximum tolerable PV and AV levels in crude oils because no literature is available on the relationship between oxidation values in the crude oil and in the final oil. However, the quality of the crude

Table 3 Recommended criteria by the European Pharmacopeia (Ph.Eu) and the Global Organization for EPA and DHA (GOED) for oxidation status in refined marine oils intended for human consumption

	[a]*Ph.Eur.7.0 (2011) (maximum values)*		[b]*GOED monograph (2006) (maximum values)*	
Type of oil	[c]*Peroxide value*	[d]*Anisidine value*	[e]*Peroxide value*	[f]*Anisidine value*
Omega-3 rich fish oil (type 1)	10	30	5	20
Omega-3 rich fish oil (type 2)[g]	5	15		
Omega-3-acid triglycerides	10	30		
Omega-3-acid ethyl esters 60	10	20		
Omega-3-acid ethyl esters 90	10	20	None	None

oil will decide the range of application and how extensive the refining that is required.

At present, no adequate international, European, or national legislation standard for origin, quality, and/or composition of marine oil for human consumption is available. The European Pharmacopeia (Ph.Eur) has developed standards with quality criteria for some types of refined marine oils intended for human consumption; cod liver oil, farmed salmon oil, omega-3 rich fish oils, omega-3-acid triglycerides, omega-3-acid ethyl esters 60, and omega-3-acid ethyl esters 90. In addition, both the Ph.Eur and the Global organization for EPA and DHA have prepared recommendations for the evaluation of oxidation status in refined fish oils and set maximum values for the quality parameters. An overview is given in **Table 3**.

Fish: Dietary Importance and Health Effects

HK Mæhre, I-J Jensen, and K-E Eilertsen, UiT The Arctic University of Norway, Tromsø, Norway

© 2016 Elsevier Ltd. All rights reserved.

Introduction

According to the Food and Agriculture Organization (FAO) of the United Nations, the worldwide production of seafood reached 149 million metric tons (MMT) in 2010. This production was divided between capture fisheries at 89 MMT and aquaculture at 60 MMT, and 128 MMT was utilized for human consumption.

Fish consumption varies greatly between countries and is influenced by several factors. Availability in forms of production (capture and aquaculture) and trade (imports and exports) is often the main variable. Factors affecting availability within different countries are geographic location and political conditions. Production is also largely dependent on climatic conditions, as extreme weather conditions such as El Niño affect both capture fisheries and the production of aquaculture feeds. The consumption pattern is also influenced by cultural variables, such as religion and dietary traditions.

Statistics from the FAO show that the general fish consumption in the world has increased over the last 50 years, from 9.0 to 17.8 kg capita^{-1} year^{-1}. This increase is recognizable in most countries. However, the variation between countries is large. For instance, in countries with no coastline, such as Mongolia, the average fish consumption is 0.4 kg capita^{-1} year^{-1}, while island states, like Faroe Islands, have an average yearly consumption of 87.7 kg capita^{-1}.

Most of the literature concerning fish consumption does not distinguish between fish and other seafood, such as crustaceans and mollusks. In the following, unless otherwise specified, fish and other seafoods are hence treated as one.

Composition and Nutritional Advantages

The biodiversity and compositional variety among species make it difficult to conclude on uniform nutritional characteristics valid for all types of fish. In the following, the nutrients particularly associated with fish consumption will be emphasized.

Lipids and Fatty Acids

Lipids are the main energy storage in the human body and also important constituents of brain tissue and other biological membranes. Fatty acids are built up of a carbon (C) chain of typically 4–22 C-atoms, with a methyl group at the proximal end and a carboxyl group at the distal end. The C-atoms are bound together by single or double bonds and the fatty acids are termed thereafter as saturated (zero double bonds), monounsaturated (one double bond), or polyunsaturated (two or more double bonds) fatty acids. The 'omega' indication refers to the location of the first double bond counting from the methyl end of the C-chain. If the first double bond is located between C-atoms 3 and 4, the fatty acid is an omega-3 fatty acid, and if the first double bond is located between C-atoms 6 and 7, it is an omega-6 FA. Two fatty acids are essential to humans, that is, they cannot be synthesized *de novo* in the body. These are linoleic acid (LA, 18:2n − 6) and α-linolenic acid (ALA, 18:3n − 3). These fatty acids are not crucial per se but are metabolized through a series of chain elongation and desaturation to the very long arachidonic acid (ARA, 20:4n – 6), eicosapentaenoic acid (EPA, 20:5n – 3), and docosahexaenoic acid (DHA, 22:6n − 3). The two former act as precursors to fatty acid hormones, called eicosanoids, while the latter has been proven essential for brain development. Depending on whether the eicosanoids originate from omega-3 or omega-6 FA, they have distinctly different qualities. In general, eicosanoids derived from ARA are proinflammatory and prothrombotic, whereas eicosanoids derived from EPA are less inflammatory and even anti-inflammatory. The optimal dietary ratio between omega-6 and omega-3 fatty acids is 2–5/1, depending on the disease in question. The change in diet towards more processed foods with high intake of omega-6 vegetable oils has shifted the omega-6/omega-3 ratio of the current western diet to 15–17/1. LA and ALA are competing substrates for the enzymatic endogenous synthesis of n − 6 and n − 3 long-chain PUFAs. The high dietary content of LA results in a more predominant endogenous production of ARA at the sacrifice of EPA and DHA. Hence, the only way for humans to achieve sufficient amount of EPA and DHA is directly through the diet. Fish contain high amounts of EPA and DHA due to direct transfer up the food chain from phytoplankton that produce them *de novo*. A daily intake between 200 and 500 mg EPA and DHA is usually recommended. This may be achieved by eating fish, preferably fatty fish twice a week. It is also recommended that energy from fat should be around 30% and that saturated fat should contribute to not more than 10% of the total energy. Fish is divided into three groups depending on their fat content: Lean fish, such as cod and saithe/pollock, have fat content less than 2%; medium fatty fish, such as catfish, redfish, and tuna, have a fat content between 2 and 8%; and fatty fish, such as salmon, herring, and mackerel, have a fat content higher than 8%.

Proteins

Fish was initially regarded as a healthy food choice because it is a low-fat protein source. Nonetheless, in the last half century, the positive health effects of seafood have generally been associated with the marine omega-3 fatty acids EPA and DHA, leaving the benefits of proteins and peptides disregarded. Proteins are molecules consisting of one or several polypeptide chains composed of amino acids bound together by peptide bounds. Twenty different amino acids constitute proteins, and of these, nine are essential to humans. The essential amino acids are histidine, isoleucine, leucine, lysine, methionine,

phenylalanine, threonine, tryptophan, and valine. The quality of a protein source is determined from the extent it meets our requirement of essential amino acids, regarding both the amount of essential amino acids and the extent we can absorb and utilize them. Fish contains 12–24% protein depending on species. The proteins contain all essential amino acids in sufficient amounts to cover our daily requirement, and fish is therefore recognized as a complete protein source. The digestibility of fish protein is excellent, and the lower content of connective tissue indicates that fish protein is more easily digestible compared to meat protein from terrestrial animals.

Carbohydrates

Together with fat and protein, carbohydrates are the third dietary source of energy. Fish contains almost no carbohydrates, while crustaceans and mollusks contain only small amounts. Seafood is therefore not a source of carbohydrates.

Vitamins and Minerals

Vitamins and minerals are also essential nutrients, although not for energy. The daily requirements of these components are hence substantially smaller than those of the energy-providing nutrients. Herein, the vitamins and minerals abundant in fish will be discussed. Fish is an important source of the water-soluble vitamin B_{12}. In addition, fatty fish is also rich in the lipid-soluble vitamins A and D. Fish is a good source of several minerals, and whereas only iodine and selenium are more abundant in fish than in terrestrial animals, fish may also be an adequate source of other minerals such as zinc, iron, magnesium, and calcium.

Vitamin A

Vitamin A is a collective term including compounds with biological effect as retinol. Carotenoids are provitamins as they are transformed into retinol in the body. Vitamin A is important in fetal development and for several functions in the body such as reproduction, vision, skin, immune system, and epithelial integrity. In Western countries, vitamin A deficiency is rare, whereas it is a major problem in developing countries. The earliest sign of vitamin A deficiency is reduced growth and night blindness. Recommended daily intakes are presented as retinol activity equivalents (RAE), where 1 RAE equals 1 μg retinol, and are 900 μg for men and 700 μg for nonpregnant and nonlactating women. While eggs and carrots are the main sources of vitamin A, fatty fish, particularly fish liver and fish oils, are also good sources. Fish contain vitamin A in its retinol form that is more easily absorbed than the carotenoids.

Vitamin D

Vitamin D is crucial in development and maintenance of the bone tissue and skeleton by ensuring adequate concentrations of calcium and phosphate in plasma and extracellular tissue. Deficiency of vitamin D can lead to low calcium and phosphate concentration and softening of the bones known as rickets in infants and osteomalacia in adults. Humans synthesize vitamin D when exposed to sunlight, but in northern latitudes, the synthesis is inadequate and additional intake through diet is necessary. The current daily recommendation of vitamin D is 10 μg per day. Good dietary sources of vitamin D are fish liver oil, fatty fish, and fortified foods. Vitamin D content in fish varies greatly, but a portion of fatty fish such as herring or mackerel will ensure the recommended daily intake.

Vitamin B_{12}

Vitamin B_{12}, or cobalamin, is one of the eight vitamins in the B-group. It has a key role in normal brain functioning and nervous system and in blood formation. The most common deficiency symptom is hence anemia. A special variety of anemia, called pernicious anemia, is the result of a hereditary condition where lack of intrinsic factor leads to reduced uptake of B_{12}. The daily requirement of B_{12} is low, around 2 μg, and one portion of 100 g fish will generally cover the recommended daily intake. In addition, most fish also contain some amounts of the other B vitamins.

Iodine

Iodine is a trace element essential in the synthesis of the thyroid hormones detrimental for growth and metabolism. Deficiency of iodine is the largest deficiency disease worldwide, causing goiter (thyroid enlargement), growth inhibition, and mental retardation (cretinism). The recommended daily intake of iodine is 150 μg. Fish, especially marine fish, are good sources of iodine and one portion of cod will cover the daily recommendations. Furthermore, iodine is the simplest micronutrient to fortify and is usually added to dietary salt.

Selenium

Selenium is another trace mineral essential for humans. Being a constituent of the antioxidative enzyme class glutathione peroxidases (GPx), it is regarded as one of the most important endogenous antioxidants. In addition, selenium is central in the thyroid hormone regulation, and a diet deficient in selenium may therefore lead to, and even intensify, some of the deficiency characteristics seen in iodine deficiencies. The recommended daily intake is 40–50 μg. Seafood is recognized as a good source of selenium, especially in areas where the soil is depleted of this trace mineral.

Bioactive components

In recent years, an increased focus has been directed towards food components with beneficial health effects beyond that of nutritional value, namely, bioactive compounds. The bioactivity in question may be linked to a vast range of physiological conditions, such as oxidative stress, hypertension, cancer, obesity, and infections. Likewise, the compounds may possess very different chemical properties. Some of the compounds and bioactivities related to fish will be discussed further.

Peptides

Peptides are parts of proteins, ranging from two to several amino acids. The bioactivity is based on the sequence and composition of typically up to 30 amino acids occasionally occurring as free peptide in foods, but commonly within their parent proteins. Within proteins, side groups of amino acids are buried and the peptides have no bioactivity. Hence, they need to be released through fermentation, food processing, proteolysis, or gastrointestinal digestion to exert any activity. Several bioactivities have been linked to fish peptides,

although three main activities are well documented, namely, antihypertensive effect, antioxidative activity, and antiobesity effect.

Taurine

Taurine (2-aminoethanesulfonic acid) is the end product of the sulfuric amino acid metabolism, and although it contains a sulfonic group instead of a carboxyl group, it is considered as an amino acid. However, it is not bound in proteins, but exists as an exclusively free amino acid in most human tissues, the concentrations being especially high in the brain, retina, skeletal muscles, heart, and leukocytes. Its participation in several physiological processes, such as osmoregulation, neuro- and immunomodulation, and bile salt formation, has been well documented. In addition, together with its precursors methionine and cysteine, it is involved in protection from oxidative stress reactions. Lately, several reviews have discussed the relationship between taurine and several other diseases, such as cardiovascular disease (CVD), hypertension, and diabetes.

The endogenous synthesis of taurine is dependent on a series of enzymes and the efficiency of the production is species-dependent. In humans, it is quite inefficient and in certain situations, the endogenous production may be inadequate. Taurine is therefore characterized as a conditionally essential amino acid that should be provided through dietary intake. The main dietary source of taurine is seafood, levels being higher in mollusks and crustaceans than in fish.

Other bioactive components

Other bioactive components frequently found in foods are ubiquinone, carotenoids, polyphenols, and phytosterols. Of these, carotenoids are considered important in relation to consumption of seafood. Carotenoids are a class of antioxidative compounds, with some chemical resemblance to vitamin A, and some of them may be chemically converted to this vitamin. The most abundant carotenoid in seafood, especially in crustaceans, is astaxanthin. This compound is produced by microalgae as a defense towards UV light and may be found in decreasing concentrations upward in the marine food web. Within the fish, it acts as an endogenous antioxidant, protecting it from autoxidation, and it is also believed to possess similar protective effects in humans. Phytosterols are cholesterol-like compounds abundant in plant materials and to a certain degree in mollusks. In fish, these compounds have traditionally not been present. However, in line with the increasing inclusion of plant materials in aquaculture feeds during the last years, an increasing amount of phytosterols has been detected in farmed fish.

Health Effects of Fish Consumption

Numerous studies have been performed in order to evaluate a potential causal relationship between fish consumption and chronic diseases. Such studies make up the foundation of evidence-based decisions and are combined by the world's large health organizations in order to establish official dietary advice for consumption of fish. There are two main approaches when studying this field, epidemiological and experimental studies, and there are advantages and disadvantages associated with both study types. A combination of studies will probably return the most solid foundation for advice.

In brief, in epidemiological studies, human populations are studied in order to describe and explain health and disease. The main advantages of these studies are that they range over a long period of time, the data material is very large, there are few restrictions in diet, and diseases can be included as end point. The main drawbacks are that they are poorly controlled and that the sources of error are many. Among epidemiological studies, several subtypes are defined: descriptive studies, ecological studies, migrant studies, case–control studies, cohort studies, randomized controlled studies, and meta-analysis.

Experimental studies are performed in a more controlled environment than are epidemiological studies. The test participants can either be human volunteers, but most experimental studies are performed in animals (*in vivo*) or in cell-based systems using human or animal cells grown in the laboratory (*in vitro*). There are also subtypes of experimental studies: human feeding studies, live animal models, *in vitro* studies, and studies of biological pathways.

The world's large health organizations, such as the World Health Organization (WHO), the World Cancer Research Fund (WCRF), the American Heart Association, and the Academy of Nutrition and Dietetics, have defined different categories describing the causal relationship between exposure/intake and morbidity, and each category has different demands of the strength of documentation. There are slight differences in the definitions of the criteria between the various organizations, but the strength of documentation is the same. The main categories used by WHO and WCRF 'Convincing relationship,' 'Probable relationship,' 'Limited relationship – suggested,' 'Limited relationship – no conclusion,' and 'Substantial effect on risk unlikely.'

The evidence-based documentation is often presented in matrices, one for each food type and disease group. Potential harmful effects/risks on intake of food are also included. The associations presented in the matrices are documented relationships and meet the demands of convincing relationship or probable relationship. Inclusion of evidence from more than one study type, no substantial unexplained heterogeneity within or between studies and control of confounding factors, and random or systematic errors are among the qualifications to be met in order to end up in one of these two categories.

Cardiovascular Diseases

The vast majority of studies regarding fish consumption and chronic diseases are related to CVDs. CVD is a collective term encompassing a group of disorders of the heart and blood vessels and is the largest cause of morbidity and a major cause of premature death worldwide. The two most frequent disorders are coronary heart disease and cerebrovascular disease (stroke), affecting blood vessels of the heart and brain, respectively.

There are several risk factors associated with the development of CVDs. Some are nonmodifiable, such as age, gender, and heredity. Yet others are modifiable, such as smoking, hypertension, unfavorable blood lipid composition, physical inactivity, obesity/overweight, and diabetes mellitus. The latter ones are recognized as lifestyle-related risk factors and may be

influenced by dietary habits. Concurrent presence of several risk factors is common and certain risk factors may in combination increase the risk of CVD considerably. Although there are several independent risk factors for the development of CVDs, causal relationship between their presence and actual disease has not been established for most of them.

CVD and Fish Intake

The vast majority of studies regarding fish intake and health benefits have been focused on their content of long-chain omega-3 fatty acids. An increased intake of these fatty acids, especially EPA, will lead to replacement of ARA in cell membranes and red blood cells. As previously mentioned, eicosanoids may be formed from both ARA and EPA. However, the properties of different eicosanoids are substantially different depending on the originating fatty acid. As mentioned previously, eicosanoids formed from ARA are proinflammatory and prothrombotic, whereas eicosanoids formed from EPA are less potent and show anti-inflammatory and antithrombotic properties. This may have impact on the atherosclerotic process. In addition, an increased intake of LC-PUFAs has been shown to improve the stability of plaques.

It is well documented that a high intake of fish reduces the level of triglycerides in the blood and, hence, attenuate the effects of dyslipidemia. The effects on blood cholesterol levels are not as consistent.

The relationship between the intake of LC-PUFAs and blood pressure has also been studied, but also here, the results are inconclusive. Some studies imply that hypertensive patients may benefit from a high intake of these fatty acids, while the same effect is not seen in persons within the normal range of blood pressure. Several fish species are also considered good sources of potassium that is essential for water and electrolyte balance and the normal functioning of neurons and other cells. Dietary potassium may lead to loss of sodium, and increased dietary intake of potassium has been associated with a decrease in blood pressure.

However, intake of fish may affect blood pressure through yet another mechanism, that is, via peptides released through gastrointestinal digestion. Numerous *in vitro* studies and animal models have shown that fish peptides exhibit blood pressure-reducing effects by inhibition of ACE. A few human studies have confirmed these findings.

Fish Intake and Other Chronic Conditions

Although not as frequent as for CVDs, studies on the correlation between fish intake and other positive health effects have also been performed. Among the studied effects are cognitive development and disorders in later life, cancer, allergy, and other immunologic conditions, along with lifestyle-related conditions, such as type 2 diabetes. Due to large heterogeneity between studies, the conclusions regarding these conditions are not as convincing as for CVDs, but some of the main suggestions and findings will be presented here.

Cognitive disorders: Development and later life

The fatty acid DHA is thought to be of great importance for neurodevelopment and most studies regarding this subject are focused on this fatty acid. However, the number of potential confounders in studies regarding cognitive development in early life is substantial. This makes it extremely challenging to draw conclusions from such studies. Despite this, most studies conclude that a high maternal intake of fish is beneficial for overall cognitive development of the offspring and that neither maternal nor postnatal supplementation with long-chained n − 3 fatty acids provides additional effects.

When cognitive decline and dementia, including Alzheimer's disease, have been investigated in relation to fish and n − 3 intake, the results are also inconclusive. In some studies, there seem to be a trend, although not significant, that fish intake, but not n − 3 supplementation, may offer a certain protection against dementia. Other studies find no correlation at all.

Cancer

Lifestyle and dietary habits have been related to several types of cancer, in particular the cancers of the gastrointestinal system. As a natural result of this, the relationship between fish intake and these cancers has been examined. For most of these cancer forms, there is no convincing or probable relationship associated with fish intake.

Allergy and immunologic reactions

Also asthma, eczema, and other atopic conditions in children have been investigated in relation to both maternal fish intake and fish intake during the first year. Although the results are inconclusive, eczema seems to be the only condition where fish intake may have positive effects. Both maternal fish intake and early introduction of fish during the first year seem to positively affect the risk of this condition.

Type 2 diabetes

Type 2 diabetes is recognized as a lifestyle-related disease. As dietary habits are a part of the factors related to the development of these diseases, the intake of several food items, including fish, has been investigated in order to discover potential correlations. So far, the number of studies regarding fish intake and type 2 diabetes is small and the heterogeneity between them is large, and hence, no correlation has yet been identified.

Adverse Health Effects

Increased fish consumption has long been recommended due to the well-documented health benefits. Nevertheless, fish as other foods can accumulate environmental pollutants and heavy metals that may reduce the overall nutritional value and alter consumer's health. In order to lower the risk of such detrimental effects, the Joint WHO/FAO Expert Committee on Food Additives has compiled guidelines and set limit values for assumed safe intakes of most contaminants. These limits, termed tolerable weekly intakes (TWI), are based on experimental data and equal the amount of a compound that may be consumed weekly during the total life span of a human being without risk of adverse health effects. In cases where experimental data are insufficient or lacking, a provisional tolerable weekly intake (PTWI) is set. The unit of both TWI and PTWI is μg or mg kg^{-1} body weight (BW) per week.

The contaminants most relevant for fish consumers are heavy metals and persistent organic pollutants (POPs). Pathogens and marine toxins can undoubtedly result in negative health effects. These risks may however be eliminated through proper cooking and are therefore not discussed here.

Heavy Metals

One definition of heavy metals is that they are elements with atomic weights ranging from 63.5 to 200.5 and specific gravities greater than 4.0. Small amounts of heavy metals occur naturally in the environment, but the vast amount of them may be attributed to human activities such as industrial emissions. Some of the heavy metals, such as iron, copper, and zinc, are essential for the human body in low doses. Others, such as arsenic, cadmium, lead, and mercury, have no known essential function in man. Common for all of the heavy metals is that they are toxic if consumed in excess, but the level of toxicity varies greatly between metals and which chemical state they are in. They have great affinity to ligands in cellular proteins and bind more easily to these than do other metals present in the body. A result of this may be inhibition of enzymatic reactions. As the elimination rate is slower than the absorption rate, heavy metals accumulate in the body.

Arsenic

Arsenic is used in a number of industrial processes including processing of glass, pigments, textiles, and ammunition. Small amounts are also used in pesticides and feed additives. High levels of arsenic are found both in the groundwater in several areas of the world and in the oceans. The toxicity of inorganic arsenic is far greater than the organic form and the PTWI of 15 $\mu g\,kg^{-1}$ BW is hence related to this form. Most of the registered adverse health effects related to arsenic are also related to the inorganic form and include peripheral vascular disease and various cancers. Fish is recognized as the most significant dietary source of arsenic, however, mainly in its less toxic organic form.

Cadmium

The main sources of exposure of cadmium are through commercial fertilizers and atmospheric pollution. Galvanizing processes and batteries are other sources. The absorption of cadmium is generally low but may increase in the presence of calcium or proteins. The main target organs for cadmium are the kidney and liver and toxic effects of it are related to these organs. Such effects include increased excretion of glucose, amino acids, and calcium, along with increased gluconeogenesis. The PTWI of cadmium is 7 $\mu g\,kg^{-1}$ BW. Shellfish are recognized as one of the food sources containing the highest level of cadmium.

Lead

Lead is abundant in nature, but also environmental contamination contributes to the total amount present. During the last half of the twentieth century, addition of lead to gasoline led to a sharp increase in contamination. Introduction of unleaded gasoline has turned this trend and lead contamination is now decreasing. The absorption of lead is around 5–15% in adults but slightly higher in children. The toxicity of lead is among other things linked to its capability of competing with essential metals for binding seats on enzymes and for inhibiting the transport of important ions such as calcium. Lead poisoning may affect the central nervous system, kidneys, and blood-producing organs. Lead is classified as a carcinogenic substance and may affect fertility. There is currently no PTWI for lead. In contaminated areas, seafood has been shown to contain high levels of lead, shellfish more than finfish.

Mercury

Mercury exists naturally in the environment, but industrial emissions are a significant contributor. It exists in elemental, inorganic, and organic forms, where the organic form is the more toxic. In aquatic environment, inorganic mercury is converted by microorganisms to methyl mercury (MeHg), which accumulate in the aquatic food chain. Humans are therefore exposed to MeHg through consumption of large predatory fish, of both marine and freshwater origins. The harmful effects of MeHg were first discovered after large-scale industrial poisonings in Japan in the 1950s and in Iraq between 1955 and 1972. These events demonstrated the harmful effects of MeHg primarily on the nervous system and in particular neurodevelopmental effects of fetuses. The PTWI for MeHg is 3.3 $\mu g\,kg^{-1}$ BW. Due to its well-documented negative developmental effects, specific dietary advice has been made for pregnant and lactating women. These state that these groups should not consume pike at all, perch above 25 cm, and trout and char above 1 kg. Dietary advice for other population groups is to not consume these species more than once a month. All groups are advised to minimize consumption of other large predatory fish such as swordfish, shark, king mackerel, and tuna.

Persistent Organic Pollutants

POPs are a large group of organic substances in which one or more hydrogen atoms have been substituted with halogens. The most important substances regarding fish consumption and adverse health effects are polychlorinated dibenzo-p-dioxins and dibenzofurans (PCDD/Fs), polychlorinated biphenyls (PCBs), and polybrominated diphenyl ethers (flame retardants). None of these substances occur naturally, but are formed when hydrocarbons and halogens are exposed to high temperatures in incineration or other industrial processes. The decomposition rate is very slow due to the lack of enzyme systems able to break carbon–halogen bindings. They are lipophilic in general and the lipophilicity increases with increasing degree of substitution. The combination of these two factors leads to bioaccumulation in the marine food web, especially in fatty fish.

Dioxins and PCBs

The chemical structures of PCDD, PCDF, and PCBs are quite similar, as all of them contain two phenol rings. Hydrogen atoms are attached to these phenol rings, eight in PCDD and PCDF and ten in PCB. All of the hydrogen atoms may be substituted with chlorine atoms, making a total of 75 possible variants of PCDDs, 135 different PCDFs, and 209 PCBs. Twelve of the 209 PCBs, those without chlorine substitution in the ortho-position or those containing only one chlorine in

ortho-position, are characterized as dioxin-like PCBs. These act on the same toxicological pathway as dioxins, that is, via the aryl hydrocarbon receptor, and share more or less the same toxic properties as the dioxins. The dioxin-like PCBs are included in the term 'dioxins' in the following section. The non-dioxin-like PCB will not be discussed further here.

Some of the common adverse health effects that may be caused by these compounds are skin reactions (chloracne), damage of the neurological and immunologic systems, organ damage, enzyme induction, carcinogenic effects, and teratogenic effects.

A common system for evaluation of total toxicity of these compounds has been prepared, in which each compound has been given a toxic equivalency factor (TEF) related to the most toxic substance 2,3,7,8-tetrachlorodibenxodioxin, whose TEF is 1. In general, PCBs are less toxic than PCDDs and PCDFs. The total amount of dioxins in a sample is reported as toxic equivalents (TEQ) and is found by multiplying the concentration of each compound with its respective TEF and finally adding them up. The TWI for dioxins is currently 14 pg TEQ kg^{-1} BW.

Due to the bioaccumulation of dioxins in the aquatic food chain, seafood is recognized as a significant dietary source of dioxins. However, dioxins are also found in most other foods, and studies of food consumption patterns show that the daily intake of dioxins is approximately equal in most populations regardless of the seafood intake.

From time to time, the issue of high levels of dioxins in farmed fish is brought forward. The assumption is that levels of these compounds may be high in farmed fish due to the use of unrefined fish oil in the aquaculture feeds. However, the substitution of fish oil with plant oils during the last years has actually led to a decrease of dioxins in the farmed fish, and currently, the levels of these compounds are actually higher in wild species.

The prevalence of dioxins in the environment has decreased during the last decades, partly because of changes in industrial processes and partly because of a ban introduced in the 1980s on the usage of PCBs in new products. However, due to their slow decomposition rates, these compounds will be present in the environment for several years to come.

Polybrominated diphenyl ethers (flame retardants)

This is a group of compounds with similar chemical structures as PCBs, the difference being that the substituting atoms are bromine instead of chlorine. Their primary function is to serve as flame retardants, and as opposed to PCBs, their use and presence in the environment are increasing. Their toxicological properties have not been studied to the same extent as the dioxins, but several recent reviews have suggested that their use should be restricted.

Risk versus Benefit Analysis

Fish and seafoods have been extensively evaluated for their risks and benefits. Balancing risks and benefits is important, particularly in countries with high *per capita* seafood consumption such as Japan, Portugal, Iceland, and Maldives. Several meta-analyses have been published evaluating the risks and benefits associated with seafood consumption. An example of a risk–benefit analysis is the one performed by the Joint WHO/FAO Expert Committee in 2010 where the increased risk of dying from cancer caused by dioxins versus the reduced risk of CVD mortality due to EPA + DHA by consumption of equal amounts of fish was evaluated. The evaluation criteria were changes in total mortality per million people by intake of one fish meal per week for a lifetime. An example of such an analysis is for farmed Atlantic salmon, 600 lost lives to cancer versus 39 800 avoided deaths due to CVD, corresponding to a ratio between benefits and risks of approximately 66:1.

Conclusions

Fish and other seafoods are excellent sources of several important nutrients, and it is concluded that a high intake of these food items lowers the risk of CVD. Although not as consistent, positive health effects related to fish consumption and other chronic diseases have been confirmed. Despite being a source of several contaminants, the benefits of seafood consumption outweigh the potential risks, and hence, the conclusion is clear; the general seafood consumption should be increased.

Seafood Sources and Production

Countries of Origin for Seafood

According to the Food and Agriculture Organization of the United Nations, in 2012, China was the major seafood exporting nation to the world (14% by value), followed by Norway at 7% by value, Thailand (6% by value), and Vietnam (5% by value). In 2012, the FAO ranked China as the top fishing country by quantity and value, followed by Indonesia, the United States, India, and Peru (primarily due to anchoveta). China is also the leading producer of aquacultured species in the world at 41.1 million tonnes, and its production is nearly 2.5 times that of its wild capture. In fact, in 2008, Asia started producing more farmed fish than wild catch, contributing 54% of the world's production in 2012, with Europe at a distant second at 18% and other continents below 15%. Other countries important to aquaculture are India (4.2 million tonnes), Vietnam (3.1 million tonnes), Indonesia (3.1 million tonnes), and Bangladesh, Norway, Thailand, Chile, Egypt, and Myanmar, each supplying less than 2 million tonnes. All these countries supply 88% of the world's production.

The most captured species is anchoveta, followed by Alaska pollock, skipjack tuna, Atlantic herring, and chub mackerel. The FAO monitors 1600 harvested marine species, but 40% of the total marine catch comes from 23 species.

In 2012, shrimp continued to be the most important commodity traded in world commerce in terms of value, accounting for about 15% of the total value of internationally traded fish proteins. Other main groups of exports are salmon and trout (more than 14%), groundfish at 9% (e.g., hake, cod, haddock, and Alaska pollock), and tuna (8%).

In 2012, about 73% of the total fishery imports in value were in developed countries, with the United States and Japan accounting for 27% of the total. The European Union represented 36% of the total world imports, which include intraregional trade among its members, and thus is the largest market in the world.

The total global capture fisheries production for 2012 is 91.3 million tonnes, while aquaculture was 66.6 million tonnes for a total of 157.9 million tonnes.

Patterns of Consumption

According to the FAO, in 2012, about 86%, or 136.1 million tonnes, of the total fishery production was used for direct human consumption. The remaining 14%, or 21.7 million tonnes, goes primarily for fish meal and fish oil. About 46% of seafood for human consumption is eaten in live or fresh form.

In 2011, the global per capita annual consumption of seafood was estimated by the FAO at 18.9 kg, with fish accounting for 16.7% of the global population's intake of animal protein and 6.5% of all proteins consumed. Globally, fish provides 3.0 billion people with almost 20% of their average per capita intake of animal protein and 4.9 billion people with 10% of such protein. Table 1, based on FAO data, is a look at the role of seafood in supplying protein to the diet. Interesting and somewhat predictable from Table 1 are the countries and continents that rely on land sources of animal protein. Fourteen countries have a consumption of fish/animal proteins greater than 50% (i.e., the British Virgin Islands, Ghana, French Guiana, Guadeloupe, Martinique, Bangladesh, Cambodia, Indonesia, Maldives, Sri Lanka, Kiribati, the Solomon Islands, Tokelau, and the Wallis and Futuna Islands). Seafood contribution to the diet is reduced by consideration of other nonanimal proteins as food sources, but the countries of the British Virgin Islands, Guadeloupe, Maldives, Kiribati, Tokelau, and the Wallis and Futuna Islands remain strong at >30% of fish/total proteins.

Health Effects

Omega-3 Fatty Acids in the Diet

Omega-3 fatty acids (omega-3s) are long-chain fatty acids (LCFAs) that contain two or more double bonds and are also known as polyunsaturated fatty acids (PUFAs). The beneficial effects of PUFAs vary depending on the length and structure of the fatty acid. The two most recognized PUFAs are omega-3 and omega-6, both of which are important for optimal growth, development, and health, and these are essential in the diet because the human body does not make omega-3 and omega-6 fatty acids.

Three of the most well-researched omega-3s include DHA (22 carbons in length with 6 double bonds) and EPA (20 carbons in length and 5 double bonds) and alpha-linolenic acid (ALA; 18 carbons in length and 3 double bonds). Both EPA and DHA are LCFAs primarily found in salmon, sardines, trout, tuna, and herring. ALA is a short-chain fatty acid (SCFA) and is found in plant sources, such as nuts, hempseeds, flax, and canola and soybean oils.

While all of these PUFAs are important for optimal health, the human body can utilize DHA and EPA much more efficiently than ALA. Because ALA is a SCFA, enzymes are necessary to convert ALA to a more bioavailable LCFA. While a small percentage of ALA can be converted to EPA (approximately a 5–15% conversion rate depending on the individual's body efficiency), there is little to no conversion of ALA to DHA.

Omega-3 PUFAs are important for heart health and brain development (discussed in the succeeding text). EPA and DHA help to lower inflammation, improve blood cholesterol levels, and reduce the risk of death from heart attacks and stroke.

The dietary recommendations for omega-3s from global organizations for the general adult population are as follows:

- World Health Organization (WHO) and FAO: Aim for 250 mg of EPA and DHA each day.
- International Society for the Study of Fatty Acids and Lipids (ISSFAL): To reduce the risk of cardiovascular disease, consume a minimum of 500 mg of DHA + EPA (combined) each day.

- NATO workshop on omega-3 and omega-6 fatty acids: 300–400 mg EPA + DHA each day.
- World Gastroenterology Organization: 3–5 servings of seafood each week.

Table 1 documents the variable importance of seafood per capita, as a percent of animal protein and as a percent of total protein in the world, including those countries where the percent of fish/animal proteins is greater than 50%. In a Harvard study of dietary fats and oils, the global mean intake of omega-3s is about 163 mg per day, far lower than the recommendations in the preceding text. This study considered 113 countries and a population of 1 630 069 or 82% of the global population. Worldwide, omega-3 intake from seafood has increased in the past 20 years by 24 mg per day. By 2020, nearly 75% of all deaths and 60% of all disability-adjusted worldwide will be attributable to noncommunicable diseases including cardiovascular diseases, type 2 diabetes, obesity, and cancers. Cardiovascular disease particularly can be better controlled by omegas.

Seafood is the premiere dietary source of omega-3s DHA and EPA. According to the FAO, Oceania boasts the highest per capita seafood consumption in the world, followed very closely by Europe (Table 1). Countries who consume the least amount of seafood include Africa and the Near East. With the exception of islands with large fishing communities, seafood consumption tends to be greater in developed countries as compared with developing countries.

Beneficial Nutrients of Seafood

Seafood is a nutrient-dense food naturally rich in protein, vitamins (especially B and D), minerals, and heart-healthy omegas. Seafood is grouped with meat, poultry, eggs, nuts, legumes, and seeds as major contributors (greater than 50%) of protein, niacin, zinc, and vitamin B_6 to the diet by the Institute of Medicine (IOM) and as an important source of greater than 10% of vitamins E and B_{12}, thiamine, and riboflavin and phosphorus, magnesium, iron, copper, potassium, and linoleic acid. Higher levels of the antioxidant selenium and the omegas EPA and DHA and generally lower levels of saturated fats compared with meat, poultry, eggs, etc., are unique to seafood, notes the IOM. In fact, says the IOM, depending on the preparation method, seafood is lower in total and saturated fats and cholesterol than some more frequently selected animal protein sources such as lean and fatty cuts of beef, pork, and poultry. Certain species of seafood (e.g., canned salmon with bones) may also be a good source of calcium.

Heart Health Benefits of Eating Seafood

Omega-3 fatty acids have been shown to be cardioprotective. While the exact mechanism of how these fatty acids benefit heart health is largely unknown, omega-3s decrease triglyceride levels and risk of arrhythmias (abnormal heartbeats), slow the growth rate of atherosclerotic plaque, and slightly lower blood pressure, according to the American Heart Association (Washington, DC). Omega-3s from seafood may also reduce the risk of sudden cardiac death.

Recent studies by the FAO/WHO have shown that modest intake of omega-3s (approximately 250–500 mg EPA + DHA per day) in various populations in the United States, Europe, Asia, and Australia lowers the risk of dying from coronary heart disease. The magnitude of the protective effect of eating seafood about twice each week is a 36% reduced risk of heart disease death. For this reason, public health organizations and experts around the world advise adults to consume at least 2–3 servings of seafood each week to help meet heart health recommendations for omega-3s.

The Mediterranean-style diet has long been touted as a heart-healthy diet. To determine whether seafood in the Mediterranean diet is beneficial to heart health, researchers examined the seafood intake of more than 3000 men and women in the Attica region of Greece. In this region, about 88% of men and 91% of women consumed fish or shellfish at least once a week. Fish intake was positively correlated to reduced levels of inflammatory markers related to cardiovascular disease.

Brain Benefits of Eating Seafood

The need for the nutrients in fish is especially high during pregnancy. During the last trimester, a fetus' brain and nervous system rapidly develops, requiring about 65 mg per day of DHA. The heightened demand for DHA continues to 2 years of age.

While the benefits of omega-3s on brain development during infancy and early childhood are well documented, there is limited evidence that omega-3s from seafood intake during later adulthood may help reduce the risk of dementia. In a study that looked at nearly 15 000 older adults (aged 65 years or older) in low- to moderate-income areas in 11 countries (including China, India, Cuba, Venezuela, Mexico, Peru, and the Dominican Republic), there was a beneficial effect of seafood on dementia in this population in all countries except India. More research is needed, but the effect of omega-3s on brain health throughout the lifetime is promising.

Mercury in Seafood

Essentially, all seafood includes traces of mercury, a compound that originates primarily from natural volcanic activity and thermal events in oceans. Although some mercury has been contributed by human activity, studies show that mercury in the oceans has remained virtually unchanged over time.

The amount of mercury equated with serious illness has only been recorded in two international industrial accidents and poisonings in Japan and Iraq in the 1950s–1970s. While the levels of mercury present in those instances are on a scale dramatically different than the levels seen in commercial seafood, the devastating effects of the poisonings, specifically on developing babies, piqued the scientific community's interest in studying cultures who eat seafood-rich diets. People from two island areas, the Faroes and Seychelles, were followed to determine the health effects of regular, high-level seafood consumption. Subclinical cognitive deficits were found among children of women in the Faroes who ate pilot whale, a mammal with a nutrient and contaminant makeup unlike seafood, during pregnancy. No pattern of harm was found among children of women who ate seafood during pregnancy in the Seychelles. Subsequent adjustment of the Faroes data to isolate the effects of seafood from whale meat also showed no harm from eating fish.

Introduction

Marine species are known to provide high proportions of important constituents for the human diet such as: (i) nutritional and digestive proteins including high levels on essential amino acids; (ii) lipid soluble vitamins (namely, A and D); (iii) microelements (I, F, Ca, Cu, Zn, Fe and others); and (iv) highly unsaturated fatty acids. Among these components, the lipid fraction is now the subject of a great deal of attention due to its high content on ω-3 polyunsaturated fatty acids (PUFA).

In spite of this profitable and valuable composition, wild and farmed marine species are known to be highly perishable products. In this sense, it should be stressed that such food products arise from poikilothermic organisms with a high water and non-protein-nitrogen content, a soft muscle and skin structure, and low collagen content. Further, the highly unsaturated lipid composition has been shown to be especially prone to lipid oxidation, which leads to important sensory and nutritional quality losses.

Marine products can be obtained through a wide range of technological processes. In order to minimize the above-mentioned deteriorative behavior, different strategies have been applied for years such as cooling (chilling, freezing and frozen storage), heating (cooking, canning, smoking), and water activity reduction (salting, drying). Among marine products, there is an increased demand for fresh products and represent very high proportions in fish production and human consumption. In order to commercialize fresh seafood, refrigerated and chilled storage have been widely employed. In spite of the reduction in temperature, it has been shown that quality loss could be produced by the following damage pathways: (a) endogenous enzyme activity; (b) microbial decomposition; (c) lipid oxidation. Consequently, significant deterioration of sensory acceptance and loss of nutritional value have been detected which lead to a strong effect on the commercial value. The rate of alteration depends on factors such as the nature of the species, size, lipid content, feeding state at the moment of capture, importance and nature of the microbial load, and storage temperature.

With a view to retarding quality deterioration and improving the storage stability of seafood, refrigeration and chilling technologies have constantly been performed. In some cases, a combination of strategies has been applied, so that each one provides different and complementary advantages (or barriers to spoilage) to ensure quality retention. In connection with the above-mentioned trend of fresh seafood consumption, public health concerns have become an issue requiring careful attention, not only to ensure sensory acceptability and nutritional value, but also safety, as the major challenges faced by marine food trade and technologists. The potential health risks associated with seafood, together with the high demand far from local fishing ports or farms, entails the need for advanced preservation techniques to be addressed continually.

The present article provides an overview on commercial technologies suitable for application in the manufacture of fresh marine products. In it, traditional and advanced strategies are overlooked.

Preliminary Steps to Storage

It is well known that prior to any technological treatment, steps like catching, harvesting, slaughtering and handling can strongly affect the quality of marine species. Such steps, carried out either in farm, on vessel or ashore, are intended to: (i) prevent physical damage; (ii) remove blood, digestive juices, slime and feces, and (iii) avoid bacterial contamination.

Soon after catching/harvesting, the fish begins to stiffen, giving rise to the rigor mortis period. This state in marine species generally has a shorter duration than in mammals. It starts 1–7 h after death; its peak in slaughtered individuals, kept in ice, lies between 5 and 22 h after death. In this period, various physiological reactions in the animals, as the use of energy reserves in the muscle and liver, and change in the acid–base balance are produced. These reactions, by changing the conditions in the tissues, affect the enzyme activity in postmortem fish and the rate of freshness degradation. Physical activity at or before slaughter affects the flesh quality negatively; as the muscle metabolism is predominantly anaerobic, rapid reduction in ATP and pH is produced, resulting in formation of lactic acid. Stressed individuals may develop shorter rigor mortis periods, and a softer muscle texture which is more susceptible to the undesirable separation of muscle blocks (gaping phenomenon). In connection to farm handling, different commercial methods of slaughtering have shown to cause varying stress and aversive behavior. Whatever method is used, the important point is to carry it out efficiently and fast. Killing requires special consideration in terms of both the welfare of the species and the quality of the final product. A prolongation of the rigor mortis period is of great economic importance.

The precise nature and speed of deteriorative changes during the on-board or ashore handling may vary with marine species, and within one species according to endogenous (anatomical, physiological, genetic, chemical composition) and exogenous (previous feeding availability, temperature, season) factors. Fish corresponding to the 'top of the catch' should be of higher quality than those caught during the beginning of the trip. Handling of fish with gaff hooks picks or forks should be avoided. Breaks in the skin and unsightly holes in the flesh quickly introduce spoilage bacteria and accelerate quality deterioration. Fish should not be exposed to direct sunlight or to the drying effect of wind, but should be carefully and safely cleaned and washed, and then cooled down as quickly as possible. Any careless treatment or delay in reducing the

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00290-7

temperature of fish will have a marked effect on their potential keeping time.

A common on-board treatment for white fish is gutting. Guts are known to be a reservoir of powerful digestive enzymes and bacteria that can spoil the flesh, resulting in unacceptable odors and flavors. As a result of gutting, many studies report an extension of shelf life during marine species refrigeration. For small-sized fatty species however, the process of gutting has shown to be impracticable and may create new cut surfaces for potential bacterial contamination and lipid oxidation development and would not benefit the shelf life.

Traditional Refrigeration Systems

Common Flake Ice

Refrigeration to about 0 °C by using common flake ice (chilled storage) is the preservation method most extensively used to cool marine species rapidly and to extend their shelf life. Under such conditions, the normal storage life of cold water species immediately after post mortem is 1–2 weeks, while species from warm tropical waters keep somewhat longer. Ideally, aquatic species should be in contact only with ice and not with each other. Finally, much of the care exercised by fishermen in handling and stowing the catch may be wasted unless good standards of cleanliness, hygiene and sanitation are maintained at all times.

The rate at which heat can be removed from marine foods during flake ice chilling depends on several parameters. In the case of packaged products, size and shape will affect the rate of heat transfer while in the case of unpacked products special attention should be paid to the relative humidity conditions, with a view to prevent dehydration of the food material. Although pure ice melts at 0 °C, the temperature of material stored in crushed ice may be slightly lower. This effect is due to the salts present in the flesh, and to the seawater on the surface of the carcasses, which cause some of the ice to melt and extract heat from the surroundings.

Quick and efficient flake ice chilling of the seafood to the lowest temperature practicable without actually freezing the flesh is essential if spoilage is to be kept to a minimum. Rapid chilling also aids bleeding and results in more attractive fillets. Besides, contributing to the cooling, the flow or meltwater also washes away bacterial slime, spoilage products and any residual blood and thus helps to preserve the fresh appearance and smell. Room temperature should be kept above 0 °C, so that a good flow of melting water is maintained; however, if this temperature is too high, the weight of necessary ice will be larger.

Chilled and Refrigerated Seawater

Chilled (CSW) or refrigerated (RSW) seawater are the terms commonly used to describe seawater which has been cooled just below 0 °C. RSW holding of marine species is accomplished by filling a hole with seawater and then recirculating it through refrigerated coils. As RSW requires complicated pumping and filtering systems, it may be replaced by CSW, a system where sufficient fresh seawater ice is taken and eventually mixed first with water and then with fish.

Both RSW and CSW are considered to be able to extend the shelf life of fish and shellfish due to the lower storage temperatures achieved. Both hydro-cooling systems have led to a wide range of commercial applications for both on-board and the in-land use, being excellent media for refrigerating and transporting whole carcasses while still at sea and for the road transport of bulk quantities. Thus, the following advantages compared to traditional flake icing have been described: (i) faster cooling; (ii) less stress on food pieces; (iii) the possibility of a lower temperature; (iv) faster handling of large quantities of aquatic material; (v) a longer storage time in a few cases.

However, some negative effects on sensory and nutritional qualities have been encountered, while its on-board handling (pumping, filtering, and so on) has also found some economical and technical difficulties. Such inconveniences when compared with flake ice employment can be resumed as follows: (i) excess of salt intake, (ii) water absorption by species of low lipid content; (iii) partial water-soluble protein loss; (iv) presence of anaerobic bacteria responsible for putrefaction; (v) appearance modification in parameters such as gills, skin and eyes.

Addition of Chemical Preservatives

One previous or simultaneous handling to refrigerated storage has been salt treatment. Such step consists of direct addition of NaCl to marine species or to the ice used to cool them or immersion of seafood material in a brine solution that is followed by the cooling treatment. The preservative effect of salt is due to a decrease in water activity, which leads to lesser potential for microbial attack, and enhancement of functional properties, leading to an increase of the shelf life time. As a result, salt is absorbed by the flesh and imparts a desired flavor to the finished product. Salting has an additional beneficial effect as it toughens the skin and prevents its adhesion to any surface. Salting also brightens the appearance of marine individuals by removing any remaining slime. Salt treatment has mostly been targeted to species that are further processed by any other technological treatment.

However, some bacteria have shown to be able to multiply in a high concentration of salt, especially when the solution carries substantial quantities of oil, blood and pieces of gut. Another problem is that salt contact with fish has been reported to enhance lipid oxidation of the highly unsaturated lipids, protein denaturation, and texture changes. NaCl is said to act as prooxidant by enhancement of the prooxidant effect of chelatable iron ions widely present in fish muscle, especially in the dark one.

Among factors limiting acceptability of crustaceans, melanosis development plays a very important role. In the presence of oxygen and polyphenoloxidase, the monophenolic compounds are first hydroxylated to o-diphenols and then oxidized to o-quinones, which react non-enzymatically with other compounds, giving rise to pigments of high molecular weight and dark color. Sulfites and SO_2 have been applied as dipping solutions in the crustacean industry as being very effective as inhibitors of such enzymatic browning by interfering with the polymerization of quinones. Thus, such preservatives have successfully been applied to delay melanosis reactions in crustaceans, thereby increasing shelf life.

Ozone is a powerful antimicrobial agent that is suitable for application in seafood in the gaseous and aqueous states. Literature resumes most research where its employment at the same time as flake ice has led to significant increases in sensory quality and shelf life of marine species. As an explanation, molecular ozone or its decomposition products rapidly inactivate microorganisms by reacting with intracellular enzymes, nucleic material and other components. In contrast to these positive effects, ozone is also reported to be a powerful oxidant, and has accordingly been said to negatively affect phospholipids, PUFA and membrane proteins. Its employment is recommended only under optimized conditions.

Advanced Strategies in Refrigeration

Super-chilling Systems: Slurry Ice

Various types of cooling systems have been used for 'super-chilling' (−4 °C to 0 °C) of seafood products. Due to the low storage temperatures achieved, such systems have permitted a significant bacterial growth delay and accordingly extend the seafood shelf life. Super-chilling techniques have been described as being especially useful when the fishing banks are so distant that storage in flake ice does not guarantee an accurate preservation of the fish quality at landing; it can either be used prior to traditional chilled distribution or throughout the storage and distribution process. However, super-chilling of muscle food can result in partial freezing, which may lead to negative changes such as drip loss and decreased water-holding capacity; in addition, enzyme activity may increase due to higher concentrations of soluble matter in unfrozen water and improved access of enzymes to substrate.

Newer chilling systems have enabled the storage at subzero temperatures of fish products through the addition of salts and other compounds to ice-water mixtures. These are called 'slurry ice systems,' 'water-binary systems' or 'liquid ice.' Slurry ice can be defined as a mixture of ice particles finely dispersed in an aqueous solution composed of water and other solid components (namely, NaCl) used to decrease its freezing point and achieve temperatures lower than 0 °C, but always above the initial freezing point of fish material. Two phases co-exist in slurry ice: 25–30% of the mixture consists of small spherical ice crystals, although this percentage can be modified according to specific applications, and the remaining 70–75% is water.

Compared with traditional flake icing, new slurry systems show a wide number of advantages which can be summarized as follows: (a) the lower temperature slows down degradative biochemical and microbiological reactions, (b) faster heat exchange that leads to faster cooling, (c) more efficient cooling by complete coverage of external surface, (d) its flow exerts a surface-washing effect, (e) size and geometry of slurry crystals limit the physical damage, (f) its fluid nature allows automation of handling and distribution, (g) versatile technique which can be combined with other preservative strategies.

Meanwhile, a main disadvantage has been identified. Thus, the temperature employed should not decrease until partial freezing of the product takes place; otherwise, sensory quality (cloudy eyes, development of dull color, etc.) could be diminished. Consequently, it is specially recommended that the slurry ice users take good advice from manufacturers in order to apply, in each case, the best combination of parameters involved (optimization pre-step): salt content, storage temperature, liquid–solid ratio and marine species size.

In the scientific literature, reports referring to the application of slurry ice systems to marine products have been extensive in the last decade. In such research, the need to recognize the main degradation processes involved in quality loss is essential. Thus, slurry ice has been applied satisfactorily at different stages: on-board storage and pre-cooling, in-land storage system, slaughtering and storage in farming production and as a treatment prior to other technological processing (chilling storage under flake ice in retail, frozen storage, cooking and canning). In such studies, comparative analysis with traditional flake ice employment was undergone, taking into account changes produced in sensory, microbiological, physical and chemical properties of marine foods.

Packaging Technologies

Different kinds of advanced packaging technologies have been proposed and applied successfully in the latest decades.

The modified atmosphere packaging (MAP) is an increasingly popular food preservation technique that involves the total or partial removal of air contained in the package followed by reintroduction of an altered or modified atmosphere consisting of other gasses, usually carbon dioxide, nitrogen, oxygen alone or in combination. It is specially recommended to preserve quality and to maintain hygienic, sanitary and sensory characteristics of perishable products such as chilled marine products. The carbon dioxide is the most important gas because of its bacteriostatic and fungistatic properties, this property being increased by increasing its concentration in the surrounding atmosphere. The extension of shelf life by using MAP has shown to depend on species, fat content, initial microbiological quality, handling, slaughtering, storage temperature, gas nature and mixture composition, packaging materials, gas-to-product volume ratio, presence of additives, and combination with other hurdle technologies.

It must be taken into account that gas level in MAP could change with time due to dissolution of gasses into the muscle tissue and/or microbiological and biochemical reactions; therefore, experiments are often conducted under controlled atmosphere packaging (CAP) condition for studying the real effect of the different gas constituents. Throughout the storage in CAP, a more stable gas composition is ensured and the accumulation of off-odors is avoided. These advantages make the use of CAP of great interest for marine species preservation on deep-sea fishing boats.

Vacuum skin packaging (VSP) is a technique which was developed to overcome some of the disadvantages of the traditional vacuum packaging. It is characterized by the instantaneous heating of the upper packaging film immediately before its descent over the food surface. The VSP concept relies upon a highly ductile plastic barrier laminate which is gently draped over a food product, thereby molding itself to the actual contours of the product to form a second skin, which is discarded when consuming the seafood. The product's natural shape, color and texture are highlighted and, since no mechanical pressure is applied while drawing the vacuum, soft or delicate products are not crushed or deformed.

Active packaging is an innovative concept in which the package, the product, and the environment interact to extend the shelf life or enhance the safety or sensory properties. This technology includes packaging materials and edible films and coatings which contain preservative substances and also techniques modifying the atmosphere within the package. Additives can be incorporated in different ways, according to the marine food encountered. It must be stressed that incorporation of preservatives into the packaging instead of its inclusion into the bulk has been made for preventing surface microbial growth or lipid oxidation. Moreover, a controlled release of the agent from the surface to the inner of the food can assure the presence of the agent in the food throughout storage. On the contrary, when the preservative is added into the food, it could be bounded to food components or react with other additives or food components losing its activity. All forms of active packaging have received remarkable attention in recent years, improving due to the important role involved in extending food shelf life.

Most of the films used are manufactured with synthetic plastic materials but for environmental reasons, an increasing attention is being paid to active edible films and coating as a result of their biodegradable properties. Proteins, lipids and polysaccharides are the main biopolymers used to produce edible films. Two materials and their combination have recently attracted most interest. On one side, gelatin from marine fish species as a renewable material; on the other side, chitosan obtained from natural chitin not only because of its film-forming capabilities but also because of its antioxidant and antimicrobial properties. It has been shown that films composed of proteins or polysaccharides are sensitive to moisture; however, films composed of lipids are more moisture resistant but are opaque and susceptible of oxidizing. Accordingly, actual trend is to use an optimized combination of biopolymers.

Addition of Natural Preservatives

Sodium and potassium salts of low molecular weight organic acids such as acetic, lactic, citric and sorbic have been used to control microbial growth, improve sensory quality and extend shelf life of many food systems including marine ones. These preservatives are able to control the development of spoilage bacteria and also possess antibacterial activity against various foodborne pathogens such as *Staphylococcus aureus*, *Yersinia enterocolitica*, *Listeria monocytogenes*, *Escherichia coli* and *Clostridium botulinum*. Moreover, these compounds represent a relevant choice because of their easy availability, low commercial cost and wide range of permitted concentration for their use.

Since ancient times, spices and herbs have been added to foods as seasoning additives due to their aromatic properties. They inhibit microbial growth of Gram-positive and Gram-negative bacteria, yeasts and molds and also exhibit useful antioxidant activity. Herbs of the Lamiaceae family, mainly oregano (*Origanum vulgare*), rosemary (*Rosmarinus officinalis*) and sage (*Salvia officinalis*), have been reported as having significant preservative capacities. The active compounds responsible for such activity in spices are primarily phenolic components of the essential oil fraction. However, their use in foods as preservatives is limited because of flavor considerations, since effective doses may exceed sensorial acceptable levels.

As already mentioned in the previous section, chitosan is a modified, natural carbohydrate polymer derived by deacetylation of chitin. As one of the most abundant natural polymers present in insects, fungi and crustaceans, it is produced from shell wastes with different deacetylation grades and molecular weights and therefore, different functional properties and biological activities. In particular, antimicrobial and antioxidant activities have shown to depend on its molecular weight and concentration. It was demonstrated that chitosan inhibited the growth of many spoilage and pathogenic bacteria and also yeast and molds; additionally, it may retard lipid oxidation by chelating ferrous ions released during storage by proteins such as myoglobin, hemoglobin and ferritin, thus eliminating pro-oxidant activity of ferrous ions or preventing their conversion into ferric ions.

Live tissues contain a complex oxidation/reduction system which controls the oxidative reactions needed for life. However, during the post-mortem stage of marine species a significant number of reactions occur affecting the oxidative equilibrium of fish muscle, so that the endogenous reducing system (alpha-tocopherol, glutathione, coenzyme-Q, ascorbic acid) is consumed. It is therefore necessary to provide exogenous antioxidants during feeding of cultivated fish and/or during processing/storage of seafood. Such antioxidants have been classified as chelators, reductants or free radical scavengers and represent an effective and profitable methodology for stabilizing seafood products or ω-3 PUFA rich products. Recently, consumers have rejected synthetic antioxidants because of their possible carcinogenicity, so that their replacement by natural ones has been widely developed; the disadvantages are their higher cost and lower effectiveness.

In recent years, the inclusion of plant extracts as a source of natural antioxidants has been a common practice in the food industry. The radical scavenging capacity of some natural compounds such as polyphenols which are known to be present in many fruits and vegetables, as well as their corresponding by-products, has resulted in their use as bioactive antioxidant compounds in food material susceptible to lipid oxidation. Purified natural compounds such as procyanidins, flavonoids and terpenoids, have shown higher antioxidant activity than their corresponding crude extracts. Hydrophilic compounds offer advantages when compared with lipophilic ones as food additives since the former can easily be incorporated into food systems by application into aqueous solutions.

Biopreservation

The term biopreservation is defined as the use of a natural or controlled microflora and/or its antimicrobial metabolites to extend the shelf life and improve the safety of food. This term is linked to lactic acid bacteria (LAB), a group of Gram-positive bacteria which are often used in food to ensure its safety, preserve its quality and develop new flavors. However, and unlike starter cultures, protective cultures used for biopreservation purposes should modify the sensory features of the seafood product as little as possible. Certain LAB species and strains have been shown to exert strong antagonistic activity against spoilage and pathogenic microorganisms such as

Listeria, *Clostridium*, *Staphylococcus* and *Bacillus* spp. Such antagonistic effect is caused by a decrease in the pH of the food – mainly motivated by the production of lactic acid and other organic acids – the competition for nutrients, and/or the production of antimicrobial metabolites.

Due to these benefits, LAB can be used as protective cultures to outgrow competitor microorganisms such as certain spoilage and pathogenic bacteria, with the subsequent benefits in terms of food safety. In addition, several LAB species and strains are able to produce bacteriocins. These molecules are synthesized by the ribosomes, released extracellularly as bioactive peptides or peptide complexes with a bactericidal or bacteriostatic effect on other closely and non-closely related species, while the producer bacterial cell exhibits specific immunity to the action of its own bacteriocin. Members of the genera *Lactococcus*, *Lactobacillus*, *Leuconostoc*, *Pediococcus*, *Carnobacterium* and *Enterococcus* are known to secrete bacteriocins, being especially relevant for the biopreservation of raw and processed seafood products the two latest genera.

Bacteriocins as food preservatives may be used for biopreservation purposes either by using the bacteriocinogenic strain as a protective culture or by using the extracellular extracts of the producing bacteria in the food formulation. LAB bacteriocins or bacteriocin-producing strains can be utilized either alone, in combination with one another, or in combination with other antimicrobials to improve the preservative effect.

Among bacteriocins, nisin is the most studied. It has been found efficient for the inhibition of *Listeria* and other spoilage and pathogenic bacteria in marine foods. Some bacteriocins (e.g., lactocin S) are much more slower acting and have different inhibition spectra against spoilage and pathogenic bacteria. Thus, combining fast- and slow-acting bacteriocins, and broad and narrow inhibition spectra, the food remains safe longer. Bacteriocin-producing *Enterococci* are widespread in nature, and they have also been isolated from a variety of seafood products. One of the principal bacteriocins produced by *Enterococci* isolated from fish is enterocin P, which shows a good antimicrobial activity against *L. monocytogenes*, *S. aureus* and other spoilage and pathogenic bacteria such as *Bacillus* spp.

An alternative to antimicrobial agents in the prevention and management of fish diseases in aquaculture facilities is the use of probiotics added to the animal feeds. Some protective cultures of LAB have been reported to exhibit probiotic activity due to their positive contribution to the healthy microflora of the human gut. Moreover, these probiotic LAB have also been introduced into animal feeds due both to their contribution to the health of farmed animals as well as for their activity for the biological control of fish pathogens in aquaculture facilities. The possible mechanisms of action of probiotics are the production of compounds that are inhibitory towards pathogens, competition with targets microorganisms for nutrients and energy, competition with undesirable species for adhesion sites, enhancement of the immune response of the animal, improvement of water quality, and interaction with phytoplankton. It should be highlighted that the probiotic LAB strain introduced in the food chain through the animal feed must also be safe for humans. Accordingly, all microbial strains intended to be used as probiotics in animal feeds must be evaluated and authorized before being used as ingredients in feedstuffs.

High Hydrostatic Pressure Processing

Since the nineties of the last century, high hydrostatic pressure (HHP) processing has been recognized as a powerful strategy to provide attractive, nutritive and safety foods. HHP technology has been shown to retain the sensory and nutritional properties of foods while inactivating microbial populations and leading to shelf-life extension and food safety enhancement. Among different food sources, seafood have proven to be easily compressed and accordingly, and be well suited for HHP processing, normally applied in the 100–600 MPa range.

From a physical point of view, an increase in pressure has an important effect on the molecules, for they get closer to each other. HHP treatment has been reported to follow the Le Châtelier principle; consequently, any reaction or phenomenon in equilibrium accompanied by a decrease in volume can be enhanced by the HHP treatment. Another interesting aspect is that this treatment operates according to the isostatic rule; in compliance with this, pressure is instantaneously and uniformly transmitted throughout the whole food matter. From a chemical point of view, HHP treatment can lead similar changes than does the thermal processing. Thus, the covalent bonds are not broken but the weak energy bonds like hydrogen and hydrophobic bonds can be irreversibly modified. This means that low-molecular-weight food components (responsible for nutritional and sensory characteristics) would not be affected, whereas high molecular weight components (proteins whose tertiary structure is important for functionality determination) are sensitive.

Concerning HHP application to seafood, previous research accounts for a wide range of studies focused on protein denaturation analysis, specially concerning the activity inhibition of deteriorative endogenous (namely, calpains, cathepsins, lipases, phospholipases) and bacterial enzymes. This research topic has been related to all kinds of marine products, both from wild and cultivated sources, and assessing the straight relationship with sensory and nutritional value. HHP conditions applied have been reported to lead to reversible or irreversible damages in proteases, this leading to a marked inhibition of their action; on the contrary, HHP treatment can also disrupt lysosomal membranes and cause the enzyme release into the fish muscle and provoking a subsequent hydrolytic activity increase. The need for HHP conditions optimization is reported to be imperative to attain important shelf life increases in fish products.

Concerning the lipid fraction, changes as a result of HHP treatment of marine foods have also been studied, although not in a so exhaustive way as for the protein fraction. Thus, lipid oxidation has shown to increase as a result of HHP treatment; however, the possible prooxidant effect of HHP treatment on muscle lipids has proved to be eliminated if a previous water washing of the muscle was applied or if a complexation compound (EDTA, e.g.) was added. Consequently, iron-bound protein denaturation during HHP treatment has been reported to facilitate a free metal ion content increase which would be responsible for lipid oxidation in fish meat after HHP treatment. The effect of the HHP treatment on other kinds of marine chemical components (vitamins and minerals) can be considered very scarce.

Finally, it is worth to point out that this technology has shown potential application in the seafood industry when

combined with other processing strategies. This accounts for surimi and kamaboko production, cold-smoked fish preparation and when assisting freezing, thawing and thermal processing. A beneficial effect on quality retention has also been observed when an HHP treatment is used prior to refrigerated, chilled or frozen storage of fish products; as above mentioned, deteriorative hydrolytic and oxidative (namely, peroxidases, lipoxygenases) endogenous enzymes would be HHP-inactivated for a further stabilization of the marine product.

Flavor Enhancers: Characteristics and Uses

D Baines, Baines Food Consultancy, Bristol, UK

Introduction

What is a Flavor Enhancer?

A flavor enhancer is a chemical compound that amplifies and intensifies the flavor impact of other flavor compounds in the mouth when food is consumed. Flavor enhancers are added to food to potentiate its flavor and taste; they are regarded as food additives and not flavorings in many countries. They are defined in European legislation as "substances which enhance the existing taste and/or odor of a foodstuff." It is often thought that flavor enhancers are tasteless; this is not the case as those in common use in the food supply have their own gustatory sensations, which are specific and recognizable as discreet tastes in their own right.

The most commonly used flavor enhancers are the sodium salt of the amino acid glutamic acid, monosodium glutamate (MSG), and the nucleotides disodium-5′-inosinate (IMP) and disodium-5′-guanylate (GMP). The use of these compounds is regulated in various parts of the world, for example, in Europe, they have been assigned E-numbers. Flavor enhancers permitted for use in food are detailed in Table 1.

MSG, IMP, GMP, and other flavor enhancers initiate the 'umami' effect on the palate, which is associated with a savory taste; umami is the Japanese word for delicious or succulent and was the fifth taste sense to be discovered. The functions of the five taste sensations recognized today are considered to be

- sweet (detection of carbohydrate for energy balance),
- sour (protection from acidic and potentially harmful substances),
- bitter (protection from toxic substances),
- salty (regulation of blood salt levels),
- umami (detection of the nutritional/protein content of food, which serves as a marker for adequate protein nutrition).

The umami taste produces salivation releasing gastric juices containing enzymes that help to digest protein to release essential amino acids in the gut. MSG taste also induces insulin secretion in anticipation of an increase in blood amino acids.

Historical Background

Glutamic acid was first isolated in 1866 by the German chemist Karl Ritthausen from an acid hydrolysate of wheat gluten, and he named it after its source. Forty-two years later, in 1908, MSG was discovered by the Japanese chemist Kikunae Ikeda in the broth derived from kombu, *Laminaria japonica*, a kelp-like seaweed used for centuries as a flavorful broth in Japanese cuisine. He patented the discovery and marketed MSG as a table condiment and flavor enhancer through a newly founded company, Ajinomoto, which roughly translated means 'essence of taste.' The Ajinomoto company remains a major force in the market for MSG today.

IMP, the disodium salt of inosinic acid, was discovered in 1913 by Shintaro Kodama a Japanese chemist and student of Kikunae Ikeda, in bonito flakes, traditionally used in Japan as a flavoring agent. Bonito is a sardine-like fish of the *Scombridae* family, common in the seas around Japan. Inosinic acid had been known for a long time since Justus van Liebig's mid-nineteenth century work on beef broth, but its significance as a flavor enhancer had not been recognized.

GMP, the disodium salt of guanylic acid, was discovered by the Japanese chemist Akira Kuninaka in 1960 in the broth derived from shiitake mushrooms used by the Japanese for hundreds of years to flavor foods. Guanylic acid had been known since 1898 when the Norwegian medical chemist, Ivar Christian Bang, elucidated the structure during the course of his work on pancreatic nucleic acid.

Japanese researchers have been instrumental in identifying the significance of MSG, IMP, and GMP as flavor enhancers through their study of the flavorings properties of the traditional Japanese products kombu, bonito, and shiitake mushroom. It is not surprising therefore that the Japanese word 'umami' is used to describe the taste sensation, which was recognized as a taste sense long before its discovery by workers at University Of Miami School Of Medicine in 2000. The team, led by Nirupa Chaudhari, discovered a receptor that interacted with glutamate in a manner consistent with the umami taste sensation and established that umami is a fundamental taste quality similar to sweet, sour, bitter, and salty.

Characteristics of Flavor Enhancers

Chemical Properties of MSG

Glutamic acid is an α,γ-amino dicarboxylate with the structure depicted in Figure 1(a). The monosodium salt (MSG) can form an α-salt or a γ-salt; the α-salt is shown in Figure 1(b).

At the correct pH, the compound has the potential to form a loosely bound cyclic tautomer between the two carboxylate functions Figure 1(c).

Compounds with related chemical structures have also been found to exhibit an umami effect such as monosodium D,L-threo-ß-hydroxy glutamate Figure 1(d), monosodium D,L-homocystate (e), monosodium L-aspartate (f), and the salts of two unusual amino acids, monosodium L-tricholomate (g) and monosodium L-ibotenate (h).

The relative umami contributions measured from these compounds is shown in Table 2.

Chemical Properties of Nucleotides

A nucleotide combines a nucleobase, a pentose sugar (ribose or deoxyribose), and at least one phosphate group. IMP is the disodium salt of inosinic acid (Figure 2), which has an

important role in metabolism. It is formed by the deamination of adenosine monophosphate (AMP). GMP is the disodium salt of guanosine monophosphate and consists of a phosphate group, the pentose sugar ribose, and the nucleobase guanine (Figure 2).

When the nucleobase is a purine moiety with a hydroxyl function on the 6-carbon of the purine ring and there is a phosphate ester on the 5′-carbon of the ribose moiety, an umami taste is imparted. Both IMP and GMP possess these chemical features (Figure 2). If the ribose moiety is phosphorylated on the 2′ or 3′ positions, the compounds are tasteless. Phosphorylation on the 5′carbon of the ribose ring is essential for umami taste.

Physical Properties

MSG, IMP, and GMP are all crystalline solids and are nonhygroscopic; consequently, they can be stored for long periods of time at ambient temperature without their appearance or quality changing. The solubility of flavor enhancers is important when they are blended into food formulations. MSG is much more soluble in water than IMP or GMP. However, IMP has a much higher solubility in vinegar than either MSG or GMP; GMP becomes gelatinous in acidic solutions, such as vinegar.

Glutamate is not decomposed during normal cooking processes. IMP and GMP are stable in aqueous solution, but under acidic conditions (pH 3.5 and below) and at high temperatures, decomposition takes place and umami taste is lost. Phosphatase enzymes, occurring naturally in plant and animal materials, remove the phosphate group from IMP and GMP. Consequently, during food processing, IMP and GMP should be added after deactivation of these enzymes by heat.

Table 2 The relative umami contributions measured from the compounds shown in Figure 1

Umami substance	*Relative umami intensity*
MSG	1.00
Monosodium D,L-threo-ß-hydroxy glutamate	0.86
Monosodium D,L-homocystate	0.77
Monosodium L-aspartate	0.077

Measurement of Flavor Enhancers in Foods

A range of methods has been used for the analysis of glutamate in food products: spectrophotometric, derivative HPLC, HPLC with UV detection, fluorescence detection, GC, paper chromatography, and potentiometric methods.

Standard methods for analysis of nucleotides are based on liquid chromatography with UV, fluorescence, and mass

spectrometer detection. Other specialist techniques, such as reverse-phase HPLC and ion-pairing HPLC, are also available.

Threshold Levels and Synergy

Studies by a number of groups of researchers into the threshold levels of the three major umami inducers have produced broadly similar results; the average detection threshold levels are shown in Table 4. When IMP and GMP are combined with MSG, there is a synergistic enhancement such that the 'umami' taste is increased to an extent that would not be expected from the sum of their individual effects; food manufacturers use combinations of MSG and nucleotides to increase the 'umami' taste of savory products.

There is also a synergistic effect between the nucleotides; a 50:50 mixture of IMP and GMP reduces the threshold of the two flavor enhancers by roughly 50%. However, the combination of low levels of MSG with the individual nucleotides produces a dramatic change to their threshold detection levels. Conversely, the addition of a small quantity of IMP to MSG lowers the detection threshold of MSG, but the effect is less dramatic (Table 5).

The nucleotides have lower thresholds than MSG; when used commercially, the prices of the nucleotides are approximately ten times higher than MSG, so exploiting the synergistic effect in food products has been aimed at lowering cost by adding small amounts of nucleotides to MSG. Table 4 shows that low concentrations of IMP and GMP can significantly reduce the amount of MSG applied to a food to produce an equivalent umami effect (Table 6).

In practice, manufacturing methods for the two 5′-nucleotides results in equal quantities of IMP and GMP being produced, which has led suppliers to offer 50:50 mixtures of IMP and GMP, and it is this mixture that is used in combination with MSG to produce the synergistic flavor enhancement of food products. Nucleotides were commercially introduced in 1960, and due to their higher flavor potency, they have increasingly been replacing MSG or reducing the amount used in foods by exploiting the synergy phenomena.

The Japanese have exploited synergy in their cuisine for centuries. For example, miso soup is made by producing a dashi stock to which miso paste is added. The dashi stock usually consists of a combination of kombu (MSG source) and bonito (IMP source). The miso paste is produced by fermenting soybeans, barley, or rice with a koji fungus, *Aspergillus oryzae*, followed by treatment with a lactic acid bacterium, which leads to the formation of high levels of glutamic acid and its salts.

Flavor Enhancers and Salt Reduction

The intake of sodium in the diet has been linked to hypertension and increased risk of cardiovascular disease. Currently, the daily adult intake of sodium is approximately three times the recommended daily allowance, and therefore, regulatory authorities are recommending a reduction in sodium intake to 2.4 g (6 g salt) per day. Food companies are investigating a range of strategies for reducing sodium or salt content of foods, and some of these involve the use of flavor enhancers to increase the salty taste of foods so that lower concentrations of salt can be used to achieve the same effect. For example, glutamic acid can be used to mask the bitter taste of potassium chloride (added as a salt replacer), and IMP and GMP can be used in conjunction with sodium acid sulfate (US Patent 2013/0171327A1) to reduce salt content of food by between 30% and 50%.

Food Occurrence

Flavor enhancers are used widely in conjunction with flavoring materials throughout the food supply chain for a number of reasons:

- To improve the palatability and enjoyment of foods
- To standardize foods and reduce natural variations in flavor
- To mask bitterness in foods
- To create brand recognition
- To create variety across a brand such as the range of flavors found in snack foods
- To create novelty and unique flavor delivery effects
- To create cultural identity
- To serve as a vehicle to deliver nutraceuticals (molecules that benefit health)

Glutamic Acid and its Salts

Glutamate is naturally present in virtually all foods especially in meat, fish, shellfish, cheese, and tomatoes. It is present not only as its sodium salt but also as its potassium, calcium, and ammonium salts depending on which cations are available to combine with glutamic acid. The highest concentrations are found in kombu, Parmesan cheese, Roquefort cheese, soy sauce, fish sauce, yeast extract, and tomatoes. The concentration of glutamates increases considerably after ripening of certain foods, such as Parmesan cheese and dry-cured ham. Free glutamates exist in certain cheeses and dry-cured meats, in tomato products, and in soy sauce. Glutamic acid in the bound form is a major constituent of food proteins (plant and animal), and free glutamic acid is naturally present in most foods providing a mild umami taste compared to MSG (Table 3).

Patterns of consumption

It is estimated that the average person consumes around 17 g of glutamate in free and bound forms (in protein) every day. It is important in brain function, and there are considerable amounts of both free and bound glutamates in our bodies at any one time – the body produces around 40 g d^{-1} to maintain normal physiological functioning. Free glutamate consumed as MSG equals around 1/1000th of the total glutamate present in the body. Individual consumption ranges from around 0.5 to 1 g d^{-1} in Western countries, but in Japan and Korea, it is typically three times this level rising to around 4–5 g d^{-1} in China, where MSG is widely used in cooking.

Nucleotides

Nucleotides are naturally occurring substances that are ubiquitous in foods especially meat, fish, shellfish, and mushrooms. GMP is present at the highest concentrations in shiitake mushrooms, while IMP is found at the highest concentration in bonito flakes (Table 4).

Pressure on the food industry to remove E-number compounds, such as flavor enhancers, from food products has led to a search for alternatives. Yeast extracts contain significant amounts of the nucleotides IMP and GMP as well as varying amounts of glutamate salts. Other sources of MSG are hydrolyzed vegetable proteins (HVPs), tomato powder or purees, and soy sauce. These materials do not require E-numbers on the label and therefore satisfy the 'clean label, additive-free' strategy adopted many food companies.

Manufacturing

Fermentation

Ajinomoto has been producing amino acids by fermentation for many years. It dominates the MSG market with a market share of 34% (200 000 tons per annum). Cheil Jedang Group in Indonesia and Daesang in Korea are also major producers of MSG using fermentation technology. Production capacity and demand for MSG are greater than for any other amino acid. It is manufactured via fermentation of corn, sugarcane, or tapioca using the bacterium, *Corynebacterium glutamicum*, which is capable of producing high yields of L-glutamic acid from sugar. Ammonia is used as the nitrogen source and oxygen is provided by passing compressed air into the fermenting vessel. The L-glutamic acid is released by the microorganism into the fermentation medium and recovered by downstream crystallization.

In addition to the amino acid MSG, these companies also produce the nucleotides disodium inosine 5′-monophosphate (IMP) and disodium guanosine 5′-monophosphate (GMP) by fermentation. They have developed microbial strains, such as *Escherichia* or *Bacillus*, capable of overproducing MSG and nucleotides. These overproducing strains have been developed using molecular biological techniques and tools, such as gene disruption and amplification and efficient gene expression systems. IMP and GMP can also be produced by the enzymatic degradation of RNA with 5′-phosphodiesterase; however, economically, this process does not compete with fermentation.

The use of fermentation to produce these nucleotides and MSG can satisfy the vegetarian market with umami flavor enhancers derived from plants. Fermentation also offers a route to natural flavor enhancers; there is an enormous consumer demand for natural foods and beverages in the United States and Europe, and the requirement for natural flavorings to satisfy this is increasing.

Health Effects

Absorption and Metabolism of Flavor Enhancers

Glutamate is absorbed from the gut by an active transport system specific for amino acids. This process can be saturated and competitively inhibited and is dependent on sodium ion concentration. Glutamic acid is a nonessential amino acid, but it is used in the synthesis of L-arginine, which is an essential amino acid for protein synthesis in cells.

Evidence from human subjects, rats, and nonprimates indicates that free glutamate acts as a signal to regulate protein intake and nutritional status. Glutamate plays an important role in the body's disposal of excess or waste nitrogen. It undergoes deamination, an oxidative reaction to produce ammonia, which is then excreted predominantly as urea, and transamination with pyruvate to yield oxaloacetic acid. This effectively allows nitrogen from the amine groups of amino

acids to be removed, via glutamate as an intermediate, and excreted from the body in the form of urea.

Glutamate is also an excitatory neurotransmitter in the vertebrate nervous system; it is stored in vesicles at chemical synapses. Nerve impulses trigger release of glutamate from the presynaptic cell, and glutamate receptors in the postsynaptic cell bind glutamate and are activated. Because of its role in synaptic plasticity, glutamate is involved in cognitive functions like learning and memory in the brain.

Nucleotides are synthesized within the cells of the body but are also ingested in foods. They are the essential monomeric building blocks of DNA and RNA for cells in the body, but they also function as cofactors and coenzymes for cellular messengers aiding with communication between the nucleus and the cytoplasm.

Most dietary nucleotides are rapidly metabolized and often excreted. However, at times of rapid growth, limited food supply, disease, stress, and immunologic challenges, dietary nucleotides become essential for healthy development and are incorporated into tissues. Under normal conditions, sufficient nucleotides are available through internal metabolic and catabolic processes: either the *de novo* synthesis of nucleotides or the reuse of nucleotides from dead cells (the 'salvage pathway'). Dietary nucleotides are reported to have significant effects on lymphoid, intestinal and hepatic tissues, and lipid metabolism. The nucleotides can serve as nucleic acid precursors and exogenous sources of purine and pyrimidine bases. Dietary purines are not significantly incorporated into hepatic nucleic acids, but pyrimidines are. Both are taken up by intestinal cells with excess purines converted to uric acid.

Health Effects of Glutamate

Chinese restaurant syndrome

Controversy regarding the use of MSG in foods stems from a letter to the *New England Journal of Medicine* in 1968, which speculated that MSG could be the cause of adverse reactions (a burning sensation in the neck, chest tightness, nausea, and sweating) following consumption of food in Chinese restaurants. This became known as Chinese restaurant syndrome (CRS) and resulted in a backlash against the use of MSG and its subsequent removal from many foods. After a considerable period of safety evaluations, the Joint FAO/WHO Expert Committee on Food Additives, the EU Scientific Committee for Food, and the US Food and Drug Administration all concluded that the levels of MSG added to food do not represent a hazard to health.

Investigation of the 'syndrome' itself has yielded no clear causative agent to date. A double-blind controlled challenge of individuals claiming to suffer from the syndrome failed to confirm MSG as the causative agent. Other studies have found that allergic-type reactions after Asian meals are more often due to other ingredients, such as shrimp, peanuts, spices, and herbs. More recently, CRS has been linked to the pathogen *B. cereus* and the practice of reheating rice in Chinese restaurants. *B. cereus* is a spore former and a toxin producer; when rice is heated, the vegetative *B. cereus* cells are destroyed but the spores survive. On cooling, they germinate, grow, and produce an emetic toxin in the product during storage. Reheating the rice prior to serving does not inactivate the toxin, which is insensitive to heat. Consuming rice containing a 'trigger' level of the toxin will produce severe food poisoning, but lower levels could cause CRS symptoms.

Glutamate in human infant milk

Human and primate milk is rich in free glutamate, about 20 times the amount found in cow's milk. So glutamate is one of the first tastes we experience in life (Table 7).

Glutamate is the most abundant free amino acid found in human milk and that of other primates. It is not found at significant levels in the milk of other species. Glutamate in human milk is at its highest concentration straight after birth and is important for inducing the newborn infant to feed.

Work in Japan with newborn infants has shown them to produce 'satisfied expressions' when fed solutions of sugar and vegetable soup containing MSG and 'dissatisfied expressions' when fed vegetable soup without MSG. Despite the clear importance of MSG to infant nutrition, its addition to baby milk is still banned following the CRS fallout. The synergistic effect between the nucleotides IMP and GMP with MSG could be important for the health of neonates.

Health Effects of Nucleotides

Although they do not fit the exact definition of a prebiotic, dietary nucleotides act like prebiotic agents, demonstrating immunomodulating and direct beneficial effects on the composition of gut microflora. Nucleotides can also be described as 'functional foods' because they have a potentially positive effect on health beyond basic nutrition.

Nucleotides in infant milk

Rapidly growing infants require nucleotides for protein synthesis and cell growth. This is particularly important in the gut, where cell turnover is high and nucleotides are constantly required to replace cells. The gut also plays a key role in the immune system: some 70–85% of the body's immune system is located there. Nucleotides are increasingly considered by nutrition experts to be essential nutrients at times when the endogenous supply is insufficient to meet elevated demands, such as under conditions of rapid growth.

A large number of studies have found that nucleotide supplementation of infant formula milk has beneficial effects on

health. Human milk contains more nucleotides than cow's milk; thus, many infant formula manufacturers add small amounts of nucleotides as an ingredient to make the formula match maternal milk more closely. A high nucleotide intake has been suggested as an explanation of some of the benefits of breastfeeding compared with formula feeding. The European Society for Paediatric Gastroenterology, Hepatology and Nutrition coordinated a study with an International Expert Group, which produced a medical position paper in 2005 on Global Standard for the Composition of Infant Formula. The paper recommends the addition of nucleotides to infant formulas at a maximum total content of 5 mg 100 $kcal^{-1}$ (as well as maximal levels of 2.5 mg 100 $kcal^{-1}$ cytidine 5′monophosphate (CMP), 1.75 mg 100 $kcal^{-1}$ uridine 5′monophosphate (UMP), 1.5 mg 100 $kcal^{-1}$ AMP, 0.5 mg 100 $kcal^{-1}$ GMP, and 1.0 mg 100 $kcal^{-1}$ IMP). No adverse effects have been reported to date in healthy infants fed nucleotide-supplemented formula milk.

The beneficial effects of nucleotide addition to infant formula include improved composition of gut microbiota, decreased risk of diarrhea, increased weight gain and head growth, and increased immunity following vaccinations against *H. Influenzae* type b, polio, and diphtheria toxoid in formula-fed infants. For example, one study carried out in 2005 by a team including the Institute of Child Health in London and the Universities of Nottingham and Dundee found that supplementation of infant formula with 31 mg nucleotides l^{-1} had a prebiotic effect on colonic microbiology by improving the ratio of *Bacteroides–Porphyromonas–Prevotella* group to *Bifidobacterium* spp. *Bifidobacterium* spp. predominate in the large intestine of breastfed infants (where they are suggested to confer health benefits by protecting against infection from enteropathogenic organisms), whereas formula-fed infants are more frequently colonized by *Bacteroides–Porphyromonas–Prevotella* spp. The study concluded that the addition of nucleotides to infant formula milk could be important for optimizing the diet of formula-fed babies.

Studies in other mammals have revealed a similar picture. The supplementation of the diet of weaning piglets with nucleotides has shown a variety of beneficial effects. When piglets are weaned, they can suffer severe stress due to a change in diet, a lack of immunity, a change in gut flora, and a marked reduction in food consumption. This can lead to a reduction in the length of the villi on the intestine wall and decreased intestinal development. Enterocytes in the gut have a high level of metabolic activity, and their renewal is constant, with an average life span in the intestine of a piglet of around 4–5 days. Piglets are born without a functional immune system, relying on maternal antibodies present in colostrum and milk for defense against disease. The internal immune system of the piglets develops as the concentration of antibodies in the maternal milk decreases. This development is not complete at weaning, and consequently, farmers can be faced with health problems, such as diarrhea, in postweaned piglets. This problem can be significantly reduced by supplementation with nucleotides.

Nucleotides improve the production parameters of animals by enhancing the development of the immune system and the intestinal mucosa of piglets and reducing the stress that the animals may suffer as a result of diseases or weaning. Animals fed nucleotide-supplemented diets generally show enhanced resistance to viral, bacterial, and parasitic infections and have an increased number of lymphocytes per villus. The effect is long-lasting and most pronounced when piglets receive nucleotides preweaning. Nucleotides fed at an early stage of life enhance the development of intestinal structures and microflora leading to an increase in the active surface of the intestinal tract, facilitating the digestion of feed and the uptake of nutrients. The feed conversion ratio is thus improved. The effects of nucleotides are dose-dependent; the final weight, the daily weight gain, and the improvement of the feed conversion ratio are dependent on the dosage of the nucleotides in the feed.

Sows can also benefit from a nucleotide-supplemented diet. When nucleotides are added to sow feeds, there is an increase in the number of litters per year, the litter size, and the number of piglets weaned. The farrowing rate was increased and the number of sows returning to service was reduced. The uniformity of the litter was also improved.

Role of Nucleotides in Immune Response

Dietary nucleotides have been shown to be required for normal immune defense in adults. In two separate double-blind clinical studies, the patients fed a diet containing nucleotides had an improved immune function compared with patients receiving a nucleotide-free diet. In addition, infectious complications and length of hospital stay were reduced by nucleotide supplementation of postoperative cancer patients compared with a control group.

T lymphocytes appear to require dietary nucleotides for normal maturation and function. Host resistance to bacterial and fungal infections was decreased in mice on nucleotide-free diets; addition of RNA or uracil prevented this vulnerability to infection. Dietary RNA is required to restore lost immune function after protein deprivation. Adult rats receiving diets containing nucleotides (yeast, RNA, and arginine) showed accelerated healing of ulcers. Investigations in animal models and clinical literature suggest that administering dietary nucleotides helps to minimize infectious complications, improve clinical outcomes, and provide cost-effective nutritional support.

Exogenous nucleotides have also shown promise as dietary supplements to enhance immunity and disease resistance of fish produced in aquaculture. Research indicates that they can improve growth of fishes in early stages of development, enhance larval quality via broodstock fortification, alter intestinal structure, increase stress tolerance, and modulate innate and adaptive immune responses. Fishes fed nucleotide-supplemented diets generally have shown enhanced resistance to viral, bacterial, and parasitic infection.

Role of Nucleotides in Brain Function

Studies indicate that nucleotides play an important role in cell-to-cell communication through P2 purinoceptors. Some P2 purinoceptors are activated by nucleotides and couple to intracellular second-messenger systems through specific proteins (heteromeric G-proteins). This represents strong evidence for

extracellular nucleotide signaling and communications in glial cells in the CNS.

Other studies have suggested that nucleotide supplements can reduce the deterioration of brain tissue and memory and prevents aging. Aging mice given a nucleotide-supplemented diet performed better in a learning capability test than the control group of mice. The nucleotides were thought to stimulate glial cell proliferation, neurotubule endothelial cell proliferation, and the growth of nerve axons by interaction with other growth factors. They also suppressed the spongy degeneration phenomenon of the brain stem reticular formation, which is closely related with learning capability and memory disorder. In an earlier study, memory-deficient senescence-accelerated mice and mice with dementia showed improved memory with dietary nucleoside and nucleotide supplementation.

Effects of Nucleotides on Liver Function

A balanced mixture of nucleosides (molecules comprising a pentose sugar and a base) and nucleotides may improve hepatic function in rats and promote earlier restoration of nitrogen balance following liver injury according to one recent study. In another report, increased hepatic cholesterol and lipid phosphorous and serum bilirubin levels and decreased liver weight and glycogen were observed when feeding nucleotide-free diets to weaning mice in comparison with mice receiving nucleotide-enriched diets.

Effects of Nucleotides on Cholesterol

Feeding a nucleotide-supplemented formula diet to rats resulted in increases in long chain polyunsaturated fatty acids in their plasma. Furthermore, when rats were fed diets supplemented with nucleotides (AMP, CMP, GMP, IMP, and UMP), the concentrations of long chain polyunsaturated fatty acids on red blood cell membranes were enhanced compared to the control group. Dietary nucleotides may have the potential to modify the conversion of essential fatty acids into their long chain derivatives, which have been shown to lower cholesterol and reduce the risk of heart disease.

Evolutionary Significance of Nucleotide Flavor Enhancers

The fact that nucleotides and MSG have a strong umami flavor as well as many health benefits may not be coincidental. It would be a clear evolutionary advantage to favor foods that guaranteed healthy development of infants as well as resistance and immunity to disease.

Concluding Remarks

Flavor enhancers have had a bad press in recent years and as a result food manufacturers have been removing them from many food products. However, humans enjoy the flavor of these compounds and have a specific taste for them; removing flavor enhancers from food reduces its palatability as well as the market share for the food companies concerned. Because flavor enhancers are as essential to savory foods as sugar is to sweet foods, alternatives, such as yeast extracts and HVPs, have been developed that naturally contain high levels of MSG, IMP, and GMP.

Over the past decade, many discoveries have been made showing the importance of flavor enhancers, in particular the nucleotides, for health. Benefits are especially significant for young animals including human infants. It is probably not surprising, therefore, that animals possess a specific taste receptor forged by evolutionary processes to detect flavor enhancers as part of a survival strategy. Education of the public about the health benefits of these food additives may change attitudes and lead to the more judicious and considered use of flavor enhancers in food products to promote health as well as flavor.

Folic acid and Folates: Physiology and Health Effects

The Vitamin Folate and Folic Acid

The generic term folate refers to a large number of mainly reduced vitamers (Figure 1) with similar chemical and nutritional properties to pteroyl-L-(mono)glutamic acid (folic acid). The term folic acid denotes the fully oxidized more stable synthetic compound of this B vitamin, which is used for food fortification and in pharmaceutical preparations. Most of the naturally occurring folates in foods are polyglutamyl vitamers of tetrahydrofolate, which are susceptible to interconversion and oxidative degradation. Oxidative cleavage of the molecule results in loss of the vitamin activity.

The vitamin participates, as a coenzyme, in one-carbon transfer reactions in the body, for example, purine biosynthesis and amino acid interconversions. A good folate status is, therefore, essential for normal cell division. Folates have a recognized role in the prevention of megaloblastic anemia and of neural tube defects (NTDs) in the fetus, such as spina bifida. A good status is also linked to several other health benefits, for example, a reduced risk for certain cancers, cardiovascular diseases (CVDs), and neuropsychiatric disorders. However, in several European countries, the estimated dietary folate intake is below nutritional recommendations. To bridge the gap between these recommendations and actual folate intake, mandatory folic acid fortification has been implemented in many different countries, for example, the United States, Canada, and Chile.

Food Sources for Folate

Folate is an essential micronutrient that has to be obtained through diet. Typical folate sources are leafy green vegetables, pulses, liver, yeast, citrus fruits, nuts, and some berries. Native folate content in food is usually low, ranging from a few to some hundred parts per million.

Traditionally, food folate composition data derive from the microbiological assay using *L. rhamnosus* ATCC7469. In order to differentiate and quantify individual folate forms, HPLC methods are also used. Depending on the chosen quantification method, sample pretreatment is more or less laborious but always a crucial step. Thorough quality control and documentation during all analytic steps is required. However, conflicting folate data also arise through variation in folate content in foods of different origins, because climate, growing area, cultivar, and maturity also affect folate content.

Foods are grouped according to their folate content into rich (>100 μg per serving), good (50–100 μg per serving), and moderate (15–50 μg per serving) sources. Rich sources of folate are dried legumes with a folate content up to 600 μg/100 g (cowpeas and chickpeas) and green leafy vegetables, which reach up to 100 μg/100 g (spinach). Other vegetables and fruits, except strawberries, which are considered a good folate source with 65–100 μg/100 g, are moderate sources. Cereals are important sources since they are consumed frequently in high amounts in many countries. A general rule is that wholegrain products or products with a high extraction rate contain more folate than the starchy endosperm. The cereal fractions bran, germs, and aleurone flour are rich folate sources. Different folate forms are found in food. In cereals and legumes, both formyl and methyl vitamers are predominant, whereas in vegetables and fruits, mainly 5-methyltetrahydrofolate is found.

Effects from Food Processing

Storage and processing of foods, under both household and industrial conditions, affect folate content. Most foods are processed before consumption and common processing methods include thermal processing, freezing, fermentation, soaking, germination, and drying.

Since most native food folates are unstable, the folate content of many processed and stored foods is considerably lower than in the raw material. Food processing techniques and storage decrease the folate content to a variable extent (Table 1), and vitamin retention is affected by the amount of soluble oxygen and protective antioxidants (e.g., ascorbic acid) present in the food. Data regarding folate retention are inconsistent and depend on processing conditions.

Food fortification is the addition of nutrients to food above levels normally present. For folic acid, this practice is governed differently as either mandatory or voluntary fortification. In the United States and Canada, cereal-grain products are fortified at 140 μg/100 g, aiming to provide an additional 100 μg folic acid on top of dietary folate intake. Other folic acid-fortified products – offered in some countries through voluntary fortification – are beverages (juices, soft drinks, and mineral water), snacks, and table salt. Also, dairy products were considered as vehicles for folic acid fortification. In retention trials with model food systems, synthetic folic acid exhibited retention several-fold higher than native food folates. However, processing techniques can also enhance folate content (Tables 2 and 3). For example, milling sequesters cereal fractions rich in folate and bioprocessing techniques; fermentation and germination can also lead to enhanced vitamin content.

Germination is a biological process used to obtain a typical flavor and texture in foods, during which folate is synthesized *de novo* for cell differentiation and growth. Germination of cereal seeds and legumes results in up to a sixfold increased folate content, depending on germination conditions (temperature and time) and plant variety (Figure 2). Soaking for just a few hours or overnight increases folate content by up to half.

Table 1 Processing that decreases folate content in foods

Process	*Food*	*Folate loss (%)*
Boiling	Various vegetables	20–80
Steaming	Various vegetables	0–40
Blanching	Various vegetables	40–90
Canning	Various vegetables	0–90
Pasteurization	Tomato puree	15
	Milk	10
Oven-baking	Bread	15–70
	Fish	30–45
	Meat	35
Chill + reheating	Various vegetables	25
Frozen + reheating	Ready-to-eat meals	5–50
Soaking + boiling	Legumes	30–70
Blanching + freezing	Legumes	30–85
Blanching + tinning	Various vegetables	80–90
Storage, frozen	Various vegetables and fruits	0–20
Storage, chilled	Juice	0–5
	Fermented milk	0
	Bread	15
Storage, ambient temperature	Various fruits	0–30
	Bread	30

Table 2 Processing that increases folate content in foods

Process	*Food*	*Folate increase*
Germination	Rye grains	1.6–6-fold
	Wheat grains	3–6-fold
	Legumes	1.8–3.5-fold
Fermentation	Wheat bread	0.6–2-fold
	Milk	3–4-fold

Table 3 Novel functional foods with increased folate content by the addition of germinated plant ingredients

Food	*Description*	*Folate increase (%)*
Bean stew foul	A canned stew prepared from soaked and boiled fava beans, consumed in Arabic countries. The novel product is prepared from germinated fava beans before canning	50
Baladi/pita bread	A flat wheat bread consumed in Arabic countries. Wheat grains are germinated, dried, and milled. 50% of wheat flour is replaced by germ flour	40
Biscuits	Wheat flour biscuits are baked replacing 25% of flour with germinated chickpea flour	570
Rye muesli	Malted rye grain flakes are produced from germinated rye and subsequent freeze-drying	250
Wheat bread	Wheat bread was leavened with a *Saccharomyces cerevisiae* strain (CBS7764) and cultured in defined medium	300–500
Fermented milk products	Several fermented milk products are prepared by fermentation with specific starter cultures and addition of fruits	200

During fermentation, raw materials undergo changes in composition, flavor, and texture. Fermentation of cereals and legumes, spontaneous or with selected microorganisms, is a common food preparation method in many African and Asian countries, although making bread is also a type of fermentation. Folate concentration increase depends on process conditions. Increases during dough fermentation can be attributed

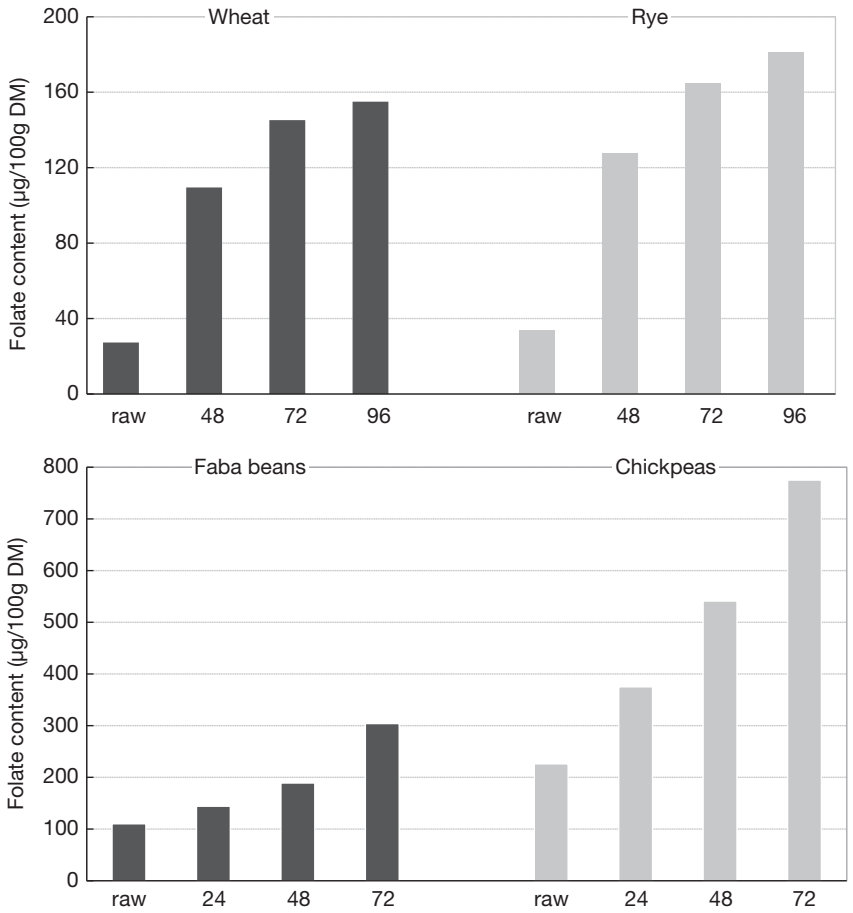

Figure 2 Folate content (μg/100 g DM) in cereals (wheat and rye) and legumes (fava beans and chickpeas) after germination at 25 °C for 24, 48, 72, or 96 h.

to the contribution from yeast cells and folate synthesis during their growth. Fermentation of bovine milk (e.g., with *L. rhamnosus* ATCC7469) increases folate content from ~4–8 μg/100 g to around 20 μg/100 g, although the increase in folate content depends on the lactic acid bacteria strain. Increased folate in hard cheese is chiefly caused not only by a reduction in the water content but also to a certain extent by the starter culture organism.

Dietary Intake of Folate

It has been estimated that populations in several European countries have a dietary folate intake of below 200 μg day^{-1} to around 300 μg day^{-1}. While these intakes prevent folate deficiency, which can result in megaloblastic anemia, they are below recommendations aiming to maintain or achieve a good folate status population-wide. With current dietary food habits, only few individuals reach the desired dietary intake (350 μg day^{-1} or greater). Raising folate intake, and in view of the low folate native content in food, it would seem necessary to develop strategies to increase folate intake. Fortification policies are thought to be an efficient tool for increasing average folate intake, and mandatory or voluntary folic acid fortification of staple foods has been introduced in several countries.

Suboptimal folate intakes observed in European populations are, commonly, attributed to the naturally low food content, processing losses, and the low bioavailability of natural food folates. Also, data from the US National Health and Nutrition Examination Survey (NHANES) suggest that 33–66% of the population was at risk of low serum and erythrocyte folate before the introduction of mandatory fortification of cereal-grain products and ready-to-eat cereals in the United States and Canada in 1998.

US and Canadian dietary reference intakes for folate, and other micronutrients, aimed to include the concept of optimal intakes and the associated long-term health benefits, going beyond simply avoiding deficiency diseases. Therefore, recommended intake levels were increased to 400–600 μg day^{-1} for women of childbearing age and during pregnancy and lactation. Many European countries also adapted this approach, and an aim of EURRECA – an EU-funded Network of Excellence – was to harmonize best practice guidance for setting science-based micronutrient recommendations including folate/folic acid. Reports from the United States and Canada suggest that in most population groups, folate status (serum folate and erythrocyte folate) improved during the postfortification period. The argument in both countries for

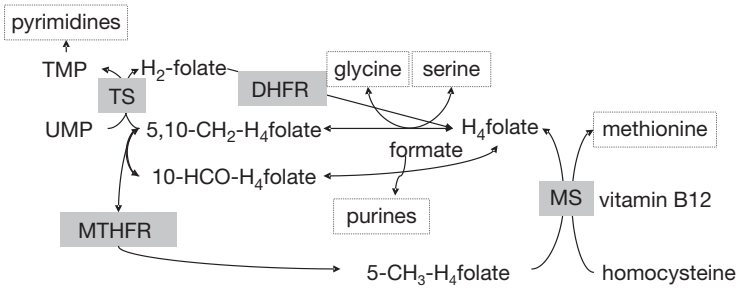

Figure 3 Role of folate in nucleotide synthesis and methylation reactions. Enzymes marked in gray and their end products in boxes. DHFR, dihydrofolate reductase; MS, methionine synthase; MTHFR, methylenetetrahydrofolate reductase; TMP, thymidine monophosphate; TS, thymidylate synthase; UMP, uridine monophosphate.

introducing mandatory folic acid fortification in 1989 was to reduce the prevalence of NTD. This aim was achieved as indicated by numerous epidemiological data, but mandatory folic acid fortification remains controversial in some countries.

In most countries, the recommended dietary allowance for folate in adults is 300 μg day^{-1} and, for women of childbearing age, up to 400 μg day^{-1}. In the United States, dietary recommendations are expressed in terms of dietary folate equivalents to account for differences in the bioavailability of food folates and folic acid from fortified foods. For pregnant and nursing women, recommendations are 500 and 600 μg day^{-1} folate to maintain erythrocyte folate. Several national health authorities recommend pregnant women should consume folic acid supplements during early pregnancy (before pregnancy and up to week 12). The US Food and Nutritional Board set an upper safe level for folic acid intake at 1 mg day^{-1}, which is also applied in other countries.

Folate Absorption and Metabolism

Dietary folate occurs mainly in the reduced polyglutamate forms. At physiological concentrations, reduced folate is deconjugated to its monoglutamate form by intestinal γ-glutamyl hydrolase before being absorbed by an active carrier-mediated process in the small intestine and being released into the blood stream via the hepatic portal vein. Folic acid has to undergo reduction for which, as shown by recent research, the human mucosa cell has limited enzymatic capacity. Indeed, it has been suggested that humans are dependent on hepatic reduction and methylation of folic acid from portal venous blood. The dominant folate form in circulating systemic blood is 5-methyltetrahydrofolate, and when present in an oral dose at higher concentrations, folate monoglutamate vitamers also pass through cell membranes by passive diffusion. The liver contains about half the body pool of folate. Up to 20% of folate absorbed by either mechanism is retained by the liver during first passage, depending on the hepatic folate status. The remainder is transported, via systemic circulation, to body tissues; tissue folates are retained in their polyglutamate form.

The biochemical function of this vitamin in cells of mammals is based on the different oxidation states of folate, because each has an essential role as one-carbon donors or acceptors. During nucleotide synthesis, folate supplies carbon units for *de novo* purine and pyrimidine bases. Folates act also as coenzymes in the methylation of proteins as well as the synthesis of neurotransmitters and phospholipids (Figure 3). A good folate status is, therefore, essential for normal cell division, and requirement increased during, for example, the growth, pregnancy, and lactation. Suboptimal folate status periconception has been shown to increase the risk of birth defects, specifically NTDs. Severe folate deficiency causes megaloblastic anemia, which is still observed in some Asian and African countries, although seldom seen in the United States and Europe.

Genetic polymorphisms can affect folate metabolism, decreasing enzyme activities and/or increasing folate requirements. Also, insufficient vitamin B_{12} can reduce the activity of a key enzyme (methionine synthase), resulting in cellular deficiency of tetrahydrofolate.

In the United States and Canada, mandatory folic acid fortification at 140 μg/100 g was anticipated to increase the average daily folate intake in women of childbearing age by an additional 100 μg while preventing excess intake by other population groups. Folate status in US populations has improved postfortification, resulting in less than 5% at risk due to increased dietary intake (>100 μg folic acid per day). However, in fastened blood samples from certain population groups, unmetabolized folic acid has been reported in addition to plasma folate 5-methyltetrahydrofolate suggesting excess intake. Various hypotheses regarding potential risks associated with this long-term exposure to high intakes of folic acid are being scrutinized (e.g., progression and growth of preneoplastic cells or subclinical cancers), and the issue of folate bioavailability and bioactivity has again gained importance.

Folate Bioavailability

The term bioavailability is commonly defined as the fraction of an ingested nutrient available for storage and metabolism under normal physiological function. Bioavailability is affected by host-related factors (e.g., folate status, health, age, sex, gastrointestinal function, and genetic factors), while the chemical nature of the ingested folate, food matrix, or food processing can influence bioavailability extrinsically. Therefore, determining folate bioavailability is still challenging. The numerous approaches for assessment of folate bioavailability from individual foods, meals, and whole diets have specific advantages or limitations and often provide conflicting

information on folate bioavailability. Only limited folate bioavailability data for vegetables, fruits, cereal products, and some fortified foods are available.

Common estimates for the bioavailability for food folate from a mixed diet are half that of folic acid, but this should be considered a rough estimate, as the bioavailability of food folate is reported to vary between 30% and 98%. Discrepancies in data about folate bioavailability can be explained by the nature of the foods or meals tested, which may affect vitamin stability and absorption, intersubject variation, different study designs and reference doses, and differences in postabsorptive metabolism among individual folate forms.

The bioactivity of dietary folates is commonly studied in 4–16-week intervention trials assessing changes in folate status parameters. Several 4-week trials with, for example, five-a-day fruits and vegetables, spinach, or yeast intervention did not improve folate status. Trials up to 16 weeks with similar and fortified foods (e.g., five-a-day or 500 g fruits and vegetables; aleurone, rye, or wholemeal breads; or a breakfast meal according to recommendations) or folic acid supplements resulted in improved folate status.

For assessment of short-term bioavailability or acute absorption of folate, several different methods have been used (Table 4). In many trials, the acute absorption of food folate has been found to be incomplete compared with folic acid.

The plasma area under the curve (AUC) approach is based on the assumption that postdose plasma folate concentration over time corresponds to the absorbed folate dose. Commonly, relative folate absorption of a single dose of food folate is compared with a reference dose (folate or folic acid). Sometimes, apparent folate absorption is estimated using biokinetic modeling. However, because of differences in metabolic handling of folic acid and reduced folate, folic acid is not an appropriate reference dose for bioavailability studies with food folate. Therefore, current bioavailability data should be interpreted carefully considering the limitations of the study design or model systems used. It has been suggested that 20–90% of supplement and food folate is absorbed.

Using the oral–fecal balance technique, folate studies in healthy ileostomy subjects, who do not possess colon microflora affecting fecal folate excretion, often in combination with the AUC technique, suggest folate absorption is inversely correlated with folate content in stomal effluent, and folate bioavailability from foods or a meal is ~50–90%.

Estimation of folate bioavailability using urinary folate excretion ratios is based on the assumption that excretion of labeled folate from an oral dose corresponds to that of a labeled intravenous reference dose. Relative folate bioavailability of food folates and synthetic folic acid ranged from 35% to above 100%, which indicates the human body handles folate vitamers differently. Similarly, whereas data on folate bioavailability were in the past thought to be contradictory, several studies now suggest reduced (food) folates and synthetic folic acid are metabolized differently.

Table 4 Methods to estimate the bioavailability and bioactivity of folate in humans

Study design	*Principle; advantages (+), disadvantages (−)* *Tested doses/foods*	*Finding*
Intervention	Intervention with test food and/or synthetic folic acid, compared to control group with no folate dose, commonly over 4–16 weeks (+) Information on the bioactivity of given dose from supplement/food/diet (−) Laborious, expensive, time-consuming, possible problems with compliance	
	Fruits, vegetables, spinach, yeast (1–4 weeks)	No effect on status
	Fruits, vegetables, aleurone, rye, or wholemeal breads, a breakfast meal (>4 weeks)	Improved or maintained status
Plasma area under the curve (AUC)	Postdose AUC corresponds to absorbed folate dose (+) Information on the acute/apparent absorption of given dose from supplement/food/diet (−) Laborious, expensive, requires strict standardization of test days, requires careful choice of reference dose, sometimes use of nonphysiological doses/large test food portions	
	Synthetic folate compounds, fruits, vegetables, dairy products, breads	Apparent absorption of 20–90%
Urinary folate excretion ratios	The urinary excretion of labeled folate from an oral dose corresponds to that of a differently labeled intravenous reference dose (+) Information on relative absorption from given dose of supplement/food (−) Labeled folate compounds required	
	Folic acid-fortified cereals-grain products, synthetic folates	Relative absorption of 35–155%
Oral–fecal balance technique	Folate absorption is inversely correlated with folate content in stomal effluent (in ileostomy subjects) (+) When combined with AUC technique, it enables safer estimation by complementation of folate excretion data with plasma data on folate absorption; when combined with AUC and stable isotope technique, it enables distinguishing between labeled folate from the dose and unlabeled endogenous folate from body stores (−) Laborious, expensive (labeled folate compounds required)	
	Fermented milk, spinach, yeast, fortified bread, breakfast meal	Absorption of 50–90%

Table 5 Health effects of folate: relation between folate intake and status with clinical and functional outcomes

Clinical/functional outcome		*Comment*
Pregnancy and birth outcomes	• *Maternal* folate status and intake are inversely associated with neural tube defects	• Strong evidence
	• Levels and means of recommended dietary folate or supplemental folic acid for protective effect	• Insufficient inconclusive data
	• Association of nonneural birth defects and folate status and intake	• Inconclusive data
Hematological status	• Mandatory folic acid fortification increases average folate intake and improves folate status	• Strong evidence
	• Detection of unmetabolized folic acid in circulating plasma after ingestion of folic acid fortificant or supplement	• No data regarding implications on human health
Neurological status	• Adequate folate intake or status protects from poor cognitive function and several neurological disorders in the elderly	• Probable
	• Folate intake is inversely associated with Alzheimer's disease and depression prevalence	• Probable
Cardiovascular diseases (CVDs)	• Adequate dietary folate intake is inversely associated with severe and subclinical CVD outcomes	• Suggestive
	• No adverse effects of dietary folate or folic acid supplements	• Probable
Cancer	• Dietary folate is inversely associated with risk for colon and colorectal cancer	• Probable
	• B vitamin supplementation including folic acid does not increase risk for colorectal cancer	• Probable
	• Dietary folate is inversely associated with risk for breast cancer	• Probable
	• Dietary folate is inversely associated with risk for bladder cancer, prostate cancer, or pancreatic cancer	• Insufficient inconclusive data

Health Effects of Folate

The vitamin folate attracted both scientific and public interests in recent years (Table 5). The role of folate in the prevention of megaloblastic anemia and of NTDs in the fetus is well established. National mandatory fortification programs of cereal-grain products or staple foods in the United States, Canada, and several other countries were launched with the public health goal of reducing the incidence of NTD-affected pregnancies, and this goal was successfully achieved. However, data regarding a particular level and means of intake for folate by food and/or folic acid supplement or fortificant are inconsistent and insufficient.

Further, a health benefit associated with a good folate intake or status is suggested to be decreased risk for CVDs.

Less consistent is the evidence regarding the protective role with respect to certain forms of cancer. Folate intake and status are inversely correlated with the risk for colon cancer. Findings regarding breast cancer are inconclusive and evidence is lacking regarding other cancers.

Also unclear is, for example, the impact of folate status on neuropsychiatric disorders, such as, dementia and Alzheimer's disease (Table 5).

Summary and Future Trends

This article summarizes briefly information on folate in the context of food and nutritional sciences. Folates have been recognized regarding their health benefit. With respect to the gap between current dietary folate intake and nutritional recommendations, further research is warranted regarding optimal level and means for intake of folate and folic acid in order to provide safe, tasty, healthy, and convenient foods.

Food Additives: Classification, Uses and Regulation

GA Blekas, Aristotle University of Thessaloniki, Thessaloniki, Greece

© 2016 Elsevier Ltd. All rights reserved.

Food additives are natural, semisynthetic, or synthetic substances or products of biotechnology, present in edible products at levels varying usually between a few mg kg^{-1} and 1% by weight. They are used either directly or indirectly during processing, treatment, packaging, transport, or storage of a food for one or more technological purposes, such as prolonging shelf life, sweetening, modifying or stabilizing consistency, enhancing taste, and enhancing or preserving color.

Directly used food additives are substances intentionally added to foodstuffs in controlled levels. The main purposes of their use are food preservation and food appeal, convenience, or processing improvement. Indirectly used food additives are substances that become part of an edible product, usually at very low levels, as a result of processing or packaging.

Classification of Food Additives

Food additives are classified in many functional classes. The Codex Alimentarius Standard CAC/GL 36-1989 includes in section 2 a table with the following additive functional classes:

- Acidity regulators, as additives that control the acidity or alkalinity of a food
- Anticaking agents, as additives that reduce the tendency of food components to adhere to one another
- Antifoaming agents, as additives that prevent or reduce foaming
- Antioxidants, as additives that prolong the shelf life of foods by protecting against deterioration caused by oxidation
- Bleaching agents, as additives used to decolorize food (except flour)
- Bulking agents, as additives that contribute to the bulk of a food without having a significant contribution to its available energy value
- Carbonating agents, as additives used to provide carbonation in a food
- Carriers, as additives that dissolve, dilute, disperse, or otherwise physically modify a food additive or nutrient without altering its function (and without exerting any technological effect themselves) in order to facilitate its handling, application, or use of the food additive or nutrient
- Colors, as additives that add or restore color in a food
- Color retention agents, as additives that stabilize, retain, or intensify the color of a food
- Emulsifiers, as additives that form or maintain a uniform emulsion of two or more phases in a food
- Emulsifying salts, as additives that rearrange proteins in order to prevent fat separation during the manufacture of processed food
- Firming agents, as additives that make or keep tissues of fruits or vegetables firm and crisp or interact with gelling agents to produce or strengthen a gel
- Flour treatment agents, as additives added to flour or dough to improve its baking quality or color
- Flavor enhancers, as additives that enhance the existing taste and/or odor of a food
- Foaming agents, as additives that make it possible to form or maintain a uniform dispersion of a gaseous phase in a liquid or solid food
- Gelling agents, as additives that give a food texture through the formation of a gel
- Glazing agents, as additives that, when applied to the external surface of a food, impart a shiny appearance or provide a protective coating
- Humectants, as additives that prevent foods from drying out by counteracting the effect of a dry atmosphere
- Packaging gases, as additives that are introduced into a container before, during, or after its filling with a food with the intention of protecting the food, for example, from oxidation or spoilage
- Preservatives, as additives that prolong the shelf life of foods by protecting against deterioration caused by microorganisms
- Propellants, as additives that expel a food from a container
- Raising agents, as additives or combination of additives that liberate gas and thereby increase the volume of a dough or batter
- Sequestrants, as additives that control the availability of a cation
- Stabilizers, as additives that make it possible to maintain a uniform dispersion of two or more components
- Sweeteners, as additives other than sugars (mono- or disaccharides) that impart a sweet taste to a food
- Thickeners, as additives that increase the viscosity of a food

Food additives are classified into both direct or secondary direct food additives and indirect food additives according the US Code of Federal Regulations (CFR). Direct food additives are divided into eight categories. Flavorings and nutrients are two of these categories. Secondary direct food additives are divided into four categories. In two of these categories, enzymes and solvents are included. Food colors are classified in certified colors and colors exempt from certification.

Regulation of Food Additives

Food additive use is regulated by international or national authorities taking into account that they are safe and technologically indispensable. Each approved food additive has been assessed for its toxicity with the aim to determine the 'no observed adverse effect level' and the 'acceptable daily intake' (ADI). The latter is taken into account by establishing its maximum use levels in various food groups. An additive to which has been allocated an ADI 'not specified' may be used in foodstuffs with 'no limitations other than current good

manufacturing practice.' Identity and purity criteria for each permitted food additive, maximum use level at the different commodities in which it may be used, and food categories or individual food items in which the use of each permitted food additive is not acceptable or where use should be restricted have been allocated in the Codex General Standard for Food Additives (GSFA, Codex STAN 192-1995). This standard has been used as a starting point for developing the European Union system that regulates food additive use.

Food additive use in European countries is harmonized by Regulation (EC) No 1333/2008 of 16 December 2008. This regulation, which replaces previous directives and decisions concerning food additives permitted for use in foods, harmonizes also the use of food additives in food additives, food enzymes, food flavorings, and nutrients. The following are not considered to be food additives:

- Substances used for the purpose of imparting flavor and/or taste or for nutritional purposes
- Substances not consumed as food itself but used intentionally in the processing of foods, which remain as residues in the final food and do not have a technological effect in the final product (processing aids)
- Food enzymes
- A number of food ingredients, such as ammonium chloride, chewing gum bases, caseinates, casein, edible gelatin, gluten, inulin, and protein hydrolysates and their salts
- Products containing pectin that are derived from dried apple pomace or peel of citrus fruits or quinces
- Physically modified starch, starch modified by acid or alkali treatment, starch modified by bleaching and dextrinated or roasted starch, starch treated by amylolytic enzymes, sugars used for their sweetening properties, and white or yellow dextrin

Commission Regulation (EU) No 1129/2011 amends Annex II to Regulation (EC) No 1333/2008 by establishing a union list of food additives approved for use in foods and conditions of their use. Part B of this list includes colors (40 substances), sweeteners (16 substances), and additives other than colors and sweeteners (266 substances). Union list of food additives, whose use is permitted in food additives, food enzymes, food flavorings, and nutrients, is replaced in Annex III to Regulation No 1333/2008 by the text of Annex to Commission Regulation (EU) No 1130/2011. Specifications for all food additives listed in Annexes II and III to Regulation No 1333/2008 are laid down in the Annex to Commission Regulation (EU) No 231/2012.

The use of food colors and other food additives in the United States is regulated by the Food and Drug Administration (FDA). Food additives are divided into generally recognized as safe (GRAS) substances, prior-sanctioned substances, and regulated direct or indirect additives. The FDA is involved to ensure that GRAS substances and prior-sanctioned substances, which were in use in foods prior to the Food Additives Amendment in 1958 to the 1938 Food, Drugs, and Cosmetics Act, are tested by applying the most modern toxicological methods. Title 21 of the CFR includes a number of parts concerning food additives. Parts 170 and 171 provide general information on food additive regulation. Food additives permitted for direct addition to food for human consumption and secondary direct food additives permitted in food for human consumption are listed in parts 172 and 173, respectively. Indirect food additive regulations are presented from parts 174 to 178. Parts 181 and 182 refer to prior-sanctioned food ingredients and GRAS substance use. Parts 70 and 71 present general information on color additive regulation. Colors exempt from certification and colors subject to certification are listed in parts 72 and 73, respectively.

Approved Food Additives and Their Use

The following description of direct food additives used in foods is based on their functional classification.

Acidity Regulators

These additives, mainly acids or their salts, hydroxides, and oxides, are used as acidifiers, buffering agents, or pH adjusting agents that affect rheological properties, taste, and texture of foods, enhance the ability of food to form gel or to absorb water for swelling, or contribute to food shelf life extension. They are mainly used in bakery products, chewing gum, chocolate and cocoa products, confections, dairy products, fruit and vegetable products, nonalcoholic beverages, and wine, usually at levels in accordance with GMP. Citric acid and phosphoric acid are the most commonly used acidifiers.

Anticaking Agents

These substances, mainly inorganic calcium and magnesium salts (carbonates, ferrocyanides, phosphates, and silicates), fatty acid calcium and magnesium salts, oxides (magnesium oxide and silicon dioxide), cellulose, and soybean hemicellulose, are added in foodstuffs containing hygroscopic ingredients to inhibit the formation of aggregates or lumps. They are added, at a level of 1% or less, in

- dried powdered foods,
- foods in tablet and coated tablet form,
- food supplements such as in capsules or tablets,
- rice,
- salt and salt substitutes,
- sliced or grated hard, semihard, or semisoft ripened and unripened cheese products,
- processed cheese products,
- sugar confections,
- spreadable fats,
- tabletop sweeteners in powdered form or in tablets, and
- whey cheese products.

Antifoaming Agents

Dimethylpolysiloxane, which is the most commonly used antifoaming agent, is mainly added in foods, such as alcoholic and nonalcoholic beverages, batters, broths, canned or bottled fruits, confections, dairy spreads, fat spreads, food supplements, frying fats, jams, jellies, marmalades, and soups, at a level of 10 mg kg^{-1}. Mono- and diglycerides of fatty acids, microcrystalline wax, and calcium alginate are other substances used as antifoaming agents.

Antioxidants

These additives protect foods against oxidative deterioration caused by color and aroma defects. They are oil- or water-soluble substances used also to avoid an earlier oxidative deterioration in fatty foods because naturally occurring antioxidants may be often destroyed during processing. Antioxidants may be divided into chain-breaking antioxidants, preventive antioxidants, reducing agents, and oxygen scavengers. Chain-breaking antioxidants are natural or synthetic phenolic substances used for the inhibition or retardation of lipid oxidation caused by free radical reactions. Metal chelating agents (sequestrants), as the most important preventive antioxidants, are used often in combination with chain-breaking antioxidants for retardation of lipid hydroperoxide decomposition catalyzed by polyvalent metal ions and also for the inhibition of ascorbic acid oxidation. Reducing agents are used to transform lipid hydroperoxides in inactive products by nonradical reactions, to inhibit color changes in foods, or to regenerate chain-breaking antioxidants. Oxygen scavengers are, at least, substances used for removing oxygen from food packaging (e.g., glucose oxidase).

Butylated hydroxyanisole (BHA), butylated hydroxytoluene (BHT), extracts of rosemary, gallic acid esters, tert-butylhydroquinone (TBHQ), and tocopherols are the most important chain-breaking antioxidants used in foods. Tocopherols are used in oils, fats, and foods for infants and young children. Extracts of rosemary are added in animal fats, fish oils, fats and oils used in the manufacture of nonheat-treated and heat-treated foods, and vegetable fats and oils containing polyunsaturated fatty acids more than 15% (w/w) of the total fatty acids. They are also used in dehydrated potato products; fine bakery wares; mustard; nonheat-treated and heat-treated meat products; nut butters; nut spreads; potato-, cereal-, flour-, or starch-based snacks; processed eggs and egg products; processed nuts; seasonings and condiments; sauces; and soups and broths. Gallic acid esters, TBHQ, BHA, and BHT are added in animal fats, fish oils, fats and oils used in the manufacture of heat-treated foods, and frying fats. They are also used in cereal-based snack foods, chewing gum, dehydrated broths, dehydrated meat, dehydrated potatoes, dehydrated soups, processed nuts, sauces, and seasonings and condiments. The addition level of chain-breaking antioxidants other than tocopherols varies between 10 and 400 mg kg^{-1}. Tocopherols are added at levels in accordance to GMP.

Ascorbic acid, which is the most important water-soluble antioxidant, acts as a metal chelating agent, as an oxygen scavenger, or as a reducing agent. It is utilized for protecting flavor constituents against oxidation in fruit and vegetable juices or nectars and beer, due to its oxygen scavenging activity, and also for improving flour or dough baking quality. Ascorbic acid and its salts are also used in dehydrated milk; foods for young children; fresh and heat-treated processed meat, unprocessed fish, crustaceans, and mollusks; and unprocessed and processed fruit and vegetables. Fatty acid esters of ascorbic acid are mainly used in fats and oils, for improving their oxidative stability, dehydrated milk, and foods for young children and infants. Isoascorbic (erythorbic) acid and its sodium salt are used in heat- and nonheat-treated cured meat products to reduce the amount of added nitrous acid salts. These additives stabilize also color in deep-frozen and frozen fish with red skin, preserved meat products, and preserved or semipreserved fish products.

Colors

Colors used to enhance the appearance of foods are synthetic, semisynthetic, or natural water-soluble or water-insoluble substances. Approved color additives are

- mainly synthetic water-soluble azo and triphenylmethane dyes,
- natural water-soluble (anthocyanins, betanin, and carminic acid) or water-insoluble (beta-carotene, trans-β-apo-8′-carotenal, bixin, capsanthin, chlorophylls, chlorophyllins, copper complexes of chlorophylls/chlorophyllins, curcumin, lutein, lycopene, and riboflavins) colors,
- water-insoluble colors that are products of biotechnology (beta-carotene and lycopene),
- caramel,
- metals (aluminum, gold, and silver),
- minerals (calcium carbonate, iron hydroxides, iron oxides, and titan dioxide), and
- vegetable carbon.

Metals are used in confection external coatings. Most natural colors, caramel, minerals, and vegetable carbon are used at levels in accordance with GMP. Bixin and lycopene are used at levels varying between 10 and 50 mg kg^{-1}. Synthetic colors, curcumin, lutein, and trans-β-apo-8′-carotenal, are used at levels of 50–500 mg kg^{-1}. The use of food colorants is permitted in a great number of foodstuffs, mainly in alcoholic beverages, chewing gum, confections, edible ices, fine bakery wares, jams, jellies, marmalades, mustard, processed meat, processed fish and fishery products, sauces, and seasonings.

Emulsifiers and Emulsifying Salts

These additives, which are used as plasticizers, dispersing agents, suspending agents, clouding agents, density-adjusting agents, crystallization inhibitors, or melding salts, are natural or synthetic surface-active agents widely used to stabilize w/o and o/w food emulsions in margarine, mayonnaise, or ice cream; to prevent fat separation in sausages; to inhibit 'fat blooming' in chocolate or starch retrogradation in bread; to improve baked product volume, crumb structure of bread, and rheological properties of chocolate; to dissolve instant powders and spice extracts; and to achieve a characteristic consistency in ice cream. The relative strength of hydrophilic and lipophilic groups present in the molecule of a surface-active agent (HBL value) is related to its main industrial application. Surface-active agents suitable for stabilization of w/o and o/w emulsions have an HLB value varying between 3 and 6 and between 8 and 18, respectively, while surface-active agents having an HLB value varying between 7 and 9 are mainly utilized as food humectants.

The most commonly used food emulsifiers are lecithin; mono- and diglycerides of fatty acids and their esters with acetic, citric, lactic, and mono- and diacetyl tartaric or tartaric

acids; polyglycerol fatty acid esters; polyoxyethylene sorbitan fatty acid esters (polysorbates); propylene glycol fatty acid esters; sorbitan fatty acid esters (Span's); stearoyl-2-lactylate salts; and sugar esters. Ammonium phosphatide, fatty acid salts, glycerol esters of wood resin, quillaia extract, and thermally oxidized soybean oil interacted with mono- and diglycerides of fatty acids are other approved emulsifiers. Additives with emulsifying properties, which are mainly utilized as food humectants, stabilizers, thickeners, and/or sweeteners, are modified starches; lactic acid salts; ortho-, di-, tri-, or polyphosphoric acid salts; propylene glycol; polysaccharides; sugar alcohols; triacetin; and triethyl citrate. The use of emulsifiers is permitted in a great number of foodstuffs, including foods for infants, babies, and young children. These additives are utilized in bread, cheese, chewing gum, chocolate and cocoa products, confections, edible ices, fat or oil emulsions, fine bakery wares, flavored fermented milk products, flavored nonalcoholic beverages, heat-treated processed meat products, liqueurs, other alcoholic beverages, processed cheese, sauces, and soups. Lecithin, modified starches, mono- and diglycerides of fatty acids, and esters of mono- and diglycerides of fatty acids are added in foods, excluding food for infants and young children, at levels in accordance with GMP. The rest of the emulsifiers are added at levels varying between 100 and 10 000 mg kg^{-1} or mg l^{-1}.

Firming Agents

Calcium and aluminum salts of inorganic acids are the main firming agents. Calcium chloride is the most commonly used, mainly in canned and bottled fruit and vegetables, fruit compotes, jams, jellies, marmalades, and similar spreads. Its use, at levels in accordance with GMP, aims to prevent the collapse of fruit tissues by forming a calcium pectate gel around them and, therefore, to protect them against softening during processing. Aluminum sulfate, aluminum sodium sulfate, and aluminum ammonium sulfate are used in the manufacture of candied, crystallized, or glace fruits, at levels of 200 mg kg^{-1}, for coating fruits with an aluminum pectate film before they are candied in saccharose or glucose syrups.

Glazing Agents

The most important substances used as glazing agents are natural or synthetic waxes, such as beeswax, candelilla wax, carnauba wax, hydrogenated poly-1-decene, microcrystalline wax, montan acid esters, oxidized polyethylene wax, and shellac. All these additives are used for surface treatments of some entire fresh fruits. Beeswax, candelilla wax, carnauba wax, and shellac are also used in chewing gum; chocolate products; coffee; confections; potato-, cereal-, flour-, or starch-based snacks; fine bakery wares coated with chocolate; and processed nuts. Microcrystalline wax and hydrogenated poly-1-decene are used in chewing gum and confections. Glazing agents, with the exception of carnauba wax and hydrogenated poly-1-decene, are used in food at levels in accordance with GMP (about 4000 mg kg^{-1}). Carnauba wax is used at levels varying between 200 and 1200 mg kg^{-1}. The maximum use level for hydrogenated poly-1-decene is 2000 mg kg^{-1}.

Humectants

These additives are hygroscopic substances that control water activity because its reduction preserves texture and enhances food stability against deterioration caused by microorganisms. They are used in a great number of intermediate moisture foods, which have a water activity ranging from 0.6 to 0.9, such as cereal products; cheese; chewing gum; confections; dietary foods; dried fruits; fermented milk products; food supplements; jams; jellies; marmalades; meat products; potato-, cereal-, or flour-based snacks; processed eggs and egg products; processed fishery products; processed nuts; salads; sandwich spreads; sauces; soups and broths; and seasonings and condiments, at levels in accordance with GMP. The most commonly used humectants are sugar alcohols, which are multifunctional substances. Other multifunctional substances used as humectants are glycerol; glycerol triacetate; polydextrose; propylene glycol; salts of ortho-, di-, tri-, and polyphosphoric acids; and polysaccharides used as stabilizers and thickeners, such as alginic acid and its salts, agar, and carrageenan.

Preservatives

These substances inhibit metabolic pathways responsible for microorganism survival by the attack of microbial cell membranes or by reaction with functional groups of microbial enzymes. They are mostly used to protect fresh prepared foodstuffs with a low microbial load against deterioration, because the reduction rate of microorganism population depends on their levels. Their use depends also on microorganism species present in a food, food pH value, and food storage temperature. Preservatives suitable for use in foods are organic acids, such as acetic, benzoic, propionic, and sorbic acids, and their salts, *p*-hydroxybenzoic acid esters and their sodium salts, and inorganic acids and/or their anhydrides or salts, such as borax, boric acid, carbon dioxide, nitric acid salts, nitrous acid salts, sulfur dioxide and sulfurous acid salts, lysozyme, natamycin, nisin, hexamethylenetetramine, and dimethyl dicarbonate. Both inorganic and organic acids are effective in their undissociated form. They show, therefore, their highest antimicrobial activity at low pH values and they are preferably used in acid foods. The maximum use level of preservatives other than acetic acid and its salts and carbon dioxide varies between 3 and 4000 mg kg^{-1}. Acetic acid, acetic acid salts, and carbon dioxide are used at levels in accordance with GMP.

Sorbic acid and its sodium, potassium, and calcium salts show antimicrobial activity mainly against molds and yeasts. Foods that may be preserved using these additives are bakery wares, alcoholic beverages (alcoholic drinks with less than 15% alcohol, aromatized wine-based drinks, aromatized wine-product cocktails, cider, fruit wine, made wine, mead, and wine), cheese, cheese products, dehydrated and concentrated frozen or deep-frozen egg products, emulsified sauces, fat emulsions, flavored drinks, and processed fruit and vegetable products. Sorbic acid salts are also used for surface treatment of unpeeled fresh citrus fruits, ripened cheese, and cheese analogues.

Benzoic acid and its sodium, potassium, and calcium salts show antimicrobial activity against molds, yeasts, and aerobic

bacteria. Benzoic acid salts are often used in combination with sorbic acid salts, because they are more effective against lactic acid bacteria, for the preservation of chewing gum; confections, excluding chocolate and cocoa products; dietary foods; food supplements; jams; jellies; liquid eggs; liquid fruit and herbal infusion concentrates; liquid broths; liquid soups; liquid tea concentrates; marmalade and similar fruit-based spreads; mustard; olive-based preparations; olives; processed fish or fishery products; salads and sandwich spreads; sauces; seasonings and condiments; tabletop sweeteners in liquid form; and vegetables in vinegar, oil, or brine.

Methyl and ethyl esters of *p*-hydroxybenzoic acid and their sodium salts show antimicrobial activity against molds, yeasts, and many bacteria. They are mainly used in combination with either sorbic acid salts or sorbic and benzoic acid salts due to their higher effectiveness against Gram-positive bacteria. In comparison with sorbic or benzoic acid salts, they are effective in a wide pH area due to their lower polarity. Foods that may be preserved using these additives in combination with sorbic and benzoic acid salts are potato-, cereal-, flour-, or starch-based snacks; processed nuts; decoration, coating, and fillings of confections; and jelly coatings of meat products.

Sulfur dioxide and sulfurous acid calcium, potassium, and sodium salts show a stronger antimicrobial activity against bacteria than against molds and yeasts. They are often used in combination with sorbic and/or benzoic acid salts. These additives are also used, at levels higher than that needed for food preservation, as antioxidants, for the inhibition of food enzymatic and nonenzymatic browning, or as bleaching agents. Therefore, sulfurous acid salts are added in food at levels varying between 10 and 2000 mg SO_2 per kg. Foods containing these additives are mainly alcoholic beverages; analogues of meat or fishery products based on protein; confections; flavored drinks; lemon juice; mustard; potato-, cereal-, flour-, or starch-based snacks; processed and unprocessed fishery products; processed and unprocessed fruit and vegetables; sugars; syrups; and whole or concentrated fruit juices for special uses. The presence of these preservatives at levels higher than 10 mg kg^{-1} or mg l^{-1} must be indicated on the label because they cause asthma symptoms in special groups of consumers.

Potassium and sodium salts of nitric and nitrous acids are utilized in nonheat-treated processed meat and cured meat products to inhibit the growth of anaerobic bacteria. They are also effective as color retention agents. Nitrous acid salts are also used in heat-treated processed meat products. The maximum use levels of nitrous acid salts vary between 50 and 150 mg kg^{-1}. Nitric acid salts are added in meat products, at levels varying between 10 and 300 mg kg^{-1}; in milk used for manufacturing ripened cheese and ripened cheese products, at a maximum level of 150 mg kg^{-1}; and in pickled sprat and herring, at a maximum level of 500 mg kg^{-1}.

Propionic acid and its sodium, potassium, and calcium salts are used in baked products, such as breads, rolls, and fine bakery wares with a water activity of more than 0.65, at levels varying between 1000 and 3000 mg kg^{-1}. They prevent mainly bread ropiness caused by the action of *Bacillus subtilis*. These additives are often used in combination with more effective preservatives against mold, such as sorbic acid salts.

Sequestrants

The most important metal chelating agents used in foods are calcium disodium salt of ethylenediaminetetraacetic acid (EDTA) and citric acid. Both substances also find use as color retention agents. Calcium disodium salt of EDTA is used in fats for frying; fat spreads with a fat content of 41% or less; emulsified sauces; canned, frozen, or deep-frozen crustaceans; canned fish; and heat-treated processed meat. Citric acid is used in fats and oils to improve oxidative stability. Other approved sequestrants are citric and tartaric acid salts; ortho-, di-, tri-, and polyphosphoric acid salts; phosphoric acid; and tartaric acid.

Stabilizers and Thickeners

These additives modify the physical properties of water. They provide many functions to foods acting as binders, bodying agents, bulking agents, colloid, emulsion or foam stabilizers, fat substitutes, flavor fixatives, gelling agents, rheology modifiers, suspension agents, and texturizers. Approved stabilizers and thickeners include

- natural polysaccharides obtained from seaweed and plant materials (agar, alginates, carrageenan, carob bean gum, cellulose, guar gum, gum arabic, karaya gum, konjac glucomannan, pectins, soybean hemicellulose, tara gum, and tragacanth gum),
- chemically synthesized polysaccharide derivatives (cellulose derivatives and chemically modified starches) or semisynthetic materials that are manufactured by microbial fermentation (gellan gum and xanthan gum), and
- additives, such as beta-cyclodextrin; fatty acid esters; ortho-, di-, tri-, and polyphosphoric acid salts;, polydextrose; and sugar alcohols.

Citric acid salts, fatty acids, invertase, tartaric acid salts, and triethyl citrate are also utilized as stabilizers in food emulsions. Glycerol, polyethylene glycol, polyvinyl alcohol, pullulan, and talc are also additives used as thickeners.

Most additives used as stabilizers and thickeners are added in foods, excluding infant, baby, and young children foods, at levels in accordance with GMP. Maximum use levels have been established for gums, such as karaya gum, cassia gum, and cross-linked cellulose gum; ortho-, di-, tri-, and polyphosphoric acid salts; propylene glycol alginate; and soybean hemicellulose. These substances are added in concentrations that vary between 0.01% and 4% by weight.

Sweeteners

These natural or synthetic substances, which are mainly used in products with no added sugar or in energy-reduced edible products to imprint a sweet sensation, are classified into nutritive or nonnutritive sweeteners. Sugar alcohols, such as erythritol, isomaltitol, lactitol, maltitol, mannitol, sorbitol, and xylitol, are utilized as nutritive sweeteners. The most commonly used nonnutritive sweeteners are artificial substances, mainly acesulfame potassium, aspartame, aspartame–acesulfame salt, cyclamic acid and cyclamic acid salts, saccharin and its salts (saccharins), sucralose, neohesperidin dihydrochalcone, and neotame.

Other nonnutritive sweeteners used in foods are also steviol glycosides and thaumatin, substances that are isolated from natural sources. Two or more nonnutritive sweeteners are often used in combination for a synergistic intensification of sweetness or for the elimination of their side or posttaste effects.

Sugar alcohols are used as sugar substitutes in food commodities suitable for diabetics because their metabolism is insulin-independent. These substances, with the exception of xylitol, are less sweet than sugar and have a low-calorie value varying between 0.2 kcal g^{-1} (erythritol) and 3.0 mg kg^{-1} (maltitol). They are used for sweetening purposes, at levels in accordance with GMP, in dietary foods, food supplements, and sugar-free or low-calorie foods, such as candies and other confections, cereal-based products and breakfast cereals, chewing gum, chocolate and cocoa products, desserts, edible ices, fine bakery wares, jams, jellies, marmalades, mustard, and sauces.

Nonnutritive sweeteners are added in foods at low or very low levels because they are 30–3000 times sweeter than saccharose. These substances have a taste profile that differs slightly from that of saccharose. They are often used in combination with low-calorie bulking agents. Their use, at levels varying between 5 and 6000 mg kg^{-1} or mg l^{-1}, is permitted in the same food products where sugar alcohols are used and also in other sugar-free or low-calorie foods, such as alcoholic and nonalcoholic beverages (alcohol-free beer, flavored drinks, fruit and vegetable nectars, mixtures of alcoholic drinks, and spirits with less than 15% alcohol, etc.); broths; potato-, cereal-, flour-, or starch-based snacks; processed nuts; salads; sandwich spreads; soups; several fruit and vegetable products; and sweet–sour preserves and semipreserves of fish or fishery products. Neohesperidin dihydrochalcone, neotame, and thaumatin are used as flavor enhancers, at levels not exceeding 5.0, 2.0, and 0.5 mg kg^{-1}, respectively, in some food commodities and food supplements.

Epilogue

The most important changes in legislation during the last decade are the use of additives that are products of biotechnology and the more detailed description of conditions for use of authorized additives in the different categories and subcategories of foods. The tendency of food industry to produce a variety of products with special sensory or technological properties resulted in the use of a greater number of different additives than in the past. There is, however, a trend to limit the level of a number of additives with a low ADI (e.g., nitrous acid salts).

Glossary

Basophil Blood cell that contains mediators of allergic reactions.

Food allergy Illness occurring in some individuals upon ingestion of certain foods that elicit an abnormal immune response in that individual to certain food components.

IgE A class of immunoglobulins (antibodies) involved in allergic reactions.

Mast cell Cell present in many tissues that contains mediators of allergic reactions.

Introduction

Food-allergic individuals in the population experience adverse reactions upon ingestion of foods that are safe and nutritious for the vast majority. Individualistic adverse reactions to foods can occur through a variety of mechanisms including food allergies, metabolic food disorders also known as food intolerances, and food sensitivities. The most serious of these illnesses are food allergies. Food allergies affect a small percentage of the population. Food allergies are caused by an abnormal immunologic response to a particular food or food component, usually a naturally occurring protein component of the food. The most common form of food allergy occurs through an immunoglobulin E (IgE)-mediated mechanism. IgE-mediated allergies are known as immediate hypersensitivity reactions because the symptoms ensue within minutes to a few hours after ingestion of the offending food. However, cell-mediated food allergies, known as delayed hypersensitivity reactions, can also occur with symptoms typically beginning 24–72 h after ingestion of the food. Delayed hypersensitivity reactions to foods are poorly understood with the possible exception of celiac disease.

IgE-Mediated Food Allergy

IgE-mediated food allergies have emerged as an important public health concern in recent decades. While the number of affected individuals is relatively small, IgE-mediated reactions can be quite severe, even life-threatening, in some affected individuals especially if a significant quantity of the offending food is inadvertently ingested. Furthermore, the degree of tolerance for the offending food is small, making the implementation of safe and effective avoidance diets more difficult.

Mechanism

IgE-mediated allergies occur in two phases: sensitization followed by elicitation. While all humans have IgE antibodies, the majority will not produce IgE antibodies specific to a particular allergen. However, in susceptible individuals, allergen-specific IgE antibodies are produced in the body in response to exposure to a specific food protein (allergen) during the sensitization phase. The IgE antibodies are highly specific and will recognize only a specific portion (known as an epitope) of the food protein that they are directed against. Occasionally, IgE antibodies produced against one particular protein in a specific food will confer sensitivity to another food either because the food is closely related or because it shares a common epitope with the allergenic protein. Some food proteins are more likely to elicit IgE antibody formation than others. While exposure to the food is critical to the development of allergen-specific IgE antibodies, exposure will not invariably result in their development even among susceptible people. Many factors including the susceptibility of the individual, the age of exposure, the immunogenic nature of the food and its constituent proteins, and the dose, duration, and frequency of exposure are likely to influence the formation of allergen-specific IgE antibodies.

Once produced, allergen-specific IgE antibodies become attached to the membrane surfaces of two types of specialized cells, mast cells, that are found in many different tissues and basophils, which are found in the blood. The sensitization process is complete once the IgE antibodies are attached to the membrane surfaces of the mast cells and basophils, activating those cells that are then ready to respond to subsequent exposure to that specific food allergen. Sensitization to a particular allergen distinguishes allergic individuals from non-allergic individuals. Normally, dietary exposure to allergenic food proteins elicits no immunologic response whatsoever, known as oral tolerance. Even among individuals susceptible to the development of food allergies, dietary exposure to most food proteins results in oral tolerance. Most food-allergic individuals will become sensitized to relatively few food allergens.

Once the mast cells and basophils are sensitized, subsequent exposure to the allergen initiates the elicitation phase of the allergic response. In this phase, the food allergen cross-links two IgE molecules on the surface of the mast cell or basophil. The interaction between the allergen and the allergen-specific IgE elicits the release of a host of mediators of allergic disease, which are either stored in or formed by the mast cells and basophils. Several dozen different physiologically active mediators are released from the mast cells and basophils including histamine, prostaglandins, and leukotrienes. The mediators are responsible for the symptoms associated with allergies through interactions with receptors in various target organs of the body. The interaction of a small amount of allergen with the allergen-specific IgE antibodies

results in the immediate release of comparatively large quantities of the various mediators into the bloodstream and tissues. Thus, exposure to extremely small amounts of allergens can elicit symptoms.

With food allergies, ingestion is the most common route of exposure to the allergenic food. However, symptoms can also be provoked by exposure through the respiratory tract or the skin. Often, responses to cutaneous or respiratory exposures to food allergens are localized to those target organs. Although consumers can respond to cutaneous or respiratory exposures to allergenic foods, occupational food allergies are known to occur in food industry workers who are exposed by inhalation or skin contact to certain allergenic foods. Baker's asthma associated with inhalation of wheat flour dust among bakery workers is a prime example. Workers with occupational food allergies on cutaneous or respiratory exposures can sometimes eat the offending food with no provocation of symptoms.

Symptoms

IgE-mediated food allergies occur with a short onset time between the ingestion of the offending food and the onset of symptoms. Because the mediators released from the mast cells and basophils can interact with receptors in a number of different tissues in the body, numerous symptoms can be associated with IgE-mediated food allergies as shown in Table 1. Most food-allergic individuals suffer from a few of the many possible symptoms. Symptoms tend to be more severe with higher exposure doses. However, exposure to even trace quantities can elicit noticeable reactions due to the large release of mediators.

Some of the symptoms of IgE-mediated food allergies, for example, the gastrointestinal manifestations and asthma, are not particularly definitive. Thus, clinical diagnosis is sometimes rather difficult. Anaphylactic shock is, by far, the most serious manifestation of food allergies and involves gastrointestinal, cutaneous, and respiratory symptoms in combination with hypotension and cardiovascular complications. Death can ensue within minutes of the onset of anaphylactic shock. Very few individuals with food allergies are susceptible to anaphylactic shock after the ingestion of an allergenic food.

Oral allergy syndrome (OAS) characterized by symptoms confined to the oropharyngeal region (pruritus, angioedema, and urticaria) is the most common and possibly the mildest form of IgE-mediated food allergy. OAS is associated with the ingestion of various fresh fruits and vegetables. In OAS, sensitization occurs to allergens present in pollen such as birch and ragweed. This pollen sensitization increases the likelihood of sensitization to specific foods. Although fresh fruits and vegetables contain comparatively low quantities of protein, sufficient exposure occurs to elicit the oropharyngeal symptoms. The fruit and vegetable allergens involved in OAS are apparently quite susceptible to digestive proteases in the gastrointestinal tract, so systemic reactions are rarely encountered in these foods. These allergens are also apparently heat-labile, since the heat-processed versions of these foods do not typically trigger OAS episodes. In some cases, a more stable allergen called lipid transfer protein has been implicated in allergic reactions to certain fruits, and these reactions are more likely to be systemic and severe.

In some individuals, allergic reactions to foods only occur when the foods are eaten coincident with exercise. Exercise-induced food allergies have occurred with numerous foods including shellfish, wheat, and celery. The symptoms of exercise-induced food allergies are individualistic, variable, and similar in nature to those involved in other food allergies. Exercise-induced allergies also occur apart from food ingestion. The mechanism of this illness is not well understood, although the involvement of IgE antibodies is apparent.

Table 1 Symptoms of IgE-mediated food allergies

Gastrointestinal symptoms	*Cutaneous symptoms*
Vomiting	Urticaria (hives)
Diarrhea	Dermatitis
Nausea	Angioedema
Respiratory symptoms	*Other symptoms*
Rhinitis	Anaphylactic shock
Asthma	Laryngeal edema

Sources

The most common allergenic foods are peanuts, tree nuts (almonds, walnuts, pecans, cashews, etc.), soybeans, cows' milk, eggs, fish, crustacean shellfish (shrimp, crab, lobster, etc.), and wheat. On a worldwide basis, these eight foods or food groups are responsible for perhaps 90% of all food allergies. In the United States, allergies to crustacean shellfish and peanuts are the most common. Peanut allergy tends to be more common in countries where peanuts are frequently consumed. Among infants and young children worldwide, cows' milk and eggs are the most common causes of food allergy due to their widespread use in the diets in this young age group. In the United States, peanut allergy is also relatively common among young children because of the popularity of peanut butter. The prevalence of any specific type of food allergy is related to some extent to cultural food preferences. For example, in Japan and Korea, buckwheat is a commonly allergenic food because of the popularity of soba noodles leading to frequent exposure to buckwheat. By contrast, buckwheat allergy is uncommon in the United States because buckwheat is not frequently eaten in the United States. Different regions of the world recognize different foods as commonly allergenic, although milk, eggs, fish, crustacean shellfish, peanuts, soybeans, tree nuts, and cereal grain sources of gluten (including wheat) are recognized in most countries. Molluscan shellfish (clams, oysters, squid, snails, etc.) and mustard are considered as commonly allergenic in Canada and the European Union. Sesame seed is identified as a commonly allergenic food in Canada, the European Union, and Australia/New Zealand. The European Union also recognizes celery and lupine as commonly allergenic. Mango is recognized as a commonly allergenic food in Taiwan.

Most foods have some potential to cause food allergies. Any food that contains protein has some potential to elicit an allergic reaction. The most common allergenic foods tend to be foods with high protein content that are frequently consumed. However, despite their frequent consumption and high protein content, beef, pork, chicken, and turkey are rarely allergenic.

Food Allergens

The vast majority of the allergens in foods are naturally occurring proteins. However, foods contain millions of proteins and most do not provoke allergic sensitization. Only a very small percentage of all food proteins are known to be allergens. Even within the commonly allergenic foods, only one or a few of the many proteins in those foods are identified as allergens. All proteins are capable of provoking immune reactions under selected circumstances of exposure, but some food proteins do not appear to elicit allergic sensitization. Some allergenic foods, such as peanuts, eggs, milk, and shrimp, contain multiple allergens, but other allergenic foods, such as cod and Brazil nut, appear to contain only a single major allergen. Major allergens are defined as proteins that elicit specific IgE formation in 50% or more of patients having that particular food allergy. Plant food allergens tend to fall into certain functional categories such as some of the pathogenesis-related proteins or certain classes of storage proteins. Legumins, vicilins, and 2S albumins are storage proteins that are major allergens in peanuts, cashews, and walnuts. Similarly, several panallergens appear to exist in allergenic animal species such as parvalbumin in fish and tropomyosin in crustacean shellfish. However, multiple allergens have been identified in other animal-based foods, including milk and eggs.

Prevalence

The overall prevalence of IgE-mediated food allergies in the United States has been estimated as high as 8%. The prevalence of food allergies is higher in infants and young children than in adults. The prevalence of allergies to specific foods is not precisely known, although surveys indicate that the prevalence of crustacean shellfish allergy approaches 2% of the US population, while peanut allergy affects 0.7–0.8% and tree nut allergy affects 0.6%. While milk allergy is relatively uncommon among adults, several studies in various countries have indicated that milk allergy affects about 2.5% of infants under the age of 3 years.

An increasing prevalence of food allergies is apparent in several developed countries, but the prevalence in developing countries is, as yet, rather poorly understood. Multiple factors could be involved in the increased prevalence. The prevalence of food allergies is higher in urban environments than rural areas perhaps because of the prevalence of bacteria in farm environments that promote oral tolerance over allergic sensitization. This observation has led to the promulgation of the hygiene hypothesis that attempts to associate the high degree of cleanliness in the modern-day home with an increased risk for allergic sensitization. Another factor is the increase in cesarean sections, which is associated with an increase in food allergies. This is understandable as the infant's intestinal tract is devoid of beneficial microbiota after cesarean births. Weaning practices (see section '**Prevention**') may be another important factor. Taken together, these factors suggest that the intestinal microbiota influences the development of food allergies, but these interactions are not yet well understood.

Persistence

Some IgE-mediated food allergies are persistent, while others are generally not. Cows' milk and egg allergies are more frequently outgrown than allergies to peanuts. The time period for the development of oral tolerance to milk and eggs ranges from a few months to several years from the time of the onset of the food allergy. More than 80% of food-allergic children develop tolerance to milk and eggs over a period of months to years. Peanut allergy tends to be very persistent, but perhaps 20% of peanut-allergic children do ultimately become tolerant. Even with milk and eggs, a few individuals do fail to achieve tolerance and become milk- or egg-allergic adults. Milk- and egg-allergic children may first become tolerant of certain processed forms of milk and eggs, for example, baked foods, while still sensitive to less heated forms of milk and eggs such as pasteurized milk and scrambled eggs.

Prevention

Strategies do exist to prevent the development of IgE-mediated food allergies in infants. Most infants have a low risk for the development of food allergies, so preventive efforts are typically focussed on those high-risk infants most likely to develop IgE-mediated food allergies. High-risk infants are those infants born to parents with histories of allergic disease of any type (pollen, mold spores, animal danders, bee venom, food, etc.). Several preventive strategies have been advocated for high-risk infants, although consensus on the optimal approach has certainly not been achieved. One strategy involves the exclusion of commonly allergenic foods such as cows' milk, eggs, and peanuts from the infant diet in the early years. This strategy can be accomplished by breast-feeding for an extended period, possible use of hypoallergenic infant formulas, and the exclusion of commonly allergenic foods from the diet of the infant at weaning and the nursing mother and possibly during pregnancy. While the exclusion of commonly allergenic foods from the environment of young infants, especially high-risk infants, seems logical and has been advocated, the efficacy of this approach has not been clinically established. In fact, recent evidence suggests that the early introduction of peanuts into the diets of young infants may actually lower the likelihood of sensitization to peanuts. Exclusive breast-feeding for extended periods of time may only delay, but not prevent the development of IgE-mediated food allergies.

Infants can occasionally be sensitized to allergenic foods through exposure to the allergens present in breast milk. Some food allergens are resistant to maternal digestion, are absorbed to some extent from the small intestine, and are secreted in breast milk leading to sensitization. Accordingly, maternal dietary avoidance of certain commonly allergenic foods, such as peanuts, during the lactation period is advocated to prevent sensitization through breast milk. However, the elimination of certain other commonly allergenic foods, such as milk and eggs, is not recommended for nursing mothers because these foods are usually considered to be too important nutritionally.

The use of probiotic bacteria during lactation may also help to diminish the likelihood of allergic sensitization. However, the results of clinical trials with probiotics have been mixed, and the use of probiotics is not yet commonly practiced in most countries.

Hypoallergenic infant formulas will also prevent the development of food allergies in high-risk infants. Hypoallergenic infant formulas, especially extensively hydrolyzed formulas,

are most often used to prevent reactions after the infant has been sensitized to milk. However, the use of a partial whey hydrolysate formula has been advocated for the prevention of the development of milk allergy in high-risk infants.

Current recommendations for weaning promote the prolonged avoidance of commonly allergenic foods such as peanuts. But, the early introduction of peanuts into the diet may actually induce oral tolerance and prevent later sensitization. At the present time, more clinical research is needed before any particular prevention strategy is advocated.

Diagnosis

Optimally, the diagnosis of food allergies should be conducted by an allergy specialist. Parental diagnosis and self-diagnosis are often incorrect leading to identification of the wrong foods or the identification of too many foods as allergens. First, the physician should take a careful history of the patient's adverse reactions, noting the foods eaten immediately before the onset of symptoms; the amount of various foods consumed; the type, severity, and consistency of symptoms; and the time intervals between eating and the onset of symptoms. Multiple episodes may need to be investigated to link a particular food to an allergic reaction. History alone can be sufficient to make the diagnosis in some situations if the cause-and-effect relationship is particularly compelling. If not, challenge tests with the suspected food(s) may be required to firmly establish the role of a specific food in the reaction. The double-blind, placebo-controlled food challenge is the most definitive clinical approach to document the cause-and-effect relationship with a particular food. A positive challenge test indicates that the food is associated with the adverse reaction but does not establish an IgE-mediated mechanism. The role of IgE can be established with either the skin prick test or use of a blood test for the presence of IgE specific to the particular food.

Treatment

The avoidance of the offending food is the primary means of treatment for IgE-mediated food allergies. With IgE-mediated food allergies, low amounts of the offending food can provoke reactions. Accordingly, the construction of a safe and effective avoidance diet can be difficult. Several common ingredients are derived from commonly allergenic foods such as casein or whey from milk, soy flour from soybeans, or wheat flour, gluten, or semolina from wheat. The avoidance diets must exclude such ingredients. The sources of ingredients derived from commonly allergenic foods must be labeled in the United States and some other countries. Refined oils from allergenic sources such as peanut oil and soybean oil appear to be safe for consumption by allergic individuals because these oils do not contain enough of the allergenic protein to provoke reactions. But, less refined oils, such as expeller-pressed or cold-pressed oils, may contain sufficient allergenic protein to pose a risk to allergic consumers. The careful reading and complete understanding of food labels is critical to the implementation of safe and effective avoidance diets. Packaged food manufacturers have the responsibility to assure that the label statements on packages are accurate. Occasionally, processing errors are made that result in the presence of undeclared residues of allergenic foods in a packaged food. The contamination of one food with another from the failure to adequately clean shared food processing equipment is one of the most common errors occurring in food manufacturing. However, restaurant and other food service meals present an even bigger challenge for food-allergic individuals. The accurate identification of all of the ingredients in food service and restaurant meals can sometimes be quite difficult, and such foods are not labeled. Furthermore, cross contamination can occur from the use of shared food preparation equipment (utensils, cooking surfaces, pots and pans, etc.). As a result, many inadvertent exposures occur among allergic consumers who are attempting to avoid their offending food(s).

Effective avoidance diets are further complicated by cross-reactions that can occur between different foods. Cross-reactions sometimes occur between closely related foods. Common examples would be cross-reactions occurring among the various species of crustacean shellfish (shrimp, crab, and lobster), among the various species of fish (cod, salmon, etc.), or, more rarely, between crustacean and mollusc-an shellfish (clam, oyster, squid, etc.). Cows' milk and goats' milk invariably cross-react as do the eggs of various avian species. Cross-reactivity is not so common among related species in plant foods. Frequently, individuals are allergic to both cashews and pistachios because these two tree nuts are quite closely related. However, among the legumes, many individuals are allergic to peanuts, but most of these individuals are not allergic to other legumes such as soybeans, lupines, peas, and green beans. A few individuals are cross-reactive between peanut and one or more other legumes. Lupine, a legume that is unfamiliar except in the EU and Australia, cross-reacts with peanuts in some allergic individuals. Cross-reactions can also occur between foods and other environmental allergens. The most common examples are the cross-reactions that occur between some fresh fruits and vegetables and certain pollen allergies in some individuals experiencing OAS and the cross-reactions that occur in a few individuals allergic to natural rubber latex with several foods including bananas and kiwis.

Pharmacological approaches can be used to treat the symptoms of allergic reactions. In particular, epinephrine (also known as adrenalin) is prescribed for individuals who experience life-threatening food allergies. The early administration of epinephrine after inadvertent exposure to the offending food can be life-saving for such patients. Antihistamines are also effective in treating the less serious symptoms of food allergies.

Immunotherapeutic approaches are under clinical development for the treatment of food allergies. In these approaches, patients are treated beginning with very small doses of the allergenic food over a period of some weeks until they are able to tolerate more typical doses of the food in their diets. The safety and long-term effectiveness of immunotherapy remain under active clinical investigation.

Minimal Eliciting Dose (Threshold)

IgE-mediated allergic reactions to food can be triggered by very low doses of the offending food in some individuals, although the range of minimal eliciting doses among the entire population of peanut-allergic individuals, for example, is quite wide (fractions of milligrams up to several grams). These

low-threshold doses for the offending food complicate effective avoidance as great care must be taken. The interaction of a rather small amount of allergen with IgE antibodies on the surfaces of mast cells and basophils stimulates the release of large quantities of biologically active mediators into the bloodstream and tissues. Accordingly, exposure to a small dose of the allergen can elicit a clinically significant reaction.

Thus, food-allergic individuals must be cautioned to exercise the complete avoidance of the offending food. However, clinical research has documented that doses do exist, below which allergic individuals will not experience adverse reactions. Although individual threshold data are rapidly emerging, population thresholds have not yet been promulgated by public health agencies. Population thresholds for specific allergenic foods could be used to guide food-allergic consumers in the construction of safe, effective avoidance diets and labeling and other allergen control strategies used by the food industry.

Occurrence of Allergic Reactions

The frequency of the occurrence of allergic reactions to foods among sensitized consumers is unknown. In all likelihood, particularly mild allergic reactions may go unnoticed by affected individuals. However, food-allergic individuals would definitely pay attention to more serious allergic reactions. While accurate records do not exist, tens of thousands of individuals seek treatment in hospital emergency rooms for food allergies each year in the United States. The factors leading up to these visits are poorly understood. Certainly, some unknown fraction of these visits occur among individuals who are experiencing an allergic reaction to food for the first time. But many such reactions are likely occurring among individuals who are aware of their food allergy and who should be avoiding the offending food. Avoidance diets take constant vigilance, and occasional errors are likely to happen.

Food allergy reactions can occur in any location where food is sold or eaten, although homes and restaurants are the most frequent locales. Several factors could lead to the occurrence of moderate to severe allergic reactions among susceptible consumers. Obviously, the food-allergic individual or their caregivers could make an error that leads to inadvertent ingestion of the offending food. Failure to read or understand food labels may also be a contributing factor in some instances. However, food manufacturers or restaurants may also contribute to food allergy reactions. Prevention of errors by food manufacturers or restaurants has become an important public health focus.

Food manufacturing errors can occur including the placement of the incorrect product in the package, the failure to adequately clean shared equipment, the use of rework (a common practice in certain segments of the industry involving the incorporation of leftover or misformulated quantities of a food product into subsequent batches of related products with identical or related formulations), and the inadvertent addition of an ingredient that is not supposed to be in the formulation. With packaged foods, the majority of food ingredients are declared on the ingredient statement on the label. These ingredient statements assist food-allergic consumers in their avoidance diets. Additionally, many food processors have begun to add precautionary labeling to food products, including terms such as 'made on shared equipment with peanuts' or 'may contain peanuts.' This sort of labeling alerts allergic consumers to the possible presence of hazardous residues of allergenic foods in the product.

Restaurants and other food service facilities represent a bigger hazard for food-allergic consumers because foods in restaurants are not labeled, and the waitstaff sometimes fail to provide correct information on menu components to allergic consumers. Additionally, errors can occur in food preparation including the use of shared cooking/serving equipment or surfaces or cooking media and mistakes or substitutions in adherence to recipes. Many adverse reactions have occurred in restaurants, school cafeterias, and similar settings.

Regulations

Public health agencies such as the US Food and Drug Administration regulate the labeling of packaged foods. US regulations require that ingredient statements on packaged foods identify the vast majority of the allergenic foods or ingredients sourced from such foods. While regulations differ around the world, the clear labeling of commonly allergenic foods is a key regulatory component in many countries.

Once regulations are established, they must be enforced. The enforcement of existing regulations is another task for the public health agencies, such as the US FDA. In the United States, one of the fastest-growing areas of recalls of packaged foods from the marketplace is the undeclared presence of allergenic foods. Improved methods for the detection of residues of allergenic foods have been pivotal to the investigation of allergic incidents and the enforcement of labeling regulations.

Detection of Allergenic Food Residues

Over the past several decades, methods have been developed to detect reliably the presence of residues of allergenic foods present in other foods. The food industry uses these detection methods to assure that their manufacturing practices are adequate to eliminate the presence of unwanted allergen residues in other foods. Where residues cannot be effectively and consistently eliminated, then precautionary labeling is often applied. Regulatory agencies can use the detection methods for the enforcement of labeling provisions on packaged foods and to investigate alleged reactions that might be attributable to the presence of an undeclared allergen in packaged foods. Commercial enzyme-linked immunosorbent assays or ELISAs with detection limits in the low ppm ($mg\,kg^{-1}$) range are available for the detection of residues of many of the most commonly allergenic foods including peanuts, eggs, and milk. Polymerase chain reaction assays are also available for the detection of DNA from allergenic food sources.

Effects of Processing on Allergenicity

Typically, food processing operations have little effect on the allergenicity of most foods since the allergenic food proteins tend to be remarkably stable to food processing conditions. Many food allergens are quite stable to thermal food processing. However, some of the allergens in fruits and vegetables are heat-sensitive. Additionally, food allergens tend to be

resistant to proteolysis allowing these proteins to survive digestive processes and arrive in the intestine in immunologically active form. Accordingly, food allergens may survive, in whole or in part, the acid and enzymatic hydrolysis methods used to prepare protein hydrolysates often used as food ingredients. Hypoallergenic infant formula is often manufactured with extensive hydrolysis of milk proteins, but that is one of the few examples where processing has an effect on eliminating or dramatically reducing allergenicity. The removal of protein in edible oil refining serves as another example.

Conclusion

While food allergies affect a small percentage of the population, reactions can range in severity from mild to life-threatening. Food allergies are caused primarily by naturally occurring proteins in foods. Food allergies can be triggered by ingestion of very small amounts of the offending food.

Food Allergies and Occurrence of Food Allergens

Food allergies are adverse immunologic reactions that occur in previously sensitized subjects after the ingestion of the triggering foods or ingredients. In most cases, the causal agent (called antigen) is a single protein or a protein family.

The immunologic reaction is not direct toward the whole protein, but only to certain specific regions, called epitopes. If the immune system recognizes the amino acid sequence (the primary structure) of that region, the epitope is defined as 'linear.' They are usually short amino acid sequences (8–11 amino acids) that are stable to proteolysis in the gastrointestinal tract. When the immune system recognizes the tertiary structure of the epitope, it is defined as 'conformational'; these epitopes are usually less stable to food processing than linear epitopes, because denaturation modifies the tertiary structure of the protein preventing the recognition of the conformational epitope.

Food allergies can be IgE-mediated or not IgE-mediated, depending on the type of antibodies involved. In the classic IgE-mediated food allergy, only IgE antibodies are involved. Two different phases can be distinguished: the sensitization phase and the reaction phase. The sensitization phase occurs during the first exposition of the immune system to the antigen. When a food allergen crosses the intestinal barrier (due to some mucosal defects), the antigen-presenting cells (APCs) recognize the epitopes and they form with them the so-called major histocompatibility complex (MHC). In this way, B lymphocytes are induced to produce specific IgE toward the target epitopes. Specific IgE will bind to the mast cell surface, making them sensitized against the allergen. The reaction phase occurs when the immune system is exposed to the allergen at a later time: the previously sensitized mast cells immediately recognize the allergen and a strong immunologic reaction starts. After the allergen recognition, in fact, mast cells will degranulate releasing proinflammatory mediators (histamine, heparin, and cytokines) that will cause the characteristic allergic symptoms. The severity of these symptoms is highly variable among allergic subjects, ranging from mild gastrointestinal problems to anaphylactic shock. In food allergy, the gastrointestinal tract is not the only target of the symptoms, but also the respiratory tract is frequently involved. The main symptoms are acute urticaria, atopic eczema, gastrointestinal anaphylaxis, and oral allergy syndrome.

In non-IgE-mediated food allergies, other types of antibodies are involved, such as IgA and IgG. Also other cells of the immune system can be involved (e.g., T lymphocyte), so that they are sometimes called 'cell-mediated food allergies.' Usually, non-IgE-mediated food allergies show a less acute and more chronic behavior. The main target is always the gastrointestinal tract, whose damages lead anyway to systemic consequences due essentially to nutrient malabsorption. Classic examples of cell-mediated food allergies are food protein-induced enterocolitis syndrome, food protein-induced proctitis, enteropathy, and celiac disease. Among these, the highest prevalence can be attributed to celiac disease. This is an autoimmune enteropathy that develops in some genetically predisposed subjects after gluten consumption or the ingestion of related proteins of barley and rye. Gluten peptides cross the intestinal epithelium due to mucosal defects and enter the lamina propria. There, they are deamidated by the enzyme tissue transglutaminase 2 and recognized by the APCs that have the heterodimer HLA-DQ2 or DQ8 on their surface, forming the MHC. The complex is recognized by T lymphocytes, which induce the differentiation of B lymphocytes into plasma cells, that produce different types of IgA and IgG antibodies. These antibodies are directed not only toward external agents (antigliadin and anti-deamidated peptides) but also against endogenous components (anti-tissue transglutaminase and anti-endomysium). Moreover, T lymphocytes secrete proinflammatory cytokines that damage the intestinal epithelium structure.

Food allergies affect an increasing number of subjects, with a high variability among countries and for the type of allergen involved. Globally, 220–250 million people are estimated to suffer from food allergy. The disease is more diffused among children, because some food allergies generally disappear in adulthood. The prevalence of food allergies has been estimated to be around 1–3% in adults and 4–6% in children. Food allergens are present in an extremely wide variety of foods (of both vegetal and animal origins), but eight main groups can be identified. It is important to underline that often, allergic patients do not react to a single food, but cross-reaction phenomena are observed. In fact, sequence similarity among the homologous proteins of different species can lead to the recognition of the epitopes by IgE in sensitized subjects. This cross-reaction can be observed also for nonfood allergens, for example, birch pollen.

Among the products of animal origin, the most important allergenic foods are the following:

- *Crustaceans*. This class includes several important foodstuffs, such as crab, crayfish, lobster, prawn, and shrimp. Allergy is mainly caused by the muscle proteins tropomyosin and myosin light chain and by the enzyme arginine kinase. While invertebrate tropomyosin is highly allergenic, vertebrate tropomyosin can be considered safe. The prevalence is variable, with higher percentages where crustacean consumption (thus the exposition) is higher, for example, in Asian countries. Prevalence in the United States is around 2%.
- *Eggs*. The worldwide prevalence of egg allergy is around 1.6–3.2%, and the main proteins involved are contained in the egg white, rather than the yolk. Egg allergy is the second for prevalence (after milk allergy) in children. Ovomucoid (probably the most important allergen),

ovalbumin, ovotransferrin, and lysozyme have already been identified as clearly allergenic proteins.

- *Fish*. Fish allergies are less common than other allergies to seafood, such as crustaceans and mollusks. Most of food allergies directed toward fish have a small calcium-binding protein as target, called parvalbumin. Fish allergies affect around 0.4% of the US population, and it is more diffused in coastal areas (e.g., Norway), where fishing is more common and fish products constitute an important part of the diet.
- *Milk*. Cow's milk allergy is much more diffuse in children (2–3%; the most common allergy) than in adults, where prevalence is around 0.1–0.5%. Allergic reaction is caused by caseins, α-lactalbumin, and/or β-lactoglobulin, depending on the patient. The different sequences of the homologous serum protein and caseins in different animals (cow, sheep, and goat) allow sometimes the consumption of milk from a particular source by subjects allergic to other species. Some hard ripened cheese can be consumed in a moderate amount by some allergic subject, due to the proteolysis that induces the breakdown of the epitopes.
- *Mollusks*. This class includes gastropods, bivalves, and cephalopods. Tropomyosin (a muscle protein) is the generally recognized major allergen of this food category. Subjects allergic to mollusks are often allergic also to crustaceans, due to sequence similarity of tropomyosin. The approximate prevalence is around 0.5–2.5%, with higher percentages in Asia, where shellfish consumption is higher.

Among the products of vegetal origin, the most important are the following:

- *Celery* (*Apium graveolens*). Several allergens were identified, Bet v 1 homologous protein, chlorophyll a/b-binding protein, profilin, and a 55/58 kDa allergen. This type of allergy is pollen-related and it is more frequent in some European countries (Switzerland, France, and Germany), where celery is usually consumed as a raw vegetable.
- *Cereals containing gluten*. The prolamin and glutelin fractions of wheat (*Triticum* spp.), barley (*Hordeum vulgare*), rye (*Secale cereale*), and presumably oats (*Avena sativa*) induce a cell-mediated food allergy in celiac subjects. Gluten constitutes more than 10% (w/w) of wheat and is the main trigger of celiac disease, which affects about 1% of the population. Other cereal allergens are involved in IgE-mediated food allergies: nonspecific lipid transfer proteins, chloroform–methanol (CM)-soluble proteins, and gluten. ω_5-Gliadins are involved in wheat-dependent exercise-induced anaphylaxis, while CM-soluble proteins are the main trigger of baker's asthma, an occupational disease.
- *Lupine* (*Lupinus* sp.). The consumption of lupine is increasing in the last years due to its use as an alternative protein source for vegetarian or gluten-free foods or as a food additive. The main triggers of lupine allergy are conglutinins, more specifically vicilin-like protein (an acid 7S globulin), legumin-like protein (an 11S globulin), sulfur-rich 2S albumin, and basic 7S globulin. Prevalence is still largely unknown.
- *Mustard*. This category is composed of three different species: *Sinapis alba*, *Brassica juncea*, and *Brassica nigra*. Mustard is a spice widely used for the preparation of sauces and dressing, mainly in some Southern European countries such as France and Spain. The main proteins recognized by IgE of allergic patients are 2S albumin, 11S globulin, lipid transfer protein, and profilin. It is more common in France (up to 8.9%), where mustard is mostly grown and consumed.
- *Tree nuts*. This category includes different species: almond (*Prunus dulcis*), Brazil nut (*Bertholletia excelsa*), cashew (*Anacardium occidentale*), hazelnuts (*Corylus avellana*), pecan nut (*Carya illinoinensis*), pistachio (*Pistacia vera*), and walnut. Peanuts are not included, because they are considered legumes. Major allergens are not only 2S albumin, 7S globulin, and 11S globulin but also PR-10 protein, profilin, ribosomal proteins, nonspecific lipid transfer proteins, and oleosin. Prevalence is around 1% of the population.
- *Peanuts*. Major allergens of peanuts (*Arachis hypogaea*) belong to the cupin superfamily (7S vicilin-like globulin and glycinin) and to the prolamin superfamily (trypsin inhibitor and 2S storage protein). Prevalence of peanut allergy is 1–2% of the US population.
- *Sesame* (*Sesamum indicum*). Sesame is used for oil production and it has been recently introduced in the production of bakery products; it is more diffuse in the oriental countries. Allergy to sesame is not very diffused (0.1%) and it is directed against a 2S albumin and oleosins.
- *Soybeans* (*Glycine max*). Soybeans are rarely consumed as such, but they are used for the production of a wide variety of food products, especially as an animal protein replacer for vegetarian food. The triggering proteins of soy allergy are the soybean hydrophobic protein Gly m 1, defensin, profilin, PR-10 protein, β-conglycinin, and glycinin. Prevalence of soy allergy is around 0.2% of the population.

Legislation on Labeling of Foods Containing Allergens

The regulatory frameworks for the labeling of foods containing allergens are highly diverse around the world. In Table 1, the regulatory frameworks of several countries are reported, also including the Codex standard that in many legislative frameworks is used as reference.

Each legislation identifies priority allergens, even if the criteria of inclusion/exclusion in this list are often unclear. The priority allergens in the legislative frameworks reported in Table 1 are given in Table 2.

Five foods are common in all the frameworks: wheat cereals, eggs, milk, peanuts, and crustaceans. Excluding Japan, also fish, soy, and tree nuts occur in every list. These allergens are actually responsible for most of the adverse allergic reactions to foods. Anyway, within every group of foods, the exact description of the species can vary from country to country.

These legislations mostly address the labeling rules when the earlier foods or derivatives obtained from them are used as ingredients in food processing, with the purpose of warning potential allergic consumers of the presence of allergenic ingredients or additives. Most of the implemented regulations include the allergenic ingredient labeling in the preexisting labeling format for ingredients, but more and more, the regulatory frameworks also foresee the use of additional warning 'contains' statements, such as in the United States, Canada, and very recently EU.

Labeling always and only concerns the presence of an allergenic ingredient, with no indications on the amounts. This is

Table 1 Most important food allergen regulatory frameworks

Jurisdiction	*Legislative framework*
Codex Alimentarius	Codex General Standard for the Labelling of Prepackaged Foods (CODEX STAN 1-1985)
Australia	Australia New Zealand Food Standards Code – Standard 1.2.3 – Mandatory Warning and Advisory Statements and Declarations
Canada	Regulations Amending the Food and Drug Regulations (1220 – Enhanced Labelling for Food Allergen and Gluten Sources and Added Sulfites)
China	General Rules for the Labeling of Prepackaged Foods (GB7718-2011)
EU	Regulation No 1169/2011 and Annex II; EU Commission Directive 2007/68/EC and Annex IIIa; EU Commission Directive 2003/897/EC and Annex IIIa
Japan	Standards and Evaluation Division, Department of Food Safety, Pharmaceutical and Medical Safety Bureau, Ministry of Health, Labour and Welfare
The United States	Food Allergens Labeling and Consumer Protection Act of 2004

due to the enormous difficulty of setting commonly agreed thresholds for consumer protection, given the extreme diversity of the allergic subjects as far as sensitivities are concerned. The absence of agreed thresholds implies that no labeling of the format 'allergen-free' has been implemented yet, being unclear what the threshold level for the 'free' declaration is. A striking exception is the gluten-containing products: since a threshold safety level of 20 ppm has been agreed, whenever a food contains <20 ppm of gluten, it can be labeled 'gluten-free.'

All the earlier labeling rules only concern the use of allergenic foods as ingredients, whereas their adventitious presence as contaminants (the 'hidden' allergens) is usually not covered by the earlier legislations.

Impact of Food Processing on the Allergenic Properties of Food Allergens

During processing, food proteins can undergo a series of modifications, including protein unfolding and aggregation, chemical modifications, and proteolysis. Only in the most extreme cases, proteins are degraded in smaller peptides, but very often, they at least experience alterations in the tertiary and secondary structures, through heating, pH changes, or adsorption to surfaces. As a common consequence, many proteins in food matrices can also undergo aggregation. All these modifications have the potential to alter their allergenic potential, both directly, affecting the way in which the proteins present themselves to the immune system, and indirectly, affecting their resistance to gastrointestinal digestion. The length of treatment, pH, temperature, and the presence of other components potentially interacting with proteins (sugars and fats) all affect the kinetic of food protein denaturation and aggregation. Allergens might roughly be divided into processing-labile and processing-stable ones.

The best example of processing-labile allergens is represented by the proteins of the Bet v 1 family of plant allergens, since they often contain conformational epitopes easily lost upon protein unfolding. Thus, as a general rule, processing will reduce the allergenicity of proteins belonging to the Bet v 1 family, but not surprisingly, also the type of processing has a high impact. For example, cooking cherries usually reduces their allergenicity, whereas roasting hazelnuts has very little impact on their allergenic potential. This is likely due to the fact that heating in a wet environment, as it is cooking, helps denaturation, whereas heating in a dry environment, like roasting, is a very inefficient way to denature proteins. Moreover, not all the members of the Bet v 1 family are equally thermolabile, with some being more stable than others. Gly m 4 from

soy is more thermostable than Mal d 1 from apple, and this can relate to the observations that the former protein can trigger allergic reactions even in highly processed soy products.

On the other side, allergens of the prolamin superfamily exhibit a very stable structure, due to disulfide bridges providing resistance to a variety of denaturing conditions, including low pH, chaotropic agents, high temperatures, and high pressures. 2S albumins and lipid transfer proteins (LTPs) belong to this class, and thus they retain their allergenic properties also in processed foods. High thermal processing does not reduce allergenicity of peach juices or apple peels, if due to these proteins, and similarly, allergenicity to maize LTP is retained also after cooking polenta. These findings correlate with the observation that subjects allergic to these proteins often undergo very severe reactions. Thermal treatments also reduce allergenicity to milk whey proteins, by a proportion that it is usually related to the length and the harshness of the thermal treatment.

Besides proteins having thermally stable structures, there are proteins that are mostly recognized through linear epitopes; thus, even if unfolded or partially unfolded by thermal treatments, they fully maintain their allergenic potential. Two major proteins falling in these categories are milk caseins and wheat gluten.

The loss of the folded structure is not the only consequence of thermal treatments. Several chemical modifications can occur to the amino acid side chain upon heating, the most notable being the Maillard reaction between free amino groups (mostly from lysine residues) and aldehyde or ketone groups from sugars, which lead to further rearrangement giving rise to diversely glycated proteins. Glycated proteins might undergo cross-link and increase their IgE-binding abilities, leading to increased allergenic potential of modified proteins. This has been observed, for instance, in the case of peanut allergens Ara h 1 and Ara h 2 and shellfish tropomyosin. However, glycation of fruit allergens, on the other side, does not seem to increase their allergenic potential.

In conclusion, there are no clear rules on how the food processing impacts the allergenic potential of the food proteins. Some allergens show a decreased allergenic potential upon treatment, others are unaltered in their allergenicity, and some can even show an increase. It is anyway clear that the response of the single individuals to allergens can be highly affected by the processing, requiring more deep insights on the matter.

Digestibility of Food Allergens and Correlation with the Allergenic Potential

The analysis of many allergenic foods indicates that many, but not all, common food allergens share the characteristic of being resistant to gastrointestinal digestion. This means that a significant portion of the intact protein might survive intact for a long time in the hostile (for proteins) gastrointestinal environment, thus increasing the chances of triggering an immune reaction. Such resistance to enzymatic digestion is often (but not always) accompanied by a similar resistance to heat treatments or other denaturing processes, leading to the suggestive concept that a general 'robustness' of the structure is a requisite, increasing the chances for a protein to become an allergen.

For milk and wheat allergens, indeed, the resistance to pepsin digestibility was well related to the induction of an allergic response, being these allergens quite resistant to pepsin attack. When the susceptibility to pepsin was increased by reducing disulfide bonds, and the allergens become more readily digested by pepsin, as a consequence, their ability to induce an allergic response was also highly reduced. Even if not all allergens are perfectly resistant to pepsin, it is true that all food allergens are more resistant to pepsin hydrolysis than common plant proteins. In the standard conditions of pepsin assay, intact plant allergens or significant portions of them were found to resist from 8 to 60 min, whereas nonallergenic plant proteins never resisted for more than 15 s. Even if the exact duration of the resistance was subsequently challenged by further experiments, nevertheless, the basic finding that allergen proteins are generally more resistant to enzymatic digestion was confirmed. Further studies on the peanut allergen Ara h 2 demonstrated that food allergen structure is linked to the stability of digestion and in turn to its ability to elicit an allergenic response through binding to the IgE.

Further studies with more sophisticated digestion models strictly simulating the gastrointestinal fluids challenged again this view, demonstrating that food allergens might be more, or equally, or less susceptible to digestion as compared to nonallergenic proteins, so digestibility alone, or rather the resistance to it, is not per se a causal reason for the induction of an allergic response. Moreover, among allergens, the resistance to digestion is a poor predictor of the potency of the allergenic response. For example, ovalbumin, a major egg allergen, is degraded in simulated gastrointestinal fluids in <5 min, whereas lysozyme, a minor allergen, is stable for more than 60 min. Alpha-casein, a major milk allergen, degrades more rapidly than bovine serum albumin, a very minor allergen.

So, even if a certain resistance to digestion seems to be a common tract of many allergens, the resistance to digestion alone is not per se the reason why a protein becomes an allergen.

Analysis of Food Allergens

Analysis of food allergens is of outmost importance from two different points of view: first, for the detection of food allergens in food and, second, for the study of the molecular features of food allergens.

Detection of food allergens is of basilar importance for the safety of allergic subjects. Since the allergic response is highly variable among subject and the type of allergy, a defined 'safe threshold' for food allergens cannot be defined. Moreover, the dose–response effect is not proportional, and in some allergic subjects, even a small trace of the triggering food can provoke serious consequences, even anaphylactic shock. So, detection of food allergen requires very sensitive and accurate methods in order to ensure protection of allergic subjects. Different approaches can be used for the detection of food allergens, but two main categories can be identified: DNA-based methods and protein-based methods. The latter are based on immunoassays or on mass spectrometry methods.

DNA-based methods are indirect detection methods: they do not detect the allergen itself, but the DNA of the allergenic ingredient. These methods are based on a real-time polymerase

chain reaction (RT-PCR) and can be qualitative (present/absent) or quantitative. In this latter case, it is necessary to have a suitable standard of the allergenic ingredient (at known concentration) to construct a calibration curve. The target genes do not necessarily encode for the specific target allergen, but they are species-specific for the organism of origin. Several problems arise from this; for example, different food ingredients cannot be distinguished, for example, chicken from egg or milk from beef. Detection can be achieved using fluorescent probes (gene-specific) or SYBR Green (nonspecific; it binds to double-stranded DNA). DNA can be extracted from the food matrix using different extraction procedures on the basis of the starting material. Briefly, cell membranes must be disrupted with detergents, and RNase treatment is necessary to degrade RNA that could interfere with the subsequent quantification and amplification. DNA is then purified using column for cleanup in which sugars, proteins, and salts are washed away. Primers (and eventually probes) are designed on a single- or multicopy gene of the target organism. Once a correct fluorescence threshold is fixed, the number of amplification cycles necessary to reach that value will be inversely proportional to the $\log_{10}$ of gene copies present in the sample. These methods are very sensitive and extremely specific (genotype is very stable) and able to detect $<0.001\%$ of allergenic ingredient (ten DNA copies are enough to achieve a correct amplification). Better performance is obtained in raw food matrices, because during food processing, DNA can degrade due to heat treatment or hydrolysis processes. DNA degradation can affect both DNA extractability from the matrix and DNA length: if the target gene is hydrolyzed, allergen content can be underestimated or even not detected. The different stability of nucleic acids and protein to technological treatments can lead to controversial results: DNA can be still detectable even when the allergenic protein is denatured and not anymore allergenic (false-positive), or, on the opposite, DNA could not be present (or it can be present in too short fragments to be amplified) but the allergen could still be intact. PCR-based methods were developed for a wide variety of allergenic foods: cashew, peanut, hazelnut, celery, sesame, lupine, mustard, pea, pecan nut, pistachio, soy, walnut, etc. A lot of ready-to-use kits are also available on the market and easily employable in routine analysis.

Protein-based methods can rely on the recognition antigen–antibody and they can be classified into ELISA (enzyme-linked immunosorbent assay) tests and LFD (lateral flow device) tests. These methods can be direct, if the target protein is the allergen, or indirect, if they detect a specific protein of that species that is not the allergenic one. They can be qualitative or quantitative: In this latter case, a standard of the allergen is required for the construction of the calibration curve. The limit of quantification varies in function of the analyte and of the food matrix, but usually, it is around a few ppm. ELISA tests can be further divided into two types: sandwich assays and competitive assays. In both cases, it is necessary to extract the protein fraction from the food matrices, and the protocol varies depending on the allergen type and the food matrix; usually, the use of denaturing and reducing agents is required. In sandwich ELISA, the wells are coated with monoclonal (highly specific) or polyclonal (less specific but sometimes more sensitive) antibodies specific for the target protein. When the protein extract is added, the antibodies on the well surface will recognize the antigens, while other compounds are washed away. The detection is achieved by means of a second antibody that will recognize a second epitope on the previously bound protein. This latter antibody is functionalized with an enzyme catalyzing a chromophore reaction. So, the absorbance can be measured spectrophotometrically and it is directly proportional to the amount of antigen. Sandwich-type immunoassays require thus that two epitopes are present on the same polypeptide, and this can lead to an underestimation of the allergen content in the case of foods undergone to a certain degree of hydrolysis. To overcome this problem, some competitive ELISA assays were developed. In this type of assay, the protein extract is incubated with specific antibodies that will recognize the antigen. Then, the mixture is added to antigen-precoated wells, where the remaining free antibodies will bind to the fixed antigen. Other compounds are washed away and the detection is achieved using a second antibody that will recognize the first one. The secondary antibody is functionalized with an enzyme catalyzing a chromophore reaction. So, the absorbance can be measured spectrophotometrically and it is inversely proportional to the amount of antigen. Finally, in LFDs, a drop of the protein extract is placed at the beginning of a strip where it will contact specific antibodies previously adsorbed. The antibodies will bind to the antigens and the complex will migrate for capillarity toward a second line, where another series of antibodies is placed. These antibodies will recognize the antigen–antibody complex previously formed, and the reaction can be monitored colorimetrically. They are only semiquantitative but useful for the on-line monitoring of cleaning processes. Protein-based assays are simple, easy, and fast, so they find broad application in quality control laboratories. Some limits to the detection can arise in the case of processed foods, where protein denaturation can strongly reduce their extractability and thus their detectability. A lot of commercially available kits are on the market for quite all the type of allergens. The different extraction protocols and the different antibodies used in every kit lead to a sometimes high interkit variability, with serious issues for the safety of allergic subjects and for the legal issues.

In the recent years, the development of mass spectrometry also had an impact in the field of allergen analysis. The technique is based on the enzymatic digestion of a protein extract or of the whole-food matrix. Then, specific marker peptides are identified for the allergenic protein. This method is direct and with a specificity comparable with that of DNA-based methods. The method can be not only qualitative (detection of the marker peptide) but also quantitative. In this latter case, a standard is necessary and the quantification can be carried out in two different ways. If there is availability of the standard of the allergenic protein, it can be digested in matrix in different concentrations in order to obtain a calibration curve. The lack of the protein standard can be overcome by direct synthesis of the marker peptide, which can thus be used for the quantification. The implementation of multiple reaction monitoring methods allows us to obtain limit of detection and of quantification comparable to those of RT-PCR and ELISA assays. At the moment, the use of mass spectrometry detection of food allergens is more suitable for confirmation analysis than for routine, since it requires very expensive equipment and trained specialists.

History and Purpose of the Food and Agriculture Organization

The Food and Agriculture Organization (FAO) of the United Nations is an autonomous agency within the United Nations (UN) system. The organization had a membership of 180 countries in 2001.

In 1943, world leaders met at Hot Springs, Virginia, the United States, and determined to lay a framework for peace through international cooperation in food and agriculture. The meeting, the UN Conference on Food and Agriculture, decided on the establishment of permanent organization in the field of food and agriculture and set up an interim commission to prepare a specific plan. This commission worked for 2 years and prepared the constitution of the FAO. The signing of the constitution and the opening of the first FAO Conference were arranged to take place in Quebec, Canada, on 16 October 1945. Representatives from 44 nations met at this date and established the FAO, the first of the UN agencies. As the commemorative tablet in Canada states, "Thus for the first time nations organized to raise levels of nutrition and to improve production and distribution of food and agricultural products." The FAO's goal is enshrined in its motto, "*Fiat Panis* – Let there be bread."

The FAO Conference is the governing body and is composed of all member nations. It meets every 2 years and is a major forum for the discussion of food and agriculture issues. It is able to take concerted action on issues of concern to its members. Recent initiatives include the adoption of the World Food Security Compact and the International Code of Conduct on the Distribution and Use of Pesticide.

The FAO Conference elects a council to which a series of committees, such as the Committees on Commodity Problems, Fisheries, Agriculture, Forestry, and World Food Security, report. Many bodies have been set up by the FAO Conference and Council to foster cooperation in particular subject areas. In adopting the International Undertaking on Plant Genetic Resources in 1983, for example, the FAO Conference provided for the establishment of the Commission on Plant Genetic Resources to guide the FAO on policy and to monitor the implementation of the undertaking. The Commission on African Animal Trypanosomiasis was established in 1979 to coordinate a large-scale FAO program to control the disease. Another example is the cooperation of the FAO with the World Health Organization (WHO) through the Joint FAO/WHO Codex Alimentarius Commission, which has issued some 200 international food standards.

Along with these bodies, the FAO organizes conferences and meetings on particular issues. For example, the FAO-serviced World Food Conference in 1974 resulted in a series of measures to promote world food security. In December 1992, the first International Conference on Nutrition (ICN) was held in the FAO's headquarters in Rome. It was jointly sponsored by the FAO and the WHO. At this conference, the World Declaration and Plan of Action for Nutrition were unanimously adopted, committing governments to prepare their National Plans of Action for Nutrition containing attainable goals and measurable targets based on the principles and relevant strategies agreed at the ICN. World leaders assembled in Rome in November 1996 for the World Food Summit aimed at renewing global commitment to the fight against hunger. The FAO called the World Food Summit in response to widespread undernutrition and growing concern about the capacity of agriculture to meet future food needs.

Besides being a major forum for the discussion of food and agriculture matters, the FAO is an information center collecting data related to its field of work. It also acts as an adviser to governments, being a useful source of independent advice on agricultural policy and planning, on the administrative and legal structures needed for development, and on ways of ensuring that national development strategies are directed toward rural development and the alleviation of poverty and malnutrition. Its role as a development agency should be highlighted: the FAO gives direct, practical help in the developing world through technical assistance projects in all areas of food and agriculture (including fishery and forestry). These field projects strengthen local institutions, assist research and training, and develop and demonstrate new techniques.

Food Security and Nutrition

The idea of international action to achieve world food security was launched by the FAO in early 1973. The international undertaking in world food security contains a set of general principles for stockholding, special assistance to developing countries (including aid to increase production), the exchange of information, and arrangements for consultations. The concept has developed further. Today, the objective of the world food security concept is to ensure that all people at all times have both physical access and economic access to the basic food they need. Its more specific aims are related to production, with special emphasis on low-income food-deficit countries, stability in the flow of supplies, and the problems of access to available supplies on the part of needy nations and social groups.

The search for policies that would cope with food shortages and surpluses has been one of the main threads in FAO history. Various activities contributed to the preparation of such a policy, including the following: expanding production, improving nutrition, stabilizing prices, obtaining a fair return for producers, and coping with famine.

Nutrition was a dominant theme at the Hot Springs Conference, with the adoption of eight resolutions dealing exclusively with various aspects of nutrition, far more than on other subjects. There is no single formula for curing malnutrition. The best approaches vary, according to local and national

circumstances. The development of policies for food and nutrition is largely a question of orienting sectoral activities to have an impact on nutrition. Thus, from the mid-1970s, the FAO worked closely with a number of governments on the incorporation of nutritional objectives into development plans.

A mass of information on every aspect of food and agriculture (including production, supply, demand, prices, and technology) is needed if government planners, traders, scientists, farmers, and technologists in every country in the world are to make rational decisions on planning, investment, marketing, research, or training. The FAO provides that essential information for food policy planning. For example, the Global Information and Early Warning System on Food and Agriculture monitors production conditions and food supply prospects worldwide and issues warnings when there are indications of trouble. The role of world food surveys cannot be overemphasized in the assessment of world nutrition status. The FAO prepares these surveys for collecting essential data on the world's food problems. These data are analyzed and distributed to all member countries and concerned bodies as reference data for the elaboration of food policies at world or national levels. At the time of writing, the latest survey is the sixth one, published in 1996.

In addition to its tasks of collecting, analyzing, and disseminating information, advising governments on food and agriculture (including fishery and forestry) policy and planning, and providing opportunities for governments to meet and discuss food and agriculture problems, the FAO carries out a major program of technical advice and assistance for the agricultural community on behalf of governments and development funding agencies. The FAO is involved at every stage of agricultural development, from demonstrating new cultivation techniques to subsistence farmers to advising governments on how to achieve more stable and equitable international trade in agricultural commodities.

Food Control

In the past several decades, nations have experienced extensive changes and faced new or greater problems in assuring adequate national food security, trade, and health. This trend is continuing for the following reasons: intensification of farm production and the centralization of food manufacturing; the development of large urban markets remote from the agricultural production areas; markets and consumer demands for consistent supply of safe, uncontaminated, and good-quality food and food products; the economic dependency of many countries on revenues from agricultural food exports; and the rapid growth in global food trade.

Within the overall mandate of the FAO with regard to production, distribution, and marketing of food, and for nutrition improvement, the necessity of providing a safe, wholesome, and nutritious food supply, and the protection of this supply from losses, waste, deterioration, contamination, and adulteration, is implicit. It is interesting that the Hot Springs Conference noted that the FAO would play a role in ensuring "protection of the public, through the medium of pure-food laws, against impurities for adulteration and against unfair competition and undesirable trade practices." It recommended that the FAO should "assist governments to extend and improve standards of nutrient content and purity of all important foods." In view of this, the FAO has developed programs to assist governments to orient their country policies and programs so as to include nutrition improvement and food protection as specific objectives.

Food safety and quality start at the farm level and continue throughout the processing and distribution chain to storage and final preparation by the consumer. Good agricultural, processing, distribution, and marketing practices are essential to ensure consumer protection. Now, more than ever, food control programs are needed in order to assure that foods are safe for consumption and are sold to the consumer on fair terms; furthermore, such programs should help to reduce food losses caused by improper handling or spoilage of raw materials, prevent 'dumping' practices of shipping nonstandard (low-quality or contaminated) food products to countries that do not have the capability of food control, and increase the earnings of foreign currency necessary for the implementation of development plans. Food control, including standards, is therefore an integrated part of the programs developed by the FAO.

Issues relating to food safety and food control draw considerable public attention and represent an important concern for governments, consumers, and the industry alike. They need to be addressed at the national level by adequate legislation, which should be developed in cooperation with all interested sectors and implemented efficiently.

The Economic and Social Development Department of the FAO and especially its Food and Nutrition Division (ESN) are the main bodies responsible for the programs oriented to guarantee food quality and safety and consumer protection. Within this division, the Food Quality and Standards Service focuses on activities in the field of food control. These activities are implemented through the Food Standards Group, which provides the Secretariat for the Codex Alimentarius Commission of the Joint FAO/WHO Food Standards Programme, and the Food Quality and Consumer Protection Group, which assists developing countries in the formulation and development of effective food control programs and gives scientific and technical support to the Codex Alimentarius Commission. Technical assistance provided by the FAO in food control is based upon the fundamental elements that all effective programs must consider:

- A basic food law complemented by detailed regulations that provide for correct hygienic practices in food and agricultural production and processing; the establishment of food standard and codes of practice; the correct use of food additives, pesticides, etc.; and the proper use of labeling to avoid consumer deception
- An effective administration of such laws and regulations through an organization, which includes technical officers, inspectors, laboratory personnel, and compliance officers, together with the necessary infrastructure to carry out their tasks adequately
- A well-informed consumer, aware of the problems related to food control, especially with respect to good handling practices and storage
- Food producers, processors, and handlers who cooperate with government agencies in assuring food quality and safety

In order to ensure food security, facilitate trade, and protect consumers, the development of the following activities receives special consideration from the FAO:

- Support of developing countries in strengthening their national strategies for quality and safety, food control systems, and contamination monitoring programs
- Preparation of food legislation, regulations, and standards on a national, regional, or international basis accordingly to meet changing consumer demands (e.g., food irradiation and biotechnology), new food ingredients (e.g., vegetable proteins), and new food safety concerns (e.g., veterinary drug residues and radionuclides)
- Technical assistance in training for food control inspectorate and laboratory personnel and for food control management staff

Joint FAO/WHO Food Standards Programme Codex Alimentarius Commission

The Hot Springs Conference noted the role of government services in ensuring the protection of the public. It recommended that the FAO, when established, should "consider the formulation and adoption of international standards to facilitate and protect the interchange of such products between countries, and agree upon international methods of determination."

In 1958, work was begun by the FAO/WHO Committee of Government Experts, in collaboration with the International Dairy Federation, on the establishment of the Code of Principles concerning Milk and Milk Products and compositional standards for milk products. A further development that took place in 1958 and that was to prove to be of great importance to both the FAO and the WHO in introducing an international program for the elaboration of food standards was the creation of a body known as the Codex Alimentarius *Europaeus*. In 1961, the Council of the European Codex Alimentarius adopted a resolution proposing that the work should be taken over by the FAO and WHO. From that moment, matters moved quickly, and the Codex Alimentarius Commission was established in 1962 by the decision of the FAO Conference and the WHO Executive Board.

The basic objectives were precisely those put forward at Hot Springs: removal of nontariff trade barriers caused by differing national food legislation, ensuring fair practices in international trade, and protection of the consumer against health risks and fraud. The commission assumed the role of an international forum for elaborating standards for foods moving in international trade and for providing guidance to countries wishing to create their own national food laws and regulations.

The Uruguay Round of multilateral trade negotiations concluded at Marrakesh in April 1994. It established the new World Trade Organization (WTO). Among the agreements were the Agreement on the Application of Sanitary and Phytosanitary Measures (the SPS Agreement) and the Agreement on Technical Barriers to Trade (the TBT Agreement). Both of these agreements are relevant in understanding the international dimensions of food. The SPS Agreement encourages the use of international standards, guidelines, or recommendations where they exist and identifies those of Codex Alimentarius (relating to food additives, veterinary drugs and pesticides residues, contaminants, methods of analysis and sampling, and codes and guidelines of hygienic practices), as consistent with provisions of the SPS. Thus, the Codex Alimentarius standards serve as a benchmark for a comparison of national sanitary and phytosanitary measures. The TBT Agreement also recognizes international standards where they exist. It requires that technical regulations on traditional quality factors, fraudulent practices, packaging labeling, etc., imposed by countries not be more restrictive on import products than they are on products produced domestically.

Membership of the Codex Alimentarius Commission is open to all member nations and associate members of the FAO and/or WHO. In 30 years, the commission has grown from the original 30 countries that were present at its first session in 1963 to 165 member countries in 2001. The distribution of member countries is as follows: Africa, 41; Near East, 19; Asia, 21; Europe, 40; Latin America and the Caribbean, 31; North America, 2; and Southwest Pacific, 11. The commission has an executive committee and 29 subsidiary bodies. All of these bodies, like the commission, are intergovernmental in character. The composition of the executive committee is such as to ensure an adequate representation of the various geographic areas of the world to which the members of the commission belong. The executive committee makes recommendations to the commission regarding the general orientation of the program of the work.

The main activities of the commission have been concerned with the development of international worldwide standards for foods as well as other texts on related matters, their publication in the Codex Alimentarius, and the registration of acceptances by member governments of standards. In addition, the commission, through its subsidiary bodies, is concerned with the elaboration of advisory codes of practice, which are adopted within the Codex Alimentarius. The commission determines priorities and initiates and guides the preparation of draft standards, whether by its own subsidiary bodies or with the assistance of other appropriate organizations.

During its lifetime, the Codex Alimentarius Commission has elaborated more than 230 individual commodity standards, 37 codes of hygienic and technological practices, and maximum residue limits (MRLs) for pesticides covering more than 3000 potential pesticide plant and animal combinations. The Codex Alimentarius itself contains standards on the following: processed, semiprocessed, or nonprocessed food products; raw materials used in manufacturing; labeling; nutrition information; food additives; contaminants; pesticide residues; veterinary drug and hormone residues in food; methods of analysis; sampling; codes of practice; and guidelines and other recommendations. All of the previously mentioned have been published in 16 volumes of the Codex Alimentarius.

Labeling

Food labeling is the primary means of communication between the producer and the consumer. One of the most vexatious problems that exporters of foodstuffs are likely to encounter is the wide disparity between different countries'

requirements with regard to labeling. The work of Codex Alimentarius in devising and issuing the General Standard for the Labelling of Prepackaged Foods must be regarded as a landmark, a major achievement, in international recommendations for food legislation.

The Codex Alimentarius has issued the Guidelines for the Production, Processing, Labelling, and Marketing of Organically Produced Foods. These guidelines set out the principles of organic production at farm, preparation, storage, transport, labeling, and marketing stages and provide an indication of accepted permitted inputs for soil fertilizing and conditioning, plant pest and disease control, and food additives and processing aids. For labeling purposes, the use of terms inferring that organic production methods have been used are restricted to products derived from operators under the supervision of a certification body or authority.

Nutrition Information

Consumer demand for nutrition information is growing, stimulated by the media, whose interpretation and presentation of the views of nutrition scientists and on national policies are not always balanced or accurate. Few consumers have any systematic training in nutritional matters or easy recourse to reliable information sources. The natural concern for the family health leads them to use the media as their information source. The problem faced by the Codex Alimentarius was how to regulate it so that accurate and balanced information could be presented without creating a rigid system. The Guidelines on Nutrition Labelling have been issued to ensure that nutrition labeling is effective:

1. Providing the consumer with information about a food so that wise choices can be made
2. Providing a means for conveying information of the nutrient content of a food on the label
3. Encouraging the use of sound nutrition principles in the formulation of foods that would benefit public health
4. Providing the opportunity to include supplementary nutrition information on the label

Nutrition labeling should not describe a product or present information that is in any way false, misleading, deceptive, or insignificant in any manner, to ensure that no nutritional claims are made without nutrition labeling.

Food Additives

The use of food additives is becoming more important in the production and worldwide distribution of food. As the demand for variety increases, and with it the desire to purchase goods from distant lands, the importance of food additives will increase, rather than diminish. None the less, this is a topic of great consumer concern, and the Codex Alimentarius has always treated it as such through the Codex Committee on Food Additives and Contaminants (CCFAC). The CCFAC considers technological needs on the one hand from information supplied by Codex commodity committees. On the other hand, it applies safety considerations based on the reports of the Joint Expert Committee on Food Additives. The CCFAC follows a risk-based approach to develop the General Standard for Food Additives, which includes a list of additives that can be used in accordance with good manufacturing practice and specific levels of use for a number of additives for which an acceptable daily intake (ADI) has been established.

Contaminants

The term 'contaminants' is used to denote the presence in food of traces of undesirable elements of substances, for example, traces of lead, cadmium, polychlorinated biphenyls, or even radioactive fallout. The CCFAC is responsible for establishing permitted maximum or guideline levels for individual food additives, for contaminants (including environmental contaminants), and for naturally occurring toxicants in foodstuffs and animal feeds. The establishment of maximum levels for contaminants is a complex subject, and there are specific difficulties to address in order to reach an agreement at the international level in this area. Sometimes, the complete or updated risk assessment is lacking, especially exposure assessment, and there is a need to update the scientific information. In addition, legislation in member countries differs widely, especially between exporter and importer countries, and it is difficult to come to a consensus; there are also several technical problems to be addressed, especially as regards methods of analysis and sampling or inspection procedures.

Pesticide Residues

The use of pesticides is essential in agriculture and horticulture if crop yields are to be economically viable and, indeed, if crops are to be successful. The fact that residues can remain in the food is another topic of considerable consumer and even wider concern. There is well-justified concern that an unrestricted and uninformed use of these substances could damage health. The Codex Committee on Pesticide Residues, on the basis of the work of the FAO/WHO Joint Meeting (Committee of Experts) on Pesticide Residues (JMPR), has established MRLs.

MRL is the maximum concentration of a pesticide residue (expressed as milligrams per kilogram) recommended by the Codex Alimentarius Commission to be legally permitted in or on food commodities and animal feeds. MRLs are based on good agricultural practice data, and foods derived from commodities that comply with the respective MRLs are intended to be toxicologically acceptable.

Codex MRLs that are primarily intended to apply in international trade are derived from estimations made by the JMPR as follows:

1. Toxicological assessment of the pesticide and its residue.
2. Review of residue data from supervised trials and supervised uses including those reflecting national food and agricultural practices. Data from supervised trials conducted at the highest nationally recommended, authorized, or registered uses are included in the review. In order to accommodate variations in national pest control

requirements, the Codex MRLs take into account the higher levels shown to arise in such supervised trials, which are considered to represent effective pest control practices. Consideration of the various dietary residue estimates and determinations at both the national level and the international level in comparison with the ADI should indicate that foods complying with the Codex MRLs are safe for human consumption.

Food Hygiene

Poor food hygiene is a major cause of human illness. Most hygiene problems are caused by faulty handling of food and, in the case of processed or packaged food, often occur after manufacture and packaging. There are powerful reasons for the great attention paid by the Codex Alimentarius to food hygiene. In matters of hygiene, it is especially true that good practices and economic benefits go hand in hand. The establishment of effective good manufacturing practice as regards hygiene is relatively simple in principle but is far from simple in practice.

The Codex Alimentarius has issued a code of practice and the General Principles of Food Hygiene. These general principles lay a firm foundation for ensuring food hygiene. The document follows the food chain from primary production through to final consumption, highlighting the key hygiene controls at each stage. It recommends a hazard analysis and critical control point (HACCP)-based approach, wherever possible, to enhance food safety. The HACCP system, which is science-based and systematic, identifies specific hazards and measures for their control to ensure the safety of food. HACCP is a tool to assess hazards and establish control systems that focus on prevention rather than relying mainly on end-product testing.

Principles for the establishment and application of microbiological criteria for foods have been approved by the Codex Alimentarius Commission. These principles are intended to give guidance on the establishment and application of microbiological criteria for foods at any point in the food chain from primary production to final consumption.

Current Issues

Matters related to biotechnology are at the center of considerable debate in many countries and also at the international level. In the framework of Codex Alimentarius, the commission decided to establish the Task Force on Food Derived from Biotechnology, in order to ensure a comprehensive approach and to consider safety, nutrition, and all relevant aspects of genetically modified organisms (GMOs) and food produced from GMOs.

Several food safety issues are related to animal feeding, especially contamination of feed with mycotoxins and other contaminants. This question drew the attention of the media owing to the recent occurrence of contamination with dioxins in feeds, but there are also several other issues, including the bovine spongiform encephalopathy. The commission decided to establish a specific Task Force on Animal Feeding to consider all aspects that can affect food safety. Another important emerging issue in relation to animal production is antimicrobial resistance in bacteria, and in view of its complexity, it should be addressed through a multidisciplinary approach. It is currently under consideration by the Committee on Food Hygiene and the Committee on Residues of Veterinary Drugs in Foods and is also relevant to the work of the task force.

Future Directions

The fundamental objective of the Codex Alimentarius Commission is to establish sound internationally agreed guidelines for national food control systems based on the criteria of consumer health protection and fair practices in trade, taking into account the needs and special concerns of all countries.

The new recognition and status that Codex Alimentarius standards, guidelines, and other recommendations acquired under the WTO Agreement on the Application of Sanitary and Phytosanitary Measures (the SPS Agreement) also brought new challenges and responsibilities, including the need to ensure that its standards and related texts are based on scientific principles and meet the needs and mandate of the organization. The WTO Agreement on Technical Barriers to Trade is also of great relevance, given the significance of the provisions pertaining to product description, labeling, packaging, and quality descriptors for consumer information and fair practices in trade. Although quality provisions are fundamentally driven by the market, the CAC has an important role in ensuring that provisions relating to quality are sound and based on the criteria of essentiality and do not constitute disguised barriers to trade.

Benjamin Caballero is professor of International Health and of Maternal and Child Health (Bloomberg School of Public Health), and professor of pediatrics (School of Medicine) at Johns Hopkins University.

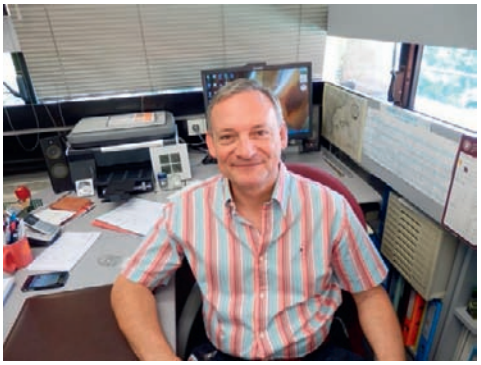
He obtained his MD from the University of Buenos Aires, his MSc in biochemistry from the University of San Carlos, and his PhD in neuroendocrine regulation from MIT, in Cambridge, MA. He started his academic career as assistant professor of pediatrics at Harvard Medical School and director of the Nutrition Unit of Boston Children's Hospital, and subsequently became the founding director of the Center for Human Nutrition at Johns Hopkins University, in Baltimore.

Prof. Caballero has focused his research on child nutrition and health in developing countries. In particular, he has explored the combination of undernutrition and overweight that has become increasingly prevalent in low- and middle-income countries. He was a member of the Food and Nutrition Board of the Institute of Medicine, National Academy of Sciences, USA, and of a number of expert panels created by the Institute, including the Dietary Reference Intakes (DRI) Committee, the Expert Panel on Macronutrient Requirements, and the Childhood Obesity Task Force. He was also a member of the Dietary Guidelines for Americans Advisory Committee, of the Scientific Advisory Board of the Food and Drug Administration (FDA), and of a number of advisory committees of the National Institutes of Health (USA).

He is the editor-in-chief of the *Encyclopedia of Food Sciences and Nutrition*, a 10-volume work on food production, consumption and biological effects. He is also editor-in-chief of the *Encyclopedia of Human Nutrition*, which received the Book of the Year Award from the British Medical Association. His *Guide to Dietary Supplements* summarizes the current scientific basis for the use of mineral and vitamin supplements. His book *The Nutrition Transition: Diet and Disease in the Developing World* explored the impact of demographic and economic development on diet- and lifestyle-related diseases in developing countries. His book *Obesity in China* summarizes research conducted in rural and urban China to track the impact of socioeconomic development on health outcomes. He is also coeditor of a widely used textbook on human nutrition, *Modern Nutrition in Health and Disease*.

He is a member of the Spanish Academy of Nutritional Sciences, and a Fellow of the American Society for Nutrition and of the Royal Society of Medicine (UK). Recent awards include the Donald Medearis Lectureship from the Massachusetts General Hospital/Harvard Medical School, the Mataix Prize for lifetime achievements in nutrition science from the Spanish Academy of Nutritional Sciences, the Ancel Keys Prize for achievements in international public health, and the Thompson–Beaudette Lectureship from Rutgers University.

Paul Finglas joined the Institute of Food Research in 1981 and is currently head of the Food Databanks National Platform and Research Leader in Food and Health at the Institute (http://www.ifr.ac.uk/science/platform/FD/default.html). He has, for most of his science career, been involved in a wide range of research in food composition and analysis, and the nutritional effects of micronutrients in food and health research. Paul has considerable experience of co-coordinating both national and international projects (e.g., EuroFIR, TDS-EXPOSURE, Bacchus and QualiFY (all EU FP7), and is currently of the spin-out EuroFIR AISBL, a non-profit international association based in Belgium, from one of these projects. Paul has a broad range of experience in science publishing and is currently editor of the journals *Food Chemistry* and *Trends in Food Science and Technology*, and was one of the coeditors for the *Encyclopedia of Food Science and Nutrition* (2nd Ed.). Paul has a degree in chemistry from Aston University in Birmingham and has published over 150 publications on a wide range of topics in food science and nutrition.



Fidel Toldrá holds a BSc in chemistry (1980), high degree on food technology (1981) and PhD in chemistry from the University of Valencia (1984). Professor Toldrá was a Fulbright postdoctoral scholar at Purdue University in West Lafayette (US, 1985–86) and visiting scientist at the University of Wisconsin-Madison (1991 and 1995), and the Institute of Food Research-Bristol (UK, 1987). Currently, he is research professor at the Instituto de Agroquímica y Tecnología de Alimentos (CSIC), in Paterna, Valencia (Spain). He is also associate professor of food technology at the Polytechnical University of Valencia.

Prof. Toldrá has focused his research on food biochemistry and its relationship with nutrition, quality and safety. He has filed 12 patents, directed 22 PhD thesis and published over 245 manuscripts in recognized scientific journals and more than 115 chapters of books. His h-index is 41. Prof. Toldrá has authored two books and edited/co-edited more than 30 books for major publishers like CRC Press, Wiley-Blackwell, Elsevier and Springer.

Prof. Toldrá is the European editor of *Trends in Food Science and Technology* (2005–) and associate editor of *Meat Science* (2014–); he was the editor-in-chief of *Current Nutrition & Food Science* (2005–2012), section editor of the *Journal of Muscle Foods* (2009–2010) and guest editor of 12 special journals issues. He is a member of the editorial boards of *Food Chemistry*, *Food Analytical Methods*, *Journal of Food Engineering*, *Journal of Food and Nutrition Research*, *The Open Nutrition Journal*, *The Open Enzyme Inhibition Journal*, *Recent Patents in Agriculture*, *Food and Nutrition*, *Food Science & Nutrition* and *Current Opinion in Food Science*.

He has been a member of the Scientific Panel on food additives, flavorings, processing aids and materials in contact with foods (periods 2003–2008) and the Scientific Panel on flavorings, enzymes, processing aids and materials in contact with foods (2008–2015) of the European Food Safety Authority (EFSA) acting as Chairman of the Working groups on Irradiation (2009–2010), Processing Aids (2011–2014) and Enzymes (2010–2015). He was a member of FAO/WHO group of experts to evaluate chlorine-based disinfectants in the processing of foods (2008–2009). He was a member of the Executive Committee of the European Federation of Food Science and Technology (EFFOST, 2002–2009). He is a Fellow of the International Academy of Food Science and Technology (IAFOST, 2008) and of the Institute of Food Technologists (IFT, 2009–). He received the Iber Award on Food and Cardiovascular Diseases (1992), the Institute Danone award in Food, Nutrition and Health (2001), the International Prize for Meat Science and Technology from the International Meat Secretariat (2002), GEA award on R+D activity from the Valencian Community (2002), and the Distinguished Research Award (2010) and Meat Processing Award (2014), both from the American Meat Science Association.

EDITORIAL ADVISORY BOARD

Siân Astley has worked extensively with individuals and organizations throughout Europe from a variety of disciplines including research, food and biotech industries, and the media. She is the author of more than 300 popular science articles for magazines and trade publications as well as 25 peer-reviewed papers, and she was awarded her Diploma in Science Communication in 2009 (Birkbeck University of London). After 14 years as a bench-scientist, Siân became communications manager for NuGO, one of the first FP6 networks of excellence, and was the European communications manager for the Institute of Food Research in Norwich (UK) until April 2012. Currently, she is the training and communications manager for the European Food Information Resource (EuroFIR AISBL) supporting training within EU-funded research projects and networks, and communication of research activities.

David J. Baer is a supervisory research physiologist with the US Department of Agriculture's Beltsville Human Nutrition Research Center located in Beltsville, Maryland. He serves as the research leader for the Center's Food Components and Health Laboratory and also serves as the director of the Center's Human Studies Facility.

Dr. Baer conducts controlled dietary intervention studies to investigate the relationship between diet and the risk for chronic degenerative diseases, especially cardiovascular disease, cancer, and diabetes in people. His research also includes studies on the health impacts of weight gain and determining the calorie content of foods. Some of the dietary interventions he has investigated include the effects of different types of protein, fats and fatty acids, fiber, margarine, butter, plant sterols, salad dressings, nuts, whole grains, berries, alcohol, and tea on overall nutrition and health. In addition to dietary intervention studies, Dr. Baer is involved in research studies to validate food survey methodologies and in developing new methods for dietary assessment.

Dr. Baer earned his bachelor's degree from the University of Illinois and his master's and doctorate in nutrition from Michigan State University.

Marina Carcea was awarded a master degree in agricultural sciences at the University of Pisa, Italy "cum laude" in 1980, and a PhD in food science also "cum laude."

She is currently a senior researcher in the Research Center on Food and Nutrition of the Council for research in agriculture and analysis of agricultural economy (CRA-NUT formerly INRAN National Research Institute on Food and Nutrition) and she was the director of the Cereals Research Programme in INRAN. CRA-NUT is a primary research institute in Italy under the egis of the Ministry of Agriculture. Dr. Carcea joined INRAN in 1989 after having worked in Italian and English universities (Queen Elizabeth College, King's College, and University of London) and after a two-year contract with the Food and Agriculture Organization (FAO) of the United Nations (UN), Rome.

She has a vast experience in the field of research on foods, cereals in particular. In recent years, her main research interests have been: chemical characterization and study of the functional properties of cereal components; study of the interactions between components and of the interrelationships between the biochemical properties of components and the technological properties of the raw material and derived products; development of new, cereal-based products; development of methods to assess technological parameters of the raw material; nutritional value of cereals; and developments of protocols for quality assurance of cereals, food authenticity.

She has taken part and/or co-ordinated several research projects within national or international programs (European Commission, FAO) involving several institutions. She is the author of more than 160 scientific publications, mostly in international journals, eight book chapters, and two scientific books. She delivered lectures on her research activity at about 150 national and international congresses and she seats in several national and international committees (Italian Ministry of Agriculture, Codex Alimentarius, and European Commission) regarding food and nutrition topics. She is also a member of the editorial board of scientific journals.

From 1994 to 2006, she has also been a lecturer of food science and technology at the University of Tor Vergata, Rome, Italy.

She is a founding member of AISTEC, the Italian Association of Cereal Science and Technology. Since 1996, she is an elected member in the Executive Committee of the same association and since 2009, president of the association.

Since 2000, she is the Italian National Delegate of the International Association for Cereal Science and Technology (ICC) and she was also the president of the same association for 2011–2012.

In 2004, she was the first woman to be awarded the International Harald Perten Prize for her excellent research achievements in the field of cereal science and technology.

She is also a member of the Georgofili Academy in Florence, Italy.

Lawrence J. Cheskin graduated from Dartmouth Medical School and completed a fellowship in gastroenterology at Yale–New Haven Hospital. He is an associate professor of health, behavior, and society at the Johns Hopkins Bloomberg School of Public Health, with a joint appointment in International Health–Human Nutrition, and in medicine (GI) at the Johns Hopkins University School of Medicine. Dr. Cheskin is also a founder and director of the Johns Hopkins Weight Management Center, a comprehensive treatment program for obesity.

In his research, Dr. Cheskin has studied the effects of medications on body weight, the gastrointestinal effects of olestra, how cigarette smoking relates to dieting and body weight, and the effectiveness of lifestyle and dietary changes in weight loss and weight maintenance.

He is also the author of four books: *Losing Weight for Good*, *New Hope for People with Weight Problems*, *Better Homes and Gardens' 3 Steps to Weight Loss*, and *Healing Heartburn*. Dr. Cheskin has appeared on television news programs and lectured to both professional and lay audiences on the topics of obesity and weight control.

Nigel Cook is a graduate of the University of Dundee. After postdoctoral research in the Universities of Aberdeen and Leicester, he moved to the Central Science Laboratory (now the Food and Environment Research Agency (FERA)) at the Food Science Laboratory, Torry, Aberdeen in September 1994, before relocating to new facilities in York. At FERA, he studies the transmission of pathogens, particularly enteric viruses, through foods and the environment. He has a visiting professorship at the Katholieke Universiteit Leuven in Belgium. He is a councilor of the International Association for Food and Environmental Virology. He is a project leader within the standardization working group ISO TC34 SC9 WG6, currently developing a standard for detection of *Cryptosporidium* and *Giardia* on berry fruits and leafy green vegetables. He was a coordinator of the European Framework 7 project "Integrated monitoring and control of foodborne viruses in European food supply chains (VITAL)," and a chair of COST Action 929 "A European Network for Environmental and Food Virology" from 2006 to 2010. Between 2009 and 2014, he was a member of various European Food Safety Authority's Working Groups preparing opinions on the risk of foodborne viruses, and represented the European Communities on the Codex Committee on Food Hygiene Working Group developing *Guidelines on the Application of General Principles of Food Hygiene to the Control of Viruses in Food*. He was a member of the UK Advisory Committee on the Microbiological Safety of Food's Viral Infections Subgroup. He was the founding editor of the journal *Food and Environmental Virology*, published by Springer.

Luca Simone Cocolin graduated in 1994 in food science with a grade of 110/110 and remark followed by food biotechnology PhD studies from 1995 to 1998. In February 1999, he defended his thesis acquiring the title of PhD in food biotechnology. From 1998 to 2001, he received a scholarship from the Friuli Venezia Giulia region (Italy). From November 1, 2001, he was an assistant professor at the University of Udine, Faculty of Agriculture, Food Science Department, Italy, and in October 1, 2006, he became an associate professor at the University of Torino, Italy. In January 2014, he had the habilitation for full professor and from June 2015, he is the full professor in food microbiology at the University of Torino.

From September 2008, he is an executive board member of the International Committee on Food Microbiology and Hygiene (ICFM) part of the International Union of Microbiological Societies (IUMS) (http://www.icfmh.org/). From January 2008, he is the editor-in-chief of the *International Journal of Food Microbiology* and he is a member of the editorial board of *Applied and Environmental Microbiology*, *Food Analytical Methods*, *Frontiers in Food Microbiology*, and *Frontiers in Nutrition and Food Science Technology*. He regularly reviews paper for *Food Microbiology*, *Meat Science*, *Journal of Applied Microbiology*, and *Letters in Applied Microbiology*. He is a co-author of more than 180 papers on national and international journals and he attended national and international congresses with oral and poster presentations. On Scopus (www.scopus.com, consulted on March 2015) he has 172 documents reviewed, which were cited 3520 times, resulting in an h index of 33.

His scientific interests comprise:

development, optimization, and application of molecular methods for the detection, quantification, and characterization of foodborne pathogens;
study of the microbial ecology of fermented foods (mainly sausage, cheese, and wine) by using culture independent and dependent methods;
bioprotection: molecular characterization of bacteriocin production and its study *in vitro* and *in situ*;
selection of new putative probiotics from artisanal fermented foods; and
study of the human microbiome and its influence on human health.

Christopher Duggan, for the past 25 years, has been performing clinical trials in the fields of pediatric nutrition, gastroenterology, and global health. His early work centered on the management of diarrheal diseases in children, including trials that demonstrated the feasibility and efficacy of oral rehydration solutions (ORS) for diarrhea management in the United States and globally. In collaboration with colleagues at Harvard TS Chan School of Public Health and Muhimbili University of Health and Allied Sciences in Dar es Salaam, Tanzania, Dr. Duggan and colleagues are evaluating the efficacy of micronutrient supplementation in infants and young children born to women with or at risk of HIV infection. Recent studies include the development of new biomarkers of environmental enteric dysfunction as well as the evaluation of nutritional status on neurodevelopment. With colleagues at St John's Research Institute in Bangalore, India, he is evaluating the efficacy of maternal vitamin B12 supplementation on biochemical and clinical parameters during pregnancy and infancy. He is a course co-director of the Bangalore, Boston Nutrition Collaborative (http://bbnc.globalhealth.harvard.edu). Past and present research support has come from the National Institutes of Health, the Gates Foundation, and the World Health Organization.

In addition to his global health research interests, he is a pediatric gastroenterologist and a nutrition physician at Boston Children's Hospital where he directs the Center for Nutrition (http://www.childrenshospital.org/nutrition). He is a medical director of the Center for Advanced Intestinal Rehabilitation, one of the largest centers in the United States for the care of children with intestinal failure/chronic diarrhea syndromes (http://www.childrenshospital.org/cair). He is also the course co-director of an inaugural Harvard College course "Nutrition and Global Health" and mentors undergraduate, graduate, and postdoctoral students at HMS and HSPH (http://www.hsph.harvard.edu/nutrition-and-global-health/).

He is a professor of pediatrics at Harvard Medical School and a professor in the Department of Nutrition at the Harvard TS Chan School of Public Health (http://www.hsph.harvard.edu/faculty/christopher-duggan/).

Jed William Fahey's current research concerns elucidating the mechanisms of how plants protect themselves against unfavorable and stressful conditions, and how this understanding can be translated to chemoprotection of eukaryotic mammalian systems. This work draws on elements of natural product chemistry, enzymology, nutritional epidemiology, and clinical research in order with isothiocyanates (e.g., sulforaphane) and glucosinolates. His work led to the discovery that broccoli sprouts are an exceptionally rich and consistent source of phytochemicals that induce the detoxification of carcinogens, and to the development of methods for their detection and for assessing their metabolism in humans. He discovered that one of the inducers, sulforaphane, has potent antibiotic activity against *Helicobacter pylori*, a causative agent of peptic ulcer and stomach cancer, and followed up with trials in animals and in *H. pylori*-infected humans. Ongoing collaborations examine the effects of broccoli, Moringa, and the other plants and their phytochemicals against a range of chronic diseases. Dr. Fahey has for years taught courses in chronic disease prevention and nutrition at both medical and public health schools.

Manuel Franco is an associate professor at University of Alcalá in Madrid (Spain) where he leads the social and cardiovascular epidemiology research group (http://www3.uah.es/cardiosocialepi/). He is also an adjunct professor at Johns Hopkins University (Baltimore).

Prof. Franco's work focuses on the social determinants of cardiovascular diseases and its major risk factors as diet. His methodological interests include the measurement of the urban environment and large social and economic changes in relation to cardiovascular health. He is the lead investigator of the Heart Healthy Hoods, study funded by the European Research Council, that will study the urban environment in relation to cardiovascular health in Madrid (http://hhhproject.eu/). This longitudinal study will be collecting neighborhood level data (via audits, Google Street view, photovoice, and qualitative methods) and linking them to clinical outcomes collected from patients enrolled at the City of Madrid primary healthcare clinics. Prof. Franco trained in Spain and Germany to obtain his MD and obtained his PhD from Johns Hopkins Bloomberg School of Public Health working with Dr. Ana Diez-Roux in the MESA study on food environment and dietary patterns. He has published over 30 international high impact articles and collaborates with universities in the United States, Europe, and Latin America.

Maria Glibetic is a research director of Centre of Research Excellence in nutrition research, Institute for Medical Research in Belgrade, University of Belgrade, Serbia, and member of executive board of directors for food data association EuroFIR AISBL. She is an experienced basic and nutritional scientist with over 250 scientific publications and presentations. Maria has considerable experience in leading national and international projects and since 2006, she participated in nine EU funded projects including EuroFIR, EURRECA, BaseFOOD, CHANCE, BACCHUS, and ODIN. Maria and her team are responsible for the creation of the first online national food database, for designing food data management system, and for the development of different nutritional tools for intake analysis. She was a principal leader of many nutrition intervention studies evaluating the plant bioactive component effects on human cardiovascular health. She leads postgraduate department for integrated nutritional sciences at University of Belgrade, where she teaches two courses.

Linda Harvey obtained her PhD from the University of East Anglia, UK. She is currently the head of the Human Nutrition Unit at the Institute of Food Research, Norwich, UK. Her research interests include micronutrient requirements, bioavailability, and metabolism.

Ronald Jackson received his bachelor's and master's degrees from Queen's University and doctorate from the University of Toronto. His time in Vineland, Ontario, and subsequent sabbatical at Cornell University, redirected his interest in *Botrytis* toward viticulture and enology. As part of his teaching duties at Brandon University, he developed the first wine technology course in Canada. For many years he was a technical advisor to the Manitoba Liquor Control Commission, developing sensory tests to assess candidates of its sensory panel, and was a member of its external tasting panel. He is the author of *Wine Science: Principles and Applications, 4th edition* (2014), *Wine Tasting: A Professional Handbook, 2nd edition* (2009), *Conserve Water, Drink Wine*, and chapters and technical reviews in other multiple books and encyclopedia. He is retired in Bronte, Ontario, but remains active writing, cycling, doing yoga, and traveling, as well as being a fellow in the Cool Climate Viticulture and Oenology Institute, Brock University, St. Catharines, Ontario, Canada.

Joe P. Kerry is a senior college lecturer and the head of the food packaging research group in the School of Food and Nutritional Sciences at University College Cork (UCC). He received his doctorate in microbiology at University College Galway in 1995. Prof. Kerry is also a qualified member of the Institute of Packaging. He is very involved in national and international research projects both at fundamental and applied levels. Primary research interests address various aspects of food packaging, shelf-life stability, food composition, and numerous aspects of food quality, particularly in relation to muscle foods. He also has very strong links with industry and his research team assists companies in relation to many aspects of new food product development. He has over 220 publications in peer-reviewed international journals, over 300 presentations at major international conferences, along with several other significant publications. His expertise includes use and manipulation of modified atmosphere packaging systems for use with foods, use of extrusion technology for the manufacture of food products/packaging materials, and applications and sensor/new technology developments within the area of food packaging, especially in the area of smart packaging.

Frédéric Leroy, after studying bio-engineering at Ghent University, obtained a PhD in applied biological sciences at the Vrije Universiteit Brussel in 2002, where he continued his academic career at the research group of Industrial Microbiology and Food Biotechnology (faculty of sciences and bio-engineering sciences). As associate professor, his lecturing activities include courses in food science and technology (i.e., "Nutrition," "Technology of animal products," "Food microbiology and ecology," and "Quantitative and predictive microbiology"). Dr. Leroy's research primarily deals with the ecology and functional roles of bacterial communities in (fermented) foods, in particular with respect to the generation of quality, safety, and/or nutritional and health advantages. Focus is mostly on meat products, but other food systems are also being studied, including fermented milks and sourdough breads. In addition, his research interests relate to elements of tradition and innovation in foods, both from a technological and societal point of view.

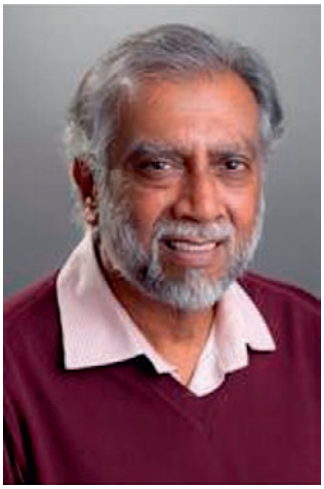
Catherine M. Logue completed her undergraduate and postgraduate degrees in Ireland and earned a PhD in meat microbiology from the University of Ulster, UK in 1996. Dr. Logue was a faculty member at North Dakota State University from 1999 to 2011 rising through the ranks of assistant to associate and full professor. In 2011, she re-located to Iowa State University's College of Veterinary Medicine and is a professor of veterinary microbiology and preventive medicine. Dr. Logue is also the director of faculty and staff advancement and equity for the college. Her research interests focus on foodborne pathogens of food animals and the contamination of meat and meat products destined for human consumption. Her research studies the detection, isolation, and characterization of a range of foodborne pathogens such as *Salmonella*, *Campylobacter*, *Listeria*, *Escherichia coli*, and methicillin-resistant *Staphylococcus aureus* (MRSA) in poultry, bovine, and swine. She also focuses her research on antimicrobial resistance in commensals and pathogens of production animals. She has been an author and a co-author on more than 90 peer-reviewed papers and book chapters as well as more than 150 abstracts and presentations at national and international meetings.

F. Xavier Malcata graduated in chemical engineering in 1986 from the University of Porto (Portugal), received a PhD in chemical engineering/food science from University of Wisconsin, Madison (USA) in 1991, and his habilitation in food science and engineering by Portuguese Catholic University in 2002. He was the dean of College of Biotechnology of Portuguese Catholic University, the chairman of Portuguese Society of Biotechnology, Portuguese representative at VI and VII European Union Framework Programs of research and development, expert for European Food Safety Agency, and a co-ordinator of Portuguese Engineering Accreditation Board in chemical engineering for Northern Region. He is currently a full professor at University of Porto.

His major research interests have focused on technological improvement of traditional Portuguese foods and upgrade of byproducts thereof, development of nutraceutical ingredients and functional foods, design and optimization of enzymatic reactors for edible oil processing, characterization of plant proteases toward cheese and whey cheese manufacture, production of starter and nonstarter cultures from adventitious microflora, and optimized application of unit operations to food processing.

With an academic career of independent research and teaching for more than two decades, Prof. Malcata published more than 450 papers in refereed journals worldwide, wrote 11 books, and prepared more than 45 chapters for edited books. Among many international distinctions, he was

recipient of Ralph H. Potts Memorial Award in 1991 by American Oil Chemists' Society (AOCS, USA), Foundation Scholar Award – Dairy Foods in 1998 by American Dairy Science Association (ADSA, USA), Young Scientist Research Award in 2001 by AOCS, Canadian/International Constituency Investigator Award in physical sciences and engineering in 2002 and 2004 by Sigma Xi (USA), Danisco International Dairy Science Award in 2007 by ADSA, Scientist of the Year Award in 2007 by European Federation of Food Science and Technology (the Netherlands), Samuel C. Prescott Award in 2008 by Institute of Food Technologists (IFT, USA), International Leadership Award in 2008 by International Association for Food Protection (IAFP, USA), Elmer Marth Educator Award in 2011 by IAFP, Distinguished Service Award in 2012 by ADSA, and William V. Cruess Award in 2014 by IFT. He has been elected for the honor societies of food science (Phi Tau Sigma, USA), scientific research (Sigma Xi, USA), and engineering (Tau Beta Pi, USA). He was also elected for fellow of IFT, ADSA, AOCS, and International Academy of Food Science and Technology.



Gopinadhan Paliyath is a professor at the Department of Plant Agriculture, University of Guelph, and the research program director for "Food for Health," under the UG/OMAFRA partnership. Dr. Paliyath is a biochemist and has an interest in various aspects of fruits and vegetables, specifically the nutraceutical components and their mechanism of action. He obtained his BSc Ed degree (botany and chemistry) from the University of Mysore, MSc degree (botany) from the University of Calicut, and PhD degree (biochemistry) from the Indian Institute of Science, Bangalore. Subsequently, he did postdoctoral work at Washington State University, University of Waterloo, and University of Guelph. Dr. Paliyath's research is focused on the biochemistry of plant senescence, specifically pertaining to postharvest biology and technology of fruits and vegetables. Investigations on the role of phospholipase D (PLD) in membrane homeostasis and signal transduction have led to advances in the understanding of the mechanism of membrane deterioration that occur during stress and senescence. Another aspect of his research is focused on understanding the mechanism of action of food components in disease prevention. The efficacy, bio-accessibility, bioavailability, and molecular mechanisms of action of nutraceuticals in fruits and processed products in relation to their cancer-preventive and anti-inflammatory actions are being investigated using mammalian cell lines, and animal model systems.

Dr. Paliyath has developed technologies and products for enhancing the shelf life and quality of fruits and vegetables based on PLD inhibition. R&D activities relevant to the industry sector include: (1) optimization of an enhanced freshness formulation for application to various fruits, vegetables, and flowers; (2) developing methods for nutraceutical carriers that would enhance the functional food quality and delivery (e.g., stabilizing lycopene in tomato juice, sauce, etc., for health beneficial effects); and (3) developing novel technologies to enhance the cancer-preventive ingredients in fruit products, etc. Patents awarded include: (1) # 6,514,914 (US) and 2,298,249 (Canada); (2) #7,198,811 (USA), 4141387-1 (Japan), 260738 (Mexico), 1469736 (Turkey), 028 284763 (China), and 223077 (India). The patents describe the use of nanoformulations based on hexanal and other generally regarded as safe (GRAS) ingredients for enhancing the shelf life and quality of fruits, vegetables, and flowers by pre or postharvest treatments. These technologies are currently being evaluated for extending shelf life and quality of mango in India and Sri Lanka with the assistance of the Canadian International Food Security Research fund. The collaboration involves researchers from Canada, India (Tamil Nadu Agricultural University), and Sri Lanka (Industrial Technology Institute).

Dr. Paliyath is also the research program director for the food and health theme-related activities under the OMAF/MRA/University of Guelph research partnership. He serves on the editorial board of several journals. He is a member of American Chemical Society and Canadian Society of Plant Biologists.

(Total-refereed publications in journals – 92; patents and intellectual properties – 2; disclosures – 4; chapters in books – 27; nonrefereed contributions – 10; research reports – 28; conference proceedings – 88; edited books – 9; book reviews – 6 (Google Scholar: h index – 31, i10 index – 68, citations – 4332; RG score – 35.63)).

Yolanda Picó is a full professor of nutrition and food science at the University of Valencia since 1998. She is currently the head of the research group on food and environmental safety of the University of Valencia. Her research interests are the development of new analytical methods to determine organic contaminants in food and the environment, identification of unknown compounds by liquid chromatography–mass spectrometry, micro-extraction separations, and environmental and food safety. To the date, she is the author of nearly 200 peer-reviewed papers, 170 scientific papers in journals of SCI, 25 book chapters, and editor of four books on food and environmental safety.

Vieno Piironen is a professor of food chemistry at the Department of Food and Environmental Sciences, University of Helsinki, Finland. She received her PhD in food chemistry at the University of Helsinki in 1987 and has approximately 35 years of experience in food research and education on bachelor, master, and PhD levels. She has participated actively in international research and education projects and networks. Her research has focused especially on chemical and nutritional properties, reactions and analysis of lipids, vitamins, and other bioactive compounds. Research on vitamins has been active from the beginning of 1980s. She has studied both lipid- and water-soluble vitamins; their chemical and nutritional properties and importance in foods and diets as well as factors influencing vitamin levels. In addition, development of analytical methods for different vitamers as well as validation and harmonization of the methods through international collaboration have been among the priorities. Recent collaboration projects have focused on enhancing vitamin contents in cereal-based foods by plant breeding, utilization of vitamin-rich grain fractions, and bioprocessing. Currently, the research focus lies on investigating microbial *in situ* synthesis of folate, vitamin B12, and other B vitamins in cereal and legume matrices as a means to improve nutritional quality of foods and to develop new food applications. In lipid research, different lipid classes and their chemical and enzymatic reactions in food matrices are studied. Diverse methods are used to study proceeding of oxidation from primary products to monomeric oxides, volatiles, and polymerization products and to study possibilities to control oxidation. Controlling enzymatic reactions leading to off-flavors in cereal and legume matrices is also among the interests. Phytosterols and their conjugates have been studied as natural food components belonging to the dietary fiber complex. On the other hand, questions related to sterol enrichment such as oxidation susceptibility and mechanisms as well as factors affecting oxidation reactions have been of interest. She has also studied nutrients and anti-nutrients in legumes and more recently started research on utilization of high value components in microalgae. She has approximately 160 papers in international journals and a number of other publications.

David Rodríguez-Lázaro is a doctor in veterinary medicine (DVM), specialized in food science (BSc and MSc) and molecular microbiology (PhD). He is a senior scientist at ITACyL and an assistant professor of microbiology at the University of Burgos. He has performed research stays in the Danish Institute for Food and Veterinary Research (Denmark), the University of Prague (Czech Republic), the Food and Environmental Research Agency (UK), and the University of Bristol (UK). He was a Leverhulme visiting professor in the Institute of Advanced Sciences in the University of Bristol during the years 2004 and 2005 and Marie Curie research fellow in the faculty of medical and veterinary sciences in the University of Bristol (UK) until 2007.

His research interest is focused on the establishment of reliable, quantitative molecular strategies for detection of important food-borne pathogens from environmental sources and various types of foodstuffs, the characterization of the prevalence of the main foodborne pathogens in food and food-related environments, and the development of emergent food preservation processes and their effects in the microbial virulence. He has participated in a number of coordinated EU-funded projects such as PROMISE, BASELINE, VITAL, FOOD-PCR, SACROHN, and MONI-QA, having established active links with the leading European research groups working in food safety.

He has published more than 100 international scientific papers and book or book chapters regarding food safety. He is currently a member of the editorial board of *Applied and Environmental Microbiology*, *International Journal of Food Microbiology*, *Food and Environmental Virology*, and *International Journal of Food Contamination* and the editor-in-chief of the journal *Food Analytical Methods*. He was awarded with the XV Jaime Ferrán Award in 2013 by the Spanish Society for Microbiology for his promising scientific career in microbiology.

Turid Rustad is a professor and the head of the food science group at the Department of Biotechnology, Norwegian University of Science and Technology. The main research focuses on the biochemistry of marine raw materials, the relationship between biochemistry and quality, and changes in raw material properties during processing. Studies of enzymatic activities in different raw materials have been linked to studies of changes in the biochemistry of these raw materials. She has worked with characterization of composition and enzymatic processes in a wide range of different raw materials, such as fish, fish by-products, and zooplankton in relation to different storage and processing methods such as chilling, heating, superchilling, and frozen storage.

Noel W. Solomons has lived and worked in Guatemala for 40 years. He was born and educated in Massachusetts in the United States. As a young child, he became an amateur naturalist and was a nature counselor at various summer camps; this would guide him to a career in science. In his young adulthood, he would participate in the civil rights and anti-war movements, only to become disillusioned by the intractable nature of the injustice elements in the fabric of American society. As a physician by graduate training, he performed his university studies at Harvard College and Harvard Medical School; it was during overseas electives in his medical training that he visited Peru and Colombia and committed to an expatriate life trajectory outside of his homeland. Clinical training included a residency in internal medicine and infectious diseases at the Hospital of the University of Pennsylvania and specialization in gastroenterology and clinical nutrition at the University of Chicago. He became a resident of Guatemala in 1974 as an affiliated investigator at the Institute of Nutrition of Central America and Panama. He would later commute for eight years to a faculty position in the Department of Nutrition and Food Science of the Massachusetts Institute of Technology. Assuming a full-time Guatemala commitment in 1985, he co-founded the Center for Studies of Sensory Impairment, Aging and Metabolism (CeSSIAM) where he remains its scientific director. Over 40 local university theses have been completed by Central American students in that institution as well as an equal number of master's degree research projects from international students from Europe, and North and South America. He has supervised doctoral dissertations for 12 PhD candidates from the United States, Canada, Germany, Spain, and the Netherlands through CeSSIAM.

Dr. Solomons has 332 publications indexed on Medline. In addition, he has edited two books and contributed over 100 articles, reviews, editorials, and commentaries in nonindexed venues and over 50 book chapters. These are dedicated to the scientific and academic interests of his career including: clinical nutrition; human growth and body composition; lactose maldigestion; dietary intake, nutritional status, intestinal absorption, and food fortification related to various micronutrients (vitamins, trace elements, and essential fatty acids); complementary feeding; nutrition in aging and chronic disease; and the interaction of malnutrition and infection.

Among the honors bestowed upon Dr. Solomons are the International Nutrition Prize of the International Union of Nutritional Sciences and the Kellogg Prize of the Society for International Nutrition Research. He is a fellow of the American Society of Nutrition. He is an academic member of the Guatemalan Academy of Medical, Physical and Natural Sciences and the Spanish Academy of Nutrition and Food Science. He was the awardee of the 2010 National Medal for Science and Technology for Guatemala.

He has been a visiting professor in university courses in Mexico, Peru, Brazil, Indonesia, and Spain. He currently holds adjunct professorial appointments at the Boston University School of Public Health, and the Friedman School of Nutrition Science and Policy and the Department of Community Medicine and Public Health, both at Tufts University. He is a founding board of directors, member of the Hildegard Grunow Foundation in Munich and the Essential Nutrient Foundation of Singapore. Finally, Dr. Solomons is a coordinator for Central America of the Nevin Scrimshaw International Nutrition Foundation in Boston, and an associate editor for the Foundation's *Food and Nutrition Bulletin*. He serves on editorial boards for ten scientific journals.

Maria Tsimidou is a professor of food chemistry and the head of the Laboratory of Chemistry and Technology in the School of Chemistry at the Aristotle University of Thessaloniki (AUTh), Greece. Her teaching is food chemistry, analysis, quality control, and food legislation. Research interests are related to virgin olive oil chemistry, quality and authenticity, saffron chemistry, authenticity and quality, antioxidant activity of plant extracts and constituents, new sources of targeted bioactive compounds (squalene, carotenoids, and phenols), and analytical procedures for their determination. She has published many research papers, review articles, and contributions to scientific books and encyclopedias on the above-mentioned topics. Currently, she is an associate editor in the *European Journal of Lipid Science and Technology* and chairs the COST ACTION FA1101 "Saffronomics."

Jorge Welti-Chanes earned his degree in biochemical engineering (1976) and master of science in food engineering (1978) at Tecnológico de Monterrey (ITESM, Mexico), later he moved to Spain to perform his doctoral studies in chemistry, in the area of food technology, obtaining his degree at the University of Valencia. He is currently the national director of graduate studies at School of Engineering and Sciences at Tecnológico de Monterrey also is professor and researcher in the areas of biotechnology and food at the same institution. He started his academic activity in 1976 as a university professor of ITESM, has additionally been a full professor at the National Polytechnic Institute (IPN, Mexico) and the University of the Americas, Puebla, Mexico (UDLA). He has an experience of 37 years as a teacher and university researcher, 20 of which were spent in combination with the development of administration work in education, science and technology. In the UDLA, he was teaching in the Departments of Chemistry and Biology and Chemical Engineering and Food, in the latter was responsible for the leadership for a period of a year and subsequently became dean of the School of Engineering (1986–1988). From January 1989 to June 2002, he was an academic vice chancellor at UDLA. He has published 14 books and has over 200 scientific publications in refereed journals and books, has given more than 250 presentations at international conferences. He is an associate editor of the journals *Food Engineering Reviews* and *Journal of Food Science* and participates as a member of the editorial boards of *Journal of Food Engineering* and *Current Opinion in Food Science*. In May 2011, he received the Life Achievement Award by the International Association for Engineering and Food (IAEF), for his career as a researcher and academic worldwide, and in January 2014, the Romulo Garza Award from the Tecnológico de Monterrey for the impact of their research work and as recognition for being one of the most productive researchers in the life of Tecnológico de Monterrey. He has been the president of ISOPOW and IAEF and is the currently president of the International Society of Food Engineering (ISFE).

Peter J. Wilde graduated in biophysics at the University of East Anglia in 1985 and has been researching the colloidal and interfacial properties of food systems at the Institute of Food Research (IFR) for over 25 years. IFR is the only publicly funded UK research institute that focuses on the underlying science of food and health to address the global challenges of food security, diet, and health, healthy aging, and food waste. IFR is the one of eight institutes that receives strategic funding from the Biotechnology and Biological Sciences Research Council (BBSRC). It also receives funding from government agencies and departments, the EU, charities, and industry, from the UK and overseas.

Pete's research expertise is the interfacial behavior of proteins and other surface active components in food relevant systems. The aim is to determine how the molecular and interfacial processes control the functionality of foams and emulsions. Currently, the functional aspects of his research have focused on improving the dietary impact of emulsified foods. These include fundamental studies on how interfacial layers control emulsion rheology to develop novel fat reduction strategies; the design of interfacial structures to control lipid digestion to promote satiety or the delivery of fat-soluble nutrients and drugs; and to determine the physico-chemical role played by the salivary film in perceiving fat content in emulsions. The impact of this research will be to aid the rational design of foods with enhanced nutritional benefits to address the global challenges of obesity, type 2 diabetes, and other major diet-related conditions.

HOW TO USE THE ENCYCLOPEDIA

All articles in the encyclopedia are arranged alphabetically as a series of entries.

1. Contents

Your first point of reference will likely be the contents. The complete contents list appears at the front of each volume providing volume and page numbers of the entry. We also display the article title in the running headers on each page so you are able to identify your location and browse the work in this manner.

2. Cross-references

The majority of articles within the encyclopedia have an extensive list of cross-references that appear at the end of each article, for example:

See also: Anemia: Causes and Prevalence; Anemia: Prevention and Dietary Strategies; Iron: Biosynthesis and Significance of Heme; Iron: Physiology of Iron.

3. Index

The index provides the volume and page number for where the material is located, and the index entries differentiate between material that is a whole article; is part of an article, part of a table, or in a figure.

4. Contributors

A full list of contributors appears at the end of volume 5.

INTRODUCTION

Until a few decades ago, virtually all known health effects of foods were related to their content of essential nutrients. The clinical description of most diet-related illnesses mirrored the signs of essential nutrient deficiencies, such as pellagra, beriberi, and others. Consequently, the key public health concern regarding diet was ensuring that everyone consumed enough food. It was only in the past 50 years that large-scale epidemiological observations began to associate chronic diseases like diabetes and cardiovascular disease with nonessential diet constituents such as saturated fat, fiber, and cholesterol. Taking advantage of the emergence of digital informatics, these studies were able to manipulate increasingly large sets of data and provide, for the first time, a picture of the secular changes in the health of large populations and its association with what they ate regularly. These findings progressively shifted the concern from eating enough to avoiding excessive consumption of certain foods. Eating enough was replaced by eating well.

But it turned out that defining how to eat well is far more complex than defining minimum needs of essential nutrients. First, there is no single paradigm to study those relationships, given the wide variety of biological mechanisms and the long exposures involved. Second, many of the experimental models used to define essential nutrient needs are not applicable to the study of long-term effects of diets in free-living populations. And it is now clear that experiments with isolated dietary compounds do not reflect the actual effects of the complex food matrix we consume daily. Finally, while the discovery of essential nutrients and their role in health was the domain of a few specialties speaking a common language (primarily biochemists and physiologists), the study of the long-term effects of whole diets in humans must of necessity involve epidemiologists, social and behavioral scientists, food scientists, clinicians, policy experts, etc., making far more difficult the development of consensus and foundational concepts.

It is thus not surprising that today we have still not achieved a stable consensus on how to eat 'well.' Furthermore, while few nonscientists would care about the minimum requirement of a vitamin to sustain life, there are plenty of opinions among nonscientists on how to eat 'well.'

Our goal in preparing this encyclopedia has been to contribute to the understanding of that complex diet–health relationship by providing a multidisciplinary, integrative and accurate source of information. We aim to serve the needs not only of established and in-training scientists, but also of the increasingly important group of professionals who are key to disseminate and sustain the practice of science: journalists, science writers, science administrators, fund raisers, donors, and policymakers. In preparing this work, we had the enormous advantage of working with one of the publishers with the most extensive expertise in major reference works, Elsevier. This first edition builds on the impressive breadth of knowledge of over 922 authors and on the tireless work of our editorial advisory board. We are very grateful to all of them.

Importance of Food Classification and Description

The preparation of reliable data on food requires precise identification of foods. Even data of good quality can be a source of error if they are derived from foods that are not clearly defined. Foods in databases are usually defined by a food ID, which should be its unique identifier in the database, by a food name, by food classification, and by food description.

A simple food name is not sufficient, as it can be inadequate or ambiguous to those who are not closely acquainted with the local language and culture. For example, the English term 'sweetbread' refers to an offal product and not pastry, while 'mincemeat pie' is sweet pastry and not a meat dish. A common name may, moreover, be misleading when the same name is used for different foods in different regions or for foods having different scientific names. For example, the name 'endive' is used for *Cichorium endivia* L. in the United Kingdom but for *C. intybus* L. in France and the United States. The situation is further confused by homonyms, synonyms, identical brand names for different products, and different culinary or technological terms. It is therefore necessary to include further information, through food classification and description, to define a food item, and to retrieve information about it.

As most databases employ different methods of identifying foods, it is difficult to exchange data between countries, between organizations within the same country, or even between workers in the same institution. This article reviews existing food classification and description systems used to define foods in databases with the view that an international understanding of standardized food classification and description could solve many of the problems arising from the misidentification of foods.

Food Classification Systems

Classification is a structure that organizes concepts into a hierarchy, from broad to narrower terms, according to common characteristics. For example, the food 'milk' can be classified under 'dairy products' and 'wine' under 'alcoholic beverages.' Classification thus facilitates information retrieval. Many national and international systems have been created to classify foods, but these exist in parallel and are rarely compatible. It is important to keep in mind that classification depends on the point of view of its creation and that food classification systems are reporting-level (e.g., as commodity, as purchased, and as eaten) and purpose-specific. The following are questions to ask when examining a food classification system:

- What is the purpose of the classification?
- At what level are the foods recorded?
- What do we want to classify: foods as consumed, ingredients, commodities, prepacked foods, etc.?

Food Classification Systems According to Purpose

A variety of food classification systems have been developed to describe food habits or to fulfill requirements set by regulatory bodies. Classification systems are often standardized, as they may be based on legal documents, the most standardized being 'vocabularies.'

National food classification systems for databases and surveys

Nutrient intake assessments are undertaken at a national and regional level to assess population nutritional status. Food composition databases and consumption studies thus use country-specific food classification systems, based on national criteria. This is mainly due to legal aspects and traditions, besides the economic and cultural importance of foods. For example, there is a separate group for coconut products in the food composition tables of the Pacific Islands and a group for edible insects in the Thai food composition database. Food classification systems for use in nutrient intake assessments are therefore country- and time-specific, reflecting known food consumption patterns at the time of the study.

Regional food classification systems for food composition databases

Some attempts have also been made to create regional classification systems for food composition databases. A good example of this is the EuroFIR (European Food Information Resource) classification used in European food composition databases, overcoming language and cultural differences. The EuroFIR classification was created by mapping classifications used in national food composition databases and food consumption surveys in Europe; definitions of food groups were based on Eurocode (see succeeding text). EuroFIR food classification is currently used to link over 29 European datasets, covering over 29 000 foods.

International food classification systems for products in commerce

Harmonized Commodity Description and Coding System

The World Customs Organization's Harmonized Commodity Description and Coding System (HS), also called tariff nomenclature, is an international nomenclature for the classification of products in commerce. It is used to classify traded goods on a common basis for customs purposes and for generating trade statistics. The trade coding system is agreed upon internationally and implemented in all countries. In Europe, it corresponds to the European Combined Nomenclature (CN). The coding system comprises 20 sections, four of which apply to foods, and the classification is based on the terms of the headings (e.g., 'leeks and other alliaceous vegetables'). HS lists products corresponding to customs tariffs of foods as purchased, that is, single, unprocessed foods, and therefore lacks details of prepared foods and food products. The PRODCOM

classification (see succeeding text), based on CN, provides statistics on the production of manufactured goods.

Global Product Classification (GS1 GPC)

Global Product Classification (GPC) is the classification system for the GS1 Global Data Synchronization Network (GDSN), which is the most widely used supply chain standards system in the world. GPC allows manufacturers, distributors, and retailers to group products in the same way to ensure data synchronization in the network. GPC is essentially a nonhierarchical system, with the addition of higher hierarchies (segment, family, and class) provided for information purposes. GPC 'bricks' define categories of similar products and can be further characterized by brick-specific attributes. Examples of bricks are 'milk and milk substitutes (perishable),' 'milk and milk substitutes (frozen),' and 'milk and milk substitutes (shelf-stable).' GPC categories thus reflect food origin and shelf life and potential for microbiological contaminants.

International food classification systems for regulatory purposes

These classification systems are based on commodities' similar potential for containing certain additives or pesticide residues and contaminants.

CIAA Food Categorization System and codex food categorization system (GSFA)

The CIAA Food Categorization System is a European-approved classification, originally developed by the Confederation of the Food and Drink Industries of the EEC. It is a hierarchical food classification system, designed to serve as an allocation tool for food additives as a basis for their authorization at the European community level. The CIAA Food Categorization System lays the basis for the codex food categorization system and the food classification used in the food additive 'positive lists' in the Nordic countries.

The Codex General Standard for Food Additives (GSFA) is maintained by the Codex Alimentarius Commission, established by the Food and Agriculture Organization of the United Nations (FAO) and World Health Organization (WHO). Inspired by the CIAA Food Categorization System, foods are classified into 16 main food categories and then subcategories, according to additive authorizations. When the use of an additive is permitted in a certain category, it is automatically permitted in all its subcategories, unless otherwise stated. Both classifications cover all foodstuffs, even those where additives are not allowed. There are special categories for prepared dishes, which may contain the additives allocated to the categories to which their ingredients belong. These classifications are food additive-driven and hence emphasize processed foods, as the methods of preparation and conservation of foods condition the use of certain additives. Since these classifications deal with foods as marketed, they are interesting in a food consumption context and have been suggested as a useful starting point for an international system of food classification for nutrient risk assessments.

Codex Classification of Foods and Animal Feeds (CCPR) and General Standard for Contaminants and Toxins in Food and Feed (GSCTFF)

The FAO/WHO Codex Alimentarius classification of food and animal feed commodities was developed by the Codex Committee on Pesticide Residues (CCPR). The classification is intended to be as complete a listing of food commodities in trade as possible, classified into groups on the basis of the commodities' similar potential for pesticide residues. In Europe, it corresponds to the EC Classification of Products of Plant and Animal Origin, a listing food and feed products to which the maximum levels for pesticide residues apply.

The Food Categorization System of the Codex Alimentarius General Standard for Contaminants and Toxins in Foods and Feed (GSCTFF) uses the system that was developed in the framework of the CCPR but extends it to include processed products at type or group level. The GSCTFF is intended to promote harmonization of grouping commodities with a similar potential for residues for which a maximum residue limit can be set. In GSCTFF, manufactured foods containing ingredients of both plant and animal origins are classified according to their main ingredient. To be used effectively on an international level, both classifications need to be reviewed to include a wider variety of foods, particularly those from regions other than Europe and North America.

Global Environment Monitoring System (GEMS/Food)

The WHO GEMS–Food Contamination and Monitoring System (GEMS/Food) informs governments, the Codex Alimentarius Commission, and other relevant institutions on the levels and trends of contaminants in food and their significance with regard to public health and trade. GEMS/Food hazard identification is used to set priorities for Codex Alimentarius committees such as the Codex Committee on Food Additives (CCFA), Codex Committee on Contaminants in Foods (CCCF), and Codex Committee on Pesticide Residues (CCPR). The GEMS/Food code is based on a hierarchical classification with 2 levels. The first level (WHO Food Group) corresponds to broad categories usually reported in food consumption surveys; these categories are expected to be valid for all types of diets around the world and should allow for an international dietary exposure assessment. The second level (WHO Food Identifier) corresponds to the detailed food descriptors used in the earlier-mentioned Codex Alimentarius committees and to particular foods, processed or not and analyzed as purchased or as consumed. GEMS/Food reports include mapping of local food identifiers with the 2 WHO levels of classification.

Food classification systems for international dietary monitoring

FAO food balance sheet

Food balance sheets are compiled by the FAO and EUROSTAT on an annual basis. A food balance sheet (FBS) presents a comprehensive picture of a country's food supply during a specific reference period. It shows for each food item (i.e., primary commodity and a number of processed commodities) the areas of supply and its utilization. The food supply available for a specific period is the result of the total quantity of

foodstuff produced, added to the total quantity imported, and adjusted to any change in stocks during this period. FBS expresses food consumption in kilogram per head per year for broadly defined food groups (e.g., bovine meat). They have the advantages of providing a harmonized set of data for all member states, being carried out on an annual basis, and providing information for member states who do not have national food consumption surveys.

PRODCOM classification for household budget surveys

All Household Budget Surveys (HBSs) in the EU member countries use the PRODCOM food classification scheme based on the European CN and transformed by EUROSTAT. The EU DAFNE project on HBS enhanced the PRODCOM classification scheme, placing more emphasis on goods such as food and improving comparability with other international food consumption classifications. Even so, the HBS classification schemes only cover products as obtained in a household (purchased or grown) and not foods as consumed.

Eurocode, European Food Groups (EFG)

An attempt was made in Europe to create a master list of foods and codes that could be used in dietary studies in all participating countries. The Eurocode food codes were, however, not specific enough to replace national codes in food composition or consumption databanks, especially for nutritional calculation or for exposure assessment. Moreover, Eurocode's monohierarchical classification of foods suffered from inconsistencies in rules for assigning food items to specific food groups (particularly for mixed foods) and from incoherencies with respect to standards set by Codex Alimentarius and/or the European Commission, thus making its use difficult for governmental bodies.

A nonhierarchical classification, EFG, was then developed, in an attempt to standardize food classification at main group level and permit international comparisons of the results of food consumption and food availability surveys. For example, 'fruit juice' is a food group separate from 'fruit' and 'beverage' in EFG. When creating the EFG system, major classification schemes used for recording food intake were compared, and 33 food groups were chosen as the 'least common denominators' of the food classification schemes, using the definitions of the corresponding food groups from Eurocode.

EPIC-SOFT food classification

The European Prospective Investigation into Cancer and Nutrition (EPIC) studies 500 000 people in ten European countries, where detailed data on diet and lifestyle are obtained by questionnaires, using EPIC-SOFT software. The EPIC-SOFT food classification system in 17 main groups and underlying 124 subgroups was used to classify the 1500–2000 items reported in the EPIC study. Because of the importance of this study in Europe, national consumption surveys often map to EPIC-SOFT food classification.

Food Classification Systems According to Reporting Level

Different survey types/methodologies will achieve different levels of detail. Individual surveys, HBS, and food balance sheets all record, to varying detail, food as eaten/prepared or as raw commodities. Foods exist on all reporting levels, but characteristics of the food change from level to level, so systems capturing this information are food level-specific and cannot cover several groups at the same time:

- Food composition databases and individual consumption surveys record foods at the intake level (food as consumed). Examples of international intake-level classification systems are EPIC-SOFT and EuroFIR food classification.
- Foods are recorded at ingredient level (prepacked foods, foods as purchased, and raw foods) in HBS, GEMS/Food surveys, CIAA and GSFA Food Categorization Systems for food additives, GS1 GPC for products in commerce, and food classifications for comparing consumption surveys (e.g., EFG and Eurocode). Food composition databases also include foods at the ingredient level.
- Classification systems that record foods at raw commodity level include food balance sheet classification, harmonized commodity system (HS), Codex CCPR and CCFAC, and GEMS/Food (**Figure 1**).

In order to compare consumption between countries, data from national dietary surveys (where foods are reported as consumed) need to be extrapolated to ingredient level using standard recipes and yield factors. Data collected at ingredient level (or extrapolated from input level) can be extrapolated to raw commodity level using processing, hydration, or equivalence factors. For example, quantities of bread consumed (intake level) can be extrapolated to quantities of flour (ingredient level), which in turn can be extrapolated to quantities of wheat (raw commodity level). However, it is impossible to extrapolate the opposite way, that is, from raw commodity level to ingredient level or from ingredient level to intake level.

Food classification systems for prepared food items, foods as purchased/ingredients, and raw commodities need to be linked through a system of processing and yield factors. Recommendations exist, but practices are very different, and some countries do not use such factors. Other countries have computerized programs, customized to their national dietary survey data collections, to undertake these tasks. In the future, it would be useful to have an international database of standard processing and yield factors available online.

Level of Detail in Food Classification

The level of detail required in a food classification system used in dietary exposure assessments depends on whether it is a nutrient of interest or hazard occurrence in food. Food classification systems for use in nutrient intake and food additive assessments include codes for processed foods and some foods as consumed in the system, whereas those for contaminant/agricultural and veterinary drug residue assessments are mainly based on raw commodities. The level of detail required in food classification is also determined to some extent by the purpose of the assessment, whether it is for reporting nutrient intake results from a dietary survey, for reporting nutrients and/or hazardous chemical results from a total diet study, or for food regulatory purposes (i.e., food standards).

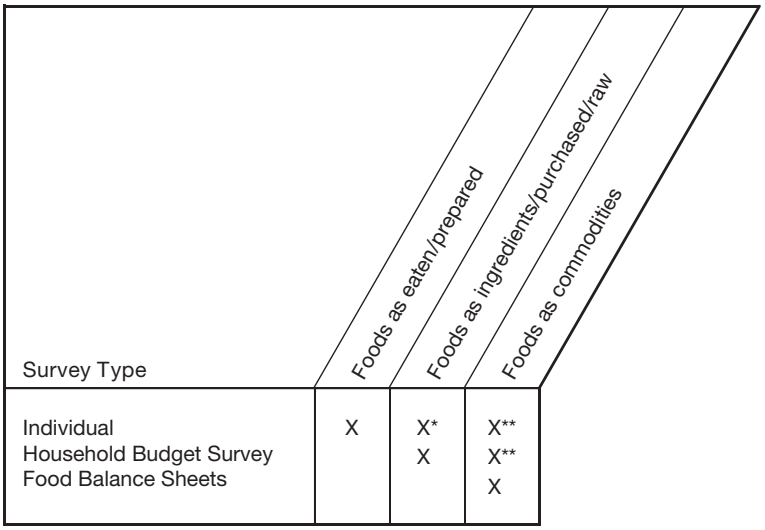

Figure 1 Survey reporting levels.

Food Description Systems

Food classification and food description have different goals, and this leads to different appearances of the systems. A classification system tends to group foods with similar characteristics; it is a tool of the end user of data. A description system, on the other hand, is a tool of the data originator, who wants to give a description of the food, as precise as possible, without the necessity of aggregating them.

Free Text Food Description

In 1987, the International Network of Food Data Systems (INFOODS) food nomenclature and terminology committee prepared Guidelines for Describing Foods, in order to provide a framework for the exchange of data between data sources and compilers of food composition databases. The INFOODS Guidelines constitute a broad, multifaceted, and open-ended mechanism designed to capture all information that might be available and that might be of some use to someone. The guidelines first propose criteria for deciding whether a food is 'single' or 'mixed' and then provide sets of descriptive facets for these two classes of foods. It is an open-ended, free-text food description system, a listing of features or entities that might influence the composition of food and that collectors of data should be encouraged to record. It does not include controlled terms to standardize description and facilitate data retrieval. The system is useful for recording food description that cannot be systematized, but has not been widely used in food databases.

Food Description Thesauri

Consistent indexing and retrieval can be attained using thesauri, in which vocabulary control is achieved by deliberately restricting the scope of terms and by displaying hierarchical relationship. A thesaurus is a controlled indexing language, formally organized so that a priori relationships between concepts (e.g., 'broader' and 'narrower') are made explicit. Concepts can be further organized into a scheme of viewpoints or facets, that is, clearly defined, mutually exclusive, and collectively exhaustive aspects, properties, or characteristics. To facilitate indexing and retrieval, many thesauri allow polyhierarchical relationships; for example, the descriptor FIELD CORN can appear under several broader terms: sugar-producing plant, starch-producing plant, oil-producing plant, and grain. In addition to broader and narrower terms within a facet, thesaurus descriptors may be given synonyms, related terms, definitions, and scope notes. The use of underlying codes renders a thesaurus more robust, allowing spelling changes and translations. Due to its flexible structure, a thesaurus can be amended by adding new viewpoints and by including more details within facets. A faceted thesaurus is thus well adapted to systematically describe features of foods.

AGROVOC thesaurus

An example of a successful implementation of a faceted thesaurus is AGROVOC, a controlled vocabulary covering all areas of interest to FAO, including food, nutrition, agriculture, fisheries, forestry, and environment. AGROVOC was first developed in the early 1980s, as a thesaurus to support uniform indexing of the FAO bibliographic catalog. To date, AGROVOC contains over 32 000 concepts organized in a faceted hierarchy, and each concept may have labels in up to 22 languages. However, its facets and terms are not sufficient or specific enough to describe food products as consumed.

LanguaL™ thesaurus

Work on the LanguaL™ thesaurus was started in the late 1970s by the Center for Food Safety and Applied Nutrition (CFSAN) of the US Food and Drug Administration (FDA) as an ongoing cooperative effort of specialists in food technology, information science, and nutrition. Since then, LanguaL™ has been developed in collaboration with the US National Cancer

Institute (NCI) and, more recently, its European partners. The European LanguaL™ Technical Committee has administered the thesaurus since 1996.

LanguaL™ is a multilingual thesaurus using faceted classification, constructed according to ISO standards. LanguaL™ allows foods to be described by a set of standard, controlled terms chosen from 14 facets characteristic of the nutritional and/or hygienic quality of a food, such as biological origin and technological treatments, plus parallel systems of food classification (e.g., EuroFIR, Codex GSFA, and GS1 GPC). The thesaurus contains about 7000 descriptors, many with definitions, links to authoritative sources, scope notes prescribing use, synonyms, and related terms. The thesaurus is language-independent at concept level: each of its descriptors possesses an underlying code that points to equivalent terms in different languages (9 languages in 2012). A stand-alone software program, LanguaL™ Food Product Indexer, assists food description by providing examples of already-indexed foods. The LanguaL™ thesaurus is used by databases in the United States (USDA National Nutrient Database for Standard Reference) and Europe (EuroFIR network), thus facilitating links between food databases and contributing to coherent data exchange.

Comparison of Food Description Systems

The two major food description systems used in food composition databases are thus the LanguaL™ thesaurus, with well-defined terms, and the INFOODS Guidelines, in free text. A comparison of these two systems was carried out by INFOODS regional data center coordinators in 1998. In this evaluation, LanguaL™ scored better in relation to addressing issues of barriers of language and culture, but maintenance of descriptors and codes was judged to be time-consuming. The INFOODS Guidelines scored better in relation to 'friendliness' and local usefulness by conventional users of food composition data. Free-text food description is simpler and quicker to use and allows information that is more detailed and thus not limited by insufficiencies in the choice of terms from a thesaurus.

The demand for a language-independent thesaurus (like LanguaL™) and the requirement for a practical, in-the-field system (like the INFOODS Guidelines) for food description in databases have led to attempts to link complementary systems to create a minimum set of standards and a harmonized approach for identifying foods worldwide.

Combined Approaches for Classifying and Describing Foods

FDA International Interface Standard for Food Databases

In the early 1990s, the USFDA developed an 'International Interface Standard for Food Databases' (IIS) in order to facilitate retrieval of information from food databases and to improve and standardize food descriptions. The IIS includes food names, LanguaL™ descriptors, free-text description in INFOODS facets, recipe information, and parallel food classification systems. Although it has not obtained international acceptance, IIS is an invaluable step toward the definition of the relevant types of metadata in the domain of food databases.

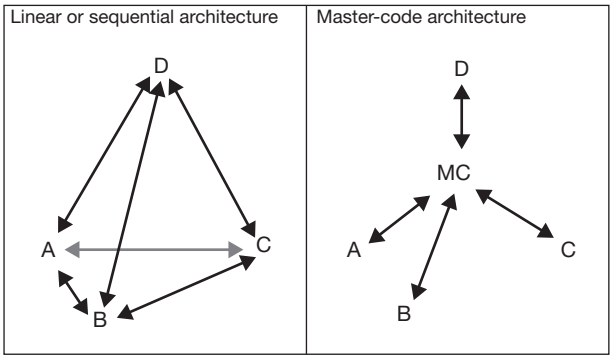

Figure 2 Architecture for code translation systems.

Mapping Between Food Classification/Description Systems

Food composition and consumption data are scattered over many food databases, each having its own system for identifying and describing foods. Combining data from two or more databases thus becomes difficult and time-consuming. It is possible, however, to create links between food identification systems in these databases, by 'mapping' one system to another. There are two ways of mapping between systems: a linear (sequential) way and using a so-called master code, which are illustrated in Figure 2.

In linear translation, a code from one system must be associated with that of the second, with that of the third, etc. Then, each code of the second system must be associated with one of the third. In the master-code approach, one coding system serves as an internal master code with which all the others are directly associated. For this to work, the master code must be more detailed than any of the other classification/description systems. All of this should be transparent to the end user, with software carrying out master-code lookups in the background. The master-code solution is flexible and allows for additions in the future, simply by providing two files: one catalog file with the new code list and one cross table file with the master code on one side and the new code on the other side. This technique was used in the CARE Food Safety project to link Italian, German, and Codex Alimentarius food codes. Because of its level of detail and use in food composition databanks, LanguaL™ has also been presented as a good potential choice for such a central mapping master-code structure.

EFSA FoodEx2

In an effort to introduce standardized reporting of food data, the European Food Safety Authority (EFSA) has recently created a food classification and description system – FoodEx2 – based on classification systems already in use for exposure studies. As an additional challenge, FoodEx2 intends to handle food at commodity, ingredient, and consumption levels. FoodEx2 consists of a detailed list of individual food items aggregated into food groups and broader food categories. The system includes parallel hierarchies, aggregating food items and food groups in different ways according to the needs of specific food safety domains: general reporting, chemical

exposure, pesticide residues, zoonoses, veterinary drugs, and animal feeds.

The use of a food list, rather than just classification, is not only a strength but also a weakness. The food list approach allows easier mapping to classification systems already in use for exposure studies but lacks sufficient detail to replace food codes in national consumption surveys and food composition databases. Moreover, the food list approach does not allow queries on new criteria; for example, a search for foods containing soy would not yield food items where 'soy' is not in the food name, for example, coffee whitener.

To provide additional information, the FoodEx2 food classification/list is complemented by facet descriptors. Some FoodEx2 facets and descriptors are straightforward and based on the LanguaL™ thesaurus, for example, food source (LanguaL™ facet B) and partly consumed/analyzed (LanguaL™ facet C). In these cases, links to the LanguaL™ thesaurus should be made clearer, as LanguaL™ is already used in major food composition databases. Other FoodEx2 facets seem to have been added to highlight specific safety risks, overlap with other facets, and lack the rigor prescribed in the ISO standard. FoodEx2 should be reviewed and provided with scope notes and examples to facilitate accuracy and consistency of food indexing.

Conclusions

All classifications are purpose-driven, created for a specific purpose and fit for use. This is a source of both strength and weakness. A classification system often cannot be used for another purpose than the one it was designed for or be used for foods at all levels (foods as eaten, ingredients, and commodities). Classifications are often contradictory, and their very existence shows that there can be no single, satisfactory, international classification system. In other words, there is no single food classification system that can serve all the needs of every database compiler. It is necessary to include food description.

The first breakthrough in international food classification and description has been the clear recognition of the advantages of using a multifaceted approach for identifying foods in food-related databases (composition and consumption). The second breakthrough has been the recognition of the need to include alternate classification/description systems. Criteria for such a combined system were laid down by the IIS: encompassing several parallel complementary schemes, structured, robust to accommodate different national languages, flexible for use by all users and for all types of foods, specific enough to avoid misclassification, adequately documented, and internationally acceptable.

The challenge of establishing a multifaceted system that can enable end users to analyze data held in different food-related databases was also the focal point in the 2010 EFSA Scientific Colloquium on Food Classification. The symposium recognized that no single system existed to meet all the potential end user needs and that it was not possible to develop a unique system to meet all requirements. At the same time, it concluded that the use of a common food classification and description system could provide a central linking system (master code) between existing systems to promote more accurate dietary exposure calculations in Europe and also at a worldwide level. Despite its shortcomings, the proposed FoodEx2 system can be seen to represent a major step toward harmonized food classification and description.

Food Colloids and Emulsions

A Sullo and IT Norton, University of Birmingham, Birmingham, UK

Introduction

Food is essential for life. It provides the micro- and macronutrients necessary to maintain body homeostasis. The concept of 'eating to live,' however, has changed dramatically through history, especially in modern affluent societies where eating is related to lifestyle choices, social identity, or pleasure and has become more than simply a means to acquire essential energy and nutrients. Against this challenging background, the food industry aims to develop novel food products, which simultaneously are healthy, tasty, and cheap. It is now belatedly recognized that some of the aforementioned, perhaps conflicting, needs can be addressed by understanding the 'microstructure' of food products as it evolves during processing, storage, and consumption. When viewed under the microscope, many of today's food products reveal a complex hierarchical structure with different coexisting phases organized on a wide range of spatial length scales from molecular to microscopic (Figure 1). Moreover, food microstructure is a dynamic concept. It changes continuously with time and the rate of change depends on many factors including composition, the environmental conditions (temperature, pH, mechanical forces, etc.), and the specific nature of the ingredient interactions. The relevance of the time and length scale to food functionality depends to some extent on the origin of the food materials but more importantly on the phenomena one is interested in. Digestion of lipids in emulsions, for example, depends on the size of the oil droplets with small droplets digested in the ileum instead of the duodenum, which impacts on the satiety. The example mentioned earlier highlights that some, if not most, of the transport, diffusion, and dissolution phenomena relevant to food functionalities (nutritional, sensory, and physicochemical) involve fat crystals, polymer networks, and oil droplet that all fall within the definition of colloids. The study of foods from a colloidal prospective extends the concept of 'microstructure' to a consideration of the nature of the interactions between the constituent elements of the food material, which are typically dominated by entropy changes rather than chemical bonds. Thus, understanding the physicochemical mechanism behind the formation and stability of colloidal structures is paramount for the design of food structure, which consider, together with the classic needs (texture and mouthfeel), the impact upon wellness and health, including modulated digestion to trigger different physiological responses.

Food colloids and emulsions can represent a significant proportion of a consumer's everyday diet, as they are often contained in a range of products such as spreads, condiments, cook-in sauces, dressings, deserts, and ice creams. In many current products, these colloids and emulsions are high in fat or can be structured with sugars leading to weight problems in the general public. In order to address these issues, the future of food colloids and emulsions is likely to focus on fat, salt, and carbohydrate reduction, as well as on the targeted delivery of nutrients.

The use of complex emulsion and colloid structures (single or multiple emulsions, fluid gels, mixed gels, etc.) offers an attractive range of tools to engineer healthier foods without compromising the organoleptic properties of the product. In order to design the appropriate microstructures and functionality, an understanding of the conditions experienced by foods in the human gastrointestinal tract is required.

Colloidal Aspects of Food Digestion

The starting point to understand the importance of food colloids in the general 'food–health' relationship requires a sound appreciation of what happens to foods once they enter the body (Table 1). Food structures evolve after food is eaten, initially as a result of oral processing and also during mixing and transport within the human gastrointestinal (GI) tract, which largely rely on its aqueous phase. In the mouth, food is essentially broken down through mastication, where the maximum hardness is limited by the chewing force (~50–150 N). As food is broken down and mixed with saliva, a thin film of food is formed between the tongue and the palate. As such, lubrication of the oral surfaces becomes progressively the most important factor determining the sensory perception of food. Saliva also affects food behavior as a result of mixing and dilution, the amylase in saliva starting the digestion of starches in the food, and the polymeric molecules (e.g., mucin) that may cause flocculation of particles or oil droplets. Food materials respond differently to the environment in the mouth depending on both their structure and composition and as such impart different sensorial properties. Oil-in-water emulsions stabilized by starch particles can undergo coalescence during oral processing as the starch is hydrolyzed by the amylase, which has been found to enhance the oral fat perception. After 15–20 chewing strokes, the food has been processed to a stage where bolus has been formed and can be swallowed. After swallowing, food enters the stomach where the digestion process starts. This is an acidic environment where a significant amount of food structure is broken down by added enzymes (e.g., pepsin and gastric lipase) and electrolytes (e.g., $Na+$, Cl^-, and Ca^{2+}). The time taken for complete digestion depends on the original food structure, with liquids being digested more rapidly than semisolids. Understanding the gelation of polysaccharides and/or protein–polysaccharide electrostatic interactions in acidic conditions relevant to the stomach environment is essential to develop fluid meals, which form gels in the stomach, thus delaying gastric empty and prolonging satiety. Upon leaving the stomach, the partially digested food, called 'chyme,' enters the small intestine where hepatic, pancreatic, and gallbladder secretions containing enzymes and phospholipids are introduced to continue digestion and allow

Table 1 Summary of the digestion steps

Digestive step	*Mechanical actions*	*Enzymatic/biochemical condition*	*Colloidal aspects*
Mouth	Mechanical breakdown Mixing with saliva	pH 6–7 Amylase Mucin	Interaction with salivary protein Emulsion droplet flocculation Phase inversion Rheology/lubrication
Stomach	Mixing Sieving Pumping	pH 1.5–3 Pepsin, trypsin, lipase	Enzymatic breakdown of droplets (interfacial) Oil droplets coalescence/emulsification Acid-induced gelation
Small intestine	Low-intensity mixing (peristaltic movement)	pH 6–7.5 Pancreatic secretions, bile salts, glucosidase	Displacement of protein from emulsion interface Swelling of biopolymer particles Mass transfer
Large intestine	Longitudinal contraction	pH 5.5–6 Microflora fermentation	Adhesion mechanism of bacteria

nutrient absorption. The presence of biosurfactants (e.g., bile salts) facilitates emulsification of lipids by adsorbing at the droplet surface or displacing some of the original surfactant favoring the access of lipase to the lipid. The presence of hydrocolloids can slow the digestion of starch, proteins, and lipids either by reducing mass transfer or by restricting access of enzymes to substrates. As such, nutrient uptake will take place toward the end of the small intestine causing the hormonal response known as ileal break, which slows gastric emptying. In the large intestine, the remaining undigested food is fermented by bacteria. This releases key health-promoting compounds for the host. Inclusion of additional health-promoting agents, self-structuring for satiety, and the limitation of nutrient absorption have all been developed from this knowledge.

Emulsions Stability and Functionality

Emulsions are essential structural components in many foods and they consist of mixtures of immiscible liquids (generally oil and water), with one dispersed within the other as droplets. The droplets usually have diameters that lie somewhere between 0.1 and 100 μm. In its simplest form, an emulsion is one of two different types, oil-in-water (e.g., mayonnaise) or water-in-oil (e.g., margarine), and the oil phases are nearly always a triglyceride in food emulsions. The mechanisms by which the droplets are formed by the different emulsification processes are now fairly well understood. Traditionally, the two fluids are mixed using high-energy input devices, breaking the dispersed phase fluid down to small droplets, within the continuous phase fluid, until the size range of the droplets approximates that desired for the final product. Droplet formation results in the enlargement of the interfacial area between the two phases, which carries a large positive interfacial energy. As such, the formation of droplets is thermodynamically unfavorable and emulsions tend to destabilize over time to minimize the interfacial area. Stability is provided by a layer of surface or interfacial active material, generally amphiphilic in nature (e.g., protein and surfactant), which lowers the interfacial tension and prevents instability phenomena, such as flocculation and coalescence through the mechanism of electrostatic and steric stabilization. The structure and physical

properties of the interfacial layers depend on the types, concentration, and the conformation adopted at the interface by the adsorbed surfactant. Proteins, such as β-lactoglobulin, once adsorbed, undergo unfolding and rearrange their secondary and tertiary structures to expose hydrophobic residues to the oil phase. Interfacial unfolding impacts on the mechanical properties of the adsorbed layer, as unfolded protein interacts with their neighbors forming a cohesive elastic structure around the droplets. On the other hand, small molecule surfactants form a compact interfacial layer, which stabilizes the droplets by charge repulsion or the Gibbs–Marangoni mechanism. Because of the greater reduction in the interfacial energy compared to protein, surfactants, given sufficient time and at sufficiently high concentrations, may completely displace proteins from the interface when both are present. Figure 2(a) shows atomic force microscopy images of the planar interface consisting of a protein film to which a nonionic surfactant (Tween 20) is added. The surfactant adsorbs at the defects in the protein network; these nucleated sites then grow, compressing the protein network. At sufficiently high surface pressure, the network fails, releasing the protein from the interface (orogenic displacement). The two-dimensional phase separation is markedly different when ionic surfactants are considered, which involves the formation of many small surfactant-rich domains, but limited domain growth (Figure 2(b)). Ionic surfactants are likely to form (electrostatic and hydrophobic) complexes with the adsorbed protein molecules and potentially interfere with the ability of protein to efficiently interact with their neighbors, thereby providing more gaps at which they may be adsorbed. Displacement and changes to the interfacial structures by surface-active compounds produced by the body are an integral part of the lipid digestion process. Bile salts are biosurfactants produced by the liver and stored in the gallbladder. They adsorb at the surface of emulsion droplets entering the intestine promoting the binding of colipase and pancreatic lipase to the droplet surface, which allows triglyceride hydrolysis to take place. The morphology of the protein displacement taking place when bile salts are added differs from those observed previously with conventional surfactants (Figure 2(c)). The different molecular structure of bile salts (e.g., derived from cholesterol) from the synthetic surfactant and the conformation they adopt at the interface certainly play a role. The process of the lipolysis reaction depends on the surface activities of the interfacial material coated on the emulsion droplets. Rational strategies for limiting lipid digestion stem from observations of the nature of the displacement of proteins from interfacial structures by bile salts. One way is to use surfactants that are strongly surface-active and do not interact with bile salts, thus resisting displacement and preventing adsorption of the lipase.

Pickering Stabilization

Submicron-sized colloidal particles also adsorb at the oil–water interface forming a rigid interfacial film of densely packed particles, which provide steric hindrance to droplet–droplet coalescence (the Pickering stabilization). Droplets that are insufficiently covered, however, tend to coalesce as 'naked' interfaces cannot repel colliding droplets. The effectiveness of particles against destabilization (e.g., coalescence) stems from their strong adsorption to the liquid–liquid interface. The energy required to remove such particles from the interface can be several orders of magnitude higher than the thermal energy, and it ultimately leads to irreversible interfacial adsorption. The energy of desorption (ΔG_d) is related to the size of the particle (r), the interfacial tension between the two phases (γ_{ow}), and the contact angle (θ) that the particle makes with the interface:

$$\Delta G_d = \pi r^2 \gamma_{ow} (1 - \cos\theta)^2 \quad [1]$$

Several factors determine whether or not particles will stabilize an interface in a satisfactory manner including particle wettability, size, shape, and particle–particle interactions. Among these, the parameter of choice, which dictates the position of the particles at the liquid–liquid interface and hence the interfacial curvature, is the particle wettability, which is best defined by the contact angle. Hydrophilic particles, with a contact angle (measured through the water phase) of $\theta < 90°$, are preferentially wetted by water and therefore tend to stabilize O/W emulsions. On the other hand, particles of $\theta > 90°$ tend to stabilize W/O emulsions (Figure 3). Particles that are completely wetted by either water or oil (contact angle = 0° or 180°) are not likely to adsorb at the interface. In addition to wettability, effective Pickering stabilization is obtained when the adsorbed particles are at least an order of magnitude smaller than the emulsion droplet they coat, due to the effect that particle size has on the energy of adsorption ($E \propto r^2$). The

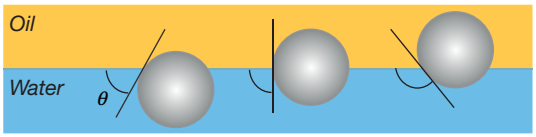

Figure 3 Effect of contact angle on the interfacial position of a solid particle.

wettability of the particle can be tailored via the adsorption of surfactant on the particle surface, which can modify the surface properties, and thus particle hydrophobicity to favor adsorption at the liquid–liquid interface. Surfactants can also displace particles from the interface depending on surfactant type and concentration. In the case of oil-in-water emulsions, the presence of a water-soluble surfactant will eventually result in the displacement of particles as their concentration in solution increases due to the greater affinity they have for the interface. On the contrary, the presence of oil-soluble surfactant, independently from its concentration, does not result in particle desorption. Many food products contain colloidal particles in their formulations and some of them participate in the stabilization of emulsions by adsorbing at the interface. Examples include cocoa particles in emulsion-based chocolate fillings, crystallized emulsion droplets in ice cream, and fat crystals in margarine. Fat crystals tend to favor the stabilization of oil-continuous emulsions by increasing interfacial viscosity or by forming a crystalline shell of sintered crystals around water droplets. The tendency to adsorb at the oil–water interface depends on the size as well as on the polymorphic form of the crystal. Tristearin α-crystals (contact angle between 20° and 30°), for instance, are more hydrophilic than β-crystals (contact angle 0°); therefore, they tend to absorb at the interface. However, surfactants are usually employed to increase crystal polarity, thus favoring adsorption. Once at the interface, crystals may form a rigid layer of sintered crystals, which contributes to the stability of the emulsion but more importantly allows the entrapment of electrolytes and other osmotically active components, independent of the magnitude of the applied osmotic pressure gradient. Release, in this case, is triggered by increasing temperature. At higher temperatures, crystals melt, and as a result, emulsion stability is compromised eventually leading to complete entrapped active (e.g., salt) release.

Hydrocolloids

A large number of biopolymers, mainly polysaccharides, routinely used in food formulations as thickening (e.g., guar gum) or gelling agents (e.g., carrageenan) to control mouthfeel, are grouped under the technical term of 'hydrocolloids.' The term 'hydrocolloids' or 'hydrophilic colloids' arises as these polymers have a marked affinity for water, due to the presence of a large number of hydroxyl (–OH) groups. In addition, when in solution, they exhibit the properties of a colloid due to their large size as macromolecular entities when compared to water molecules. As mentioned earlier, many hydrocolloids are polysaccharides, which typically contain several hundred of thousands of monosaccharide units. The position of the linkage between adjacent sugars and the orientation of the bonds to the glycosidic oxygen (axial or equatorial) dictate the overall shape (conformation) of the individual chains and the way in which they interact with one another. This has a profound effect on the physical state of polysaccharides and consequently on their physiological role as constituents of digest. In the case of starch, a direct consequence of the α $(1\rightarrow4)$-linkages in the polyglucose sequences of amylose and amylopectin is the formation of coaxial double helices, which are densely packed to form crystalline spherical granules. Because of its crystalline structure, starch is insoluble in cold water, and it is far less susceptible to breaking down by human digestive enzymes (i.e., resistant starch). On heating, however, the amylopectin helices melt and lose its crystalline structure; the granules swell with the release of disordered amylose in a process known as gelatinization. As a result of this order–disorder transition, starch molecules become highly hydrated and susceptible to enzymatic hydrolysis. An important use of polysaccharide chain when present in food systems as disordered coils is to increase the viscosity of the solution by restricting the flow of the solvent. This is strongly dependent on the molecular weight and conformation of the polymer in solution as well as on its concentration. Figure 4(a) shows changes in specific viscosity, η_{sp}, defined as

$$\eta_{sp} = \frac{\eta - \eta_s}{\eta_s} \qquad [2]$$

where η is the viscosity of the solution and η_s is the viscosity of the solvent, as function of concentration for a solution of methylcellulose. In dilute solutions, the individual coils are free to move independently and generate viscosity by tumbling around and interfering with the flow of the solvent. The viscosifying capacity at such low concentrations is correlated to the volume that the molecules occupy in solution (hydrodynamic volume), which is a consequence of its molecular weight, branching chains, and affinity with the solvent. As the polymer concentration is raised, these molecules begin to come into contact with one another and to overlap and interpenetrate one another. The formation of entangled network of interpenetrating chains occurs at a critical concentration known as coil overlap concentration (C*) and is accompanied by a sharp increase in the concentration dependence of viscosity. With increase in concentration, shear-thinning behavior is often observed (Figure 4(b)). At low rates of deformation (i.e., low shear rates), there is sufficient time for entanglements, pulled apart by the imposed stresses, to be replaced by new entanglements with different chains, and as a result, the viscosity remains constant (the Newtonian plateau). However, at higher shear rates, where there is insufficient time for new entanglements to form, the extent of coil overlap is decreased and the viscosity decreases (shear thinning).

Hydrocolloids Gelation

While all hydrocolloids thicken and increase the viscosity of aqueous dispersions, some of them also have another major property of being able to form gels. The formation of a cohesive network requires enough ordered association (as in the solid state) or cross-linking to hold the three-dimensional network together, but there must also be sufficient residual

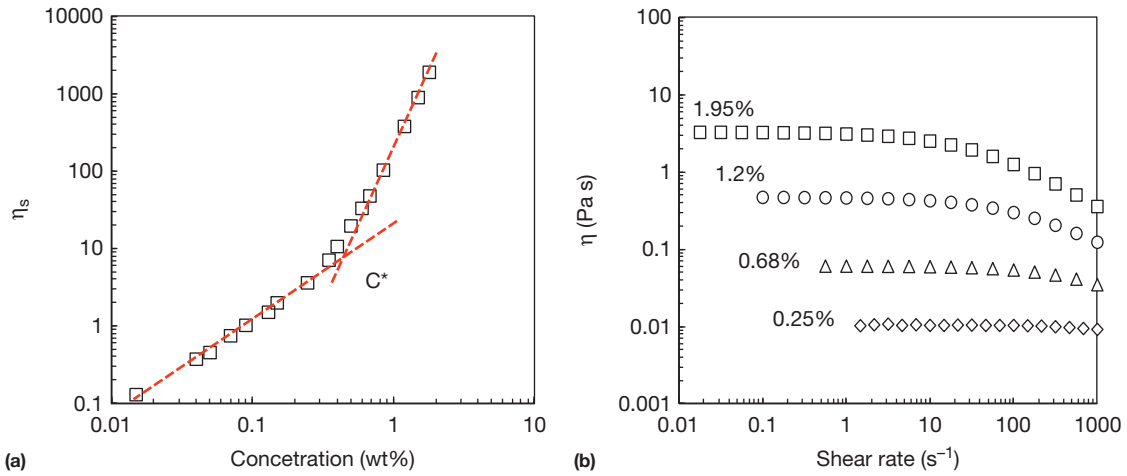

Figure 4 (a) Variation of specific viscosity (25 °C) with concentration for methylcellulose. (b) Viscosity curves for aqueous solution of methylcellulose at 25 °C.

disorder (as in solution) to maintain hydration and prevent the network collapsing to a close-packed solid. This requires that the number of ordered association known as 'junction zones' must terminate at some point so that the remaining unordered segments of the polymer chain are free to participate or not in other junction zones with other polymer chains. The minimum length can vary substantially from one polysaccharide to another but is typically in the range 8–20 residues. Termination of junction zones usually results from structural irregularities that include changes from one type of residue to another type in the polysaccharide chain or branch points, which can inhibit ordered packing and promote solubility. Charge also promotes solubility by introducing electrostatic repulsion between the chains. Negatively charged polysaccharides may, however, associate forming junction zones in the presence of cations that can bind to the chains and balance their charge (e.g., κ-carrageenan). The physical characteristic of the network depends on several factors including the number and length of the 'junction zones' and the number of molecules in the junction zones. The latter can vary across the different hydrocolloids; junction zones may be formed by two (e.g., alginate) or more polymer chains (e.g., κ-carrageenan), which has a direct impact on the rigidity of the gel. In addition, there are also various types of conformations present in ordered junction zones in gels. These include helical structures, such as the coaxial double helices found in carrageenan and agar gels, which form aggregated assemblies incorporating cations to balance the charge on the polymer chains and the 'egg-box' structure found in alginate gels. The thermal stability of the gels is also a direct consequence of the nature of their junction zones. Gelatin melts at low temperatures because the junction zones are only bound by relatively weak hydrogen bonds. On the other hand, it is possible to make alginate gels that do not melt on heating because of the strength of calcium bridges in the junction zones. Knowledge of the conditions required for gelling of particular hydrocolloid dispersions and the characteristics of the gels produced are very important aspects in the design of hydrocolloid-based foods, which might convey properties in the GI tract, related to promotion of health. These include the effect that gelation has on the GI transit time, where an extended residence time in the stomach produces a 'sensation of fullness' and hence a potential way for appetite control. With gelation, the greater sensation of satiety is thought to be a combination of viscosity increase and mechanical properties of the gel. Strong gels would be less likely to be broken up by the grinding action of the stomach, which is reported to apply forces in the order of 0.65 N. Gelation can be triggered by the physiological conditions found in the gastric lumen, that is, low pH and body temperature. Low-acyl gellan, a polysaccharide obtained from *Aeromonas elodea*, forms a threefold double helix structure (similar to that of carrageenan) at low temperature. Lowering the pH promotes gelation by reducing the charge density, thus suppressing electrostatic repulsion between individual helices. As such, in acidic environments similar to those present in the stomach, low-acyl gellan forms strong elastic gels where maximum gel strength is observed between pH 3 and 4 (Figure 5). The rate of gelation is likely to play a major role in determining the effect of intragastric gelation on satiety. The rate of gelation should be sufficiently fast to allow structuring while the digesta stay in the stomach. However, if the gelation rate is too fast, only part of the digesta will be trapped in the gel structure, thus decreasing the impact on satiety. This requires a detailed understanding of the relationship between the fine chemical structure and the physicomechanical properties of the chosen hydrocolloids to generate the desired gel microstructures.

Biopolymer Mixtures

Mixtures of biopolymer are frequently used in food to impart specific flow behaviors, texture, and appearance to the final food product, for example, low-fat spreads, salad dressings, sauces, and ice creams. The structures and morphologies that such mixtures develop in relation to their functionalities are the direct consequence of the thermodynamic compatibility of the macromolecular components and the interfacial phenomena. On the basis of the interaction taking place

between the two polymers, it is convenient to distinguish two types of phase separation: segregative and associative. In the case of associative phase separation, the two polymers, usually oppositely charged polyelectrolytes, will interact and collect in the same phase. The result is a system in which one phase is enriched in both polymeric components existing in equilibrium, with another phase poor in both. If the interaction is repulsive, then, above certain polymer concentrations, the two polymers will separate in two phases each containing primarily one biopolymer with only a small amount of the other. A phase diagram (Figure 6) is used to determine the composition of polymers needed to induce phase separation in

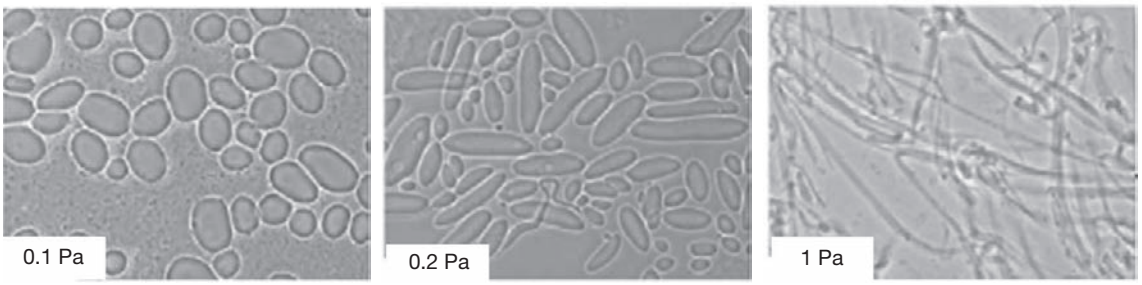

Figure 7 Different particle morphologies produced by increasing the shear regimen during gelation of various biopolymer mixtures. Reproduced with permission from Norton et al. (2006). Fluid gels, mixed fluid gels and satiety. *Food Hydrocolloids* **20**, 229–239. Elsevier.

an aqueous biopolymer mixture. Phase diagrams are usually constructed by plotting the polymer concentrations as an x–y plot as the solvent in the mixture often constitutes more that 90% of the sample. The binodal curve shows the cosolubility profile of the two biopolymers in water. It divides the miscible region at low polymer concentrations (single-phase region) from immiscible region at higher polymer concentrations (two-phase region). The compositions of the phases formed are determined by a number of factors, including the solvent condition, the temperature, and the molecular weight of the two polymers. Molecular weight (M_w) plays a direct role on the phase compositions, since higher M_w polymers have a smaller entropic term, so that increasing the M_w of one of the components will have the effect of increasing the concentration. Temperature also has a major effect on the phase separation. A reduction in temperature reduces the entropy of mixing leading to an increase in incompatibility and, more importantly, often inducing molecular ordering, which has the potential to increase the effective molecular weight of the components. The way in which the phase morphology initially forms and then evolves follows essentially two types of mechanisms: nucleation and growth and spinodal decomposition. Microstructure of biopolymer solutions whose composition lies within the two-phase region (spinodal line) takes the form of suspensions of droplets (~2–20 μm) of one component in a continuous phase of the other, similar to that of conventional oil-in-water emulsions (Figure 6). In fact, these structures have been found to depend on the same physical principles (droplet breakup and coalescence) as conventional emulsions. Once the droplets have formed, they can start to ripen through droplet coalescence, and if the process is allowed to continue undisturbed, then bulk phase separation is expected. A competing event in these systems is the gelation of one or both phases, which arrests the process of ripening of the phase structure. Another factor, unique to mixed biopolymer mixtures in determining the structure, is the low interfacial tension between the separated phases due to the fact that the main component of the two phases is water. A surface tension of $\sim 10^{-5}\ \mathrm{Nm}^{-1}$ is generally measured, which is about three orders of magnitude below that normally measured for an oil-in-water system. The low interfacial tension and the high viscosity of the two phases impact on the timescales involved in the recovery from the effects of applied shear, which is slow. Therefore, the combination of gelation with a suitable sample flow history can be used to kinetically trap flow-induced structures, the morphology of which is determined by both the thermal history and process shear conditions. Examples of the anisotropic structures, which can be generated, include ellipsoidal gel particles and fiber-like structure (Figure 7). These asymmetrical particles exhibit different rheological properties to those possessing a spherical phase structure, for example, higher viscosity at lower phase volumes and complex flow patterns. Although biopolymer mixtures have been long considered to control of oral breakdown, this is arguably only their main function in food. In principle, such formulations offer the promise of a dual stage and breakdown profile, with the second stage leading to structuring of material in the stomach or gut. Such properties are potentially beneficial in terms of enhancing the sensation of satiety or in controlling the uptake of food macronutrients.

Emerging Developments

Multilayer Emulsion

A powerful emerging approach to achieve effective control over emulsion stability and release of functional ingredients is the formation of a multilayer interface. Production of multilayer emulsions generally involves the sequential deposition of charged biopolymers onto an oppositely charged emulsion surface (Figure 8). Adsorption of the charged biopolymer occurs until saturation of the surface is obtained. The reversal of net charge on the interface, which creates an electrostatic repulsion between the surface and the nonadsorbed biopolymer in solution, prevents further adsorption. Charge reversal then also allows the adsorption of an additional oppositely charged biopolymer onto the surface. This process can be repeated a number of times to form oil droplets coated by laminated shells of three or more layers. Multilayer emulsions have been prepared from protein–proteins, protein–polysaccharides, phospholipids–polysaccharides, and surfactant–proteins. The properties of the interfacial multilayers, such as its thickness and permeability, are dictated by the strength of molecular interaction between adjacent layers. This is controlled by charge density of the adsorbing biopolymer and the prevailing solution conditions. Changes in pH in the GI tract can potentially be used to weaken electrostatic interactions between the layers and provide a means for the transport and release of bioactive compounds. Equally important is the ionic strength of the solution. The presence of salts

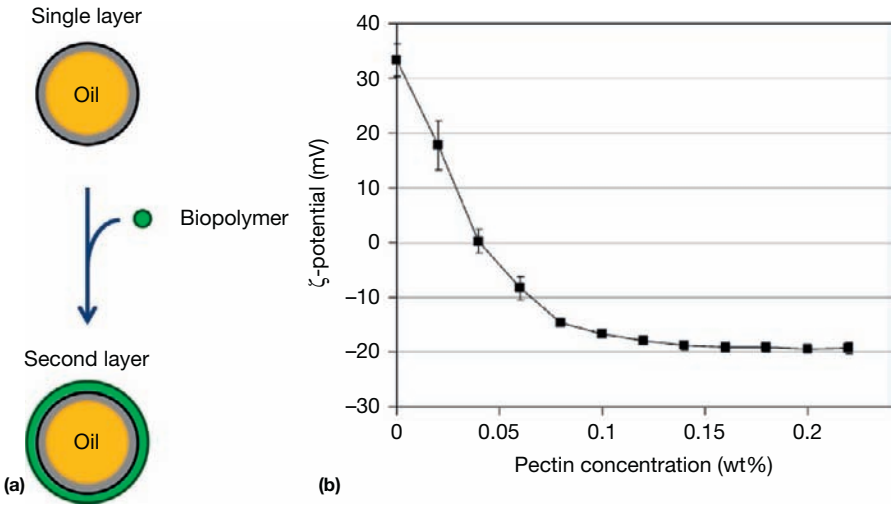

Figure 8 (a) Schematic representation of the adsorption of a layer of biopolymer onto droplets surface. (b) Change of the surface electrical charge of emulsion droplets stabilized by β-lactoglobulin (β-Lg) as function of pectin concentration (5 wt% corn oil, 0.45 wt% β-Lg, 5 mM imidazole/acetate buffer, pH 3.0) after dilution. Figure 9 Schematic representation of (a) water-in-oil-in-water ($W_1/O/W_2$) emulsion and (b) oil-in-water-in-oil emulsion ($O_1/W/O_2$).

can reduce the strength of the electrostatic interaction between oppositely charged biopolymers influencing the stability and thickness of the layers. Multilayer coating can be, potentially, designed to make oil-in-water emulsion completely inaccessible to digestive enzymes in the GI tract so that they could be used to reduce the calorie content of foods while maintaining good sensorial acceptability. In addition, understanding the design rules that control the structure and instability of the laminated shells opens up a wide array of opportunities to engineer emulsion with multilayer membrane that responds to physiological stimuli (e.g., pH, enzymes, and salt) providing a means of selective triggering and release of functional molecules at desired sites through the GI tract.

Double Emulsions

Another emerging technology is double or duplex emulsions. These are emulsions that have a ternary structure where an inner emulsion is formed within an emulsion. There are two main types of such systems: water-in-oil-in-water ($W_1/O/W_2$) emulsions with water droplets inside oil droplets and oil-in-water-in-oil emulsions ($O_1/W/O_2$) with oil droplets inside water droplets (Figure 9). The potential benefit of such high-order structures is that they can be used to encapsulate health-promoting ingredients (e.g., peptides) whose unpleasant taste will not be perceived upon consumption as the internal phases will not come into contact with the sensory organs during oral processing. In addition to encapsulation, the use of $W_1/O/W_2$ emulsions in products such as mayonnaise allows the possibility of lowering the fat content as the dispersed oil phase itself contains water allowing a volumetric reduction of the oil without changes in the perceived oil phase fraction. Despite their commercial relevance, double emulsions are faced with a number of significant challenges, namely, the means by which the inner phase destabilizes during manufacture as well as during the subsequent storage. Production of double emulsions relies on two separate emulsification steps: a primary high-intensity mixing or valve homogenization to obtain the smallest possible droplets, followed by secondary emulsification under mild condition (e.g., membrane emulsification) to avoid any destabilization of the primary emulsion during the process. Instabilities on storage may occur at many different

levels: coalescence between internal phase droplets (W_1) or between outer phase droplets (W_2) and/or release of the internal phase (W_1) in the external one (W_2). The stability of duplex emulsions is highly dependent on the type and concentration of emulsifiers used. The use of polymeric emulsifier (e.g., whey protein isolate), on at least one interface, providing steric stabilization to the emulsion, markedly improves double emulsion stability against coalescence. Their large molecular size prevents them from migrating between interfaces. They will also not form reverse micelles, which can transport water and/or solute through the oil phase. Another common cause of instability comes from the large Laplace pressure (Π) of small inner droplets (W_1), resulting in a thermodynamic driving force for water to diffuse through the oil phase. In principle, the creation of a solid shell layer by the Pickering stabilization with fat crystals and subsequent sintering at the emulsion interface is an efficient way to prevent molecular migration through the interface resulting in highly stable double emulsions.

Fluid Gels

Many hydrocolloids such as egg albumin, whey protein, agar, alginate, and κ-carrageenan form microgel suspension ('fluid gel') if a suitable shear field is applied to the sample during gelation. This process can produce a material, which contains a high phase volume of spherical particles with droplet diameters in the 1–10 μm range (i.e., the same size range as oil droplets in many food emulsion systems). If the shearing process is not applied for the whole of the gelation process, then some cross-linking between gel particles can be induced resulting in a material with a yield stress, whose properties depend, among other things, on the concentration of the biopolymer used to produce the sample. By careful selection of the hydrocolloid and its concentration and by careful control of the shear and temperature/time profile, a range of textures and emulsion-type properties can be achieved. This is clearly an interesting colloidal structure with potential applications in many food products for fat replacement or for controlled release of other food ingredients such as sugars.

Colloidal Structure in Action: Where We Are?

Food colloids in many, if not most, food offer much potential for controlling their functionality. The structure and interfacial properties of colloids are critical to manipulate and control stability both before and after consumption. More questions arise as to how the dynamics and kinetics of nutrient uptake are influenced by food colloids structures (e.g., particle size and shape and self-assembled structures) where the timescales range from nanoseconds (enzyme reactions) to hours (transit time in the GI tract). Indeed, it is not yet possible to predict with confidence what will happen in the real systems until it has been studied previously. Further development in this area is needed to establish a solid link; on the one hand, between the biological mechanisms of digestion and, on the other, the engineering of food structures that can deliver desired physiological impacts.

Food Composition Databases

PR Pehrsson and DB Haytowitz, Nutrient Data Laboratory, Beltsville, MD, USA

Published by Elsevier Ltd.

Introduction

Food composition is the undertaking to determine and compile what is in the foods we eat and is the critical bridge between nutrition, health, and disease prevention and food production. This intersection is extensively described in the Dietary Reference Intakes prepared by the Institute of Medicine of the National Academies and the Dietary Guidelines for Americans prepared by the US Department of Agriculture (USDA) and the US Department of Health and Human Services and in similar documents from other countries. These include components essential to survival (protein, carbohydrates, fat, minerals, and vitamins) and compounds that have the potential to cause diseases, ranging from trace to excess concentrations. Of increasing interest are various bioactive compounds, which may have a protective effect against certain diseases such as cancer and coronary heart disease.

Food production incorporates agriculture to produce the raw materials and the processing and food science that turns raw commodities into the myriad of different foods available. These different processes impact the amounts of components in foods and the determination of the amounts of these components composes food composition databases or tables (FCDBs/FCTs). The uses of FCDBs are multidimensional and include the following: (1) evaluation and monitoring of nutritional status, (2) monitoring of changes in dynamic food supplies, and (3) inclusion of new information on the characteristics of commodity-level foods (growing conditions and feeding practices) and commercially prepared foods (brand differences), market share distributions, and reformulations. FCDBs are also important in world trade, particularly with the diversity of foods available from many countries. Increasingly, consumers want to know what is in the foods they eat. Foods, particularly commodity-level foods, are sold based on the content of certain components. In some cases, knowing the composition of a specific food can be used to uncover adulteration or other fraudulent activities. Many of these standards are established in the Codex Alimentarius – a set of international food standards, guidelines, and codes of practice.

History of Nutrition Monitoring and Food Composition

The study of the composition of foods and the connection to health and disease prevention has been a worldwide initiative for almost 200 years. Many diseases are considered preventable through diet and physical activity, so comprehensive information on the composition of foods is critical to health promotion and disease management. The first US FCTs were compiled by Atwater and Woods and were entitled 'Investigations on the Chemistry and Economy of Food.' This publication included data for 178 food items on five proximate components (water, protein, fat, total carbohydrates, and ash), kilocalories (called fuel in the Atwater table), and refuse. In subsequent decades, the USDA published a number of reports on the composition of foods, extending the number of foods and components covered. Researchers around the world expanded food composition research and data tables. In 1950, the USDA published Agriculture Handbook No. 8, which was updated in 1963 and again in section by food groups between 1976 and 1993. Concomitantly, data files were made available for use with various computer programs – first on punch cards and magnetic tape, followed by diskettes and CD-ROM. Today, the database is available on the Internet. In 1980, Release 1 of the USDA National Nutrient Database for Standard Reference (SR) was made available. The latest version, SR27 (2014), contains data for up to 150 components for nearly 8600 food items; the SR is available on NDL's website and is updated annually.

Types of Data

Knowing the composition of foods is essential to understanding the promotion of health and prevention of diseases. These data are used by researchers, nutrition policy makers, health professionals, the food industry (e.g., labeling, research, and development), and a wide consumer base. Electronic collection, storage, and rapid dissemination are standard, making currency and accuracy of the data more important than in the past.

There are a number of different types of data found in FCDBs/FCTs including analytic data. Analytic data are values determined by direct analysis of a food sample and in most cases are the highest quality data. Several types of information are essential if analytic data to be used in an FCDB/FCT. This includes a good sampling plan to ensure representative values, proper sample handling, and selection of the appropriate analytic method for the food matrix and component being analyzed and appropriate quality control materials to validate the results. The USDA's National Food and Nutrient Analysis Program (NFNAP) incorporates all of these features.

An accurate and comprehensive food description is critical for it to be added to the FCBD/FCT. A good description should include the name of the food, how it was processed (specifying any fortification or enrichment), how it is prepared, and any added ingredients. Basic commodities, for example, a plant or animal food, should include the cultivar or breed, whether it was from a wild or domesticated plant or animal, along with the scientific name. Color, maturity, and refuse should also be specified. It is also important to specify the edible portion and describe any refuse.

The average supermarket in the United States contains tens of thousands of unique food products; the latest version of the USDA National Nutrient Database for Standard Reference, SR27, contains over 8600 food items for up to 150 food

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00308-1

components. It is not possible to analyze all foods in the food supply or even those reported in national food consumed, due to both the cost of the sample collection, preparation, and analysis and the resources needed to handle data. The USDA has used the key foods approach, which accounts for 75% of the intake for nutrients of public health significance, to identify and prioritize foods for analysis; key foods are determined by multiplying the reported consumption of foods by their respective nutrient concentrations, in order to prioritize foods for analysis.

Not all components are found in every food. For example, vitamin B_{12} and cholesterol are not found in plant foods, while fiber and vitamin C are not found in animal products. As such, it would not be a prudent use of resources to analyze these nutrients in such cases as the values can be assumed to be zero. The database compiler should document that decision in the FCBD/FCT. However, when considering processed foods, which are mixtures of many components, these assumptions do not apply. Furthermore, there are often additional exceptions to these general rules, and the database compiler must be cognizant of them.

- *Analytic data*: Analytic programs are funded by national governments (e.g., USDA) and through collaborations with other government agencies, the food industry, and academic institutions. Analytic data are generally the highest quality data and often include a prioritized list of foods, which are sampled nationally and analyzed using officially accepted analytic methods, sufficient number of samples to address nutrient variability, rigorous quality control procedures (both in handling of samples and in analysis of raw data), and appropriate statistical methods for data aggregation. At the USDA, a national sampling program, the NFNAP is a long-standing collaboration with the National Institutes of Health to expand and improve the quality of composition data for foods consumed by Americans. To date, composition profiles for approximately 2000 foods have been developed under this program.
- *Calculated data*: Missing values may be imputed from similar foods and adjusted for moisture content or normalized according to base nutrient, for example, fatty acids to total fat and amino acids to total protein. Missing values for multicomponent foods are often calculated through linear regression programs based on a list of ingredients in descending order from manufacturers or labels (with high-quality data for ingredients) and nutrient levels from the Nutrition Facts panel. When using values from the Nutrition Facts panel, issues may arise due to rounding permitted when calculating values for the label, for example, trans fat can be rounded to 0 if the value is less than 0.5 g per serving. This can result in underestimating the content when the values are calculated to 100 g, particularly with small servings.
- *Assumed zero*: In many cases, a specific nutrient is known not to exist in certain foods, for example, cholesterol in plant-based foods. In these cases, zeros may be used to populate missing fields.
- *Manufacturers' data*: Label data may be used to complete nutrient profiles where analytic data are not available.

As discussed in the preceding text, it is not possible to analyze every form of a food. Missing values can be calculated from other forms of the same food by adjusting for changes in moisture and fat content. If the food is processed or prepared, changes in nutrient content can be determined by the use of appropriate retention factors. Other procedures for calculating missing values have been developed. Another approach for calculating missing values is the use of a recipe for the food item of interest. Information on the quantity of the various ingredients (e.g., from recipes with specific preparation techniques and known ingredients and quantities) is entered into a computer program with adjustments for assumed moisture and fat losses/gains and for nutrient losses due to preparation practices (e.g., heat or exposure to air). This produces a nutrient profile for the food item.

For many processed foods, the ingredients are listed on the product label in descending order of content but their quantity is considered proprietary by the manufacturer and is not available. By using the label ingredient information, along with the Nutrition Facts panel, and the composition data in the SR, it is possible to use a linear programming calculation to estimate the proportion of the various ingredients in a particular food item. The ingredients and their proportions can then be used in the recipe program described in the preceding text to calculate a nutrient profile for the food item.

Types of FCDBs

There are a number of different types of FCDBs/FCTs available. Perhaps, the most common is a national database, which is developed for a specific country, such as the SR developed by the USDA's Nutrient Data Laboratory in Beltsville, Maryland. Release 1 of this database was made available in 1980 and the latest version, Release 27, was issued in 2014. The SR replaces printed tables issued as far back as 1892 and is complemented by an online search program, which enables users to look up the nutrient content of their food items. Development of national and regional FCDBs is recognized in Latin American countries, Europe, Canada, Asia, and Africa, in addition to the United States.

Regional FCDBs/FCTs are developed in areas where a number of small countries exist with similar climates and cuisines. An example is the West African FCT developed by the Food and Agriculture Organization (FAO) and other organizations. FCTs for population-specific groups (American Indians/Alaska Natives in the United States and indigenous peoples in Canada) have arisen to address specific eating practices of these groups and research on the health issues they face.

Special interest databases (SIDs) are often developed by database compilers. In the United States, these were developed for a number of various compounds (Table 1). In other cases, they may be included in appendix tables to an FCT, where values for all the foods in the main database are not available.

SIDs are developed for emerging nutrients of interest to researchers working on various diseases. The data from a number of these SIDs have been expanded, updated, and incorporated into the SR. As can be seen from the earlier table, these databases typically include several hundred food items. After incorporation into the SR, a particular nutrient may be considered appropriate to be included in the Food and Nutrient Database for Dietary Studies (FNDDS), which is used to assess the dietary intake of various nutrients in the US National

Table 1 Special interest databases developed by the USDA

Database	*Year*	*No. of foods*	*Compounds*
Sugars[a]	1987	522	Monosaccharides (galactose, glucose, and fructose), disaccharides (lactose, sucrose, and maltose), other sugars (trioses and tetroses), total sugar
Carotenoids[a]	1998	206	Alpha-carotene, beta-carotene, beta-cryptoxanthin, lutein + zeaxanthin, lycopene
Selenium[a]	1992	506	Selenium
Trans-fatty acids[a]	1989–1993	214	Individual trans-fatty acids
Vitamin D[a]	1999	122	Vitamin D
Vitamin K[a]	1994	194	Vitamin K (phylloquinone)
Fluoride[a]	2005	427	Fluoride
Choline	2008	630	Betaine, glycerophosphocholine, phosphocholine, phosphatidylcholine, sphingomyelin, total choline[a]
Isoflavones	1999	128	Genistein, daidzein, glycitein
	2008	549	
Flavonoids	2003	220	Flavonols, flavones, flavanones, flavan-3-ols, anthocyanidins
	2007	385	
	2011	500	
Expanded flavonoids	2013	2926	Includes data for 29 compounds from isoflavone and flavonoid databases
Proanthocyanidins	2004	205	Monomers through polymers of flavan-3-ols

[a]Now included in the SR.

Health and Nutrition Examination Survey (NHANES). In these cases, values for missing data points are calculated using the procedures described in the preceding text.

There are a number of commercially available FCDBs developed for a variety of purposes. Some of these include databases for use in clinical studies such as the Nutrient Data System for Research developed by the Nutrition Coordinating Center at the University of Minnesota. Others are developed for dietitians to use in counseling their clients or for research and development groups at food companies to use in formulating their products. The National Nutrient Databank Conference has compiled a directory of these, the International Nutrient Databank Directory. Once the purpose of the database is established, parameters for the targeted population, specific foods and components, and strategies for gathering data are defined.

Criteria for FCDB

An FCDB/FCT should be representative for the population of interest. However, it is not possible to have data for the precise food consumed by an individual. In some clinical studies, matching food samples are prepared; one is consumed by the subject and the other is analyzed for its composition. This requires an enormous amount of resources and is not practical in most situations. Therefore, it is necessary to devise a sampling plan that will examine a sufficient number of samples with sufficient dispersion to ensure that any food consumed by an individual will fall within the universe defined by the FCDB/FCT values for the food. The USDA has developed a sampling plan, proportional to size, based on US Census data to identify sampling locations. Food sales data are used to identify specific brands of food items for purchase. The USDA typically samples in 12 locations and endeavors to select those brands that will account for 75–80% of the market. For some foods and/or nutrients where more variability is expected, a larger number of sampling locations might be desirable. In those cases, where one or two brands command a large share of the market for a specific food item, fewer samples may be acceptable.

While it is certainly desirable to include as many foods as possible to reflect the food supply, resource limitations often make this difficult or impossible. One must consider the cost/benefit of adding more foods, particularly if it requires new sampling and analysis. The FCDB/FCT should cover the most commonly consumed foods but must also consider the diversity of the population. Some foods may not be widely consumed across the entire national population but are important sources of various nutrients for certain population subgroups, either age, gender, or ethnically based.

When developing an FCDB/FCT, it is important to use good quality data. The USDA has developed a data quality evaluation system to evaluate analytic data. It looks at five key attributes: (1) sampling plan, (2) sample handling, (3) number of samples, (4) analytic method, and (5) analytic quality control. Each of these attributes is scored and summed to yield a quality index for the nutrient in each food. For an FCDB/FCT compiler to properly evaluate the data, it is critical that this information be included in journal articles and various reports.

One of the most critical pieces of information about a food is its description. Descriptions must be clear and unambiguous. They should include a complete description of the food including processing and preparation. For example, for a frozen food, the description should indicate if it is prepared or unprepared. A canned food should indicate if the entire can contents or just the drained solids were analyzed. If a food was fried, the type of oil used should be indicated. The FAO/INFOODS has prepared Guidelines for Checking Food Composition Data prior to the Publication of a User Table/Database.

Values should be presented in a consistent manner, for example, a given component should always be presented in the same units. In FCDBs/FCTs, data are presented per 100 g,

edible portion. This allows easy conversion to other household measures. Data are also presented on a wet-weight basis. While many analysts report results on a dry-weight basis, foods are consumed as prepared. When combining data from various sources, the developer will encounter a variety of units of measurement. Sometimes, a given component will be provided in milligrams and sometimes in micrograms. For the purposes of comparison with other FCDBs/FCTs, the developer should use the standard units of measurement conventionally used, for example, mg or ppm. The FAO/INFOODS has developed Guidelines for Converting Units. This publication also contains the recommended units for each component.

The source of the data should be clearly identified. If from a study sponsored by the FCDB/FCT developer, the name of the study and when it was conducted should be given. If data are used from a journal article, a full citation should be provided. If values were calculated, codes indicating how the calculations were performed should be developed and used. The USDA has a set of derivation codes that describe how the values were calculated (SR27 documentation). If values were calculated from another food, the identification number for that food should also be supplied. The FAO/INFOODS has prepared Guidelines for Food Matching, Version 1.2, which can be of assistance in this endeavor.

Users often wish to compare data from different databases. To do so, both databases must have clear, unambiguous descriptions. If combining multiple databases, care should be taken to ensure that food item identifiers are unique across the databases. This may require the use of a composite key, where one element identifies the specific database and the other element identifies the food item. The aforementioned comments regarding food description are of particular importance when comparing data across different FCDBs/FCTs.

Certain uses of FCDBs/FCTs, that is, dietary assessment or various clinical studies, require complete datasets with no missing values. The developer should be cognizant of the intended uses of the FCDB/FCT. The USDA maintains a hybrid system, where complete profiles for a selected set of nutrients are provided for all foods used in the What We Eat in America component of the NHANES. Other foods, not used for the NHANES, may contain fewer nutrients, in some cases, basically those found on a Nutrition Facts panel.

While the developer of an FCDB/FCT provides average values for dissemination, users frequently want to see the values behind the means. Some users may want to calculate different means more suitable for their needs. To do this, clear links between the mean values and the individual data points need to be provided.

International Databases

In 1983, international experts on food composition met in Bellagio, Italy. Based on their recommendations, the International Network of Food Data Systems (INFOODS) was formed in 1984. Initially, the INFOODS was established under the auspices of the United Nations University. Today, the FAO of the United Nations serves as the global coordinator. The INFOODS seeks to establish and maintain international standards and guidelines for the generation and compilation of food composition data. A series of regional data centers were established to facilitate interactions between member nations in each region in order to encourage the exchange of data and information on the composition of foods. A list of FCTs and databases was compiled and is available on the INFOODS website. These are organized by the regional data centers and many can be viewed online. A number have searchable databases that allow one to look up the composition of foods in the particular database.

International Guidelines

Books were published in the areas of nomenclature and food descriptions to facilitate data interchange among member countries. Since food composition as an academic discipline is not usually covered in detail, a number of training courses were held in the Netherlands and in other locations. Much of the information contained in these courses has been incorporated into an e-learning course available on the Internet. In recent years, the FAO/INFOODS has assembled a series of guidelines covering Food Matching, Checking Food Composition Data prior to the Publication of a User Table/Database, and Converting Units, Denominators, and Expressions.

The Guidelines for Food Matching grew out of an effort by the FAO to match data used by different coding schemata with that used by the FAOSTAT in order to update food balance sheets prepared by the FAO. It points out the need for accurate food descriptions when comparing data from different FCDBs or when using data from one database to impute values in another. When matching foods, various descriptive factors must be considered. These include processing and preparation, state of the food, color, biodiversity, maturity stage, refuse/edible portion, and fortification/enrichment.

The FAO/INFOODS Guidelines for Converting Units, Denominators and Expressions, Version 1.0, was published in 2012. The objectives of these guidelines are the following: (1) to provide a comprehensive list of conversions for standardization purposes, (2) to make users aware of possible difficulties concerning units and denominators, (3) to motivate users to pay more attention to units and expressions, and (4) to encourage data generators to publish all necessary data in order to be able to perform conversions and thus make their data available for the development of FCTs/FCDBs, in addition to research. While these guidelines include the common metric system conversions, such as micrograms to milligrams, they also include less common ones such as converting data on a dry-weight basis to a fresh-weight basis. Also included is information on handling edible portion coefficients.

Before releasing an FCDB/FCT, there are a number of quality control steps that must be undertaken to ensure a high-quality product. The FAO/INFOODS Guidelines for Checking Food Composition Data prior to the Publication of a User Table/Database was published in 2012 with input from many database developers around the world. Among these checks are making sure that, to the extent possible, all fields are complete. Another check is to make sure that various calculations are completed and correct, such as calculating carbohydrate by difference; calculating energy by multiplying protein, fat, and carbohydrate by the appropriate factors; and calculating

vitamin A from individual carotenoids. Other checks include ensuring values for related nutrients are complete. For example, if individual fatty acid data are available, there should also be values for total saturated fatty acids, total monounsaturated fatty acids, and total polyunsaturated fatty acids. Nutrient values should also be compared from release to release to make sure any changes in the values can be explained. The USDA has built these checks into its Nutrient Databank System and participated in the development of the FAO/INFOODS guidelines.

Future Needs: Nutrients, Foods, Technology, and Information Dissemination

Over the years, the SR has been expanded to include many more foods and nutrients (Table 2). Since 1998, over 2500 food items have been added to the SR. Nutrients have been added after identifying a need for the data by the scientific community and the availability of published data and a validated analytic method to determine the values. New or emerging nutrients of interests are typically first released as an SID (Table 1) and then moved into the SR. The typical SID contains data for several hundred food items, while over 3000 are supplied for use in the FNDDS. Therefore, if a nutrient is to be 'expanded' for use in the FNDDS, values have to be calculated for about 2500–3000 food items.

Many of these are for branded, multicomponent foods. Public–private partnership agreements to compile label and manufacturer data are evolving to allow the submission of current information through data portals. In most cases, the companies will provide data for those nutrients found on the Nutrition Facts panel. However, missing nutrients may need to be calculated through different techniques to populate the database with concentrations of important nutrients, which do not appear of the food label, for example, nutrients needed for the FNDDS. This will be accomplished with an enhanced version of the formulation module described in the preceding text. Other improvements will be made to the USDA's database infrastructure to better handle large amounts of data.

In the future, improvements to the database will enable users to see the values behind the mean values reported in the SR and SID. This will allow users to combine data in a variety of ways, generating data to meet their needs. A gateway is being planned to enable users to access all USDA food composition data, developed by various organizations within the department through a single portal. Potentially, this can be expanded to other federal departments to include their food composition data. No matter where the data originate, it will always be identified so the user can check back to the data's source.

Challenges

In general, it is a monumental task to reflect the food supply of a given country in a single FCDB and demand that data are current, comprehensive (nationally representative), and accurate. Tens of thousands of foods and tens of thousands of food components require systematic guidelines for the inclusion of foods and food components. The frequency with which the food industry reformulates commercially processed and packaged foods may be as often as every 6 months. Commercially processed foods and restaurant foods contribute to roughly half of the foods consumed by the US public, and this is a growing trend around the globe. Ingredient lists are becoming more complex and proprietary and the number of brand names, which represent a single commercially processed food, continues to grow. It is critical in describing a single highly consumed food that the majority of the market for that food is represented in the value and variability estimates (e.g., lot-to-lot and brand-to-brand variability). In addition, analytic methods must be developed for many compounds of emerging scientific interest. For commodity-level foods, capturing estimates of nutrient variability within a food (e.g., cultivar-to-cultivar, soil makeup, and trace elements) is highly dependent on a multitude of factors such as shipping and storage conditions, fertilizer use, and animal feeding practices. This information is not always available and assumptions are often necessary. The need to capture information on biodiversity in foods connects with the emerging concerns on the sustainability of the global food supply as we move into the future of a heavily populated planet. With the global food supply crossing country borders through import and export programs, characteristics on a more global scale – country of origin and related information – are needed. Products change over time and include, for example, stealth reductions in sodium (based on official recommendations) and fortification changes, such as folic acid (1994) in US grain-based products. Therefore, updates to the FCDB must be timely.

Table 2 Nutrients added to the SR since 1998

Release	*Year*	*Nutrient*
SR12	1998	Selenium
SR13	1999	Vitamin D
SR14	2001	Folic acid, food folate, DFE
SR15	2002	Vitamin A (RAE), retinol
SR16	2003	Individual carotenoids (5), vitamin K, alpha-tocopherol, total sugar
SR18	2005	Vitamin E, added, and vitamin B_{12}, added
SR19	2006	Total choline, fluoride
SR20	2007	Expanded total choline
SR22	2009	Revised and expanded vitamin D
SR26	2013	Tocotrienols

This article summarizes the state of FCDBs as they become as specific as tribe-specific foods and as broad as a global network of international databases. Comprehensive, high-quality databases are crucial in our understanding of health–disease relationships, population specific to global nutrition policies, and food production and national and international trade.

Introduction: Population Determinants of Diet

Diet is a modifiable risk factor for an important number of diseases and conditions, such as cardiovascular diseases, certain types of cancer (e.g., colorectal cancer), hypertension, and diabetes. Underlying these effects are calorie imbalances and direct effects of certain dietary components. A healthy dietary pattern has been shown to reduce the risk of many of these diseases, increase well-being, and prolong life expectancy.
